Macular GA is significantly more common in women, usually at age 30–70. Flat or only slightly palpable erythematous or red-brown lesions occur, especially on the upper medial thighs and in bathing-trunk distribution. Lesions may closely simulate cutaneous T-cell lymphoma or morphea. Individual lesions average at least several centimeters in diameter but may be much larger. On careful palpation, small papules can be felt in some patients, and on stretching the skin the papules or small annular lesions can be seen. Such papules are the most fruitful sites for biopsies. Both well-formed necrobiotic granulomas and the interstitial pattern of GA may be seen on biopsy.

Subcutaneous granuloma annulare (deep granuloma annulare, pseudorheumatoid nodule)

Subcutaneous GA is most common in children, with boys affected twice as frequently as girls. Childhood cases appear at any age from 1 year to adolescence, with one congenital case reported. Lesions tend to occur on the lower legs, especially the dorsal foot, but may also occur on the distal upper extremity or scalp. Multiple lesions are usually present. There is often a history of trauma to the affected area preceding the appearance of a lesion. Typically, lesions are skin-colored, deep dermal or subcutaneous nodules up to several centimeters in diameter (Fig. 31-5). Superficial papular lesions are present in about one quarter of patients with subcutaneous GA. Lesions in general are asymptomatic and resolve over a few years. The major clinical problem occurs when the initial pathologic interpretation is "rheumatoid nodule" and an unnecessary extensive rheumatologic workup is performed. An unusual variant

Fig. 31-3 Granuloma anulare on the dorsal foot.

Fig. 31-4 Generalized granuloma annulare.

Fig. 31-5 Granuloma annulare, subcutaneous and dermal lesion.

remains localized to the penis or scrotum, an atypical location for GA in general. Adult women without rheumatoid arthritis may develop similar lesions around the joints.

Perforating granuloma annulare

Perforating GA usually appears on the dorsal hands and presents as papules with a central keratotic core (Fig. 31-6). This core represents transepidermal elimination of the degenerated material in the center of GA lesions and clinically can resemble a pustule.

Palmar granuloma annulare/acute-onset painful acral granuloma annulare

This clinical variant of GA does not resemble other forms of the disease, and the diagnosis is often missed clinically. Palmar or acral GA can be chronic but is often acute. Males and females present with the sudden onset of painful lesions on the hands and feet and a scattering of lesions at other sites. The lateral, dorsal, and marginal hands and, to less extent, the feet are affected. Lesions are tender to palpation and, when present on the palms, are dusky and may vaguely resemble erythema multiforme. Patients may have associated arthralgias and diarrhea, and they feel feverish, features of a "cytokine storm." The erythrocyte sedimentation rate (ESR) may be elevated, even above 50 mm/hr. Lesions resolve over months,

Fig. 31-6 Perforating granuloma annulare.

at times after systemic corticosteroid or hydroxychloroquine therapy. The authors have seen one such case associated with Hodgkin disease.

Granuloma annulare in HIV disease

Granuloma annulare may occur in persons with human immunodeficiency virus (HIV) infection at all stages of disease. Lesions are typically papular, and generalized GA is more common (60%) than localized GA (40%). Photodistributed and perforating lesions may also occur. The histology is identical to GA in the normal host. The natural history of GA in HIV patients is unknown.

Granuloma annulare and malignant neoplasms

The occurrence of GA and a cancer in the same patient is rare, but it has been reported many times. Most of these patients are age 35–75. Half the cases occur in lymphoma/leukemia patients and half in those with solid tumors. The diagnosis of the neoplasm usually predates the diagnosis of GA but can precede it. In some cases, lesions are described as "atypical" in that they may be painful (see earlier).

Other conditions associated with granuloma annulare

Granuloma annulare may occur after a bee sting, after waxing induced pseudofolliculitis in a patient, and after injections at a medical spa for mesotherapy or bacille Calmette-Guérin (BCG) immunization. Two groups of infectious diseases have been described as having GA-like lesions either histologically or clinically: borreliosis and tuberculosis (TB). Both Lyme disease in the United States and *Borrelia* infections in Europe have been described rarely as demonstrating interstitial granulomatous inflammation; clinically, however, at least in Europe, the lesions resemble morphea rather than GA. Despite laboratory evidence of infection, treatment of the patient with appropriate antibiotics may not lead to resolution of the skin lesions. A tuberculid can closely resemble disseminated GA, although histologically, caseous necrosis may be seen in the center of the granulomas. Treatment for TB leads to resolution of the skin lesions. In the appropriate patient, evaluation for TB and antituberculous treatment may be indicated. Medications can trigger interstitial granulomatous cutaneous reactions, at times resembling GA (see Interstitial granulomatous drug reaction).

Granuloma annulare and eye disease

Anterior and chronic intermediate uveitis has been described in patients with localized GA. The uveitis can be unilateral or bilateral, may be mild and may respond to topical therapy, or may be aggressive, resulting in visual impairment. The frequency of uveitis in patients with GA seems to be too low to recommend that all patients with GA be screened by an ophthalmologist. However, GA patients should be questioned about visual symptoms, including reduced visual acuity. If these are present, ophthalmologic evaluation would be appropriate.

Histology

Because there are many clinical patterns of GA, skin biopsies are often performed to confirm the diagnosis. In general, two histopathologic patterns often coexist in the same patient. The classic pattern of GA is a palisading granuloma characterized by histiocytes and epithelioid cells surrounding a central zone of altered collagen. In well-developed lesions, there is mucin deposition within the foci of altered collagen. Fibrin and nuclear dust may also be present in the degenerated foci. Lesions are most often located in the upper and middle reticular dermis but may involve the deep dermis or subcutaneous tissue. At the periphery of lesions, a leukocytoclastic vasculitis may rarely be found. IgM and C3 in the blood vessels of the skin lesions are found in about half of patients.

In the second pattern of GA, the interstitial, lesions may be entirely interstitial, or an interstitial pattern may be seen adjacent to well-formed palisaded lesions. A patchy dermal infiltrate of histiocytes and other mononuclear cells with occasional neutrophils is interspersed between collagen bundles. The patchy distribution within the dermis is best appreciated at scanning magnification. Interstitial mucin is often present in the affected areas, and is best demonstrated with a colloidal iron stain. Although these features are sufficient to confirm the diagnosis of GA, further sectioning may reveal typical palisaded granulomas. If the number of histiocytes in the infiltrate is small and lymphocytes predominate, the diagnosis of interstitial cutaneous T-cell lymphoma should be considered.

Treatment

Patients regularly report that a biopsy of the lesion will cause its involution. Because the lesions are often asymptomatic and spontaneous involution occurs, no treatment is required in many mild cases. Numerous modalities have been reported to improve GA, suggesting that no one treatment is uniformly efficacious and the "treatment of choice." It is best to develop a therapeutic ladder for both localized and generalized cases of GA. For localized cases, the intralesional injection of triamcinolone suspension is effective and is a reasonable initial treatment. Most patients relapse within 3–7 months. Superpotent topical corticosteroids or topical calcineurin inhibitors, or imiquimod, may be effective in some patients, especially those with more macular lesions. Phototherapy in the form of pulsed dye laser, high-intensity ultraviolet (UV) therapy with a laser designed to treat psoriasis (excimer), psoralen plus UVA (PUVA), and photodynamic therapy (PDT) can all be efficacious.

Generalized GA patients represent a major therapeutic challenge. Although systemic corticosteroids may be very effective, the high doses required and the usual immediate relapse as the steroids are tapered make this approach untenable in most situations. In addition, because dyslipidemia or metabolic syndrome may be present, systemic corticosteroids may be relatively contraindicated. Many systemic agents have been

reported as effective, but few have been tested in large numbers of patients or in blinded or controlled trials. For any treatment, 3–6 months of therapy appears necessary for efficacy or failure to be demonstrated. With all treatments, the GA may clear, only to recur when therapy is stopped. Antibiotics such as doxycycline; the combination of rifampin, ofloxacin, and minocycline, once monthly; pentoxiphylline, 400 mg three times daily; or high-dose nicotinamide, potassium iodide, oral calcitriol, or dapsone, 100 mg/day, can be effective. Fumaric acid esters over 1–18 months have also shown efficacy. Oral retinoids, especially isotretinoin, can be considered at a dose of 0.5 mg/kg or slightly more. Hydroxychloroquine and chloroquine in standard doses can be effective, and in very high doses (hydroxychloroquine at 9 mg/kg) probably will give a higher rate of response, although at potentially a greater risk of toxicity. Phototherapy in the form of narrow-band (NB) UVB, PUVA, or UVA1 can be effective in select patients. About half of patients clear with phototherapy but may relapse or may require maintenance. The combination of fumaric acid esters with PUVA appears to give the highest level of response with phototherapy. For patients with severe disease, tumor necrosis factor (TNF) inhibitors can be considered. Etanercept, infliximab, and adalimumab have all been reported to be effective. It is of interest that these medications can also cause GA. Systemic agents, such as cyclosporine, interferon (IFN) gamma, and hydroxyurea, have been reported to be effective in small series of patients. The potential toxicity of these medications limits their use to patients with significant GA.

Annular elastolytic giant cell granuloma (Meischer's), annular elastolytic granuloma, and actinic granuloma (O'Brien)

Annular elastolytic giant cell granuloma (AEGCG) and actinic granuloma are unified by their histopathologic appearance. Annular elastolytic granuloma has been proposed as an alternative term to describe this spectrum of cases. Perhaps some cases called facial annular sarcoidosis and non-diabetes-associated necrobiosis lipoidica of the face can been included in this category. It is currently unclear whether these simply represent variants of GA, occurring most frequently on sun-damaged skin, or are distinct diseases.

Two patterns of AEGCG have been reported. The first is a single, asymptomatic, atrophic-appearing, yellow, thin plaque on the forehead (Meischer's granuloma) (Fig. 31-7). Fine wrinkling and loss of elasticity characterize the skin within the ring. Clinically, this pattern resembles facial necrobiosis lipoidica more than GA. The second variant consists of multiple extensor upper extremity and sometimes trunk lesions, occurs more frequently in women, and favors sun-exposed areas. In these cases, the lesions have an active erythematous border with central clearing. A papular variant has been described. Although the vast majority of cases occur in adults, children and even an infant have been affected. Except for temporal arteritis, as described later, most patients are otherwise well. However, AEGCG has been described in association with acute myelogenous leukemia (which resolved with remission and recurred with relapse of the leukemia) and pleomorphic cutaneous T-cell lymphoma, At times, as in GA, the lesions of

Fig. 31-7 Annular elastolytic giant cell granuloma (Meischer), atrophic annular plaque.

AEGCG may heal with loss of elastic tissue and clinical features of skin laxity and anetoderma. The condition is chronic.

Actinic granuloma, as described by O'Brien, may represent the same disorder as AEGCG. It presents as papules and plaques on sun-exposed skin. Lesions are frequently numerous and may coalesce to cover much of the exposed skin. A history of onset after significant sun exposure and the distribution on physical examination should lead to suspicion of the diagnosis. A few lesions may occur on sun-protected sites or may spill over from affected areas to more photoprotected sites. Rarely, open comedones, scarring, and milia formation may be present clinically. Actinic granuloma may be associated with transepidermal elimination of damaged connective tissue or loss of elastic tissue surrounding the follicular ostia, leading to a Favre-Racouchot–like appearance. This condition affects older adults (usually over age 50) and can be intensely pruritic. Actinic granuloma is not associated with diabetes mellitus, but in numerous reports, it occurred in patients with temporal arteritis. It is speculated that the vasculitis is also caused by actinic injury to the connective tissue surrounding the temporal artery. Conjunctival involvement has been reported.

Histologically, all these conditions show a characteristic histology. The dermal infiltrate of macrophages is largely interstitial, and well-formed palisaded granulomas are uncommon. Multinucleated giant cells, often quite large, are numerous. Mucin is scant or lacking. The macrophages characteristically contain fragments of actinically damaged elastic tissue (elastophagocytosis). When this typical histology is seen in concert with the classic clinical features previously noted, it may be reasonable to make these specific diagnoses. These conditions cannot, however, be diagnosed on clinical or histologic grounds alone. Some cases with the clinical features of AEGCG or actinic granuloma will show histology more characteristic of typical GA or even sarcoidosis, suggesting a spectrum of both clinical and histologic features in these patients.

Treatment of AEGCG (annular elastolytic granuloma) and actinic granuloma has been difficult. Aggressive sun protection should be encouraged for patients with lesions primarily on sun-exposed skin. Topical and intralesion corticosteroids and topical calcineurin inhibitors can be used for individual lesions. Many patients respond to systemic corticosteroids, but relapse immediately when the steroids are tapered or discontinued. Oral antimalarials are at times effective. Insulin improved diabetic control and the actinic granuloma in one patient. Other anecdotal treatments include oral retinoids, fumaric acid, PUVA, pentoxiphylline, tranilast, dapsone, cyclosporine, and methotrexate.

Neutrophilic sebaceous adenitis presents with asymptomatic annular plaques on the face of men more than women. Fewer than 10 cases have been reported. It may be photosensitive. The condition resolves spontaneously after weeks to months without scarring. Histologically, in early lesions there is a neutrophilic, multifocal infiltrate around sebaceous glands with necrosis of some sebocytes. In later lesions the inflammation is primarily lymphohistiocytic. In addition to granuloma annulare/annular elastolytic giant cell granuloma, tinea facei, pemphigus foliaceus, a gyrate erythema, and lupus erythematosus are in the clinical differential diagnosis.

Interstitial granulomatous drug reaction

Interstitial granulomatous drug reaction (IGDR) is an uncommon but increasingly recognized pattern of adverse reactions to medication. Cases reported as GA induced by a medication often have an "interstitial" pattern, and some of the same medications cause both IGDR and "GA," so medication-induced granuloma annulare and IGDR are considered together here. Although it may occur within a few days of starting the medication, most patients with IGDR have been taking the medication for months to years. A wide variety of medications have been implicated, including calcium channel blockers (most common cause reported), lipid-lowering agents, angiotensin-converting enzyme (ACE) inhibitors, diuretics, nonsteroidal anti-inflammatory drugs (NSAIDs), antihistamines, anticonvulsants, antidepressants, allopurinol, darifenacin, sorafenib, ganciclovir, trastuzumab, strontium ranelate, sennoside (common over-the-counter laxative), Chinese herbs, and even soy. Immunomodulatory medications, including thalidomide, lenalidomide, anakinra, IFNs alpha and beta, and TNF inhibitors have been implicated in causing IGDR in many cases. At times, drug-induced hypersensitivity syndrome (DIHS/DRESS) cutaneous eruptions will have the histology of IGDR.

Clinically, the lesions are erythematous annular plaques with an indurated border and sometimes a tendency to central clearing. Lesions favor the creases (groin, axillae, popliteal fossae) but may also affect the trunk, proximal extremities, palms, and soles. Lesions may be photodistributed, affecting the face and dorsal extensor forearm and hands. Pruritus is minimal or absent. Mucous membranes are spared.

Histologically, there is a diffuse deep dermal infiltrate that is perivascular but has a prominent interstitial component. The inflammatory infiltrate is centered in the lower two thirds of the dermis; it contains neutrophils, eosinophils, histiocytes, and multinucleated giant cells. Degenerated collagen bundles may be surrounded by histiocytes, neutrophils, and eosinophils, forming "Churg-Strauss" granulomas, and mucin is usually scant or absent. Necrobiotic granulomas are usually incomplete but at times have been reported to resemble those seen in GA. Unique features that should suggest IGDR over GA include an interface component and "atypical" lymphocytes in the infiltrate. The histologic differential diagnosis includes interstitial granulomatous dermatitis associated with arthritis, palisaded neutrophilic granulomatous dermatitis, papular eruption of methotrexate, and interstitial GA. Lesions resolve over months once the offending ingestant is stopped.

Granuloma multiforme (Leiker)

Granuloma multiforme (GM) is seen most frequently in central Africa, where it is a common disorder, and rarely elsewhere. It affects adults over age 40 and is more common in women. Lesions are most frequently found on the upper trunk and arms and in sun-exposed areas. GM begins as small papules that evolve within 1 year into round or oval plaques up to 15 cm in diameter. The active edge of lesions may be elevated to as much as 4 mm in height and the center slightly depressed and hypopigmented. Pruritus can occur, and coalescing lesions may form unusual polycyclic shapes. The course is chronic. GM is, most importantly, separated from tuberculoid leprosy. Histologically, GM resembles GA, but multinucleated giant cells are prominent. Giant cells typically contain phagocytosed connective tissue, and elastic tissue is decreased in the areas affected by the granulomas. GM shares many features with AEGCG and actinic granuloma, or GA of sun-exposed skin, and in fact may be considered identical to these disorders.

Necrobiotic xanthogranuloma

Necrobiotic xanthogranuloma (NXG) is an uncommon multisystem disease with prominent skin findings. The cause is unknown. Some consider it to exist along a spectrum of "adult orbital xanthogranulomatous disease" (AOXGD), which also includes adult-onset xanthogranuloma (AOX), and adult-onset asthma with periocular xanthogranuloma (AAPOX). NXG is gradually progressive, affecting men and women equally, and beginning on average at about age 50 (range 25–80 or older). The most common site affected is the periorbital area (>80% of patients). Multicentric involvement is typical. Lesions may be localized or initially present in scars. The characteristic skin lesions are yellow (xanthomatous) plaques and nodules. Periorbitally, they may be mistaken for xanthelasma, but they are deep, firm, and indurated and may extend into the orbit. The trunk and proximal extremities may have orange-red plaques with an active red border and an atrophic center with superficial telangiectasias (Fig. 31-8). These plaques may grow to 25 cm in diameter. The skin lesions ulcerate in 50% of cases, leading to atrophic scarring. Acral nodules may also occur, some localized solely to the subcutaneous tissue. Extracutaneous involvement most often affects the eyes. Patients may complain of burning, itching, or pain around or in the eyes. Diplopia and inflammation in various compartments of the eye can occur, including conjunctivitis, keratitis, scleritis, uveitis, iritis, ectropion, or proptosis. Ulceration and scarring of the plaques and distortion of the eye may lead to visual occlusion. Blindness may result. Lymphadenopathy, hepatosplenomegaly, and mucosal, myocardial, and pulmonary lesions may occur. There is a monoclonal IgG (usually κ) paraproteinemia in 80% of cases and rarely an IgA

Fig. 31-8 Necrobiotic xanthogranuloma.

paraproteinemia. Thrombocytopenia, neutrophilia, neutropenia, and eosinophilia may be present. The bone marrow may show leukopenia, plasmacytosis (25–50% of patients), or frank myeloma (10–20%). In some patients, a myelodysplastic syndrome may be present or may develop (chronic lymphocytic lymphoma, Hodgkin or non-Hodgkin lymphoma). The NXG predates the development of the myeloma or myelodysplastic syndrome by an average of 2.5 years, but as long as 20 years.

Histologically, there are extensive zones of degenerated collagen surrounded by palisaded macrophages. These macrophages are of various forms: foamy, Touton cells, epithelioid, and giant cells, sometimes with more than 50 nuclei. Atypical multinucleated giant cells with multiple nuclei clustered at one end of the cell (polarized nuclei) are seen in 80% or more of cases. The process extends into the fat, obliterating fat lobules. Cholesterol clefts and extracellular lipid deposits are prominent, but not universally present. Within this process is a perivascular and interstitial infiltrate of lymphocytes and plasma cells. Lymphoid follicles are present. In the skin, the lymphoid aggregates are polytypic. The histologic differential diagnosis includes necrobiosis lipoidica and other histiocytoses. NXG has more atypical and Touton giant cells, lymphoid nodules, and cholesterol clefts. As in plane xanthomas seen with paraproteinemia, the associated monoclonal gammopathy of undetermined significance (MGUS) appears to enhance the intracellular accumulation of cholesterol within the macrophages/histiocytes.

The treatment is usually directed at the paraprotein or underlying malignancy. Treatment of the malignancy may lead to resolution of the NXG lesions. Other treatments have included systemic corticosteroids, IFN alpha, alkylating agents (e.g., chlorambucil, cyclophosphamide, melphalan), plasmapheresis, or local radiation therapy (for eye lesions). Numerous reports have documented response to high-dose intravenous immunoglobin. In addition, extracorporeal photophoresis and thalidomide have induced remissions. Simple excision is an option, but lesions may recur.

SARCOIDOSIS

Sarcoidosis is a chronic multisystem inflammatory disease characterized by granuloma formation in most affected tissues. Sarcoidosis occurs worldwide. In Europe, it is most prevalent in Scandinavia, especially in Sweden, with a prevalence of 64 per 100,000 population. In the United Kingdom, the rate is 20 per 100,000, and in France and Germany, about 10 in 100,000, with lower rates in Spain and Japan of 1.4 in 100,000. In the United States, the southeastern states and certain urban centers (New York City, Detroit, Washington, DC) show the highest prevalence, and there is a marked racial variation, with a rate of 10.9 per 100,000 for white persons and 35.5 per 100,000 for African Americans. Women are affected slightly more often than men, with the highest incidence in African American women between ages 30 and 39. The lifetime risk for the development of sarcoidosis is 0.85% for white and 2.4% for black U.S. residents. The disease begins most frequently between ages 20 and 40, with a second peak at ages 65–69. Patients with late-onset sarcoidosis are five times more frequently women than men, have uveitis, and have specific skin lesions in one third of cases.

Interleukin-2 (IL-2)– and IFN-γ–secreting CD4+ helper T (Th) cells are important in causing lesions, as are other Th1 and Th17 cytokines. Several genetic associations have been made with sarcoidosis, but the underlying cause still remains a mystery. HLA-DQB1*0201 and HLA-DRB1*0301 are strongly associated with acute disease and a good prognosis. Mutations in the promoter region of TNF are associated with erythema nodosum (EN) in sarcoidosis in Caucasians, and a variant in intron 1 of the lymphotoxin alpha *(LTA)* gene is associated with EN in female Caucasian sarcoidosis patients. Polymorphisms in the IL-23 receptor are associated with sarcoidal uveitis.

Cutaneous involvement is present in 25–30% of patients with sarcoidosis and may be classified as specific, which reveals granulomas on biopsy, or nonspecific, which is mainly reactive, such as EN. In about 20% of patients, the skin lesions appear before the systemic disease; in 50%, the skin and systemic lesions appear simultaneously; and in 30%, the skin lesions appear up to 10 years after the systemic disease has occurred. This is often coincidental with the tapering of systemic corticosteroids for pulmonary sarcoidosis. The cutaneous manifestations of sarcoidosis are varied, and numerous morphologic lesion types have been described, including: papules, nodules, plaques, subcutaneous nodules, scar sarcoidosis, erythroderma, and ulcerations. The lesions may be verrucous, ichthyosiform, hypomelanotic, psoriasiform, or alopecic. They are usually multiple, firm, and elastic when palpated. They extend to involve the entire thickness of the dermis. The overlying epidermis may be slightly

thinned, discolored, telangiectatic, or scaly. The color is faint, showing dull tints of red, purple, brown, or yellow, according to the stage of development. Usually, the lesions are asymptomatic, but approximately 10–15% of patients itch. There is a racial difference in the frequency of cutaneous lesions in sarcoidosis. Among white patients, EN is as common as the specific cutaneous manifestations, and both types of cutaneous involvement occur in about 10% of white patients with sarcoidosis. In black patients, EN is much less common; however, specific cutaneous manifestations occur in 50% or more of patients. The skin lesions in general do not correlate with the extent or nature of systemic involvement or with prognosis. The exceptions are EN, which is associated with a good prognosis, and subcutaneous sarcoidosis and lupus pernio. The morphologic types of sarcoidosis are discussed next, and when possible, the relationship to systemic sarcoidosis.

Erythema nodosum in sarcoidosis

Erythema nodosum is the most common nonspecific cutaneous finding in sarcoidosis. EN rarely occurs in sarcoidosis beginning after age 65. Sarcoidosis may first appear with fever, polyarthralgias, uveitis, bilateral hilar adenopathy, fatigue, and erythema nodosum. This combination, known as Lofgren syndrome, occurs frequently in Scandinavian whites and is uncommon in American blacks. The typical red, warm, and tender subcutaneous nodules of the anterior shins are distinctive and are most frequently seen in young women. The face, upper back, and extensor surfaces of the upper extremities may less frequently be involved. There is a strikingly elevated ESR, frequently above 50 mm/hr. EN is associated with a good prognosis, with the sarcoidosis involuting within 2 years of onset in 80% of patients. Conversely, the absence of EN is a risk factor for persistent disease activity. Sweet syndrome may also rarely be seen in association with sarcoidosis as a nonspecific finding.

Papular sarcoid

Papules are the most common morphology of cutaneous sarcoidosis and are usually less than 1 cm in diameter. Lesions may be localized or generalized, in which case small papules predominate (Fig. 31-9). This is also known as miliary sarcoid. The papules are especially numerous over the face, eyelids, neck, and shoulders. Plaques may occur by the expansion or coalescence of papules. In time, the lesions involute to faint macules. Hyperkeratosis may rarely be prominent, giving the lesions a verrucous appearance. "Papular sarcoidosis of the knee" is distinctive, in that disease is often limited to this site. In this region, the sarcoidal granulomas often contain foreign bodies. In Caucasians, it often occurs in the context of Lofgren syndrome (see earlier) and has a good prognosis. Papular lesions along the alar rim in African Americans, in contrast, may be the first evidence of lupus pernio (see later) and portend a poor prognosis.

Annular sarcoidosis

Papular lesions may coalesce or be arranged in annular patterns, usually with a red-brown hue (Fig. 31-10). On palpation, the lesions are indurated. Central clearing with hypopigmentation, atrophy, and scarring may occur. Lesions favor the head and neck and are usually associated with chronic sarcoidosis. Alopecia may result in the center of the lesion. Annular plaques of sarcoidosis can preferentially develop in sun-exposed areas.

Hypopigmented sarcoidosis

Hypopigmentation may be the earliest sign of sarcoidosis and is usually diagnosed in darkly pigmented races. Lesions vary from a few millimeters to more than 1 cm in diameter and favor the extremities. Although they appear macular, a dermal or subcutaneous component is often palpable.

Lupus pernio

Lesions typically are brown to violaceous, smooth, shiny plaques on the head and neck, especially the nose (Fig. 31-11), cheeks, lips, forehead, and ears. They can be very disfiguring. Involvement of the nasal mucosa and underlying bone may occur and lead to nasal perforation and collapse of the nasal bridge. Upper aerodigestive tract involvement is also common. Ear, nose, and throat (ENT) evaluation is recommended. In three quarters of lupus pernio patients, chronic fibrotic respiratory tract involvement is found. In 43%, lupus pernio is associated with granulomas in the bones (punched-out cysts), most often of the fingers. Chronic ocular lesions occur in 37% of patients. Sarcoid involving the sinus is associated with lupus pernio in 50% of cases. Lupus pernio is typically seen in women in their fourth or fifth decade. The skin lesions rarely involute spontaneously. At times, lupus pernio may resemble rhinophyma. It is important to make the correct diagnosis,

Fig. 31-9 Sarcoidosis, characteristic papules on the nares.

Fig. 31-10 Sarcoidosis, annular plaque.

Fig. 31-11 Sarcoidosis, lupus pernio with rhinophymatous nasal changes.

because ulceration of sarcoidal lesions may occur with laser treatment, even with pulsed dye laser.

Ulcerative sarcoidosis

Ulcerative sarcoidosis is very rare, affecting about 0.5% of patients with sarcoidosis. It affects primarily blacks, but it is also well recognized in Japanese. It is two to three times more common in women than men. In one third of cases, it is the presenting finding of sarcoidosis, except in Japan, where it is usually a late finding in patients with known sarcoidosis. The ulcerations may occur de novo or in sarcoidal plaques. Lesions favor the lower extremities, but most patients have lesions in more than one anatomic region. Trauma may be the inciting event. The clinical appearance may not be specific, but skin biopsies are diagnostic. Lupus pernio may also be present. Many patients have multisystem sarcoidosis, although infrequently, no other evidence of sarcoidosis is found. Biopsies may show necrosis in the center of sarcoidal granulomas. Methotrexate, which can be therapeutic in sarcoidosis, may also lead to ulceration in sarcoidosis patients.

Subcutaneous sarcoidosis

Subcutaneous sarcoidosis is also known as Darier-Roussy sarcoid and consists of a few to numerous 0.5–3 cm, deep-seated nodules on the trunk and extremities; only rarely do they appear on the face. The overlying epidermis may be normal (30%), erythematous (50%), or slightly violaceous (10%). The lesions are usually asymptomatic. About 90% of patients will have multiple lesions, and the upper extremity is most frequently affected (virtually 100% of patients). Lesions on the upper extremity have a tendency to form indurated linear bands from the elbow to the hand on the cubital side of the forearm. The amount of subcutaneous involvement in the upper extremity may be so extensive as to simulate chronic cellulitis. A biopsy is usually required to confirm the diagnosis. About 90% of patients also will have systemic involvement, usually bilateral hilar adenopathy. Overall, however, the prognosis is good.

Fig. 31-12 Sarcoidosis, ichthyosiform type; biopsy showed noncaseating granuloma, although there was no palpable dermal component to the lesions.

Plaques

These distinctive lesions are flat-surfaced, slightly elevated plaques that appear with greatest frequency on the cheeks, limbs, and trunk symmetrically. Superficial nodules may be superimposed, and coalescence of plaques may lead to serpiginous lesions. Involvement of the scalp may lead to permanent alopecia. The finding of alopecia in an annular plaque with a raised border should raise the diagnostic consideration of sarcoidosis.

Erythrodermic sarcoidosis

Erythrodermic sarcoidosis is an extremely rare form of sarcoidosis. A diffuse infiltrative erythroderma of the skin usually begins as erythematous, scaling patches that merge to involve large portions of the body. A biopsy is confirmatory, but the diagnosis can be clinically suspected if small, "apple jelly" papules are seen on diascopy throughout the erythroderma.

Ichthyosiform sarcoidosis

Ichthyosiform sarcoidosis resembles ichthyosis vulgaris or acquired ichthyosis, with fine scaling usually on the distal extremities (Fig. 31-12). It is virtually always seen in nonwhite persons, especially African Americans. Almost all patients have or will develop systemic disease. In 75% of patients, the skin lesions follow or occur at the same time as the diagnosis of systemic sarcoidosis. Although the lesions have no palpable component, a biopsy will reveal dermal noncaseating granulomas.

Fig. 31-13 Sarcoidosis, scarring alopecia of scalp.

Fig. 31-14 Sarcoidosis, papules and plaques arising in a tattoo.

Alopecia

Alopecia on the scalp caused by sarcoidosis can have multiple morphologies. Plaques may extend into and involve the scalp, leading to scarring hair loss (Fig. 31-13). More rarely, macular lesions from one to several centimeters in diameter appear on the scalp and closely resemble alopecia areata. This form may be permanent or reversible. Diffuse alopecia, scaly plaques resembling seborrheic dermatitis, and cicatricial lesions resembling discoid lupus erythematosus or pseudopelade may also occur. A biopsy of all forms of alopecic sarcoid will reveal dermal granulomas and sometimes loss of follicular structures. Scalp sarcoidosis is virtually always seen in African or African American women. In cases where sarcoidosis affects the scalp, causing alopecia, the patient almost always has other cutaneous lesions, and the vast majority of cases will demonstrate systemic involvement. Syringotropic involvement may lead to hypohidrosis.

Morpheaform sarcoidosis

Extremely rarely, specific cutaneous lesions of sarcoidosis may be accompanied by substantial fibrosis and simulate morphea. Less than 10 cases have been described to date. Most often, the lesions are localized and resemble linear morphea. Skin biopsy will demonstrate noncaseating granulomas. African American women are most frequently affected. This form of sarcoidosis responds favorably to antimalarial therapy.

Sarcoidosis in scars (scar sarcoid)

Infiltration and elevation of tattoos and old, flat scars are two variants of scar sarcoid. Previously flat scars become raised and may become erythematous or violaceous. These lesions may be confused with hypertrophic scars. Infiltration of tattoos may be the first manifestation of sarcoidosis and can be confused with a granulomatous hypersensitivity reaction to the tattoo pigment (Fig. 31-14). Cosmetic tattooing, as may be performed in a dermatology office, may result in sarcoidal granulomas in patients with pulmonary sarcoidosis. Hyaluronic acid injections can also be complicated by the development of sarcoidal lesions in patients with sarcoidosis. As noted later, patients with hepatitis C virus (HCV) infection receiving IFN therapy are at high risk for developing sarcoidosis and can develop disfiguring sarcoidal reactions after cosmetic filler injections. Similar granulomatous reactions may occur in the earlobe after ear piercing and represent granulomatous allergic dermatitis to metals introduced by the procedure or the earring. Titanium, nickel, cobalt, zinc, gold, and palladium can all be the allergen.

From 22% to 77% of biopsies from patients with cutaneous sarcoidosis will contain polarizable foreign material, suggesting that scar sarcoidosis is very common. The foreign material seems to be a nidus that favors the development of sarcoidal granulomas. Scar sarcoid sometimes occurs in patients with acute disease and EN, especially if the lesions are small papules on the knees. It may also occur in patients with chronic sarcoidosis. The presence of polarizable material in a granulomatous process does not confirm the diagnosis of "foreign body granuloma," but rather should result in evaluation of the patient for evidence of systemic sarcoidosis. When foreign material is found, infection must be carefully excluded if no other features of sarcoidosis are found.

Nail sarcoidosis

Sarcoidosis of the nail can affect any compartment of the nail, causing onycholysis, subungual hyperkeratosis (nail bed involvement), brittle nails, pitting, ridging, or rough nails (trachyonychia), distal matrix involvement, and even pterygium (nail matrix destruction). Nails may be hyperpigmented. Sarcoidal dactylitis and phalangeal bone disease as well as intrathoracic sarcoidosis often accompany nail sarcoidosis. Drumstick dactylitis is associated with lupus pernio.

Mucosal sarcoidosis

The lesions in the mouth are characterized by pinhead-sized papules that may be grouped and fused together to form a flat plaque. The hard palate, tongue, buccal mucosa, or posterior pharynx may be involved. They may simulate Fordyce spots. In lupus pernio, the nasal mucosa is frequently involved. Rarely, in ulcerative sarcoidosis, the oral mucosa may be involved. Sarcoidosis may also infiltrate the gingiva, causing "strawberry gums" that simulate Wegener's granulomatosis.

Systemic sarcoidosis

Sarcoidosis may involve virtually every internal organ, and its presentations are protean. Many cases of sarcoidosis are

asymptomatic, and only when routine radiographs of the chest reveal some abnormality is sarcoidosis suspected. Fever may be the only symptom of the disease or may be accompanied by weight loss, fatigue, and malaise.

Intrathoracic lesions, including parenchymal lung lesions and hilar adenopathy, are the most common manifestation of the disease, occurring in 90% of cases of sarcoidosis. All patients with cutaneous sarcoidosis, even without any respiratory symptoms, should be evaluated with chest radiograph and pulmonary function tests. Pulmonary radiograph changes are staged as follows:

Stage 0: normal
Stage I: bilateral hilar and/or paratracheal adenopathy
Stage II: adenopathy with pulmonary infiltrates
Stage III: pulmonary infiltrates only
Stage IV: pulmonary fibrosis.

The panda sign correlates with gallium uptake in the nasopharynx and lacrimal and parotid glands; the lambda sign correlates with uptake in the paratracheal lymph nodes. These characteristic findings, plus a skin biopsy demonstrating typical sarcoidal granulomas, can be used as presumptive evidence for sarcoidosis. Lymphadenopathy, especially of the mediastinal and hilar nodes, and generalized adenopathy, or adenopathy confined to the cervical or axillary areas, may be an initial sign of sarcoidosis or may occur during the course of the disease. Polyarthralgias may be seen with acute sarcoidosis or as a component of chronic disease. Chronic arthritis may occur (Fig. 31-15). Osseous involvement is often present in chronic disease. The most characteristic changes are found radiographically in the bones of the hands and feet, particularly in the phalanges. These consist of round, punched-out, lytic, cystic lesions. These are seen frequently in patients with lupus pernio. The bone lesions represent epithelioid granulomas.

Ocular involvement is present in 30–50% of patients, so all patients with sarcoidosis, even if asymptomatic, should have routine ophthalmologic examinations. Any eye findings should be treated because even asymptomatic ocular sarcoidosis can lead to blindness. Anterior uveitis is the most common ocular manifestation. The lacrimal gland may be involved unilaterally or bilaterally by painless nodular swellings. Lesions of the iris are nodular and painless. There may also be lesions of the retina, choroid, sclera, and optic nerve. Optic neuritis with vision or color vision loss is an emergency. Ophthalmic disease is highly correlated with systemic involvement. Conjunctival biopsy is positive in about 50% of patients with sarcoidosis, making it an easy site to sample and confirm the diagnosis.

Fig. 31-15 Sarcoidosis, fusiform swelling of digits.

Parotid gland and lacrimal gland enlargement with uveitis and fever may occur in sarcoidosis; this is known as uveoparotid fever or Heerfordt syndrome and usually lasts 2–6 months if not treated. Facial nerve palsy and central nervous system (CNS) disease are frequently seen in Heerfordt syndrome. Mikulicz syndrome is bilateral sarcoidosis of the parotid, submandibular, sublingual, and lacrimal glands.

Clinically apparent hepatic involvement occurs in about 20% of patients; however, a blind liver biopsy will reveal granulomas in 60% of cases. Hepatomegaly with elevation of serum alkaline phosphatase, biliary cirrhosis with hypercholesterolemia, and portal hypertension with esophageal varices are some of the manifestations. Liver biopsy showing hepatic granulomas is an excellent means of confirming the diagnosis of sarcoidosis.

Renal disease may be caused by direct involvement with granulomas or secondary to hypercalcemia. Hypercalcemia results from the macrophage in the granulomas having large amounts of 25-hydroxyvitamin D–1α-hydroxylase, which converts 25-hydroxyvitamin D to the more active 1,25-dihydroxyvitamin D. Nephrolithiasis may result. Cardiac involvement occurs in 5% of cases, but in a higher percentage of autopsy cases. Baseline cardiac evaluation with a detailed cardiac history and electrocardiogram is recommended. Fatal arrhythmias and heart failure can develop.

Neurosarcoidosis occurs in 5–10% of patients. It can present in numerous ways, from focal cranial nerve involvement (most often facial nerve palsy) to aseptic meningitis, seizures, psychiatric changes, stroke, and space-occupying lesions. Neurosarcoidosis tends to be chronic and relapsing, with a higher mortality rate. Vision loss in sarcoidosis after heat exposure is called the Uhthoff phenomenon. Magnetic resonance imaging (MRI) with or without gadolinium is useful for detecting CNS lesions of sarcoidosis and following therapy.

Measuring ACE levels in sarcoidosis patients has little utility. ACE levels may be elevated in all granulomatous diseases, including infectious granulomatous disorders. An elevated ACE level is suggestive of, but not diagnostic for, granulomatous inflammation. A normal ACE level cannot be used to rule out sarcoidosis, and an elevated level does not necessarily indicate the presence of multisystem involvement. The use of 18F-fluorodeoxyglucose (FDG) positron emission tomography (PET) is more accurate in identifying extent of involvement and monitoring response to treatment.

Pediatric sarcoidosis

Childhood sarcoidosis is rare. The clinical features are very age dependent. Older children, age 10–15, typically have lung, lymph node, and eye involvement. Calcium abnormalities are present in 30% of children with sarcoidosis. Older children develop specific sarcoidal skin lesions at the same rate as adults, about 30% of the time. One presentation resembles granulomatous periorificial dermatitis.

Blau syndrome is caused by mutations in the *NOD2* gene and is associated with early-onset sarcoidosis (age <5 years). It is more common in white patients. The triad of skin, joint, and eye involvement is characteristic and often confused with juvenile rheumatoid arthritis. Skin lesions are typically small papules and are the first clinical feature in more than half of patients, starting at a median age of 1 year. The skin lesions

are often generalized and may be flat topped, giving them a lichenoid appearance. They are red-brown to tan and can occur in clusters or linear arrays. The face may have confluent lesions.

Histopathology

The histology of sarcoidosis in all affected tissues is identical. The characteristic finding is that of the "naked tubercle," composed of collections of large, pale-staining, epithelioid histiocytes. There may be small foci of necrosis in the center of the granulomas, and multinucleate giant cells, sometimes with inclusions (asteroid bodies, Schaumann bodies), may be present. Although classically there are few lymphocytes around the granulomas, they may be numerous. The granulomas may be nodular, diffuse, or tubular along neurovascular structures. Perifollicular and other periadnexal involvement can be seen in sarcoidosis.

The histologic differential diagnosis is broad, and the diagnosis of sarcoidosis cannot be definitively made histologically. Allergic granulomas caused by metals are histologically identical to sarcoidosis. Other foreign body granulomas (especially as a result of silica), granulomatous rosacea, granulomatous secondary syphilis, tuberculoid leprosy, atypical mycobacterial infections, and leishmaniasis may closely simulate sarcoidosis.

The diagnosis of sarcoidosis is established by the demonstration of involvement consistent with sarcoidosis in two different organ systems. This is usually done histologically, or by characteristic findings with radiologic techniques, including gallium scans, PET, and MRI. If cutaneous sarcoidal granulomas are identified in a patient with no prior history of sarcoidosis, the first diagnostic test should be a chest radiograph. If this is abnormal, further pulmonary evaluation is indicated. Ophthalmologic evaluation and conjunctival biopsy may be useful. Since many patients with sarcoidosis may develop ocular involvement that may be asymptomatic, every patient should see an ophthalmologist. Blind biopsy of the minor salivary glands may demonstrate sarcoidal granulomas in about 50% of patients with systemic sarcoidosis. Otherwise, histologic evaluation of any involved tissue may be considered. The site for biopsy may be guided by PET scans, which, if characteristic, can be used to support the diagnosis.

Sarcoidosis in the setting of immunologic abnormalities

Numerous reports document sarcoidosis occurring in patients with various forms of spontaneous or iatrogenic immunologic aberrations. Patients with ataxia-telangiectasia, severe combined immunodeficiency, and common variable immunodeficiency—three primary immunodeficiencies with both B-cell and T-cell defects—are predisposed to sarcoidal granulomas in the skin. Histologically, these have a low CD4/CD8 ratio, in contrast to classic sarcoidosis, which is rich in CD4+ T cells. Sarcoidosis may be associated with lymphoma, especially Hodgkin disease (sarcoidosis-lymphoma syndrome). B-cell lymphoma, chronic myeloid and lymphoid leukemia, and mucosa-associated lymphoid tissue (MALT) lymphoma have all been described in patients with sarcoidosis. Sarcoidosis patients are about 40–60% more likely to develop malignancy, including solid tumors such as nonmelanoma skin cancers (threefold risk), renal cancer, and nonthyroid endocrine tumors. In addition, adenopathy in patients with lymphoma or solid tumors may demonstrate sarcoidal granulomas without tumor. This is important to know when a patient with a cancer develops an enlarged node, and sampling of the node becomes important to avoid unnecessary therapy. Sézary syndrome with extensive cutaneous granulomas has been described.

Alteration of the immune system with medications can lead to the development of systemic sarcoidosis. These typically cause a constellation of pulmonary and cutaneous disease. Etanercept, adalimumab, and infliximab (the TNF inhibitors) have all been reported to trigger sarcoidosis. This is ironic, since they are also often therapeutic in sarcoidosis (analogous to the situation with TNF inhibitors and psoriasis). Numerous reports document the appearance of sarcoidosis in association with IFN alfa therapy, usually for the treatment of HCV infection. HCV alone may also trigger sarcoidosis. Cutaneous lesions (60% of patients), pulmonary findings (75%), or both, as well as other features of sarcoidosis, occur in 5% of patients treated with IFN alfa for HCV. The addition of ribavirin may increase the risk. In more than 80% of patients, the sarcoidosis resolves after the treatment is discontinued. Treatment of HIV infection with highly active antiretroviral therapy (HAART) has led to the appearance of sarcoidosis or tattoo granulomas, apparently by enhancing the number and function of Th cells. Sarcoidosis is now well recognized as a feature of immune reconstitution syndrome (IRIS). Hematopoietic stem cell transplantation (HSCT), both allogenic or autologous, has been associated with the appearance of pulmonary sarcoidosis. If HSCT is performed for malignant disease, the presence of hilar adenopathy may be interpreted as recurrent or metastatic disease, and inappropriate treatment may be given. Other medications causing sarcoidosis include alemtuzumab (anti-CD52 monoclonal antibody for CTCL), vemurafenib (*BRAF* inhibitor), and ipilimumab (anti-CTLA4 monoclonal antibody for malignant melanoma).

Patients with sarcoidosis are at increased risk to develop other immune-mediated and chronic inflammatory diseases, including systemic lupus erythematosus, autoimmune chronic hepatitis, multiple sclerosis, coeliac disease, thyroid disease, and ulcerative colitis (but not Crohn's disease).

Differential diagnosis

Granulomatous secondary syphilis may closely simulate sarcoidosis both clinically and histologically. Blau syndrome, an autosomal dominant granulomatous disease, is similar to childhood sarcoidosis (see earlier). It can be distinguished from sarcoidosis by the lack of pulmonary involvement. Granulomatous cutaneous T-cell lymphoma (CTCL) can usually be distinguished histologically and by the presence of pulmonary involvement in sarcoidosis.

Treatment

Numerous therapies have been reported as beneficial in cutaneous sarcoidosis, usually after anecdotal observation. Virtually no information exists regarding what types of therapy are best for which of the various cutaneous manifestations. The cutaneous disease may spontaneously remit without treatment. Because most skin lesions are asymptomatic, the major indication for treatment is cosmetic. Treatment begins by evaluating the patient for systemic disease. If found, the treatment of the systemic disease may clear the skin lesions. Otherwise, a stepwise approach to management based on extent, severity, and rapidity of progression can be considered.

Systemic corticosteroids are almost always beneficial in cutaneous sarcoidosis. Unfortunately, the doses required to control cutaneous disease may be too high (usually in excess of 15 mg/

day) to be ideal for long-term use. For limited skin disease, intralesional injection of 2.5–5.0 mg/mL of triamcinolone acetonide suspension is very effective. For thinner lesions, superpotent topical corticosteroids, topical tacrolimus, and UVA1 phototherapy may be effective. Antibiotic treatment with a single agent (usually minocycline or doxycycline, 100 mg twice daily) may be considered in patients with skin lesions in whom systemic disease does not require treatment. About one quarter of patients have complete resolution of their skin lesions, and more than half have a partial remission. A more aggressive antibiotic regimen called CLEAR—combined levofloxacin, 500 mg/day; ethambutol, 25 mg/kg/day, up to 1200 mg; azithromycin, 250 mg/day; and rifampin, 10 mg/kg/day, or up to 300 mg/day—is also effective. Maximum response occurs after several months of therapy.

Local surgical procedures can be beneficial for some forms of sarcoidosis. Pulsed dye laser, used repeatedly, PDT, and even CO_2 laser remodeling may be effective in the appropriate cases. In severe lupus pernio, nasal skin excision followed by flap reconstruction can lead to dramatic improvement.

Systemic corticosteroid therapy is indicated for acute systemic involvement with fever and weight loss, in active eye disease, for sarcoidal involvement of the myocardium, in active pulmonary disease with functional disability, in hypersplenism, in hypercalcemia, and for symptomatic CNS involvement.

Antimalarials, both chloroquine and hydroxychloroquine, have been used to treat extensive cutaneous sarcoidosis, in doses of 250 mg/day or 200–400 mg/day, respectively. About three quarters of patients appear to respond partially or completely. In some cases, the associated CNS disease or hypercalcemia also improves. These agents may also be used to reduce the dose of systemic steroids required. Antimalarial therapy can be combined with antibiotic treatment.

Methotrexate, in doses of 15–25 mg/week, is also efficacious and seems to help patients with severe lupus pernio or ulcerative sarcoidosis who are otherwise difficult to treat. Methotrexate-induced hepatitis occurs in 15% of patients with sarcoidosis treated. Leflunomide may be given similar to methotrexate and may be used in patients with gastrointestinal intolerance for methotrexate. Response rates are about 75%. The retinoids, principally isotretinoin, have been reported as beneficial in some patients, usually at doses of 0.5–1.0 mg/kg. Response is only seen after 6 weeks or more. Thalidomide, 50–200 mg/day, has led to improvement of the skin lesions after several months. It should not be used to treat pregnant patients, however, because of possible teratogenic effects on the fetus. Venous thrombosis may complicate thalidomide therapy, especially if doses above 100 mg/day are used. Thalidomide is an option when methotrexate is contraindicated. Azathioprine and cyclophosphamide had been used for refractory disease, and mycophenolate mofetil has shown efficacy in mucocutaneous disease and may be considered an effective form of rescue and steroid-sparing therapy. The combination of thalidomide, an immunosuppressive agent, with an antimalarial may be effective when these agents fail individually. TNF is an important cytokine in the formation of granulomas. Not surprisingly, TNF inhibitors, including infliximab, etanercept, and adalimumab, can be effective in refractory cutaneous and systemic sarcoidosis. Infliximab appears to be particularly beneficial in controlling severe lupus pernio. Combination therapy with thalidomide, an immunosuppressive agent, a TNF inhibitor, and an antimalarial may be used in severe, refractory cutaneous disease. Fumaric acid esters and apremilast (PDE-4 inhibitor) both have improved cutaneous sarcoidosis and may be considered when other agents fail.

HISTIOCYTOSES

These disorders are characterized by infiltrates that contain either Langerhans cells (the X-type histiocytoses) or infiltrates of non–Langerhans cell histiocytes (the non-X histiocytoses).

Non-X histiocytoses

Zelger and Burgdorf proposed classifying this group of disorders as the "xanthogranuloma family." Their classification scheme relies on the morphology of the monocyte/macrophage composing the lesion. Weitzman and Jaffe refined this concept and outlined the immunohistochemical features of the cells involved. These classification schemas are useful for this uncommon group of disorders. However, since the histiocytes within any disorder can change their appearance, no one specific morphologic cell type absolutely characterizes these disorders. There are three large families of histiocytoses based on these classification schema: X-type histiocytosis or Langerhans cell histiocytosis (LCH); non-LCH histiocytoses of the juvenile xanthogranuloma (JXG) family (which have the phenotype of dermal dendritic cells, being positive for factor XIIIa, fascin, MS-1, and CD68); and multicentric reticulohistiocytosis and sinus histiocytosis with massive lymphadenopathy (SHML; Rosai-Dorfman disease), which are thought not to be in the JXG family of non-X histiocytoses. In the end, the final diagnosis is established by typical clinical features, a compatible histology, and an evolution typical for that disorder (Fig. 31-16).

The non-X histiocytoses are divided clinically into three groups: those involving primarily or only the skin (JXG); those that affect the skin but have a major systemic component (Erdheim-Chester disease); and those that are primarily a systemic disease with occasional skin lesions as a part of the disease (SHML). At any level of differentiation or appearance of the histiocyte, there may be a disease in any category. Conceptually, this allows one to think of the JXG group of non-X histiocytoses as lying along a spectrum: benign cephalic histiocytosis, JXG, Erdheim-Chester disease, generalized eruptive histiocytosis, xanthoma disseminatum, and progressive nodular histiocytosis. Most diseases at the beginning of the spectrum are localized, benign disorders; as one progresses through the diseases, they tend to become more generalized but are still benign; at the end of the spectrum lie diseases that are less likely to involute and may have visceral involvement. This parallels the histologic appearance of the infiltrating histiocyte, which progresses from scalloped to vacuolated to xanthomatized and finally spindled. In any disease, however, many morphologies of the histiocyte may be seen.

Zelger B, Burgdorf WHC: The cutaneous "histiocytoses." In Advances in Dermatology. St Louis: Mosby, 2001.

Juvenile xanthogranuloma

Juvenile xanthogranuloma is the most common non-LCH. Between 20% and 35% of lesions are congenital. The vast majority of lesions (70%) are diagnosed within the first year of life. The mean age of onset is 22 months, and the median, 5

months, demonstrating the proclivity for early onset. About 80% of cases are solitary (Fig. 31-17). Boys are more often affected than girls. In adults, lesions tend to occur in the late twenties to early thirties, and the gender distribution is equal. JXG is 10 times more common in white than in black persons, but it occurs in all races. Multiple cutaneous lesions affect male children much more frequently (12:1).

The JXGs begin as well-demarcated, firm, rubbery, round to oval dermal papules or nodules 5–10 mm in diameter. Early lesions are pink to red with a yellow tinge and become tan-brown over time. On dermoscopy, the lesions have an orange-yellow background, a subtle erythematous border with branched and linear vessels running from the edge to the center of the lesion, and "clouds" of paler yellow areas representing areas of xanthomatized histiocytes. Most lesions are asymptomatic. The head and neck are the most common locations, followed by the upper trunk and upper extremities. Lesions have been divided into three types: small nodular (2–5 mm; Fig. 31-18); large nodular (5–20 mm; Fig. 31-19); and giant xanthogranuloma (>20 mm). The small-type lesions are more numerous than the large type. Often, however, one patient will have both types of lesion, and the proposed increased risk for ocular involvement in the micronodular type and other internal involvement in the macronodular type has been refuted. Skin lesions regress spontaneously within 3–6 years in children. In adults, lesions are usually persistent. Hyperpigmentation, atrophy, or anetoderma may remain after lesions resolve.

Multiple atypical presentations have been described. These include hyperkeratotic nodules; macronodular tumors 2–10 cm in diameter; clustered (agminated) forms; linear lesions; flat, plaquelike lesions; and pedunculated or cylindrical exophytic lesions. Atypical sites of involvement include the genitalia, lips, palms, soles, earlobes, and fingers. The most common location for JXGs after the dermis is the subcutaneous tissue, again most often on the head and neck. About 15% of JXGs present in this manner, usually as a solitary mobile mass up to 3 cm in diameter. Subcutaneous JXG typically appears before age 1 and often before age 3 months. Oral JXG may develop in infancy or childhood and is most frequently a solitary lesion of the tongue, lip, or palate.

Extracutaneous JXG is uncommon and occurs as visceral involvement, in association with either multiple cutaneous lesions or a solitary extracutaneous lesion. Visceral disease of both types accounts for only 4% of childhood JXGs and for 5–10% of all JXG cases. Ocular involvement occurs in about 0.3–0.4% of children with multiple JXGs, and 41% of children with ocular JXGs have skin lesions. Skin lesions appear after eye lesions in 45% of cases. In 92%, eye lesions occur during the first 2 years of life. The most common location is the iris, where JXG can present as a tumor, unilateral glaucoma, unilateral uveitis with spontaneous hyphema, or as heterochromia iridis. The eyelid or posterior eye may also be involved. Ocular screening is recommended for all children with multiple cutaneous lesions before age 2 years.

Mass lesions of the nasal, orbital, and paranasal sinus region can occur and cause erosion of the orbit and extend to the skull. Other extracutaneous sites and their presentations, in order of frequency, include the lung (respiratory distress and nodular opacities on chest radiograph), liver (hepatomegaly and, rarely, fatal giant cell hepatitis), testis (mass), and rarely, the CNS, kidney, spleen, and retroperitoneum. Other evaluations for extracutaneous JXGs are not indicated unless there are symptoms or findings suggesting their presence. Extracutaneous lesions also spontaneously regress. If surgical intervention is required, extracutaneous lesions tend not to recur, even if they are incompletely excised. Rarely, the burden of visceral JXGs may be so great that the patient's life is threatened. These cases have been called disseminated JXG, systemic JXG, or systemic xanthogranuloma. In 25% of these patients, no skin lesions are found, or the skin lesions may appear after the systemic disease is identified. Progressive CNS, liver, or bone marrow involvement usually mandates aggressive therapy and is usually managed with the protocols used to

treat LCH. Bone marrow involvement can also produce hemophagocytic lymphohistiocytosis syndrome with profound cytopenias. Locally aggressive tumors may be radiated.

The JXGs have been reported in association with neurofibromatosis (NF-1) and juvenile myelomonocytic leukemia (JMML). Patients with NF-1 and JXG were reported to be 20–32 times more likely to develop JMML, but this association has recently been questioned. Since JMML occurs in infancy or early childhood, café au lait macules often are the only findings of NF-1 at the time. Sometimes, all three conditions affect the same patient, with males having a 3:1 predominance and usually a maternal history of NF-1. Children with JXG should be examined for stigmata of NF-1. If these stigmata are found, especially in a boy with a maternal history of NF-1, the pediatrician should be alert to the possible, although uncommon, occurrence of JMML. Nevus anemicus may be seen in children with JXG and NF-1. The presence of nevus anemicus in a young infant with JXG should put the health care team on alert that this patient may have NF-1. Rarely, JXG in childhood may be associated with mastocytosis or childhood acute lymphoblastic leukemia. The leukemia and the JXG can have the same clonality, and the JXG lesions may occur after the treatment of the leukemia or less often, concurrently. Similarly, Wiskott-Aldrich syndrome has been reported with multiple JXGs. Multiple xanthogranulomas are rare in adults, and it is quite unusual for them to occur in an eruptive manner. At least six cases have been associated with hematologic malignancy (chronic lymphocytic leukemia, essential thrombocytosis, large B-cell lymphoma, adult T-cell lymphoma/leukemia, and monoclonal gammopathy). Systemic involvement with JXG in adults is also rare and usually requires histologic confirmation.

Lesions appear histologically as nonencapsulated but circumscribed proliferations in the upper and middle reticular dermis and may extend more deeply into the subcutaneous tissue or abut directly on the epidermis with no grenz zone. Epidermotropism does not occur. As classically proposed, the histopathology varies in accordance with the age of the lesion. Very early lesions are composed of mononuclear cells with abundant amphophilic cytoplasm that is poorly lipidized or vacuolated. Later, the cells become more vacuolated and multinucleated forms appear. In mature lesions, foam cells, multinucleated foam cells (Touton giant cells) and foreign body giant cells are present. Touton giant cells are characteristic of JXG but not specific for it. The inflammatory infiltrate consists of lymphocytes, eosinophils, and neutrophils and lacks plasma cells. Fibrosis occurs in the older lesions. The histology just described is characteristic of cutaneous JXGs. Soft tissue and visceral JXGs present with more monomorphous cytology, may have very few of the characteristic Touton giant cells, and can have a prominent spindle cell appearance. Immunohistochemistry is especially valuable in confirming the diagnosis of extracutaneous JXG. The cells of JXG of all anatomic locations stain with factor XIIIa, vimentin, fascin, MS-1, and CD68, but not with CD1a, S-100, or other specific markers for Langerhans cells.

The treatment for most cases of JXG is observation. By age 6 years, most lesions have resolved, often leaving normal or only slightly hyperpigmented skin. In adults, spontaneous involution is slower, and local removal with surgery could be considered. Injection of bevacizumab intravitreally may be used to treat JXG of the iris.

It is noteworthy that the patterns of involvement by JXG and LCH are similar, with childhood onset and primary cutaneous involvement; when visceral disease occurs, the liver, bone, and lungs are usually involved. Without histologic confirmation, isolated JXG of the bone would be most likely diagnosed as isolated LCH, a much more common condition. These clinical similarities between JXG and LCH may occur because both diseases are caused by antigen-presenting dendritic cells. JXG is a proliferation of dermal dendrocytes, and LCH is a proliferation of Langerhans cells. The clinical features favoring JXG include lack of crusting or scale and the distribution and uniformity of size of lesions. Histologic evaluation is definitive in difficult cases, because JXGs are negative for the Langerhans cell marker CD1a. Unlike LCH, JXGs are usually negative for S-100, although a few S-100–positive cells may be seen in a JXG. JXG may appear in a patient who also has LCH. Benign cephalic histiocytosis may be difficult to distinguish both clinically and histologically, although its lesions tend to be flatter and are mainly on the head and neck. Papular xanthoma can be distinguished histologically. Clinically, mastocytosis will urticate when scratched (Darier's sign) and can be distinguished histologically. Solitary JXG appearing in a child must be distinguished from a Spitz nevus, which usually requires a biopsy.

Benign cephalic histiocytosis

Benign cephalic histiocytosis (BCH) is a rare condition affecting boys and girls of all races equally. The onset is between 2 and 34 months of age (rarely up to 5 years), with 50% of cases beginning between 5 and 12 months. The disease begins initially on the head in virtually all cases, often the cheeks, eyelids, forehead, and ears. Lesions may later appear on the neck and upper trunk and less often, more caudad. There are always multiple lesions, but often few in number (5–20), although they can number more than 100. Individual lesions are slightly raised, reddish-yellow papules 2–4 mm in diameter. Lesions may coalesce to give a reticulate appearance. The lesions cause no symptoms. The mucosa and viscera are not involved. Lesions spontaneously involute over 2–8 years, leaving behind hyperpigmented macules. Some cases of BCH have evolved to become JXGs, and one patient later developed generalized eruptive histiocytoma many years after the involution of BCH. This supports the concept outlined earlier that these conditions lie along a spectrum, and all derive from the same cell type, a dermal dendritic cell. Histologically, there is a diffuse dermal infiltration of monomorphous macrophages, which stain positive for CD68 and factor XIIIa and negative with S-100 and CD1a.

Patsatsi A, et al: Benign cephalic histiocytosis: case report and review of the literature. Pediatr Dermatol 2014: 31:547.

Generalized eruptive histiocytoma (generalized eruptive histiocytosis)

Generalized eruptive histiocytosis (GEH) is a very rare disease, usually presenting in young adulthood. The diagnostic criteria follow:

1. Widespread, erythematous, essentially symmetric papules, especially involving the trunk and proximal extremities, sparing the flexors, and rarely involving the mucous membranes (there is no visceral involvement)
2. Progressive development of new lesions, often in crops, over several years with eventual spontaneous involution to hyperpigmented macules
3. Benign histologic picture of monomorphous, vacuolated macrophages

Lesions appear in crops and may be grouped or clustered. (Since Winkelmann's initial report of this entity, several cases with grouped lesions have been reported, so finding grouped lesions does not exclude the diagnosis of GEH.) They are skin-colored, brown, or violaceous. GEH is rare in childhood. It may be difficult to distinguish from widespread BCH in childhood, if indeed it is a separate condition. In adults and children, GEH may suddenly appear several weeks after a bacterial or viral illness; in adults it may be associated with underlying malignancy, usually leukemia or lymphoma. GEH is distinguished from xanthoma disseminatum by the lack of visceral disease, the benign course, and by the scalloped appearance of the macrophages in xanthoma disseminatum. Histologically, there is a dermal infiltrate of monomorphous vacuolated macrophages and mononuclear histiocytes. The GEH cells stain positive for vimentin, CD68, and usually factor XIIIa, and negative for S-100, and CD1a. The natural history of GEH is unpredictable, with complete resolution in some cases and persistence in others. Some cases have progressed to widespread xanthogranulomas, xanthoma disseminatum, or progressive nodular histiocytosis, again supporting the concept that these diseases all fall along a spectrum and derive from the same cell type. In childhood, no treatment may be required. In adulthood, treatment with PUVA or isotretinoin could be considered.

Xanthoma disseminatum (Montgomery syndrome)

Xanthoma disseminatum (XD) is a very rare, potentially progressive non-LCH that preferentially affects males in childhood or young adulthood (2:1 male/female ratio). XD is characterized by the insidious onset of small, yellowish red to brown papules and nodules that are discrete and disseminated. They characteristically involve the eyelids and flexural areas of the axillary and inguinal folds and the antecubital and popliteal fossae. Over years, the lesions increase in number, forming coalescent xanthomatous plaques and nodules. About 30–50% of cases have mucous membrane involvement, most often of the oropharynx (causing dysphagia), larynx (causing

dysphonia and airway obstruction), and conjunctiva and cornea (causing blindness). Diabetes insipidus, usually transient, occurs in 40% (30% at presentation). CNS involvement, with epilepsy, hydrocephalus, and ataxia, can occur. Synovitis and osteolytic bone lesions have been described. The natural history of the disease is variable. About one third of XD patients undergo spontaneous complete remission, one-third have partial remission, and one-third have persistent or progressive disease. Patients who have a spontaneous complete remission do not have evidence of systemic disease other than diabetes insipidus. Spontaneous remission often leaves areas of atrophy or anetoderma, caused by local loss of elastic tissue.

The serum lipids are abnormal in 20% of XD cases, which may lead to confusion with hyperlipidemic xanthomatosis. Histologic examination of early lesions shows surprisingly nonfoamy, scalloped macrophages. Later, lesions show xanthoma cells, Touton giant cells, and frequently a mild inflammatory cell infiltrate of lymphocytes, plasma cells, and neutrophils. The macrophages stain with CD68 and factor XIIIa.

Disseminated xanthosiderohistiocytosis is a variant of XD in which the lesions have a keloidal consistency; they have annular borders, a cephalad distribution, and extensive iron and lipid deposition in the macrophages and connective tissue.

Progressive XD can produce considerable morbidity and can even be fatal. Therefore, aggressive therapy may be indicated. Lipid-lowering therapy has improved lesions in a few patients. 2-Chlorodeoxyadenosine, 0.14 mg/kg/day for 5 days every month for five to eight cycles, resulted in substantial improvement in five eighths of patients with limited toxicity. 18F-FDG PET or computed tomography (CT) can be useful in defining extent of disease and response to treatment of visceral lesions.

Progressive nodular histiocytosis

Progressive nodular histiocytosis (PNH) is a very rare disorder that affects men and women equally and usually begins between ages 40 and 60 years. The characteristic clinical feature is the development of two types of lesion: superficial papules and deeper, larger, subcutaneous nodules. The superficial lesions are small xanthomatous papules up to 5 mm in diameter. They are diffusely distributed on the body, but spare the flexors (unlike xanthoma disseminatum, which favors the flexors). The larger deep lesions can be up to 5 cm in diameter and are associated with pain, ulceration, and disfigurement. Smaller lesions may evolve to the larger lesions over time. On the face, lesions may coalesce, giving the patient a leonine facies and creating ectropion. New lesions progressively appear, and spontaneous resolution of individual lesions can be seen, but general involution of all the lesions does not occur. Mucosal lesions are unusual but can involve the conjunctiva and larynx. Iron deficiency anemia can occur because the histocytes in the nodules may accumulate iron, reducing available body iron stores. Histologically, the superficial lesions show foamy macrophages, and the deeper lesions show a densely cellular proliferation of spindle-shaped histiocytes with multinucleated giant cells. It is the development of these deep lesions composed of primarily spindled histiocytes that is the diagnostic feature of PNH. Local excision may be used for symptomatic lesions.

Papular xanthoma

Papular xanthoma (PX) is a rare form of non-LCH that is poorly defined. The disease can occur at any age, but usually appears in early childhood or after adolescence. PX usually presents as a solitary lesion favoring men 4:1 over women. The primary lesion is a small, yellow papule 1–10 mm in diameter. If multiple, lesions are generalized, not grouped, and do not favor the flexors. No abnormalities are found on lipid profile examination. Erosive arthritis (resembling multicentric reticulohistiocytosis) has been reported in one child and one adult. Histologically, there are aggregates of xanthomatized foamy macrophages in the dermis, with Touton giant cells. Inflammatory cells are scant or absent. Cells stain positive for markers of monocytes/macrophages such as CD68, but are negative for factor XIIIa. The differential diagnosis includes normolipemic plane xanthomas and normolipemic papuloeruptive xanthomatosis. In infants, the natural history is for spontaneous involution. In one adult patient, treatment with doxycycline was effective.

Erdheim-Chester disease

A rare non-LCH, Erdheim-Chester disease (ECD) is primarily a visceral disorder with cutaneous lesions in 20–30% of patients (half at presentation). ECD can begin at any age from childhood to the ninth decade. The characteristic feature is bilateral and symmetric sclerosis of the metaphyseal and diaphyseal regions of the long bones. These radiologic findings are considered pathognomonic. Diabetes insipidus may occur, from involvement of the pituitary and retroperitoneal fibrosis affecting the kidneys. Despite a normal gross appearance, many internal organs are affected. The course is progressive with infiltration of many visceral organs, followed by fibrosis. This is often fatal, usually from pulmonary fibrosis and cardiac failure; 1-year and 5-year survival are 96% and 68%, respectively. Skin lesions typically present as red-brown or

xanthomatous, 2–15 mm papules or nodules. Lesions favor the eyelids (as with xanthomas), axilla, groin, neck, trunk (inframammary areas), and face (similar to lesions seen in XD). As in LCH, a significant percentage of patients (~50%) have the *BRAF* V600E mutation. Some patients have simultaneously both LCH and ECD (called mixed histiocytosis), apparently driven by these mutations. Less often, patients have had *NRAS* mutations. Initial treatment is with IFN alfa; in unresponsive patients, anakinra or infliximab (cytokine blockade) may be beneficial. In patients who progress despite these treatments, a *BRAF* inhibitor (vemurafenib) or *NRAS* inhibitor (if a mutation is detected) could be considered. Cladribine and imatinib are options if no mutation is detected.

Progressive mucinous histiocytosis in women

Progressive mucinous histiocytosis is a rare autosomal dominant or X-linked hereditary disorder described primarily in women. The skin lesions consist of a few to numerous skin-colored to red-brown papules, ranging from pinhead to pea sized, which tend to appear on the face, arms, forearms, hands, and legs. Onset is in the second decade of life, with slow progression and no tendency to spontaneous involution. Visceral and mucosal lesions have not been reported. Histologically, in the middermis there is a proliferation of spindle-shaped and epithelioid monocytes. Superficial telangiectatic vessels and increased mast cells are found. Abundant mucin is demonstrated by alcian blue staining, indicating the presence of acid mucopolysaccharides. This condition can be distinguished from the other non–Langerhans cell histiocytoses by its familial pattern, lack of lipidized and multinucleated cells, and presence of mucin. Immunoperoxidase studies most consistently show positivity for CD68 and negativity for CD1a, S-100, and CD34.

Reticulohistiocytosis

Two distinct forms of reticulohistiocytosis occur: reticulohistiocytoma and multicentric reticulohistiocytosis (MRH). The two forms have identical histology but distinct clinical manifestations.

Reticulohistiocytoma

Reticulohistiocytoma usually occurs as a solitary, firm dermal lesion less than 1 cm in diameter. Lesions favor the trunk and extremities. Solitary lesions and multiple lesions without systemic involvement, in contrast to MRH, have been described, mainly in adult men and rarely in children.

Multicentric reticulohistiocytosis

A multisystem disease, MRH usually begins about age 50 (range 6–86 years). It is twice as common in women as men and affects all races. The primary manifestations are skin lesions and a potentially destructive arthritis. In 40% of cases the joint disease occurs first, in 30% the skin lesions precede the joint symptoms, and in 40% the joint and skin disease appear simultaneously.

Clinically, there may be a few to a few hundred firm, skin-colored to red–brown papules and nodules, mostly 2–10 mm in diameter, but some reaching several centimeters in size (Fig. 31-20). These occur most frequently on the fingers and hands, with a tendency to cause par onychial lesions. In about half of MRH patients, lesions will be arranged around nailfolds, giving a "coral bead" appearance, which may be associated with nail dystrophy. The upper half of the body, including the arms, scalp, face, ears, and neck, are also common sites. About 90% of patients have lesions on the face and hands. Nodular and papular involvement of the pinnae and a symmetric distribution of the lesions, especially over joints, are characteristic. The nodules on the arms, elbows, and knees may resemble rheumatoid nodules. Diffuse erythematous lesions can occur, at times simulating erythroderma. Patients may present initially with macular or minimally infiltrated erythema on sun-exposed sites, simulating a photodermatitis or dermatomyositis. Small papules are often present, which are useful in confirming the diagnosis of MRH. Lesions may ulcerate. Xanthelasma occurs in 30% of patients. Atypical patchy areas of hypopigmentation over the face and upper limbs have been noted. About 10% of MRH patients may complain of pruritus. The itching is not localized to the skin lesions and may precede their appearance.

Fig. 31-20 Multicentric reticulohistiocytosis.

Mucous membrane involvement is seen in one third of MRH patients and is most common on the lips and tongue; other sites are the gingiva, palate, buccal mucosa, nasopharynx, larynx, and sclera. Lesions of the esophagus can lead to dysphagia. One-third have hypercholesterolemia and xanthelasma. Rheumatoid factor is usually negative.

Osteoarticular changes are the most important aspect of MRH. No association exists between the extent, size, or severity of the skin eruption and the course of the joint disease. The associated arthropathy is an inflammatory, symmetric, polyarticular arthritis that can affect many joints, including the hands, knees, shoulders, wrists, hips, ankles, elbows, feet, and spine. The arthritis can be rapidly destructive and mutilating, with absorption and telescopic shortening of the phalanges and digits—doigts en lorgnette (opera-glass fingers). In earlier reports, at least 50% of cases developed arthritis mutilans, but this has been reduced to about 11%. The infiltrating cells in the skin and joints are identical on microscopic examination and immunophenotypic evaluation. The clinical course varies. In many cases, there is complete involution after about 8 years. The joint destruction is permanent, however, and is a cause of severe disability. The joint involvement may resemble rheumatoid arthritis and psoriatic arthritis. Weight loss and fever occur in one third of patients.

About 15% of patients with MRH have associated autoimmune disorders. Thyroiditis, Sjögren syndrome, ulcerative colitis, and vitiligo have all been reported. About 25% of reported cases have had an associated malignancy. Given this high rate of malignancy, every patient with MRH should have a careful history and physical examination and a complete age-appropriate cancer screening, repeated at regular intervals (similar to the protocol followed for patients with dermatomyositis). No specific tumor type has been associated; cancers reported with MRH include breast, gastrointestinal tract, genitourinary tract, and melanoma, as well as leukemia and lymphoma. The skin lesions usually appear before diagnosis of the malignancy, but synchronous behavior of the skin lesions and underlying malignancy is only occasionally reported. In one case, tuberculosis was identified, and treatment of the TB led to resolution of the MRH.

Other organs and tissues may be involved, such as bone, muscle, lymph nodes, liver, myocardium, pericardium, lungs, pleura, and stomach. Myocardial involvement may be fatal. Usual interstitial pneumonia or typical MRH cells may be seen in pulmonary lesions.

Histologically, the skin lesions are usually centered in the middermis and tend to occupy much or all of the dermis. The infiltrating cells are mononuclear and multinucleate monocytes/macrophages. The giant cells are most characteristic, with an abundant smooth or slightly granular, eosinophilic or amphophilic, "ground-glass" cytoplasm. Their cytoplasm is darker in the center than at the periphery. These cells stain positive for periodic acid–Schiff (PAS) after diastase digestion. The overlying epidermis may be thinned but is usually separated from the dermal process by a narrow zone of collagen (grenz zone). Characteristically, there is a polymorphous infiltrate of lymphocytes, neutrophils, eosinophils, and plasma cells within the lesions. On immunohistochemistry, monocyte/macrophage cells stain positive for CD68, vimentin, and CD163. In MRH, the cells in the skin and joints stain positive for acid phosphatase that is tartrate resistant (TRAP) and cathepsin K, markers for osteoclasts. This may explain the response of MRH to bisphosphonates, which cause apoptosis of osteoclasts and are taken up by cells in the reticuloendothelial system.

Given the aggressive nature of the arthritis, early and adequate treatment should be considered. However, associated malignancy is common and can be worsened by immunosuppressive therapy. The same would be true if the patient had underlying asymptomatic TB. Initially, the patient should be screened for these two conditions, and these should be adequately treated if found. In patients free of neoplasia and TB, the treatment is individualized. Spontaneous remissions are common, making efficacy of treatment difficult to determine. The major goal of treatment is to prevent the destruction of the joints that are the cause of disability. If systemic therapy is considered, two approaches can be taken. One is the use of the combination of systemic corticosteroids, methotrexate (or leflunomide), and a TNF inhibitor. Of the TNF inhibitors, infliximab has proved more effective than etanercept and should probably be the initial agent used. The other approach is to use a combination of immunosuppressives and a bisphosphonate. The infiltrating cells in MRH seem phenotypically to be osteoclastic in behavior, so this therapy is logical and appears to be joint sparing. In refractory cases, use of a bisphosphonate and TNF inhibitor with methotrexate and systemic corticosteroids could be considered. For patients with skin lesions only, therapy is not required. PUVA, antimalarials, topical nitrogen mustard, and low-dose methotrexate, a bisphosphonate, or a TNF inhibitor could be considered if symptoms are severe.

Indeterminate cell histiocytosis

Indeterminate cell histiocytosis (ICH) is a rare histiocytosis composed of cells that stain variably with markers for Langerhans cells (S-100 and CD1a) but are negative for langerin (CD207) and do not demonstrate Langerhans cell granules on electron microscopy. The cells may be CD68 positive, suggesting a monocyte/macrophage lineage. The exact origin of these cells is unclear. ICH affects both children and adults. Solitary and multiple lesions may occur, and the color of lesions varies from yellow to red-brown. Lesions may be papules, plaques, or nodules 3 mm to 10 cm in size. These clinical features are not specific and resemble the papular lesions seen in many forms of non-LCH. Conjunctival involvement has been reported. Solitary malignant tumors with similar immunohistochemistry have been described, clinically resembling atypical fibroxanthoma. ICH seems to have a benign course in the vast majority of patients, and no therapy is required. UVB, PUVA, and total-skin electron beam therapy have resulted in clearing of skin lesions. Pravastatin, thalidomide (alone or with isotretinoin), and methotrexate have been effective. Many patients have been treated with numerous chemotherapeutic agents similar to those used for LCH., but therapeutic response has been equivocal. Acute myelogenous leukemia has followed some of these courses of chemotherapy. Solitary lesions with malignant histology should be managed with surgical excision, ensuring adequate margins. The utility of adjunctive therapy and sentinel lymph node sampling is not known. Postscabietic nodules and rarely post–pityriasis rosea lesions may contain a proliferation of cells that are immunohistologically identical to indeterminate cells.

Sea-blue histiocytosis

Sea-blue histiocytosis may occur as a familial inherited syndrome or as an acquired secondary or systemic infiltrative process. The characteristic and diagnostic cell is a histiocytic cell containing cytoplasmic granules that stain blue-green with Giemsa and blue with May-Gruenwald stain. The disorder is characterized by infiltration of these cells into the marrow, spleen, liver, lymph nodes, and lungs, as well as the skin in some patients. Skin lesions include papules or nodules, facial waxy plaques, eyelid swelling, and patchy-gray pigmentation of the face and upper trunk. Similar histologic findings have occurred in patients with myelogenous leukemia, light-chain deposition disease, adult Niemann-Pick disease (type B), sphingomyelinase deficiency, or mutations in the apolipoprotein E gene, and following the prolonged use of intravenous fat supplementation or liposomal amphotericin B. The unifying feature in all these conditions is an abnormal lipid metabolism by the infiltrating histiocytes. This condition has been seen in the infiltrate of a patient with CTCL.

X-type histiocytoses (Langerhans cell histiocytosis)

The X-type group of histiocytoses is caused by infiltration of the skin, and in some cases, other organs, by Langerhans cells. The spectrum of disease is broad, with solitary, usually benign and autoinvoluting lesions at one end and multicentric, multiorgan visceral and skin disease at the other. Most cases of LCH demonstrate clonality and telomere shortening. In addition, *BRAF* and *ARAF* mutations have been detected in a majority of cases. All these features would suggest LCH as a "neoplastic" condition. Adult patients with LCH may have myeloid and solid cancers supporting a "neoplastic" phenotype. In the case of associated leukemias, the leukemic cells may share the same surface markers and may be clonally related. However, preliminary evidence shows that IL-17A is elevated, and IL-17A receptor status determines extent of disease. This suggests that LCH represents a "hybrid" condition with features of both neoplasia and immunologic

dysregulation. This helps to explain the variable outcome from spontaneous involution to progressive and fatal disease.

Histologically, in all cases of LCH in the skin, there is a dense dermal infiltrate of Langerhans cells. This can be superficial and immediately below the epidermis (usually corresponding to small papules or scaly patches clinically), folliculocentric, or deep and diffuse (in papular and nodular lesions). The Langerhans cells are recognized by their abundant, amphophilic cytoplasm and eccentric round or kidney bean–shaped nucleus. There is frequently exocytosis of the abnormal cells into the overlying epidermis. If this is extensive, macroscopic vesicles can be seen, and erosion can occur secondarily. The dermal infiltrate is accompanied by many other inflammatory cells, including neutrophils, eosinophils, lymphocytes, and plasma cells. Dermal edema and hemorrhage are characteristically present. In larger and older lesions, the infiltrating histiocytic cells become foamy, and fibrosis may be present. These older lesions may lack immunoreactivity for specific Langerhans cell markers and can resemble JXG. The histologic features of the Langerhans cells, such as nuclear atypia and mitotic indices, do not predict prognosis and are not reproducible. Histology is not predictive of biologic behavior. Immunohistochemistry is useful in confirming the diagnosis. The infiltrating cells in LCH are positive for S-100 and CD1a. Langerin is a protein expressed in the Birbeck granule and stained with CD207. Electron microscopy is rarely required to diagnose LCH because of this panel of Langerhans cell, "characteristic" markers.

Congenital self-healing reticulohistiocytosis (Hashimoto-Pritzker disease)

Congenital self-healing reticulohistiocytosis (CSHR) is an autoinvoluting, self-limited form of LCH. It can be considered as one end of the spectrum of LCH, and although cases continue to be described, it is best approached as a variant of LCH, not a separate entity. CSHR is usually present at birth or appears very soon thereafter, although a case in an 8-year-old child has been reported. CSHR has been described in two forms: a solitary and a multinodular variant. Solitary or generalized lesions can affect any part of the cutaneous surface. Lesions range from 0.2 to 2.5 cm in diameter (Fig. 31-21). Lesions may grow postnatally. Exceptionally large tumors up to 8 cm in diameter can occur. At presentation, the lesions can be papules or nodules, with or without erosion or ulceration. Individual lesions are red, brown, pink, or dusky. Lesions may rarely appear as hemorrhagic bullae. Lesions greater than 1 cm characteristically ulcerate as they resolve. Lesions are asymptomatic and spontaneously involute over 8–24 weeks, leaving atrophic scarring from the ulcerated nodules. Internal involvement has been reported on the mucosa and even in the lungs (which also have spontaneously involuted), making distinction of CSHR and autoinvoluting LCH difficult to separate. Histologically, the skin lesions are composed of Langerhans cells, and no histologic features identify this variant of LCH. Because LCH with systemic involvement may present in identical fashion, systemic evaluation is recommended, including a physical examination, complete blood count, liver function tests, and radiologic evaluation of the bones. The affected child must be followed regularly because, as in other forms of LCH, late recurrences can occur in about 10% of cases.

Langerhans cell histiocytosis

A rare disease, LCH is characterized by proliferation of Langerhans cells. Many organs can be affected. International standardization of terminology and treatment protocols has resulted in improved management of patients and has allowed for investigational protocols rapidly to determine efficacy of treatments identified by recent scientific advancements, such as use of vemurafenib with the identification of *BRAF* V600E mutations.

Age of onset is an important determinant of the natural history of the disease, and therefore childhood and adult forms of LCH are considered separately. Adults are more likely to have mucocutaneous lesions, twice as likely to reactivate (63% vs. 37%), and more likely to die of their disease (24% vs. 11%). It is also quite clear that patients may begin with any pattern of disease and evolve or relapse to another pattern. This is especially true of younger children. Up to 50% of children under age 1 year diagnosed with skin-limited LCH progress to have multisystem disease. Repeated evaluation and close follow-up are required.

Childhood Langerhans cell histiocytosis

In childhood LCH, boys are slightly more often affected than girls. The incidence in children is about 2.6 cases per 1 million,

with a greater rate in children under 1 year of age (7 per 1 million), 2 cases per 1 million in ages 1–4, and about 1 case per 1 million in ages 5–14. Children conceived through in vitro fertilization (IVF) before 2002 appear to have increased risk for development of LCH. Neonatal disease occurs in 6% of cases but at times is unrecognized, especially if involving an internal organ asymptomatically but not affecting its function. Thus, many of the neonatal cases have predominantly cutaneous lesions. Overall, in childhood LCH, bone lesions represent about two thirds of cases and skin disease about one third. Only 10% of cases have neither skin nor bone involvement. In children under 1 year of age, the skin is involved in three quarters of cases, with ear and bone being involved in about one third. Two thirds of children under 1 year have multisystem disease, with half having involvement of liver, lungs, or bone marrow. In children age 1–4, bone disease is most common, but two-thirds or more have multisystem disease. In children age 5–14, bone disease is almost always seen, and multisystem disease is seen in less than 20%.

Skin lesions

About 10% of children have single-organ disease involving only the skin, and 50% of children with multisystem LCH have skin involvement, making skin the second most commonly involved organ in childhood LCH. Almost 90% of children less than 1 year old with multisystem LCH have skin lesions. The pattern of skin disease does not predict the presence or extent of systemic disease. The most common form of skin disease in children is that described in Abt-Letterer-Siwe disease. The skin lesions are tiny red, red-brown, or yellow papules that are widespread but favor the intertriginous areas, behind the ears, and the scalp (Figs. 31-22 and 31-23). There is a superficial resemblance to seborrheic dermatitis, but on careful inspection, the lesions are individual papules with focal hemorrhage. The papules are often folliculocentric. Lesions may erode or weep. In children, this pattern is frequently associated with multisystem disease. In a rare variant of this LCH pattern, vesicles appear (Fig. 31-24), usually in infants. The vesicles rupture easily, resulting in widespread erosions. This presentation may be confused with other bullous diseases, especially congenital candidiasis, herpesvirus infections, bullous impetigo, bullous mastocytosis, primary immunobullous diseases, and epidermolysis bullosa. The vesicles result from large intraepidermal collections of Langerhans cells, and a Tzanck smear may lead one to suspect the diagnosis. A less common presentation is with slightly larger papules, up to 1 cm in diameter. These lesions tend to be yellow-red and resemble xanthomas or xanthogranulomas (Fig. 31-25). They can be numerous and widespread. A rare variant resembling lichen planopilaris has been reported. Congenital lesions with hemorrhage have been reported as resembling "blueberry muffin" babies, but the biopsies show typical LCH.

Although uncommon, nail changes can occur, including nail dystrophy, nail bed purpura, loss of the nail plate, and paronychia. Both fingernails and toenails may be affected. Most patients with nail involvement have multisystem disease. LCH restricted to the genitalia is rare, but vulvar, inguinal, and perianal disease may be the initial manifestation of LCH. It tends to be painful and ulcerative and may simulate hidradenitis suppurativa or cutaneous Crohn's disease, because axillary and scalp involvement may also be present.

Fig. 31-26 Langerhans cell histiocytosis, gingival lesions.

Fig. 31-27 Langerhans cell histiocytosis, eosinophilic granuloma of rib that eroded through to the skin.

Oral mucosa lesions

The oral mucosa may be involved in children with LCH. Lesions may be mucosal ulcerations that are painful and inflamed. They affect primarily the buccal mucosa. Most oral disease is caused by alveolar bone lesions. These osteolytic lesions can lead to significant periodontitis. Gingival ulceration can result (Fig. 31-26). Teeth detach from the underlying bone and on x-ray films appear to be "floating." Palpable masses and gingival lesions should be sought and a dental evaluation completed in all patients. Cervical adenopathy is common. Bilateral parotid swelling may occur.

Visceral involvement

The most commonly involved organ in LCH children is the bone (Fig. 31-27). The lesions may be asymptomatic or may cause pain. The skull is most often involved, followed by the long bones, then the flat bones. Bony lesions tend to occur in older children and young adults. Lesions are treated with curettage, intralesional corticosteroids, or radiation. Endocrine dysfunction occurs, usually in the form of diabetes insipidus, which is more common in patients with bone disease of the skull and in those with extensive disease. Diabetes insipidus is one of the common long-term sequelae of children recovering from LCH.

The bone marrow may be affected, resulting in cytopenias. This may present as purpura in the skin. The liver may be involved directly by infiltration with Langerhans cells or may be affected indirectly by enlarged nodes in the porta hepatis, leading to obstructive disease. Either pattern can lead to biliary cirrhosis. Pulmonary disease with diffuse micronodular infiltrates and cysts occurs less frequently in children than in adults with LCH.

Adult Langerhans cell histiocytosis

In adults, the peak age of presentation is between 20 and 35 years, with multisystem disease in one third to two thirds of adults with LCH. Bones are the most common organ involved, and 12% of adult LCH patients have disease limited to one or several bones. Skin and mucosal involvement is the second most common manifestation in adults. Diabetes insipidus occurs in 20% of patients, and other endocrine abnormalities can result from hypothalamic-pituitary involvement. These remain a problem after the LCH is treated and require constant monitoring. In the skin, lesions can be papular or diffuse, sometimes with both forms of lesion present at different sites. Acneiform lesions of the chest and back, identical clinically to acne vulgaris, can occur. Xanthomatous lesions may be seen. A pattern repeatedly reported in the skin of adults with LCH is a red, erosive, intertriginous eruption, with a close resemblance to deficiency dermatitis. It favors the groin and inframammary areas, especially in elderly women. Pulmonary LCH occurs on average at age 33 years. A diffuse micronodular pattern on chest radiograph may progress to cyst formation (honeycomb lung), large bullae, and pneumothorax. More than 90% of adults with pulmonary LCH are tobacco or marijuana smokers. Pneumothorax occurs in 25% of cases. High-resolution CT is useful for diagnosis. Five-year survival is 88%. Lung transplantation may be required. It is unclear if isolated pulmonary LCH is a reactive process or a variant of LCH.

Treatment and prognosis

In childhood LCH, outcome is determined by the extent of involvement and, more importantly, the function of affected organs. Children younger than 1 year with multisystem disease have the worst prognosis, with mortality approaching 50%, children age 1–4 years have a 30% or lower mortality, and mortality is only 6% in children 5 years or older. Involvement of the ear and lung is a poor prognostic finding in patients with multisystem disease. Early initial response to multidrug chemotherapy in childhood multisystem LCH is an important predictor of survival, with survival of 92% of responders and 11% of nonresponders after 6 weeks of treatment. Baseline and repeated evaluation is important. Lesions in one organ system may resolve while disease progresses in another organ. Skin lesions may spontaneously resolve, only for the disease to recur, even years later, so patients must be followed regularly.

For treatment and prognosis, patients are classified as having single-system LCH or multisystem LCH. Those with multisystem LCH are further stratified into those with involvement of high-risk "organs" (bone marrow, liver, spleen, and CNS) and those without involvement of these organ systems. Patients with multisystem disease should be referred to a center for evaluation and treatment recommendations and potentially, new investigational treatment protocols. Most often, vinblastine and a corticosteroid are used as initial treatment, but reactivation remains a problem. Patients with localized skin disease can be managed by the dermatologist. Topical nitrogen mustard, PUVA, NB-UVB (or excimer laser), thalidomide (100 mg/day), methotrexate (20 mg/wk), and azathioprine can be considered, depending on the extent of skin disease. Also, 5% imiquimod may be effective for limited skin lesions. Oral retinoids (acetretin and isotretinoin) can be used adjunctively with other treatments.

Associated lymphomas, solid tumors, and myelodysplasias have occurred in patients with LCH, with acute lymphoblastic leukemia and myelodysplastic syndrome preceding the

appearance of LCH, and acute myelogenous leukemia and acute lymphoblastic leukemia following it. In some cases of cutaneous and systemic lymphomas, aggregates of Langerhans cells are seen in the tissue affected by the lymphoma. Whether this represents the coexistence of LCH and lymphoma, or a reactive proliferation of Langerhans cells within the tissue affected by the lymphoma, is unknown.

Differential diagnosis

The diffuse, small papular form of LCH is frequently misdiagnosed as seborrheic dermatitis. The yellow color of the lesions and the presence of hemorrhage in the small papules, if present, should suggest the diagnosis of LCH. Nodular lesions of scabies can closely simulate LCH. This includes the finding of Langerhans or indeterminate cells in the dermal infiltrate on electron microscopy and S-100 and CD1a staining. The larger papules resemble JXG and xanthomas. Erosive genital disease may simulate deficiency dermatitis and cutaneous Crohn's disease.

32 Cutaneous Lymphoid Hyperplasia, Cutaneous T-Cell Lymphoma, Other Malignant Lymphomas, and Allied Diseases

CUTANEOUS LYMPHOID HYPERPLASIA (LYMPHOCYTOMA CUTIS, LYMPHADENOSIS BENIGNA CUTIS, PSEUDOLYMPHOMA)

The term cutaneous lymphoid hyperplasia refers to a group of benign disorders characterized by collections of lymphocytes, macrophages, and dendritic cells (DCs) in the skin. These processes can be caused by known stimuli (e.g., medications, injected foreign substances, infections, arthropod bites) or may be idiopathic. The disorders may have a purely benign histologic appearance or may resemble cutaneous lymphoma. If there is a histologic resemblance to lymphoma, the term pseudolymphoma is sometimes used. By standard techniques, most cases of cutaneous lymphoid hyperplasia will be found to lack clonality. Cases of monoclonal B-cell and T-cell cutaneous lymphoid hyperplasia do occur. Thus, a finding of monoclonality does not equate to the diagnosis of malignancy or lymphoma, and it does not predict biologic behavior.

Two clinical patterns of cutaneous lymphoid hyperplasia exist. The nodular form consists of nodular and diffuse dermal aggregates of lymphocytes, macrophages, and DCs. The clinicohistologic differential diagnosis is cutaneous B-cell lymphoma. The diffuse type is usually associated with drug exposure or photosensitivity (actinic reticuloid). Histologically, it must be distinguished from cutaneous T-cell lymphoma.

Cutaneous lymphoid hyperplasias—nodular B-cell pattern

The nodular pattern of cutaneous lymphoid hyperplasia is the most common pattern. It usually presents in adults and is two to three times more common in women. It favors the face (cheek, nose, or earlobe), and the majority of cases present as a solitary or localized cluster of asymptomatic, erythematous to violaceous papules or nodules. Less frequently, lesions may affect the trunk (36%) (Fig. 32-1) or extremities (25%). At times, the lesions may coalesce into a plaque or may be widespread in one region, where they present as miliary papules. Systemic symptoms are absent and, except for rare cases with regional lymphadenopathy, there are no other physical or laboratory abnormalities. It is usually idiopathic but can be caused by tattoos, *Borrelia* infections, herpes zoster scars, antigen injections, acupuncture, drug reactions, and persistent insect bite reactions.

Borrelia-induced cutaneous lymphoid hyperplasia is an uncommon manifestation of this infection, occurring in 0.6–1.3% of cases reported from Europe. The lack of borrelial pseudolymphoma in the United States compared with Europe may relate to the presence of different borrelial species in Europe, specifically *Borrelia afzelii*, that cause borreliosis. Lesions occur at the site of the tick bite or close to the edge of a lesion of erythema migrans. They may appear up to 10 months after infection. Lesions may be multiple and favor the earlobes, nipple/areola, nose, and scrotal area and vary from 1 to 5 cm in diameter. Usually, there are no symptoms, but associated regional lymphadenopathy may be present. Late manifestations of *Borrelia* infection are uncommon. The diagnosis is suspected from a history of a tick bite or erythema migrans, the location (earlobe or nipple), and the histologic picture. The diagnosis is confirmed by an elevated anti-*Borrelia* antibody (present in 50% of cases) and the finding of borrelial DNA in the affected tissue. The treatment is penicillin. Some cases progress to true lymphoma.

Histologic examination of nodular cutaneous lymphoid hyperplasia reveals a dense, nodular infiltrate that occupies primarily the dermis and lessens in the deeper dermis and subcutaneous fat (i.e., it is "top-heavy"). The process is usually separated from the epidermis by a clear grenz zone. The infiltrate is composed chiefly of mature small and large lymphocytes, histiocytes, plasma cells, DCs, and eosinophils. In the deeper portions, well-defined germinal centers are usually seen, with central large lymphoid cells with abundant cytoplasm and tingible body macrophages, and a peripheral cuff of small lymphocytes. A plasma cell–predominant variant has been described. Reactive hyperplasia of adnexal epithelium is common and characteristic, but it may also occasionally be seen in true lymphomas. Germinal centers are symmetric and surrounded by a mix of B and T cells. BCL-6 and CD10 expression is limited to the germinal centers, which also have an intact CD21+ network of DCs. Typically, more than 90% of the cells in the germinal center express the proliferative marker Ki-67 (MIB-1). There is no evidence of light-chain restriction by in situ hybridization. CD30+ cells may occasionally be prominent, raising concern about the development of a CD30+ lymphoproliferative disorder.

Because most lesions are asymptomatic, treatment is often not required. If the process has been induced by a medication, use of the medication should be discontinued. Infection should be treated and localized foci of infection removed. Intralesional steroidal agents are sometimes beneficial, but lesions may recur in a few months. Potent topical corticosteroids may also be tried for superficial lesions. Intralesional corticosteroids, cryosurgery, thalidomide (100 mg/day for a few months), interferon (IFN) alfa, IFN alfa-2b, laser ablation, and surgical excision can all produce good results. Low-dose radiation therapy is usually very effective and may be used on refractory facial lesions that cannot be satisfactorily removed surgically.

Cutaneous lymphoid hyperplasias—bandlike T-cell pattern

Cutaneous lymphoid hyperplasias may histologically show a bandlike and perivascular dermal infiltrate, at times with epidermotropism. The lesions may be idiopathic or may be caused

Fig. 32-1 Cutaneous lymphoid hyperplasia.

by photosensitivity (formerly called actinic reticuloid; now called chronic actinic dermatitis), medications (usually anticonvulsants, but also many others), or contact dermatitis (so-called lymphomatoid contact dermatitis). Clinically, these patients have lesions that clinically resemble mycosis fungoides: widespread erythema with scaling. Thicker plaques may occur as well, and these cases are frequently caused by medications. The treatment is to stop any implicated medication. If stopping the medication is ineffective, topical and intralesional corticosteroids, psoralen plus ultraviolet A (PUVA) therapy, and, for persistent localized lesions, radiotherapy may be considered. Histologically, a T-cell–rich band of lymphocytes is present. Epidermotropism, atypia, and even clonality may suggest mycosis fungoides, but the lesions resolve when the drug or other inciting agent is withdrawn.

Jessner lymphocytic infiltrate of the skin

The existence of this entity has recently been challenged, and the condition may best be classified as a variant of lupus erythematosus (LE). Clinically, Jessner infiltrate is a persistent papular and plaquelike eruption that is photosensitive and occurs primarily on the face. Histologically, there is a superficial and deep perivascular and periadnexal lymphocytic infiltrate. Interface dermatitis is absent. The infiltrating lymphocytes are suppressor T cells (CD8+). Features that suggest this may be distinct from other forms of cutaneous LE include the absence of an interface dermatitis, lack of mucin, and negative direct immunofluorescence (DIF). Tumid LE also lacks interface dermatitis but has ample mucin. Polymorphous light eruption (PMLE) is distinguished from Jessner infiltrate by having edematous papules and plaques that are more transient and by the presence of dermal edema. In PMLE, the infiltrating cells are also CD8+. True cases of lymphocytic infiltration of the skin may still exist. To distinguish them clearly from LE and PMLE, the lesions must contain predominantly CD8+ suppressor T cells, must lack dermal mucin and dermal edema, and must be fixed (not transient as with PMLE); patients must have negative DIF and serologic testing for LE. Both Jessner lymphocytic infiltrate and chronic cutaneous LE can respond to antimalarials.

CUTANEOUS LYMPHOMAS

Because cutaneous Hodgkin disease is very rare, the term non-Hodgkin lymphoma has little meaning when speaking of a lymphoma in the skin, because virtually all cutaneous lymphomas are "non-Hodgkin lymphomas." Cutaneous lymphoma can be considered to be either primary or secondary. Primary cutaneous lymphomas are those that occur in the skin, and where no evidence of extracutaneous involvement is found for some period after the appearance of the cutaneous disease. Secondary cutaneous lymphoma includes cases that have simultaneous or preceding evidence of extracutaneous involvement. These cases are best classified and managed as lymph node–based lymphomas with skin involvement. This conceptual separation is not ideal, but it has been important in developing classification schemes and determining prognosis in cutaneous lymphomas.

For many years, classification of lymphomas has been based on their histologic appearance, and lesions from all organ systems were classified histomorphologically in an identical manner to lymphomas arising in lymph nodes. It had been recognized that these classification schemes have major shortcomings when applied to extranodal lymphomas. Specifically, they did not uniformly predict clinical behavior. The new World Health Organization (WHO) classification scheme recognizes distinct forms of primary cutaneous lymphoma.

Cutaneous lymphomas are classified based on their cell type. There are B-cell lymphomas and T-cell lymphomas, but B-cell lymphomas can be T cell rich. In the latter cases, atypia is restricted to the B-cell population, and immunoglobulin gene rearrangements are detected. Histologic features used in the classification system include cell size (large vs. small), nuclear morphology (cleaved or noncleaved), and immunophenotype. Because appropriate classification may be prognostically important, experienced dermatopathology consultation should be sought in cases of cutaneous lymphoma.

Primary cutaneous T-cell lymphomas

A major insight into cutaneous lymphoma was the finding that the majority of lymphomas in the skin were of T-cell origin. This is logical, since T cells normally traffic through the skin and are important in "skin-associated lymphoid tissue." Unfortunately, dermatologists frequently use the term cutaneous T-cell lymphoma (CTCL) synonymously with mycosis fungoides (MF). Although MF represents the large majority of primary CTCLs, up to 30% of primary CTCLs are not MF. The following discussion is divided into MF and related conditions, Sézary syndrome, lymphomatoid papulosis, and non-MF primary CTCLs.

Mycosis fungoides

Mycosis fungoides is a malignant neoplasm of T-lymphocyte origin, almost always a memory T-helper (Th) cell. The incidence has been cited as 1 in 300,000 per year, but has been increasing. MF affects all races. In the United States, black persons are relatively more often affected than white persons. MF is twice as common in men as in women.

Natural history

In most cases, MF is a chronic, slowly progressive disorder. It usually begins as flat patches (patch stage), which may or may not be histologically diagnostic of MF. This inability to diagnose early cases has more to do with the limits of diagnostic capabilities than a transformation from some nonneoplastic (premycotic) condition to MF, and these cases are best considered MF from the onset. Pruritus, sometimes severe, is usually present at this stage. Over time, sometimes years, the lesions become more infiltrated, and the diagnosis is usually confirmed with repeated histologic evaluation. Infiltrated plaques occur eventually (plaque stage). In some cases, tumors may eventually appear (tumor stage). Some MF patients may present with or progress to erythroderma. Most rarely, patients may present with tumors de novo, the so-called d'emblée form. With immunophenotyping, many MF cases are now recognized as non-MF T-cell lymphomas. Eventually, in some patients, noncutaneous involvement is detected. This is usually first identified in lymph nodes. Peripheral blood involvement and visceral organ involvement may also occur.

In general, MF affects elderly patients and has a long evolution. However, once tumors develop or lymph node involvement occurs, the prognosis is guarded, and MF can be fatal. In most fatal cases, the patient dies of septicemia. Early, aggressive chemotherapy in an attempt to "cure" MF is associated with excessive morbidity and mortality and is not indicated.

Evaluation and staging

The North American Mycosis Fungoides Cooperative Group has developed a staging system. Because MF is a systemic disease from the onset (because lymphocytes naturally traffic throughout the body), concepts used for solid tumors, such as tumor burden and metastasis, cannot be readily applied. The TNMB system scores involvement in the skin (T), lymph node (N), viscera (M), and peripheral blood (B) and is in evolution. Skin involvement is divided into less than 10% (T1), more than 10% (T2), tumors (T3), and erythroderma (T4). Node involvement is normal clinically and pathologically (N0), palpable but pathologically not MF (N1), not palpable but pathologically MF (N2), or clinically and pathologically involved (N3). Viscera and blood are either not involved (M0 and B0) or involved (M1 and B1).

- Stage IA is T1,N0,M0.
- Stage IB is T2,N0,M0.
- Stage IIA is T1–2,N1,M0.
- Stage IIB is T3,N0–1,M0.
- Stage IIIA is T4,N0,M0.
- Stage IIIB is T4,N1,M0.
- Stage IVA is T1–4, N2–3,M0.
- Stage IVB is T1–4,N0–3,M1.

The "B" or blood status does not alter staging of the disease.

A staging workup would include a complete history and physical examination, with careful palpation of lymph nodes and mapping of skin lesions; a complete blood cell count (CBC) with assays for circulating atypical cells (Sézary cells); serum chemistries, including renal and liver function tests with lactate dehydrogenase; a chest radiograph evaluation; and a skin biopsy. If palpable, lymph nodes should be examined histologically. Fine-needle aspiration is not an ideal mode of evaluation, since early lymph node involvement may be localized to certain areas of the affected nodes and often requires architectural evaluation for detection. If any abnormalities are detected through these evaluations, they should be pursued. Computed tomography (CT) can be performed to assess chest, abdominal, and pelvic lymph nodes and visceral organs. These tests are useful in patients with stage II–IV disease, but are not indicated in patients with stage IA disease. Whether patients with stage IB disease should undergo these tests is unknown.

The value of this staging system is confirmed in large series. Stage IA patients have a life expectancy identical to that of a control population; only 8–9% progress to more advanced disease, and only 2% die of their disease. By contrast, patients with T2 disease have shorter survival than controls (median survival of 11.7–15.6 years); 24% of T2 patients progress to more advanced disease. T3 patients have a median survival of 3.2–8.4 years, and T4 patients, 1.8–3.7 years. Palpable adenopathy is associated with a median survival of only 7.7 years, whereas patients without adenopathy have survival of 21.8 years. Lymphadenopathy, tumors, and cutaneous ulceration are cardinal prognostic factors; no patient dies without having developed one of these, and patients with all three (in any order) survive a median of 1 year.

Clinical features

In the early patch/plaque stage, the lesions are macular or slightly infiltrated patches or plaques varying in size from 1 to 5 cm or more. Folliculotropic disease can resemble lichen nitidus. Except for the folliculotropic variant, lesions greater than 5 cm are virtually always present in true cases of MF. In contrast, most histologic simulators present with smaller skin lesions. The eruption may be generalized or may begin localized to one area and then spread. The lower abdomen, buttocks, upper thighs, and breasts of women are preferentially affected. The lesions may have an atrophic surface or may present as true poikiloderma with atrophy, mottled dyspigmentation, and telangiectasia. Poikiloderma vasculare atrophicans most often represents a clinical form of patch-stage MF. Likewise, large-plaque parapsoriasis and cases of small-plaque parapsoriasis with poikilodermatous change are early patch-stage lesions of MF. In contrast, typical digitate dermatosis probably never evolves into MF. "Invisible" MF is generalized skin involvement that is not visible to the naked eye but can be documented histologically. With current diagnostic methods, this can usually be confirmed. In general, the patch-stage lesions (Fig. 32-2) resemble an eczema, being round or ovoid, although annular, polycyclic, or arciform configurations can occur. Less common forms are the verrucous or

Fig. 32-2 Mycosis fungoides, patch stage.

Fig. 32-3 Mycosis fungoides, hypopigmented patches.

Fig. 32-4 Mycosis fungoides, plaque stage. (Courtesy of Dr. Ellen Kim.)

hyperkeratotic form, the hypopigmented form (Fig. 32-3), lesions resembling a pigmented purpura, and the vesicular, bullous, or pustular form. The hypopigmented form seems to be more common in persons of color and is a typical presentation for adolescents and children with MF. Subtle lesions of MF may manifest clinically during anti–tumor necrosis factor (TNF) therapy.

In the plaque stage, lesions are more infiltrated and may resemble psoriasis (Fig. 32-4), a subacute dermatitis, or a granulomatous dermal process such as granuloma annulare. The palms and soles may be involved, with hyperkeratotic, psoriasiform, and fissuring plaques. The infiltration of the plaques, at first recognized by light palpation, may be present in only a few of the lesions. It is a manifestation of diagnostic importance. Different degrees of infiltration may exist, even in the same patch, and sometimes it is more pronounced peripherally, the central part of the plaque being depressed to the level of the surrounding skin. The infiltration becomes more marked and leads to discoid patches or extensive plaques, which may be as wide as 30 cm.

Eventually, through coalescence of the various plaques, the involvement becomes widespread, but there are usually patches of apparently normal skin interspersed. When the involvement is advanced, painful superficial ulcerations may occur. During this phase, enlarged lymph nodes usually develop. They are nontender, firm, and freely movable.

Fig. 32-5 Mycosis fungoides, early tumor stage.

Fig. 32-6 Follicular mycosis fungoides. (Courtesy of Dr. Ellen Kim.)

The tumor stage is characterized by large, variously sized and shaped nodules on infiltrated plaques and on apparently normal skin (Fig. 32-5). These nodules tend to break down early and to form deep oval ulcers, whose bases are covered with a necrotic grayish substance and which have rolled edges. The lesions generally have a predilection for the trunk, although they may be seen anywhere on the skin or may involve the mouth and upper respiratory tract. Infrequently, tumors may be the first sign of MF.

The erythrodermic variety of MF is a generalized exfoliative process, with universal redness. The hair is scanty, nails are dystrophic, palms and soles are hyperkeratotic, and at times, generalized hyperpigmentation may occur. Erythroderma may be the presenting feature.

Alopecia mucinosa

The infiltrating cells of MF can demonstrate a predilection for involving the hair follicle (Fig. 32-6). This may be observed simply by folliculotropism of the cells (pilotropic or follicular

Fig. 32-7 Alopecia mucinosa.

Fig. 32-8 Syringotropic mycosis fungoides.

MF) or by the appearance of follicular mucinosis (Fig. 32-7). In all cases of follicular mucinosis, the histologic specimen should be carefully examined and the diagnosis of MF considered. Among patients older than 40 who have follicular mucinosis, a large percentage will have MF or go on to develop it. However, the finding of a T-cell clone in lesions of follicular mucinosis without MF is not predictive of the development of CTCL.

Selective tropism of the CTCL cells to the sweat glands and ducts is termed syringotropic CTCL (Fig. 32-8). This is often seen in conjunction with follicular involvement. Syringolymphoid hyperplasia may be seen in these cases histologically and may mimic eccrine carcinoma. Cases previously termed "syringolymphoid hyperplasia with alopecia" are now considered to be cutaneous T-cell lymphoma. Clinically, the lesions present as discrete follicular and nonfollicular erythema, along with alopecia, milia, and follicular cysts. The initial clinical diagnosis in such cases is often discoid lupus erythematosus. The prognosis in MF with adnexal involvement is as predicted by the staging system for other MF forms. Patients with granulomatous MF have a poorer prognosis and a poorer response to skin-directed therapy.

Systemic manifestations

Mycosis fungoides as a form of malignant lymphoma may progress to include visceral involvement. Lymph node involvement is most common; it predicts progression of MF in at least one quarter of patients and reduces survival to about 7 years. Any other evidence of visceral involvement is a poor prognostic sign. An abnormal result on liver-spleen scan, chest radiograph or CT evaluation, abdominal or pelvic CT scans, or bone marrow biopsy is associated with a survival of about 1 year. The prognosis is worse in non-Caucasian patients with early-onset MF, especially African American women.

Pathogenesis

Mycosis fungoides is a neoplasm of memory Th cells in most cases. Rare cases of suppressor cell (CD8+) MF have been reported. These CD8+ cases may behave indolently, like MF, or aggressively. The aggressive subset tends to present with plaques rather than patches. The events leading to the development of the malignant T cells are unknown. Some speculate that it is caused by chronic exposure to an antigen, but this has yet to be confirmed. Patients with atopic dermatitis appear to be at increased risk for development of MF, suggesting that persistent stimulation of T cells may lead to development of a malignant clone.

The inflammatory nature of the skin lesions has led to investigation of the interactions of the malignant T cells and both keratinocytes and antigen-presenting cells (APCs, including Langerhans cells) in MF. MF skin lesions have many features of skin that is immunologically "activated." MF cells express cutaneous lymphocyte antigen (CLA), the ligand for E selectin, which is expressed on the endothelial cells of inflamed skin. This allows the malignant cells to traffic into the skin from the peripheral blood. CCR4, another homing molecule, is expressed on MF cells, and the ligand for this receptor is on basal keratinocytes. APCs are increased in MF lesions and have increased functional capacity to activate T cells. There is increased expression of major histocompatibility complex (MHC) class II antigens on the surface of the APCs. Through cytokines, infiltration of neoplastic and reactive T cells is increased. The pattern in early MF is more Th1-like, and the nonneoplastic infiltrating cells (tumor-infiltrating lymphocytes, TILs) may play a role in downregulating and controlling the neoplastic cells. There are more CD8+ cells in these early lesions, and these TILs may control the malignant clone. In fact, MF patients with more than 20% CD8+ cells in their skin survive longer than those with less than 15%. In summary, early MF is a condition in which host immunity is intact and the host immune system effectively limits proliferation of the malignant T-cell clone. In more advanced MF and in Sézary syndrome, perhaps through interleukin (IL)-4 and IL-10, a Th2 environment exists. This downregulates suppressor cell function and allows the malignant clone to proliferate. In addition, the Th2-dominant environment reduces effective Th-cell function, explaining the increased risk of infection and secondary cancer in patients with advanced CTCL. Correcting the aberrant immune response in advanced CTCL is the basis of some treatment approaches.

Common chromosomal alterations in MF include gain of 7q36 and 7q21–7q22 and loss of 5q13 and 9p21. This characteristic pattern differs from that seen in Sézary syndrome, suggesting that the two disorders are distinct. Low levels of human herpesvirus (HHV) 8 have been detected in large-plaque parapsoriasis as well as MF, but an etiologic link has not been established.

As MF advances, the number of circulating malignant T cells increases. Standard cytologic evaluation (the Sézary preparation) is expensive and not very accurate, even when enhanced by specific labeling techniques. Use of standard laboratory tests, such as the CD4/CD8 ratio test, which increases as MF progresses, and assessment of the number of CD4+,CD7– or CD4+,CD26– circulating cells, which relatively specifically identify MF cells, yield indicators of tumor burden with advanced disease but are of limited value in early disease.

Histopathology

Perhaps more than in any other situation in dermatopathology, the ability to diagnose mycosis fungoides histologically correlates closely with the skill, training, and experience of the reviewing pathologist. When the clinician is considering a diagnosis of MF, consultation with a skilled dermatopathologist should be strongly considered if original histologic reports are nonconfirmatory or nonspecific.

In patch-stage lesions, subtle epidermotropism of lymphocytes resembles a vacuolar interface dermatitis with a lymphocyte in every vacuole. As lesions progress, there is a distinct bandlike distribution of lymphocytes with epidermotropism. At this stage, a large, dark lymphocyte is present in every vacuole. The lymphocytes within the epidermis may be numerous or few but are typically larger, darker, and more angulated than those in the dermis. Papillary dermal fibrosis is typically present. The superficial perivascular lymphoid infiltrate that surrounds the postcapillary venule is typically more prominent above the vessel than below the vessel ("bare underbelly" sign).

Plaques of MF show a more prominent, superficial bandlike lymphoid infiltrate and a deeper perivascular dermal component than patch-stage lesions. Papillary dermal fibrosis is more prominent, and the subpapillary plexus is shifted downward. Epidermotropism is much more marked and is typically associated with minimal spongiosis. This helps distinguish patch-stage MF from spongiotic dermatitis. Vesicular variants are an exception to this rule. In vesicular variants, spongiosis is prominent and results in intraepidermal and subcorneal vesiculation. Eosinophils are common in folliculotropic MF (with or without follicular mucinosis) but are uncommon in other MF forms.

In thick plaques and tumors, epidermotropism may be substantially diminished. The diagnosis of MF is confirmed by the presence of dense sheets of infiltrating lymphocytes in the dermis and subcutaneous fat. These cells may have cerebriform nuclei.

Cardinal features that should suggest a diagnosis of MF include the following:

- Solitary or small groups of lymphocytes in the basal cell layer
- Epidermotropism of lymphocytes, with disproportionately scant spongiosis
- More lymphocytes within the epidermis than would normally be seen in an inflammatory dermatosis, with little accompanying acanthosis or spongiosis
- Lymphocytes in the epidermis larger than those in the dermis
- Papillary dermal fibrosis with bundles of collagen arranged haphazardly
- Prominent folliculotropism or syringotropism of the lymphocytes, especially with intrafollicular mucin deposition (follicular mucinosis)

Features that should suggest a diagnosis of inflammatory dermatosis over MF include the following:

- Prominent upper dermal and papillary edema
- Marked epidermal spongiosis
- Accumulation of the intraepidermal inflammatory cells in flask-shaped collections, with the top open to the stratum corneum

Immunohistochemistry is of some value in assessing MF. MF cells characteristically are CD4+, but lose the CD7 and CD26 antigens (i.e., they are CD4+,CD7–,CD26–). This phenotype is very unusual for nonmalignant T cells and thus is useful in evaluating biopsy specimens and peripheral blood lymphocytes. Loss of CD7 expression within the large, dark lymphocytes in the epidermis, with normal expression in the benign recruited lymphocytes in the infiltrate below, suggests a diagnosis of MF. DNA hybridization or a Southern blot test is frequently performed in equivocal cases to detect clonal rearrangement of the T-cell receptor (TCR). However, these data must be interpreted with caution; again, clonality does not confirm a diagnosis of malignancy. Benign processes may contain clonal TCR rearrangements. In early lesions of MF, the number of infiltrating cells may be insufficient for a clone to be detected, so a negative test does not exclude the diagnosis of MF. Testing with fresh tissue is somewhat more sensitive than with fixed tissue using current methods. Similar techniques can be used to evaluate lymph nodes in MF patients. Lymph node involvement can be detected by these molecular methods, whereas routine histologic evaluation yields normal results. Patients with more advanced disease are more likely to have clones in their lymph nodes, and the presence of clonality is predictive of shorter survival.

Differential diagnosis

In the early patch stage, MF may be difficult to diagnose. The skin lesions usually resemble a nondescript form of eczema with some scale. Interestingly, despite the itching, scratch marks and lichenification are usually absent. MF presenting as papuloerythroderma of Ofuji is an obvious exception. The multiple morphologies of MF make the differential diagnosis vast. Plaquelike lesions may resemble subacute dermatitis or psoriasis. Tumors must be differentiated from other forms of lymphoreticular malignancy and metastases.

Treatment

Effective therapy that reliably prolongs survival of MF patients has not yet been documented. Many forms of therapy induce remissions of variable length. The therapeutic choice depends on extent of disease, the patient's overall health and physical status, the physician's experience and preference, and the availability of various options. Topical corticosteroids, topical nitrogen mustard or 1,3-bis-(2-chloroethyl)-l-nitrosourea (carmustine, BCNU), bexarotene gel 1%, and PUVA or narrowband UVB are generally good choices for stages IA, IB, and IIA disease. Patch-stage MF has responded to alefacept. Total-skin electron beam therapy can be used for refractory stage IIA and IIB cases. Single-agent chemotherapy or photophoresis can be used as initial management for stage III patients. Low-dose methotrexate may control the skin lesions of MF but has been associated with development of a secondary aggressive lymphoma in a few patients. Pegylated liposomal doxorubicin and combinations of IFN alfa, retinoids (bexarotene or isotretinoin), photophoresis, IFN gamma, skin-directed PUVA, sargramostim (granulocyte-macrophage colony-stimulating factor), alemtuzumab, and perhaps IL-2, IL-12, and IFN alfa may be effective in stage IV disease, as well as for patients who have failed the therapies previously cited for stages IIB and III MF. Multiagent systemic chemotherapy is used much less often with the advent of immunomodulatory treatments for MF. Chemotherapy should be considered only when all other treatment options have failed. Treatment of early-stage disease is in general restricted to skin-directed treatments. More advanced disease is treated with different modalities at different institutions. Combinations of agents are often used, and the combinations and their order of use vary among institutions. In general, therapies that also enhance the patient's immune system are favored in persons with more advanced disease. Complete remission of MF has been noted after a severe reaction to combined therapy with bexarotene, vorinostat, and high-dose fenofibrate. The reaction included fever, extensive skin necrosis, and granuloma formation.

Topical corticosteroids

The availability of superpotent class I topical corticosteroids has led to a reassessment of their possible role in the management of early MF (patch stage, T1 and T2). Zackheim et al. reported a 63% complete remission rate for patients with T1 disease and a total response rate of 94%. In T2 patients, complete response was seen in only 25% but total response in 82%. The predominant side effect was a temporary and reversible suppression of the hypothalamic-pituitary axis in about 13% of patients. The responses were short-lived if therapy was stopped, but given the limited toxicity, this is not necessary in many patients. The adjunctive value of topical corticosteroids in T1 MF requires reappraisal because the response rates are similar to other modalities used for early MF, and the toxicity is very low.

Topical nitrogen mustard

Anhydrous gel or ointment-based mustard products are being used more often, but aqueous mustard is still used as well. The contents of a 10-mg vial of mechlorethamine hydrochloride (Mustargen-MSD) are dissolved in 60 mL of tap water and applied to the entire skin surface, except the face, axillae, and genitalia, with a 2-inch paint brush or gauze pad. The last milliliter may be diluted to half-strength or greater dilution for application to the face, axillae, and genitalia. Daily applications are made until complete clearing occurs, which usually takes several months or longer, and may be continued indefinitely. Such treatment leads to complete responses in 80% of patients with stage IA disease, 68% in stage IB, 61% in stage IIA, 49% in stage IIB, and 60% in stage III patients. About 10% of patients obtain a durable and long-lasting remission of more than 8 years. The major side effects of topical nitrogen mustard (NH2) therapy are cutaneous intolerance, which occurs in almost 50% of patients, and allergic contact dermatitis, which occurs in 15%. Short (1 h) contact does not reduce this rate of sensitization. This can be reduced by the use of an ointment formulation, but response rates have been reported to be inferior with the ointment form. At least half of patients will relapse when therapy is stopped, but they frequently will respond again to NH2.

The duration of maintenance therapy after achieving remission varies in different centers. Some treat for an additional 6 months, and others taper treatment over 1 year or more, or continue treatment indefinitely. In many centers, topical nitrogen mustard has been a proven mainstay of therapy for patch- or plaque-stage MF without lymphadenopathy.

Topical BCNU (carmustine)

Topical BCNU, 2 mg/mL in 150-mL aliquots, dissolved in ethanol, is dispensed to the patient. From this stock solution, the patient takes 5 mL and adds it to 60 mL of water at room temperature. This is applied once a day to the whole body, sparing the folds, genitals, hands, and feet (if they do not have lesions). If the extent of disease is limited, only the affected areas are treated. The average treatment course is 8–12 weeks. If, after 3–6 months, the patient's condition is not responding, the concentration may be doubled and the treatment repeated for 12 weeks. For small or persistent lesions, the straight stock solution may be applied daily. Patients tolerate BCNU better than nitrogen mustard, contact sensitization is uncommon, and responses are more rapid. CBC should be monitored monthly during treatment, but marrow suppression occurs in less than 10% of patients treated with the low concentrations. Telangiectasia, which may be persistent and severe, can occur after prolonged BCNU therapy or following an adverse cutaneous reaction to the medication.

Ultraviolet therapy

Both UVB (narrow- or broad-band) and PUVA (systemic or bath) have been effective in the management of MF. About 75% of patients with patch-stage disease will have a complete clinical remission with UVB therapy. Home therapy is successful. PUVA has been used more extensively and, because of its deeper penetration, is perhaps better suited to the treatment of a disorder with a dermal component. Complete clearing is seen in 88% of patients with limited patch/plaque disease and in 52% of patients with extensive disease. Tumor-stage MF patients do not clear. Erythrodermic patients have poor tolerance for PUVA. Up to 50% of patients with a complete response to PUVA may have a remission of up to 10 years. Retinoids and IFN alfa may be added to PUVA. Retinoids may reduce the total number of PUVA treatments required. Low-dose IFN alfa plus PUVA may be used in patch-stage patients in whom topical therapy and PUVA alone are ineffective. The excimer laser may be used once or twice a week to deliver the phototherapy if the patient has a limited number of lesions. On average, 5–6 weeks of treatment is required, and remissions of up to 2 years or more can be achieved.

Extracorporeal photochemotherapy (photophoresis, ECP) is a therapeutic modality in which the circulating cells are extracted and treated with UVA outside the body; the patient ingests psoralen before the treatment. Complete responses are seen in about 20% of MF patients, and a partial response occurs in a similar percentage. In the original reports, the overall response rate for erythrodermic patients was 80%, but many of these patients failed to have at least the 50% clearing required to be considered a partial response. In one comparative trial, standard PUVA was significantly more effective than photophoresis alone, and photophoresis was judged ineffective in plaque-stage (T2) MF. ECP is now used in combination with other agents, especially IFN alfa, and appears to have better efficacy. Insulin-dependent diabetic patients respond poorly.

Photodynamic therapy

Photodynamic therapy (PDT) with methyl-aminolevulinic acid has been used successfully for paucilesional MF. Responses were seen in 75% of patients, and patient satisfaction was high.

Radiation

Total-skin electron beam (TSEB) therapy in doses in excess of 3000 Gy is very effective in the management of MF. Stage T1 patients have a 98% complete response; stage T2, 71%; stage T3, 36%; and stage T4, 64%. Long-term remissions occur in about 50% of T1 patients and 20% of T2 patients. Erythrodermic patients tolerate TSEB therapy poorly; other modalities should be attempted initially. Adjuvant therapy with a topical agent or PUVA can be considered if the patient relapses, as frequently occurs. The most common side effects of TSEB therapy are erythema, edema, worsening of lesions, alopecia, and nail loss. Persistent hyperpigmentation and chronically dry skin are also problems after TSEB therapy. Orthovoltage radiation may be used to control tumors or resistant thick plaques in patients whose conditions have been otherwise controlled with another modality.

Biologic response modifiers (multimodality immunomodulatory therapy)

The appearance of circulating malignant T cells in MF may indicate failure of the host immune system to control the disease. Immunomodulatory agents are used in an attempt to enhance host immune function and gain control of the disease. It is often combined with treatments that increase malignant

cell apoptosis, so that the "tumor antigens" released will be recognized and immunologically "attacked" by the host immune system. These immunomodulatory agents both activate APCs and enhance Th1 immune function directed against the malignant T-cell clone. IFN alfa and IFN gamma have been shown to have efficacy against MF. IFN alfa is associated with a positive response in about 60% of patients and a complete response in 19%. If it is used as a single agent, toxicity is high and includes fever, chills, myalgias, neutropenia, and depression. Low-dose IFN-alfa and IFN-gamma treatments and granulocyte-macrophage colony-stimulating factor (GM-CSF) are now used in adjunctive fashion in combination with retinoid therapy, phototherapy, and other modalities. This is termed multimodality immunomodulatory therapy. IL-2 and IL-12 may be used in a similar manner in the future.

Retinoids

Both isotretinoin and etretinate have efficacy in the treatment of MF. A clinical response is noted in about 44% of patients. Dosage of isotretinoin is about 1 mg/kg/day to start and may be increased up to 3 mg/kg/day as tolerated. Retinoids may be effective in stage IB (T2) and stage III patients, and as a palliative treatment in those with stage IVA disease. Bexarotene (Targretin), a synthetic retinoid that is bound preferentially by the retinoid X receptor (RXR), is thought to work by inducing apoptosis in the malignant T cells. It is available as a topical gel and as an oral tablet. Topical therapy is used in patients with stage IA–IIA CTCL. Patients improve about 50% with this treatment. Oral bexarotene at a dose of 300 mg/m^2 also has a response rate of about 50% in early-stage CTCL. This dose is complicated by hypercholesterolemia, marked hypertriglyceridemia (at times complicated by pancreatitis), central hypothyroidism, and leukopenia. It may be combined with PUVA and other forms of treatment at a lower dose.

Systemic chemotherapy

For most forms of cancer, combinations of chemotherapeutic agents are given. In mycosis fungoides, however, multidrug chemotherapy often exacerbates the ongoing immune imbalance and may prevent the patient's immune system from attacking the malignant T cells. For this reason, and because of the enhanced efficacy of combination immunomodulatory treatment regimens, systemic chemotherapy is now very uncommonly used for MF. Methotrexate, in doses from 5 to 125 mg/week, is effective for the management of T3 patients. In these patients, Zackheim et al. reported that 41% had a complete response, and an additional 17% a partial response, giving a total response of 58%. The median overall survival was 8.4 years, and 69% of patients were alive at 5 years. For advanced MF, higher doses of methotrexate with citrovorum-factor rescue were successful in obtaining a response, which was then maintained with lower doses of methotrexate, not requiring rescue. Similarly, vorinostat (and other histone deacetylase inhibitors), pentostatin, etoposide, fludarabine, and 2-chlorodeoxyadenosine have been used. Systemic chemotherapy beyond methotrexate, especially multiagent chemotherapy, is best managed by an oncologist. Systemic chemotherapy is only indicated in stage III and IVA patients who have failed all the available immunoenhancing treatment protocols previously noted. A number of new agents are being evaluated for the treatment of MF. Histone deacetylase inhibitors, including vorinostat, demonstrate responses in a subgroup of patients. Forodesine is a novel inhibitor of purine nucleoside phosphorylase, and pralatrexate is a novel targeted antifolate agent.

Fusion toxin

The toxin DAB389IL-2 is the fusion of a portion of the diphtheria toxin to recombinant IL-2. This selectively binds to cells expressing the IL-2 receptor and leads to their death. A series of MF patients who expressed the IL-2 receptor demonstrated a response rate of 37%, including a complete response in 14%. These patients had failed conventional therapies. Patients in stages I–III achieved response, but no patient with stage IV disease did so. Fever, chills, hypotension, nausea, and vomiting were common, and at high doses, a vascular leak syndrome occurred. This agent is reserved for advanced-stage patients who have failed other modalities.

Pagetoid reticulosis

Localized epidermotropic reticulosis, pagetoid reticulosis, or Woringer-Kolopp disease is an uncommon lymphoproliferative disorder considered be a form of mycosis fungoides. Other terms suggested for these cases have included acral mycosis fungoides or mycosis fungoides palmaris et plantaris. In large, MF clinics, such cases represent about 0.6% of all MF cases. Pagetoid reticulosis is divided into classic Woringer-Kolopp, which usually describes solitary lesions, and cases with multiple lesions (Ketron-Goodman variant). The unique features of Woringer-Kolopp disease are clinical. The disease presents as a solitary lesion that is often located on an extremity and frequently has a keratotic rim. If there is more than a single lesion, the lesions often tend to involve both the palms and the soles. Frequently, over months to years, the lesion gradually enlarges, reaching more than 10 cm in size. In some cases, the lesions spontaneously come and go over many years. About 20% of cases occur in patients who are younger than 15 years. The long duration without progression has been a clinical hallmark of Woringer-Kolopp disease. Histologically, there is prominent epidermotropism of lymphocytes, with many lining up in the basal cell layer. This histologic pattern correlates with strong αEβ7- and α4β7-integrin expression by the infiltrating cells. This integrin expression is also seen in the epidermotropic cells of classic MF and contact dermatitis. In MF, most cases are CD4+, but in the acral MF cases, they may be CD4+, CD8+, or negative for both. TCR gene rearrangements can be detected in many cases of Woringer-Kolopp disease. Therapeutically, local excision and radiation therapy have been "curative" in many patients. Topical and systemic PUVA and PDT have also proved effective. Local recurrence is possible.

Sézary syndrome

Sézary syndrome is the leukemic phase of mycosis fungoides. The characteristic features are generalized erythroderma, superficial lymphadenopathy, and atypical cells in the circulating blood. Although patients with classic MF may progress to Sézary syndrome, patients with Sézary syndrome usually are erythrodermic from the onset. The skin shows a generalized or limited erythroderma of a typical fiery red color. Associated features can include leonine facies, eyelid edema, ectropion, diffuse alopecia, hyperkeratosis of the palms and soles, and dystrophic nails. Some patients develop lesions identical to vitiligo, especially on the lower legs. The symptoms are those of severe pruritus and burning, with episodes of chills. Prognosis is poor, with an average survival of about 5 years.

Superficial lymphadenopathy is usually found in the cervical, axillary, and inguinal areas. Leukocytosis up to 30,000 cells/mm^3 is usually present. In the peripheral blood, skin infiltrate, and lymph nodes, Th cells with deeply convoluted nuclei are found, the so-called Sézary cells. Chromosomal aberrations are common but differ from the typical pattern seen in MF. Resistance to Fas-ligand and TNF-related apoptosis has been demonstrated.

Histologically and on immunohistochemistry, there are no reproducible differences between cases of MF and Sézary syndrome. In a fair number of Sézary patients, the cutaneous histology may be nonspecific, showing a spongiotic dermatitis. Additional hematologic evaluation may be necessary to confirm the diagnosis in the erythrodermic patient. T-cell gene rearrangement studies are frequently used to confirm the diagnosis of Sézary syndrome. In addition, an increased CD4/CD8 ratio in the blood, with an increase in the number of CD3+/CD4+/CD7–/CD26– circulating cells, is suggestive of leukemic MF.

The erythroderma of Sézary syndrome must be distinguished from chronic lymphocytic leukemia (CLL), psoriasis, atopic dermatitis, photodermatitis, seborrheic dermatitis, contact dermatitis, drug reaction, and pityriasis rubra pilaris. This is done primarily by histopathologic and immunopathologic examination. In Sézary syndrome, the infiltrating T cells in the skin have a Th2 phenotype, and Th2 cytokines are produced by these cells. This explains the reduced delayed-type hypersensitivity, elevated IgE, and eosinophilia seen in these patients.

Sézary syndrome is difficult to treat. Low-dose methotrexate has a reasonable response rate of about 50% and an overall survival of 101 months, suggesting a survival benefit with its use. Photophoresis, used in combination with other agents, is effective in some patients, but the median survival time is only 39–60 months (see earlier). TSEB radiation has produced some complete cutaneous responses, as well as improvement in the blood burden of malignant cells. Zanolimumab has also been used in this setting.

Granulomatous slack skin

Granulomatous slack skin is a rare variant lymphoma that typically presents in middle-age adults and gradually progresses over years. It occurs more often in men. Lesions are erythematous, atrophic, bulky, infiltrated, pendulous, and redundant plaques in the axillae and groin (Fig. 32-9). Unusual presentations may resemble Hansen's disease or acquired ichthyosis. Histologically, there is a lymphohistiocytic infiltrate extending through the dermis into the subcutaneous fat. Focal collections of huge, multinucleated cells with 20–30 nuclei arranged in a wreathlike pattern are characteristic. Elastophagocytosis is prominent and elastic tissue is absent in areas of inflammation. Lymphocytes are also found within the multinucleate giant cells and are arranged around them. Epidermotropic lymphocytes are also seen. Immunohistologically, the cells are CD4+. T-cell gene rearrangements can be detected. In most patients, the condition evolves into mycosis fungoides, but about one third of patients with granulomatous slack skin develop Hodgkin disease after years to decades.

Lymphomatoid papulosis

Lymphomatoid papulosis (LyP) is an uncommon, but not rare, disorder. It occurs at any age, including childhood, but is most common in adults with a mean age of 44. In typical cases, the lesions and course are very similar to Mucha-Habermann disease (pityriasis lichenoides et varioliformis acuta), except that the lesions tend to be slightly larger and fewer in number and have a greater propensity to necrosis. Symptoms are usually minimal. The primary lesion is a red papule up to about 1 cm in diameter (Fig. 32-10). The lesions evolve to papulovesicular, papulopustular, or hemorrhagic, then necrotic papules over days to weeks. They typically heal spontaneously

within 8 weeks, somewhat longer in larger lesions. Lesions are usually generalized, although cases limited to one anatomic region have been reported.

There may be crops of lesions or a constant appearance of a few lesions. In most patients, however, the condition tends to be chronic, and lesions are present most of the time if no treatment is given. The average number of lesions present at any one time is usually 10–20, but cases with more than 100 lesions occur. Lesions heal with varioliform, hyperpigmented, or hypopigmented scars. Cases previously reported as solitary, large nodules of lymphomatoid papulosis would now be classified as CD30+ large cell lymphomas or as overlaps between LyP and lymphoma, termed borderline cases. Localized agminated LyP may be seen in areas typical for mycosis fungoides.

The diagnosis of LyP is confirmed histologically. There is a dermal infiltrate that is wedge shaped, patchy, and perivascular. In larger lesions, the infiltrate may occupy the whole dermis. It may also be bandlike. The infiltrate may involve the epidermis, with epidermotropism of inflammatory cells. As lesions evolve, epidermal necrosis and ulceration may occur. The dermal vessels may demonstrate fibrin deposition and, more rarely, a lymphocytic "vasculitis." The dermal infiltrate is composed of lymphoid cells, eosinophils, neutrophils, and larger mononuclear cells. Atypical, large or small lymphoid cells are present and may represent up to 50% of the infiltrate. Histologically, lesions have been classified into type A, type B, and type C lesions.

Type A lesions contain atypical large cells with abundant cytoplasm and prominent nuclei, with prominent eosinophilic nucleoli. If these cells contain two nuclei, they closely resemble Reed-Sternberg cells. In type B lesions, the atypical cells are smaller, with a smaller cerebriform, hyperchromatic nucleus. These resemble the atypical cells of MF. In both types of lesion, atypical mitotic figures may be observed. Immunophenotypically, the large atypical cells mark as T cells, usually Th type. The atypical cells, especially those of the type A lesions, stain for the activation marker Ki-1 or CD30. Bcl-2 expression occurs in about 50% of cases. When clonal rearrangement studies are performed, clonal rearrangements may be found in up to 40% of LyP lesions, but this finding is not predictive of the behavior of that lesion or the case in general. Type C lesions overlap with primary cutaneous large cell lymphoma, with no clear distinction between the two. Type D, CD8+ LyP is a rare variant in which CD8+ T cells proliferate, mimicking cytotoxic lymphoma. Type E has been proposed as an angioinvasive type resembling angiodestructive lymphoma histologically, but with a self-healing course. The follicular type resembles folliculotropic MF with a relapsing course.

Lymphomatoid papulosis types A and B are associated with lymphoma. In the general literature, this number is about 5–10%, but some reports have documented rates as high as 20%, and at the University of California at San Francisco (UCSF), up to 40% of cases of LyP have an associated lymphoma. The lymphoma may occur before, concurrently with, or after the appearance of the LyP. In most cases, LyP precedes development of lymphoma, sometimes by a long period—up to 20 years. The associated lymphoma is most often mycosis fungoides (40%), a CD30+ T-cell lymphoma (30%), or Hodgkin disease (25%). The lymphoma and LyP may behave quite independently. If the lymphoma is successfully treated and cleared, the LyP typically continues. Despite this independent behavior, the lymphoma and the LyP may contain the same clonal TCR gene rearrangement. Patients with pure type B lesions are much less likely to develop lymphoma than patients with type A lesions. Lesions of LyP may occur on a background of MF and must be distinguished from CD30+ large cell transformation of MF. Papular lesions of LyP tend to occur in crops. Even though the LyP lesions may demonstrate the same clonal rearrangements as the MF, they often continue to appear in crops, even when the MF lesions respond to therapy.

Therapy may not be necessary; no evidence shows that treatment of LyP prevents development of secondary lymphoma. When any therapy is stopped, the LyP invariably returns. Therefore, patients only need to be treated if they are moderately symptomatic and the treatment has fewer potential complications than the benefits gained. Superpotent topical corticosteroids have been beneficial in some childhood cases. Topical bexarotene may abort early lesions, and oral bexarotene may suppress lesion formation. PUVA systemically or topically may be effective, although maintenance treatment is usually required. Both narrow- and broad-band UVB may be successful. Of all the systemic agents, methotrexate gives the most dependable response, with up to 90% of LyP patients improving significantly. It is given in weekly doses similar to those used for rheumatoid arthritis, usually 7.5–15 mg/week. Higher doses may be required in some patients. Response is rapid. Some patients treated with methotrexate may have remissions of the LyP. In most, however, maintenance therapy is required.

Pityriasis lichenoides

Both the acute and the chronic form of pityriasis lichenoides are lymphocytic vasculitides. The lymphoid infiltrate may contain a clonal proliferation. However, progression to cutaneous lymphoma is rare.

Pityriasis lichenoides et varioliformis acuta (Mucha-Habermann disease)

Pityriasis lichenoides et varioliformis acuta (PLEVA) is a disorder that usually appears suddenly in children or young adults. Individual lesions are erythematous macules, papules, or papulovesicles. Lesions tend to be brownish red and evolve through stages of crusting, necrosis, and varioliform scarring. Lesions tend to appear in crops and may number from a few to more than 100 (Fig. 32-11). In general, PLEVA patients have more and smaller lesions than patients with LyP. The trunk is favored, but even the palms and soles may infrequently be involved. The patient feels otherwise well. The natural history is benign, with spontaneous involution occurring over 1–3 years. In children, diffuse cases resolved more quickly than cases that were purely central; cases with primarily peripheral lesions took almost twice as long to resolve.

Histologically, PLEVA is characterized by epidermal necrosis, together with prominent hemorrhage and a dense perivascular infiltrate in the upper and middle dermis in a wedge-shaped pattern. Lymphocytic vasculitis may be seen. T-cell gene rearrangements may be detected, but the significance of this finding is unclear at this time. Treatment of PLEVA may include oral erythromycin or tetracyclines and phototherapy (broad- or narrow-band UVB, PUVA, or PDT). Topical tacrolimus may be effective. Low-dose methotrexate,

Fig. 32-11 Mucha-Habermann disease.

5.0–15 mg/week, may be required in severe cases. A rapid response to azithromycin has been reported. Etanercept has been reported as effective, but infliximab has been reported to cause pityriasis lichenoides.

An unusually severe form of PLEVA, febrile ulceronecrotic Mucha–Habermann disease, is characterized by the acute onset of diffuse, coalescent, large, ulceronecrotic skin lesions associated with high fever and constitutional symptoms. The condition may begin as typical PLEVA, but the ulceronecrotic lesions usually begin to appear within a few weeks. Skin necrosis may be extensive, especially in the intertriginous regions. Associated symptoms include gastrointestinal (GI) and central nervous system (CNS) symptoms, pneumonitis, myocarditis, and even death (in adult cases). The condition favors boys age l8 or younger. This severe form of PLEVA usually lasts several months with successive outbreaks, then resolves or converts to more classic PLEVA. Reported triggers include viral infections and radiocontrast injection. Treatment is systemic corticosteroids, and if response is limited, methotrexate. Dapsone may also be useful, for maintenance and as a steroid-sparing agent. Febrile ulceronecrotic Mucha-Habermann disease has been treated successfully with methotrexate as well as with infliximab and intravenous immune globulins.

Pityriasis lichenoides chronica

Pityriasis lichenoides chronica (PLC) is a chronic form of pityriasis lichenoides related to PLEVA by its common histology. Lesions are erythematous, scaly macules and flat papules with very slow evolution. Lesions each last several months. The eventual resolution of lesions of PLC distinguishes it from guttate parapsoriasis, which it may resemble clinically. Lesions of small-plaque parapsoriasis do not spontaneously resolve. Lesions of PLC favor the lateral trunk and proximal extremities. Patients may have from 10 to hundreds of lesions, but usually fewer than 50. Resolution may leave persistent areas of hypopigmentation, which last for months to years. In many patients, the hypopigmented macules are the most prominent clinical finding. Unlike PLEVA, PLC tends to last for many years. Lesions may occur at any age. The condition often affects children, and onset at birth has been described.

Histologically, the changes in PLC are similar to PLEVA but much more subtle. A mild interface or perivascular lymphocytic infiltrate with overlying parakeratosis may be present. T-cell gene rearrangement studies may demonstrate monoclonality; however, the meaning of this finding is unclear at this time. Treatment with phototherapy (natural sunlight, UVB, UVA1, or PUVA) is most effective. Topical corticosteroids or tacrolimus may be tried. No treatment is required.

Generally, PLC is a benign disease. Rare patients have progressed to develop CTCL. The authors recommend that patients with PLC be followed regularly; changes in lesion morphology, including induration, erosion, atrophy, persistent erythema, or poikiloderma, should trigger repeat pathologic evaluation.

Primary cutaneous T-cell lymphomas other than mycosis fungoides

Once a cutaneous lymphoma has been identified as being of T-cell origin and the diagnosis of mycosis fungoides and its variants has been excluded, the most important evaluation is to determine the CD30-staining pattern. CD30 is a marker found on some activated, but not resting T and B cells. It also marks the Reed-Sternberg cells of Hodgkin disease. Monoclonal antibodies Ki-1 and Ber H2 are used to identify CD30 positivity. A cutaneous lymphoma is considered to be CD30+ if there are large clusters of CD30+ cells or more than 75% of the anaplastic T cells are CD30+. Systemic CD30+ lymphoma with cutaneous involvement has a poor prognosis. Those cases that express anaplastic lymphoma kinase (ALK-1) associated with a 2:5 translocation have a somewhat better prognosis. Primary cutaneous large T-cell lymphomas that are CD30+ are typically ALK-1 negative, have a very good prognosis, and tend to run a relapsing course similar to that of lymphomatoid papulosis. Individual lesions respond to irradiation, and the relapsing course may remit with low-dose methotrexate. Large cell lymphomas of the skin have similar histologic and clinical features, so immunophenotyping is essential for prognosis. Clonal TCR gene rearrangements are present in large T-cell lymphoma. The group of T-cell lymphomas that are not large cell and CD30+ are classified in the WHO system as peripheral T-cell lymphomas.

CD56 is rapidly becoming the second most important immunophenotypic marker for cutaneous lymphomas. Four important variants of CD56+ cutaneous lymphomas have been identified: a subset of subcutaneous panniculitis-like T-cell

Fig. 32-12 CD30+ anaplastic large cell lymphoma. (Courtesy of Dr. Misha Rosenbach.)

lymphoma, natural killer (NK)/T-cell lymphoma, blastic NK cell lymphoma, and CD8+ aggressive epidermotrophic cytotoxic T-cell lymphoma.

Peripheral T-cell lymphoma is a heterogeneous grouping that includes primary cutaneous CD30+ nonanaplastic large cell lymphoma, primary cutaneous CD30– anaplastic and nonanaplastic large cell lymphoma, and primary cutaneous CD30– pleomorphic small/medium cell lymphoma.

CD30+ cutaneous T-cell lymphoma (primary cutaneous anaplastic large cell lymphoma)

Clinically, the CD30+ CTCLs present as solitary or localized skin lesions that have a tendency to ulcerate (50%), spontaneously regress (25%), and relapse. They are rare in children and occur with slightly greater frequency in males. Lesions are usually firm, red to violaceous tumors up to 10 cm in diameter (Fig. 32-12). Tumors may grow in a matter of weeks. There is no favored anatomic site. Onset has been reported during glatiramer acetate treatment of multiple sclerosis.

Relapses in the skin are common, but the development of extracutaneous, bone marrow, or lymph node involvement is uncommon. Clonal populations may occasionally be demonstrated in peripheral blood, but differ from those in the skin. Lymph node involvement is associated with a poorer prognosis. The "pyogenic lymphoma" of the skin is a neutrophil-rich CD30+ lymphoma with skin lesions that clinically resemble Sweet syndrome, pyoderma gangrenosum, halogenoderma, leishmaniasis, or deep fungal infection. IL-8 overexpression by the anaplastic CD30+ cells causes the neutrophilic infiltration. The number of neutrophils present may make histologic interpretation difficult. Cases with features of both LyP and CD30+ anaplastic CTCL have been described, sometimes under the designation type C LyP. Histologically, there is a dense dermal nonepidermotropic infiltrate with atypical tumor cells whose large nuclei have one or several prominent nucleoli and abundant cytoplasm. The malignant cells can be further characterized as anaplastic, pleomorphic, and immunoblastic, but this distinction may be difficult and has yet to be determined to be of prognostic or therapeutic value. This form of primary CTCL has an excellent prognosis, with a 5-year survival of 90%. Lesions are highly responsive to radiotherapy. Early individual lesions can even be surgically excised. Topical imiquimod has been therapeutically successful. Chemotherapy causes regression of lesions, but a rapid relapse usually occurs. Other than low-dose methotrexate, chemotherapy generally has little role in the treatment of this disease. Local hyperthermia has been used successfully, as has inhibition of the mammalian target of rapamycin.

Secondary cutaneous CD30+ large cell lymphoma

The CD30+ large cell lymphomas may arise in cases of MF, in patients with LyP, and in patients who have documented extracutaneous disease (secondary cutaneous anaplastic large cell lymphoma). Skin lesions of pyogenic lymphoma may be seen secondary to a pyogenic lymphoma of other organs. The prognosis is poor in patients who have extracutaneous disease preceding or near the time of cutaneous involvement. Among those with systemic disease, the expression of ALK-1 associated with a t(2; 5) translocation is a favorable prognostic feature. Kempf et al. reported that MUM1 expression is common in secondary anaplastic large cell lymphoma and in LyP, but uncommon in primary cutaneous anaplastic large cell lymphoma. Other authors have disputed that MUM1 is a useful marker. Patients with LyP who develop cutaneous CD30+ lymphoma and who do not have systemic lymphoma or MF typically have an excellent prognosis. The prognosis for MF patients who develop CD30+ anaplastic large cell lymphoma is poor.

Non–mycosis fungoides CD30– cutaneous large T-cell lymphoma

Non-MF CD30– large CTCLs usually present as solitary or generalized plaques, nodules, or tumors of short duration. There is no preceding patch stage that distinguishes it from MF. The prognosis is poor, with 5-year survival of 15%. The malignant cells are pleomorphic, large or medium cell types or are immunoblastic. The cells may be cerebriform, and epidermotropism may be present. Some cases previously called d'emblée MF are better classified in this group. Multiagent chemotherapy is recommended.

Pleomorphic T-cell lymphoma (non–mycosis fungoides CD30–pleomorphic small/medium-sized cutaneous T-cell lymphoma)

This group comprises about 3% of all primary cutaneous lymphomas. Pleomorphic small/medium-sized CTCL is distinguished from the large cell type by having less than 30% large pleomorphic cells. It is distinguished from MF by clinical features (lack of patch or plaque lesions). These primary cutaneous lymphomas usually present with one or several red-purple papules, nodules, or tumors 5 mm to 15 cm in size. Immunophenotypically, they are usually of Th-cell origin, and clonal rearrangements of the TCR gene are usually present. A CD4 phenotype, as opposed to a CD8 phenotype, is associated with a more favorable prognosis, but a CD4/CD56 phenotype has a poorer prognosis. The presence of a mixed population of suppressor cells, B cells, and histiocytes usually favors the diagnosis of reactive lymphoid hyperplasia. The overall prognosis is intermediate, with 5-year survival of 62%. The optimal therapy for this form of lymphoma has not been determined. Therapeutically, localized lesions have been treated

Fig. 32-13
Subcutaneous T-cell lymphoma.

with radiation therapy or surgical excision. Chemotherapy, retinoids, IFNs, and monoclonal antibodies have been used in widespread or progressive disease.

Lennert lymphoma (lymphoepithelioid lymphoma)

Lennert lymphoma is a rare CD4+ systemic T-cell lymphoma. Cutaneous lesions occur in less than 10% of patients and present as papules, plaques, or nodules. The skin lesions may not represent lymphoma cutis because palisaded granulomatous and nonspecific dermal infiltrates may occur. The clinicohistologic appearance may closely resemble granuloma annulare. The course is low-grade until the lymphoma transforms to a high-grade, large cell lymphoma.

Subcutaneous (panniculitis-like) T-cell lymphoma

Clinically, patients are usually young adults who present with subcutaneous nodules (Fig. 32-13), usually on the lower extremities. The alpha/beta phenotype is generally associated with indolent disease, and gamma/delta lymphoma, which is associated with a more aggressive course, is now considered a separate provisional entity in the WHO classification. Weight loss, fever, and fatigue are common and may herald the onset of a rapidly progressive hemophagocytic syndrome.

Histologically, there is a lacelike infiltration of the lobules of adipocytes, mimicking panniculitis, especially lupus profundus. A characteristic feature is rimming of neoplastic cells around individual adipocytes with nuclear molding and atypia. Immunophenotypically, the neoplastic cells mark as T cells (CD2+, CD3+). Most cases are derived from α/β T cells and are CD56–. Subcutaneous γ/δ T-cell lymphomas are typically CD56+. Karyorrhectic debris, dermal involvement, and epidermotropism are clues to the diagnosis of γ/δ T-cell lymphoma. Multiagent chemotherapy is recommended, at times with stem cell support. Denileukin diftitox (Ontak) was reported to produce a favorable response.

Nasal/nasal-type NK/T-cell lymphoma (angiocentric lymphoma)

Natural killer/T-cell lymphoma most frequently presents in extranodal tissue and is characterized by a high incidence of nasal involvement. It is more common in Asia, where it affects primarily women with a mean age of 40. In Korea, it is reported to be the most common form of cutaneous lymphoma after mycosis fungoides. It is uncommon in the United States. Nasal NK/T-cell lymphoma presents clinically as dermal or subcutaneous papules or nodules that may ulcerate. Lesions are usually widespread and involve the lower extremities. A hydroa vacciniforme-type has been described in children in Mexico and in adults and children in Japan and Korea. Skin lesions are facial, and extremity papulovesicles ulcerate and heal with scarring. Skin lesions are exacerbated by sun exposure and are reproduced with UVA irradiation.

Histologically, the dermis and subcutaneous fat are infiltrated with intermediate-sized, atypical lymphocytes, within and around the walls of small and medium-sized vessels. Epidermotropism may be noted. The lymphoma cells express a spectrum of T- and NK-cell immunophenotypic markers, variably expressing CD2, CD3, CD4, CD8, and the NK-cell marker CD56. CD56 is not cell lineage specific, and a subset of CD56 cutaneous lymphoma cases is classified under the SPTCL category. Epstein-Barr virus is present in the NK variants and variably present in the T-cell variants. T-cell clonality is detected if the T-cell immunophenotype is present. The prognosis is poor.

Adult T-cell leukemia/lymphoma

Infection with human lymphotropic virus type 1 (HTLV-1) may lead to acute T-cell leukemia/lymphoma (ATL) in 0.01–0.02% of infected persons. This virus is endemic in Japan, Southeast Asia, the Caribbean region, Latin America, and equatorial Africa. ATL usually has an acute onset, with leukocytosis, lymphadenopathy, and HOTS (hypercalcemia, osteolytic bone lesions, T-cell leukemia, and skin lesions). Lesions resemble mycosis fungoides, except that patches are uncommon, and plaques and nodules predominate. Histologically, the skin lesions contain lichenoid infiltrates of medium-sized lymphocytes with convoluted nuclei. Epidermotropism and

Fig. 32-14 Lymphoma, B-cell.

involvement around and within adnexa occur. Granuloma formation may occur in the dermis. ATL cells are usually CD4+/CD7– and show T-cell gene rearrangements.

CUTANEOUS B-CELL LYMPHOMA

Primary cutaneous B-cell lymphomas (Fig. 32-14) occur less often than cutaneous T-cell lymphomas; 25% of cases of primary cutaneous non-Hodgkin lymphomas are B cell in origin). Although the morphologic appearance of the malignant lymphocytes composing these primary cutaneous lymphomas is identical to lymphomas based in lymph nodes, they have a distinctly different clinical behavior and immunophenotypic profiles. This renders the classification systems based on lymph node histology of limited benefit in the diagnosis of primary cutaneous B-cell lymphomas. More simplified schemes have thus been proposed that apply to primary cutaneous lymphomas only. Most entities classified by the European Organization for Research and Treatment of Cancer (EORTC) have now been accepted in the WHO classification, but some remain provisional entities.

The great majority of primary cutaneous B-cell lymphomas are composed of cells with the morphologic characteristics of the B cells normally found in the marginal zone or germinal centers of lymph nodes. Classification schemes used primarily for lymph node–based lymphomas divide these lymphomas into multiple types based on histomorphology. Secondary cutaneous involvement can occur with all forms of B-cell lymphoma based primarily in lymph node or other sites. The clinical features are similar to those of primary cutaneous lymphoma, with violaceous papules or nodules (Fig. 32-15). Typically, the histologic structure of secondary lesions in the skin is similar to that of the lymphoma at the site of origin, usually the lymph nodes. The pattern in the skin, however, may not be sufficient to classify the lymphoma, making lymph node biopsy necessary in most patients. In secondary cutaneous B-cell lymphomas, the prognosis is generally poor. It is therefore critical to evaluate any patient suspected of having primary cutaneous B-cell lymphoma to exclude involvement at another site. Radiation is typically used for indolent forms of cutaneous B-cell lymphoma, but excision, rituximab, intralesional corticosteroids, and systemic chemotherapy have also been used in select cases. Higher-grade lymphomas, such as leg-type lymphoma, primary cutaneous follicle center lymphoma occurring on the leg, and precursor B-cell lymphoblastic lymphoma, are typically treated with systemic chemotherapy regimens, including combinations of anthracycline-containing chemotherapies and rituximab.

Fig. 32-15 Secondary cutaneous B-cell lymphoma.

Primary cutaneous marginal-zone lymphoma (PCMZL, MALT-type lymphoma, including primary cutaneous immunocytoma)

These lymphomas present as solitary or multiple dermal or subcutaneous nodules or tumors, primarily on the upper part of the body, trunk, or extremities. Widespread lesions suggest secondary skin involvement by systemic lymphoma. Women are affected by PCMZL more than men. Immunocytomas are associated with European *Borrelia* and occur as tense, shiny, pink to red nodules on the legs of older patients.

Histologically, the infiltrate may be nodular or diffuse. The neoplastic cells are medium-sized gray cells with predominantly cleaved nuclei that proliferate within the space surrounding and between benign germinal centers. Plasma cells are typically present and may be numerous. Light-chain restriction is easiest to identify in the plasma cell population by means of in situ hybridization. Immunophenotypically, the cells are CD20+, CD79+, and BCL-2+. Clonal immunoglobulin gene rearrangements can usually be demonstrated, and light-chain restriction can typically be demonstrated in plasma cells at the periphery of the lymphoid aggregates. The prognosis is excellent, with 5-year survival close to 100%. Local radiation therapy, or excision if lesions are few, is recommended. In some *Borrelia*-endemic areas in Europe, immunocytomas are common. They present on the legs of older men and are characterized by sheets of plasmacytoid B cells with Dutcher bodies. Treatment is similar to other forms of PCMZL.

Primary cutaneous follicle center cell lymphoma (PCFCCL, diffuse and follicular types)

Clinically, most patients with PCFCCL present with single or multiple papules, plaques, or nodules, with surrounding erythema, in one anatomic region. About two thirds of cases present on the trunk, about 20% on the head and neck (vast majority on scalp), and about 15% on the leg. PCFCCLs are more common in men than women. Males outnumber females 4:1 in trunk lesions, whereas women disproportionately have head and leg lesions. Untreated, the lesions gradually increase in size and number, but extracutaneous involvement is

uncommon. The prognosis is excellent; 5-year survival with treatment approaches 100%. Secondary cutaneous involvement of systemic follicular lymphoma has a poor prognosis.

Histologically, the neoplasm is composed of centroblasts (uncleaved nuclei with peripheral nucleolus) and centrocytes (cleaved nuclei with peripheral nucleolus). The diffuse form is more common than the follicular form. In the diffuse form, the neoplastic cells retain the normal BCL-6+ phenotype of a follicle center cell, but typically lose expression of CD10. The follicular growth pattern is composed of irregularly shaped, asymmetric follicles that crowd together like pieces of a jigsaw puzzle. The cells typically stain for both BCL-6 and CD10, and these stains demonstrate neoplastic cells that have "wandered" beyond the confines of the follicle center. Elongated "carrot-shaped" nuclei are often present within the follicular centers, and CD21 staining shows defects in the net of DCs in the follicle center.

In early lesions, the neoplastic cells are smaller, and a substantial portion of normal T cells surround and mix with the neoplastic B cells. Over time, the neoplastic B cells become a more predominant portion of the infiltrate, the neoplastic cells are larger, and tumor-infiltrating T cells diminish. Immunophenotypically, the neoplastic cells stain with B-cell markers (CD20), and clonal rearrangement of the immunoglobulin gene can be demonstrated by polymerase chain reaction (PCR). The absence of expression of BCL-2, lack of adenopathy, and lack of involvement of the bone marrow help to exclude nodal follicle center lymphoma. Nodal follicular lymphoma usually expresses BCL-2, and there is a t(14:18) translocation in more than 80% of cases. The translocation and BCL-2 expression are usually lacking in primary cutaneous follicular lymphoma.

Radiation therapy totaling 30–40 Gy and including all erythematous skin and a 2-cm margin of normal skin is very effective for lesions of the head and trunk. A combination of intralesional IFN alfa, 5-MU every 4 weeks, and topical bexarotene gel 1% twice has also been used. Anthracycline-based chemotherapy or rituximab may be used for relapses, as well as for more aggressive lesions of the leg. In Europe, a few cases of PCFCCL are associated with *Borrelia* infection and may arise in lesions of acrodermatitis chronica atrophicans.

Diffuse large B-cell lymphoma (primary cutaneous large B-cell lymphoma)

Clinically, lesions present as solitary or localized red or purple papules, nodules, or plaques. In general, solitary or localized lesions are typical of primary disease, and widespread lesions suggest secondary cutaneous involvement of primary nodal lymphoma. Lesions on the head and neck have an excellent prognosis. Lesions on the leg have a poorer prognosis, with a 5-year survival of about 50%, and are considered in some classifications as a separate entity (Fig. 32-16).

The diffuse large B-cell lymphoma is composed of large lymphocytes. Tumors consisting of sheets of centroblasts and immunoblasts (noncleaved nuclei with peripheral or central nucleoli, respectively) should be stained for MUM1, a marker for leg-type lymphoma. If the tumor cells express MUM1, the prognosis is worse. Immunophenotypically, cells usually express CD20 and monotypic immunoglobulin, and leg-type lymphoma expresses BCL-2. Secondary cutaneous involvement with nodal large B-cell lymphoma is also associated with a poor prognosis.

Richter transformation of chronic lymphocytic leukemia (CLL) into a high-grade lymphoma occurs in 3–10% of CLL patients. Its onset is often heralded by fever, night sweats, and weight loss. The lymphoma usually arises in the lymph nodes or bone marrow, but can also present in the skin or internal organs.

Fig. 32-16 B-cell lymphoma of the leg. (Courtesy of Dr. Misha Rosenbach.)

Intravascular large B-cell lymphoma (malignant "angioendotheliomatosis," angiotropic large cell lymphoma)

Clinically, these patients present with variable cutaneous morphologies, often subtle and nonspecific. Some intravascular large B-cell lymphomas resemble classic lymphoma with violaceous papules or nodules. Others more closely resemble intravascular thrombotic disorders, with livedo reticularis–like lesions or telangiectatic patches. Sclerotic plaques may also occur. Even normal skin can show the characteristic changes on biopsy. Patients often present with fever of unknown origin. CNS symptoms are prominent, with progressive dementia or multiple cerebrovascular ischemic events that may precede skin findings by many months.

Histologically, the features are characteristic and diagnostic. Dermal and subcutaneous vessels are dilated and filled with large neoplastic cells. Focal extravascular accumulations may be seen. The neoplastic cells are CD20+ and CD79a+ and monotypic for immunoglobulin. Clonal Ig gene rearrangements may be detected. Despite the large number of intravascular cells in the skin and other affected organs, the peripheral blood smears and bone marrow may be normal histologically. The prognosis is very poor, and multiagent chemotherapy is recommended. Rare cases of intravascular lymphoma may be of T-cell origin, but the behavior is similar to that of the B-cell variant.

Plasmacytoma (multiple myeloma)

True cutaneous plasmacytomas are seen most often in the setting of myeloma, although they are rare, occurring in only 2% of myeloma patients. These cases are called secondary cutaneous plasmacytoma. Plasmacytomas may also occur by direct extension from an underlying bone lesion (Fig. 32-17). They may appear at sites of trauma, such as biopsies or intravenous catheters (inflammatory oncotaxis). Most often, secondary cutaneous plasmacytomas occur in the patient with advanced myeloma, and the prognosis is poor. Less often, the skin lesions may be the initial clinical finding, leading to the diagnosis of myeloma. Many cutaneous lesions formerly classified as primary cutaneous plasmacytomas are now classified as plasma cell–rich primary cutaneous marginal-zone lymphoma.

Anetoderma may show plasmacytoma on biopsy. A rare manifestation of a solitary plasmacytoma of bone is an overlying erythematous skin patch that may be 10 cm or more in diameter. The chest is the most common location. Lymphadenopathy is present, and some of the patients have or develop POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes). This syndrome has been called adenopathy and extensive skin patch overlying a plasmacytoma (AESOP).

Histologically, plasmacytomas are nodular and diffuse collections of plasma cells with varying degrees of pleomorphism and atypia. The degree of atypia may predict prognosis. The cells are monotypic for Ig production and produce the same light chain as the myeloma. The immunoglobulin produced is most often IgG or IgA, and rarely IgD or IgE. CD79 is positive, but CD19 and CD20 are negative.

In addition to plasmacytomas, patients with myeloma may develop a vast array of cutaneous complications, including normolipemic plane xanthomas, amyloidosis, vasculitis, and calcinosis cutis. An unusual but characteristic skin finding in myeloma is multiple follicular spicules of the nose, forehead, cheeks, and chin. They are yellowish and firm to palpation and can be removed without bleeding. Numerous small ulcerations may occur on the trunk. Both the spicules and the ulcers contain an eosinophilic material composed of the abnormal monoclonal protein produced by the malignant cells. The spicules are not made of keratin. Clinically similar cutaneous spicules composed of keratin can be seen in vitamin A deficiency, chronic renal failure, acquired immunodeficiency syndrome (AIDS), Crohn's disease, and other malignant diseases.

The appropriate treatment of plasmacytomas is determined by the presence or absence of associated systemic disease. Solitary or paucilesional primary cutaneous plasmacytomas have been treated successfully with local surgery and radiation therapy. Systemic chemotherapy may be required if these modalities fail. The treatment for secondary plasmacytomas and for patients with numerous primary cutaneous plasmacytomas is chemotherapy.

Cutaneous and systemic plasmacytosis

Cutaneous plasmacytosis and systemic plasmacytosis occur primarily in Asians, slightly favoring men. They typically occur between ages 20 and 55. These conditions are characterized by polyclonal proliferations of plasma cells and hyperglobulinemia and were originally considered variants of Castleman's disease. Cutaneous plasmacytosis affects only the skin, but patients may have lymphadenopathy and systemic symptoms of fever and malaise. Systemic plasmacytosis usually involves two or more organ systems, in addition to the skin, lung, bone marrow, and liver. Dyspnea may result from interstitial pneumonia. Infrequently, cases of systemic plasmacytosis may progress to lymphoma. The course is chronic and benign, and response to various cytostatic and immunosuppressive treatments has been poor. PUVA and topical tacrolimus have been reported to be effective for skin lesions. The skin lesions in cutaneous and systemic plasmacytosis are identical, consisting of multiple brown-red plaques, mostly of the central upper trunk but also the face. The lesions, 1–3 cm in diameter, are often considered simply as postinflammatory hyperpigmentation until they are palpated. Histologically, they show a dense perivascular infiltrate of mature plasma cells, which stain for both κ and λ light chains (polyclonality). The disease may be a manifestation of IgG4-related disease, a clinical entity characterized by elevated levels of serum IgG4 and tissue infiltration of IgG4+ plasma cells in various organ systems. Elevated IL-6 has been reported in some patients.

Honda R, et al: Cutaneous plasmacytosis: report of 6 cases with or without systemic involvement. J Am Acad Dermatol 2013; 68(6):978–985.

Yamaguchi H, et al: Cutaneous plasmacytosis as a skin manifestation of IgG4-related disease. Eur J Dermatol 2013; 23(4):560–562.

IgG4-related skin disease

IgG4-related skin disease presents with mass-forming lymphoplasmacytic cutaneous infiltrates, often with eosinophils. IgG4 is elevated in serum, and many IgG4+ cells can be identified in the affected tissue. These findings are not specific for the disease, however, and clinicopathologic correlation is essential. Erythematous and itchy plaques and nodules typically involve the head and neck, particularly the periauricular region, cheeks, and jawline. Systemic infiltrates may involve the lymph nodes, lacrimal and salivary glands, or parenchymal organs such as the kidney and pancreas. Retroperitoneal fibrosis may occur. Accumulated data suggest no association with systemic malignancy. Randomized controlled trials (RCTs) are lacking, but the associated autoimmune pancreatitis typically responds to oral corticosteroids, and both rituximab and dapsone have been reported as effective in individual patients.

HODGKIN DISEASE

The vast majority of reports of cutaneous Hodgkin disease actually represent type A lymphomatoid papulosis. These two diseases have a considerable number of overlapping features. The type A cells of LyP have similar morphology and share immunophenotypic markers with Reed-Sternberg cells. LyP can be seen in patients with Hodgkin disease. Primary cutaneous Hodgkin disease without nodal involvement is thus difficult to prove and is extremely rare, if it exists.

Most cases of Hodgkin disease of the skin usually originate in the lymph nodes, from which extension to the skin is either retrograde through the lymphatics or direct. Lesions present as papules or nodules, with or without ulceration. Lesions resembling scrofuloderma may occur. Miliary dissemination to the skin can occur in advanced disease.

Nonspecific cutaneous findings are common in patients with Hodgkin disease. Generalized, severe pruritus may precede other findings of Hodgkin disease by many months or may occur in patients with a known diagnosis. Secondary prurigo nodules and pigmentation may occur as a result of scratching. An evaluation for underlying lymphoma should be considered in any patient with severe itching, no primary skin lesions, and no other cause identified for the pruritus. Acquired ichthyosis, exfoliative dermatitis, and generalized and severe herpes zoster are other cutaneous findings in patients with Hodgkin disease.

Introcaso CE, et al: Cutaneous Hodgkin disease. J Am Acad Dermatol 2008; 58(2):295–298.

MALIGNANT HISTIOCYTOSIS (HISTIOCYTIC MEDULLARY RETICULOSIS)

Most cases considered to be malignant histiocytosis in the past are now considered to be other forms of lymphoma or lymphomas with large components of reactive histiocytes. Very rare cases of true malignancies of histiocytes may still occur and can have cutaneous lesions, most characteristically erythematous nodules. Often, the bone marrow examination in these patients is initially normal, but cases are rapidly progressive and fatal, and the bone marrow becomes involved.

LEUKEMIA CUTIS

Clinical features

Cutaneous eruptions seen in patients with leukemia may be divided into specific lesions (leukemia cutis) and nonspecific lesions (reactive and infectious processes). Overall, about 30% of biopsies from patients with leukemia will show leukemia cutis. All forms of leukemia can be associated with cutaneous findings, but skin disease is more common in certain forms of leukemia. Myeloid leukemia with monocytic differentiation involves the skin more often than other types of myeloid leukemia. CD68 and lysozyme immunostains can be helpful in distinguishing this form of leukemia. Dermatologic manifestations are frequently seen in patients with acute myelogenous leukemia (AML) and myelodysplastic syndrome (MDS). AML includes types M1–M5. In AML and MDS patients, only about 25% of skin biopsies will show leukemia cutis, the remainder showing complications of the leukemia. These include infections, graft-versus-host disease, drug reactions, or the reactive conditions associated with leukemia sometimes referred to as leukemids. By contrast, in patients with acute lymphocytic leukemia (ALL), chronic myelogenous leukemia (CML), and chronic lymphocytic leukemia (CLL), about 50% of biopsies will show leukemia cutis. Lesion presentation may be subtle and may include macular erythema, hyperpigmentation, or morbilliform rash.

Fig. 32-18 Leukemia cutis.

Specific eruptions

The most common morphology of leukemic infiltrations of the skin in all forms of leukemia is multiple papules or nodules (60% of cases) or infiltrated plaques (26%). These lesions are usually flesh colored, erythematous, or violaceous (plum colored) (Figs. 32-18 and 32-19). They are rubbery on palpation, and ulceration is uncommon. Extensive involvement of the face may lead to a leonine facies.

Less common manifestations of leukemia cutis are subcutaneous nodules resembling erythema nodosum or panniculitis, arciform lesions (in juvenile CML), ecchymoses, palpable purpura, erythroderma, ulcerations (which may resemble pyoderma gangrenosum or venous stasis ulceration), and urticaria-like, urticaria pigmentosa–like (in ALL), and guttate psoriasis–like lesions. Rare manifestations are a lesion resembling Sister Mary Joseph nodule and cutaneous sarcoidal lesions. Myelogenous leukemia may be complicated by lesions resembling stasis dermatitis or chilblains. Gingival infiltration causing hypertrophy is common in, and relatively unique to, patients with acute myelomonocytic leukemia (Fig. 32-20).

Leukemia cutis most often occurs concomitant with or after the diagnosis of leukemia. The skin may also be a site of relapse of leukemia after chemotherapy, especially in patients who present with leukemia cutis. Infrequently, leukemia cutis may be identified while the bone marrow and peripheral blood are normal. These patients are classified as "aleukemic leukemia cutis" because they have normal bone marrow

Fig. 32-19 Leukemia cutis.

Fig. 32-20 Gingival involvement in leukemia.

evaluations and no circulating blasts. These cases are often misdiagnosed as cutaneous lymphomas and undertreated. They eventually relapse, with full-blown leukemia. The key to the diagnosis is a Leder stain, which will identify the atypical cells as myeloid. Systemic involvement occurs within 3 weeks to 20 months (average 6 months). Leukemia cutis is a poor prognostic finding in leukemia patients, with 90% having extramedullary involvement and 40% with meningeal infiltration.

The term congenital leukemia applies to cases appearing within the first 4–6 weeks of life. Leukemia cutis occurs in 25–30% of such cases, the vast majority being congenital myelogenous leukemia. The typical morphology is multiple, red or plum-colored nodules. In about 10% of patients with congenital leukemia cutis (or 3% of all cases of congenital leukemia), the skin involvement occurs while the bone marrow and peripheral blood are normal. Systemic involvement is virtually always identified in 5–16 weeks. Unlike in other forms of leukemia, cutaneous infiltration does not worsen prognosis in congenital leukemia. Congenital leukemia cutis has been complicated by disseminated linear calcinosis cutis. Early-onset aleukemic leukemia cutis can occasionally undergo spontaneous regression. One report involved a child with mastocytosis who also developed a leukemia clone with a t(5; 17)(q35; q12), nucleophosmin (NPM)–retinoic acid receptor-α (RARA) fusion gene.

Granulocytic sarcoma (chloroma)

Granulocytic sarcomas are rare tumors of immature granulocytes. They occur in about 3% of patients with myelogenous leukemia. Granulocytic sarcoma is seen in four settings: in patients with known AML; in patients with CML or MDS as a sign of an impending blast crisis; in undiagnosed patients as the first sign of AML; or after BMT as the initial sign of relapse. Most lesions occur in the soft tissues, periosteum, or bone. Skin lesions represent 20–50% of reported cases. They may be solitary or multiple and appear as red, mahogany, or violaceous firm nodules with a predilection for the face, scalp, or trunk.

The name "chloroma" comes from the green color of fresh lesions, which can be enhanced by rubbing with alcohol; this is caused by the presence of myeloperoxidase. This appearance is variable, so the preferred term is now granulocytic sarcoma.

The diagnosis is not difficult if the diagnosis of leukemia has been established. Such patients are treated with appropriate chemotherapy. However, if the skin lesion is the initial manifestation of leukemia, and the blood and bone marrow are normal, the lesion may be misdiagnosed as a large cell lymphoma. The treatment of such patients is controversial, but most go on to develop AML within months, so chemotherapy is often given.

Blastic plasmacytoid dendritic cell neoplasm (formerly blastic NK-cell lymphoma, CD4, CD56+ hematodermic neoplasm)

The majority of patients are men, with a mean age of about 60 years. All patients present with multiple, rapidly expanding plaques and/or nodules on noncontiguous sites. Lesions are characteristically purple in color. The course is aggressive in most patients, with rapid cutaneous relapse after chemotherapy and systemic involvement. Histologically, the cells infiltrate the dermis or subcutaneous fat, and the neoplastic cells tend to form in single file within dermal collagen. There is usually a grenz zone below the epidermis. The lymphoma cells are small/medium to large, blastic lymphocytes. Angiocentricity may be noted but is not prominent. Immunophenotyping is usually CD3–, CD4+/CD56+. MIB-1 shows a proliferation activity greater than 50%, and T-cell gene rearrangements are negative. A response to pralatrexate has been reported, but in general, results with radiation therapy and chemotherapy have been poor. Bone marrow transplantation (BMT) may play an important role in therapy.

Hairy cell leukemia

Skin involvement is rare in hairy cell leukemia. Violaceous papules and nodules, which are the characteristic morphology of other forms of leukemia cutis, are extremely rare in hairy cell leukemia. Rather, a diffuse erythematous, nonpruritic eruption occurs, often in the setting of a systemic mycobacterial infection or a drug reaction. This may progress to erythroderma or a severe blistering eruption. Stopping the medication usually leads to resolution of the eruption. This is especially common in patients treated with 2-chlorodeoxyadenosine and allopurinol; the former treatment alone does not lead to these severe skin reactions, suggesting that the allopurinol is the cause. Patients with hairy cell leukemia also develop lesions of pustular vasculitis of the dorsal hands, a neutrophilic dermatitis closely related to bullous Sweet syndrome. This is sometimes termed a "vasculitis" in the oncology literature.

Nonspecific conditions associated with leukemia (leukemids)

Leukemia and its treatment are associated with a series of conditions that may also be seen in patients without leukemia, but that are seen frequently enough in leukemic patients to be recognized as a complication of leukemia or its treatment.

When a dermatologist or dermatopathologist is consulted to evaluate a patient with leukemia and skin lesions, the differential diagnosis usually includes four groups of conditions: drug reactions, leukemia cutis, an infectious complication, and a reactive condition. Drug reactions include all forms of reactions but are usually erythema multiforme, morbilliform reactions, or acral erythema. Infections may present in many ways but are usually purpuric papules, pustules, or plaques, if they are caused by bacteria or fungi. Ulceration is typical. Herpes simplex and herpes zoster should be considered in all erosive, ulcerative, or vesicular lesions. The reactive conditions include a group of neutrophilic dermatoses with considerable clinical overlap (e.g., Sweet syndrome, pyoderma gangrenosum, neutrophilic hidradenitis, leukocytoclastic vasculitis). Transient acantholytic dermatosis and eosinophilic reactions resembling insect bites may occur, most often in patients with CLL, in whom a pruritic and unremitting exfoliative erythroderma is a unique feature. A granulomatous rosacea-like leukemid and cutaneous reactive angiomatosis have also been described in patients with leukemia.

Evaluation of these patients must be complete, and extensive diagnostic tests and empiric treatment are often pursued until the diagnosis is established. In the acute setting, a clinical diagnosis is made based on morphology. Possible infectious complications are covered by appropriate antibiotics, especially if the patient is febrile or the diagnosis of a herpesvirus infection is made. A skin biopsy is often diagnostic. For herpes infections, a PCR or direct fluorescent antibody test should be done because the results are virus specific and rapid, so appropriate treatment can be given quickly. Once the diagnostic tests return, the therapy is tailored to the appropriate condition. Except for herpes infections, a skin biopsy is often required. If infection is considered, a portion of the biopsy should be sent for culture.

CUTANEOUS MYELOFIBROSIS

Myelofibrosis is a chronic myeloproliferative disorder characterized by a clonal proliferation of defective multipotential stem cells in the bone marrow. Overproduction and premature death of atypical megakaryocytes in the bone marrow produce excess amounts of platelet-derived growth factor (PDGF), a potent stimulus for fibroblast proliferation and collagen production. Extramedullary hematopoiesis (EMH) is a hallmark of myelofibrosis. Myelofibrosis may coexist with signs of mastocytosis. Blast cells and committed stem cells escape the marrow in large numbers, enter the circulation, and form tumors of the same atypical clone in other organs, especially the spleen, liver, and lymph nodes. EMH in the skin of neonates is usually caused by intrauterine viral infections. In adults, cutaneous EMH has rarely been reported, characteristically associated with myelofibrosis. Skin lesions are dermal and subcutaneous nodules. Histologically, the cutaneous lesions are composed of dermal and subcutaneous infiltrates of mature and immature myeloid cells, erythroid precursors (in only half of cases), and megakaryocytic cells (which may predominate). There is marked production of collagen fibers in the cutaneous lesions by the mechanism previously described. Myelofibrosis must be distinguished from CML, since both have elevated white blood cell counts with immature myeloid forms, defective platelet production, and marrow fibrosis. Both may terminate in blast crisis, and myelofibrosis may rarely convert to CML. CML is associated with the Philadelphia chromosome, whereas chromosomal abnormalities occur in 40% of myelofibrosis cases on various chromosomes.

Miyata T, et al: Cutaneous extramedullary hematopoiesis in a patient with idiopathic myelofibrosis. J Dermatol 2008; 35(7):456–461.

HYPEREOSINOPHILIC SYNDROME

Idiopathic hypereosinophilic syndrome (HES) is defined as eosinophilia with more than 1500 eosinophils/mm^3 for more than 6 months, with some evidence of parenchymal organ involvement; there must also be no apparent underlying disease to explain the hypereosinophilia and usually no evidence of vasculitis. About 90% of patients reported have been men, mostly between ages 20 and 50. Childhood cases are rare. Presenting symptoms include fever (12%), cough (24%), fatigue, malaise, muscle pains, and skin eruptions. Two pathogenic variants of HES have been defined: m-HES (myeloproliferative HES) and l-HES (lymphocytic HES). Patients with m-HES are overwhelmingly males, and anemia, thrombocytopenia, elevated serum B_{12} levels, mucosal ulcerations, splenomegaly, and endomyocardial fibrosis are the clinical features. Isolated Loeffler's endocarditis has been reported as a presenting sign. Eosinophil clonality and interstitial deletion on 4q12 result in fusions of *FIP1qL1* and *PDGFRa* genes, forming an F/P fusion protein displaying constitutive activity, are pathogenically related to m-HES cases. Increased mast cells and elevated tryptase levels with myeloid precursors in peripheral blood and myelofibrosis may be found, suggesting that mast cells may be pathogenically related to this form of HES. Leukemia may develop in patients with m-HES patients. The l-HES variant has been associated with circulating T-cell clones of CD4+ phenotype, which secrete Th2 cytokines, especially IL-5. Women and men are equally affected by l-HES, and cutaneous manifestations are observed in virtually all patients. Skin manifestations include urticaria, angioedema, pruritus, eczema, and erythroderma. Splinter hemorrhages and necrotic skin lesions are seen in some HES patients as well. Endomyocardial fibrosis is uncommon, but pulmonary and digestive symptoms are common. Some cases of l-HES are clinically identical to Gleich syndrome or episodic angioedema and hypereosinophilia. Over time, some patients with l-HES will develop lymphoma.

Treatment is determined by classifying cases appropriately as m-HES or l-HES. Patients with m-HES may be treated with corticosteroids, hydroxyurea, IFN alfa, and chemotherapeutic agents. Imatinib mesylate (Gleevac, 100 mg/day or less) can be highly effective for m-HES patients with the F/P mutation because it inhibits the phosphorylation of the F/P protein and leads to apoptosis of cells producing this protein. Imatinib has

rapidly become first-choice treatment for this subset of patients. Response may be dramatic, with eosinophil levels improving, and skin and GI manifestations clearing in days. For l-HES patients, systemic glucocorticoids, and perhaps IFN alfa with glucocorticoids, can be used and are usually effective. Monoclonal anti-IL-5 antibody, cyclosporine, anti-IL-2Rα, infliximab, and CTLA-4-Ig may be treatment options. If lymphoma supervenes, intense chemotherapy and allogenic stem cell transplantation can be considered.

ANGIOIMMUNOBLASTIC T-CELL LYMPHOMA (ANGIOIMMUNOBLASTIC LYMPHADENOPATHY WITH DYSPROTEINEMIA)

Angioimmunoblastic lymphoma is an uncommon lymphoproliferative disorder. Patients are middle-aged or elderly and present with fever (72%), weight loss (58%), hepatomegaly (60%), polyclonal hyperglobulinemia (65%), and generalized adenopathy (87%). Pruritus occurs in 44% and a rash in 46%. The skin eruption is usually morbilliform in character, resembling an exanthem or a drug reaction. Petechial, purpuric, nodular, ulcerative, and erythrodermic eruptions have also been reported and may mimic infection. In about 30% of cases, the eruption is associated with the ingestion of a medication. The eruptions usually resolve with oral corticosteroids, misleading the clinician into believing that the eruption was benign. Reversible myelofibrosis has been described. Recent evidence suggests that the neoplastic cells are derived from germinal center Th cells because they express genes unique to this population, including programmed death-1 *(PD-1)* and *CXCL13.*

Histopathologically, there is a patchy and perivascular dermal infiltrate of various types of lymphoid cells, plasma cells, histiocytes (enough rarely to give a "granulomatous" appearance), and eosinophils. The lymphoid cells are usually Th cells (CD4+). Some portion of the lymphoid cells is atypical in most cases, suggesting the diagnosis. Blood vessels are increased and the endothelial cells are prominent, often cuboidal. Unfortunately, these changes may not be adequate to confirm the diagnosis. However, clonal T-cell gene rearrangement is found in three quarters of these skin lesions and is the same as the clone in the lymph node. Immunophenotyping of the skin lesions does not give a consistent pattern. At times, the skin lesions will show leukocytoclastic vasculitis on biopsy. Lymph node biopsy is usually required to confirm the diagnosis and exclude progression to lymphoma.

Angioimmunoblastic lymphadenopathy with dysproteinemia (AILD) appears to develop in a stepwise manner. Initially, there is an immune response to an unknown antigen. This immune reaction persists, leading to oligoclonal T-cell proliferation. Monoclonal evolution may occur, eventuating in lymphoma (angioimmunoblastic lymphoma, AILD-L). These are usually T-cell lymphomas, but B-cell lymphomas can also occur. In the case of AILD-L, skin lesions may contain the neoplastic cells (secondary lymphoma cutis). In up to 50% of cases, multiple unrelated neoplastic cell clones have been identified. Clones identified in the skin may be different from clones found in lymph node. Trisomy 3 or 5 or an extra X chromosome may be found. AILD is an aggressive disease, with mortality of 48–72% in various series (average survival 11–60 months). The cause of death is usually infection. Epstein-Barr virus and HHV-6 and HHV-8 have been implicated in AILD.

Treatment of AILD has included systemic corticosteroids, methotrexate plus prednisone, combination chemotherapy, fludarabine, 2-chlorodeoxyadenosine, IFN alfa, and cyclosporine. Early treatment with systemic steroids during an oligoclonal or prelymphomatous stage may induce a long-lasting remission. Asymptomatic patients may not be treated initially but must be watched very closely. More aggressive chemotherapy achieves better remission. Nonetheless, recurrence rates are high, and average survival is 1–3 years.

SINUS HISTIOCYTOSIS WITH MASSIVE LYMPHADENOPATHY (ROSAI-DORFMAN DISEASE)

Sinus histiocytosis with massive lymphadenopathy (SHML), or Rosai-Dorfman disease, usually appears in patients in the first or second decade of life as a febrile illness accompanied by massive cervical (and often other) lymphadenopathy, polyclonal hyperglobulinemia, leukocytosis, anemia, and elevated erythrocyte sedimentation rate. Males and black persons are especially susceptible. Extranodal involvement occurs in 40% of cases, with skin being the most common site. About 10% of patients with SHML have skin lesions, and 3% have disease detectable only in the skin. The terms cutaneous sinus histiocytosis and cutaneous Rosai-Dorfman disease have been applied to these patients. Skin lesions consist of isolated or disseminated, yellow-brown papules, pustules, or nodules (Fig. 32-21) or macular erythema. Large annular lesions, resembling granuloma annulare, may occur. Most patients with cutaneous Rosai-Dorfman disease are older (40–60).

Fig. 32-21 Rosai-Dorfman disease. (Courtesy of Dr. Ellen Kim.)

Histologically, there is a superficial and deep perivascular infiltrate of lymphocytes and plasma cells. Nodular and diffuse infiltration of the dermis by large, foamy histiocytes is present. An important diagnostic feature is the finding of intact lymphocytes (and less often plasma cells) in the cytoplasm of the histiocytic cells; this is called emperipolesis. Foamy histiocytes may be seen in dermal lymphatic channels. The cutaneous histology in some cases may be very nonspecific, except for the finding of emperipolesis, and only on evaluation of lymph node or other organ involvement does the diagnosis become clear. Immunohistochemistry and electron microscopy may be very useful, because the infiltrating cells are positive for CD4, factor XIIIa, and S-100 but do not contain Birbeck granules.

The cause of SHML is unknown, but numerous reports have identified HHV-6 in involved lymph nodes. The condition usually clears spontaneously, so no treatment is required. Numerous agents have been used therapeutically, with variable success, but are indicated only if the condition puts the patient at risk for death or a significant complication (usually by compressing a vital organ). Treatments have included radiation, systemic corticosteroids, and thalidomide. Single-agent and multiagent chemotherapy is met with mixed to poor response. To treat skin lesions, cryotherapy, topical corticosteroids, acitretin, and intralesional corticosteroids may be tried.

POLYCYTHEMIA VERA (ERYTHREMIA)

Polycythemia vera (PCV) is characterized by an absolute increase of circulating red blood cells, with a hematocrit level of 55–80%. Leukocyte and platelet counts are also increased. The skin changes are characteristic. The skin tends to be red, especially on the face, neck, and acral areas. The mucous membranes are engorged and bluish. The phrase "red as a rose in summer and indigo blue in winter" has been ascribed to Osler in describing PCV. Telangiectases, bleeding gums, and epistaxis are frequently encountered. Cyanosis, purpura, petechiae, hemosiderosis, rosacea, and koilonychia may also be present.

In 50% of patients with PCV, aquagenic pruritus occurs. In about two-thirds, this is of limited severity and does not require treatment. The pruritus is typically triggered after a bath or shower, and the feeling induced may be itching, burning, or stinging. It usually lasts 30–60 min and is independent of the water temperature. Pruritus unassociated with water exposure may also occur. There is a concurrent elevation of blood and skin histamine. Pruritus is present in about 20% of patients at presentation and develops in the remaining 30% over the course of their disease. Patients with pruritus have lower mean corpuscular volumes and higher leukocyte counts. Some have suggested that iron deficiency plays a role in PCV-associated pruritus, so a ferritin level and a trial of iron therapy may be indicated. Platelet counts are no different between PCV patients who itch and those who do not.

The treatment of PCV-associated pruritus may be difficult. Initial therapy would include first- or second-generation H1 antihistamines. Hydroxyzine was reported as the most effective antihistamine by a group of PCV patients. H2 blockers can be added. Narrow-band UVB therapy has been reported to be effective in 80% of patients. Topical therapy is of limited benefit, but paroxetine (Paxil), 20–60 mg/day, may be dramatically effective. Phlebotomy may be useful in patients with elevated hematocrit, and imatinib mesylate appears effective in many patients.

Diseases of the Skin Appendages 33

DISEASES OF THE HAIR

Normal human hairs can be classified according to cyclic phases of growth. Anagen hairs are growing hairs; catagen hairs are those undergoing transition from the growing to the resting stage; and telogen hairs are resting hairs, which remain in the follicles for variable periods before they fall out (teloptosis). The lag period between loss of the telogen hair and growth of a new anagen hair has been called kenogen.

Anagen hairs grow for about 3 years (1000 days), with a range between 2 and 6 years. The follicular matrix cells grow, divide, and become keratinized to form growing hairs. Catagen hairs are in a transitional phase, lasting 1 or 2 weeks, in which all growth activity ceases, with the eventual formation of the telogen "club" hair. Many apoptotic cells are present in the outer root sheath of the catagen hair as it involutes. Telogen club hairs are resting hairs, which continue in this state for 3–5 months (~100 days) before they are released.

Of human hairs plucked from a normal scalp, 85–90% are anagen hairs, and 10–15% are telogen hairs. Catagen hairs normally constitute less than 1% of scalp hairs. The scalp normally contains an estimated 100,000 hairs, and the average number of hairs shed daily is 100–150. The hair growth rate of terminal hairs is about 0.37 mm/day. Contrary to popular belief, neither shaving nor menstruation has any effect on hair growth rate. The average uncut scalp hair length is estimated to be 25–100 cm, although exceptional hairs may be as long as 170 cm (70 inches).

Lanugo hair is the fine hair present on the body of the fetus. This is replaced by the vellus and terminal hairs. Vellus hairs are fine and usually light colored and have a narrow hair shaft thinner than the width of the inner root sheath. Terminal hairs are coarse, thick, and dark, except in blond-haired persons. Hair occurs on all skin surfaces except the palms, soles, labia minora, lips, nails, glans, and prepuce. Terminal hairs are typically present on a man's face, chest, and abdomen, but vellus hairs usually predominate on these sites in women.

Causes of alopecia are generally divided into the broad categories of cicatricial and noncicatricial alopecia. The evaluation should take into account the patient's age and ethnicity. Examination of hair shafts can establish a diagnosis of trichodystrophy. Hair counts, hair pull, and hair pluck (trichogram) can establish the degree of hair shedding, the type of hair that is shed, and the anagen/telogen ratio. Biopsies can also determine the anagen/telogen ratio and provide information regarding the potential for regrowth, as well as providing a diagnosis. Biopsies are particularly valuable in the evaluation of cicatricial alopecia. Often, a correct diagnosis hinges on a synthesis of clinical, histologic, serologic, and immunofluorescent data.

Noncicatricial alopecia

Alopecia areata

Clinical features

Alopecia areata (in French, pelade) is characterized by rapid and complete loss of hair in one or more round or oval patches, typically 1–5 cm in diameter, usually on the scalp, bearded area, eyebrows, eyelashes, and less frequently, on other hairy areas of the body. A few resting hairs may be found within the patches. Early in the course, there may be sparing of gray hair, and white hairs are rarely affected. Sudden whitening of hair may represent widespread alopecia areata in a patient with salt-and-pepper hair. In about 10% of alopecia areata patients, especially in long-standing cases with extensive involvement, the nails develop uniform pits that may form transverse or longitudinal lines. Trachyonychia, onychomadesis, and red or spotted lunulae occur, but less often. Dermoscopic examination typically demonstrates diffuse, round, or polycyclic perifollicular yellow dots.

Complete loss of scalp hair is referred to as alopecia totalis, and complete loss of all hair as alopecia universalis. Loss may occur confluently along the temporal and occipital scalp (ophiasis) (Fig. 33-1) or on the entire scalp except for this area (sisaipho). Rarely, alopecia areata may present in a diffuse pattern that may mimic pattern alopecia. Clues to the correct diagnosis include a history of periodic regrowth, nail pitting, and the presence of tapered fractures or "exclamation point" hairs (Fig. 33-2). Alopecia areata generally presents as an anagen effluvium, with an inflammatory insult to the hair matrix resulting in tapering of the hair shaft and fracture of anagen hairs. As the hair miniaturizes or converts from anagen to telogen, the remaining lower portion of the hair rises above the level of the scalp, producing the exclamation point hair.

Alopecia areata is associated with a higher incidence than usual of atopic dermatitis, Down syndrome, lichen planus, and autoimmune diseases, such as systemic lupus erythematosus (SLE), thyroiditis, diabetes mellitus, myasthenia gravis, and vitiligo. However, most cases of alopecia areata occur without associated disease, and routine screening for these disorders is of little value unless prompted by signs or symptoms.

Migratory poliosis of the scalp may represent a forme fruste of alopecia areata. Patients with this disorder present with migrating circular patches of white hair, but never lose hair. The histology resembles alopecia areata.

Etiologic factors

Oligoclonal and autoreactive T lymphocytes are present in the peribulbar inflammatory infiltrate, and many patients respond

Fig. 33-1 Alopecia areata.

Fig. 33-2 Exclamation point hairs of alopecia areata.

to immunomodulating drugs. Affected alopecia areata scalp skin grafted on to nude mice with severe combined immunodeficiency demonstrates loss of infiltrating lymphocytes and hair growth. In this model, injecting T lymphocytes with scalp homogenate can reproduce the alopecia. Follicular melanocytes substitute for scalp homogenates to produce alopecia areata in this model, providing evidence that follicular melanocytes are the targets for activated T cells in this disease. This hypothesis is also supported by the observations that white hair is rarely affected and regrowing hair is often depigmented.

The early phase of hair loss appears to be mediated by type 1 cytokines, including interleukin (IL)–2, interferon (IFN)–γ, and tumor necrosis factor (TNF)–α. The hair bulb normally represents an area of relative immune privilege during anagen, as evidenced by a very low level of expression of major histocompatibility complex (MHC) class Ia antigens. This immune privilege may prevent antigen recognition by autoreactive CD8+ T cells. Alopecia areata may be related to collapse of this immune privilege.

Overall, almost 25% of patients have a positive family history; there are reports of twins with alopecia areata. Patients with "early onset, severe, familial clustering alopecia areata" have a unique and highly significant association with the human leukocyte antigens (HLAs) DR4, DR11, and DQ7. The "later onset, milder severity, better prognostic" subsets of patients have a lower frequency of familial disease and do not share these HLAs. Familial alopecia areata associated with hereditary thrombocytopenia related to mutations in genes on chromosome 17 has been described. R620W (c.1858C>T, a variant of the protein tyrosine phosphatase nonreceptor 22 gene, *PTPN22*) is associated with a variety of autoimmune disorders, including alopecia areata. It is associated with early onset of disease, widespread hair loss, and a positive family history.

Histology

In early alopecia areata, there is a lymphoid infiltrate in the peribulbar area of anagen or early catagen follicles. Eosinophils may be present in the infiltrate, and lymphocyte-mediated damage to the bulb produces melanin pigment incontinence in the surrounding stroma. The presence of many catagen hairs and pigment casts within the follicular canal can cause histologic confusion with trichotillomania. The follicles eventually miniaturize, appearing as small, dystrophic anagen hairs high in the dermis, often with a persistent lymphocytic peribulbar infiltrate. Fibrous tract remnants beneath the miniaturized bulbs of alopecia areata may contain lymphoid cells, eosinophils, and melanin pigment. With time, the lymphocytes disappear, but focal eosinophils and pigment remain. Finally, only focal melanin pigment remains in the fibrous tract remnants. Every histologic feature of alopecia areata may be seen in syphilis. The presence of plasma cells is suggestive of syphilis, but plasma cells are also lacking in about one third of syphilis biopsies. Plasma cells may be present in biopsies from any form of inflammatory alopecia if the biopsy is taken from the occipital scalp, because this site readily recruits plasma cells.

Differential diagnosis

The sharply circumscribed patch of alopecia with exclamation point hairs at the periphery and the absence of scarring are indicative of alopecia areata. Tinea capitis, androgenetic alopecia, early lupus erythematosus (LE), syphilis, congenital triangular alopecia, alopecia neoplastica, and trichotillomania should be kept in mind when alopecia areata is considered. In endemic areas of Southwest Asia, *Pheidole* ants shear hair shafts during the night, resulting in overnight loss of clumps of hair. The resulting round patches of hair loss closely mimic alopecia areata.

Treatment

The natural course of the hair loss is highly variable. Some patches will regrow in a few weeks without any treatment. In a series of 63 consecutive responders to a follow-up questionnaire, hair had spontaneously regrown in all but four after 1 year and in all but one after 2 years. The great majority had recovered in 3 months after their only office visit. Therefore, anecdotal reports of success must be interpreted carefully in the light of the high rate of spontaneous recovery.

Intralesional injections of corticosteroid suspensions are the treatment of choice for localized, cosmetically conspicuous patches, such as those occurring in the frontal hairline or involving an eyebrow. Injections of triamcinolone, 2–10 mg/mL, are typically given intradermally or in the superficial subcutaneous tissue. Large volumes and higher concentrations of triamcinolone present a greater risk of atrophy. Injection under significant pressure or with a small-bore syringe increases the likelihood of retinal artery embolization. High-strength topical corticosteroids may be used as a safer first-line therapy but are less reliable than injections. Several investigators have reported the use of pulsed oral corticosteroids in rapidly progressing or widespread disease. However, long-term treatment is frequently needed to maintain growth, and the attendant risks should be carefully weighed against the benefits. In a study of 66 patients age 9–60 years, monthly methylprednisolone was administered at a dose of 500 mg/day for 3 days, or 5 mg/kg

twice daily over 3 days in children. More than 60% of patients with widespread patchy alopecia responded. Half the patients with alopecia totalis had a good response, whereas a quarter of those with universal alopecia responded. Patients with ophiasic alopecia areata did not respond. Predictors of response include disease duration of 6 months or less, younger than 10 years at disease onset, and multifocal disease.

Induction of contact sensitivity to squaric acid dibutyl ester, dinitrochlorobenzene (DNCB), and diphencyprone can be useful in refractory cases. Topical or oral methoxsalen (psoralen) and ultraviolet A (PUVA) therapy is an option for refractory or widespread lesions. Short-contact topical anthralin 1% cream (applied for 15–20 min and then shampooed off) can be of benefit. Topical minoxidil may be combined with other treatments or used as a single agent. Psoriatic doses of methotrexate and sulfasalazine in doses up to 1.5 g three times daily may be beneficial. Cyclosporine has been used alone or combined with other modalities, including PUVA. Biologics have produced mixed, and largely disappointing, results, and alopecia areata has developed during biologic therapy for other conditions. The 308-nm xenon chloride excimer laser (300–2300 mJ/cm^2/session) has been reported to produce regrowth after 11 and 12 sessions over 9–11 weeks. Periocular pigmentation is associated with use of travoprost for eyelash disease. Therapeutic results are mixed. Botanicals, including peony glucosides and glycyrrhizin, demonstrate some promise. In a mouse model, a fusion protein of parathyroid hormone and a bacterial collagen-binding domain produced hair regrowth.

Alopecia areata can cause tremendous psychological stress. Education about the disease process, cosmetically acceptable alternatives (especially information about wigs), and research into innovative therapies should all be made available to the patient. In addition to the information conveyed by the dermatologist, an excellent resource is the National Alopecia Areata Foundation (www.naaf.org, info@naaf.org).

Prognosis

The tendency is for spontaneous recovery in alopecia areata patients who are postpubertal at onset. At first, the regrowing hairs are downy and light in color; later, they are replaced by stronger and darker hair with full growth. Predictors of a poor prognosis are the presence of atopic dermatitis, childhood onset, widespread involvement, ophiasis, duration of longer than 5 years, and onychodystrophy. Acute diffuse and total alopecia is a newly defined subtype of alopecia areata that occurs in young adults and has a good prognosis.

Telogen effluvium

Telogen effluvium presents with excessive shedding of normal telogen club hairs. This excessive shedding of telogen hairs most often occurs 3–5 months after the premature conversion of many anagen hairs to telogen hairs induced by surgery, parturition, fever, drugs, dieting, or traction. Local patches of early telogen conversion may be induced by papulosquamous diseases affecting the scalp. Alternatively, follicles may remain in prolonged anagen rather than normally cycling into telogen. This occurs during pregnancy. On delivery, many follicles are then released simultaneously into telogen, and shedding occurs 3–5 months later. Prolongation of telogen also occurs during pregnancy and results in an initial wave of hair loss soon after delivery or heralding early termination of a pregnancy. Shortening of the anagen phase occurs in pattern (androgenetic) alopecia and in chronic telogen effluvium. A greater proportion of hairs in telogen at any one time results in a chronic increase in telogen shed. Administration of topical minoxidil may produce a telogen effluvium by premature termination of telogen necessary to initiate anagen in responding follicles. This causes early telogen release and a brief telogen effluvium.

Whatever the cause of the telogen loss, the hair is lost "at the root." Each hair will have a visible depigmented club-shaped bulb and will lack a sheath (Fig. 33-3).

Telogen shed may be estimated by the pull test: grasping 40 hairs firmly between thumb and forefinger, followed by a slow pull that causes minimal discomfort to the patient. A count of more than 4–6 club hairs is abnormal, but the result is influenced by recent shampooing (2–3 hairs being abnormal in a freshly shampooed scalp), combing, and the phase of telogen effluvium (whether resolving or entering a chronic phase). The clip test may also be useful; 25–30 hairs are cut just above the scalp surface and mounted. Indeterminate and telogen hairs are short and of small diameter. Many hairs of this type may be present in telogen effluvium or pattern alopecia. Trichogram evaluation (50 hairs plucked with Kelly clamp with rubber drains over teeth) can also provide information on the anagen/telogen ratio.

Age, gender, race, and genetic factors influence the normal average daily hair loss in an individual. Again, a full head of hair numbers about 100,000; of these, approximately 100–150 are lost daily. In telogen effluvium, estimates of loss vary from 150 to more than 400. Patients may be instructed to collect and count the hair daily; however, they should make sure they collect all small hairs and those that come out in washing and in the bed, as well as those present on the comb or brush. When the pull test is positive, hair shed counts are not needed. An alternative is to collect all hairs lost during a 1-minute combing session. For this technique, developed by Dr. Jeffrey

Fig. 33-3 Anagen and telogen hair. Anagen hair has a pigmented bulb and is surrounded by a gelatinous root sheath; telogen hair has a nonpigmented bulb and lacks a root sheath.

Fig. 33-4 Telogen effluvium secondary to "crash" dieting.

Miller, the patient combs for 1 minute before shampooing on 3 consecutive days. The patient is instructed to comb from the vertex to the anterior hairline. The normal range of lost hairs with this technique is 10–15. Loss of more than 50 is common in telogen effluvium. Serial 1-minute hair counts can be performed to monitor progress.

Telogen effluvium may be related to protein or other nutrient deprivation (Fig. 33-4). Assessment of dietary habits and determination of iron saturation and ferritin are the simplest ways to determine nutritional status. Iron replacement is advisable if saturation or ferritin is low, but in one study, iron replacement alone did not result in resolution of telogen effluvium. Iron may merely serve as a marker for overall nutritional status. Patients with evidence of deficiency should be given supplements to correct the identified deficiency and encouraged to eat a varied diet. Sources of blood loss, such as menstrual bleeding and gastrointestinal (GI) blood loss, should be investigated. Hypothyroidism, allergic contact dermatitis to hair dyes, and renal dialysis with secondary hypervitaminosis A may also be associated with telogen effluvium. Drug-induced telogen effluvium has been noted with the use of aminosalicylic acid, amphetamines, bromocriptine, captopril, carbamazepine, cimetidine, coumarin, danazol, enalapril, etretinate, levodopa, lithium carbonate, metoprolol, metyrapone, pramipexole, propranolol, pyridostigmine, and trimethadione. Postnatal telogen effluvium of infants may occur between birth and the first 4 months of age. Usually, regrowth occurs by 6 months of age. Telogen counts by Kligman in six infants varied from 64% to 87%. He also found a tendency for the alopecia to occur in the male-pattern distribution. Idiopathic chronic telogen effluvium has been described by Whiting in a group of 355 patients (346 women and 9 men) with diffuse generalized thinning of scalp hair. Most were 30–60 years old, and their hair loss started abruptly, with increased shedding and thinning. There was a fluctuating course and diffuse thinning of the hair all over the scalp, accompanied by bitemporal recession. This chronic form is related to shortening of the anagen phase and may respond to 5% minoxidil solution.

Trichodynia is a common symptom in patients with telogen effluvium, as it is in pattern hair loss. Trichodynia may also coexist with signs of depression, obsessive personality disorder, or anxiety.

If a 4-mm punch biopsy is performed, 25–50 hairs are normally present for inspection in transverse (horizontal) sections. If more than 12–15% of terminal follicles are in telogen, this indicates a significant shift from anagen to telogen. Pattern (androgenetic) alopecia demonstrates miniaturization, variable hair shaft diameter, and an increased proportion of telogen hairs. Traction alopecia and trichotillosis (trichotillomania) result in an increased number of catagen and telogen hairs. Pigment casts, empty anagen follicles, trichomalacia, and catagen hairs help distinguish these entities from simple telogen effluvium.

No specific therapy is required for most patients with telogen effluvium. In the majority of cases, the hair loss will stop spontaneously within a few months, and the hair will regrow. Drug-induced telogen effluvium responds to discontinuation of the offending agent. The prognosis is good if a specific event can be pinpointed as a probable cause. Papulosquamous scalp disorders may precipitate telogen hair loss and should be addressed. Iron and thyroid status should be determined if the course is prolonged or if history or physical examination suggests an abnormality. Patients should be encouraged to eat a balanced diet. In a mouse model, sonic stress can produce catagen. This model may be useful in the study of agents for the treatment of telogen effluvium.

Anagen effluvium

Anagen effluvium usually results from hair shaft fracture. It is frequently seen following the administration of cancer chemotherapeutic agents, such as the antimetabolites, alkylating agents, and mitotic inhibitors. These agents result in temporary shutdown of the hair matrix with resultant tapering of the shaft (Pohl-Pinkus constrictions). Trichograms reveal tapered fractures. Only anagen hairs are affected. The 10% of scalp hairs in telogen have no matrix and are unaffected. The loss tends to be diffuse but not complete. Severe loss is frequently seen with doxorubicin, the nitrosureas, and cyclophosphamide. When high doses are given, loss of anagen hairs becomes most apparent clinically in 1–2 months. Hair loss after chemotherapy is usually, but not always, reversible. Permanent alopecia

Fig. 33-5 Loose anagen hair with "rumpled sock" cuticle.

after chemotherapy resembles pattern alopecia histologically. A pressure cuff applied around the scalp during chemotherapy and scalp hypothermia have been reported to prevent such anagen arrest; because the scalp may be a site of metastasis, however, it may be better not to spare the scalp from the effects of chemotherapy. Topical minoxidil has been shown to shorten the period of baldness by an average of 50 days.

In addition to the cytotoxic chemotherapeutic agents, various agents, such as isoniazid (INH), thallium, and boron, may induce anagen effluvium. Anagen effluvium with tapered fractures also occurs in alopecia areata and syphilis. In these diseases, an inflammatory insult to the hair bulb results in tapered fractures.

Anagen loss may also occur at the root. Loose anagen syndrome, described by Price in 1989, is a disorder in which anagen hairs may be pulled from the scalp with little effort. It occurs mostly in blond girls and usually improves with age. The syndrome appears to be related to a defect in the hair cuticle. Instead of anchoring the hair firmly, the cuticle simply folds back like a rumpled sock (Fig. 33-5), allowing the hair shaft to be extracted. Woolly hair can be associated with loose anagen hair syndrome. A keratin mutation, E337K in K6HF, was identified in three of nine families studied. Colobomas have also been associated with loose anagen hair.

Anagen hairs may be easily extracted from active areas of LE and lichen planopilaris. They usually lack the root sheath that normally surrounds a plucked anagen hair. Anagen effluvium has also been described in lesions of pemphigus.

Pattern alopecia (androgenetic alopecia)

Male-pattern baldness

Male-pattern alopecia (common baldness) shows itself during the teens, twenties, or early thirties with gradual loss of hair, chiefly from the vertex and frontotemporal regions. The process may begin at any time after puberty, and the presence of "whisker" or kinky hair may be the first sign of impending male-pattern alopecia. The anterior hairline recedes on each side, in the Geheimratswinkeln ("professor angles"), so that the forehead becomes high. Eventually, the entire top of the scalp may become devoid of hair. Several patterns of this type of hair loss occur, but most common is the biparietal recession with loss of hair on the vertex. The rate of hair loss varies among individuals. Sudden hair loss may occur in the twenties and then proceed relentlessly, though very slowly, for a number of years. The follicles produce finer and lighter hairs with each hair cycle until terminal hairs are eventually replaced by vellus hairs. During evolution of the process, hair shafts vary significantly in diameter. The parietal and occipital areas are usually spared permanently from this process of progressive miniaturization.

Early-onset male-pattern alopecia is related to the androgen receptor gene. There is no doubt that inherited factors and the effect of androgens such as dihydrotestosterone on the hair follicle are important. Arguments for polygenic inheritance include the high prevalence, gaussian curve of distribution in the population, increased risk with number of affected relatives, increased risk in relatives of severely affected women compared with mildly affected women, and greater import of an affected mother than an affected father. The possibility that the early onset (before age 30) and later onset (after 50) forms may be inherited separately by single genes is also hypothesized.

Male-pattern alopecia is dependent on adequate androgen stimulation and appears to be related to the androgen receptor gene. Eunuchs do not develop baldness if they are castrated before or during adolescence. If they are given androgen therapy, baldness may develop. The 5α-reduction of testosterone is increased in the scalp of balding individuals, yielding increased dihydrotestosterone. Androgen-inducible transforming growth factor (TGF)–β1 derived from dermal papilla cells appears to mediate hair growth suppression. In congenital 5α-reductase deficiency, the type 2 isoenzyme is lacking, and baldness does not occur. Pattern alopecia does occur in males with X-linked ichthyosis, indicating that steroid sulfatase is not critical for the production of alopecia.

Progressive shortening of the anagen phase of hair growth is noted as the hair shaft diameter decreases, so hairs not only are narrowing, but also are becoming shorter. A higher proportion of telogen hairs in the affected area results in greater telogen shed. There may also be an increase in the duration of the lag phase between telogen and anagen (the kenogen lag phase).

Histologically, a decrease in anagen and increase in telogen follicles is present. Follicular miniaturization and variability in shaft diameter are noted. These features are particularly evident in transverse sections. Below the level of the miniaturized or telogen follicle, a vascular or fibromucinous fibrous tract remnant is present. These tracts appear numerous in cross section. Many mast cells may be noted in the fibrous tract remnant, but inflammatory cells are absent. Sebaceous glands may be enlarged, and hair thinning may be associated with solar elastosis. Sparse lymphoid inflammation with spongiosis may be noted at the level of the follicular infundibulum. This may represent associated seborrheic folliculitis. A sparse lymphoid infiltrate may also be noted at the level of the hair bulge.

Miniaturized human hair follicles grafted on to immunodeficient mice can quickly regenerate and grow as well as or better than terminal follicles from the same individual. This suggests that even advanced pattern alopecia may be reversible. Partial reversal of pattern alopecia has been noted after chemotherapy or treatment of psoriasis with methotrexate. Unfortunately, available pharmacologic interventions produce little effect in advanced pattern alopecia.

Men with spinal and bulbar muscular atrophy (Kennedy disease), an X-linked neurodegenerative disease caused by an expansion of a polymorphic tandem CAG repeat within the androgen receptor gene, have a decreased incidence of pattern alopecia.

Minoxidil, an oral hypotensive drug that causes hypertrichosis when given systemically, is available as topical solutions (Rogaine). Minoxidil promotes the survival of dermal papilla cells, prolongs anagen phase, and results in enlargement of shaft diameter. Clinically, apparent success is best in early cases (<10 years) of limited extent (bald area <10 cm in diameter on vertex) in whom pretreatment hair density is greater than 20 hairs/cm^2. Minoxidil is available without a prescription as a solution or foam. Those who respond must continue to use minoxidil indefinitely to maintain a response.

Finasteride, a type 2 5α-reductase inhibitor, given as a 1-mg tablet daily, is effective in preventing further hair loss and in increasing the hair counts to the point of cosmetically appreciable results in men age 18–41 with mild to moderate hair loss at the vertex, in the anterior midscalp, and in the frontal region. Finasteride has been shown to stop hair loss in up to 90% of men for at least 5 years. Approximately 65% of men demonstrate hair regrowth. As with minoxidil, continued use of finasteride is required to sustain benefits. Hair patterning on the temples is not improved. Hair growth will be evident only after 6 months or more of therapy. If no effect is seen after 12 months, further treatment is unlikely to be of benefit. In one study, regimens that included finasteride were more effective than minoxidil alone, and therapeutic efficacy was enhanced by combining the two drugs. Short-term side effects related to finasteride are infrequent; however, the need to take this medication indefinitely suggests that study of long-term side-effect profiles is critical. A prostate cancer prevention trial with a different dosage form of the same drug showed a decrease in the incidence of cancer. However, those cancers that did occur in the treatment group had a higher average Gleason score, possibly because only lower-grade cancers were prevented.

Dutasteride blocks both type 1 and type 2 5α-reductase and is effective in the treatment of male-pattern hair loss. Other treatments that show some promise in preliminary studies include fluridil (topical antiandrogen that suppresses human androgen receptor), topical adenosine, and hormone-enriched topical cell culture medium. Hair transplantation using micrografts of hair follicles from the occipital area to the anterior scalp may satisfactorily recreate hairlines and give excellent cosmetic results.

Female-pattern alopecia (androgenetic alopecia in women)

Women generally have diffuse hair loss throughout the apical scalp with the part wider anteriorly. There is typically sparing of the frontal hairline, although a subset of women exhibits a "male" pattern of temporal recession. Although maintenance of the frontal hairline is the rule in women, a progressive decrease in hair density from the vertex to the front of the scalp does occur. The same basic changes—reduced hair density and diameter and diminished anagen and increased telogen hair—occur in women as in men. Sebaceous gland hyperplasia may be present but is less common than in men. Transverse histologic sections demonstrate variability in the size of hair follicles (anisotrichosis).

The cause is now believed to be a genetic predisposition with an excessive response to androgens. Both women and men with pattern alopecia have higher levels of 5α-reductase and androgen receptor in frontal hair follicles than in occipital follicles. Evidence also suggests a hierarchy of androgen sensitivity within follicular units. Follicular miniaturization relates to unrepaired DNA damage and a reduced proliferation rate of matrix keratinocytes. Smoking may be an independent risk factor. Most women with pattern alopecia have normal menses and fertility. If other evidence of androgen excess is present, such as hirsutism, menstrual irregularities, or acne, or if the onset is sudden, evaluation as outlined for hirsutism (see later) should be performed. Topical minoxidil, and oral antiandrogens, such as spironolactone and cyproterone acetate, have been used to treat androgenetic alopecia in women. In one study, cyproterone acetate was more effective than minoxidil when there were other signs of hyperandrogenism, hyperseborrhea, and menstrual abnormalities, and when the body mass index was high. When these other factors were absent, minoxidil was the more effective treatment.

Treatment with finasteride is of limited benefit for most women, although the subset with temporal recession may show some benefit. Finasteride treatment is contraindicated in women who may become pregnant. Hair transplantation, wigs, or interwoven hair may give satisfactory cosmetic results. In a pilot study, topical melatonin appeared to prolong anagen phase and may prove to be of some benefit. In some women, telogen effluvium may produce worsening of preexisting pattern alopecia. Reversible causes of telogen effluvium, such as seborrheic dermatitis, nutrient deficiency, and thyroid disease, should be addressed.

Trichotillomania (trichotillosis)

Trichotillomania is the compulsive practice of plucking hair from the scalp, brows, or eyelashes. Typical areas are irregular patches of alopecia that contain hairs of varying length. The scalp has a rough texture, resulting from the short remnants of broken-off hairs. Trichotillomania is seen mostly in girls younger than 10, although boys and all adults may engage in the practice as well. Some patients relate exquisite pain localized to a follicle (Fig. 33-6) that can only be relieved by plucking the hair.

When speaking with a patient with characteristic areas of alopecia, rather than asking "if," one should ask "how" removal of the hair is done. If this fails to uncover a history of hair pulling, shaving a 3-cm^2 area in the involved part of the scalp will result in hairs too short for plucking, and normal regrowth in the "skin window" within 3 weeks. Finally, a biopsy, especially if cut horizontally, may demonstrate empty anagen follicles, catagen hairs, pigment casts within the infundibulum, trichomalacia, and hemorrhage. Alopecia areata shares many of these histologic features, and care must be taken to search for the presence of peribulbar lymphocytes or inflammatory cells within the fibrous tract remnants.

Trichotillomania is usually a manifestation of an obsessive-compulsive disorder but may also be associated with depression or anxiety. It may be associated with compulsive

swallowing of the plucked hairs (trichophagia) and may result in formation of a gastric bezoar (Rapunzel syndrome). Behavior modification, psychotherapy, and appropriate psychopharmacologic medication (e.g., clomipramine, olanzapine) may be helpful. *N*-acetylcysteine was effective in a study in adults, but a separate study showed disappointing results in children. Valproic acid, quetiapine, and naltrexone have been reported as effective in some patients. Bimatoprost has been used when eyelashes are involved.

Other forms of noncicatricial alopecia

Alopecia syphilitica may have a typical moth-eaten appearance on the occipital scalp (Fig. 33-7), may show a generalized thinning of the hair, or may resemble alopecia areata. Other areas, such as the eyebrows, eyelashes, and body hair, may be involved. The alopecia may be the first sign of syphilis.

Follicular mucinosis (alopecia mucinosa) most often occurs on the scalp or beard area and manifests as a boggy, red plaque or hypopigmented patch with hair loss. Comedolike lesions may exude mucin when expressed. Biopsy demonstrates deposition of mucin in the outer root sheath and sebaceous glands. The mucin stains as hyaluronic acid, rather than epithelial sialomucin. Primary cases (unassociated with underlying disease) usually occur as localized lesions of the head or neck. Young people are primarily affected and may demonstrate clonality even in lesions that do not progress clinically. The secondary type is associated with mycosis fungoides–type cutaneous T-cell lymphoma or a chronic inflammatory skin disease. Lesions associated with mycosis fungoides are generally widespread and chronic and occur in older patients.

Vascular or neurologic alopecia, most often of the lower extremities, may be seen in diabetes mellitus or atherosclerosis. In meralgia paresthetica, there may be alopecia of the anesthetic area of the outer thigh.

Endocrinologic alopecia may occur in various endocrinologic disorders. In hypothyroidism, the hair becomes coarse, dry, brittle, and sparse. The proportion of telogen hairs has been shown to be three to seven times higher than the normal 10%. In hyperthyroidism, the hair becomes extremely fine and sparse. Oral contraceptives (OCs) have been implicated in some cases of androgenetic alopecia. It develops in predisposed women who are usually taking androgenic progestogens. It is advisable to discontinue the androgen-dominant pill and substitute an estrogen-dominant OC. Some women develop telogen effluvium 2–4 months after discontinuing anovulatory agents, which is analogous to postpartum alopecia.

Congenital alopecia occurs as total or partial loss of hair, or a lack of initial growth, accompanied usually by other ectodermal defects of the nails, teeth, and bone. The hair is light and sparse and grows slowly. Congenital triangular alopecia (Fig. 33-8) and aplasia cutis congenita are examples of congenital localized absence of hair. Hidrotic ectodermal dysplasia is a diffuse abnormality of hair associated with dental and nail changes.

Lipedematous alopecia consists of thickening of the scalp that gives the impression of thick cotton batting. The hair may be normal or shortened and sparse. Biopsy shows an increase in thickness of the subcutaneous fat and variable lymphoid inflammation. This disease appears to affect black persons primarily.

Fig. 33-9 Loss of follicular ostia in scarring alopecia.

Cicatricial alopecia

Cicatricial alopecia appears as areas of hair loss with absence of follicular ostia (Fig. 33-9). Acute lesions may appear as erythematous plaques, perifollicular papules, keratotic follicular spines, or pustules. Deep inflammatory lesions may be boggy or may resemble noncicatricial areata clinically. The inflammatory nature of the lesion may only be evident on biopsy.

Discoid lupus erythematosus (DLE), lichen planopilaris, sarcoidosis, and folliculitis decalvans are the most common inflammatory causes of cicatricial alopecia. Chronic bacterial and fungal infections may produce inflammatory alopecia that mimics primary scarring alopecia. For example, fungal folliculitis may mimic LE.

Biopsy can confirm the diagnosis and provide prognostic information regarding the potential for new growth. A 4-mm punch biopsy will provide the pathologist with an adequate specimen. Smaller specimens are of limited value. The punch should be placed parallel to the direction of hair growth to avoid transecting follicles, and the punch should be advanced to the deep subcutaneous fat. The biopsy site will typically bleed profusely, but a 4-mm-wide strip of gel foam advanced into the defect will generally provide rapid hemostasis. Sutures are rarely necessary, and because the scar from a sutured biopsy site generally stretches back to the original dimensions of the biopsy, suturing provides little benefit to the patient.

The biopsy should be taken from a well-established lesion that is still active, rather than from the advancing edge.

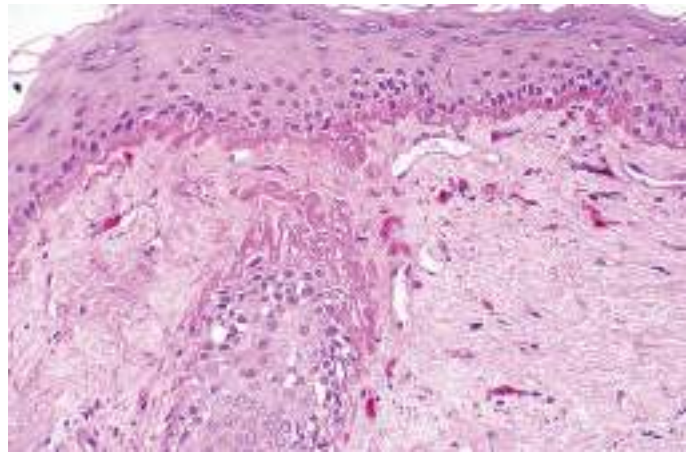

Fig. 33-10 Basement membrane thickening in lupus erythematosus (periodic acid–Schiff [PAS] stain).

Dermoscopy may be helpful in selecting the biopsy site. The pathologist may prefer vertical or transverse (horizontal) sectioning of the specimen. Each has advantages. Every follicular unit in the specimen will be demonstrated in transverse sections. Vertical sections are superior for demonstrating changes in the surface epidermis, dermoepidermal junction (DEJ), superficial dermis, and subcutaneous fat. In general, the features of androgenetic (pattern) alopecia, telogen effluvium, and trichotillomania are better demonstrated in transverse (horizontal) sections through the specimen. Alopecia areata and syphilitic alopecia are well demonstrated in transverse sections if serial step sections are obtained to demonstrate deeper planes of section, or if the block is cut horizontally in a bread-loaf fashion before embedding. They are equally well demonstrated with serial vertical sections through the block. LE and lichen planopilaris are more easily demonstrated in serial vertical sections.

The diagnostic yield can be enhanced by pairing vertical and transverse sections. If two biopsies are done, one specimen can be bisected vertically for direct immunofluorescence (DIF) and hematoxylin and eosin (H&E) processing. It is most easily split by laying it on its side and bisecting it with a No. 15 blade pushed cleanly through the specimen in a single downward motion. Sawing at the specimen will not produce a satisfactory result. One-half the bisected specimen is placed in formalin and the other half in immunofluorescent media. The second specimen can be bisected for transverse sections in the clinic or left for the laboratory to bisect after processing. If to be bisected in the clinic, it should be placed on its side. The 15 blade should be pushed downward through the specimen in a single motion at the level of the middermis. All pieces for vertical and transverse sections may be placed in a single bottle to be embedded in a single cassette. If a single biopsy specimen is submitted for H&E sections, it can be bisected vertically, then one-half bisected transversely 1 mm above the fat (Tyler technique). This provides the advantages of both vertical and transverse sections with a single specimen.

In LE, the biopsy must be from a lesion of several months' duration in order to demonstrate hyperkeratosis, follicular plugging, basement membrane zone thickening (Fig. 33-10), and dermal mucin. Only biopsies from established lesions of lupus will demonstrate reliable immunofluorescence.

When biopsies of the most active area of alopecia have failed to yield a definite diagnosis, a biopsy from a scarred area may provide additional information. Scars show loss of elastic tissue with the Verhoeff–van Gieson stain. The pattern of elastic tissue loss is the "footprint" of the preceding inflammatory process (Figs. 33-11 and 33-12), and remains the gold

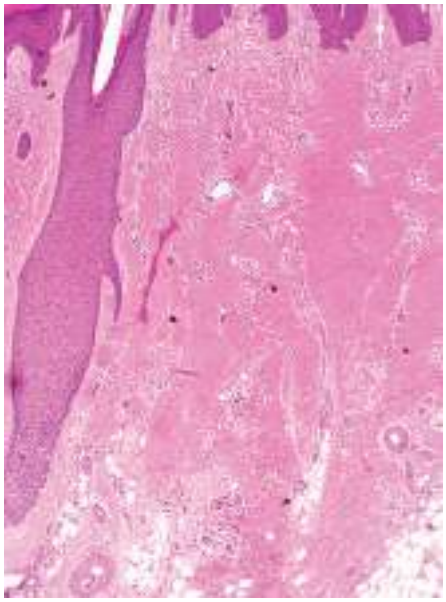

Fig. 33-11 Scarring alopecia (hematoxylin-eosin [H&E] stain).

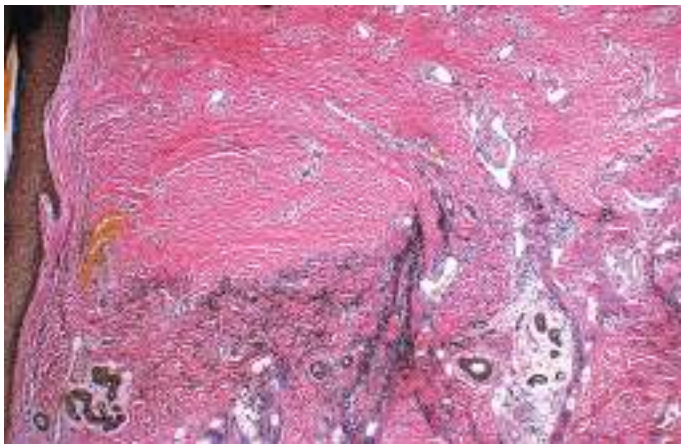

Fig. 33-12 Scarring alopecia (elastic stain). Normal elastic fibers (black) indicate the nonscarred portions of the dermis.

standard for evaluation of scarring alopecia, although polarized microscopy and immunofluorescence of H&E-stained sections can also be useful. Lichen planopilaris and folliculitis decalvans both affect the infundibulum. Both result in wedge-shaped superficial dermal scars. DLE results in scarring of both the follicular units and the intervening dermis. Morphea does not produce a scar, but rather hyalinization of collagen bundles with preservation of the elastic fibers. In idiopathic pseudopelade, the fibrous tract remnants are widened, but the elastic tissue sheath at the periphery of the fibrous tract is preserved.

Most patients with cicatricial alopecia experience gradual progression of the alopecia, and the prolonged course of the disease may lead to inappropriate therapeutic complacency. The progressive destruction of hairs will result in ever-expanding areas of permanent alopecia. Therefore, cicatricial alopecia must be treated aggressively and early to avoid permanent disfigurement. Surgical revision of the hairless plaque is an option for stable end-stage alopecia, but unless the underlying disease is controlled, surgery may only lead to a flare of the underlying disease with progression of hair loss. Therapy may be forestalled by the inability to establish a definite diagnosis. To help guide therapy for patients who defy diagnosis, work groups of the North American Hair Research Society have proposed a classification scheme based on the type and pattern of inflammation. Some forms of destructive alopecia are lymphocyte mediated; others are suppurative processes. The type of infiltrate and the portion of the pilosebaceous unit affected can be used to guide therapy. This classification system may also allow patients to enroll in clinical trials, even in the absence of a definite diagnosis.

Lymphoid-mediated disorders

Lupus erythematosus

Chronic cutaneous (discoid) lupus of the scalp (DLE) is a common cause of cicatricial alopecia. In active disease, anagen hairs may be easily extracted from the involved area. Usually, erythema, atrophy, follicular plugging, and mottled hyperpigmentation and hypopigmentation are present. Patients with chronic cutaneous lupus of the scalp may have accompanying SLE or skin lesions of DLE on other parts of the body. The external ear canal and concha should always be examined because they are common sites for discoid lesions. Occasionally, alopecia occurs in a plaque of tumid lupus. Lupus panniculitis may occasionally result in alopecia in the absence of surface skin changes. SLE is often associated with discoid lesions of the scalp. Patients with SLE may also have short miniaturized "lupus hairs" on the anterior scalp.

Biopsy of early lesions of DLE is often nondiagnostic. Patchy lymphoid inflammation and perifollicular mucinous fibrosis may be the only histologic findings. Focal vacuolar interface dermatitis may or may not be noted. Active established lesions, present for several months, have a higher diagnostic yield. Active established lesions usually demonstrate hyperkeratosis, follicular plugging, vacuolar interface dermatitis, basement membrane zone thickening, pigment incontinence, and dermal mucin. Perivascular and periadnexal lymphoid infiltrates are patchy and involve the eccrine coil and fibrous tract remnants. Fibrous tract involvement creates dense vertical columns of lymphocytes. The underlying subcutaneous tissue may demonstrate nodular lymphoplasmacytic infiltrates and fibrin or hyaline rings around necrotic fat. Hypertrophic lesions of chronic cutaneous LE often demonstrate lichenoid dermatitis. DIF typically demonstrates continuous granular deposition of IgG, IgA, IgM, and C3 at the DEJ ("full house" pattern). This pattern is particularly helpful in distinguishing lichenoid hypertrophic LE from lichen planopilaris. Burnt-out lesions of DLE demonstrate loss of elastic fibers throughout the dermis, which differs from the focal peri-infundibular wedge-shaped scars of lichen planopilaris. In SLE, follicular atrophy may be associated with pronounced dermal mucinosis.

Chronic cutaneous lupus may respond to intralesional or potent topical corticosteroids, but systemic therapy is frequently required. Antimalarials, retinoids, dapsone, thalidomide, sulfasalazine, mycophenolate mofetil, and methotrexate have been used successfully. Topical tazarotene and topical calcineurin inhibitors are generally disappointing.

Lichen planopilaris

Lichen planopilaris presents with perifollicular erythema and progressive scarring. Small follicular papules may be noted, or the lesion may resemble the ivory-white irregular patches of pseudopelade. In some patients, typical polygonal flat-topped papules are present on the wrists and ankles, and lacy white lesions are noted on the oral and genital mucosa. Widespread follicular papules may be present on the trunk or

Fig. 33-13 Frontal fibrosing alopecia. (Courtesy of Dr. Don Adler.)

extremities. In most patients, however, only the scalp is involved. Frontal fibrosing alopecia appears to be a variant of lichen planopilaris. Most patients are older women with band-like frontotemporal alopecia (Fig. 33-13), often with "genitalized" kinky hairs. Graham Little–Piccardi-Lasseur syndrome includes cicatricial alopecia on the scalp, keratosis pilaris in the skin of the trunk and extremities, and noncicatricial hair loss in the pubis and axillae. It has been described in association with complete androgen insensitivity syndrome, a condition that also presents with noncicatricial alopecia in the axillary and pubic hair.

Diagnostic biopsies demonstrate lichenoid interface dermatitis of the follicular unit and sometimes the intervening epidermis. The entire fibrous tract may be filled with cytoid bodies (Fig. 33-14). The changes usually occur focally and may be best visualized with serial vertical sections. Perifollicular mucinous fibrosis is common, and focal perifollicular lymphoid infiltrates tend to involve the infundibulum (infiltrates of LE tend to involve isthmus). DIF may be negative or may reveal cytoid bodies and shaggy linear fibrin at the DEJ.

Lichen planopilaris responds to oral and intralesional corticosteroids. Topical corticosteroids may be adequate in a few patients, but resulting scalp atrophy with prominence of capillary plexus may be misinterpreted as erythema signifying active disease. As in lupus, topical tazarotene and topical macrolactams are generally disappointing. Oral retinoids and excimer laser can be effective, but antimalarials are usually not effective in preventing disease progression. Similarly, the peroxisome proliferator activated receptor-γ agonist pioglitazone is ineffective at halting progression in the majority of patients. In the authors' experience, mycophenolate mofetil is generally reliable for patients with refractory disease. Biologics have been suggested as therapy, but onset of lichen planopilaris has been noted during etanercept therapy. Dutasteride is often effective as first line therapy in the setting of frontal fibrosing alopecia.

Central centrifugal cicatricial alopecia

Central centrifugal cicatricial alopecia (CCCA) is seen most often in African American women, is slowly progressive, usually begins in the crown, and advances to the surrounding areas (Fig. 33-15). The term is often used as a broad category that includes "hot comb alopecia," idiopathic pseudopelade, and central elliptical alopecia. Some patients will demonstrate crops of crusts at the periphery of the patches, a feature of folliculitis decalvans. Treatment of CCCA is difficult and often

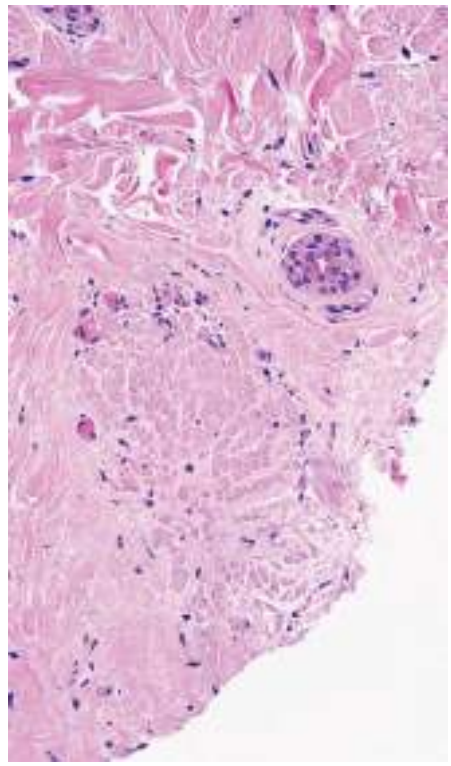

Fig. 33-14 Lichen planopilaris. Note cytoid bodies completely filling the fibrous tract remnant.

Fig. 33-15 Central centrifugal cicatricial alopecia.

unsatisfactory. Discontinuation of chemical and heat processing and reduction of traction are recommended. Patients with overlapping features of folliculitis decalvans may respond to long-term antibiotic therapy and topical corticosteroids. In such overlapping cases, the histology shows a lymphocytic infiltrate during the chronic stage, but periodic crops of pustules demonstrate a neutrophilic folliculitis.

Neutrophil-mediated disorders

Folliculitis decalvans

Folliculitis decalvans presents with crops of pustules that result in cicatricial alopecia. Successive crops of pustules, crusts, or erosions lead to expansion of the alopecic patches. Staphylococci are sometimes cultured from the lesions, and some authors have suggested that folliculitis decalvans merely

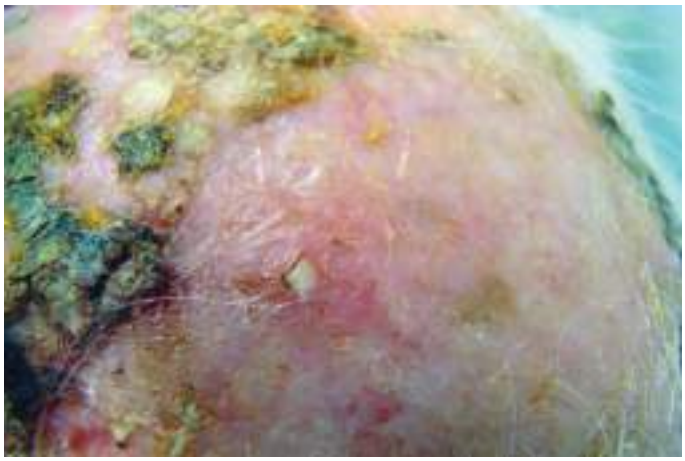

Fig. 33-16 Erosive pustular dermatitis.

Fig. 33-17 Dissecting cellulitis.

represents a chronic staphylococcal infection. It is more likely that follicular destruction is the result of an abnormal suppurative immune response. Staphylococci and other organisms probably play a role in inciting the response. Erlotinib-induced folliculitis decalvans has been reported. The lesions often respond to long-term treatment with a tetracycline. The improvement may reflect the antineutrophil effects of the drug or its antimicrobial effects. Many patients also respond to other forms of antistaphylococcal therapy, but the lesions generally recur after the antibiotic is discontinued. In contrast, long-term tetracycline treatment generally results in a continued response. Some sustained responses have been noted after combination therapy with rifampin and clindamycin. Rifampin alone may promote the emergence of bacterial resistance. Selenium sulfide shampoo and topical corticosteroids may be useful as adjunctive therapy. Oral retinoids, oral and topical fusidic acid, oral zinc sulfate, photodynamic therapy (PDT) and topical tacrolimus have been reported as successful, and anti-TNF biologics have been used for refractory disease.

A variant of folliculitis decalvans occurs in African American patients who present with pseudofolliculitis of the beard, acne keloidalis nuchae, and scarring alopecia in the vertex and parietal scalp. The scalp demonstrates ingrown hairs, crops of pustules or crusts, and permanent scarring alopecia. Although pseudofolliculitis barbae is generally accepted to be the result of ingrown hairs, the pathogenesis of acne keloidalis nuchae remains in question. Histologically, ingrown hairs are common in advanced lesions. Early lesions may not demonstrate the hair. Some patients merely develop small papules on the nape of the neck, whereas others develop pustules, crusts, and progressive alopecia. This latter group overlaps with folliculitis decalvans, and patients generally respond to treatment with a topical corticosteroid and an oral tetracycline.

Acne necrotica

Acne necrotica presents with discrete excoriated follicular papules in the scalp. Biopsy demonstrates an inflammatory crust and suppurative folliculitis. Usually, there is no associated scarring alopecia, but occasional cases overlap with folliculitis decalvans.

Erosive pustular dermatitis of the scalp

Pustular dermatitis often presents as expanding eroded patches on the scalp with moist granulation tissue (Fig. 33-16). The lesions often follow trauma or a surgical procedure and tend to be chronic and progressive. They respond best to class I topical corticosteroids. PDT has also been used effectively.

Fig. 33-18 Tufted doll's hairs, cicatricial alopecia.

Dissecting cellulitis (perifolliculitis capitis abscessens et suffodiens of Hoffman)

Dissecting cellulitis often coexists with acne conglobata and hidradenitis suppurativa. It may also occur with folliculitis decalvans. The lesions are deep, boggy, and suppurative (Fig. 33-17). They may respond to tetracyclines, retinoids, and intralesional corticosteroids.

Tufted folliculitis

Tufted folliculitis presents with doll's hair–like bundling of follicular units. It is seen in a wide range of scarring conditions, including chronic staphylococcal infection, chronic LE, lichen planopilaris, Graham Little syndrome, folliculitis decalvans (Fig. 33-18), acne keloidalis nuchae, immunobullous disorders, and dissecting cellulitis. Compound hairs (two or more hairs sharing a common infundibulum) occur physiologically on the occipital scalp and legs and should not be confused with tufted folliculitis.

Other forms of permanent alopecia

Pseudopelade of Brocq

Also known as alopecia cicatrisata, this pseudopelade is a rare form of cicatricial alopecia in which destruction of the hair follicles produces multiple round, oval, or irregularly shaped,

hairless, cicatricial patches of varying sizes. They are usually coin sized and are white or slightly pink in color, with a smooth, shiny, marblelike or ivory, atrophic, "onion skin" surface. Interspersed in the patches may be a few spared follicles with hairs growing from them. A clinical inflammatory stage is completely absent. No pustules, crusts, or broken-off hairs are present. The onset, as a rule, is insidious, with one or two lesions appearing on the vertex. The condition affects females three times more often than males and has a prolonged course. In advanced cases, large irregular patches are formed by coalescence of some of the many small macules, a pattern referred to as "footprints in the snow." The alopecia is permanent and the disease slowly progressive. Most cases of pseudopelade demonstrate scarring in a wedge-shaped pattern in the superficial dermis and represent an end stage of lichen planopilaris. A distinct subset called idiopathic pseudopelade accounts for most patients with CCCA. In these patients, the dermis is contracted into a thin band of dense collagenous tissue. Elastic fibers are intact and quite thick as a result of elastic recoil related to dermal contraction. Fibrous tract remnants are wide and hyalinized with an intact elastic sheath. Lymphoid and neutrophilic inflammation is absent, but loss of the inner and outer root sheaths with subsequent hair fiber granuloma formation is noted. Sebaceous glands are decreased or absent, as they are in most forms of permanent alopecia. DIF is negative.

Traction alopecia

Traction alopecia occurs from prolonged tension on the hair, either from wearing the hair tightly braided or in a ponytail, pulling the hair to straighten it, rolling curlers too tightly, or from the habit of twisting the hairs with the fingers. Traction alopecia most often involves the periphery of the scalp, especially the temples and above the ears, but a fringe of hair is characteristically present at the frontal and temporal hairline (Fig. 33-19).

Sarcoidosis

Sarcoidosis of the scalp presents with diffuse or patchy hair loss. The involved scalp is often indurated, and a raised peripheral border may be present. The lesions are often red-brown in color and may have an "apple jelly" appearance on diascopy. Biopsy reveals noncaseating granulomas. Treatment is the same as for other forms of sarcoidosis.

Fig. 33-19 Traction alopecia.

Pressure alopecia

Pressure alopecia occurs in adults after prolonged pressure on the scalp during general anesthesia, with the head fixed in one position. It may also occur in chronically ill persons after prolonged bed rest in one position (Fig. 33-20), which causes persistent pressure on one part of the scalp. It probably arises because of pressure-induced ischemia.

Tumor alopecia

Tumor alopecia refers to hair loss in the immediate vicinity of either benign or malignant tumors of the scalp. Syringomas, nerve sheath myxomas, and steatocystoma multiplex are benign tumors that may be limited to the scalp and may cause alopecia. Alopecia neoplastica is the designation given to hair loss from metastatic tumors, most often from breast or renal carcinoma (Fig. 33-21).

Keratosis pilaris atrophicans

Keratosis pilaris atrophicans includes many forms of keratosis pilaris with cicatricial alopecia. Variants include keratosis pilaris atrophicans faciei, atrophoderma vermiculatum, keratosis follicularis spinulosa decalvans, and ichthyosis follicularis.

Keratosis pilaris atrophicans faciei (ulerythema ophryogenes, keratosis pilaris rubra atrophicans faciei, folliculitis

Fig. 33-20 Pressure alopecia with scalp demonstrating pressure-induced geometric pressure necrosis.

Fig. 33-21 Alopecia neoplastica.

rubra, lichen pilare, xerodermie pilaire symmétrique de la face) begins in infancy as follicular papules with perifollicular erythema. Initially, the lesions are restricted to the lateral eyebrows. With time, they spread to involve the cheeks and forehead. There may be associated keratosis pilaris on the extremities and buttocks. The condition may also be associated with an atopic diathesis, ectodermal dysplasia, or Noonan syndrome.

Atrophoderma vermiculatum (acne vermoulanti, honeycomb atrophy, folliculitis ulerythematosa reticulata, ulerythema acneiforme, folliculitis ulerythematous reticulata, atrophodermia reticulata symmetrica faciei, atrophoderma reticulatum) presents with erythematous follicular papules on the cheeks in childhood. With time, the lesions develop into pitlike depressions (reticulate atrophy). Autosomal dominant inheritance has been described. This condition generally spares the scalp and eyebrows.

Keratosis follicularis spinulosa decalvans is a rare X-linked disorder described by Siemens in 1926. The gene has been mapped to Xp21.2–p22.2. It begins in infancy with keratosis pilaris localized on the face, then evolves to more diffuse involvement. Progressive cicatricial alopecia occurs on the scalp, eyebrows, and sometimes eyelashes. The alopecia starts during childhood, and active disease may remit during the early teenage years. Corneal and conjunctival inflammation, corneal dystrophy, and blepharitis occur, and photophobia is usually a prominent finding.

Ichthyosis follicularis also demonstrates extensive spiny follicular hyperkeratosis, permanent alopecia, and photophobia. Palmar plantar keratosis, nail deformities, atopy, and recurrent cheilitis have been described.

Atrichia with papular lesions

Atrichia with papular lesions is a rare autosomal recessive disorder with early onset of atrichia, followed by a papular eruption appearing within the first years of life. The condition has been linked to chromosome 8p21, and mutations have been detected in what is now referred to as the hairless gene. It is discussed in more detail in Chapter 27.

HAIR COLOR

Melanin in the hair follicles is produced in the cytoplasm of the melanocytes. Organelles involved include the endoplasmic reticulum, ribosomes, and Golgi apparatus. Melanocytes producing hair pigment are associated with the hair matrix, and melanogenesis occurs only during anagen. This cyclic melanin synthesis distinguishes follicular melanogenesis from the continuous melanogenesis of the epidermis. With age, cyclic melanocytic activity in the follicular unit declines. By age 40, most individuals show evidence of graying. Graying results primarily from a reduction in tyrosinase activity within hair bulb melanocytes. Defective migration of melanocytes from a diminishing reservoir in the outer root sheath may play a role. Physiologic graying may also be related to reactive oxygen species–mediated damage to nuclear and mitochondrial DNA in bulbar melanocytes. The melanocortin 1 receptor gene *(MCR1)* is closely related to red hair, freckling, and sun sensitivity.

The pigment in black and dark-brown hair is composed of eumelanin, whereas in blond and red hair, it is pheomelanin. In black hair, the melanocytes contain the densest melanosomes. Brown hair differs only by its smaller melanosomes. Light-brown hair consists of a mixture of the melanosomes of dark hair and the incomplete melanosomes of blond hair. Many of the melanosomes in blond hair develop only on the matrix fibers and not in the spaces between the fibers.

Red hair shows incomplete melanin deposits on the matrix fibers, to produce a blotchy-appearing melanosome. Pheomelanin is distinguished by its relatively high content of sulfur, which results from the addition of cysteine to dopaquinone along the biosynthetic pathway of melanin synthesis.

In gray hair (canities), melanogenic activity is decreased as a result of fewer melanocytes and melanosomes, as well as a gradual loss of tyrosinase activity. Graying of the scalp hair is genetically determined and may start at any age. Usually, it begins at the temples and progresses with time. The beard usually follows, with the body hair graying last. Premature whitening of scalp hair is usually caused by vitiligo, sometimes without recognized, or actually without, lesions of glabrous skin.

Early graying (before age 20 in white or before age 30 in black persons) is usually familial; however, it may occur in progeria and in Rothmund-Thomson, Böök (PHC), and Werner syndromes, as well as after radiation exposure.

In poliosis, gray or white hair occurs in circumscribed patches. This may occur in Waardenburg syndrome and piebaldism, Tietz syndrome, Alezzandrini syndrome, neurofibromatosis, and tuberous sclerosis. Poliosis is also found in association with regressing melanoma, vitiligo, and Vogt-Koyanagi syndrome and may be seen in alopecia areata when the new hairs grow. Migratory poliosis without hair loss may represent a forme fruste of alopecia areata.

Green hair has been traced to copper in the water of a swimming pool. This occurs only in blond or light hair and may be treated with topical EDTA, penicillamine-containing

shampoos, or 1.5% aqueous 1-hydroxyethyl diphosphonic acid. Tars and chrysarobin stain light-colored hair brown.

Changes in hair color occur in various disorders. The hair is blond in phenylketonuria and homocystinuria. Light hair is also seen in oasthouse urine disease (familial methionine malabsorption syndrome), Menkes steely (kinky) hair syndrome, and albinism. In Griscelli and Chédiak-Higashi syndromes, the hair has a silvery sheen. In kwashiorkor, hair assumes a red-blond color and may demonstrate periodic banding (flag sign, segmental heterochromia). Alternating light and dark bands may also occur in iron deficiency anemia and with courses of sunitinib. In vitamin B_{12} deficiency and with IFN therapy, whitening may occur. The disorder has been called canities segmentata sideropenica and responds completely to iron supplementation. Triparanol is associated with hypopigmented hair. By changing vellus to terminal hairs, minoxidil causes darkening of hair. Another hypotensive agent, diazoxide, gives the hair a reddish tint. Chloroquine therapy may cause hair whitening, usually in redheads and blonds, but not in brunettes. Pigmentation of the eyelashes and irides has been described with latanoprost. Xanthotrichia (yellow hair) has been noted with selenium sulfide and dihydroxyacetone.

Many black patients with acquired immunodeficiency syndrome (AIDS) have experienced softening, straightening, lightening, and thinning of their hair. Patients with human immunodeficiency virus 1 (HIV-1) infection may also experience elongated eyelashes and telogen effluvium.

HAIR STRUCTURE DEFECTS

Examination of hairs for structural defects is greatly facilitated by a method devised by Shelley: putting a piece of double-stick tape on a microscope slide and aligning 5-cm segments of hair in parallel on it. Dermoscopy can be useful in assessing hair morphology. Microscopic mounts of hairs are best examined under a dissecting microscope or polarized light. Gold coating and scanning electron microscopy (SEM) can also be done on hairs so mounted. Hairs from multiple body sites may need to be sampled. This has been documented in Netherton syndrome, where scalp hair can be normal while eyebrow hair demonstrates the characteristic hair shaft defect.

Hair casts (pseudonits)

Hair casts represent remnants of the inner root sheath. They often occur in great numbers and may mimic nits in the scalp. Whereas nits are firmly cemented to the hair shaft, however, hair casts slide freely along the shaft. Taeb et al. reviewed 36 published cases and distinguished two groups: girls age 2–8 years with diffuse involvement and no scalp disease, and children and adults with psoriasis, lichen planus, seborrheic dermatitis, traction, or trichotillomania. Keipert made a similar distinction, separating a large group of cases with some keratinizing disorder of the scalp and dark, oddly shaped masses of keratin adherent to or surrounding the hairs, which he called "parakeratotic" hair casts; and lighter-colored tubular casts 2–4 mm long, which he called "peripilar" hair casts. Taeb et al. found 0.025% tretinoin lotion to be effective. False hair casts may occur as a result of hair spray or deodorant concretions. Immunoglobulin casts and cutaneous spicules have been noted in multiple myeloma.

Pili torti

Also known as "twisted hairs," pili torti is a malformation of hair characterized by twisting of the hair shaft on its own axis (Fig. 33-22). The hair shaft is segmentally thickened, and light and dark segments are seen. Scalp hair, eyebrows, and eyelashes may be affected. The hairs are brittle and easily broken.

In the classic type, unassociated with other disorders, onset is usually in early childhood; by puberty, it has usually improved. Clinically, pili torti may be associated with patchy alopecia and short, broken hairs. It usually follows a dominant inheritance pattern, although recessive and sporadic cases have been reported. Acquired cases have been described in young women with anorexia nervosa. Pili torti may be seen with associated abnormalities. The Björnstad syndrome consists of congenital deafness of the cochlear type, with pili torti. Both autosomal dominant and autosomal recessive inheritance patterns have been described. *BCS1L* mutations cause the Björnstad syndrome. The gene encodes an adenosine triphosphatase (ATPase) necessary for the assembly of complex III in mitochondria. *BCS1L* mutations also cause lethal conditions, including the complex III deficiency and the GRACILE syndrome, with severe multisystem and neurologic manifestations.

Pili torti also may occur in citrullinemia (argininosuccinate synthetase deficiency), Menkes steely (kinky) hair syndrome, Bazex follicular atrophoderma syndrome, ectodermal dysplasias, Crandall syndrome (pili torti, nerve deafness, hypogonadism), Netherton syndrome (along with bamboo hair), with isotretinoin and etretinate therapy, in anorexia nervosa, and in trichothiodystrophy.

Fig. 33-22 Pili torti.

Laron syndrome is an autosomal recessive disease with primary insulinlike growth factor 1 deficiency and primary growth hormone insensitivity. Affected children have sparse hair and frontal recession. Pili torti et canaliculi, tapered hair, and trichorrhexis nodosa have been noted.

Menkes steely (kinky) hair syndrome

Pili torti and often monilethrix and trichorrhexis nodosa are all common in the hairs in this sex-linked recessively inherited disorder. It has also been called steely hair disease because the hair resembles steel wool. The characteristic ivory color of the hair appears between 1 and 5 months of age. Drowsiness, lethargy, convulsive seizures, severe neurologic deterioration, and periodic hypothermia ensue, with death at an early age. Hairs become wiry, sparse, fragile, and twisted about their long axis. Osteoporosis, and dental and ocular abnormalities are common. The skin is pale and the face pudgy, and the upper lip has an exaggerated "Cupid's bow" configuration. The occipital horn syndrome, primarily a connective tissue disorder, is a milder variant of Menkes syndrome. Patients have a deficiency of serum copper and copper-dependent enzymes, resulting from mutations in the *ATP7A* gene. The gene encodes a trans–Golgi membrane–bound copper transporting P-type ATPase. Loss of this protein activity blocks the export of dietary copper from the GI tract and causes the copper deficiency. Low serum copper and ceruloplasmin levels are characteristic, but are not seen in all patients; levels are particularly variable in the first weeks of life. Other tests helpful for screening include the ratio of catechols, such as dihydroxyphenylalanine, to dihydroxyphenylglycol. High levels of the catechols dopa, dihydrophenylacetic acid, and dopamine and low levels of dihydroxyphenylglycol are characteristic. Studies of copper egress in cultured fibroblasts have also been used.

Early detection allows for genetic counseling and institution of copper histidine treatment, which has shown promising results in some infants. Pamidronate treatment is associated with an increase in bone mineral density in children with Menkes disease. In zebra fish, antisense morpholino oligonucleotides directed against the splice-site junctions of two mutant calamity alleles were able to correct the molecular defect. Also, L-threo-dihydroxyphenylserine can correct neurochemical abnormalities in a mouse model. This is a promising area for research.

Trichorrhexis nodosa

The affected hair shafts fracture easily and may have small white nodes arranged at irregular intervals. These nodes are the sites of fraying of the hair cortex. The splitting into strands produces a microscopic appearance suggestive of a pair of brooms stuck together end to end by their bristles. The hairs soon break at these nodes (Fig. 33-23). The number of these nodes along one hair shaft varies from one to several, depending on its length. These fractured hairs are found mostly on the scalp, often in just a small area or areas, but other sites, such as the pubic area, axillae, and chest, may be involved.

Several categories or types of trichorrhexis nodosa have been described. Proximal trichorrhexis nodosa involves the proximal shafts of the hairs of black patients who traumatize their hair with styling or chemicals. The involved hairs break a few centimeters from the skin surface, resulting in patches of short hair. It appears to occur in genetically predisposed patients. Distal trichorrhexis nodosa affects primarily Asians and white patients; it occurs several inches from the scalp and

Fig. 33-23 Trichorrhexis nodosa.

is associated with trichoptilosis, or longitudinal splitting, known as "split ends." Acquired localized trichorrhexis nodosa is a common type in which the defect occurs in a localized area a few centimeters across. Diseases that accompany localized trichorrhexis nodosa in which pruritus is a prominent symptom (perhaps caused by scratching and rubbing) include circumscribed neurodermatitis, contact dermatitis, and atopic dermatitis.

The occurrence of trichorrhexis nodosa in some patients with argininosuccinicaciduria has suggested an etiologic connection. Trichorrhexis nodosa has been described in Menkes steely hair syndrome, Netherton syndrome, hypothyroidism, ectodermal dysplasia, the syndrome of intractable infant diarrhea, biotinidase deficiency, and trichothiodystrophy. Trichoschisis, a clean transverse fracture across the hair shaft, is more often present in trichothiodystrophy. The curly hair that may result from isotretinoin therapy has been attributed to extensive trichorrhexis nodosa. Because trauma may induce this hair shaft abnormality, the specificity of this finding in the previous conditions may simply be fortuitous. Treatment is directed toward the avoidance of trauma to the hair.

Trichorrhexis invaginata

Also known as "bamboo hair," trichorrhexis invaginata is caused by intussusception of the hair shaft at the zone where keratinization begins. The invagination is caused by softness of the cortex in the keratogenous zone. The softness may be caused by inadequate conversion of –SH to S–S proteins in the cortex. The patient with bamboo hair will have nodose ball-and-socket deformities, with the socket forming the proximal and the ball part forming the distal portion of the node along the hair shaft. This type of hair is associated with Netherton syndrome. Occasionally, only the proximal half of the abnormality is seen; this has been called "golf tee hairs."

Trichorrhexis invaginata associated with congenital ichthyosiform erythroderma or ichthyosis linearis circumflexa constitutes Netherton syndrome. Atopic manifestations and high IgE levels are typically present. The bamboo hairs may be present not only on the scalp but also on the eyebrows, eyelashes, and rarely in other hairy areas. Hair sparsity is noted all over the body. The bamboo hairs may become normal within a few years. Other reported findings include pili torti, trichorrhexis nodosa, moniliform hairs, urticaria, angioedema, growth retardation, recurrent infections, multiple epithelial neoplasms, and mental retardation. An autosomal recessive mode of inheritance has been suggested, although reported

cases involving women far outnumber men. Pathogenic mutations have been identified in serine protease inhibitor Kazal-type 5 *(SPINK5)* on chromosome 5q32, a gene encoding lymphoepithelial Kazal-type-related inhibitor (LEKTI), a serine protease inhibitor involved in skin barrier formation and immunity. PUVA therapy has been reported to help the circumflex linear ichthyosis, and etretinate has both exacerbated and improved skin findings.

Menne et al. reported the bamboo hair defect in very thin, probably vellus, hairs in a 7-year-old boy with short, thin, brittle scalp hairs and no eyebrows. They termed this a "canestick deformity."

Pili annulati (ringed hair, spangled hair)

Pili annulati is an unusual disease in which the hair seems banded by alternating segments of light and dark color when seen in reflected light. The light bands are caused by clusters of abnormal air-filled cavities, which scatter light, and reduplicated lamina densa in the region of the root bulb. Hair growth is normal in patients with pili annulati, although it is rarely associated with trichorrhexis nodosa–like breaks of the hair shaft. There are no other associated abnormalities of skin or other organ systems. It is inherited by autosomal dominant mode, begins in infancy, and requires no treatment, since the spangled appearance of the hair is not unattractive. The condition has been reported to disappear following recovery from alopecia totalis.

Pili pseudoannulati

This anomaly of human hair mimics pili annulati. The two differ in that the light bands in pili annulati are caused by internal effects, whereas the bright segments in pili pseudoannulati are caused by reflection and refraction of light by flattened, twisted surfaces of hair. The pseudo type is a variant of normal hair.

Monilethrix

Monilethrix, also known as "beaded hairs," is a rare hereditary disease. It is characterized by dryness, fragility, and sparseness of the scalp hair (Fig. 33-24), with fusiform or spindle-shaped swellings of the hair shaft separated by narrow atrophic segments. The hair tends to break at the delicate internodes. There is an occasional rupture at the node and longitudinal fissuring of the shaft, which also involves the nodes.

The disease is often associated with keratosis pilaris of the extensor surfaces, temples, and back of the neck. Hair on regions other than the scalp may be affected. Leukonychia may occur. Inheritance of monilethrix is an autosomal dominant trait. It has been described in association with Menkes syndrome. Mutations in the gene for desmoglein 4 are seen in monilethrix and in localized autosomal recessive hypotrichosis, a disorder that shares clinical features with monilethrix but lacks the characteristic hair shaft changes. Several cases of monilethrix have been linked to the type II keratin gene cluster on chromosome 12q13. Causative heterozygous mutations of a highly conserved glutamic acid residue of the type II hair keratins hHb6 and hHb1 occur. Both hHb1 and hHb6 are largely coexpressed in cortical trichocytes of the hair shaft, confirming that monilethrix is a disease of the hair cortex. The hair may improve during pregnancy, but after delivery, the hair returns to its original state. Improvement may also occur with age, and there may be seasonal improvement during the summer. Improvement with acitretin has been reported.

Fig. 33-24 Monilethrix.

Intermittent hair follicle dystrophy

Birnbaum et al. reported a disorder of the hair follicle leading to increased fragility of the shaft, with no identifiable biochemical disturbance. The prevalence of this disorder is unknown.

Bubble hair deformity

Bubble hairs appear as areas of hair with altered texture. Fragility has been reported. The hairs may be curved or straight and stiff. Small, bubble-like defects are found within the hair shafts on light microscopy and electron microscopy. The condition is produced by overheating of wet hair with a malfunctioning hair dryer, analogous to the popping of popcorn. All damp hair will develop bubbles of gas when exposed to high heat.

Uncombable hair syndrome

First reported in 1973 by Dupré et al. as cheveux incoiffables ("undressable hairs") and by Stroud and Mehergan as "spun-glass hair," the microscopic abnormality of a triangular cross-sectional appearance with a longitudinal groove gives the disease its other name, pili triangulati et canaliculi.

Clinically, the defect is noted in the first few years of life as dry, blond, shiny hair that stands straight out from the scalp and cannot be combed (Fig. 33-25). On light microscopy, it may appear quite normal when viewed lengthwise, but on horizontal sectioning and on SEM, it shows the longitudinal grooves that make it abnormally rigid. These depressions are sometimes seen in unaffected persons, and thus 50% of hairs need to be affected for the condition to be clinically detectable.

Autosomal dominant, autosomal recessive, and sporadic forms have been described. Uncombable hair has been associated with angel-shaped phalangoepiphyseal dysplasia. It has also been seen in combination with retinal dystrophy, juvenile cataract, and brachydactyly. It has also been reported in a patient who acquired the abnormality at age 39 after an episode of diffuse alopecia treated with spironolactone. Although there are usually no associated ectodermal defects, isolated cases have been reported in which uncombable hair is one component of several clustered findings. Until more experience is available in the literature, grouping these cases into new syndromes is premature.

Some patients have responded clinically to biotin, 0.3 mg orally three times daily. Some cases improve spontaneously in late childhood.

Calderon P, et al: Uncombable hair syndrome. J Am Acad Dermatol 2009; 61(3):512–515.

Kinking hair

Acquired progressive kinking of the hair, first described and named by Wise and Sulzberger in 1932, involves a structural abnormality of kinking and twisting of the hair shaft at irregular intervals. The main recognized variant of this disorder begins in men in their late teens or early twenties on the frontotemporal or vertex regions, then progresses to both the parietal and the frontal area. Usually straight, light-brown hair becomes curly, frizzy, and lusterless.

When this occurs in the androgen-dependent areas of young men, it is a precursor of male-pattern hair loss; usually these men have a strong family history of androgenetic alopecia. Treatment with topical minoxidil has not prevented development of hair thinning. "Whisker" hairs, the short dark hairs that grow anterior to the ears in young people who eventually develop androgenic alopecia, is believed to be a variant of acquired kinking of the hair.

Acquired hair kinking has been described in other clinical situations. Some reports detail prepubertal patients or women, as well as men, in whom kinking develops in non-androgen-dependent areas such as the eyebrows or lashes. In these reports, alopecia has not developed, and the curly, frizzy hair may remain present or may revert to its previous condition.

Widespread kinking of the hair may be induced by drugs, notably retinoids, and it may also occur in patients with AIDS.

Fig. 33-25 Uncombable hair syndrome.

Woolly hair

Woolly hair is present at birth and is usually most severe during childhood (Fig. 33-26), when it is often impossible to brush the hair. In adult life, there is a variable amelioration in the condition. A clear distinction exists between the appearance of the affected and nonaffected members of a family. Both autosomal dominant and autosomal recessive inheritance have been described. Woolly hair nevus has partial scalp involvement by woolly hair, which has a greatly reduced diameter. Naxos' disease is an autosomal recessive syndrome with arrhythmogenic right ventricular cardiomyopathy, diffuse nonepidermolytic palmoplantar keratoderma, and woolly hair. Hair abnormalities are a reliable marker for subsequent heart disease. The disease is caused by a mutation in the gene encoding plakoglobin. Carvajal syndrome is a familial cardiocutaneous syndrome consisting of woolly hair, palmoplantar keratoderma, and heart disease. It is caused by a recessive deletion mutation in desmoplakin.

Woolly hairs tend to unite into tight locks, whereas the hairs of black persons remain individual. The hair may not grow beyond a length of 12 cm, but may attain a normal appearance in adult life. In the familial group, the eyebrows and hairs on

Fig. 33-26 Woolly hair. (Courtesy of Dr. Shyam Verma.)

the arms, legs, and pubic and axillary regions may be short and pale. There are no associated cutaneous or systemic diseases. A Dutch kindred has been described with premature loss of curly brittle hair, premature loss of carious teeth, nail dystrophy, and acral keratoderma. It has been designated the curly hair–acral keratoderma–caries syndrome.

The microscopic findings of woolly hair include a decreased diameter, an ovoid shape on cross section, a pili torti–like twisting about a longitudinal axis, trichorrhexis nodosa, and pili annulati.

Plica neuropathica (felted hair)

Plica neuropathica is a curling, looping, intertwisting, and felting or matting of the hair in localized areas of the scalp. Predisposing factors include kinky hairs, changes in hair care, and a neurotic mental state. Plica polonica is a former name for this condition.

Pseudofolliculitis barbae

Pseudofolliculitis barbae ("razor bumps") consists of hairs that, after appearing at the surface, curve back and pierce the skin as ingrowing hairs. This results in inflammatory papules and pustules, which may scar (Fig. 33-27). In severe cases, large deforming keloids may result in the beard area. Pseudofolliculitis of the beard is seen in more than 50% of black men, who must sometimes give up shaving to alleviate the disorder. A single nucleotide polymorphism, giving rise to a disruptive Ala12Thr substitution in the 1A α-helical segment of the companion layer–specific keratin K6hf, appears to be partially responsible for the phenotype. White persons are infrequently affected; however, it is more common in renal transplant recipients. Tenderness responds to midstrength topical corticosteroids. The use of clippers or chemical depilatories, glycolic acid lotion, and adjunctive antibiotic therapy may be helpful. Benzoyl peroxide 5%/clindamycin 1% gel has been shown to be effective in double-blind evaluation. Laser hair removal with the long-pulse neodymium:yttrium-aluminum-garnet (Nd:YAG) laser is suitable for a wide range of skin types, and topical eflornithine can prolong responses. The diode laser and PDT have also been used.

Pili multigemini

This rare malformation is characterized by the presence of bifurcated or multiple divided hair matrices and papillae, giving rise to the formation of multiple hair shafts within the individual follicles (Fig. 33-28). Pili multigemini sometimes follows lines of Blaschko. Mehregan et al. reported a patient with cleidocranial dysostosis and extensive pili multigemini over the heavily bearded chin and cheek areas. There is no treatment.

Pili bifurcati

In this disorder, bifurcation is found in short segments along the shafts of several hairs. Each branch of the bifurcation is covered with its own cuticle. It has been seen in association with the trisomy 8 mosaic syndrome. Pili bifurcati differs from pili multigemini, in which a single follicular matrix produces two different-sized hair shafts with separate cuticles that do not fuse again. Trichoptilosis is characterized by split distal ends that are never surrounded by a complete cuticle.

Lester L, et al: The prevalence of pili multigemini. Br J Dermatol 2007; 156(6):1362–1363.

Trichostasis spinulosa

Trichostasis spinulosa is a common disorder of the hair follicles that clinically gives the impression of blackheads (Fig. 33-29), but the follicles are filled with funnel-shaped, horny plugs within which are bundles of vellus hairs (Fig. 33-30). The hairs are round at their proximal ends and shredded distally. The disease occurs primarily on the nose and forehead, but may also occur on the trunk and may be accompanied by pruritus. Dermoscopy or microscopy can be used to establish the diagnosis. The condition may be more common in patients in renal failure.

Trichostasis spinulosa results from retention of telogen hairs, which are derived from a single hair matrix. It is primarily caused by a hyperkeratosis of the follicular infundibulum, which leads to a partial obstruction of the follicular orifice and thus does not permit shedding of small telogen hairs.

The plugs may be removed with hydroactive adhesive (Biore) pads. Keratolytics are also effective after using a wax

Fig. 33-28 A, Pili multigemini of beard. B, Multiple hair shafts in single follicle.

depilatory. The pulsed diode and alexandrite lasers have been used successfully, and application of 0.05% tretinoin solution, applied daily for 2 or 3 months, may also produce satisfactory results.

Trichodysplasia spinulosa (viral-associated trichodysplasia)

Trichodysplasia spinulosa is seen in immunosuppressed patients and is associated with a polyomavirus. The condition is characterized by follicular distention with keratotic spines, especially on the face. Electron microscopy, immunohistochemistry, and viral load measurements indicate an etiologic role for the virus.

Fig. 33-30 Trichostasis spinulosa.

HYPERTRICHOSIS

Hypertrichosis is an overgrowth of hair not localized to the androgen-dependent areas of the skin. Several forms exist. Many cases are induced by medications, including minoxidil, cyclosporine, and efalizumab. The excessive hair growth can be managed with bleaching, trimming, shaving, plucking, waxing, chemical depilatories, and electrosurgical epilation. Treatment with long-pulse Nd:YAG, diode, ruby, and long- and short-pulse alexandrite lasers as well as with intense pulsed light sources can be effective. Skin type must be considered when choosing a laser system. The greatest experience in dark skin types has been with the long-pulse Nd:YAG laser.

Localized acquired hypertrichosis

Eyelash trichomegaly can occur with erlotinib, latanoprost, and intentionally with bimatoprost. Dermal tumors, such as melanocytic nevi, smooth muscle hamartomas, meningiomas, and Becker nevi, may have excessive terminal hair growth. Repeated irritation, trauma, occlusion under a cast, eczematous states, topical steroid use, linear melorheostotic scleroderma, lymphedema associated with filariasis, the Crow-Fukase (POEMS) syndrome, and pretibial myxedema may be other situations with a localized increase in hair growth. Porphyrias generally show a localized hypertrichosis over the malar area, such as in porphyria cutanea tarda or variegate porphyria. In the Gunther variety of erythropoietic porphyria, however, the hypertrichosis may be generalized or more diffuse.

Localized congenital hypertrichosis

Hypertrichosis cubiti (hairy elbows) consists of long vellus hair on the extensor surfaces of the distal third of the upper arm and the proximal third of the forearm bilaterally. It is a progressive, excessive growth of lanugo hairs that often begins in infancy; the hairs may reach a length of 10 cm. Later, they become coarser, but regression has been observed during adolescence. There appear to be familial cases and a sporadic form. Short stature and some developmental abnormalities are present in some patients; however, endocrine studies or other evaluations are not necessary. The condition appears to be of cosmetic significance only.

Other causes of localized congenital hypertrichosis include congenital nevocytic nevi, anterior cervical hypertrichosis, and simple nevoid hypertrichosis. Localized hypertrichosis may be a sign of underlying spinal dysraphism when it occurs over the sacral midline, or a sign of an underlying neoplasm.

Generalized congenital hypertrichosis (congenital hypertrichosis lanuginosa)

This rare type of excessive and generalized hairiness is a fully penetrant, X-linked dominant trait. The entire body is covered with fine vellus hairs 2–10 cm long (Fig. 33-31). The scalp hair appears to be normal. Except for the palms and soles, all other areas are covered. Congenital hypertrichosis lanuginosa may be associated with dental anomalies and gingival fibromatosis. This type of hairiness has attracted considerable attention over the centuries. Hair removal by laser may be quite useful.

Other cases of congenital generalized hypertrichosis may be secondary to drug ingestion by the mother. The fetal hydantoin syndrome is characterized by hypertrichosis, depressed nasal bridge, large lips, a wide mouth, and a short, webbed neck. The fetal alcohol syndrome includes hypertrichosis, a small face, capillary hemangiomas, and physical and mental retardation. A case of generalized hypertrichosis and multiple congenital defects was reported in a baby born to a mother who used minoxidil throughout pregnancy. Fetal valproate syndrome is characterized by generalized hypertrichosis sparing the palms and soles, coarse facies, gum hypertrophy, hypotonia, club feet and hands, and abnormal dermatoglyphics.

Generalized or patterned acquired hypertrichosis

These cases include those caused by acquired hypertrichosis lanuginosa, those associated with various syndromes, and those secondary to drug intake. Acquired hypertrichosis lanuginosa is an ominous sign of internal malignancy (Fig. 33-32).

Fig. 33-31 Hypertrichosis lanuginosa. (Courtesy of Brooke Army Medical Center Teaching File.)

Fig. 33-32 Hypertrichosis lanuginosa associated with an internal malignancy (malignant down).

Syndromes associated with increased hair growth include lipoatrophic diabetes, stiff skin syndrome, Down syndrome, Rubenstein-Taybi syndrome, Laband syndrome, Cornelia de Lange syndrome, Hurler syndrome, leprechaunism, Winchester syndrome, Schynzel-Giedier syndrome, presymptomatic Leigh syndrome (neurometabolic mitochondrial disorder), and hypertrichosis with acromegalic features. Drugs associated with hypertrichosis include minoxidil, cyclosporine, diphenylhydantoin, diazoxide, streptomycin, penicillamine, corticosteroids, danazol, psoralens, hexachlorobenzene, PUVA, topical bimatoprost, topical corticosteroids, and topical androgens.

HIRSUTISM

Clinical features

Hirsutism is an excess of terminal hair growth in women in a pattern more typical of men. Androgen-dependent growth areas affected include the upper lip, cheeks, chin, central chest, breasts, lower abdomen, and groin (Fig. 33-33). This altered growth pattern of the hair may be associated with other signs of virilization, which include temporal balding, masculine habitus, deepening of the voice, clitoral hypertrophy, and amenorrhea. Acne is an additional sign of hyperandrogenism.

Pathogenesis

When virilization accompanies hirsutism, especially when progression is rapid, a neoplastic cause is likely. In the absence of virilization, a neoplastic cause is extremely unlikely. Most medically significant hirsutism is related to the polycystic ovarian syndrome (PCOS, hyperinsulinemic hyperandrogenism with anovulation). In a study of 873 patients with medically significant hirsutism, PCOS was present in 82%. Idiopathic hirsutism was present in 4.7%, and 6.75% of the patients had elevated androgen levels and hirsutism with normal ovulation.

Ethnic variation should be considered when evaluating hirsutism. Women of Southwest Asian, Eastern European, and southern European heritage usually have facial, abdominal, and thigh hair; whereas Asian and Indian women generally have little terminal hair growth in these areas.

In women, androgen biosynthesis occurs in the adrenal gland and ovary. Testosterone and the androgen precursor androstenedione are secreted by the ovary. The adrenal contributions are preandrogens: dehydroepiandrosterone (DHEA), DHEA sulfate, and androstenedione. These require peripheral conversion in the skin and liver to testosterone. Testosterone is converted to dihydrotestosterone, the androgen that promotes androgen-dependent hair growth, in the hair follicle by 5α-reductase. Receptor molecules in the end organ are necessary for binding and hormone action at that level. Because testosterone is normally bound to carrier molecules in the plasma at a 99% level, and it is the unbound testosterone that is active, the levels of free testosterone correlate with clinical evidence of androgen excess.

Fig. 33-33 Hirsutism.

Hirsutism may result from excessive secretion of androgens from either the ovary or the adrenal gland. The excessive secretion may be from functional excesses or rarely from neoplastic processes. Ovarian causes include PCOS (Stein-Leventhal syndrome) and a variety of ovarian tumors, both benign and malignant. PCOS is defined by anovulation (fewer than nine periods a year or periods longer than 40 days apart) with clinical evidence of hyperandrogenism. Ovarian cysts are not required for the diagnosis, and laboratory and imaging studies are not required to establish the diagnosis, according to the U.S. National Institutes of Health (NIH) consensus criteria. Rotterdam criteria for diagnosing PCOS require the presence of two of the following criteria: androgen excess, ovulatory dysfunction, or polycystic ovaries. The pathogenesis of PCOS may relate to insulin resistance, with resultant elevated insulin levels leading to ovarian overproduction of androgens. Prevalence rates of PCOS for black and white women in the United States are 8.0% and 4.8%, respectively.

Ovarian tumors include unilateral benign microadenomas, arrhenoblastomas. Leydig cell tumors, hilar cell tumors, granular/theca cell tumors, and luteomas are rare causes of hirsutism. In tumor-associated hirsutism, the onset is usually rapid, occurs with other signs of virilization, and begins between ages 20 and 40.

Adrenal causes include congenital adrenal hyperplasia (CAH) and adrenal tumors, such as adrenal adenomas and carcinomas. The adrenogenital syndrome or CAH is an autosomal dominant disorder that may result from deficiency of the enzyme 21-hydroxylase (most common form), 11β-hydroxylase, or 3β-hydroxy steroid dehydrogenase. Onset is generally in childhood, with ambiguous genitalia, precocious growth, and virilism. Nonclassic (adult-onset) CAH may present with hirsutism.

Pituitary causes include Cushing's disease, acromegaly, and prolactin-secreting adenomas. Patients with prolactin-secreting microadenomas have a 20% incidence of hirsutism and acne. Prolactin elevations may be seen in patients with PCOS. Other settings where prolactin levels may be elevated and that may lead to hirsutism include hypothyroidism, phenothiazine intake, and hepatorenal failure.

Other causes of hirsutism include the exogenous intake of androgens. End-organ hypersensitivity may be a mechanism in patients with a normal evaluation. Drugs such as minoxidil, diazoxide, corticosteroids, and phenytoin, which have been reported to cause hirsutism, generally cause hypertrichosis—a generalized increase in hair that is not limited to the androgen-sensitive areas.

Evaluation

Most hirsutism is related to ethnic heritage or PCOS. 21-Hydroxylase–deficient nonclassic adrenal hyperplasia, the hyperandrogenic insulin-resistant acanthosis nigricans syndromes, and androgen-secreting tumors are relatively uncommon causes. A careful history and physical examination are essential. The history should focus on onset and progression, virilization, menstrual and pregnancy history, and family/racial background. Physical examination may reveal signs of Cushing's disease, hypothyroidism, or acromegaly. Other signs to be evaluated are the distribution of muscle mass and body fat, clitoral dimensions, voice depth, and galactorrhea.

Laboratory evaluation is controversial. In the authors' opinion, testing is of value only when it affects management. If this is accepted, there is no mandatory hormonal testing for stable hirsutism in patients who have no signs of virilization.

A diagnosis of PCOS can be made clinically and does not require laboratory confirmation. Determination of serum lipids and testing for glucose intolerance may be the most important laboratory evaluations in patients with PCOS because these have the greatest impact on management and long-term prognosis. When the history and physical examination suggest the possibility of a neoplasm, laboratory evaluation should include a total testosterone level. A DHEA sulfate level is usually performed if an adrenal cause is suspected. A 24-hour urine cortisol test is the gold standard for the diagnosis of Cushing's disease. Measurement of thyroid-stimulating hormone (TSH), growth hormone, and somatomedin C levels are indicated if the history and physical examination suggest hypothyroidism or acromegaly.

Dexamethasone suppression tests are recommended by some authorities, but the results often do not affect management. A baseline 17-hydroxyprogesterone (17-HP) and adrenocorticotropic hormone (ACTH) stimulation test can screen for late-onset CAH, but steroid replacement has not been proved to result in better outcomes than empiric treatment with antiandrogens. Baseline 17-HP may be normal in some women with nonclassic 21-hydroxylase deficiency, and ACTH stimulation may result in overdiagnosis of the syndrome. An exaggerated 17-HP response to ACTH stimulation is common in PCOS at a pharmacologic dose (250 μg) but not at a physiologic dose (1 μg) of ACTH. An ovarian origin of hirsutism can be identified by a buserelin test in 30% of patients with hirsutism and by dexamethasone in 22% of patients, but data proving that buserelin challenge results in better outcomes are lacking. A prolactin level will screen for prolactin-secreting tumors but will also lead to further expensive testing in many patients ultimately diagnosed with PCOS. A prolactin level should be obtained in any patient with galactorrhea but is of limited value as a routine screening test for patients with hirsutism alone.

If signs of acromegaly, Cushing's disease, or virilization are present clinically, referral to an endocrinologist is recommended. The presence of major menstrual irregularities is also an indication for referral to an endocrinologist or gynecologist. Although 90% of women with hirsutism have an elevated testosterone level, increases greater than 200 ng/dL and rapid onset or progressive virilization suggest serious underlying disease. A major elevation in the DHEA sulfate level (>7000 ng/mL) suggests an adrenal neoplasm, and imaging of the adrenal gland is recommended. Many patients with late-onset CAH will have normal screening DHEA sulfate. Patients with prolactin levels above 20 ng/mL should likewise be referred for further evaluation with magnetic resonance imaging (MRI) or computed tomography (CT). Polymorphisms in the gene coding for sex hormone–binding globulin have been identified in some families with hirsutism, but such testing does not affect management.

Treatment

Various forms of mechanical, chemical, and laser epilation can be performed for hirsutism, as for hypertrichosis. Spironolactone with various OCs, cyproterone acetate plus ethinyl estradiol, gonadotropin-releasing hormone agonists (e.g., leuprolide, nafarelin), flutamide, finasteride, and topical eflornithine have been used successfully alone and in various combinations to treat hirsutism. The optimal combination and dosage remain to be determined, but in one study, 20 μg of ethinyl estradiol was as effective as 30 μg when used in association with drospirenone. The Endocrine Society clinical practice guideline recommends hormonal OCs as the first-line management for menstrual abnormalities and hirsutism in patients with PCOS. The guideline notes that hormonal OCs and metformin are the best treatment options in adolescents with PCOS, that thiazolidinediones have an unfavorable risk-benefit ratio compared with other treatments, and that statins require further study.

Finasteride at doses of 2.5–5 mg/day has been shown to decrease hair number and diameter in women with hirsutism. The combination of spironolactone, 100 mg/day, plus finasteride, 5 mg/day, has been shown to be superior to spironolactone, 100 mg/day, alone. An analysis of the current literature suggested that spironolactone alone, 100 mg/day, is superior to finasteride alone, 5 mg/day, and to low-dose cyproterone acetate alone, 12.5 mg/day for the first 10 days of a cycle, in the treatment of hirsutism. Spironolactone is typically used at a dose of 100 mg twice daily, so further studies are needed comparing this higher dose with other modes of therapy. In a prospective, randomized study of Diane 35 (cyproterone acetate [CPA], 2 mg, and ethinyl estradiol, 35 μg), Diane 35 plus spironolactone, and spironolactone alone, all treatments were well tolerated. Combination therapy resulted in superior measured endocrine responses, but the authors concluded that spironolactone alone was the most cost-effective treatment. The choice of an OC is also controversial. Third-generation OCs result in a significant increase in sex hormone–binding globulin and a decrease in free testosterone, but both second-generation and third-generation OCs are clinically effective in treating hirsutism. When flutamide is used, initial treatment with 250 mg/day is followed by a long maintenance treatment period using 125 mg/day.

Metformin therapy has been shown to control menstrual cycles and improve fertility in women with PCOS. It causes a decline in testosterone and insulin levels. Oligomenorrheic women with an increased luteinizing hormone to follicle-stimulating hormone (LH/FSH) ratio and lower testosterone levels respond best. Spironolactone, 50 mg/day, was superior to metformin, 1000 mg/day, in the treatment of hirsutism and menstrual cycle frequency in a study of 82 adolescent and young women with PCOS. Doses of 200 mg/day are typically used to treat hirsutism. At this dose, menstrual irregularities induced by the drug are common, and it may be best used in combination with an OC. Good correlation has been noted between an increase in ovulation frequency with clomiphene citrate and the chance of pregnancy in women with PCOS. Other options include acarbose, gonadotrophins, and laparoscopic ovarian drilling. Infertility is best managed by a specialist in this field. Empiric treatment with an antiandrogen may be as effective as steroid replacement for the management of hirsutism in patients with nonclassic CAH.

TRICHOMYCOSIS AXILLARIS

Discrete nodules 1–2 mm in size and attached firmly to the hair shafts of the axillary or pubic areas characterize trichomycosis. The color of the nodules may be yellow (Fig. 33-34), red, or black. Hyperhidrosis of the affected regions is usually present. A yellowish discoloration of the axillae is sometimes noted. Large numbers of *Corynebacterium* are present in the concretions. Trichomycosis axillaris may coexist with erythrasma and pitted keratolysis. Treatment with a topical antibiotic preparation (e.g., clindamycin or erythromycin) or naftifine, which has antibacterial properties, combined with any modality that will decrease the hyperhidrosis, is effective, but shaving is faster.

Trichomycosis axillaris. (Courtesy of Dr. Anthony Slagel.)

ASSOCIATED HAIR FOLLICLE DISEASES

Tinea amiantacea (pityriasis amiantacea)

Thick, asbestos-like (amiantaceous), shiny scales on the scalp characterize pityriasis amiantacea. The silvery-white or dull-gray crusting may be localized or, less often, generalized over the entire scalp. The proximal parts of the hairs are matted together by the laminated crusts. There are no structural changes in the hair, but in some patches where the crusting is thick, there may be some purulent exudate under the crust and temporary alopecia such as occurs after some cases of furunculosis of the scalp.

The cause is most often severe or untreated seborrheic dermatitis or psoriasis, although it may occur paradoxically during tumor necrosis factor-alpha inhibitor therapy. In a prospective study of 85 patients, psoriasis was documented in 35% and processes suggesting seborrheic dermatitis or atopic dermatitis occurred in another 35%. Tinea capitis was the eventual diagnosis in 13%. *Staphylococcus* was found in 96.5% of patients, compared with 15% of controls. The patient should shampoo daily or every other day with selenium sulfide suspension or a tar- or steroid-containing shampoo for 2 weeks. Prior application of peanut oil or a keratolytic a few hours before shampooing facilitates removal of the scales and crusts. With such debridement, followed by topical steroid solution in Caucasians or steroid ointment in African Americans, the secondary bacterial infection usually resolves without the need for oral antistaphylococcal therapy.

Folliculitis nares perforans

Perforating folliculitis of the nose is characterized by small pustules near the tip of the inside of the nose. The lesion becomes crusted, and when the crust is removed, the bulbous end of the affected vibrissa is found to be embedded in the inspissated material. The affected hairs are typical of those occurring inside the nostril. *Staphylococcus aureus* may at times be cultured from the pustules. The hair should be removed and antibiotic ointment such as mupirocin applied.

White SW, et al: Pseudofolliculitis vibrissae. Arch Dermatol 1981; 117:368.

Acquired perforating dermatosis

Perforating folliculitis, Kyrle's disease, and acquired perforating collagenosis are designations that have been supplanted by the more inclusive term acquired perforating dermatosis. The condition is not uncommon and is most often associated with renal failure or diabetes, or both. Between 4% and 10% of dialysis patients develop umbilicated dome-shaped papules on the legs, or less often on the trunk, neck, arms, or scalp, with variable itchiness (Fig. 33-35). Early lesions may be pustular; late lesions resemble prurigo nodularis both clinically and histologically. A central hyperkeratotic cone projects into the dermis, so that when it is removed, a pitlike depression remains. Usually the papules are discrete, but they may coalesce to form circinate plaques. Coalescing verrucous plaques are frequently seen, especially on the lower extremities. Koebner phenomenon may also be observed, in which

Fig. 33-35 Acquired perforating disease in uremia. (Courtesy of Dr. Curt Samlaska.)

case plaques or elevated verrucous streaks are formed, primarily in the antecubital and popliteal spaces. Atrophic scars are seen on involution of these lesions.

Histologically, the epidermis becomes edematous, the granular layer disappears, and parakeratosis develops. Eventually, the epidermis becomes atrophic, with disruption of the sites over the papillae. Through these sites, necrobiotic connective tissue, degenerating inflammatory cells, and collagen bundles are extruded into a cup-shaped epidermal depression.

Acquired perforating dermatosis is thought to be a response to trauma, usually scratching or rubbing in response to the pruritus of the associated renal failure or dry skin. Other predisposing conditions reported include HIV infection, sclerosing cholangitis or other liver diseases, hypothyroidism, hyperparathyroidism, Hodgkin disease, healed areas of herpes zoster, and reactions to laser hair removal or indinavir and several biologic agents (e.g., gefitinib, infliximab, etanercept, bevacizumab, sorafenib, and natalizumab).

Ultraviolet treatment, either PUVA or UVB, helps the pruritus of renal disease and improves the perforating disorder. Hydration of the skin with a soaking tub bath in plain water, followed immediately (without drying) by triamcinolone ointment just before bedtime, is also useful. Topical retinoic acid (0.1% cream), tacalcitol, allopurinol, doxycycline, amitriptyline, photodynamic therapy, isotretinoin, and etretinate have been effective in flattening lesions. HIV-infected patients may respond well to thalidomide. The disease may remit promptly after renal transplantation.

Reactive perforating collagenosis

Reactive perforating collagenosis is an inherited condition characterized by pinhead-sized, skin-colored papules that grow to a diameter of 4–6 mm and develop a central area of umbilication in which keratinous material is lodged (Fig. 33-36). The discrete papules may be numerous and may involve sites of frequent trauma, such as the backs of the hands, forearms, elbows, and knees. The lesion reaches a maximum size of about 6 mm in 4 weeks and then regresses spontaneously in 6–8 weeks. This is believed to be caused by a peculiar reaction of the skin to superficial trauma. Koebnerization is often observed. Young children are most frequently affected. Most reports support an autosomal recessive mode of inheritance; in one family, however, it appeared to be inherited by autosomal dominance. No specific treatment is indicated because the lesions involute spontaneously. Tretinoin 0.1% cream may be effective.

Traumatic anserine folliculosis

Traumatic anserine folliculosis is a curious gooseflesh-like follicular hyperkeratosis that may result from persistent pressure and lateral friction of one skin surface on another. Such friction is often caused by habitual pressure on the elbows, chin, jaw, or neck, often while watching television. Two thirds of patients who develop this are atopic.

Padilha-Gonalves A: Traumatic anserine folliculosis. J Dermatol 1979; 6:365.

Erythromelanosis follicularis faciei et colli

Erythromelanosis follicularis faciei et colli is an erythematous pigmentary disease involving the follicles. A reddish brown,

sharply demarcated, symmetric discoloration involves the preauricular and maxillary regions. At times, the pigmentation may be blotchy. In addition, follicular papules and erythema are present. Under diascopic pressure, the reddish brown area, containing telangiectases, becomes pale, and the light-brown pigmentation becomes more apparent. Pityriasiform scaling and slight itching may occur. Keratosis pilaris on the arms and shoulders is frequently found. It preferentially affects Asian and Indian patients.

Histologically, a slight hyperkeratosis occurs, with epidermal hyperpigmentation and dilation of the upper dermal vessels. The hair follicles may be enlarged in the infundibular area, and the sebaceous glands may be hypertrophic. A lymphocytic infiltration surrounds the adnexa. Successful treatment with topical tacalcitol or a dual-wavelength laser system has been reported.

Kim WJ, et al: Topical tacalcitol ointment can be a good therapeutic choice in erythromelanosis follicularis faciei et colli. J Am Acad Dermatol 2012; 67:320.
Li YH, et al: Treatment of erythromelanosis follicularis faciei et colli using a dual-wavelength laser system. Dermatol Surg 2010; 36:1344.

Disseminate and recurrent infundibulofolliculitis

Hitch and Lund described a disseminate follicular eruption on the torso of a black man that involved all the pilosebaceous structures. The lesions were irregularly shaped papules pierced by a hair. They likened the eruption to cutis anserina viewed through a magnifying glass. The eruption is mildly pruritic at times and is chronic, with recurrent exacerbations. The papules are uniform and 1 or 2 mm in diameter. They involve all the follicles in the affected areas, which are usually the upper trunk and neck, although the entire trunk and proximal extremities may be involved. Rarely, pustules may occur.

Histologically, the infundibular portion of the follicles is chiefly affected, and the lesions are inflammatory rather than hyperkeratotic. Edema, lymphocytic and neutrophilic infiltration, and slight fibroblastic infiltration surround the affected follicles. Treatment with topical steroids, isotretinoin, or PUVA may be effective.

Aroni K, et al: Disseminate and recurrent infundibulofolliculitis: response to isotretinoin. J Drugs Dermatol 2004; 3:434.
Hinds GA, et al: A case of disseminate and recurrent infundibulofolliculitis responsive to treatment with topical steroids. Dermatol Online J 2008; 14:11.

Lichen spinulosus

Lichen spinulosus (keratosis spinulosa) is primarily a disease of children and is characterized by minute, filiform horny spines, which protrude from follicular openings independent of any papules. The spines are discrete and grouped. The lesions appear in crops and are symmetrically distributed. There is a predilection for the neck, buttocks, abdominal wall, popliteal spaces, and extensor surfaces of the arms. Minimal or no itching is present. Occasional cases of a generalized form in adults with HIV infection or alcoholism have been reported.

Histologic evaluation shows simple inflammatory changes and follicular hyperkeratosis. The lesions may respond to keratolytics and emollients, such as salicylic acid, lactic acid, or urea gels or ointments. Tretinoin or tacalcitol creams are other alternatives. The lesions tend to involute at puberty.

DISORDERS OF THE SWEAT GLANDS

Hyperhidrosis

Hyperhidrosis, or excessive sweating, may be localized to one or several areas or may be more generalized. True generalized hyperhidrosis is rare; even hyperhidrosis caused by systemic diseases is usually accentuated in certain regions.

Palmoplantar hyperhidrosis (emotional hyperhidrosis)

Palmoplantar hyperhidrosis is usually localized to the palms, soles, and/or axillae and may worsen during warm temperatures. Patients with palm and sole hyperhidrosis often have axillary hyperhidrosis, but only 25% of patients with axillary hyperhidrosis have palmoplantar hyperhidrosis. The hands may be cold and may show a dusky hue. The soggy keratin of the hyperhidrotic soles is frequently affected by pitted keratolysis and has a foul odor. Sweating may be constant or intermittent; in the latter case, anxiety, stress, or fear may trigger it. This type of sweating can be autosomal dominant inherited. Its onset is in childhood for the palmar and plantar type and adolescence for axillary disease. It tends to improve with age. Sweating typically ceases during sleep.

Gustatory hyperhidrosis

Certain individuals regularly experience excessive sweating of the forehead, scalp, upper lip, perioral region, or sternum a few moments after eating spicy foods, tomato sauce, chocolate, coffee, tea, or hot soups. Gustatory sweating may be idiopathic or caused by hyperactivity of the sympathetic nerves (Pancoast tumor or postoperatively), sensory neuropathy (diabetes mellitus or subsequent to zoster), parotitis or parotid abscess, and surgery or injury of the parotid gland (auriculotemporal syndrome of von Frey). Frey syndrome occurs in one third or more of patients after parotid surgery. Fortunately, only 10% of affected patients require treatment.

Other localized forms of hyperhidrosis

Localized sweating can occur over lesions of blue rubber bleb nevus syndrome, glomus tumors, and hemangiomas (sudoriferous hemangioma), and in POEMS syndrome, Gopalan (burning feet) syndrome, complex regional pain syndrome resulting from spinal cord tumors (especially when unilateral palmar hyperhidrosis is the complaint), and pachydermoperiostosis.

Generalized hyperhidrosis

Febrile diseases, vigorous exercise, or a hot, humid environment (e.g., tropical milieu) may induce generalized hyperhidrosis. Hyperthyroidism, acromegaly, diabetes mellitus, pheochromocytoma, hypoglycemia, salicylism, substance abuse, lymphoma, carcinoid syndrome, pregnancy, and menopause may also produce generalized hyperhidrosis. Additional causes of hyperhidrosis include concussion, Parkinson's disease, other disturbances of the sympathetic nervous system, and metastatic tumors producing a complete transection of the spinal cord. Drugs such as anticholinesterases, antidepressants of the selective serotonin reuptake inhibitor or tricyclic types, antiglaucoma agents, bladder stimulants, opioids, and sialogogs may cause hyperhidrosis.

Treatment

Therapy of generalized hyperhidrosis focuses on treating the underlying systemic disease. Virtually all cases of hyperhidrosis seen by dermatologists are of the palmoplantar or axillary types, and the treatments discussed below relate primarily to these conditions. Hoorens et al. provide an excellent review with an excellent step-by-step approach to therapy.

Topical medication

Topical aluminum chloride or aluminum chlorhydroxide are the agents most often used for hyperhidrosis. For the axillae, application of a 10–35% solution nightly to a very dry axilla (blown dry with hair dryer) is usually very effective. To limit irritation, lower concentrations should be tried first. Also, it should be washed off in 6–8 h. Occlusion is usually not required. In palmar hyperhidrosis, the application of aluminum chloride nightly in up to a 50% concentration, alone or occluded with plastic gloves, has produced good results for some patients. After topical treatment is effective when performed nightly, the frequency may be reduced to once or twice a week with continued benefit.

Iontophoresis

Iontophoresis with plain tap water is an alternative for patients for whom topical treatments fail. It is frequently effective, using either a Drionic device or a Fischer unit. Treatments generally require 20–30 min sessions each day or twice a day. Once response has occurred, treatments may be used intermittently (even to once every 2 weeks) for maintenance. Use of glycopyrrolate 0.01%, botulinum toxin, and aluminum chloride 2% in the iontophoresis medium may hasten the response. The dry-type iontophoresis requires more study before it can be recommended.

Botulinum toxin

Injection of botulinum A toxin into 4-cm^2 areas on the palms, soles, or axillae dramatically reduces sweating at the treated areas to at least 25% and often to less than 10% of baseline rates. Dosages vary according to the type of botulinum toxin used and the site of treatment. Grunfeld et al. offer a complete review of injection techniques and tips. (Also see Chapter 39 for a discussion of this treatment.) Complications are rare but include some grip weakness when higher doses are used in the palms. This problem, the expense, and the painful injections limit its use especially in the palms and soles. The hypohidrosis continues for an average of 7 months, with some patients continuing to have substantial benefit at 16 months after one injection. Repeated injections generally do not lose efficacy and result in similar response and complication rates. This form of treatment should be offered to all patients who fail topical treatments before surgical modalities are considered. Frey syndrome remits for 1–1.5 years in almost every patient treated. This treatment may be considered for other rare forms of localized hyperhidrosis. Myobloc (botulinum toxin B) is also effective, but with more limited duration of response.

Internal medication

The use of anticholinergic agents such as propantheline bromide, oxybutynin (available in extended-release formulation, which may result in lower efficacy), and glycopyrrolate may be helpful. The dosage of each is regulated by the patient's tolerance and response. Often, sweating is suppressed just as anticholinergic side effects reach intolerable levels, and this approach has to be abandoned. Side effects of acetylcholine-blocking agents may also cause or aggravate such conditions as glaucoma and convulsions. The effects on sweating generally last 4–6 h, and many patients prefer to use the medication to ensure dryness for special occasions only, rather than as continuous treatment. Other agents reported to reduce localized hyperhidrosis include diltiazem and clonidine.

Surgical treatment

Axillary hyperhidrosis may be effectively controlled by excision of the most actively sweating portion of the axillary skin, followed by undercutting and subcutaneous resection of the sweat glands for 1–2 cm on each side of the elliptical excision. This procedure is virtually always effective. Alternatively, liposuction or surgical ultrasonic aspiration removal may be used. The most important preoperative consideration is the accurate mapping of the most active sweating areas of the axillae. The responsible eccrine glands are not necessarily located in the same areas as the axillary hair and are often in a reasonably limited area. Mapping may be performed with cobalt chloride or starch iodide. In a comparative trial the effectiveness of botulinum toxin injections were superior to suction-curettage surgery.

Upper thoracic sympathectomy has been found to be effective in excessive palmar sweating when all other measures have failed. Sympathetic denervation of the upper extremities is performed through endoscopy by reversibly clipping or electrocautery of portions of the third through fifth rib levels. The levels interrupted depend on the type of hyperhidrosis being treated and a risk benefit discussion with the patient. Acute surgical complications occur in less than 2% of patients but include chronic pain, infection, pneumothorax, hemothorax, bleeding, pneumonia, and even death. Sweating of the hands can be stopped or improved; however, since compensatory and gustatory hyperhidrosis occurs in many patients, satisfaction is compromised. This may be severe and as debilitating as the original problem. Topical glycopyrrolate may help alleviate compensatory hyperhidrosis, but it does not decrease with time. Horner syndrome may rarely result. Microwave technology and Nd:YAG laser treatments are newer, less well studied methods that may be useful in the future.

Anhidrosis and hypohidrosis

Anhidrosis is the absence of sweating. Hypohidrosis, or reduced sweating, is part of the spectrum of these disorders. Dysfunction in any step in the normal physiologic process of sweating can lead to decreased or absent sweating. It may be localized or generalized. Generalized anhidrosis occurs in anhidrotic ectodermal dysplasia, miliaria profunda (tropical asthenia), Sjögren syndrome, Fabry syndrome, hereditary sensory neuropathy (type IV) with anhidrosis, and in some patients with diabetic neuropathy, thyroid dysfunction, and multiple myeloma. The many drugs that may cause hypohidrosis include anticholinergics, tricyclic antidepressants, antiepileptics, antihistamines, antihypertensives, antipsychotics, antiemetics, antivertigo drugs, bladder antispasmodics, gastric antisecretory drugs, muscle relaxants, neuromuscular paralytics, and opioids. Anhidrosis may follow infections, may be part of a neurodegenerative disorder, may occur as a symptom related to toxin exposure, may be a paraneoplastic phenomenon, or may be secondary to autoimmune inflammation. Atopic dermatitis is frequently associated with reduced sweating and pruritus when sweating is triggered. Patients with psoriasis may have similar symptoms, but less frequently. There remains an idiopathic category; this variant may respond to oral steroid treatment. Remission is possible but not universal. Immunosuppressants have been ineffective.

Anhidrosis with pruritus is a rare syndrome of young adults. Severe itching occurs whenever the person is stimulated to sweat. No sweat is delivered to the skin surface, but when the body temperature is raised by about 0.5°C, fine papules appear at each eccrine orifice. The associated pruritus is so severe that the patient feels completely incapacitated and distracted. Cooling immediately resolves the symptoms. This may represent one form of tropical asthenia or a mild form of the autonomic neuropathies described later. The natural history is unknown, but spontaneous resolution may occur after several years. These patients are frequently misdiagnosed as having cholinergic urticaria.

Segmental anhidrosis may be associated with tonic pupils (Holmes-Adie syndrome); this is called Ross syndrome. Patients have heat intolerance and segmental areas of anhidrosis on the trunk, arms, or legs. Loss of deep tendon reflexes in the arms, trunk, and legs is consistently seen. Compensatory segmental hyperhidrosis of functionally intact areas may occur. A selective degeneration of the cholinergic sudomotor neurons is the hypothesized abnormality.

Autonomic neuropathies associated with antibodies to nicotinic acetylcholine receptors may cause a variety of symptoms related to dysfunction of systems controlled by autonomic nerves. There is a spectrum of abnormalities ranging from severe autonomic failure characterized by orthostatic hypotension, GI dysmotility, anhidrosis, bladder dysfunction, and sicca syndrome to isolated anhidrosis and heat intolerance. In this condition, a biopsy may reveal an inflammatory infiltrate surrounding the eccrine glands, and some patients respond to pulse steroids or immunosuppressants. It may also spontaneously resolve.

Anhidrosis localized to skin lesions occurs regularly over plaques of tuberculoid leprosy. This is also true of segmental vitiligo (but not the generalized type), in the hypopigmented streaks of incontinentia pigmenti, in lesions of syringolymphoid hyperplasia with alopecia and anhidrosis, and on the face and neck of patients with the rare Bazex syndrome, consisting of follicular atrophoderma, basal cell carcinomas, and hypotrichosis, an X-linked dominant disorder.

Bromhidrosis

Also known as fetid sweat, osmidrosis, and malodorous sweating, bromhidrosis is chiefly encountered in the axillae. Bacterial decomposition of apocrine sweat, producing fatty acids with distinctive offensive odors, is considered to be the cause. Often, patients who complain of offensive axillary sweat actually have no offensive odor; the complaint represents a delusion, paranoia, phobia, or a lesion of the central nervous system. Intranasal foreign body and chronic mycotic infection in the sinuses are additional causes. True bromhidrosis is usually not recognized by the patient.

Fish odor syndrome (trimethylaminuria) should be considered in patients presenting with complaints of offensive odor. It is caused by excretion of trimethylamine, which has a rotten-fish odor, in the eccrine sweat, urine, saliva, and other secretions. This chemical is produced from carnitine and choline in the diet and is normally metabolized in the liver. An autosomal dominant defect in the ability to metabolize trimethylamine because of a defect in flavin-containing monooxygenase 3 is the cause of this syndrome. Dietary reduction of foods high in carnitine and choline is beneficial.

Antibacterial soaps and many commercial deodorants are quite effective in controlling axillary malodor. Frequent bathing, changing of underclothes, shaving of the axillae, and topical application of aluminum chloride (Drysol) are all helpful measures. Surgical removal of the glands either by excision or tumescent liposuction is possible, as in axillary hyperhidrosis, but this is rarely indicated. Botulinum toxin A injections in the axilla have controlled body odor in this site as well in the pubic area.

Plantar bromhidrosis is produced by bacterial action on eccrine sweat–macerated stratum corneum. Hyperhidrosis is the main associated factor, and pitted keratolysis is often present. Careful washing with an antibacterial soap and use of dusting powders on the feet are helpful in eliminating bromhidrosis. Use of topical antibiotics, such as clindamycin, may be beneficial. Previously described measures to control

plantar hyperhidrosis should be instituted. Botulinum toxin A is likely to be effective.

Chromhidrosis

Chromhidrosis, or colored sweat, is an exceedingly rare functional disorder of the apocrine sweat glands, frequently localized to the face or axilla. It has been less often noted on the abdomen, chest, breasts, thighs, groin, genitalia, and lower eyelids. The colored sweat may be yellow (most common), blue, green, or black. The colored secretion appears in response to adrenergic stimuli, which cause myoepithelial contractions. Colored apocrine sweat fluoresces and is caused by lipofuscin. Treatment with botulinum toxin A or topical capsaicin has been reported to be effective.

Eccrine chromhidrosis is caused by the coloring of the clear eccrine sweat by dyes, pigments, or metals on the skin surface. Examples are the blue-green sweat seen in copper workers and the "red sweat" seen in flight attendants from the red dye in the labels on life vests. Brownish staining of the axillae and undershirt may occur in ochronosis. Yellow sweat has been reported to be secondary to long-term intake of bisacodyl. Bile secretion in eccrine sweat occurs in patients with liver failure and marked hyperbilirubinemia. Small, round, brown or deep-green macules occur on the palms and soles.

Fox-Fordyce disease

Fox-Fordyce disease is rare, occurring mostly in women during adolescence or soon afterward. It may occasionally be familial in nature. It is characterized by conical, flesh-colored or grayish, intensely pruritic, discrete follicular papules in areas where apocrine glands occur (Fig. 33-37). The axillae and areolae are the primary sites of involvement, but the umbilicus, pubes, labia majora, and perineum may be affected. Apocrine sweating does not occur in affected areas, and hair density may be decreased. In some cases, there is no itching. About 90% of cases occur in women between ages 13 and 35, but the disease also may present postmenopausally, after laser hair removal, or in males. Pregnancy invariably leads to improvement.

Histologically, Fox-Fordyce disease is characterized by obstruction of the follicular ostia by orthokeratotic cells. An inflammatory infiltrate of lymphocytes surrounds the upper third of the hair follicles and upper dermal vessels. An associated spongiosis of the infundibulum occurs at the entrance of the apocrine duct into the hair follicle. In one case, detached apoeccrine cells obstructed the duct. Foam cells have been noted as a histologic marker, because many of these findings are either nonspecific or difficult to demonstrate. Localized axillary xanthomatosis has been postulated to be either a variant of Fox-Fordyce disease or a type of verruciform xanthoma.

Fig. 33-37 Fox-Fordyce disease.

No form of therapy is universally effective for patients with Fox-Fordyce disease. OCs, topical tretinoin or adapalene, topical pimecrolimus or weak corticosteroid creams, intralesional steroids, topical clindamycin solution, benzoyl peroxide, isotretinoin, fractional CO_2 laser, and UV phototherapy have all been effective in small numbers of patients. Excision or liposuction-assisted curettage may be successful in axillary sites.

Granulosis rubra nasi

Granulosis rubra nasi is a rare familial disease of children, occurring on the nose, cheeks, and chin. It is characterized by diffuse redness, persistent hyperhidrosis, and small, dark-red papules that disappear on diascopic pressure. The tip of the nose is red or violet. A few small pustules may occur. Hyperhidrosis precedes the erythema. The tip of the nose is cold and is not infiltrated. The disease usually disappears spontaneously at puberty, leaving no trace. The cause is unknown. Histologically, blood vessels are dilated, and an inflammatory infiltrate is seen around the sweat ducts. Treatment is with local preparations for relief of the inflammation, with involuiton expected at puberty. Botulinum toxin A has been effective in one case.

Hidradenitis

Hidradenitis is a term used to describe diseases in which the histologic abnormality is primarily an inflammatory infiltrate around the eccrine glands. This group includes neutrophilic eccrine hidradenitis and idiopathic plantar hidradenitis (recurrent palmoplantar hidradenitis). Hidradenitis suppurative is discussed in Chapter 13.

Neutrophilic eccrine hidradenitis

Ninety percent of patients with neutrophilic eccrine hidradenitis (NEH) have a malignancy. NEH has been described primarily in patients with acute myelogenous leukemia (AML); however, other leukemias, lymphomas, and infrequently solid tumors may be present. It usually begins about 10 days after the start of chemotherapy. Although the majority of patients have been treated with cytarabine, NEH has not been uniformly linked to any chemotherapeutic agent and may occur in untreated patients. Patients with AML in remission have been reported to develop NEH, with associated sclerodermoid changes that herald a relapse of the leukemia. Granulocyte colony-stimulating factor, imatinib mesylate, zidovudine, decitabine, acetaminophen, and various antibiotics have also been implicated as triggers for this neutrophilic dermatosis.

The lesions are typically erythematous and edematous papules and plaques of the extremities, trunk, face (periorbital), and palms (in decreasing frequency). Pigmentation, purpura, or pustules may be present within the papules and plaques. Fever and neutropenia are often present. Histologically, there is a dense neutrophilic infiltrate around and infiltrating eccrine glands. Necrosis of sweat glands may be present, with or without the inflammatory infiltrate. Syringosquamous metaplasia may occur. This finding can also occur in fibrosing alopecia, in burn scars, adjacent to various nonmelanoma skin cancers and ischemic and surgical ulcers, in alopecia mucinosa, and in ports of radiation therapy.

The lesions may recur with repeated courses of chemotherapy, but many do not. Resolution over 1–4 weeks (average 10 days) usually occurs. Nonsteroidal anti-inflammatory drugs or oral corticosteroids may hasten the healing. Prophylactic administration of dapsone prevented recurrence in one patient.

Infections may also precipitate neutrophilic hidradenitis as a recurrent, pruritic, papular eruption. *Serratia, Enterobacter cloacae, Nocardia,* and *Staphylococcus aureus* have been implicated, and appropriate antibiotics for bacterial agents are curative. The diagnosis is confirmed by histologic evaluation and culture of affected tissue (surface cultures may not be adequate). Additionally, many HIV-infected patients have developed neutrophilic eccrine hidradenitis. An idiopathic generalized variant has occurred in four healthy Asian children ages 6 to 16 months. Spontaneous resolution is reported.

Recurrent palmoplantar hidradenitis

Recurrent palmoplantar hidradenitis is primarily a disorder of healthy children and young adults. Lesions are primarily painful, subcutaneous nodules on the plantar surface, resembling erythema nodosum. Rarely, palmar lesions also occur. In some children, *Pseudomonas* infection may be the cause (pseudomonal hot foot syndrome; see Chapter 14, *P. aeruginosa* folliculitis). Children may present refusing to walk because of plantar pain. The condition is typically recurrent and may be triggered by exposure to wet shoes or cold, damp weather. The use of oral and topical steroidal preparations may be beneficial.

Nail-associated dermatoses

Numerous dermatoses are associated with characteristic, sometimes specific, nail changes. Many are considered in other chapters.

Lichen planus of nails

The reported incidence of nail involvement in lichen planus varies from less than 1% to 10%. Lichen planus of the nails occurs without skin changes, but 25% with nail disease will have lichen planus at other locations. Although it may occur at any age, most frequently it begins during the fifth or sixth decade of life. The nail plate may be greatly thinned, and at times, distinct papules of lichen planus may involve the nail bed. Twenty-nail dystrophy (trachyonychia) may be the sole manifestation of lichen planus. Other nail changes are irregular longitudinal grooving and ridging of the nail plate, thinning of the nail plate, pterygium formation (Fig. 33-38), shedding of the nail plate with atrophy of the nail bed, subungual keratosis, or even onychopapilloma, erythronychia (red streaks), subungual hyperpigmentation, and nail degloving. This last sign involves partial or total shedding of the nail or the entire nail apparatus. The surrounding skin may also slough. This may be caused by trauma, ischemia and gangrene, or severe dermatologic disease such as toxic epidermal necrolysis or lichen planus.

The histologic changes of lichen planus may be evident in any individual nail constituent or a combination of them. The constituent most frequently involved is the matrix.

Treatment with intralesional injection of corticosteroids may be effective. Digital nerve blocks should be considered before infiltration of the matrix or nail bed. Topical corticosteroids under polyethylene occlusive dressings are usually inadequate; however, when applied with tazarotene it may be successful. Oral prednisone (0.5–1 mg/kg for 3 weeks) or oral retinoids in combination with topical corticosteroids applied

Fig. 33-38 Pterygium caused by lichen planus. (Courtesy of Dr. Lawrence Lieblich.)

Fig. 33-39 Pitting caused by psoriasis.

to the involved sites has been successful in some patients. Tosti et al. reported that children with typical lichen planus of the nails responded to 0.5–1 mg/kg/month of intramuscular triamcinolone acetonide given for 3–6 months, until the proximal half of the nail was normalized. Disease recurred in only two patients during the follow-up period. Although twenty-nail dystrophy was not treated, patients spontaneously improved; those with idiopathic atrophy of the nails were unchanged. (See Chapter 12 for additional therapeutic considerations.)

Psoriatic nails

Nail involvement in psoriasis is common, with the reported incidence varying from 10% to 78%. Older patients, those with active exacerbations of disease, and those with psoriatic arthritis are more likely to express nail abnormalities. The nail plate may have pits (Fig. 33-39), or much less often, furrows or transverse depressions (Beau's lines), crumbling nail plate, or leukonychia, with a rough or smooth surface. Splinter hemorrhages are found in the nail bed, with reddish discoloration of a part or all of the nail bed, and horny masses. In the hyponychium, subungual hyperkeratosis, oil spots, and a yellowish green discoloration may occur in the area of onycholysis. Onychomycosis may be closely simulated. The severity of nail disease may correlate with the severity of skin and joint disease. Pustular psoriasis may produce onycholysis, with lakes of pus in the nail bed or in the perionychial areas. Rarely, anonychia may result. Other papulosquamous diseases may affect the nails similar to psoriasis, with the exception of nail pitting. Reiter's disease, pityriasis rubra pilaris, Sézary syndrome, and acrokeratosis paraneoplastica produce hypertrophic nails with subungual hyperkeratosis.

Psoriatic nail disease may be a solitary finding or may be part of a widespread skin and nail involvement. The treatment options selected depend on the degree of cutaneous and nail involvement (see Chapter 10 for additional information and therapeutic options). Successful systemic treatment of psoriasis will usually also improve or clear the nail changes. Methotrexate, PUVA, cyclosporine, biologics, or acitretin may be effective. All local therapies have limitations. Intralesional injection of triamcinolone acetonide suspension, 3–5 mg/mL, with a 30-gauge needle is frequently helpful. Digital nerve block facilitates adequate injection. Topical 5-fluorouracil (5-FU) applied to the proximal nailfold has been reported to be effective. It is best to avoid the free edge of the nail when applying 5-FU because it may cause distal onycholysis. Topical cyclosporine and topical tazarotene 0.1% gel may also be helpful. Topical calcipotriol improves about 50% of patients with localized pustular psoriasis of the nails and may be used as a maintenance treatment after successful intervention with systemic retinoids.

Darier's disease

Longitudinal, subungual, red or white streaks, associated with distal wedge-shaped subungual keratoses, are the nail signs diagnostic for Darier-White disease. Keratotic papules on

Fig. 33-40 Clubbing. (Courtesy of Dr. Lawrence Lieblich.)

the dorsal portion of the nailfold may clinically resemble acrokeratosis verruciformis, but histologically, they have features of Darier's disease. Other nail findings include splinter hemorrhages and leukonychia. All these findings are less pronounced on the toenails.

Bae-Harboe YS, et al: JAAD Grand Rounds quiz: Nail dystrophy and multiple hyperkeratotic papules on the face and neck. J Am Acad Dermatol 2013; 69:847.

Clubbing

Clubbing is divided into two types: idiopathic and acquired, or secondary. The changes occur not only in the nails but also in the terminal phalanges. The nails bulge and are curved in a convex arc in both transverse and longitudinal directions. The eponychium is thickened. The angle formed by the dorsal surface of the distal phalanx and the nail plate (Lovibond's angle) is approximately 160 degrees; with clubbing, however, this angle is obliterated and becomes 180 degrees or greater (Fig. 33-40). There is no diamond-shaped window when the dorsal surfaces of the corresponding finger of each hand are opposed (Schamroth's sign). The soft tissues of the terminal phalanx are bulbous and are mobile when pressure is applied over the matrix. Thickening of the nail bed is present and can be assessed reliably by a plain radiograph of the index finger.

Idiopathic clubbing is either the isolated dominantly inherited type or the pachydermoperiostosis type with its associated findings. In the hereditary isolated type, mutations of the human *HPGD* gene encoding NAD(+)-dependent 15-hydroxyprostaglandin dehydrogenase and the prostaglandin transporter SLCO2A1 have been identified. Secondary (acquired) clubbing is usually a consequence of pulmonary, cardiac, thyroid, hepatic, or GI disease. About 36% of HIV-infected patients have clubbed nails. Typically, there is periostitis, with periosteal new bone formation in the phalanges, metacarpals, and distal ulna and radius. This is called hypertrophic osteoarthropathy and is responsible for the painful clubbing. It typically occurs in men with bronchogenic carcinoma. Unilateral or asymmetric clubbing may also occur in Takayasu arteritis and sarcoidosis.

Fig. 33-41 Koilonychia.

Shell nail syndrome

Cornelius described a shell nail in association with bronchiectasis. The nail resembles a clubbed nail, but the nail bed is atrophic instead of being a bulbous proliferation of the soft tissue.

Cornelius CE: Shell nail syndrome. Arch Dermatol 1969; 100:118.

Koilonychia (spoon nails)

Spoon nails are thin and concave, with the edges everted so that if a drop of water were placed on the nail, it would not run off (Fig. 33-41). Koilonychia may result from faulty iron metabolism and is one of the signs of Plummer-Vinson syndrome, as well as of hemochromatosis. Spoon nails have been observed in coronary disease, syphilis, polycythemia, and acanthosis nigricans. Familial forms are also known to occur. Other associations include psoriasis, lichen planus, Raynaud syndrome, scleroderma, acromegaly, hypothyroidism and hyperthyroidism, monilethrix, palmar hyperkeratoses, and steatocystoma multiplex. A significant number of cases are idiopathic. Manual trauma in combination with cold exposure may result in seasonal disease. Sherpas are Tibetan people living in the Nepalese Himalayas, who often serve as porters on mountain-climbing expeditions. Chronic cold exposure, in combination with hypoxemia, may contribute to the high frequency with which koilonychia is observed among them and people living in the Leh Ladahk region of India.

Yanamandra U, et al: Ladakhi koilonychias. BMJ Case Rep 2014 Jan 16; Pii: bcr2013202567.

Congenital onychodysplasia of index fingers

Congenital onychodysplasia of the index fingers is defined by the presence of the condition at birth, index finger involvement (unilateral or bilateral), variable distortion of the nail or lunula, and polyonychia, micronychia, anonychia, hemionychogryphosis, or malalignment. It may also involve adjacent fingers, such as the middle fingers and thumbs. An underlying bone dysplasia may be present beneath the involved nail. Cases have occurred in an autosomal dominant pattern; other proposed causes include in utero ischemia or exposure to teratogens.

Hussein TP, et al: Malformations of the index nails. Clin Exp Dermatol 2009; 34:890.
Park SW, et al: Treatment of congenital onychodysplasia of the index finger with specialized nail device. Clin Exp Dermatol 2013; 38: 791.

Trachyonychia

The nails may become opalescent, thin, dull, fragile, and finely ridged longitudinally (and as a result, distally notched). When this involves all 20 nails, it is referred to as twenty-nail dystrophy. This latter presentation may be seen at any age from 1½ years to adulthood, although it is most frequently diagnosed in children. It can be idiopathic or may be caused by alopecia areata, psoriasis, lichen planus, atopy, ichthyosis vulgaris, or other inflammatory dermatoses. Familial forms exist. In some cases, spongiosis may be found on nail biopsy. Trachyonychia has also been reported associated with autoimmune processes such as selective IgA deficiency, vitiligo, sarcoidosis, and graft-versus-host disease. Unilateral involvement may occur in complex regional pain syndrome. Thus it is caused by a heterogeneous group of inflammatory conditions. Tazarotene alone or in association with topical corticosteroids may improve the condition. Childhood cases may resolve spontaneously; in one study, 50% cleared within 6 years.

Blanco FP, et al: Trachyonychia. J Drugs Dermatol 2006; 5:469.
Gordon KA, et al: Trachyonychia. Indian J Dermatol Venereol Leprol 2011; 77:640.
Sakata S, et al: Follow up of 12 patients with trachyonychia. Australas J Dermatol 2006; 47:166.

Onychauxis

In onychauxis, the nails are thickened but without deformity (simple hypertrophy). Simple thickening of the nails may be the result of trauma, acromegaly, Darier's disease, psoriasis, or pityriasis rubra pilaris. Some cases are hereditary. Treatment involves periodic partial or total debridement of the thickened nail plate by mechanical or chemical (40% urea paste) means. Matricectomy and nail ablation are options, as they are in onychogryphosis, congenital nail dystrophies, and chronic painful nails, such as recalcitrant ingrown toenails or splits within the medial or lateral third of the nail.

Baran R, et al: Matricectomy and nail ablation. Hand Clin 2002; 18:696.
Singh G, et al: Nail changes and disorders among the elderly. Indian J Dermatol Venereol Leprol 2005; 71:386.

Onychogryphosis

Hypertrophy may produce nails resembling claws or a ram's horn. Onychogryphosis may be caused by trauma or peripheral vascular disorders but is most often caused by neglect (failure to cut the nails for very long periods). It is most often seen in elderly persons. Some recommend avulsion of the nail plate with surgical destruction of the matrix with phenol or the CO_2 laser, if the blood supply is good.

Nath AK, et al: Congenital onychogryphosis. Dermatol Online J 2011; 17:9.

Onychophosis

A common finding in the elderly population, onychophosis is a localized or diffuse hyperkeratotic tissue that develops on the lateral or proximal nailfolds, within the space between the nailfolds and the nail plate. It may involve the subungual area, as a direct result of repeated minor trauma, and most frequently affects the first and fifth toes. The use of comfortable shoes should be encouraged. The areas involved should be debrided and treated with keratolytics. Emollients are also helpful.

Singh G, et al: Nail changes and disorders among the elderly. Indian J Dermatol Venereol Leprol 2005; 71:386.

Anonychia

Absence of nails, a rare anomaly, may be the result of a congenital ectodermal defect, ichthyosis, severe infection, prenatal phenytoin exposure, severe allergic contact dermatitis, self-inflicted trauma, Raynaud phenomenon, lichen planus, epidermolysis bullosa, or severe exfoliative diseases. Permanent anonychia has been reported as a sequel of Stevens-Johnson syndrome. It may also be found in association with congenital developmental abnormalities, such as microcephaly, and wide-spaced teeth (autosomal recessive inheritance), autosomal dominant Cooks syndrome (brachydactyly-anonychia), which has been associated with duplications of the noncoding elements of Sox9, DOOR syndrome (deafness, onycho-osteodystrophy, mental retardation), and the glossopalatine syndrome (abnormal mouth, tongue being attached to temporomandibular joint).

Anonychia may also present as an autosomal recessive disorder with anonchyia as the solitary finding. It has been found to be caused by a mutation in the gene for R-spondin 4. R-spondins are secreted proteins that activate the Wnt/β-catenin signaling pathway. R-spondin 4 is exclusively expressed in the mesenchyme underlying the digit tip epithelium in embryonic mice.

Babu S, et al: Anonychia due to prenatal phenytoin exposure. J Assoc Phys India 2012; 60:64.
Ishii Y, et al: Mutations in R-spondin 4 underlie inherited anonychia. J Invest Dermatol 2008; 128:867.

Wasif N, et al: A novel nonsense mutation in *RSP04* gene underlies autosomal recessive congenital anonychia in a Pakistani family. Pediatr Dermatol 2013; 30:139.

Onychoatrophy

Faulty underdevelopment of the nail may be congenital or acquired. The nail is thinned and small. Vascular disturbances, epidermolysis bullosa, lichen planus, Darier's disease, multicentric reticulohistiocytosis, and Hansen's disease may cause onychoatrophy. Onychoatrophy is also seen in congenital syndromes such as Apert, Goltz, Turner, Ellis–van Creveld, nail-patella, dyskeratosis congenita, cartilage-hair hypoplasia, progeria, hypohidrotic ectodermal dysplasia, incontinentia pigmenti, popliteal web, trisomy 13, trisomy 18, and as a side effect of etretinate therapy.

Al Hawsawi K, et al: Anonychia congenita totalis. Int J Dermatol 2002; 41:397.

Onychomadesis

Onychomadesis is a periodic idiopathic shedding of the nail beginning at its proximal end. The temporary arrest of the function of the nail matrix may cause onychomadesis. Neurologic disorders, peritoneal dialysis, cutaneous T-cell lymphoma, Kawasaki's disease, pemphigus vulgaris, drug allergy, hand, foot, and mouth disease, varicella infection, Cronkite-Canada syndrome, and keratosis punctata palmaris et plantaris have been reported causes. It may appear as a periodic finding in runners. Immobilization from casting for fractures may cause onychomadesis. Medications such as antineoplastic agents, valproic acid, azithromycin, and retinoids may cause

Fig. 33-42 Beau's lines.

Fig. 33-43 Half and half nails.

onychomadesis as well. It may be an idiopathic finding in adults and neonates.

Bettoli V, et al: Onychomadesis following hand, foot, and mouth disease. Int J Dermatol 2013; 52:728.
Kocak AY, et al: Onychomadesis in two sisters induced by *Varicella* infection. Pediatr Dermatol 2013; 30:e108.
Parmar B, et al: Neonatal onychomadesis. Pediatr Dermatol 2010; 27:115.
Piraccini BM, et al: Twenty nail onychomadesis. J Am Acad Dermatol 2010; 63:172.

Beau's lines

Beau's lines are transverse furrows that begin in the matrix and progress distally as the nail grows (Fig. 33-42). They are ascribed to the temporary arrest of function of the nail matrix. Although usually found to be bilateral, unilateral Beau's lines may occur. Various systemic and local traumatic factors may cause the lines. They may result from almost any systemic illness or major injury, such as a broken hip. Some specific associations are childbirth, measles, paronychia, acute febrile illnesses, high-altitude exposure, and drug reaction. When the process is intermittent, the nail plate may resemble corduroy. Shelley "shoreline" nails appear to be a severe expression of essentially the same transient growth arrest. Beau's lines have been reported in all 20 nails of a newborn.

Park J, et al: Images in clinical medicine. Multiple Beau's lines. N Engl J Med 2010; 362: e63.
Ryu H, et al: Beau's lines of the fingernails. Am J Med Sci 2014 Mar 24. (Epub ahead of print.)

Half and half nails

Half and half nails show the proximal portion of the nail white and the distal half red, pink, or brown, with a sharp line of demarcation between the two halves (Fig. 33-43). About 76% of hemodialysis patients and 56% of renal transplant patients have at least one type of nail abnormality. Half and half nails are the most common, affecting 20% of hemodialysis patients. Absence of lunula, splinter hemorrhage, and half and half nails were significantly more common in hemodialysis patients, whereas leukonychia was significantly more common in transplant patients.

Iorizzo M, et al: Half and half nails. Cutis 2011; 88:138.

Fig. 33-44 Muehrcke's lines.

Salem A, et al: Nail changes in chronic renal failure patients under haemodialysis. J Eur Acad Dermatol Venereol 2008; 22:1326.

Muehrcke's lines

Muehrcke described narrow, white transverse bands occurring in pairs as a sign of chronic hypoalbuminemia. The lines may resolve when serum albumin is raised to or near normal (Fig. 33-44). Unlike Mees' lines, the disturbance appears to be in the nail bed, not in the nail plate. Similar lines have been reported in patients with normal albumin levels who are receiving chemotherapy. In a case of unilateral Muehrcke's lines associated with trauma, it was suggested that edema effects this change by inducing microscopic separation of the normally tightly adherent nail from its bed.

Short N, et al: Muehrcke's lines. Am J Med 2010; 123:991.
Stanifer J, et al: Muehrcke's lines as a diagnostic clue to increased catabolism and a severe system disease state. Am J Med Sci 2011; 342:331.

Fig. 33-45 Terry nails.

Mees' lines

Mees described single or multiple white transverse bands in 1919 as a sign of inorganic arsenic poisoning. They have also been reported in thallium poisoning, septicemia, dissecting aortic aneurysm, parasitic infections, chemotherapy, and both acute and chronic renal failure.

Chauhan S, et al: Mees' lines. Lancet 2008; 372:1410.
Lu CI, et al: Short-term thallium intoxication. Arch Dermatol 2007; 143:93.

Terry nails

In Terry nails, the distal 1–2 mm of the nail shows a normal pink color (Fig. 33-45), whereas the entire nail plate or proximal end has a white appearance as a result of telangiectases in the nail bed. These changes have been noted in 25% of hospitalized patients, most often those with cirrhosis, chronic congestive heart failure, and adult-onset diabetes, and in very elderly patients.

Albuquerque A, et al: Hepatobiliary and pancreatic: Terry's nails and liver disease. J Gastroenterol Hepatol 2012; 27:1539.
Baran B, et al: Terry's nail: an overlooked physical finding in cirrhosis. Hepatobiliary Pancreat Dis Int 2013; 12:109.
Nia AM, et al: Terry's nails: A window to systemic diseases. Am J Med 2011; 124:602.

Onychorrhexis (brittle nails)

Brittleness with breakage of the nails may result from frequent soap and water exposure, nail polish remover, hypothyroidism, anorexia or bulimia, or after oral retinoid therapy. It affects up to 20% of the population, women twice as often as men. Fragilitas unguium (nail fragility) is part of this process. In a series of 35 patients treated with biotin, 63% showed clinical improvement. The nail plate thickness in patients treated with biotin increases by 25%. Daily application of white petrolatum after soaking in water is also helpful.

Gequelim GC, et al: Perception of brittle nails in dermatologic patients. An Bras Dermatol 2013; 88:1022.

Fig. 33-46 Onychoschizia.

Nanda S, et al: Utility of gel nails in improving the appearance of cosmetically disfigured nails. J Cutan Aesthet Surg 2014; 7:26.
Uyttendaele H, et al: Brittle nails: pathogenesis and treatment. J Drugs Dermatol 2003; 2:48.
Van de Kerkhof PC: Brittle nail syndrome. J Am Acad Dermatol 2005; 53:644.

Onychoschizia

Splitting of the distal nail plate into layers at the free edge is a very common problem among women and represents a dyshesion of the layers of keratin, possibly as a result of dehydration (Fig. 33-46). Longitudinal splits may also occur. Patients with biotinidase deficiency may manifest onychoschizia, along with total or partial alopecia and an eczematous or desquamating periorificial eruption. Hypotonia, seizures, and developmental delay in children and depression in adults are the most common systemic abnormalities. Lack of treatment may result in loss of hearing and vision.

Nail polish should be discontinued; nail buffing can be substituted. Use of gel nails is well accepted and effective. Frequent application of emollients may be helpful. Biotin has also been shown to be effective in doses up to 2.5 mg/day, or two to four times that much in deficient patients.

Gequelim GC, et al: Perception of brittle nails in dermatologic patients. An Bras Dermatol 2013; 88:1022.
Nanda S, et al: Utility of gel nails in improving the appearance of cosmetically disfigured nails. J Cutan Aesthet Surg 2014; 7:26.

Stippled nails

Small, pinpoint depressions in an otherwise normal nail characterize this type of nail change. This may be an early change seen in psoriasis. Stippled nails are also seen with some cases of alopecia areata, in early lichen planus, psoriatic or rheumatoid arthritis, chronic eczematous dermatitis, perforating granuloma annulare, and in some individuals with no apparent disease. The deeper, broader pits are more specific for psoriasis. The pitting in alopecia areata tends to be shallower and more regular, suggesting a "Scotch plaid" (tartan) pattern.

Tosti A, et al: Prevalence of nail abnormalities in children with alopecia areata. Pediatr Dermatol 1994; 11:12.

Racquet nails (nail en raquette)

In racquet nails, the end of the thumb is widened and flattened, the nail plate is flattened as well, and the distal phalanx is abnormally short (Fig. 33-47). Racquet nails occur on one or both thumbs and are usually inherited as an autosomal

Fig. 33-47 Racquet nails.

dominant trait. Acquired cases have been documented in hyperparathyroidism and Erasmus syndrome (systemic sclerosis following silica exposure).

Baran R, et al: Acquired racquet nails. J Eur Acad Dermatol Venereol 2013 May 20. Doi: 10.1111/jdv.12187. (Epub ahead of print.)
Vetrichevvel TP, et al: Acquired racquet nails in Erasmus syndrome. Int J Dermatol 2010; 49:932.

Chevron nail (herringbone nail)

This entity is a rare, transient fingernail ridge pattern of children. The ridges arise from the proximal nailfold and converge in a V-shaped pattern toward a midpoint distally.

Delano S, et al: Chevron nails: a normal variant in the pediatric population. Pediatr Dermatol 2014; 31:e24.

Hapalonychia

Softened nails result from a defect in the matrix that makes the nails thin and soft so that they can be easily bent. This type of nail change is attributed to malnutrition and debility. It may be associated with myxedema, rheumatoid arthritis, anorexia, bulimia, Hansen's disease, Raynaud phenomenon, oral retinoid therapy, or radiodermatitis.

Baran R, et al: Baran and Dawber's Diseases of the Nails and Their Management. Oxford: Blackwell Scientific, 2008.

Platonychia

The nail is abnormally flat and broad. It may be seen as part of an autosomal dominant condition in which multiple nail abnormalities are present in many members of a large family.

Hamm H, et al: Isolated congenital nail dysplasia: a new autosomal dominant condition. Arch Dermatol 2000; 136:1239.

Nail-patella syndrome (hereditary osteo-onychodysplasia, Fong syndrome)

Nail-patella syndrome comprises numerous anomalies and is characterized by the absence or hypoplasia of the patella and congenital nail dystrophy. Triangular lunulae are characteristic (Fig. 33-48). Other bone features are thickened scapulae, hyperextensible joints, radial head abnormalities, and posterior iliac horns. The skin changes may also include webbing of the elbows. Eye changes such as cataracts, glaucoma, and heterochromia of the iris may also be present. Hyperpigmentation of the pupillary margin of the iris ("Lester iris") is a characteristic finding in about half the cases. Patients with nail-patella syndrome may exhibit glomerulonephritis with

Fig. 33-48 Nail-patella syndrome. (Courtesy of Dr. Marshall Guill.)

urinary findings of albuminuria, hematuria, and casts of all kinds, especially hyaline casts. They may be predisposed to developing hemolytic-uremic syndrome, edema, and hypertension. About 60% of patients have renal abnormalities, and 20% develop renal failure. It is an autosomal dominant trait; mutations of the human *LMX1B* gene result in this syndrome.

Alvarez-Martin N, et al: Nail-patella syndrome. Nefrologia 2013; 33:585.
Fernandes GC, et al: Nail-patella syndrome. J Clin Rheumatol 2011; 17:402.

Granata A, et al: Nail-patella syndrome and renal involvement. Clin Nephrol 2008; 69:377.

Onychophagia

Nail biting is a common compulsive behavior that may greatly shorten the nail bed, sometimes damages the matrix, and at times leads to longitudinal melanonychia or pterygium formation. It is a difficult habit to cure. If there is strong motivation, habit reversal training with awareness training, competing response training, and social support may help. Psychopharmacologic intervention with medications, such as serotonin reuptake inhibitors, and hypnosis are other options.

Anolik RB, et al: Onychophagia-induced longitudinal melanonychia. Pediatr Dermatol 2012; 29:488.
Durdu M, et al: Clinical and cytologic features of antibiotic-resistant acute paonychia. J Am Acad Dermatol 2014; 70:120.

Pacan P, et al: Onychophagia and onychotillomania. Acta Derm Venereol 2014; 94:67.

Onychotillomania

Onychotillomania is a compulsive neurosis in which the patient picks constantly at the nails or tries to tear them off. This obsessive-compulsive disorder may be treated by habit reversal training, hypnosis, or psychopharmacologic agents.

Pacan P, et al: Onychophagia and onychotillomania. Acta Derm Venereol 2014; 94:67.
Reese JM, et al: Onychotillomania. J Cutan Pathol 2013; 40:419.
Snorrason I, et al: Nail picking disorder (onychotillomania). J Anxiety Disord 2014; 28:211.

Onycholysis

Onycholysis is a spontaneous separation of the nail plate, usually beginning at the free margin and progressing proximally. Rarely, the lateral borders may be involved, with spread

confined to these. Less often, separation may begin proximal to the free edge, in an oval area 2–6 mm broad, with a yellowish brown hue ("oil spot"). This is a lesion of psoriasis; distal onycholysis is also often caused by psoriasis. The nail itself is smooth and firm with no inflammatory reaction. Underneath the nail, a discoloration may occur from the accumulation of bacteria, most frequently *Pseudomonas,* or yeast, usually *Candida.* Color changes, such as green (a result of pyocyanin from *Pseudomonas*), black, or blue may be seen. One or more nails may be affected.

Onycholysis is noted most often in women, probably secondary to traumatically induced separation. It is common in patients with hand dermatitis. Keratinization of the distal nail bed, chronic exposure to irritants, untreated dermatitis, and secondary infection with *Candida albicans* are potential reasons for the failure of the nail to reattach itself.

The many systemic causes include hyper/hypothyroidism, pregnancy, porphyria, pellagra, and syphilis. Onycholysis has also been associated with atopic dermatitis, eczema, lichen planus, congenital abnormalities of the nails, trauma induced by clawing, pinching, stabbing (manicuring), and foreign body implantation. It may be caused by mycotic, pyogenic, or viral (herpes) infections. Women should be checked for vaginal candidiasis, because that anatomic location may be the source of the infection opportunistically invading and aggravating onycholysis. Chemical causes may include the use of solvents, nail polish base coat, nail hardeners containing formalin derivatives, artificial fingernails, and allergic or irritant contact dermatitis from their use. Rarely, photo-onycholysis may occur during or soon after therapy with tetracycline derivatives, psoralens, fluoroquinolones, or chloramphenicol and subsequent exposure to sunlight. Chemotherapeutic agents and systemic retinoids may induce onycholysis. On rare occasions, it may be a sign of subungual exostoses, squamous cell carcinoma, or metastasis. Autosomal dominant hereditary forms are also known.

Trauma and chemical irritants should be completely avoided and the nail bed kept completely dry. The affected portion of the nail should be kept clipped away. Drying by exposing the nail bed in this way will rid the area of *Pseudomonas* and assist greatly in eliminating *Candida.* The combination of drying and topical corticosteroids to minimize inflammation will often allow for reattachment of the nail and improvement or cure. Usually, this process takes 3–6 months or more.

Median nail dystrophy (dystrophia unguis mediana canaliformis, solenonychia)

Median nail dystrophy consists of longitudinal splitting or canal formation in the midline of the nail. The split, which often resembles a fir tree, occurs at the cuticle and proceeds outward as the nail grows (Fig. 33-49). Trauma has been suspected of being the chief cause. Repeated typing with the nail tip on a personal digital assistant (PDA) has been reported to cause a median nail dystrophy. Some cases will resolve with avoidance of trauma or occlusive therapy with tacrolimus ointment; however, many will persist for years despite scrupulous care. The deformity may result from a papilloma or glomus tumor in the nail matrix, producing a structure resembling a tube (solenos) distal to it. Familial cases and an onset with isotretinoin or retonavir therapy are other associations.

Pterygium unguis

Pterygium unguis forms as a result of scarring between the proximal nailfold and matrix. The classic causative example is lichen planus. It has been reported to result from sarcoidosis, porokeratosis of Mibelli, peripheral circulatory disturbances, and Hansen's disease. Onychomatricoma may infrequently simulate pterygium, but histologic examination will confirm the nature of this benign tumor.

Kim DS, et al: Pterygium unguis formation in porokeratosis of Mibelli. Br J Dermatol 2007; 156:1384.
Perrin C, et al: Onychomatricoma with dorsal pterygium. J Am Acad Dermatol 2008; 59:990.

Pterygium inversum unguis

Pterygium inversum unguis is characterized by adherence of the distal portion of the nail bed to the ventral surface of the nail plate (Fig. 33-50). The condition may be present at birth or acquired and may cause pain with manipulation of small objects, typing, and close manicuring of the nail. It results from the extension of the zone of the nail bed that normally contributes to the formation of the nail plate. This eventually leads to a more ventral and distal extension of the hyponychium. The most common forms of pterygium inversum unguis are the acquired secondary types caused by systemic connective tissue diseases, particularly progressive systemic sclerosis and SLE.

Fig. 33-50 Pterygium inversum unguis.

Fig. 33-51 Pincer nails.

Hangnail

Hangnail is an overextension of the eponychium (cuticle), which becomes split and peels away from the proximal or lateral nailfold. These lesions are painful and annoying; persistent cuticle biting frequently develops. Trimming these away with scissors is the best solution. The use of emollient creams to keep the cuticle soft is also recommended.

Lee HJ, et al: Minor cutaneous features of atopic dermatitis in South Korea. Int J Dermatol 2000; 39:337.

Pincer nails

Pincer nails, trumpet nails, or omega (from the shape of the Greek letter) nails are alternative terms for a common toenail disorder in which the lateral edges of the nail slowly approach one another, compressing the nail bed and underlying dermis (Fig. 33-51). It may less often occur in the fingernails and, surprisingly, is usually asymptomatic. Infrequently, pain, recurrent or chronic infections, or even underlying osteomyelitis may complicate this condition. It may be an autosomal dominant inherited condition, may be acquired after trauma, or associated with Kawasaki's disease, renal disease, LE, or use of β-adrenergic blockers or pamidronate.

Some treatment success has been obtained using commercial plastic braces after flattening of the nail. Urea ointment under occlusion, various surgical approaches, and chemical matricectomy with phenol and surgical nail bed repair have also been reported to be effective.

Onychocryptosis (unguis incarnatus, ingrown nail)

Ingrown toenail is one of the most frequent nail complaints. It occurs chiefly on the great toes, where there is an excessive lateral nail growth into the nailfold, leading to this painful, inflammatory condition. The lateral margin of the nail acts as a foreign body and may cause exuberant granulation tissue. Unguis incarnatus may be caused by wearing improperly fitting shoes and by improper trimming of the nail at the lateral edges so that the anterior portion cuts into the flesh as it grows distally. Drugs such as isotretinoin, lamivudine, and indinavir may induce periungual granulation tissue, mimicking onychocryptosis.

In mild cases, soaking the foot in warm soapy water and insertion of a cotton pad, dental floss, or a flexible plastic tube beneath the distal corner of the offending nail may make surgery unnecessary. When surgical intervention is necessary, simple removal of the lateral portion of the nail plate can produce significant relief. Another simple procedure involves removal of the overhanging lateral nailfold so that the nail does not cut into it. When healed, the nail edge resembles that of the thumb, and an excellent functional result occurs. The nail is not altered, since it is not touched.

Partial or complete nail avulsion with ablation of the nail matrix will prevent recurrence. Ablation can be accomplished surgically, with phenol, 10% sodium hydroxide, or with a CO_2 laser. When phenol is used, the proximal nailfold should be incised and reflected to avoid burning it. As an alternative, the nailfold can be left in place and injected with a corticosteroid to reduce the subsequent inflammation. Liquid nitrogen spray to the area of tissue and nail involved for a freeze time of 20–30 s has been successful in some patients. This may be painful, however, and is reserved for patients who are not candidates for other surgical approaches.

Retronychia

Retronychia is an unusual event associated with ingrowing of the nail plate into the proximal nailfold. This then induces a chronic paronychia. The cause in the few cases reported has been trauma, usually of the great toe. An incomplete shedding of the nail plate results in the new, growing nail pushing the old, partially detached nail plate up and backward into the proximal nailfold. Avulsion is curative.

Leukonychia or white nails

Five forms of white nail are recognized: leukonychia punctata, leukonychia striata, longitudinal leukonychia, leukonychia partialis, and leukonychia totalis. The punctate variety is common in normal persons with otherwise normal nails (Fig. 33-52). Leukonychia striata, or transverse white parallel line, may be hereditary, of traumatic origin, or associated with systemic diseases such as HIV or Kawasaki's, or with drugs such as those used in chemotherapy. Longitudinal white lines are seen in Hailey-Hailey disease and with oncychopapillomas. Partial leukonychia may occur with tuberculosis, nephritis, complex regional pain syndrome, Hodgkin disease, chilblains, metastatic carcinoma, or Hansen's disease, or it may be idiopathic.

Leukonychia totalis may be hereditary, of a simple autosomal dominant type. Mutations in the *PLCD1* gene are responsible. It may also be associated with electron beam therapy, typhoid fever, Hansen's disease, cirrhosis, ulcerative colitis, HIV, nail biting, use of emetine or vorinostat, complex regional pain syndrome, cytostatic agents, and trichinosis. Leukonychia may result from abnormal keratinization, with persistence of keratohyalin granules in the nail plate. A syndrome comprising leukonychia totalis, multiple sebaceous cysts, and renal calculi in several generations has been reported. Other reports have linked total leukonychia with deafness or with koilonychia; however, it is most often inherited as an isolated finding.

Longitudinal erythronychia

Longitudinal red bands in the nail plate that commence in the matrix and extend to the point of separation of the nail plate and nail bed may occur on multiple nails with inflammatory conditions, such as lichen planus, graft-vs-host disease, amyloidosis, acrokeratosis verruciformis of Hopf, or Darier's disease, or as an isolated finding. When only a localized single or bifid streak is present on a single digit, this may signal a benign or malignant tumor of the matrix. The fingernails of middle-age persons are most often affected, with the thumbnail usually involved. There may be a benign lesion such as a glomangioma, a distal keratosis, as with Darier's disease, human papillomavirus (HPV) infection, or an onychopapilloma; however, malignancies such as squamous cell carcinoma or amelanotic melanoma may be present. Excision of this distal keratosis, however, usually does not result in cure or diagnostic findings; biopsy of the affected matrix is necessary. When the presentation is polydactylous, biopsy is rarely done. In solitary monodactylous, single or bifid bands in men over 50 a biopsy should be seriously considered. If observation is the decision, as in longitudinal melanonychia, if the band broadens over time, excisional biopsy is indicated, because this may be secondary to an amelanotic melanoma or squamous cell carcinoma. In patients with painful lesions excision will result in cure and diagnosis.

Perrin C: Tumors of the nail unit. Am J Dermatopathol 2013; 35:621.

Melanonychia

Black or brown pigmentation of the normal nail plate is termed melanonychia. The entire nail may be involved or multiple longitudinal or transverse bands on several nails may occur. In such cases the following conditions may be responsible; it is when there is a solitary acquired longitudinal band that concern for malignancy is paramount. The nail pigment may be present as a normal finding on many digits in black patients. Longitudinal black or brown banding of the nails has been reported to occur in 77–96% of black persons and 11% of Asians. Other causes include trauma, systemic disease, or medication; or as a postinflammatory event from such localized events as lichen planus or fixed drug reaction. Pigmentation of the nails may occur with acanthosis nigricans, Addison's disease, Peutz-Jeghers syndrome, or vitamin B_{12} deficiency; after adrenalectomy for Cushing syndrome; as a part of Laugier-Hunziker syndrome (pigmentation of nails associated with buccal and lip hyperpigmentation); with PUVA or ionizing radiation treatment; and as drug-induced melanocyte activation with such medications as chemotherapy, antimalarials, minocycline, antivirals (zidovudine [Fig. 33-53] or lamivudine), or metals (gold, arsenic, thallium, mercury). Drugs may induce both transverse and longitudinal bands, with multidrug chemotherapy causing most transverse bands. Friction may cause longitudinal pigmented bands in the toenails, and subungual hemorrhage or black nail caused by *Proteus mirabilis* or a variety of fungi may enter into the differential diagnosis of a dark nail.

When only one nail is affected by melanonychia striata—a single, longitudinal, brown or black band (Fig. 33-54)—a tumor of the nail matrix is the most important consideration. The location in the matrix can be inferred from the location of the pigment in the nail plate when viewed end-on. Dorsal nail plate pigmentation results from a proximal matrix lesion. Ventral nail-plate pigmentation is the result of a lesion in the distal matrix.

Fig. 33-53 Zidovudine-induced hyperpigmentation of the nail.

Fig. 33-54 Longitudinal melanonychia.

Tosti et al. studied 100 white adult patients with a single band of longitudinal melanonychia of unknown cause. Biopsies revealed melanocytic hyperplasia in 65, nevi in 22, melanocytic activation in 8, and melanoma in 5. Whereas the authors were unable to ascertain any clear clinical criteria that would exclude melanoma, they recommended a biopsy in any adult with the appearance of a longitudinal band of pigment in only one nail without a clear relation to a definite cause. Other reasons to biopsy include a band that has a triangular shape (wider at proximal than distal part), a blurred lateral border of the band, a lack of homogeneity of the pigmentations (bands or lines of different color), a band over 6 mm in width, or pigmentation of the periungual skin (Hutchinson's sign). The latter is not pathognomonic, however, because Bowen's disease may produce this appearance, and pigmentation of the nail matrix and proximal nail bed may reflect through the nailfold (pseudo-Hutchinson's sign). Finally, dermoscopic features that suggest melanoma are a brown coloration of the background and the presence of irregular coloration, spacing, or thickness of longitudinal lines or disruption of their parallelism. Retracting the proximal nailfold to expose the origin of the streak at the matrix allows selection of the best biopsy site. The recommended biopsy includes the whole lesion; this may be accomplished by the tangential matrix excision, which may leave minimal scarring in some patients, or more certainly, this is accomplished by longitudinal excision.

Recommendations for prepubertal children, however, are different. Longitudinal melanonychia that appears in children is usually benign in nature, and it is recommended that since an ungual melanocytic band can appear at an age when other nevi appear, the majority can be followed. If the lesion is alarming in its appearance, however, especially if widening or darkening, sampling the whole lesion by tangential matrix or longitudinal excision is necessary.

Green nails

When onycholysis is present, a green discoloration may occur in the onycholytic area as a result of an infection with *Pseudomonas aeruginosa* (see Chapter 14). The color change may also occur as transverse green stripes. The stripes are ascribed to intermittent episodes of infection. Green nails may also result from copper in tap water.

Hengge UR, et al: Green nails. N Engl J Med 2009; 360:1125.

Staining of nail plate

Nicotine, dyes (including hair dyes and nail polish), potassium permanganate, mercury compounds, hydroquinone, elemental iron, mepacrine, photographic developer, anthralin, chrysarobin, glutaraldehyde, or resorcin may cause nail plate staining. This is only a partial list; Mendiratta and Jain provide a complete listing. A helpful diagnostic maneuver to distinguish nail plate staining from exogenous sources and nail plate pigmentation from melanin or endogenous chemicals is to scrape the surface of the nail plate several times firmly with a glass slide or scalpel blade. Exogenous stains frequently scrape off completely if the agent has not penetrated the entire nail plate. If the stain follows the curvature of the lunulae, it is probably endogenous; if it follows the curvature of the proximal and lateral nailfolds, it is exogenous.

Mendiratta V, et al: Nail dyschromias. Indian J Dermatol Venereol Leprol 2011; 77:652.

Red lunulae

Dusky erythema confined to the lunulae has been reported in association with alopecia areata. About 20% of patients with SLE have been reported to have this abnormality. Red lunulae may also be seen in patients taking oral prednisone for severe rheumatoid arthritis or dermatomyositis, as well as in cardiac failure, cirrhosis, lymphogranuloma venereum, psoriasis, vitiligo, chronic urticaria, lichen sclerosus et atrophicus, CO_2 poisoning, chronic obstructive pulmonary disease, twenty-nail dystrophy, and reticulosarcoma. The cause may be vascular congestion.

Tunc SE, et al: Nail changes in connective tissue diseases. J Eur Acad Dermatol Venereol 2007; 21:497.

Spotted lunulae

This distinctive change occurs with alopecia areata.

Cohen PR: The lunula. J Am Acad Dermatol 1996; 34:943.

Purpura of nail beds

Purpura beneath the nails usually results from trauma. Causes of toe involvement include physical pressure on the toes, such as that seen in surfboarding caused by a windsurfer trying to maintain balance, or exogenous pressure exerted from poorly fitting shoes. Nail bed purpura may simulate a melanoma if the patient does not communicate the acuteness at onset.

Pierson JC, et al: Pen push purpura. Cutis 1993; 51:422.

Blue nails

A blue discoloration of the lunulae is seen in argyria and cases of hepatolenticular degeneration (Wilson's disease). The blue color in the latter is probably related to the changes in copper metabolism by the patient. It has also been reported in hemoglobin M disease and hereditary acrolabial telangiectases. Lunular blue color, as well as blue discoloration of the whole nail bed, occurs with some therapeutic agents, especially 5-FU, minocycline, imipramine, mepacrine and other antimalarials, hydroxyurea, phenolphthalein, and azidothymidine. Blue discoloration may also result from subungual hematoma, blue nevi, and melanotic whitlow. Blue nails are a normal variant finding in black people.

Kim Y, et al: A case of generalized argyria after ingestion of colloidal silver solution. Am J Ind Med 2009; 52:246.

Yellow nail syndrome

The yellow nail syndrome is characterized by marked thickening and yellow to yellowish green discoloration of the nails often associated with systemic disease, most often lymphedema and compromised respiration. The nails are typically overcurved both transversely and longitudinally, grow very slowly (<0.2 mm/week), are often subject to onycholysis, and lose both lunulae and cuticles (Fig. 33-55). Lymphedema, pleural effusions, chronic pulmonary infections, and chronic sinusitis most frequently precede the nail changes. Other less frequently associated conditions include autoimmune disorders, immunodeficiency states, use of gold or D-penicillamine, and malignancies. In the latter cases, treatment of the underlying lymphoma or solid tissue tumor has resulted in improvement of the nail findings. Individual clinical responses have been seen with oral zinc or 800 IU/day of D-α-tocopherol alone or in combination with itraconazole. Although 30–50% of patients experience spontaneous improvement in the condition of their nails, fluconazole taken in combination with vitamin E cured or improved all 13 patients treated by Baran et al.

NEOPLASMS OF THE NAIL BED

Various benign and malignant neoplasms may occur in or overlying the nail matrix and in the nail bed. Signs heralding such neoplasms are paronychia, ingrown nail, onycholysis, pyogenic granuloma, nail plate dystrophy, longitudinal erythronychia, bleeding, and discolorations. Symptoms of pain, itching, and throbbing may also occur with various neoplasms.

Benign tumors of the nails include verruca, pyogenic granuloma, fibromas, nevus cell nevi, myxoid cysts, angiofibromas (Koenen tumors), onychopapillomas, and epidermoid cysts. Pyogenic granuloma–like lesions may occur during treatment with isotretinoin, lamivudine, indinavir, or the epidermal growth factor receptor inhibitor family of drugs. Glomangioma is readily recognized by exquisite tenderness in the nail bed. Enchondroma of the distal phalanx often presents as a paronychia. Subungual exostoses may also present as an inflammatory process, but more often resemble a verruca at the start. Most of these are on the great toe, and radiographic evaluation will aid in the diagnosis of these last two entities. Onychopapillomas are benign tumors of the nail bed that usually present as longitudinal erythronychia. Tender swelling of the distal finger with nail distortion and radiographic evidence of solitary lytic changes can be caused by intraosseous epidermoid cysts.

Onychomatricoma is a benign tumor of the nail matrix. It presents as a yellow, thickened plate growing out from under

Fig. 33-56 Onychomatricoma. (Courtesy of Dr. Adam Rubin.)

Fig. 33-57 Bowen's disease.

the proximal nailfold and then extending distally in a longitudinal band (Fig. 33-56). There is an increased transverse curvature of the nail, and splinter hemorrhages often are seen in the proximal nail. Infrequently, it can appear as a cutaneous horn emanating from the proximal nailfold, with dorsal pterygium formation. Biopsy at the matrix origin will permit diagnosis.

Bowen's disease and squamous cell carcinoma of the nail bed are uncommon. Radiographs may reveal lytic changes in the distal phalanx. Metastases are rare. Mohs surgery is the treatment of choice. When these lesions occur on more than one digit, they are proved to be secondary to HPV infection. Bowen's disease may be pigmental (Fig. 33-57). When keratoacanthoma occurs, there is often lysis of underlying bone, which fills in after excision of the tumor. Basal cell carcinoma may occur but is uncommon in this location.

Subungual melanoma is frequently diagnosed late in the course of growth (Fig. 33-58), since it simulates onychomycosis or subungual hematoma, with which it is confused. Amelanotic melanoma may occur and may be mistaken for granuloma pyogenicum. Although melanoma is rare among Japanese, periungual and subungual melanoma is more frequently found in Japanese than in other ethnic populations. Melanoma in this location is discussed in Chapter 30 and in the melanonychia section of this chapter.

Onycholemmal carcinoma is a slowly growing, malignant tumor of the nail bed epithelium. It is composed of small cysts filled with eosinophilic amorphous keratin. The cyst wall is lined with atypical keratinocytes. No granular layer is seen.

Fig. 33-58 Subungual melanoma.

Also, solid nests and strands of atypical keratinocytes fill the dermis and may invade the bone. Mohs excision or even disarticulation of the digit may be necessary.

Evaluation of these masses may be carried out by plain x-ray films, looking for bone lysis or other changes. MRI by both T1-weighted spin-echo images and turbo spin-echo T2-weighted images may offer excellent diagnostic information about these tumors as well. Histologic examination remains the diagnostic gold standard.

34 Disorders of the Mucous Membranes

Lesions on the mucous membranes may be more difficult to diagnose than lesions on the skin, and not merely because they are less easily and less often seen. There is less contrast of color and greater likelihood of alterations in the original appearance because of secondary factors, such as maceration from moisture, abrasion from food and teeth, and infection. Vesicles and bullae rapidly rupture to form grayish erosions, and the epithelium covering papules becomes a soggy, lactescent membrane, easily rubbed off to form an erosion. Grouping and distribution are less distinctive in the mouth than on the skin, and in some cases, it is necessary to establish the diagnosis by observing the character of any associated cutaneous lesions or by noting subsequent developments.

CHEILITIS

Cheilitis exfoliativa

The term cheilitis exfoliativa has been used to designate a primarily desquamative, mildly inflammatory condition of the lips, of unknown cause, and also a clinically similar reaction secondary to other disease states. The former is a persistently recurring lesion that produces scaling and sometimes crusting; it most often affects the upper lip. The recurrent exfoliation leaves a temporarily erythematous and tender surface.

In the latter form, the lips are chronically inflamed and covered with crusts that from time to time tend to desquamate, leaving a glazed surface on which new crusts form. Fissures may be present, and there may be burning, tenderness, and some pain. The lower lip is more often involved, with the inflammation limited to the vermilion part. The cheilitis may be secondary to seborrheic dermatitis, atopic dermatitis (AD), psoriasis, retinoid therapy, pyorrhea, long-term actinic exposure, or the habit of lip licking (Fig. 34-1). Infrequently, the initial or only manifestation of AD may be a chronic cheilitis. Irritating or allergenic substances in lipsticks, dentifrices, and mouthwashes may be causative factors. Dyes in lipsticks may photosensitize. Candidiasis may be present. Cheilitis may be part of Plummer-Vinson or Sjögren syndrome. Cheilitis is seen in patients with acquired immunodeficiency syndrome (AIDS), and it is a known common complication of protease inhibitor therapy. These and other, uncommon causes of cheilitis are discussed in more detail within the specific entities.

The only uniformly effective treatment of cheilitis exfoliativa is the elimination of causes when they can be found. Topical tacrolimus ointment, pimecrolimus cream, or low-strength corticosteroid ointments and creams are usually helpful. If the underlying etiology is determined, specific therapy may be instituted. When there are fissures, petrolatum or zinc oxide ointment may be useful.

Mani SA, et al: Exfoliative cheilitis. J Can Dent Assoc 2007; 73:629.

Allergic contact cheilitis

The vermilion border of the lips is much more likely to develop allergic contact sensitivity reactions than is the oral mucosa. Allergic cheilitis is characterized by dryness, fissuring, edema, crusting, and angular cheilitis. Over 90% of patients are women and over half of the reactions are caused by lipsticks. While patch testing with standard allergens will reveal a relevant positive in approximately 25–30% of patients, about 1 in 5 will only react to their own product. It may result from use of topical medications, dentifrices and other dental preparations, antichap agents, lipsticks, and sunscreen-containing lip balms; from contact with cosmetics, nail polish, rubber, and metals; or from eating foods such as mangoes. Fragrance and nickel are the most commonly identified individual sensitizers.

Treatment includes discontinuation of exposure to the offending agent and administration of topical tacrolimus, pimecrolimus, or corticosteroid preparations.

Actinic cheilitis

Actinic cheilitis is an inflammatory reaction of the lips to chronic excessive sunlight exposure over many years. The lower lip, which is usually the only one involved, becomes scaly, fissured, atrophic, and at times eroded and swollen; leukoplakia and squamous cell carcinoma (SCC) may develop (Fig. 34-2). Painful erosions may occur; actual ulceration is very rare unless carcinoma has developed. Hereditary polymorphous light eruption can resemble chronic actinic cheilitis, but it has no malignant potential.

Fig. 34-1 Cheilitis secondary to lip licking.

Fig. 34-2 Actinic cheilitis.

Avoiding sun exposure and the use of sunscreen containing lip pomades suffice to minimize further damage. A biopsy should be performed on any suspicious, thickened areas that persist; preferably, a shave technique should be used to avoid scarring.

Cryosurgical treatment may be effective, particularly for localized lesions. In cases with diffuse involvement, application of topical 5-fluorouracil (5-FU), imiquimod, ingenol, or photodynamic therapy (PDT) may be curative. Treatment with a thulium fractionated or ablative erbium laser, dermabrasion, or electrodesiccation may be required for severe disease and provides excellent results. Long-term follow-up is necessary; residual dysplasia is present with each treatment. Should treatment fail, vermilionectomy of the lower lip may be necessary. Excision of the exposed vermilion mucous membrane with advancement of the labial mucosa to the skin edge of the outer lip is effective, but this is performed less frequently since the advent of laser therapy. Refer to Chapter 29 for more information on actinic cheilitis.

Cheilitis glandularis

Cheilitis glandularis is characterized by swelling and eversion of the lower lip, patulous openings of the ducts of the mucous glands, cysts, and at times, abscess formation. There is general enlargement of the lips (Fig. 34-3). Mucus exudes freely to form a gluey film that dries over the lips and causes them to stick together during the night. When the lip is palpated between the thumb and index finger, the enlarged mucous glands feel like pebbles beneath the surface. The lower lip is the site of predilection. Middle-age men are most often affected. Cheilitis glandularis is a chronic inflammatory reaction that is caused by an exuberant response to chronic irritation, or to atopic, factitious, or actinic damage.

On biopsy, there is a moderate histiocytic, lymphocytic, and plasmacytic infiltration in and around the glands. Cheilitis glandularis has been reported to eventuate in SCC, but these cases may be attributed to chronic sun exposure, which frequently precedes cheilitis glandularis.

Treatment depends on the nature of the antecedent irritation; in most cases, treatment as described for actinic cheilitis is appropriate. Surgical debulking may be necessary. Intralesional triamcinolone may be beneficial in some patients, as may the combination of minocycline and tacrolimus ointment.

Reiter S, et al: Cheilitis glandularis. Oral Diseases 2011; 17:335–339.

Angular cheilitis

Angular cheilitis is synonymous with perlèche. Fissures radiate downward and outward from the labial commissures. It is an intertriginous dermatitis caused by excessive wetness or dryness. It is often complicated by secondary infection with *Candida albicans* or *Staphylococcus aureus*.

The disease usually occurs in elderly people who wear dentures, but it may develop simply from an overhanging of the upper lip and cheek, and recession and atrophy of the alveolar ridges in old age. Measuring the facial dimensions with a ruler and tongue blade will help with objective assessment of the importance of decreased vertical facial dimension in the development of perlèche. If the distance from the base of the nose

to the lower edge of the mandible is greater than or equal to 6 mm less than the distance from the center of the pupil to the parting line of the lips, the vertical dimension is decreased. In these circumstances, drooling is usually a factor. In children, angular cheilitis occurs frequently in thumb suckers, gum chewers, and lollipop eaters. Other inciting factors include riboflavin deficiency, anorexia nervosa, Down syndrome, intraoral candidiasis, especially in patients with diabetes, AIDS, chronic mucocutaneous candidiasis, Sjögren syndrome, orthodontic treatment, drug-induced xerostomia, and AD.

Opening the "bite" by improving denture fit, capping teeth, replacing lost teeth, or increasing denture height, combined with topical use of nystatin and iodochlorhydroxyquin in hydrocortisone ointment, is usually effective when the condition is associated with anatomically predisposing factors. Stubborn cases typically respond to a slightly stronger corticosteroid, such as desonide, in combination with a topical anticandidal agent. Injection of collagen or insertion of Softform implants to obliterate the angular creases may be beneficial. Therapy for underlying diseases should be maximized. If *S. aureus* is present, mupirocin ointment may be needed. Excision of the region, followed by a rotating flap graft, is another therapeutic option, but surgery should be reserved for resistant cases.

Plasma cell cheilitis

This is also referred to as plasma cell orificial mucositis or, when the gingival is the site of involvement, plasma cell gingivitis. It is characterized by a sharply outlined, infiltrated, dark red plaque with a lacquer-like glazing of the surface of the involved area. This lesion has the same microscopic features as Zoon balanitis plasmacellularis. There is plasma cell infiltration in a bandlike pattern. Plasma cell cheilitis is not a response that is specific for any stimulus but rather represents a reaction pattern to any one of a variety of stimuli. Successful therapies include application of topical tacrolimus ointment or clobetasol propionate ointment twice daily.

Plasmoacanthoma

Plasma cell cheilitis and plasmoacanthoma have been reported in the same patient and are believed to represent a spectrum of the same disease. Plasmoacanthoma is a verrucous tumor with a plasma cell infiltrate involving the oral mucosa, particularly along the angles. Other locations may occur, such as the perianal, periumbilical, or inguinal areas and toe webs. *C. albicans* has been found within the tissue, suggesting that it may be implicated as a cause of this disease. Excision, destruction, anticandidal preparations, and intralesional steroids are all options for treatment.

Fig. 34-4 Fixed drug eruption.

Drug-induced ulcer of the lip

Painful or tender, well-defined ulcerations without induration on the lower lip may heal after withdrawal of oral medications. The causative drugs may be phenylbutazone, chlorpromazine, phenobarbital, methyldopa, or thiazide diuretics. Solar exposure appears to be a predisposing causative influence; in some cases, this reaction may represent a fixed drug photoeruption. On rare occasions, fixed drug eruptions may also involve the lip, usually caused by naproxen, one of the oxicams, or trimethoprim-sulfamethoxazole (Fig. 34-4).

Pemberton MN, et al: Fixed drug eruption to oxybutynin. Oral Surg Oral Med Oral Pathol Oral Radiol Endod 2008; 106:e19.

Other forms of cheilitis

Several diseases discussed elsewhere may affect the lips, including lichen planus, lupus erythematosus, erythema multiforme, AD, and psoriasis. A high percentage of patients with Down syndrome have cheilitis of one or both lips. Lip biting may be a factor.

ORAL AND CUTANEOUS CROHN'S DISEASE

Crohn's disease is a chronic granulomatous disease of any part or parts of the bowel. Patients with Crohn's disease may develop inflammatory hyperplasia of the oral mucosa, with metallic dysgeusia and gingival bleeding. Reported typical changes include diffuse oral swelling, focal mucosal hypertrophy and fissuring (cobblestoning), persistent ulceration, polypoid lesions, indurated fissuring of the lower lip, angular cheilitis, granulomatous cheilitis, or pyostomatitis vegetans. Oral involvement occurs in 10–20% of patients with Crohn's disease, and 90% have granulomas on biopsy. Males with early-onset disease are most often affected. Concomitant involvement of the anal and esophageal mucosa is common.

Many cases of Crohn's disease with other cutaneous manifestations have been reported, notably pyoderma gangrenosum (more closely associated with ulcerative colitis) and erythema nodosum, polyarteritis nodosa, pellagra, pernicious anemia, an acrodermatitis-like eruption, urticaria, and necrotizing vasculitis. Direct extension to perianal skin may occur.

Metastatic Crohn's disease denotes noncaseating granulomatous skin lesions in patients with Crohn's disease. In the absence of bowel involvement, the diagnosis cannot be made. The morphologic appearances seen include genital swelling or

condyloma-like lesions, leg ulceration, pyogenic granuloma–like lesions of the retroauricular skin, and erythematous nodules, plaques, or ulcers in other locations.

Treatment of the gastrointestinal (GI) manifestations with sulfasalazine, metronidazole, systemic corticosteroids, infliximab, or immunosuppressive medications such as cyclosporine, azathioprine, mycophenolate mofetil, and methotrexate can improve the cutaneous findings. Several delivery systems use only the active ingredient of sulfasalazine, mesalamine, including Asacol, Pentasa, Rowasa, and olsalazine, and may be useful in treating the skin involvement of Crohn's disease. A mouthwash containing triamcinolone acetonide, tetracycline, and lidocaine may provide symptomatic and objective improvement. Cutaneous ulcerated granulomas and erythematous plaques caused by Crohn's disease may respond to high-potency topical corticosteroids or tacrolimus ointment. Curettage and zinc by mouth have resulted in healing in several reported patients. Dietary manipulation is another measure that can be helpful in select individuals. The course is often prolonged over several years.

PYOSTOMATITIS VEGETANS

Pyostomatitis vegetans, an inflammatory stomatitis, is most often seen in association with ulcerative colitis but may also occur in other inflammatory bowel diseases, such as Crohn's disease. Edema and erythema with deep folding of the buccal mucosa characterize pyostomatitis vegetans, together with pustules, small vegetating projections, erosions, ulcers, and fibrinopurulent exudates (Fig. 34-5). Eroded pustules fuse into shallow ulcers, resulting in characteristic "snail-track" ulcers. It has also been associated with sclerosing cholangitis. Several cases have been reported with no underlying systemic disorder.

Histologically, there are dense aggregates of neutrophils and eosinophils. At times, crusted erythematous papulopustules that coalesce into asymmetric annular plaques may occur with or after the oral lesions. These associated skin lesions favor the axillae, groin, and scalp and are termed pyodermatitis vegetans. Topical corticosteroids or tacrolimus ointment may be effective; systemic corticosteroids or infliximab, however, are usually necessary.

CHEILITIS GRANULOMATOSA

Cheilitis granulomatosa is characterized by a sudden onset and progressive course, terminating in chronic enlargement of the lips. Usually, the upper lip becomes swollen first; several months may elapse before the lower lip becomes swollen. Usually, only enlargement is present, without ulceration, fissuring, or scaling. The swelling remains permanently. It may be a part of the Melkersson-Rosenthal syndrome when associated with facial paralysis and plicated tongue.

The cause is unknown. Histologically, cheilitis granulomatosa is characterized by an inflammatory reaction of lymphocytes, histiocytes, and plasma cells and by tuberculoid granulomas consisting of epithelioid and Langerhans giant cells. At times, intralymphatic granulomas are found and may account for the clinical swelling. In the differential diagnosis, solid edema, angioedema, cheilitis glandularis, sarcoidosis, oral Crohn's disease, infectious granulomas, contact allergy, reaction to silicone fillers, and Ascher syndrome must be considered. This cheilitis may be the presenting sign in a patient who will develop Crohn's disease or sarcoidosis at a later time.

Treatment with intralesional injections of corticosteroids is usually successful but temporary. Combining this modality with oral anti-inflammatory agents for long-term control, such as doxycycline, dapsone, colchicine, sulfasalazine, hydroxychloroquine, anti–tumor necrosis factor (TNF) agents, or topical tacrolimus ointment, is an excellent strategy. In the firmly established case, surgical repair of the involved lip through a mucosal approach and, in some cases, concomitant intralesional corticosteroid treatment provide the best results.

Fig. 34-6 Melkersson-Rosenthal syndrome. (Courtesy of Dr. Shyam Verma.)

MELKERSSON-ROSENTHAL SYNDROME

Melkersson in 1928 and Rosenthal in 1930 described a triad consisting of recurring facial paralysis or paresis, soft nonpitting edema of the lips, and scrotal tongue. Attacks usually start during adolescence, with permanent or transitory paralysis of one or both facial nerves, repeated migraines, and recurring edema of the upper lip, cheeks, and occasionally the lower lip and circumoral tissues. Swelling of the skin and mucous membranes of the face and mouth is the dominant finding and most important diagnostic feature (Fig. 34-6). In order of frequency, the swelling occurs first on the upper lip, then the lower lip, and then other regions. Chronic eyelid swelling may occur.

Extrafacial swellings appear on the dorsal aspect of the hands and feet and in the lumbar region. The pharynx and respiratory tract may be involved, with thickening of the mucous membrane. The relapsing condition produces an overgrowth of connective tissue, edema, and atrophy of the muscle fibers, with permanent deformities of the lips, cheeks, and tongue.

The cause of Melkersson-Rosenthal syndrome is unknown. The association at times with megacolon, otosclerosis, and craniopharyngioma supports the theory of a neurotrophic origin. It may be familial.

Histopathologic evaluation shows a tuberculoid type of granuloma with lymphedema and a banal perivascular infiltrate. Intralymphatic granulomas may account for the swelling. In the differential diagnosis, a number of diseases characterized by edema of the lips must be considered. Ascher syndrome consists of swelling of the lips with edema of the eyelids (blepharochalasis) and is inherited. Melkersson-Rosenthal syndrome must also be differentiated from the acute swellings produced by angioedema, trauma, and infections of all types. Lymphangioma, hemangioma, neurofibroma, and sarcoidosis are some of the clinical considerations.

Melkersson-Rosenthal syndrome is frequently seen in an incomplete form, and other granulomatous diseases may present as swellings of the lips or orofacial tissues. It is worthwhile calling these, as a group, "orofacial granulomatosis" so that various underlying disease states or etiologic factors will not be missed when evaluating such patients. Oral Crohn's disease, patients who will develop typical Crohn's or sarcoidosis in the future, cheilitis granulomatosa, sarcoidosis, granulomatous infiltrates associated with tooth infections, and patients with food or contact allergic reactions should all be considered.

Intralesional injections of corticosteroids may be beneficial therapy. Again, combining this with oral anti-inflammatory agents for long-term control, such as doxycycline, dapsone, colchicine, sulfasalazine, hydroxychloroquine, anti-TNF agents, or topical tacrolimus ointment, is an excellent strategy. Clofazimine and thalidomide are reported to be useful, but availability and side effects limit their use. Surgery alone may be used, or surgery combined with intralesional corticosteroid injections and oral medications may be more successful than any of the three alone. Compression therapy is another adjuvant intervention that may add improvement without side effects. Decompression of the facial nerve may be indicated in patients with recurrent attacks of facial palsy. Odontogenic infection has been reported to initiate this condition, and antibiotic therapy for this may lead to remission.

FORDYCE'S DISEASE (FORDYCE SPOTS)

Fordyce spots are ectopically located sebaceous glands, clinically characterized by minute, orange or yellowish, pinhead-sized macules or papules in the mucosa of the lips, cheeks, and less often the gums. Similar lesions may occur on the areolae, glans penis, and labia minora. Prominent lip involvement may result in a lipstick-like mark left on the rim of a glass mug after consuming a hot beverage (Meffert's sign). Involvement of the labial mucosa with pseudoxanthoma elasticum may simulate Fordyce spots. Because the anomaly is asymptomatic and inconsequential, treatment should be undertaken only if there is a significant cosmetic problem. The carbon dioxide (CO_2) laser, electrodesiccation and curettage, bichloracetic acid, PDT, and isotretinoin are therapeutic options.

Errichetti E, et al: Areolar sebaceous hyperplasia associated with oral and genital Fordyce spots. J Dermatol 2013; 40(8):670.

STOMATITIS NICOTINA

Also known as smoker's keratosis and smoker's patches, stomatitis nicotina is characterized by distinct, umbilicated papules on the palate. The ostia of the mucous ducts appear as red pinpoints surrounded by milky-white, slightly umbilicated, asymptomatic papules. The intervening mucosa becomes white and thick and tends to desquamate in places, leaving raw, beefy-red areas. Ulceration and the formation of aphthous ulcers may occur. Stomatitis nicotina is attributed to heavy smoking in middle-age men, although it has also been reported in nonsmokers who habitually drink hot beverages. Heat may be the causative event. Indeed, the most severe cases are associated with the type of tobacco use that produces intense heat—pipe and reverse smoking. Treatment consists of abstaining from the use of tobacco or the ingestion of hot liquids.

TORUS PALATINUS

Torus palatinus is a bony protuberance in the midline of the hard palate, marking the point of junction of the two halves of the palate. It is asymptomatic. Exostoses also frequently occur in the floor of the mouth, involving the inner surface of the mandible.

FISSURED TONGUE

Also known as furrowed tongue, scrotal tongue, or lingua plicata, fissured tongue is a congenital and sometimes familial condition in which the tongue is generally larger than normal, and plicate superficial or deep grooves are usually arranged so that there is a longitudinal furrow along the median raphe, reminiscent of scrotal rugae (Fig. 34-7).

Fissured tongue is seen in Melkersson-Rosenthal syndrome and in many patients with Down syndrome. Individual case reports have been seen in association with pachyonychia congenita, pemphigus vegetans, and Cowden syndrome. Geographic tongue occurs together with fissured tongue in 50% of patients, and both are more often present in psoriasis patients than nonpsoriatic patients.

The condition gives rise to no difficulty, and treatment is not necessary, except that the deep furrows should be kept clean by use of mouthwashes. Herpetic geometric glossitis may mimic fissured tongue, but it is painful, affects predominantly immunocompromised individuals, and is centered on the back of the dorsal tongue.

GEOGRAPHIC TONGUE

Geographic tongue is also known as lingua geographica, transitory benign plaques of the tongue, glossitis areata exfoliativa, and benign migratory glossitis. In some patients, it is a manifestation of atopy, and in others, of psoriasis. In most, however, it is an isolated finding.

The dorsal surface of the tongue is the site usually affected. Geographic tongue begins with a small depression on the lateral border or the tip of the tongue, smoother and redder than the rest of the surface. This spreads peripherally, with the formation of sharply circumscribed, ringed or gyrate, red patches, each with a narrow, yellowish white border, making the tongue resemble a map. The appearance changes from day to day; patches may disappear in one place and manifest in another. The disease is characterized by periods of exacerbation and quiescence. The lesion may remain unchanged in the same site for long periods. The condition is frequently unrecognized because it produces no symptoms except for the occasional complaint of glossodynia.

There are two clinical variants of geographic tongue. In one type, discrete, annular "bald" patches of glistening, erythematous mucosa with absent or atrophic filiform papillae are noted. Another type shows prominent circinate or annular, white raised lines that vary in width up to 2 mm. The clinical appearance and histopathologic findings of the tongue lesions in pustular psoriasis, reactive arthritis (Reiter syndrome), and geographic tongue are identical; when the tongue lesions occur with psoriasis or reactive arthritis, the name annulus migrans has been suggested for this entity (Fig. 34-8). It has been reported as being acquired in patients with AIDS or as a result of lithium therapy.

Histologically, the main features are marked transepidermal neutrophil migration with the formation of spongiform pustules in the epidermis and an upper dermal mononuclear infiltrate. Although treatment is not usually necessary, a 0.1% solution of tretinoin solution (Retin-A) applied topically has produced clearing within 4–6 days.

Fig. 34-9 Black hairy tongue.

BLACK HAIRY TONGUE

Black or brown hairy tongue occurs on the dorsum of the tongue anterior to the circumvallate papillae, where black, yellowish, or brown patches form, consisting of hairlike intertwining filaments several millimeters long (Fig. 34-9). The "hairs" result from a benign hyperplasia of the filiform papillae of the anterior two thirds of the tongue, resulting in retention of long, conical filaments of orthokeratotic and parakeratotic cells. It occurs much more frequently in men than in women.

Black hairy tongue may be associated with several conditions that may be predisposing factors in its causation: smoking, use of oral antibiotics, xerostomia, psychotropic drugs, and presence of *Candida* on the surface of the tongue.

This lesion may be differentiated both clinically and histologically from oral hairy leukoplakia, which is seen in human immunodeficiency virus (HIV)–infected patients. Hairy leukoplakia is usually seen on the lateral surface of the tongue, at first in corrugated patches, then with time, as solid white plaques that are adherent. Microscopic examination reveals acanthosis, parakeratosis, irregular projections of keratin, and vacuolated keratinocytes with Epstein-Barr virus (EBV) present within them.

A toothbrush may be used to scrub off the projections, either alone, with 1–2% hydrogen peroxide, or after application of Retin-A gel, 40% aqueous solution of urea, or papain (meat tenderizer). Such predisposing local factors as smoking, antibiotics, and oxidizing agents should be eliminated, if possible, and scrupulous oral hygiene maintained.

SMOOTH TONGUE

Also known as bald tongue or atrophic glossitis, the smooth glossy tongue is often painful and results from atrophy of the filiform and eventually the fungiform papillae (Fig. 34-10). When present with vitamin B_{12} deficiency, it has been termed Moeller or Hunter glossitis. It begins with the tip and lateral surfaces of the tongue becoming intensely red, well-defined irregular patches in which the filiform papillae are absent or thinned and the fungiform papillae are swollen. The disease is chronic, and the patches are painful and sensitive, so eating may be difficult and taste impaired. With time, the entire tongue becomes smooth, and a leukoplakia may result. Treatment of pernicious anemia with vitamin B_{12} therapy will result in improvements in the appearance and sensitivity of the tongue.

Fig. 34-10 Smooth tongue in Plummer-Vinson syndrome.

Atrophic glossitis is also a distinctive sign of pellagra; it results from a deficiency of niacin or its precursor, tryptophan. The sides and tip of the tongue are erythematous and edematous, with imprints of the teeth. Eventually, the entire tongue assumes a beefy-red appearance. Small ulcers appear, and all the mucous membranes of the mouth may be involved. Later, the papillae become atrophied to produce a smooth, glazed tongue, as seen in pernicious anemia. Burning or pain in the ulcers may be present. Increased salivary flow early in the disease may lead to drooling and angular cheilitis. In malabsorption syndrome, riboflavin deficiency, anorexia nervosa, alcoholism, and sprue, similar changes may be noted. Vitamin B complex is curative.

Patients with iron deficiency anemia, alone or with esophageal webs (Plummer-Vinson syndrome), and those with folic acid deficiency, syphilis, amyloidosis, celiac disease, Sjögren syndrome, or Riley-Day syndrome, may all manifest smooth tongue. Candidiasis may result in tongue pain and a partial or total atrophic appearance, along with a red or magenta color, on the dorsum of the tongue. In such patients, anticandidal therapy results in rapid improvement.

ERUPTIVE LINGUAL PAPILLITIS

Lacour and Perrin first described this acute, self-limiting inflammatory stomatitis in 1997. It affects children of both genders equally, with a mean age at onset of 3½ years. It has a seasonal distribution, with the majority of cases occurring in the spring. Fever (40%), difficulties in feeding (100%), and intense salivation (60%) are common symptoms. The tongue

Fig. 34-11 Eruptive lingual papillitis.

Fig. 34-12 Median rhomboid glossitis.

examination reveals inflammatory hypertrophy of the fungiform papillae on the tip and dorsolateral sites (Fig. 34-11). Additional signs include submandibular or cervical adenopathy (40%) and angular cheilitis (10%). Associated skin eruptions have not been described. Spontaneous involution occurs in a mean of 7 days (range 2–15 days). Recurrence is noted in 13%. Eruptive lingual papillitis is thought to result from a viral infection, and the 50% transmission among family members further supports this theory.

Mondal A, et al: Eruptive lingual papillitis. Indian Pediatr 2014; 51(3):243.
Roux O, et al: Eruptive lingual papillitis with household transmission. Br J Dermatol 2004; 150:299.

MEDIAN RHOMBOID GLOSSITIS

Median rhomboid glossitis is characterized by a shiny, oval or diamond-shaped elevation, invariably situated on the dorsum in the midline immediately in front of the circumvallate papillae (Fig. 34-12). The surface is abnormally red and smooth. In some cases, a few pale-yellow papules surmount the elevation. On palpation, the lesion feels slightly firm, but it usually causes no symptoms. It persists indefinitely, with minimal or no increase in size. There is no relationship to cancer.

Median rhomboid glossitis may result from abnormal fusion of the posterior portion of the tongue, but it is almost always chronically infected with *Candida.* If there is palatal inflammation above the inflamed part of the tongue, AIDS should be suspected and an HIV test obtained. Histologically, the changes are those of a simple, chronic inflammation with fibrosis, and usually with fungal hyphae in the parakeratin layer. Treatment with clotrimazole troches or oral antifungals, such as itraconazole, may lead to improvement.

Noonan V, et al: Median rhomboid glossitis. J Mass Dent Soc 2011; 59(4):41.

EOSINOPHILIC ULCER OF THE ORAL MUCOSA

Eosinophilic ulcer occurs most frequently on the tongue but may occur anywhere in the oral mucosa. It is characterized by an ulcer with indurated and elevated borders that is usually covered by a pseudomembrane. It develops rapidly, most often on the posterior aspect of the tongue, and spontaneously resolves in a few weeks. A traumatic cause has been postulated for this benign, self-limited disorder. The histopathologic findings show a predominantly eosinophilic infiltrate with some histiocytes and neutrophils.

In some multifocal, recurrent cases, CD30+ cells have been reported. These patients may have the oral counterpart of primary cutaneous CD30+ lymphoproliferative disease, or may simply be a simulator of this disorder. In one positive case, EBV staining was positive; the lesion resolved in 4 weeks. HIV-infected patients may develop ulcerations of the oral mucosa, resulting from a variety of infectious agents, such as herpes simplex virus (HSV), candidiasis, and histoplasmosis. However, 5 of the 16 patients reported had no evidence of infection and simply showed eosinophilic infiltrates below the ulcer.

Damevska K, et al: Eosinophilic ulcer of the oral mucosa. Am J Dermatopathol 2014; 36(7):594–596.

CAVIAR TONGUE

William Bean gave the picturesque name caviar tongue to the purplish venous ectasias so commonly found on the undersurface of the tongue after age 50. They are attributed to elastic tissue deterioration with aging and may be associated with Fordyce angiokeratomas of the scrotum. Phleboliths or thrombophlebitis may occasionally complicate this condition.

CUTANEOUS SINUS OF DENTAL ORIGIN (DENTAL SINUS)

In dental (or odontogenous) sinus, chronic periapical infection around a tooth produces a burrowing, practically asymptomatic, occasionally palpable, cordlike sinus tract that eventually appears beneath the surface of the gum, palate, or periorificial skin. It forms a fistulous opening with an inflamed red nodule at the orifice. It may appear anywhere from the inner ocular

Fig. 34-13 Odontogenic sinus.

Fig. 34-14 Oral hairy leukoplakia of HIV.

canthus to the neck, but is most often seen on the chin or along the jawline (Fig. 34-13). Bilateral involvement has been reported. Dental radiography is diagnostic. Pyogenic granuloma, actinomycosis, SCC, osteomyelitis of the mandible, congenital fistulas, the deep mycoses, bisphosphonate-related osteonecrosis of the jaw, and foreign body reactions must be considered in the differential diagnosis. Treatment requires the removal of the offending tooth or root canal therapy of the periapical abscess.

NEOPLASMS

Many tumors may involve the oral cavity. Most are discussed elsewhere in this book, and several are uncommon entities that affect specialized oral structures, such as the many subtypes of benign and malignant proliferations that occur in the major and minor salivary glands. These are not covered further here, and only a few select neoplasms are presented.

Leukoplakia

Clinical features

Leukoplakia presents as a whitish thickening of the epithelium of the mucous membranes, occurring as lactescent superficial patches of various shapes and sizes that may coalesce to form diffuse sheets. The surface is generally glistening and opalescent, often reticulated, and may even be somewhat pigmented. The white pellicle is adherent to the underlying mucosa, and attempts to remove it forcibly cause bleeding. At times, it is a thick, rough, elevated plaque. The lips, gums, cheeks, and edges of the tongue are the most common sites, but the lesion may arise on the anus and genitalia. Leukoplakia is found chiefly in men over age 40.

Biopsy of these white lesions may reveal orthokeratosis or parakeratosis with minimal inflammation, or there may be evidence of varying degrees of dysplasia. A benign form is usually a response to chronic irritation and has very little chance of conversion into the precancerous dysplastic form. Premalignant leukoplakia, with atypical cells histologically, is present in only about 10–20% of leukoplakia. Unfortunately, it is not possible to predict clinically which lesions will be worrisome histologically, except that if ulceration, red areas, or erosions are scattered throughout, the lesion is most likely precancerous. Therefore, biopsy is indicated.

When the lesion occurs on the lip, leukoplakia is closely related to chronic actinic cheilitis, which consists of a circumscribed or diffuse keratosis, almost invariably on the lower lip. It is preceded by an abnormal dryness of the lip and may be caused by smoking (especially pipe smoking) or chronic sun exposure. This type of leukoplakia is distinguished from SCC of the lip by the absence of infiltration, from lichen planus and psoriasis of the lips and mouth by the absence of lesions elsewhere, and from lupus erythematosus by the absence of telangiectases. Biopsy is necessary, however, to differentiate these conditions fully.

Intraoral leukoplakia appears to progress to SCC in no more than 1% of lesions per year. In time, an extensive, thick, white pellicle may cover the tongue or oral mucosa. In old lesions, the epithelium may be desquamated, and there may be fissures or ulcerations. Such changes are associated with more or less hyperemia and tenderness, and with a tendency to bleed after slight trauma. If transformation to carcinoma occurs, it generally follows a lag time of 1–20 years, although immunosuppressed transplant patients may have a rapid course of transformation.

Oral hairy leukoplakia is a term used to describe white, corrugated plaques that occur primarily on the sides of the tongue of patients with AIDS (Fig. 34-14). This is a virally induced lesion, discussed in Chapter 19, which has a characteristic histology.

Leukoplakia of the vulva usually occurs in obese women after menopause as grayish white, thickened, pruritic patches that may become fissured and edematous from constant rubbing and scratching. Secondary infection with edema, tenderness, and pain may occur. It is differentiated from lichen planus by the absence of discrete, rectangular, or annular flat papules of violaceous hue in the mucosa outside the thickened patches, about the anus, on the buccal mucosa, or on the skin. Leukoplakia of the vulva is most frequently confused with lichen sclerosus et atrophicus and other vulval atrophies. On the penis, although leukoplakia may occur, a similar precancerous process called erythroplasia (of Queyrat) is usually seen instead.

Etiology

Numerous factors are involved in the cause of leukoplakia. It may develop as a result of tobacco smoking; use of smokeless tobacco; areca, qat, or betel nut chewing; reverse smoking; alcohol; poorly fitting dentures; sharp and chipped teeth; or improper oral hygiene. Extensive involvement of the lips and oral cavity with leukoplakia may exist for years with no indication of carcinoma. On the other hand, small, inflamed patches may be the site of a rapidly growing tumor, which, with relatively insignificant local infiltration, may involve the cervical lymphatics. Carcinoma in leukoplakia usually begins as a localized induration, often around a fissure, or as a warty excrescence or a small ulcer. There is a 6–10% transformation rate of intraoral leukoplakia into SCC. Predictors of a higher risk of SCC development include older age; female gender; nonsmokers; large size; presence on the lateral or ventral tongue, floor of the mouth, or retromolar/soft palate complex; erythroleukoplakia; and a nonhomogeneous morphology.

The degree of epithelial atypia may be considered in staging the risk of developing malignancy. Aneuploid leukoplakia has a high rate of transformation into aggressive SCC, and the cancers derived from it are more likely to be lethal.

Treatment

It must be remembered that cancer develops frequently on histologically dysplastic leukoplakia, and thus its complete removal should be the goal in each case—first by conservative measures, then by surgery or destruction, if necessary. The use of tobacco should be stopped and proper dental care obtained. Fulguration, simple excision, cryotherapy, PDT, and CO_2 laser ablation are effective methods of treatment. Medical therapies that have been the subject of randomized clinical trials may lead to temporary resolution of the lesions, but relapses and adverse effects are common, and there is no evidence that they prevent the transformation to malignancy.

Leukoplakia with tylosis and esophageal carcinoma

Leukoplakia associated with tylosis and esophageal carcinoma is extremely rare but may occur.

Epidermization of the lip

Relatively smooth leukokeratosis of the lower vermilion, blending evenly into the skin surface distally and having a steep, sharp, irregular proximal margin, may easily be mistaken clinically for precancerous leukoplakia. Histologically, it shows only hyperkeratosis, without parakeratosis or cellular atypia. A shallow shave excision suffices to cure it and to rule out precancerous leukoplakia; no fulguration is required.

Erythroplakia

The term erythroplakia is applied to leukoplakia that has lost (or has not developed) the thick keratin layer that makes leukoplakia white; it is the usual pattern in mucocutaneous junctions. A focal red patch with no apparent cause should be suspected of being precancerous when found on the floor of the mouth, soft palate, or buccal mucosa or under the tongue (Fig. 34-15). Histologically, there is cellular atypia, pleomorphism, hyperchromatism, and increased mitotic figures. Carcinoma in situ or invasive carcinoma is found in 90% of lesions.

Fig. 34-15 Erythroplakia.

Oral florid papillomatosis

Oral florid papillomatosis is a confluent papillomatosis covering the mucous membranes of the oral cavity. The distinctive picture is that of a white mass resembling a cauliflower, covering the tongue and extending on to the other portions of the mucous membranes, including the oropharynx, larynx, and trachea. Usually, there is no lymphadenopathy.

The course of the disease is progressive. Many lesions eventuate in SCC, whereas others continue for many years, with the patient dying of some intercurrent disease. Oral florid papillomatosis should be regarded as a verrucous carcinoma, which has been defined as a distinctive, slowly growing, fungating tumor representing a well-differentiated SCC in which metastases occur very late or not at all. The histologic features are those of papillomatosis, acanthosis, and varying degrees of dysplasia of the epithelium, without disruption of the basement membrane. It is reasonable to expect the eventual development of epidermoid carcinoma in most patients. Esophageal involvement and keratotic papules of the extremities may occur. In the differential diagnosis, leukoplakia, proliferative verrucous leukoplakia, candidiasis, acanthosis nigricans, and condyloma acuminatum should be considered. The recommended treatment is surgical excision; however, it is often followed by recurrence and spread.

Proliferative verrucous leukoplakia

Proliferative verrucous leukoplakia is a slowly progressive condition that begins as multifocal sites of hyperplasia of the oral mucous membranes and proceeds to thicken and enlarge until SCC results (Fig. 34-16). Women outnumber men 4:1. Initially flat, usually white patches are present, but the lesions relentlessly become warty, exophytic masses. About 70% of patients develop SCC, most frequently of the palate and gingiva, with 40% of the total patients dying of it. There has been an irregular association with human papillomavirus (HPV)–16 infection, and risk factors for SCC of the oral cavity are usually not present. Treatment is difficult because of the multifocal nature of the lesions. Aggressive early surgical therapy is best. Many patients develop recurrence after only a short interval.

Squamous cell carcinoma

Squamous cell carcinoma is the most common oral malignancy and constitutes 2–3% of all new cancers. With almost 30,000

Fig. 34-16 Proliferative verrucous leukoplakia; three sites of squamous cell carcinoma: lip and twice in palate.

Fig. 34-18 Acquired dyskeratotic leukoplakia.

Fig. 34-17 Oral squamous cell carcinoma. (Courtesy of Dr. Shyam Verma.)

yearly cases in the United States, SCC is the tenth most common malignancy. It occurs primarily in older men. The most frequent sites are the lower lip, tongue, soft palate, and floor of the mouth (Fig. 34-17). SCC of the lip develops from actinic damage, with 95% of the cases involving the lower lip. Intraoral lesions frequently develop from leukoplakia or erythroplakia, at sites of frequent irritation, or from long-standing mucosal inflammatory disease such as ulcerative lichen planus. About 20% of oral squamous cell cancers have an associated focus of leukoplakia; these tend to be diagnosed at a less advanced stage than those where no associated leukoplakia exists. Tobacco smoking, use of smokeless tobacco; areca, qat, or betel nut chewing; and reverse smoking are risk factors for the development of intraoral SCC. Alcohol has not been shown to be an independent risk factor. Many are positive for HPV-16 or HPV-18. The risk factors may also complicate xeroderma pigmentosa (tip of tongue), dyskeratosis congenita, dystrophic epidermolysis bullosa, erosive lichen planus, and oral submucous fibrosis. Unfortunately, the survival rate has remained at 50% for many years because disease is often discovered late, after it has metastasized to the cervical lymph nodes. Exfoliative cytology is a practical and accurate aid to oral cancer screening. Surgical excision is the treatment of choice; the role of sentinel lymph node dissection and adjuvant chemotherapy and/or radiation are all controversial issues undergoing active study.

Acquired dyskeratotic leukoplakia

James and Lupton reported a patient with acquired dyskeratotic leukoplakia that manifested as distinctive white plaques on the palate, gingivae, and lips (Fig. 34-18). There were similar lesions of the genitalia. Histologically, there was a unique finding of clusters of dyskeratotic cells in the prickle cell layer in all affected sites. Aggressive laser treatment was

followed by recurrence. Use of etretinate afforded some improvement, but the condition continued unabated more than 20 years.

White sponge nevus

The mouth, vagina, or rectum may be the site of this spongy, white overgrowth of the mucous membrane, with acanthosis, vacuolated prickle cells, and acidophilic condensations in the cytoplasm of keratinocytes, which electron microscopy has shown to be aggregated tonofilaments. The buccal mucosa is the most common site of involvement. There are no extramucosal lesions. Progression of the disorder generally stops at puberty. The disease is inherited as an autosomal dominant disorder. A mutation in the mucosal keratin pair K4 and K13 has been identified as the inherited defect. HPV-16 DNA has been present in some patients, the significance of which remains to be determined. Antibiotics, particularly tetracycline, may give significant improvement. A 0.25% aqueous preparation of tetracycline as a mouth rinse, 5 mL swished in the mouth for 1 min twice daily, has been successful.

Melanocytic oral lesions

A wide variety of melanocytic lesions appear on the mucous membranes. Nevi of the oral mucosa in general are extremely uncommon. Among the melanocytic nevi of the cellular type, the intramucosal type occurs most frequently, with the compound nevus next and the junction nevus occurring only rarely. Ephelis, lentigo, blue nevus, and labial melanotic macules are other types of focal hyperpigmentation. Ephelides darken on sun exposure and are usually limited to the lower lip. The blue nevus has dendritic cells in the submucosa. Lentigines show acanthosis of rete ridges on biopsy. Oral melanotic macules are solitary, sharply demarcated, flat, pigmented lesions that occur chiefly in young women, do not change on sun exposure, and show only acanthosis and basal-layer melanin on biopsy.

Oral melanoacanthoma is a simultaneous proliferation of keratinocytes and melanocytes. It is most frequently observed in young black patients (average age 23) on the buccal mucosa. It seems to be a reactive process, usually following trauma and resolving spontaneously in 40% of patients.

Melanoma occurs infrequently, mostly in older patients. It is recognized by being larger than the usual benign pigmented lesion and more irregular in shape, with a tendency to ulcerate and bleed. A peripheral areola of erythema and satellite pigmented spots may be present. There is a striking predilection for palatal (or less often gingival) involvement. The overall prognosis is poor (<5% survival at 5 years) because the lesions are usually deeply invasive by the time they are discovered. Whereas oral nevi are uncommon, biopsy of solitary pigmented oral lesions is indicated when the clinical diagnosis is uncertain. Biopsy of a pigmented tumor will occasionally reveal an SCC.

Melanosis

Pigmentation of the oral cavity tends to occur most frequently in black persons. In other races, the darker the skin, the more mucosal pigmentation may be expected. Oral melanosis may occur with Albright syndrome, Peutz-Jeghers syndrome, Carney complex, Laugier-Hunziker disease, and Addison's disease, or rarely, as an idiopathic process with no associated disease.

James et al. reported a patient with inflammatory acquired oral hyperpigmentation that first occurred at age 30 with numerous distinct pigmented macules, similar to those seen in Peutz-Jeghers syndrome. However, the condition progressed rapidly to a diffuse oral hyperpigmentation (Fig. 34-19). This appeared to be caused by an undefined inflammation, and slow partial resolution occurred after several years of observation.

The differential diagnosis of oral hyperpigmentation should include the amalgam tattoo, a focal, brownish blue macule arising from fragments of dental silver or amalgam implanting into the gums (Fig. 34-20). Heavy-metal poisoning may also induce such lesions. Bismuth, lead, and cisplatin may produce a pigmented line along the gums near their margin. A multitude of drugs will cause pigmentation; the most common include amodiaquine, chloroquine, imatinib, oral contraceptives, phenothiazines, phenolphthalein, quinacrine, quinidine, thallium, nicotine (tobacco), and zidovudine.

Fig. 34-20 Amalgam tattoo.

Osseous choristoma of the tongue

Osseous choristoma of the tongue presents as a nodule on the dorsum of the tongue containing mature lamellar bone without osteoblastic or osteoclastic activity. This does not recur after simple excision.

Goswamy M, et al: Osseous choristoma of the periodontium. J Indian Soc Periodontol 2012; 16(1):120–122.
Naik VR, et al: Choristoma of the base of the tongue. Indian J Pathol Microbiol 2009; 52:86.

Peripheral ameloblastoma

This is a neoplasm of the gingivae, which appears most often on the lower jaw. The mean age at onset is the early fifties and men outnumber women. Peripheral ameloblastoma presents as a growing, pink to red, sessile or pedunculated mass. Excision is followed by recurrence in 19% of the cases, but the lesion is benign. It can simulate basal cell carcinoma histologically.

Bertossi D, et al: Peripheral ameloblastoma of the upper gingiva. J Clin Exp Dent 2014; 6(2):e180–e184.

TRUMPETER'S WART

Trumpeter's wart is a firm, fibrous, hyperkeratotic, pseudoepitheliomatous nodule on the upper lip of a trumpet player. A similar callus may grow on the lower lip of trombone players.

Gambichler T, et al: Skin conditions in instrumental musicians. Contact Dermatitis 2008; 58:217.

EPULIS

The term epulis means any benign lesion situated on the gingiva. The majority of these are reactive processes that display varying degrees of fibrosis, inflammation, and vascular proliferation on biopsy. Giant cell epulis (peripheral giant cell granuloma) is a solitary, bluish red, 10–20 mm tumor occurring on the gingiva between or around deciduous bicuspids and incisors. Lesions may be induced by dental implants. Similar lesions may occur in the autosomal dominant inherited syndrome, cherubism. Histologically, epulides resemble giant cell tumor of the tendon sheath.

Banthia R, et al: Peripheral giant cell granuloma. Gen Dent 2013; 61(1):e12–e14.
Roginsky VV, et al: Familial cherubism. Int J Oral Maxillofac Surg 2009; 38(3):218–223.
Yee J: Congenital epulis in a newborn. Minn Med 2014; 97(5):39.

Pyogenic granuloma

Pyogenic granuloma is an exuberant overgrowth of granulation tissue, frequently occurring in the oral cavity, most often involving the gingiva. It may also occur on the buccal mucosa, lips, tongue, or palate. It is a red to reddish purple, soft, nodular mass that bleeds easily and grows rapidly, but is usually not painful. When it develops during pregnancy, it is called pregnancy tumor or granuloma gravidarum. Surgical excision, pulsed dye, erbium:yttrium-aluminum-garnet (Er:YAG) or neodymium:YAG laser, and cryosurgery offer effective methods of treatment.

Cardoso JA, et al: Oral granuloma gravidarum. J Appl Oral Sci 2013; 21(3): 215-228.

Kocaman G, et al: The use of surgical Nd:YAG laser in an oral pyogenic granuloma. J Cosmet Laser Ther 2014; 16(4):197–200.

GRANULOMA FISSURATUM

Granuloma fissuratum is a circumscribed, firm, whitish, fissured, fibrous granuloma occurring in the labioalveolar fold. The lesion is discoid, smooth, and slightly raised, about 1 cm in diameter. The growth is folded like a bent coin, so that the fissure in the bend is continuous on both sides with the labioalveolar sulcus. Symptoms are slight. It is an inflammatory fibrous hyperplasia that usually results from chronic irritation caused by poorly fitting dentures. In the dental literature, it is called epulis fissuratum, particularly when there is a deep cleft traversing the lesion. Treatment is by surgical extirpation, CO_2 laser ablation, or electrodesiccation after biopsy.

Mohan RP, et al: Epulis fissuratum. BMJ Case Rep 2013; Jul 17. pii: bcr20132000054.

ANGINA BULLOSA HAEMORRHAGICA

The sudden appearance of one or more blood blisters of the oral mucosa characterizes angina bullosa haemorrhagica. There is no associated skin or systemic disease. The blisters may be recurrent, occur most often in the soft palate, and usually present in middle-age or elderly patients. No treatment is necessary.

Singh D, et al: Angina bullosa haemorrhagica. BMJ Case Rep 2013; Feb 8.
Yayli S, et al: Angina bullosa haemorrhagica. J Dtsch Dermatol Ges 2012; 6:436–437.

MUCOCELE

The term mucocele refers to a lesion resulting from trauma or obstruction of the minor salivary ducts. The most common type is the mucous extravasation phenomenon, which is usually seen inside the lower lip because it is caused by trauma from biting (Fig. 34-21). The inside of the upper lip and buccal mucosa are infrequently involved. It presents as a soft, rounded, translucent projection and usually has a bluish tint.

Fig. 34-21 Mucocele.

The lesion varies from 2 to 10 mm in diameter. It is painless, fluctuant, and tense. Incision, or sometimes merely compression, releases sticky, straw-colored fluid (or bluish fluid if hemorrhage has occurred into it). Usually, the lesions are solitary; however, multiple superficial mucoceles have been reported to occur with graft-versus-host disease and lichenoid inflammation. In these patients, topical corticosteroids may help prevent recurrences.

The cause of mucocele is rupture of the mucous duct, with extravasation of sialomucin into the submucosa to produce cystic spaces with inflammation. Granulation tissue formation is followed by fibrosis. Excisional biopsy will document the diagnosis and eliminate the problem. Cryotherapy and laser ablation have also been reported to be successful.

There are mucous retention cysts in which true obstruction of the duct leads to an epithelial-lined cavity. These are seen more in the posterior portions of the oral mucosa. A ranula (from *Rana,* the frog genus) is a mucocele of the floor of the mouth.

Two other cysts may be present in the mouth. The parotid duct cyst occurs in musicians who use wind instruments; it develops opposite the upper second molar on the buccal mucosa. The dermoid cyst may occur on the floor of the mouth, especially in the sublingual area.

ACUTE NECROTIZING ULCERATIVE GINGIVOSTOMATITIS (TRENCH MOUTH, VINCENT'S DISEASE)

Acute necrotizing ulcerative gingivitis (ANUG) is characterized by a rapid onset of characteristic punched-out ulcerations appearing on the interdental papillae and marginal gingivae. A dirty-white pseudomembrane may cover the ulcerations. The lesions may spread rapidly and involve the buccal mucosa, lips, and tongue, as well as the tonsils, pharynx, and entire respiratory tract. The slightest pressure causes pain and bleeding. There is a characteristic foul, fetid odor that is always present. ANUG may lead to loss of attachment of the gingiva and alveolar bone (necrotizing ulcerative periodontitis).

Trench mouth begins in a nidus of necrotic tissue, which provides an anaerobic environment for the infection by fusospirochetal organisms *(Bacteroides fusiformis)* in association with *Borrelia vincentii* and other organisms. Poor dental hygiene, smoking, poor nutrition, ingestion of methylenedioxymethamphetamine (ecstasy), and immunosuppression are predisposing factors. It may be seen as a component of the oral infections and inflammatory lesions that occur in immunocompromised HIV-infected patients.

Acute herpetic gingivostomatitis, or primary HSV infection, may be confused with ANUG. Young children are susceptible to this severe febrile stomatitis with lymphadenitis. It is not primarily gingival in location and does not cause necrosis of the interdental papillae. Noma is a form of fusospirillary gangrenous stomatitis occurring in children with low resistance and poor nutrition. The onset is often triggered by measles. At the onset, there is ulceration of the buccal mucosa; this rapidly assumes a gangrenous character and extends to involve the skin and bones, with resultant necrosis. It may end in the patient's death.

Treatment consists of thorough dental hygienic measures under the supervision of a dentist. Penicillin with debridement is the treatment of choice. Use of a 3% hydrogen peroxide mouthwash is also helpful.

ACATALASEMIA

Acatalasemia (Takahara's disease) is a rare disease in which the enzyme catalase is deficient in the liver, muscles, bone marrow, erythrocytes, and skin. There are several forms. The absence of catalase leads to progressive gangrene of the mouth, with recurrent ulcerations resulting from increased susceptibility to infection by anaerobic organisms.

Almost 60% of patients with acatalasemia develop alveolar ulcerations, beginning in childhood. The mild type of the disease is characterized by rapidly recurring ulcers. In the moderate type, alveolar gangrene develops, with atrophy and recession of the alveolar bone, so that the teeth fall out spontaneously. In the severe type, widespread destruction of the jaw occurs. After puberty, all lesions heal, even in individuals who have the severe type.

There is no gross difference in appearance between the blood of an acatalasic patient and that of a normal individual, but when hydrogen peroxide is added to a sample of blood, acatalasic blood immediately turns blackish brown, and the peroxide does not foam. Normal blood remains bright and causes the peroxide to foam exuberantly because of the presence of erythrocyte catalase.

Acatalasia is a rare peroxisomal disorder and is inherited as an autosomal recessive trait. Treatment consists of extraction of the diseased teeth and the use of antibiotics to control the harmful effects of the causative bacteria.

Wang Q, et al: Long-term follow-up evaluation of an acatalasemia boy with severe periodontitis. Clin Chim Acta 2014 Jun 10; 433:93–95.

CYCLIC NEUTROPENIA

Cyclic, or periodic, neutropenia is characterized by a decrease of circulating neutrophils and dermatologic manifestations. At regular intervals (21 days), neutropenia and mouth ulcerations develop, usually accompanied by fever, malaise, and

arthralgia. Ulcerations of the lips, tongue, palate, gums, and buccal mucosa may be extensive. The ulcers are irregularly outlined and are covered by a grayish white necrotic slough. The anterior teeth may show a grayish brown discoloration. Premature alveolar bone loss and periodontitis occur. In addition, opportunistic cutaneous infections, such as abscesses, furuncles, noma, pyomyositis, and cellulitis, may develop during the neutropenic stage. Urticaria and erythema multiforme have been reported.

There is a cyclic depression of neutrophils occurring at intervals of 12–30 days (average 21 days) and lasting 5–8 days. The neutrophils in the peripheral blood regularly fall to low levels or completely disappear. Some cases have been associated with agammaglobulinemia. The cause of cyclic neutropenia is a germline mutation of the gene encoding neutrophil elastase *(ELANE)*. This is thought to produce apoptosis of bone marrow progenitor cells. Both autosomal dominant disease and sporadic cases have this abnormality. Severe congenital neutropenia is caused by a mutation in the same gene but at a different site. The latter condition predisposes to the development of myelodysplasia and acute myelogenous leukemia, whereas cyclic neutropenia does not.

The differential diagnosis includes other periodic fever syndromes, such as the periodic fever, aphthous stomatitis, pharyngitis, and adenopathy (PFAPA) syndrome; Mediterranean fever; Hibernian fever and hyperimmunoglobulin D syndrome; TNF receptor–associated periodic syndrome (TRAPS); and pyogenic sterile arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome. All share a predisposition to the development of aphthouslike oral ulcerations. PFAPA syndrome is defined clinically and is characterized by 4 days of high fevers (>40°C) that recur at regular intervals every 2–8 weeks, separated by well-being between episodes. Associated with fevers are aphthous stomatitis (70%), pharyngitis (72%), and cervical adenitis (88%). The disease is not familial, begins before 5 years of age, and responds to small doses of prednisone for 1–2 days. Tonsillectomy has been reported to cure it. *SPAG7* is a candidate gene for PFAPA. The autoinflammatory syndromes are discussed in detail in Chapter 7.

Use of recombinant human granulocyte colony-stimulating factor (G-CSF) has been successful in the treatment of cyclic neutropenia patients. If the potential side effects limit use of this therapy, cyclosporine has been reported to be effective as well. Administering antibiotics during infections seems to expedite recovery. Careful attention to oral hygiene, including plaque control, helps improve mouth lesions and reduces the risk of infections. Death may occur from pneumonia, sepsis, gangrenous pyoderma, or granulocytopenia.

RECURRENT INTRAORAL HERPES SIMPLEX INFECTION

Recurrent intraoral infection with HSV is characterized by numerous small, discrete vesicles occurring in one or a few clusters. The site of involvement is a key feature in suspecting the diagnosis. The keratinized or masticatory mucosa—the palate, gingiva, and tongue—is affected. The grouped vesicles rupture rapidly to form punctate erosions with a red base. Smears from the base prepared with Wright stain will show giant multinucleated epithelial cells. Immunofluorescent tests and viral cultures are also confirmatory.

Fig. 34-22 Chronic herpes in patient receiving cancer chemotherapy.

The differential diagnosis of this uncommon manifestation of HSV includes oral herpes zoster, herpangina, and oral aphthosis. The latter two involve nonattached mucosa, whereas recurrent HSV involves mucosa fixed to bone. Differentiation from zoster is made on clinical grounds or by culture and immunofluorescent testing.

Chronic progressive ulcerative and nodular intraoral herpes are seen occasionally in HIV-infected patients or those with leukemia or neutropenia (Fig. 34-22). The presentation may mimic mucosal toxicity to chemotherapy. Solitary painful erosions of the tongue or attached mucosa should be tested for HSV in such patients. Additionally, herpetic geometric glossitis may occur, with linear longitudinal, cross-hatched, or branching fissures of the dorsal tongue, usually along the central area. This condition may be quite painful and may limit oral intake. Although the glossitis usually affects only immunocompromised patients, at least one immunocompetent patient has been affected.

RECURRENT APHTHOUS STOMATITIS (CANKER SORES, APHTHOSIS)

Clinical features

Aphthous stomatitis is a painful, recurrent disease of the oral mucous membrane. It begins as small, red, discrete, or grouped papules, which in a few hours become necrotizing ulcerations. They are small, round, shallow, white ulcers (aphthae), generally surrounded by a ring of hyperemia (Fig. 34-23). As a rule, they are tender; they may become so painful that they interfere with speech and mastication. They are mostly about 5 mm in diameter but may vary in size from 3 to 10 mm. When larger, they are called major aphthae. A third subcategory, herpetiform aphthae, consists of small, 1–3 mm lesions grouped into a coalescing larger plaque, which may take 1–4 weeks to resolve. Usually, one to five lesions occur per attack; however, they may occur in any number. They are located in decreasing frequency on the buccal and labial mucosa, edges of the tongue, buccal and lingual sulci, and soft palate. There is a

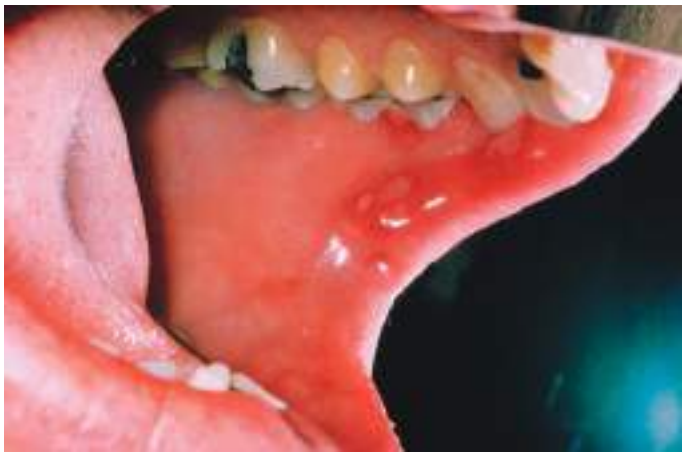

Fig. 34-23 Aphthous stomatitis.

marked predilection for the nonkeratinized mucosa (any not bound to underlying periosteum). This fact, and because they are rarely confluent, even when they occur as small crops of 1-mm or 2-mm lesions (herpetiform aphthae), help to distinguish them from the uncommon, recurrent intraoral HSV infection. Aphthae may also occur on the vagina, vulva, penis, anus, and even the conjunctiva. When they involve the oral and genital mucosa and number three or more, the term complex aphthosis is applied.

The lesions tend to involute in 1–2 weeks, but recurrences are common. These recurrences may be induced by trauma (e.g., self-biting, toothbrush injury, dental procedures), spicy foods, citrus, fresh pineapple, walnuts, allergy, emotional stress, or hormonal changes in women, as in menstruation, pregnancy, menarche, and menopause. A familial predisposition has also been described as familial epidemic aphthosis.

Recurrent aphthous stomatitis is the most common lesion of the oral mucosa, affecting 10–20% of the population. It typically starts in the second or third decade, and patients may experience recurrent bouts of lesions several times yearly for many decades. When present in neonates or young children, autoinflammatory syndromes should be considered. In PFAPA syndrome, the high fevers and associated findings occur with striking periodicity every 4 weeks, last 4–6 days, and resolve only to recur the following month. The children are otherwise well. One or two doses of prednisone (2 mg/kg) abort the attack, and tonsillectomy may cure it. Aphthous oral ulcerations may also be seen in the autoinflammatory syndromes, such as familial Mediterranean fever, TRAPS, hyperimmunoglobulinemia D and periodic fever, PAPA syndrome, and deficiency of the interleukin-1 receptor antagonist (DIRA) syndrome.

Ulcerations such as these may also be the presenting sign in Behçet syndrome, HIV infection, malabsorption syndromes, gluten-sensitive enteropathy, pernicious anemia, cyclic neutropenia, neutropenia, ulcerative colitis, and Crohn's disease. History, physical examination, complete blood count, and long-term follow-up documenting the recurrent course, in the absence of other symptoms, will secure the diagnosis. Some patients have aphthosis associated with low folate, vitamin B_{12}, or iron levels, so testing should include this evaluation.

Etiologic factors

Although individual patients often suspect that one of the factors just mentioned is responsible for precipitating recurrence of the lesions, investigators favor infectious or immunologic causation. The true cause is unknown.

Histologically, the lesion consists of a lymphocytic inflammatory infiltration with occasional plasma cells and eosinophils, which suggests delayed hypersensitivity.

Diagnosis

Aphthous stomatitis must be differentiated from mucous patches of early syphilis, candidiasis, Vincent angina, the avitaminoses (particularly pellagra and scurvy), erythema multiforme, pemphigus, cicatricial pemphigoid, lichen planus, primary HSV infection of the mouth, recurrent labial herpes, and recurrent intraoral HSV infection.

Treatment

No permanent cure is available for aphthosis. Several topical agents will lessen the pain. A mixture of equal parts of elixir of Benadryl and Maalox, held in the mouth for 5 min before meals, is soothing. Kaolin may also be added to the mixture. Lidocaine (Xylocaine Viscous) 2% solution, keeping 1 teaspoonful in the mouth for several minutes, is also helpful in allaying pain. Another useful topical anesthetic is dyclonine hydrochloride (Dyclone) 0.5% applied to the lesions. A large number of reasonably effective over-the-counter remedies are also available. Triggers, such as spicy foods, citrus, walnuts, pineapple, and other irritating substances, should be avoided.

Other measures may be used to shorten the course and induce healing of lesions. Chlorhexidine mouthwashes are used twice daily with any of the other treatments described. A mixture of equal parts of fluocinonide ointment and Orabase, applied to the ulcers three or four times daily, is effective in aiding the healing of existing ulcers; however, it does not prevent new ulcers. Some patients object to the thick, sticky texture of Orabase and prefer fluocinonide gel. Clobetasol ointment can also be very effective. Intralesional corticosteroids and short, 3-day or 4-day courses of oral corticosteroids may help, particularly for indolent or large lesions. Nonsteroidal alternatives include 5 mL of an oral suspension containing 250 mg of tetracycline; this is held in the mouth for 2 min and then swallowed. This is done four times daily for 1 week. Amlexanox 5% oral paste (Aphthasol) is a useful topical therapy both to induce healing and to relieve pain. Sucralfate suspension, alone or compounded with a topical corticosteroid, may be useful, as described in peptic ulcer disease and the ulcerations of Behçet's disease.

To try to prevent new lesions, known triggers for the individual patient should be avoided as much as possible. Colchicine at 0.6 mg/day for 1 week, then increasing to 1.2 or even 1.8 mg/day, is recommended. If this is ineffective or GI or other side effects limit dosage, dapsone may be added to colchicine or substituted for it. It is given in steadily increasing doses of 25 mg for 3 days, then 50 mg for 3 days, then 75 mg for 3 days, then 100 mg for 7 days. If the blood count is normal, no side effects are present, and the disease is not controlled, further increases to 125 or even 150 mg may be given. Thalidomide is another effective alternative, but caution regarding teratogenicity and neurotoxicity is necessary if this is considered. One method is thalidomide, 300 mg/day to start, 200 mg/day after 10 days, and 100 mg/day after 2 months. Relapses are treated with 100 mg/day for 12 days.

Several investigators have reported finding low folate, iron, or B_{12} levels in about 20% of aphthosis patients investigated, but others do not see this with such high frequency. Still, it is worth investigating, since correction of the abnormality clears

Fig. 34-24 Major aphthae.

Fig. 34-25 Behçet's disease.

or improves the condition in most patients who have an abnormality. Two studies document improvement with cyanocobalamin, even in those without abnormality.

MAJOR APHTHOUS ULCER (PERIADENITIS MUCOSA NECROTICA RECURRENS)

In Sutton's disease, a major aphthous ulcer begins as a small, shotlike nodule on the inner lip, buccal mucosa, or tongue that breaks down into a painful, sharply circumscribed ulcer with a deeply punched-out and depressed crater. It may at times begin in the faucial pillars or oropharynx (Fig. 34-24). It may persist for 2–12 weeks before healing with a soft, pliable scar. There are seldom more than one to three lesions present at one time. However, remissions tend to be short, and new lesions may appear before old ones have healed. The term major aphthous ulcers has supplanted the unwieldy Latin name for this disease.

The cause is unknown, but evidence favors an immunologic or infectious etiology. These painful lesions are frequently present in immunocompromised HIV-infected patients who may experience similar lesions in the esophagus, rectum, anus, and genitals. Treatment is difficult, and the general measures discussed under recurrent aphthae should be employed. Intralesional or systemic corticosteroids in short courses may be effective and are often given. If recurrences are such that systemic steroids are prescribed for more than two or three short courses per year, alternative oral medications, such as colchicine, dapsone, or thalidomide, may be tried.

BEHÇET SYNDROME (OCULO-ORAL-GENITAL SYNDROME)

Clinical features

Behçet syndrome consists of recurrent oral aphthous ulcerations that recur at least three times in one 12-month period in the presence of any two of the following: recurrent genital ulceration, retinal vasculitis or anterior or posterior uveitis, cutaneous lesions (erythema nodosum; pseudofolliculitis or papulopustular lesions; or acneiform nodules in postadolescent patients who are not receiving corticosteroid treatment), or a positive pathergy test.

Oral lesions occur on the lips, tongue (Fig. 34-25), buccal mucosa, soft and hard palate, tonsils, and even in the pharynx and nasal cavity. The lesions are single or multiple, 2–10 mm or larger in diameter, and sharply circumscribed, with a dirty-grayish base and a surrounding bright-red halo. Other patients show deep ulcerations that leave scars resembling those caused by Sutton major aphthous ulcers. The lesions are so painful that eating may be difficult. A foul mouth odor is in most cases very noticeable.

Genital lesions occur in men on the scrotum and penis or in the urethra and in women on the vulva, cervix, or vagina; lesions may be found in both genders on the genitocrural fold, anus, or perineum or in the rectum. These ulcerations are similar to those seen in the mouth. In addition, macules, papules, and folliculitis may develop on the scrotum. Lesions in women may lead to deep destruction of the vulva. Swellings of the regional nodes and fever may accompany oral and genital attacks.

The ocular lesions start with intense periorbital pain and photophobia. Retinal vasculitis is the most classic eye sign and the major cause of blindness. Conjunctivitis may be an early accompaniment of uveitis, and hypopyon may be a late one. Iridocyclitis is frequently seen. Both eyes are eventually involved. Untreated disease leads to blindness from optic atrophy, glaucoma, or cataracts.

Neurologic manifestations are mostly in the central nervous system and resemble most closely those of multiple sclerosis. Remissions and exacerbations are the rule. Thrombophlebitis occurs with some frequency. Thrombosis of the superior vena cava may also occur. Arthralgia is most often present in the form of polyarthritis.

Unfortunately, the international criteria include nonspecific common cutaneous lesions (pseudofolliculitis, papulopustular or acneiform lesions). Demonstration of either leukocytoclastic vasculitis or a neutrophilic vascular reaction on histologic examination of a lesion would make the cutaneous criteria more specific.

There is a relatively high prevalence of Behçet's disease in the Far East and Mediterranean countries, whereas in the United States and Western Europe, it is much less common. In large series of patients from areas of high prevalence, men with an age of onset in the thirties predominate. They tend to have a worse prognosis than women. Mangelsdorf et al. reported on 25 patients in a U.S. university dermatology referral practice; 22 were young women with a high frequency of mucocutaneous lesions and a low prevalence of ocular involvement. This may reflect referral bias or could indicate that the disease is less severe and female predominant in the United States.

On histologic examination, the early lesions show a leukocytoclastic vasculitis. There is perivascular infiltration, which is chiefly lymphocytic in older lesions, with endothelial proliferation that obliterates the lumen. The cause of Behçet's disease has been postulated to have an infectious, immunologic, and/or genetic basis, but the evidence is still inconclusive for any of these.

Diagnosis

Usually, the disease starts with a single oral ulceration, which is followed by others. It may take years before additional lesions develop. Again, the diagnosis requires two classic signs in addition to oral ulcerations. In women, anal and genital lesions predominate, often with subsequent involvement of the eyes.

Behçet's disease must be differentiated from herpetic or aphthous stomatitis, pemphigus, oral cancer, and Stevens-Johnson syndrome (erythema multiforme). A skin puncture or pathergy test may be used to investigate patients further; however, it is not reliable in that it may be negative in otherwise well-documented cases. It is done by injecting 0.1 mL of normal saline solution into the skin or by simply pricking the skin with a sterile needle. A pustule appears at the site within 24 h. If results are negative, the test should be repeated at two to five points before results are accepted. Pathergy has been observed in patients with Behçet's disease, pyoderma gangrenosum, Sweet syndrome, and bowel-associated dermatosis–arthritis syndrome.

Treatment

Usually, the ulcerations heal spontaneously. Chlorhexidine mouthwashes twice daily and toothpastes and restricted use of the toothbrush should be prescribed when there are oral lesions. For treating the symptoms and healing of the aphthae, local treatments as described for aphthae may be used. Sucralfate suspension has been studied in Behçet oral and genital ulcers and was found to decrease pain and healing time. On the whole, the therapeutic problem of aphthosis is not the healing of the individual lesions but the prevention of new attacks. For that purpose, several options exist, none of which is optimal. Colchicine, 0.6 mg twice daily, may be started for 2 weeks. In the absence of response and GI side effects, the dose may be increased to three times daily. Although this may not totally alleviate the mucocutaneous lesions, it may decrease their recurrence rate by 50% or more. Dapsone may be substituted or added to this for improvement of response. The usual therapeutic final dose is 100 mg/day. Thalidomide has been found to be effective in many patients. One dosing method is thalidomide, 200 mg twice daily for 5 days, and 100 mg twice daily for 15–60 days. It has no effect on iridocyclitis. Again, long-term treatment will usually be complicated by neurotoxicity, and the teratogenicity of thalidomide is well known.

Methotrexate, in a weekly oral dose of 7.5–20 mg, should be reserved for severe refractory cases, as should more aggressive systemic treatments such as systemic corticosteroids, azathioprine, chlorambucil, cyclosporine, interferon alfa, TNF antagonists, and cyclophosphamide.

The long-term outlook is for intermittent recurrent flares that may be lifelong. Blindness, neurologic impairment, and vascular thromboses are potential serious complications of Behçet syndrome.

Cutaneous Vascular Diseases 35

RAYNAUD PHENOMENON AND RAYNAUD DISEASE

Raynaud phenomenon is characterized by episodic, recurrent vasospasm of the fingers and toes resulting in white, blue, and red discoloration provoked by cold or stress. When it occurs in the presence of an associated disease, usually collagen vascular disease and often systemic sclerosis/scleroderma, it is called secondary Raynaud phenomenon. Raynaud disease (or primary Raynaud disease) occurs in the absence of associated illness. Although no significant structural changes occur in primary Raynaud disease, in secondary Raynaud phenomenon, especially when associated with connective tissue disease, sustained and recurrent vasospasm may lead to vessel wall damage.

In a series of 165 patients with Raynaud phenomenon, 51 had primary Raynaud disease. A defined connective tissue disease was present in about one third of the remaining patients, but 54 had undefined connective tissue disease (35 with positive antinuclear antibody [ANA] titer). In another study of 142 patients with idiopathic Raynaud phenomenon followed for more than 10 years, 14% progressed to a definite connective tissue disease. The initial presence of ANAs, thickening of fingers, older age at onset, and female gender were predictors of connective tissue disease. In a larger study of 3035 patients with primary Raynaud phenomenon, age of onset after 40 and progressively worsening Raynaud attacks were predictive of eventual diagnosis of a connective tissue disease (and reclassification as secondary Raynaud phenomenon), a development that occurred in 37.2% of patients after a mean of 4.8 years of follow-up. Sequential nailfold capillary microscopy and autoantibody determinations can predict development of systemic sclerosis in those with Raynaud phenomenon. The absence of nailfold capillaroscopic findings, conversely, predicts the presence of primary Raynaud disease (no associated systemic illness). Laser Doppler perfusion imaging may enhance the evaluation of vascular damage from Raynaud disease. Technetium digital blood flow scintigraphy and skin temperature measurement of the fingers and toes by digital thermography may aid in the early diagnosis of Raynaud phenomenon of either the primary or secondary type.

Many of the studies on pathogenesis and therapy in Raynaud phenomenon are conducted on patients with systemic sclerosis/scleroderma, so it may not be possible to translate these findings to patients with primary Raynaud disease. Apparently, however, cold exposure is a major trigger of vasospasm in all Raynaud patients. The exaggerated sympathetic response to cold may be caused by both excessive vasoconstrictor tone and a weak systemic vasodilation process, centrally mediated at least in part. The abnormal sympathetic response may also explain why some patients say that "stress" triggers Raynaud attacks. High homocysteine levels have been detected in patients with both primary and secondary Raynaud phenomenon. Patients with systemic sclerosis and Raynaud disease have elevated levels of endothelin 1 (ET-1), which correlates with both nailfold capillaroscopic findings and more advanced disease.

Secondary Raynaud phenomenon

Raynaud phenomenon is produced by an intermittent constriction of the small digital arteries and arterioles. The digits have sequential pallor, cyanosis, and rubor. The involved parts are affected by ischemic paroxysms, which cause them to become pale, cold to the touch, and numb. The phenomenon is more frequently observed in cold weather. When exposed to cold, the digits become white (ischemic), then blue (cyanotic), and finally red (hyperemic). Over time, the parts may fail to regain their normal circulation between attacks and become persistently cyanotic and painful. If this phenomenon persists over a long period, punctate superficial necrosis of the fingertips develops; later, even gangrene may occur.

Secondary Raynaud phenomenon occurs most frequently in young to middle-age women. It occurs with scleroderma, dermatomyositis, lupus erythematosus (LE, particularly those with anti-Sm and anti-RNP antibodies), mixed connective tissue disease, Sjögren syndrome, rheumatoid arthritis, and paroxysmal hemoglobinuria. Scleroderma was the underlying diagnosis in more than half of patients in one series. Occlusive arterial diseases, such as embolism, thromboangiitis obliterans, arteriosclerosis obliterans, and large-vessel vasculitis (Takayasu arteritis), may be present. In addition, various diseases of the nervous system, including cervical rib, scalenus anticus syndrome, and complex regional pain syndrome (reflex sympathetic dystrophy), may produce the disorder. Physical trauma, such as hand-transmitted vibration, as occurs with pneumatic hammer operation, can induce a syndrome identical to Raynaud and has been termed "vibration white finger" or "hand-arm vibration syndrome." Pianists and typists may also develop this phenomenon. Raynaud phenomenon is a well-recognized complication following cold injury, especially frostbite. Pharmacologic agents, such as bleomycin, cisplatin-based chemotherapy, ergot, β-adrenergic blockers (including eye drops), cyclosporine, interferon (IFN)–α and IFN-β, vinyl polychloride exposure, and cocaine, may also be the cause. The clumping of red blood cells is believed to be responsible for the induction of Raynaud phenomenon, with high titers of circulating cold agglutinins. It may occur in cryoglobulinemia and polycythemia vera. Patients with cancer may develop Raynaud as a paraneoplastic phenomenon. Endocrine disorders, such as acromegaly, pheochromocytoma, carcinoid, and hypothyroidism, may present with or be associated with Raynaud phenomenon. Raynaud of the nipple is a variant of Raynaud disease that is difficult to diagnose. It presents with severe pain during lactation and must be distinguished from nipple candidiasis and eczema. Patients report the onset of symptoms during pregnancy and, when asked,

will say that the symptoms are triggered by cold and accompanied by biphasic or triphasic color changes of the nipple. Nifedipine can be highly effective in this condition and is safe for use during lactation; minimal drug is found in the breast milk.

Simple tests and physical examination will generally distinguish Raynaud disease from secondary Raynaud phenomenon. Sclerodactyly, digital pitted scars, puffy fingers with telangiectasias, positive ANA, subcutaneous calcifications, basilar lung fibrosis, and changes on nailfold capillary microscopy (avascular "skip" areas with irregularly dilated capillary loops) are signs of connective tissue disease.

Raynaud disease (primary Raynaud disease)

Raynaud disease is a primary disorder of cold sensitivity primarily seen in young women. The intermittent attacks of pallor, cyanosis, hyperemia, and numbness of the fingers are identical to those in secondary Raynaud phenomenon (Fig. 35-1). The disease is usually bilateral, and gangrene occurs in less than 1% of cases.

The diagnosis requires the absence of the diseases enumerated under secondary Raynaud phenomenon. An international panel proposed the following consensus criteria for differentiation of Raynaud disease from secondary Raynaud phenomenon: normal capillaroscopy; absence of physical findings suggestive of secondary causes, such as sclerodactyly, calcinosis, and ulcerations; no history of existing connective tissue disease; and negative or low-titer ANA (e.g., 1:40). Although some suggest that Raynaud disease should be present for 2 years before being classified as a primary process, it may take as long as 11 years for some systemic disorders to manifest. Overall, fewer than half of patients presenting with Raynaud symptoms will prove to have a connective tissue disease. The prognosis is good for patients with primary Raynaud disease.

Treatment

Treatments have often been studied but only in patients with secondary Raynaud phenomenon and digital ulceration associated with connective tissue disease, so not all treatments can be assumed to be effective in primary Raynaud disease or Raynaud secondary to other causes. If an underlying cause is found, treatment of the associated condition will often lead to improvement of Raynaud phenomenon. In both primary and secondary Raynaud, exposure to cold should be avoided. This includes avoidance of exposure to cold not only of the extremities but also of other parts of the body, since vasospasm may be induced by reduction of core body temperature, and Raynaud attack of atypical sites, such as the tongue, may occur. Warm gloves should be worn whenever possible. Trauma to the fingertips should be avoided. Smoking is absolutely contraindicated. A Raynaud attack may be broken at times by swinging the affected arm in a wide circle from the shoulder—the "windmill" maneuver. The use of standard nitroglycerin paste has had minimal efficacy and can produce systemic side effects. A new form of topical nitroglycerin, MQX-503, significantly improved skin blood flow without serious adverse events in a recent randomized controlled trial (RCT). Alternative treatments, including ginkgo and other herbal medications, have limited efficacy compared with the standard treatments and cannot be recommended for patients with significantly symptomatic disease.

Calcium channel blockers are the first-line therapy used in Raynaud disease because of their efficacy and low side effect profile. Prolonged-release amlodipine or nifedipine is usually recommended. Some studies indicate that up to two thirds of treated patients will respond favorably. However, a Cochrane review of RCTs of calcium channel blockers for primary Raynaud disease concluded their benefit was minimal, translating to 1.72 fewer attacks per week compared with placebo. Sildenafil and other phosphodiesterase-5 inhibitors are moderately effective in reducing Raynaud severity score, as well as the frequency and duration of Raynaud episodes, and may improve digital ulcer healing. These have become the second-line agents of choice. The angiotensin receptor antagonist losartan reduced the frequency and severity of attacks to a greater extent than nifedipine in an RCT. Conversely, angiotensin-converting enzyme (ACE) inhibitors failed to show benefit in an RCT and are therefore not recommended. Data on selective serotonin reuptake inhibitors (fluoxetine or ketanserin) are mixed, but SSRIs may be useful in refractory cases or when other agents are not tolerated. Intravenous biweekly *N*-acetylcysteine was effective in reducing the number of attacks in an observational study, relatively free of side effects. The use of statins, specifically atorvastatin, in patients with Raynaud caused by systemic sclerosis/scleroderma was associated with a reduction in Raynaud-associated symptoms, possibly through the vasoprotective actions of statins. Statin administration was associated with reduced circulating markers of vascular injury, which are usually elevated in scleroderma patients. Bosentan, an endothelin receptor (ETA and ETB) antagonist, significantly reduces the frequency of Raynaud attacks and reduces new digital ulcers. Iloprost, a prostaglandin analog, has substantial efficacy in scleroderma-associated Raynaud disease and digital ulceration, but it is only slightly better than nifedipine and significantly more expensive. Oral prostaglandins appear to lack similar efficacy, except perhaps at high doses.

In cases refractory to these medical treatments, surgical modalities can be considered. If single digits are involved, botulinum toxin injections in the palm around each involved neurovascular bundle may lead to dramatic and at times immediate pain reduction. Ulcerations of the affected digits heal after the injections. The duration of response is often months to years, and injections can be repeated with similar efficacy. Fat grafting or fat transfer to the hand has also been reported effective in a pilot study. Local digital sympathectomy can be effective and avoids amputation of chronically ulcerated digits. Cervical sympathectomy and endoscopic thoracic sympathectomy may give initial relief, but Raynaud symptoms often recur after 12 to 18 months. However, despite the return of symptoms, digital ulceration is greatly reduced. Compensatory hyperhidrosis is a common complication of thoracic sympathectomy.

ERYTHROMELALGIA

Also called erythermalgia and acromelalgia, erythromelalgia has a population-based incidence of 1.3 per 100,000 per year: 2.0 per 100,000 in women and 0.6 per 100,000 in men. Erythromelalgia is characterized by paroxysmal vasodilation of the feet, with burning, localized pain, redness, and high skin temperature. Infrequently, the hands (Fig. 35-2), face, and ears may be involved. The burning paroxysms may last from a few minutes to several days and are usually triggered by an increase in environmental temperature or by exercise. The average patient has 1–2 attacks per week, but in some patients, the attacks are much more frequent. Cooling and limb elevation can reduce the symptoms, but often relief can only be obtained by immersing the burning feet in ice water. More than 20% of patients will have evidence of cold injury, and more than 1% will have gangrene or undergo amputation. Quality of life is severely impacted by the condition.

Erythromelalgia can be considered primary, secondary, or familial. For treatment purposes, secondary cases of erythromelalgia should be carefully divided into those associated

Fig. 35-2 Erythromelalgia of the hands; normal hands lateral to the patient's hands.

with myeloproliferative diseases, often with elevated platelet counts, and other disorders. Myeloproliferative diseases associated with erythromelalgia include polycythemia vera, thrombotic thrombocytopenic purpura (TTP), and various forms of thrombocythemia. Administration of romiplostim, a thrombopoiesis-stimulating protein, has resulted in erythromelalgia. Low-dose aspirin is effective therapy for erythromelalgia associated with platelet abnormalities. If this fails, other methods to reduce the platelet count, such as administration of hydroxyurea, should be considered.

Acquired erythromelalgia has been reported secondary to topical exposure to isopropyl alcohol and after mushroom poisoning with *Clitocybe acromelalga* and *Clitocybe amoenolens*. Medications that have induced erythromelalgia include calcium channel blockers (both nifedipine and verapamil), ergot derivatives such as bromocriptine and pergolide, and cyclosporine. There may be a long period of treatment (years) with these agents before the appearance of the erythromelalgia. Stopping the medication usually leads to improvement of symptoms within weeks.

In the vast majority of cases seen by dermatologists, erythromelalgia is probably a neurologic disorder. It can be seen in various neurologic conditions or diseases associated with neurologic sequelae, such as peripheral neuropathy, myelitis, multiple sclerosis, autoimmune small-fiber axonopathy, or diabetes mellitus. Erythromelalgia is sometimes associated with Raynaud phenomenon; both are disorders of abnormal neurovascular function. In many patients, no associated neurologic disease may be detected by routine neurologic examination, but careful neurologic testing will reveal evidence of a small-fiber neuropathy in the majority of such cases.

Inherited, familial, or hereditary erythromelalgia usually has its onset in childhood or adolescence (early or late onset). Familial cases have an autosomal dominant inheritance pattern. Familial erythromelalgia is now known to be an "inherited neuronal ion channelopathy." The mutation is in the gene *SCN9A,* which encodes a peripheral sodium channel $Na_V1.7$. This is a mainly peripheral sodium channel with robust expression in dorsal root ganglion neurons and sympathetic ganglion neurons, especially those with nociceptive function. This sodium channel acts as a "threshold" channel and sets the gain in nociceptors. Many mutations in the affected gene have been mapped. Gene mutations causing erythromelalgia occur in areas that affect the structure of the actual channel by substituting amino acids in this critical location. The mutations causing erythromelalgia are gain-of-function mutations that lead to a hyperpolarizing shift of activation, allowing Nav1.7 to open at lower potentials, enhancing excitability. Furthermore, high temperatures have been shown in vitro to cause a significant depolarizing shift in the mutant channels.

The amount of gain of function correlates with age of onset of the disease; more significant mutations have earlier onset. The nature of the mutation also affects the binding of medications to the channel, so various mutations may have different responses to the same medication, depending on whether that mutation allows the drug to bind to the channel. Other gain-of-function mutations in *SCN9A* cause "paroxysmal extreme pain disorder" (formerly called familial rectal pain syndrome). This disorder has prominent autonomic manifestations that include skin flushing, sometimes with only half the face turning red (harlequin color change), syncope with bradycardia, and severe burning pain, most often rectal, ocular, or mandibular. One mutation in $Na_V1.7$ produced a clinical syndrome with features of both erythromelalgia and paroxysmal extreme pain disorder. Autosomal recessive nonsense mutations that cause loss of function of the $Na_V1.7$ channel result in the inability to sense pain. These patients are otherwise neurologically normal.

Interestingly, the association of secondary erythromelalgia with autoimmune conditions has led to the supposition that autoantibodies to the $Na_V1.7$ sodium channel may be present. Immunomodulatory therapy such as intravenous immune globulin (IVIG) has been used successfully in some patients with autoimmune disease and erythromelalgia. When severe, erythromelalgia is a life-altering disease, and aggressive management is warranted. Patients may benefit from referral to special clinics for pain management or pain rehabilitation. At times, simple measures such as immersion in cool water may stop pain crises. Biofeedback can be of benefit. In general, no more than 50% of patients with erythromelalgia of the neuropathic type will respond to any one medication, so the treatment must be tailored to each patient, and often combinations of agents are used. Topical amitriptyline 1% and ketamine 0.5% in a gel are safe topical options and are especially reasonable for affected thin-skinned areas, such as the face or ears, where penetration would be optimal. Oral amitriptyline, sertraline, nortriptyline, pregabalin, and venlafaxine have shown benefit in some patients. Mexiletine, which has a normalizing effect on pathologic gating properties of the $Na_V1.7$ sodium channel mutation, has been reported effective in some patients, as have carbamazepine and the combination of carbamazepine and gabapentin. Neurosurgical intervention has been used in the most severely affected, carefully selected patients who have failed medical management.

Red ear syndrome

Red ear syndrome describes a rarely reported disorder characterized by relapsing attacks of redness and burning affecting both ears, usually only one ear at a time. The attacks are more common in the winter and are precipitated by touching, movements, and exposure to warmth. Associated conditions include neural disorders of the trigeminal and glossopharyngeal nerves, migraines, and LE. It is unclear if red ear syndrome is a disease sui generis or is actually erythromelalgia of the ears. Treatment with oral and topical tricyclic antidepressants has been beneficial. Red ear syndrome must be distinguished from the springtime variant of polymorphous light eruption seen in young males with cold exposure, relapsing polychondritis (the lobe is also involved in red ear syndrome), cellulitis, and borrelial lymphocytoma.

LIVEDO RETICULARIS, LIVEDO RACEMOSA

Livedo reticularis is the term used to describe a netlike, mottled or reticulated, pink or reddish blue discoloration of the skin, mostly on the extremities, especially the legs. It is more prominent with exposure to cold and may vanish with warming. It is usually seen on the lower extremities in young children and women. The pathogenic basis is reduced blood flow and lowered oxygen tension in the venous plexus of the skin. Cutis marmorata is another name for livedoid physiologic mottling of skin exposed to cold. For clinical purposes, it is best to separate livedo reticularis (a benign condition in most cases) from fixed livedo reticularis, better known as livedo racemosa. Livedo racemosa forms irregular networks and broken circular segments that are fixed and do not vary appreciably with temperature changes (Fig. 35-3). The lesions are usually asymptomatic. If necrosis or purpura occurs over the livedoid areas, the terms necrotizing livedo and "retiform purpura," respectively, may be used. Livedo racemosa and livedo with purpura or necrosis are almost always associated with significant systemic disease that requires treatment. Unfortunately, the literature does not always accurately separate these entities, and patients may present with variable livedo (resembling livedo reticularis) and later develop more fixed lesions. In addition, some patients who have more variable livedo may have serious underlying disease that may require evaluation and treatment. These patients may not be easily identifiable initially on physical examination features alone. In this section, the term livedo will be used to describe this cutaneous finding and its association with other conditions. When livedo reticularis is seen, the clinician should consider the following categories of diseases as possibly causal: physiologic, hypercoagulable states (including myelodysplasias, cancer, and antiphospholipid and Sneddon syndromes), vasculitis (especially medium and large vessel), emboli, medications, and neurologic disorders.

Drugs may cause livedo. Amantadine (Symmetrel) can cause livedo reticularis. Quinidine and quinine may be associated with a photosensitivity that is livedoid in appearance, but on biopsy an interface dermatitis will be present. Minocycline can cause livedo, and this is a marker for the development

Fig. 35-3 Livedo racemosa.

of an antineutrophil cytoplasmic antibody (ANCA)–positive vasculitis in these patients. The medication must be stopped immediately. Other medications associated with livedo include gemcitabine, heparin (perhaps associated with heparin-induced antiplatelet antibodies), IFN-β, and bismuth.

Neurologic disorders can create livedo reticularis by altering innervation and, consequently, blood flow in the skin. Brain injury, multiple sclerosis, diabetes mellitus, poliomyelitis, and Parkinson's disease are some examples.

Many of the syndromes with fixed livedo (livedo racemosa) have important systemic implications. These conditions can be either primary thrombotic processes or vascular inflammatory processes. If the vessels of the skin are affected, are the vessels in other organs, specifically the central nervous system (CNS) and kidneys, at risk? Sneddon syndrome usually occurs in young to middle-age women. These patients present with livedo and then develop cerebrovascular infarcts. The prognosis is poor. Frequently, patients have antiphospholipid antibodies (up to 85%) and may have enough features to be diagnosed with systemic lupus erythematosus (SLE). They would be accurately diagnosed as having antiphospholipid antibody syndrome. Other connective tissue diseases, such as dermatomyositis, rheumatoid arthritis, and systemic sclerosis, may have antiphospholipid antibodies and thus feature livedo. For this reason, patients with SLE and livedo are likely to have more severe disease manifestations, such as renal disease, vasculitis, and antiphospholipid antibodies, even in the absence of full-blown Sneddon syndrome. Headache may be the presenting symptom in these patients, and the misdiagnosis of migraine may initially be entertained. Not all patients with Sneddon syndrome can be diagnosed as having antiphospholipid antibody syndrome, however, and their optimal evaluation and management is unclear. Other significant disorders with livedo as a skin manifestation include thrombotic processes (hypercoagulable states, type I cryoglobulinemia), microangiopathic hemolytic anemias (TTP, hemolytic uremic syndrome, disseminated intravascular coagulation), medium- and large-vessel vasculitides, and septicemia. Moyamoya disease is a rare, chronic cerebrovascular occlusive condition characterized by progressive stenosis of the arteries in the circle of Willis. Patients present with ischemic strokes or cerebral hemorrhages. Both idiopathic moyamoya disease and disease connected with factor V Leiden mutation have been associated with livedo reticularis. Divry–van Bogaert syndrome, with livedo racemosa, seizures, and significant CNS disease, may be related to moyamoya or Sneddon syndrome.

Oxalosis may lead to livedo reticularis from deposition of oxalate crystals in and around blood vessel walls. The characteristic crystals are seen on biopsy. Calciphylaxis, with calcium deposits in vessels and tissue, may cause livedo. Other possible causes of livedo include cryofibrinogenemia, Graves' disease (associated with anticardiolipin antibodies), atrial myxoma, tuberculosis (perhaps as a complication of vascular inflammation: vascular-based tuberculid), and syphilis.

Cholesterol emboli

Cholesterol emboli resulting from severe atherosclerotic disease, usually of the abdominal aorta, may cause unilateral or bilateral livedo of the lower extremities. The livedo may not be present with the patient supine and may only be present when the legs are dependent. Patients frequently have concomitant cyanosis (blue toes), purpura, nodules, ulceration, or gangrene (Fig. 35-4). Pain often accompanies the skin lesions. Acute renal failure occurs in up to 75%, and about one third of patients will have characteristic skin lesions. An eosinophilia on complete blood count (CBC) is present in 80% of cases. Older men with severe atherosclerotic disease are at greatest risk. They are often receiving anticoagulant therapy, and many have recently undergone vascular surgery or instrumentation. Slightly more than 1% of left-sided heart catheterizations are complicated by cholesterol emboli. The differential diagnosis includes vasculitis, septic staphylococcal emboli resulting from endocarditis or an infected aneurysm, and polyarteritis nodosa. Cholesterol emboli can involve all organs except the lungs; therefore, disease burden can range from mild to overwhelming. Mortality can be significant, as high as 90% among those with multisystem involvement, in whom renal failure, bowel infarction, and other devastating complications can occur. Livedo reticularis of recent onset in an elderly person warrants consideration of this diagnosis. Deep biopsy with serial sections may demonstrate the characteristic cholesterol clefts within thrombi. Frozen-section evaluation with polarized microscopy is particularly sensitive. Retinal emboli occur in up to 25% of patients, so funduscopic examination can also aid in diagnosis. Low-dose corticosteroids may

Fig. 35-4 Cholesterol emboli.

be useful for treatment of cholesterol emboli–associated renal insufficiency.

Evaluation of the patient with possible cutaneous vascular disorders

In the evaluation of patients who present with livedo, purpura, or ulceration, a broad differential diagnosis must be entertained. The diseases considered should include primary pathology of the cutaneous vasculature. In general, these vascular disorders of the skin are divided into two main groups: vasculitis and vasculopathy. Vasculitis includes disorders in which the primary damage in the blood vessels results from inflammatory cells infiltrating and damaging vessel walls. As a consequence of inflammation within vessels, the clotting cascade is triggered, and subsequent thrombosis may be seen in and adjacent to involved vessels. In vasculopathy, the primary process is thrombosis. This is usually caused by a hypercoagulable state. Once thrombosis occurs, inflammatory cells enter the vessel and vessel wall in an attempt to reestablish local circulation. Thus, late in a primary thrombotic process, vascular inflammation is seen and can be misinterpreted as "vasculitis." Emboli can result in a similar histologic picture, because late embolic lesions may also be inflammatory and histologically misleading. All these processes—vasculitis, vasculopathy, and emboli—alter cutaneous blood flow and can be accompanied by livedo. If vessels lose competence, they leak, creating purpura. If vasculitis, vasculopathy, or embolus is severe enough or affect a large enough vessel, the viability of the overlying skin is compromised, and necrosis and ulceration may occur.

Because these entities resemble one another both clinically and histologically, accurate diagnosis is difficult for even the most skilled dermatologist. Careful sampling of early lesions, with large and deep biopsies, if necessary, may be required to find the "primary" vascular pathology. Since vasculitis can be a focal process, step sections may be required to find the diagnostic features. In addition, the diagnosis proposed must be interpreted in the context of other elements of the patient's medical condition, such as medications, infections, underlying diseases, and involvement of other organ systems besides the skin.

LIVEDOID VASCULOPATHY

Synonyms for livedoid vasculopathy include livedoid vasculitis, atrophie blanche, segmental hyalinizing vasculitis, livedo reticularis with summer/winter ulceration, and painful purpuric ulcers with reticular pattern of the lower extremities (PURPLE). It is a hylalinizing, thrombo-occlusive vascular disease characterized by clotting of medium-sized arterioles. The disorder is chronic, recurrent, and painful. Clinically, purpuric macules and papules cluster around the lower legs, ankles, and dorsal feet. These lesions may develop a hemorrhagic crust, then break down to form irregular, superficial ulcers bordered by violaceous erythema (Fig. 35-5). Over many months, the ulcers heal with porcelain-white, atrophic scars with peripheral telangiectasias, termed atrophie blanche.

Fig. 35-5 Livedoid vasculopathy.

Other cutaneous findings, such as livedo reticularis, may also be present. About two thirds to three quarters of patients are female; mean age of onset is 45 years. The condition is bilateral in 80% of patients, and ulceration occurs in 70%.

This clinical presentation must be distinguished from other disorders that can cause purpura and ulcers. The differential diagnosis is broad because many conditions can cause livedo reticularis with ulceration of the lower extremities. Atrophie blanche–like lesions are a fairly common end result of ulceration and are therefore not specific for livedoid vasculopathy.

Conditions that mimic livedoid vasculopathy and must be excluded include, most importantly, the vasculitides—cutaneous small-vessel vasculitis, cryoglobulinemic vasculitis, ANCA-associated vasculitis, and polyarteritis nodosa. Vasculitis involving medium-sized cutaneous vessels can present with ulceration and atrophic, stellate scarring. The presence of other systemic manifestations typical for these conditions should help differentiate them from livedoid vasculopathy. Venous insufficiency, arterial insufficiency, and traumatic ulceration may heal with atrophie blanche and therefore mimic livedoid vasculopathy. Features such as lower extremity edema, hemosiderosis, and venous varicosities may suggest the presence of venous insufficiency, whereas absent pulses, cool extremities, diminished hair growth, and severe pain are typical of arterial insufficiency. A history of trauma should be obtained. A history of characteristic ulcers should be used to distinguish livedoid vasculopathy from other disorders that can lead to atrophic scarring. Ultimately, however, biopsy should be used to confirm the diagnosis and exclude other causes of ulceration, especially vasculitis.

Biopsy of an affected area must be sufficiently deep to sample medium-sized vessels in the deep dermis or subcutis. Typical findings include hyalinized, thickened dermal blood vessels with fibrin deposition and focal thrombosis. Perivascular hemorrhage and mild perivascular lymphocytic infiltrate can be seen. Notably, no leukocytoclasis or true vasculitis is seen. Results of direct immunofluorescence (DIF) studies are nonspecific. Biopsies of older lesions of atrophie blanche may be most notable for epidermal atrophy and flattening of the rete ridges, as well as recanalization of occluded vessels. In about 15% of patients, an initial biopsy does not reveal diagnostic histology, and a second is required. After two biopsies, diagnostic pathology is found in 98% of patients.

Livedoid vasculopathy is a vaso-occlusive condition, a hypercoaguable state with spontaneous thrombosis leading to local hypoxia and skin ulceration. A variety of risk factors for thromboembolism have been identified in association with livedoid vasculopathy. These include genetic and acquired

disorders predisposing to thrombosis such as factor V Leiden mutation; protein C or S deficiency; hyperhomocysteinemia, which results in increased clotting; increased plasminogen activator inhibitor (PAI)–1, an important inhibitor of the fibrinolytic system; methylenetetrahydrofolate reductase gene mutation; increased platelet aggregation; low tissue-type plasminogen activator (tPA) levels; enhanced fibrin formation; high levels of lipoprotein A; antithrombin III deficiency; antiphospholipid antibodies; physiologic decrease in levels of protein C and S, as in pregnancy; and other underlying hypercoaguable states (e.g., connective tissue diseases, malignancies).

A review of 45 patients with livedoid vasculopathy included 29 with hypercoaguable workup, 12 of whom (41%) had abnormalities, some multiple. In addition, a number of patients were noted to have connective tissue disease, solid-organ carcinoma, or hematologic malignancy. Livedoid vasculopathy was associated with a comorbid disease or procoagulant state in 58% (26/45). This likely represents an underestimate because exhaustive coagulation screening was not performed in most patients. In a prospective study of 34 patients, 52% (18 patients) screened had laboratory evidence of a coagulopathy, of whom 32% (11) responded to anticoagulant therapy. Some patients diagnosed with "idiopathic" livedoid vasculopathy, in whom no associated abnormality is found, actually have underlying hypercoaguable states discernible only after subsequent, more thorough, workup. As testing for coagulation abnormalities evolves, a greater percentage of livedoid vasculopathy cases will likely be associated with underlying disorders.

Livedoid vasculopathy has been associated with deep venous thrombosis, pulmonary embolism, and cerebrovascular accident (stroke), among other systemic thromboembolic events. Limited data exist to guide management, but in general, treatment of livedoid vasculopathy should be directed at treating the underlying hypercoaguable state, if any. In patients with coagulopathy or personal or family history of thromboembolism, more aggressive therapy may be warranted. A therapeutic ladder for treatment of livedoid vasculopathy begins with local wound care and compression for edema, along with basic measures to decrease risk of thromboembolism (e.g., smoking cessation), followed by the addition of relatively low-risk pharmacologic interventions (e.g., pentoxifylline or aspirin), before moving on to anticoagulants (e.g., warfarin, low-molecular-weight heparin, rivaroxaban), and other agents with a less favorable risk profile, if needed. Exceptions to this order might include the introduction of hydroxychloroquine for connective tissue disease, folic acid and vitamin B complex for methylenetetrahydrofolate reductase mutation, danazol or stanozolol for cryofibrinogenemia, and warfarin for antiphospholipid antibody syndrome or a history of systemic thromboembolism. Controlled trials are needed to define better the role of these agents in the treatment of livedoid vasculopathy as well as the possible role of therapy in preventing systemic thromboembolic complications. Systemic immunosuppression is usually not beneficial for livedoid vasculopathy, because its pathogenesis is thrombo-occlusive, not inflammatory. A dramatic response to high-dose corticosteroids, for example, suggests an alternate diagnosis.

CALCIPHYLAXIS

Calciphylaxis (calcific uremic arteriolopathy) is an increasingly reported and frequently fatal syndrome that occurs most often in the setting of chronic renal failure but may also occur with normal renal function (nonuremic calciphylaxis). In calciphylaxis, progressive calcification of the media of arterioles leads to vessel injury, intimal fibrosis, and thrombosis, followed by ischemic necrosis of the skin and soft tissue. About 1–4% of patients on hemodialysis and 4% of patients on peritoneal dialysis develop calciphylaxis. About half of patients are diabetic, and more than half have a body mass index (BMI) greater than 30; every gain in BMI of 1 point over 30 increases the risk for calciphylaxis by 10%. Women outnumber men 3:1 to 4:1. Other identified risk factors include liver disease, hypoalbuminemia, protein C deficiency, and exposure to warfarin or systemic glucocorticoids.

The pathogenesis of calciphylaxis remains poorly understood. Precipitation of calcium phosphate in vessel walls is generally thought to be mediated by elevated serum calcium, phosphate, and parathyroid hormone (PTH) levels, as are seen in chronic renal failure. Indeed, PTH levels are often elevated in affected patients, and the disease can be seen in the setting of primary hyperparathyroidism as well as the secondary hyperparathyroidism of chronic renal failure. Calcium-phosphate product is greater than 70 in about 20% of

calciphylaxis patients. However, a case control-study showed no statistical difference in serum calcium, phosphate, PTH, or calcium-phosphate product in patients with calciphylaxis compared with other dialysis patients. Calcium ingestion, as in the form of calcium-containing phosphate binders, did increase risk.

Calciphylaxis may be best thought of as a disease resulting from exposure of a susceptible host with dysfunctional calcium homeostasis to a particular "challenging" agent or precipitating factor, such as metal salts, fluctuation in renal function, or vascular inflammation. For calcification to occur, vascular smooth muscle cells must transform into osteoblast-like cells. Skin lesions in calciphylaxis exhibit significant upregulation of bone morphogenic protein 2 (BMP-2) and increased expression of inactive uncarboxylated matrix Gla protein (Glu-MGP), osteopontin, fibronectin, laminin, and collagen I, indicating extensive remodeling of the subcutaneous extracellular matrix.

Calciphylaxis begins as fixed livedo reticularis (livedo racemosa), which is frequently firm or hard to the touch. Areas within the livedo become increasingly violaceous and eventually purpuric, bullous, and necrotic (Fig. 35-6). Affected tissue has reduced oxygenation. Lesions affect the legs below the knees in 90% of patients. More proximal lesions and those of the fatty areas of the thighs, buttocks, and abdomen occur in about two-thirds. Severe pain is a cardinal feature of calciphylaxis, often requiring narcotic analgesia for control. Ischemic myopathy may occur in severe cases, and muscle pain may precede the appearance of the skin lesions. Penile calciphylaxis is a particularly painful variant. The glans penis develops a deep necrotic ischemic ulceration. Penectomy is often required for pain management. Calciphylaxis of the temporal artery may resemble temporal arteritis.

Necrotic skin lesions are resistant to healing, and infection of open wounds with septicemia is the most common cause of death. The mortality of calciphylaxis patients is about 50% at 1 year and 80% at 2 years; for patients with both proximal and distal disease, the 1-year mortality is 90%. Mortality doubles in those with ulcerative lesions.

Skin biopsy is generally recommended to confirm the diagnosis of calciphylaxis. It should be adjacent to the necrotic area where there is erythema or early purpura, and it should be deep and large enough to identify diagnostic features. This may require an incisional rather than a simple punch biopsy. Vascular calcification is common in all patients with chronic renal failure, so this alone cannot confirm the diagnosis. In addition, there should be evidence of tissue damage (necrosis), extravascular calcification, and thrombosis in the arterioles of the dermis and subcutaneous tissue. Because the sensitivity of biopsy may be poor, and the clinical presentation often strongly suggests the diagnosis, the true importance of skin biopsy in calciphylaxis is uncertain. Plain x-ray films of affected areas may reveal a characteristic netlike pattern of calcification.

Much of the treatment for calciphylaxis is directed at altering abnormal calcium metabolism. Because of its high mortality rate, patients are frequently treated with multiple agents at once, making the efficacy of any single agent particularly difficult to determine. Low-calcium dialysate, non–calcium carbonate phosphate binders, cinacalcet, bisphosphonates, and intravenous sodium thiosulfate have all been used with some success. Combination therapy is increasingly favored, and retrospective data appear to support its use. Potential exacerbating or triggering agents, such as vitamin D, calcium, warfarin, and iron, should be stopped. Pain control is essential. Once ulcerations are present, gentle debridement is associated with healing and increased survival. Intralesional sodium thiosulfate, if tolerated, may play a role in localized calciphylaxis. Hyperbaric oxygen therapy may be a useful adjunctive therapy for ulcer healing. Parathyroidectomy is best reserved for patients refractory to the previous regimens who have continued marked PTH elevation.

MARSHALL-WHITE SYNDROME AND BIER SPOTS

Bier spots are pale, irregularly shaped macules about 10 mm in size, usually found on the upper and lower extremities of young adults. The spots are a type of vascular mottling that can be elicited by placing the limbs in a dependent position; they resolve when the limbs are raised and disappear when the surrounding skin is blanched. They likely represent areas of localized vasoconstriction surrounded by relative vasodilation. Although primarily idiopathic, asymptomatic, and transient, there are case reports of Bier spots in association with such disorders as cryoglobulinemia and scleroderma renal crisis and with pregnancy. Awareness of the condition can prevent misdiagnosis of a pigmentary disorder.

Heller M: Diffuse Bier spots. Dermatol Online J 2005; 11(4):2.

PURPURA

Purpura is the term used to describe extravasation of blood into the skin or mucous membranes. It presents as distinctive, brownish red or purplish macules a few millimeters to many centimeters in diameter. Several terms are used to describe various clinical manifestations of purpura.

Petechiae are superficial, pinhead-sized (<3 mm), round, hemorrhagic macules, bright red at first, then brownish or rust-colored. They are most often seen in dependent areas, occur in crops, regress over days, and usually imply a disorder of platelets rather than of coagulation factors, which typically give rise to ecchymoses or hematomas rather than petechiae.

Ecchymoses are commonly known as bruises. These extravasations signify a deeper, more extensive interstitial hemorrhage that forms a flat, irregularly shaped, blue-purple patch. Such patches gradually turn yellow and finally fade away.

Vibices (singular, vibex) are linear purpuric lesions.

Hematoma designates a pool-like collection of extravasated blood in a dead space in tissue that, if of sufficient size, produces swelling that fluctuates on palpation. Hematomas are usually walled off by tissue planes.

Pathogenesis

Purpura may result from hypercoagulable and hypocoagulable states, vascular dysfunction, idiopathic thrombocytopenic purpura, TTP, disseminated intravascular coagulation (DIC), drug-induced thrombocytopenia, bone marrow failure, congenital or inherited platelet function defects, acquired platelet function defects (aspirin, renal or hepatic disease, gammopathy), and thrombocytosis secondary to myeloproliferable diseases. Most of these disorders produce findings of nonpalpable purpura. Ecchymosis predominates in procoagulant defects, such as hemophilia, pharmacologic anticoagulation, vitamin K deficiency, and advanced hepatic disease resulting in impaired synthesis of clotting factors. There is often a component of trauma. Increased ecchymosis can be the result of poor dermal support of blood vessels, most often localized to the area of trauma, and may result from actinic (senile) purpura, topical or systemic corticosteroid therapy, scurvy, systemic amyloidosis, Ehlers-Danlos syndrome, or pseudoxanthoma elasticum.

Prothrombotic disorders form characteristic "retiform" purpura or purpura associated with livedo reticularis. These include disorders in which fibrin, cryoglobulin, or other material occludes vessels. Representative causes include monoclonal cryoglobulinemia, cryofibrinogenemia, DIC, purpura fulminans, protein C or S deficiency, warfarin-induced necrosis, heparin necrosis, cholesterol emboli, oxalate crystal occlusion, and antiphospholipid syndrome.

Evaluation

A history and physical examination are often sufficient to evaluate for purpura. A family history of bleeding or thrombotic disorders, duration of symptoms, use of drugs and medications that might affect platelet function and coagulation, and review of medical conditions that may result in altered coagulation should be documented. Physical examination should stress the size, type, and distribution of purpura; a search for telangiectasias; a joint examination; and an evaluation of skin elasticity, unusual scars, and unusual body habitus. Correlation of purpura morphology with pathogenesis allows for a more focused approach.

A CBC and differential can be used to assess for microangiopathic anemia, screen for myeloproliferative disorders, and assess the number and morphology of platelets. A bleeding time is the preferred method of assessing platelet function. The partial thromboplastin time (PTT) and prothrombin time (PT) are tests to evaluate abnormal coagulation states.

THROMBOCYTOPENIC PURPURA

Thrombocytopenic purpura may be classified into two large categories: states resulting from accelerated platelet destruction and states resulting from deficient platelet production. Accelerated platelet destruction may be immunologic or nonimmunologic. The former may be caused by antibodies (autoimmune or drug-induced thrombocytopenia), isoantibodies (congenital or posttransfusion), immune complex disease, or other immunologic processes, such as erythroblastosis fetalis, neonatal lupus, scleroderma, other connective tissue diseases, or acquired immunodeficiency syndrome (AIDS). The group of thrombocytopenias with accelerated platelet destruction also includes TTP and DIC. Deficient platelet production may be related to diseases such as aplastic anemia and leukemia.

Immune thrombocytopenic purpura (immune thrombocytopenia)

Immune thrombocytopenic purpura (ITP) was also known as "idiopathic" thrombocytopenic purpura or Werlhof's disease. It is an autoimmune disease characterized by an isolated thrombocytopenia (platelet count <100,000). The causative antibodies are directed at molecules on the platelet surface, leading to their premature sequestration and destruction, primarily in the spleen. ITP is called primary in the absence of another cause, or secondary if there is a causal association, such as "secondary ITP (SLE-associated)." Bleeding symptoms are minimal or absent in a large proportion of cases. Cutaneous manifestations can include an acute or gradual onset of petechiae or ecchymoses on the skin and mucous membranes, especially in the mouth. Epistaxis, conjunctival hemorrhages, hemorrhagic bullae in the mouth (Fig. 35-7), and gingival bleeding may occur. Melena and hematemesis are also present, as well as menorrhagia, which may be the first sign of the disease in young women. Chronic leg ulcers occasionally develop.

Bleeding can occur when the platelet count is less than 50,000/mm^3. Posttraumatic hemorrhage, spontaneous

Fig. 35-7 Oral hemorrhagic bullae as presenting complaint in immune thrombocytopenic purpura.

hemorrhage, and petechiae may appear. The risk of serious hemorrhage is greatly increased at levels below 10,000/mm^3. The most serious complication is intracranial hemorrhage. ITP may be fatal, but most mortality in adults results from treatment complications. Bleeding time is usually prolonged and coagulation time normal, whereas clot retraction time is abnormal and capillary fragility increased. Increased numbers of megakaryocytes are found in the bone marrow.

The age of onset determines the clinical manifestations and course. In children, onset is often acute and follows a viral illness in 50–60% of patients. Parvovirus B19 is frequently complicated by thrombocytopenia, which may be ITP or simply a consequence of reduced bone marrow production of platelets. The average lag between purpura and the preceding infection is usually 2 weeks (range 1–4). Most of these cases resolve spontaneously. Since children are at much less risk of developing serious hemorrhagic complications, a more conservative management approach may be taken. A few patients will develop chronic thrombocytopenia, and deaths, usually from cerebral hemorrhage, have been reported. In a series of 332 children with ITP, 58 (17%) had episodes of major hemorrhage. One death resulted from sepsis. In another series of 427 cases, 323 (72%) had mild to benign disease. About 85% of children who undergo splenectomy experience remission. More than half of the remaining patients spontaneously remit within 15 years.

The chronic form of ITP occurs most often in adults, is persistent, and has a female/male ratio of 2:1 to 4:1. Secondary ITP is more common in adults. Human immunodeficiency virus (HIV) infection, hepatitis C, and autoimmune disease are the most common associated disorders. Treatment of associated disease may lead to improvement of the thrombocytopenia. Breast cancer has been associated with ITP, with a parallel course in one third of cases. Other malignancies have also been associated with ITP. *Helicobacter pylori* infection as a cause of ITP is controversial, but testing for *H. pylori* antibodies and treatment for infection carry limited toxicity and thus could be considered.

In elderly patients, ITP is more difficult to manage. Patients more frequently have major bleeding complications, more complications from immunosuppressive agents, especially corticosteroids, and more complications from splenectomy. Corticosteroids have a particularly low response rate in elderly ITP patients. Danazol has demonstrated reasonable safety and efficacy in the elderly population.

The differential diagnosis of ITP includes drug-induced thrombocytopenia, myelodysplasia, TTP, and congenital/hereditary thrombocytopenia. The goal of treatment for ITP is to raise the platelet count above 20,000 to 30,000 and to stop all bleeding symptoms. Platelet transfusions are indicated if there is significant bleeding or if the platelet count is dangerously low. If the platelet count is greater than 20,000–30,000, the patient may be closely monitored. The treatment of ITP has changed with the availability of new approaches. Initial treatment is a short course of high-dose corticosteroids, either for 1–2 weeks or as monthly pulses. IVIG or anti-(Rh)D, also known as IV Rh immune globulin (IG), may be given with this treatment. Platelet survival is increased if transfused immediately after immunoglobulin infusion. If the patient relapses or has persistent symptoms, systemic corticosteroids are given with rituximab, anti-(Rh)D, IVIG, or a thrombopoietin agonist such as eltrombopag or romiplostim. Splenectomy can be considered a second-line treatment, although age over 60 makes this treatment less desirable. Danazol can be added as a second-line agent, especially in the elderly patient. When second-line treatments have failed in patients with chronic and persistent or worsening disease, immunosuppression with mycophenolate mofetil (MMF), azathioprine, cyclosporine, vincristine, lymphoma-type chemotherapeutic regimens, and even autologous transplantation could be considered.

Drug-induced thrombocytopenia

Thrombocytopenic purpura resulting from drug-induced antiplatelet antibodies may be caused by agents such as heparin, sulfonamides (antibiotics and hydrochlorothiazide), digoxin, quinine, quinidine, chlorothiazide, penicillin, cephalosporins, minocycline, acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), statins, fluconazole, protease inhibitors, H2 blockers, antiplatelet agents, rifampin, and lidocaine.

Heparin-induced thrombocytopenia (HIT) is associated with life-threatening arterial and venous thrombosis and, to a lesser extent, hemorrhagic complications. The platelet count usually begins to fall 4–14 days after starting heparin, more frequently in a patient with prior exposure to the medication. Platelet counts drop to about 50% of their pre-HIT level, usually with a nadir of about 50,000, and rarely 10,000. HIT is mediated by an antibody to the platelet factor 4 (PF4)–heparin

complex. The antibody cross-links FcγRII receptors on the platelet surface, resulting in platelet activation, aggregation, and simultaneous activation of blood-coagulation pathways. Tests for HIT antibodies include immunoassays such as enzyme-linked immunoassay (ELISA) and functional tests.

Treatment for drug-induced thrombocytopenia consists of removal of the offending agent. All forms of heparin, including heparin flushes, should be discontinued. Because the HIT antibody continues to activate platelets after heparin cessation, patients with HIT have a persistently high risk of thrombosis and an ongoing need for anticoagulation. A nonheparin anticoagulant (e.g., argatroban, bivalirudin, fondaparinux) should be begun immediately unless there is a strong contraindication to anticoagulation, such as active bleeding or high bleeding risk. Warfarin can cause microthrombosis in these patients, so it should be avoided until after the patient is stably anticoagulated with another agent and the platelet count has recovered to 150,000 or higher. The total duration of anticoagulation should be at least 2–3 months in the absence of a thrombotic event and 3–6 months if thrombosis has occurred.

THROMBOTIC MICROANGIOPATHY

The diagnosis of a thrombotic microangiopathy is made in the presence of a microangiopathic hemolytic anemia and thrombocytopenia, in the absence of another plausible explanation. Thrombotic thrombocytopenic purpura and hemolytic uremic syndrome are the two major diseases in this group. Certain drugs, such as cyclosporine, quinine, ticlopidine, clopidogrel, mitomycin C, docetaxel, trastuzumab, and bleomycin, have been associated with a thrombotic microangiopathy.

Thrombotic thrombocytopenic purpura

Classically, TTP consists of the pentad of microangiopathic hemolytic anemia, thrombocytopenic purpura, neurologic abnormalities, fever, and renal disease. However, only the minority of patients (20–30%) present classically; many patients do not have renal disease, and CNS findings are not required for the diagnosis. The diagnosis of TTP requires only a Coombs-negative microangiopathic hemolytic anemia and thrombocytopenia with platelet aggregation in the microvasculature. Most patients will develop neurologic findings. Fever is present in 75%. Multiple ecchymoses and retiform purpura may be found on the skin. The presence of schistocytes on a blood smear is the morphologic hallmark of the disease, and a schistocyte count greater than 1% in the absence of other known causes of thrombotic microangiopathy strongly suggests a diagnosis of TTP. Tests may show a decreased hematocrit and decreased platelets, an elevated lactate dehydrogenase level, and elevated indirect bilirubin. A delay in diagnosis may lead to a mortality rate as high as 90%. For this reason, the presence of microangiopathic hemolytic anemia and thrombocytopenia in the absence of an obvious cause (e.g., DIC) is justification enough to begin empiric therapy. Biopsies demonstrate hemorrhage and fibrin occlusion of vessels. Inflammation is absent. Studies of plasma samples from patients with active TTP show the presence of unusually large von Willebrand factor (vWF) multimers. The underlying cause of TTP is a congenital or acquired deficiency of the vWF-cleaving protease, ADAMTS13. vWF is secreted by the endothelial cell in long multimers, which should be cleaved into monomers by ADAMTS13 and released into the circulation. Instead, multimers circulate and extend from the surface of the endothelial cells in the microvasculature. Platelets adhere to these multimers and the surface of the endothelial cell, leading to microvascular thrombosis.

The two forms of TTP are idiopathic and congenital (Upshaw-Schulman syndrome). Congenital TTP is less common (<10% of cases) and usually presents in infancy or childhood with jaundice and thrombocytopenia. Some patients with a congenital deficiency of ADAMTS13 do not present until adulthood or may even remain asymptomatic. The course is frequently relapsing TTP at regular intervals. Idiopathic TTP is a rare disease, about 10 cases per 1 million population per year. Women represent 70% of cases, and those of African descent have a ninefold greater risk of developing idiopathic TTP. Idiopathic TTP is caused by an autoantibody directed against ADAMTS13 that can be detected in up to 85% of cases. Neurologic symptoms are the most frequent presentation, ranging from confusion to seizures to coma.

Plasma exchange with fresh frozen plasma is the treatment of choice for TTP. Before it was instituted, 80% of these patients died; now, 80% survive. Plasma exchange clears the vWF multimers, reduces the autoantibody, and replenishes the inhibited ADAMTS13. If plasma exchange is not immediately available, simple plasma infusion can be performed until it can be instituted. Plasma exchange is usually continued daily until clinical symptoms improve and the platelet count is above 150,000, generally about 5–10 total exchanges. In conjunction with plasma exchange, glucocorticoids may be given, although their success is variable. Platelet transfusions should be avoided except in the setting of life-threatening (i.e., CNS) bleeding. Cyclosporine, cyclophosphamide, and rituximab have been used in refractory cases, with promising results. Splenectomy can also be considered. Congenital TTP is usually much easier to treat, with only small amounts of normal plasma infusion required to provide the missing ADAMTS13 and stop the clotting.

Hemolytic uremic syndrome

Hemolytic uremic syndrome (HUS) has many similarities to TTP but is now considered a distinct entity, both clinically and pathogenically. HUS is usually a disease of childhood. Patients have a microangiopathic hemolytic anemia, often following a diarrheal illness caused by Shiga toxin (Stx)–producing *Escherichia coli*. The annual incidence is 6.1 cases per 100,000 population. It is the most common cause of acute renal injury requiring transplantation in children age 1–5. *Streptococcus pneumoniae* infection can also precipitate HUS. Cases of HUS not following such infections are called "atypical HUS."

Fever is usually absent in HUS patients. Renal insufficiency occurs in all patients and is the hallmark of HUS. Neurologic

disease can occur but affects less than half of patients. Skin involvement is unusual but may take the form of retiform purpura and petechiae.

The pathogenic mechanism of typical HUS is endothelial damage caused by the bacterial toxin and subsequent complement activation on the endothelial surface. The affected vessels are thickened, endothelial cells are detached, and the vascular lumen is narrowed and occluded by platelet thrombi. The renal vessels are at particular risk, since the subendothelial membrane is exposed and vulnerable to complement-mediated damage. In atypical and familial HUS, similar complement activation via the alternative pathway (through C3b) occurs on endothelial surfaces, leading to endothelial damage and intravascular thrombosis.

In atypical and familial HUS, mutations in the alternative complement cascade have been identified. Complement factor H (CFH) mutations are most common, and many patients are heterozygotes. The abnormal CFH complexes with the normal CFH, inactivating it. CFH is the major downregulator of the alternative complement cascade as it degrades C3b. Loss of CFH activity allows for unopposed C3b activity and complement activation. Other mutations are in complement factor I (CFI), which cleaves c3B and C4b. Mutations in membrane cofactor protein (MCP), a cofactor for CFI, in C3 itself, in complement factor B (component of C3b), and in thrombomodulin can also cause atypical HUS. The type of mutation determines the clinical course of atypical HUS, with CFH, CFI, CFB, and thrombomodulin mutations having rates of death or end-stage renal disease of more than 50%. HUS recurs in more than three quarters of patients with CFH and CFI mutations. Some patients are compound heterozygotes with mutations in two of the genes previously noted. About 6% of patients have an autoantibody to CFH and have "autoimmune HUS."

Although atypical or familial HUS is a disorder caused by a genetic deficiency in most cases, onset may not occur until middle age. About 67% of atypical HUS occurs during childhood, with almost all patients with anti-CFH antibodies diagnosed before age 16. Oral contraceptive (OC) use may trigger HUS in 8% of patients with CFH and 20% of patients with CFI mutations.

The treatment of HUS is primarily supportive, including management of renal failure. Plasma exchange may be used but unfortunately does not have the same degree of benefit in HUS as in TTP. Eculizumab, a humanized monoclonal antibody to C5, is effective for the treatment of complement-mediated HUS caused by CFH and CFI mutations and is the first treatment approved by the U.S. Food and Drug Administration (FDA) for atypical HUS. Some data suggest eculizumab may also be beneficial for Stx-associated HUS, but this remains controversial. The cost of the medication, about $400,000 (U.S.) per year, may be prohibitive.

Corticosteroids, azathioprine, vincristine, MMF, and rituximab may be used in atypical HUS. The role of kidney transplantation in atypical HUS is unclear because of the high rate of recurrence and loss of the graft. The likelihood for a successful outcome after transplantation depends on mutation type.

NONTHROMBOCYTOPENIC PURPURA (DYSPROTEINEMIC PURPURA)

Cryoglobulinemia and cryofibrinogenemia

The term cryoglobulinemia refers to the presence in the serum of proteins that precipitate at temperatures below 37°C and redissolve on rewarming. These tend to be chronic conditions, unless the underlying disease process is treated. Abnormal serum proteins behaving as cryoglobulins and cryofibrinogens may be IgG, IgM, or both. Type I cryoglobulinemia results from monoclonal immunoglobulins, usually IgM and less frequently IgG, IgA, or light chains caused by an underlying lymphoproliferative disorder, usually multiple myeloma or macroglobulinemia. Type II cryoglobulinemia results from monoclonal IgM (rarely IgG and IgA) immunoglobulins, which have rheumatoid factor (RF)–like activity and form complexes to the constant, fragment crystallizable (Fc) region of polyclonal IgG. This can occur in many connective tissue diseases and may also be caused by the B-cell proliferation seen in hepatitis C virus (HCV) infection. Type III cryoglobulinemia (mixed cryoglobulinemia), in which the cryoglobulins

Fig. 35-8
Cryoglobulinemia.

are polyclonal and of various classes, is associated with HCV infection in more than 90% of cases. Together, types II and III cryoglobulinemia constitute 80% of cases.

Purpura is most likely to occur on exposed surfaces after cold exposure. It may be of sudden onset and may clear rapidly once the patient is kept warm. Marked brown hyperpigmentation of the dorsal feet, at times in a livedoid pattern, may suggest this diagnosis. Cryoglobulinemia can be the cause of chronic leg ulcers (Fig. 35-8). An unusual clinical presentation of type I cryoglobulinemia in association with multiple myeloma is follicular hyperkeratosis of the central face, especially the nose.

Systemic complications in type I cryoglobulinemia relate primarily to hyperviscosity and thrombosis. Manifestations of type II and III disease are multisystem and similar to those of other types of small-vessel to medium-vessel vasculitis, including arthralgias and myalgias, glomerulonephritis, interstitial pulmonary infiltrates, and neuropathy.

In monoclonal disease, the biopsy reveals amorphous, jelly-like, eosinophilic material in the vessel lumen. In types II and III cryoglobulinaemia, a skin biopsy reveals classic leukocytoclastic vasculitis and less often, features of polyarteritis nodosa.

Asymptomatic disease need not be treated. With symptomatic disease, the aim of therapy is to treat, eliminate, or control the underlying condition and to suppress the associated immune response. For type I cryoglobulinemia, this means addressing the associated myeloproliferative disorder. Thalidomide was beneficial in one patient with a type I cryoglobulin, retiform purpura and clonal plasma cell expansion. For cryoglobulinemia associated with HCV or connective tissue disease, options include systemic corticosteroids, colchicine, immunosuppressants such as cyclophosphamide or azathioprine, and IVIG. Plasmapheresis is indicated for severe or refractory disease. Simple plasma exchange can be helpful, but cryofiltration apheresis is the best method to remove cryoproteins in the treatment of cryoprecipitate-induced diseases. Reduction of the HCV viral load is the long-term solution in HCV-associated cases and can result in disappearance of the cryoglobulins. Improved treatment options for HCV are increasingly available. Mixed cryoglobulinemia with renal, neurologic, and cardiac disease refractory to other treatments may respond to rituximab.

Compared with cryoglobulinemia, cryofibrinogenemia is less often symptomatic and generally more readily treatable. Patients most often present with purpura, skin necrosis, and arthralgias; ulceration and gangrene can result. The precipitating cryofibrinogen is a cold-insoluble complex of fibrin, fibrinogen, and fibrin split products with albumin, cold-insoluble globulin, factor VIII, and plasma proteins. Associated collagen vascular disorders, infections, and malignancies are significantly more common in patients with both cryofibrinogens and cryoglobulins than in those with isolated cryofibrinogenemia. Cryofibrinogen has been associated with calciphylaxis in the setting of renal disease and livedoid vasculopathy when accompanied by other prothrombotic risks. Familial primary cryofibrinogenemia manifests as painful purpura, with slow-healing ulcerations and edema of both feet during the winter months. Therapy beyond cold avoidance is with aspirin, corticosteroids, or stanazol for moderate disease. Immunosuppressive and antithrombotic therapies are given for severe disease. Response rates are high, but relapses are common.

Waldenström hyperglobulinemic purpura (purpura hyperglobulinemica)

Waldenström hyperglobulinemic purpura presents with episodic showers of petechiae that may burn or sting, occurring mainly on the lower extremities. The dorsa of the feet are intensely involved, and the petechiae diminish on the ascending parts of the feet (Fig. 35-9). A diffuse "peppery" distribution is typically noted, resembling Schamberg's disease. The petechiae may be induced or aggravated by prolonged standing or walking or by wearing constrictive garters or stockings.

Serum protein electrophoresis demonstrates a broad-based peak (polyclonal hypergammaglobulinemia). The bulk of the protein increase is IgG, although occasionally, increased amounts of IgA are also found. IgM is usually normal or decreased. RF in varying amounts is present in almost all patients. Antithyroglobulins, increased erythrocyte sedimentation rate (ESR), leukopenia, antinuclear factors, and proteinuria may be found. Almost 80% of patients with hypergammaglobulinemic purpura of Waldenström have antibodies to Ro/SSA.

Hyperglobulinemic purpura occurs most frequently in women between ages 18 and 40 and is often seen with Sjögren syndrome and rheumatoid arthritis. Adverse fetal outcomes in these women may be associated with the presence of SSA or SSB autoantibodies. Hyperglobulinemic purpura may also be a primary, chronic, benign illness. When it is associated with hepatitis C, it has a predilection for men and has manifestations that usually last longer than those associated with Sjögren syndrome.

In about one third of patients, leukocytoclastic vasculitis is present. These patients have a higher prevalence of articular involvement, peripheral neuropathy, Raynaud phenomenon, renal involvement, ANA, RF, and anti-Ro/SSA antibodies. The course of the disease is essentially benign but chronic.

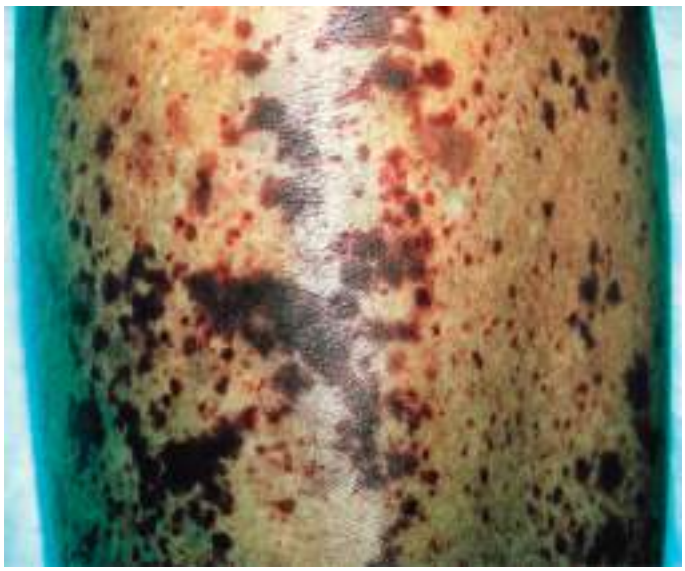

Fig. 35-9 Waldenström hyperglobulinemic purpura.

Rare deaths are related to associated cryoglobulin disease. Hyperglobulinemic purpura may be a manifestation or harbinger of connective tissue or hematopoietic diseases, and rarely, progression to myeloma has been reported.

Patients often improve with support stockings. Corticosteroids should be reserved for severe disease. Indomethacin and hydroxychloroquine may be of value in the treatment of milder disease, especially in patients who have connective tissue disease or are SSA/B (Ro/La) positive. Aspirin and colchicine have been used with some success.

Waldenström macroglobulinemia

Waldenström macroglobulinemia (WM) is a lymphoplasmacytic lymphoma of B lymphocytes characterized by elevated levels of circulating IgM. Disease manifestations relate to hyperviscosity and vascular complications resulting from the circulating paraprotein as well as from neoplastic lymphoplasmacytic infiltration of important structures such as the bone marrow, lymph nodes, spleen, and other organs. Lymphadenopathy, hepatosplenomegaly, and anemia are characteristic.

Immunoglobulin M is responsible for some of the skin manifestations of the disorder. Elderly men are predominantly affected, and there is a strong familial predisposition. The cutaneous manifestations of WM can be divided into two categories: nonspecific and specific. Nonspecific manifestations are related to the hyperviscosity syndrome created by the circulating IgM and include purpura of the skin and mucous membranes. The purpura may be surmounted by tense giant bullae. Bleeding of the gums and epistaxis can occur. The IgM may behave as a cryoglobulin, resulting in purpura, livedo, cutaneous ulcerations, and vasculitis. Urticaria (some patients satisfy the diagnostic criteria for Schnitzler syndrome or progress from that disorder), disseminated xanthoma, and amyloid deposition can be seen. Specific skin lesions are of two types: specific skin deposits of aggregates of IgM (cutaneous macroglobulinosis) and cutaneous infiltrates with neoplastic lymphoid cells. The specific skin lesions usually occur once the diagnosis of WM is already known, but infrequently the skin lesions are the first clue to the diagnosis. The specific IgM deposits present clinically as subepidermal blisters (clinically and histologically resembling bullous amyloidosis) or translucent 1–3 mm papules. They are found most often on the lower extremity, even on the sole. Slight hyperkeratosis may be seen over the papules.

Histologically, the papules are composed of dermal nodular, homogeneous, and fissured pink deposits that tend to involve newly formed vessels. They are periodic acid–Schiff (PAS) positive but negative for Congo red. DIF identifies the dermal globules as being composed of IgM and is a useful diagnostic approach. When WM results in cutaneous lymphoid aggregates, the presentation is very nonspecific. Small, red-brown

to violaceous macules, papules, nodules, or plaques may be present, usually on the face. Rosacea is often initially entertained as a diagnosis. Widespread skin involvement with a "deck-chair sign" (sparing the abdominal skinfolds) has been reported.

The natural history of WM is that of an indolent myelodysplasia. Treatment is directed at reducing the volume of neoplastic cells and should be managed by an oncologist. Most asymptomatic patients are followed or treated only when clinical disease occurs. Chlorambucil, cyclophosphamide, fludarabine, systemic corticosteroids, and rituximab or bortezomib, used alone or in combination, are initial therapeutic options. Plasmapheresis can be effective in controlling acute symptoms of hyperviscosity syndrome. Rituximab is not used as a monotherapy in WM patients with hyperviscosity because they may experience a flare of their disease. Soluble CD27 can be used as a marker of disease response to therapy.

PURPURA SECONDARY TO CLOTTING DISORDERS

Hereditary disorders of blood coagulation usually result from a deficiency or qualitative abnormality of a single coagulation factor, as in hemophilia or von Willebrand's disease. Acquired disorders usually result from multiple coagulation factor deficiencies, as in liver disease, biliary tract obstruction, malabsorption, or drug ingestion. Acquired clotting disorders may also involve platelet abnormalities, as in DIC. Hemorrhagic manifestations are common and may be severe, especially in hereditary forms. Ecchymoses and subcutaneous hematomas are common, especially on the legs. Severe hemorrhage may follow trauma, and hemarthrosis is frequent. Other hemorrhagic manifestations include respiratory obstruction resulting from hemorrhage into the tongue, throat, or neck; epistaxis; gastrointestinal (GI) and genitourinary tract bleeding; and rarely CNS hemorrhage.

DRUG-INDUCED AND FOOD-INDUCED PURPURA

Drug-induced purpura may be related to platelet destruction, vessel fragility, interference with platelet function, or vasculitis. Drug-induced thrombocytopenic purpura is discussed earlier in this chapter. Purpurogenic drugs include aspirin and other NSAIDs, allopurinol, thiazides, gold, sulfonamides, cephalosporins, hydralazine, phenytoin, quinidine, ticlopidine, and penicillin. Combinations of diphenhydramine and pyrithyldione can induce purpuric mottling and areas of necrosis. Cocaine-induced thrombosis with infarctive skin lesions is associated with skin popping.

Topical EMLA cream can induce purpura within 30 min of application, a result of a toxic effect on the capillary endothelium. Agave ingestion can induce purpura and vasculitis-like lesions because of a direct toxic effect on the endothelium. Purpura has been associated with the use of acetaminophen in patients with infectious mononucleosis. Small-vessel vasculitis, including urticarial vasculitis, has been caused by the ingestion of tartrazine dye. Pseudoephedrine can induce a pigmented purpura–like reaction. Patch testing reproduces the eruption. Purpuric contact dermatitis is rare and usually caused by rubber chemical or textile dyes.

PURPURA FULMINANS

Purpura fulminans is a rapidly progressive and fatal syndrome of intravascular thrombosis, circulatory collapse, and cutaneous infarction. Also known as purpura gangrenosa, there are three forms of the disease, as follows:

1. Infectious (associated with bacterial or viral infection and DIC)
2. Neonatal/hereditary (deficiency of protein C or S, or antithrombin III)
3. Idiopathic (generally following a febrile illness, leading to acquired protein S deficiency)

Fig. 35-10 Neonatal purpura fulminans secondary to homozygous protein C deficiency.

Fig. 35-11 Purpura fulminans.

The most common form is that associated with an infectious illness, usually bacterial septicemia (most often meningococcemia) but sometimes a viral infection (varicella). Asplenic patients, who are at risk for pneumococcal or meningococcal sepsis, are predisposed to purpura fulminans. Neonates with homozygous protein C or protein S deficiencies may have purpura fulminans (Fig. 35-10). Some patients develop transient deficiencies of proteins C and S in response to infection. A number of reported cases of purpura fulminans have been associated with infections and factor V Leiden mutation, with normal protein C and protein S levels. Meningococcemia, streptococcal sepsis, *Capnocytophaga* sepsis (from a dog bite), staphylococcal septicemia, and urosepsis are the most common causes. Rickettsial disease and malaria may present as purpura fulminans. Active human herpesvirus 6 (HHV-6) replication with acquired protein S deficiency and purpura fulminans has been described.

Purpura fulminans presents as the sudden appearance of large ecchymotic areas, especially prominent over the extremities, progressing to acral hemorrhagic skin necrosis. (Fig. 35-11). The term "symmetric peripheral gangrene" is used to describe cases when acral gangrene is present. Fever, shock, and DIC usually accompany the skin lesions, which on biopsy show noninflammatory necrosis with platelet-fibrin thrombi occluding the blood vessels.

Other disease, such as the fibrinolysis syndrome, may have purpura fulminans as part of the symptom complex. An acquired form has been reported secondary to alcohol and acetaminophen ingestion, as well as from diclofenac or propylthiouracil. When purpura fulminans occurs in the setting of SLE, the catastrophic antiphospholipid antibody syndrome (CAPS) must be considered (Fig. 35-12). Purpura fulminans has been reported as a presenting feature of Churg-Strauss syndrome and other ANCA-positive vasculitides.

Fig. 35-12 Catastrophic antiphospholipid antibody syndrome.

Management is usually supportive, with treatment of the underlying disease process (e.g., antibiotics for septicemia) and replacement therapy using fresh frozen plasma. Protein C and antithrombin replacement is useful in treating patients shown to have deficiencies. Plasmapheresis has been used in nonbacterial cases. Heparin anticoagulation can be used. Despite these measures, amputation (often multiple extremities) and death continue to occur in patients with severe disease. The use of pressors to maintain blood pressure during the septic episode may contribute to reduced peripheral circulation and peripheral tissue damage. Fasciotomy during the initial management of these patients may reduce the depth of soft tissue involvement and the extent of amputation.

DISSEMINATED INTRAVASCULAR COAGULATION

Up to two thirds of patients with DIC have skin lesions, which may be the initial manifestation of the syndrome. Minute, widespread petechiae; ecchymoses; ischemic necrosis of the skin; and hemorrhagic bullae are the usual findings. Purpura fulminans may supervene and progress to symmetric peripheral gangrene. DIC may be initiated by a variety of disorders, including septicemic hypotension, hypoxemia, acidosis, malignancies, chemotherapy, obstetric crises, antiphospholipid antibody syndrome, SLE, arthropod envenomation, and leukemia. Long-term treatment with granulocyte colony-stimulating factor (G-CSF) has also been reported to precipitate DIC. Children with kaposiform hemangioendotheliomas are at risk for consumptive coagulopathy (Kasabach-Merritt syndrome).

The disease results from widespread intravascular coagulation in which certain coagulation factors are consumed faster than they can be replaced. Laboratory findings include decreased platelets, decreased fibrinogen (only in severe cases; normal in 57% of cases), elevated PT/PTT (50–60% of cases), increased fibrin degradation products, and elevated D-dimers. Control of the underlying disease is the paramount consideration, and often, antibiotics or surgical drainage of loculated infection may lead to spontaneous resolution of DIC. Bleeding is treated with platelet transfusion in the presence of thrombocytopenia and fresh frozen plasma to correct coagulation factor abnormalities. Heparin is considered when thrombosis in the form of venous, arterial, or widespread microvascular thrombosis (purpura fulminans) is present. Protein C concentrate may benefit patients with severe sepsis and DIC.

CONGENITAL FIBRINOGEN DISORDERS

Deficiencies of fibrinogen are classified as reductions in quantity (afibrinogenemia or hypofibrinogenemia) or in quality (dysfibrinogenemia). Afibrinogenemia occurs at a rate of about 1 case per 1 million population. It may present at birth with umbilical cord bleeding. Epistaxis, menorrhagia, hemarthrosis (much less than in hemophilia and with far fewer musculoskeletal sequelae), trauma, and surgery-related bleeding can occur. The severity of the bleeding tendency is highly variable from patient to patient, and some have no bleeding problems. Pregnancy complications include recurrent miscarriage and peripartum hemorrhage. Ironically, because of the loss of the antithrombotic effect of fibrinogen, thrombotic events are increased in afibrinogenemia. Arterial and venous thrombosis can occur. Patients with hypofibrinogenemia are seen more often; in general, they are less symptomatic and only occasionally require treatment. Hypofibrinogenemia may be associated with pregnancy losses and rarely with liver disease due to accumulation of abnormal fibrinogen in the endoplasmic reticulum of hepatocytes. Dysfibrinogenemia is asymptomatic in 55% of patients, 25% exhibit bleeding tendencies, and 20% tend to develop thrombosis. This group represents only 0.8% of patients with deep venous thrombosis, so screening for this condition is not cost-effective unless there is a family history. Mutations in the fibrinogen gene cluster cause all three of these fibrinogen disorders.

BLUEBERRY MUFFIN BABY

Originally coined to describe the characteristic appearance of the purpuric lesions observed in newborns with congenital rubella, the term "blueberry muffin baby" is associated with many disorders that produce extramedullary erythropoiesis. The eruption consists of generalized, dark-blue to magenta, nonblanchable, indurated, round to oval, hemispheric papules ranging from 1 to 7 mm. Lesions favor the head, neck, and trunk. Etiologic factors include congenital infections (toxoplasmosis, rubella, cytomegalovirus, herpes simplex, parvovirus B19), hemolytic disease of the newborn (Rh incompatibility, blood group incompatibility), hereditary spherocytosis, twin transfusion syndrome, recombinant erythropoietin administration, neuroblastoma, rhabdomyosarcoma, extraosseal Ewing sarcoma, Langerhans cell histiocytosis, and congenital leukemia. Patients with multiple vascular disorders, such as hemangiopericytoma, hemangioma, blue rubber bleb nevus, and glomangioma, may be mistaken for a blueberry muffin baby. Evaluation should include a peripheral blood cell count, hemoglobin level, serologies for congenital TORCH infections, viral cultures, and a Coombs test. A skin biopsy may also be helpful in determining the cause.

MISCELLANEOUS PURPURIC MANIFESTATIONS

Deep venous thrombosis

Deep venous thrombosis (DVT) is a common medical condition that can result in immediate (pulmonary embolism) or long-term (venous insufficiency, postphlebitic syndrome) consequences. Risk factors include female gender, obesity, immobilization, low atmospheric pressure, winter season, and the presence of cancer. In 35% of cancer-associated cases, the thrombosis is the first sign of the cancer. The use of erythropoiesis-stimulating agents doubles the risk of venous thromboembolism (VTE) for cancer patients. Hereditary mutations that result in a hypercoagulable state also increase the risk for VTE. The left leg is more often affected than the right. The mean age is 52 years. Significant superficial vein thrombosis is considered a risk factor for DVT. The risk of pulmonary embolism from DVT is the major concern.

On examination, a palpable cord, calf tenderness, unilateral edema, warmth, redness, and venous dilation may suggest the diagnosis. Pretest probability of DVT can be calculated with a simple tool such as the Wells score, and selective use of D-dimer can help exclude DVT. Ultrasound is used to confirm the diagnosis. Preventive strategies include exercise, weight control, and pharmacologic prophylaxis for high-risk patients, (e.g., postoperative, after stroke). Symptomatic proximal DVT is treated with at least 3 months of therapeutic anticoagulation to reduce the risk of pulmonary embolism.

Superficial thrombophlebitis

Superficial venous thrombosis is an inflammatory thrombotic condition that classically presents with painful induration and erythema, often in a cordlike, linear or branching configuration (Fig. 35-13). Patients may also exhibit indurated subcutaneous nodules and overlying purpura or brown discoloration indicative of postinflammatory hyperpigmentation.

Primary hypercoagulable states that may be associated with superficial thrombophlebitis include deficiencies of antithrombin III, heparin cofactor II, protein C, protein S, and factor XII; disorders of tPA; abnormal plasminogen; dysfibrinogenemia; and lupus anticoagulant. Secondary hypercoagulable states include varicosities, malignancy (Trousseau syndrome), pregnancy, OC use, infusion of prothrombin complex concentrates, Behçet's disease, thromboangiitis obliterans, acute thrombophlebitis of superficial veins of the breast (Mondor's disease), septic thrombophlebitis, psittacosis, secondary syphilis, intravenous (IV) catheters, IV drugs (sugar solutions, protein hydrolysates, calcium, potassium, hypertonic concentrates, diazepam, nitrogen mustard, acridinylaniside, dacarbazine, and carmustine), and street drugs (cocaine, bulking agents such as paregoric, quinine, dextrose, sucrose, and lactose).

In the evaluation of superficial thrombophlebitis, the physician should consider the possibility of underlying deep venous disease. Superficial femoral vein involvement should alert the physician to underlying deep venous disease requiring anticoagulation. Lesser saphenous vein thrombophlebitis is also frequently associated with underlying DVT. Elliptical biopsies across the palpable cord may be required to exclude other considerations, such as sarcoidal granulomas, cutaneous polyarteritis nodosa, Kaposi sarcoma, and vasculotropic metastasis.

Treatment is directed at the underlying cause. Leg elevation and local heat will help to promote the dissolution of clots, which may take up to 8–12 weeks to resolve. Heparin therapy may reduce the incidence of thromboembolic complications in high-risk individuals.

Mondor's disease

Mondor's disease occurs three times more frequently in women than in men. Most patients are between 30 and 60 years of age. The sudden appearance of a cordlike thrombosed vein along the anterolateral chest wall is characteristic (Fig. 35-14). It is at first red and tender and subsequently changes into a painless, tough, fibrous band. There are no systemic symptoms. Both sides of the chest have the same rate of involvement. Mondor's disease may be associated with strenuous exercise, pregnancy, IV drug abuse, jellyfish stings, breast cancer, and breast surgery. The condition represents a localized thrombophlebitis of the veins of the thoracoepigastric area. The veins involved are the lateral thoracic, thoracoepigastric, and superior epigastric. In the end stage, a thick-walled vein remains that has a hard, ropelike appearance and occasionally may result in a furrowing of the breast. Infrequently, a vein coursing up the inside of the upper arm and across or into the axilla may be thrombosed, leading to the "axillary web syndrome." Similar stringlike phlebitis findings have been described in the penis, antecubital fossa, groin, and abdomen. Treatment is symptomatic, with hot, moist dressings and analgesics or NSAIDs. The disease process runs its course in 3 weeks to 6 months.

Fig. 35-14 Mondor's disease.

Postcardiotomy syndrome

Between 2 and 3 weeks after pericardiotomy, fever, pleuritis, pericarditis, or arthritis may appear together with petechiae on the skin and palate. Postcardiotomy syndrome may be confused with infectious mononucleosis and bacterial endocarditis.

Orthostatic purpura (stasis purpura)

Prolonged standing or even sitting with the legs lowered (as in a bus, airplane, or train) may produce edema and a purpuric eruption on the lower extremities. Elevation of the legs and the use of elastic stockings are helpful preventive strategies.

Obstructive or traumatic purpura

Purpura may be evoked by mechanical obstruction to the circulation, with resulting stress on the small vessels. This may be encountered in cardiac decompensation or after convulsions, vomiting episodes, Valsalva maneuver, pertussis, or sexual climax. Nonpalpable purpura has been reported in association with the use of a mucus-clearing device, which requires the patient to exhale forcefully through a flutter valve (flutter valve purpura). Local obstruction of the blood flow with purpura may result from compression of the veins by tumors or a gravid uterus or by occlusions from thrombosis.

Purpuric lesions in children lead to suspicion of the battered child (Fig. 35-15). Bruises and ecchymoses on the genital area, buttocks, left ear or cheek, or hands suggest an abused child. Linear lesions on accessible areas raise suspicion of factitial disease. Ecchymoses of bizarre shapes may also correspond to trauma inflicted during religious rituals or cultural practices, such as coin rubbing and cupping performed as remedies for common diseases. "Passion purpura" on the palate may result from fellatio. On the neck or upper arms, it results from biting and sucking and is better known as a "hickey." Facial, cheek, and periorbital purpura can be postictal and may be mistaken

Fig. 35-15 Child abuse; purpura of the face from the sole of a shoe.

for spousal abuse. Bathtub suction-induced purpura occurs on the lower back location in a U-shaped distribution. It may be mistaken for abuse.

Paroxysmal nocturnal hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired intravascular hemolytic anemia that usually occurs in young adults, median age 40 years. It is an acquired clonal disorder resulting from a somatic mutation in a multipotent hematopoietic stem cell that produces all the bone marrow–derived cell lines (neutrophils, lymphocytes, platelets, and erythrocytes). The clinical manifestations of PNH are intravascular hemolysis, smooth muscle dystonia caused by depletion of tissue nitric oxide (abdominal pain, esophageal spasm, fatigue, erectile dysfunction), and life-threatening venous thrombosis. Some cases occur after recovery from aplastic anemia. Widespread cutaneous thrombosis can occur, with initial erythematous cutaneous plaques progressing to hemorrhagic bullae. Vascular thrombi are found on biopsy. The cause of PNH is a mutation in an X-linked gene, phosphatidylinositol glycan class A *(PIGA)*. The gene product is the first step in the biosynthesis of all glycosyl-phosphatidylinositol (GPI) anchors on the surface of hematopoietic cells. Erythrocytes in PNH lack two GPI-anchored proteins, CD55 and CD59, which function is to prevent complement activation on the erythrocyte surface. CD55 accelerates the rate of breakdown of membrane-bound C3 convertase, and CD59 reduces the number of membrane attack complexes that are formed. Without these proteins, amplification of the complement system is uncontrolled, leading to intravascular destruction of red blood cells (RBCs). The diagnosis of PNH can be made by detecting the loss of CD55 and CD59 through monoclonal antibody tests. The FLAER (fluorescent aerolysin) flow cytometry test is now often used to diagnose PNH. Hematopoietic stem cell transplantation may be curative, after either ablative or nonablative conditioning regimens. Eculizumab, a humanized monoclonal antibody against C5, inhibits terminal complement activation. It stabilizes hemoglobin levels and reduces transfusion requirements in PNH patients.

Paroxysmal hand hematoma (Achenbach syndrome)

Spontaneous focal hemorrhage into the palm or the volar surface of a finger may result in transitory localized pain, followed by rapid swelling and localized bluish discoloration. The lesion resolves spontaneously within a few days. Spontaneous hemorrhage from an arteriole appears to be responsible. The acute nature, purpuric findings, and rapid resolution are distinguishing features of Achenbach syndrome.

Easy bruising syndromes

Young women who bruise easily despite normal coagulation profiles and normal platelet counts may have antiplatelet antibodies. Otherwise, specific platelet function defects should be suspected. Bernard-Soulier syndrome is a rare inherited disorder characterized by giant platelets, thrombocytopenia, and a prolonged bleeding time. It is caused by genetic defects of the glycoprotein Ib–IX complex that constitutes the vWF receptor. Sebastian syndrome consists of giant platelets, leukocyte inclusions, and thrombocytopenia. Fechtner syndrome is a rare type of familial thrombocytopenia associated with large platelets, leukocyte inclusions, and features of Alport syndrome. The May-Hegglin anomaly consists of easy bruising with giant platelets and Döhle-like cytoplasmic inclusions in granulocytes. The inclusions appear as electron-dense long rods and needles oriented along the long axis of the spindle. All four of these syndromes are caused by abnormalities in the *MYH9* gene. Glanzmann thrombasthenia, with dysfunctioning $\alpha IIb3$ receptor, is a platelet storage pool defect causing similar clinical findings.

Painful bruising syndrome (autoerythrocyte sensitization, Gardner-Diamond syndrome, psychogenic purpura)

Painful bruising syndrome is a distinctive localized purpuric reaction occurring primarily in young to middle-age women, usually who manifest personality disorders. They may have depression, anxiety, or hysterical or masochistic character

Fig. 35-16 Gardner-Diamond syndrome.

traits or may be unable to deal with hostile feelings. A recurrent type of eruption, psychogenic purpura is characterized by extremely painful and tender, poorly defined ecchymoses on the extremities (Fig. 35-16) and sometimes on the face or trunk. The lesions evolve in a few hours and resolve within 5–8 days. New lesions may appear in crops. Emotional upsets are generally associated with the appearance of these painful purpuric lesions. Some patients will report a premonition as to when they will develop new lesions a few hours before by the tingling and burning sensation at the site of a future lesion. Extracutaneous somatic symptoms are common, such as headache, paresthesias, transient paresis, syncope, diplopia, abdominal distress, diarrhea, nausea and vomiting, and arthralgia.

Gardner and Diamond reported that intracutaneous injections of erythrocyte stroma evoked typical lesions. Since then, many have reported similar reactions to autologous whole blood, packed or washed RBCs, or fractions of erythrocyte stroma. These are difficult to assess because similar reactions have been reported to substances as diverse as hemoglobin, phosphatidyl serine, histamine, histidine, trypsin, purified protein derivative (PPD), autologous serum, and platelets. Blinded controlled testing, trying to avoid factitial trauma, has given mixed responses. Abnormalities in tPA-dependent fibrinolysis, thrombocytosis, and anticardiolipin antibodies have also been implicated. Most now believe this syndrome is psychosomatic and artifactual. The most effective treatment is to address the underlying psychological dysfunction. Improvement of the underlying psychopathology usually leads to disappearance of the cutaneous manifestations.

PIGMENTARY PURPURIC ERUPTIONS (PROGRESSIVE PIGMENTARY DERMATOSIS, PROGRESSIVE PIGMENTING PURPURA, PURPURA PIGMENTOSA CHRONICA)

The pigmented purpuric eruptions (PPEs) are a group of common dermatoses (capillaritis) of unknown pathogenesis.

Fig. 35-17 Schamberg's disease.

The most common variant of progressive pigmentary dermatosis is Schamberg's disease. The typical lesions are thumbprint-sized and composed of aggregates of pinhead-sized petechiae resembling grains of cayenne pepper on a background of golden-brown hemosiderin staining. The lesions usually begin on the lower legs, with slow proximal extension (Fig. 35-17). These lesions seldom itch. The favored sites are on the lower shins and ankles, but lesions may be more widespread and occasionally affect the upper extremities or trunk.

Majocchi's disease is also known as purpura annularis telangiectodes. The early lesions are 1–3 cm annular patches composed of dark-red telangiectases with petechiae and hemosiderin staining. Central involution and peripheral extension produce ringed, semicircular, targetlike, or concentric rings. The eruption begins symmetrically on the lower extremities, spreads up the legs, and may extend on to the trunk and arms. Involution of individual patches is slow and, because new lesions continue to form, may continue indefinitely. The lesions are asymptomatic.

Gougerot-Blum syndrome (pigmented purpuric lichenoid dermatitis) is characterized by minute, rust-colored to violaceous, lichenoid papules that tend to fuse into plaques of various hues between red, violaceous, and brown (purpura with lichenoid dermatitis). Favorite locations are the legs, thighs, and lower trunk. The chief difference between this and Schamberg's disease is the deeper color and the presence of induration, both of which relate to the presence of a lichenoid band of lymphoid inflammation. Similar lesions have also occurred during IFN therapy for hepatitis C.

Ducas and Kapetanakis pigmented purpura is scaly and eczematous. The eczematous patches also demonstrate petechiae and hemosiderin staining. Pruritus is common, and the lesions are often more extensive than the other PPEs. It is distinguished histologically by the presence of spongiosis. Purpuric pityriasis rosea may resemble Ducas and Kapetanakis purpura.

Lichen aureus is characterized by the sudden appearance of one or several, golden or rust-colored, closely packed macules or lichenoid papules. The macules may be grouped into a patch and may occur on any part of the body, but the vast majority of lesions occur on the feet or lower leg. The patches are usually solitary and asymptomatic but may occasionally

be painful. Adults predominate, but children may also be affected.

Rare variants of the pigmented purpuric dermatoses are the linear or zosteriform type and the transitory type. These tend to be more transient than the other variants. A single case of evolution to linear morphea has been reported.

Histologically, all forms of PPE demonstrate superficial perivascular lymphocytic (and at times granulomatous) infiltrate associated with extravasation of RBCs and, in later lesions, hemosiderin deposition. The degree of hemosiderin deposition may be variable and is insufficient to confirm the diagnosis histologically. The infiltrating cells are primarily CD4+ lymphocytes. There may be a lichenoid band of lymphoid inflammatory cells (Gougerot-Blum type) or spongiosis (Ducas and Kapetanakis type). An iron stain (Perl, Prussian blue, ferricyanide) is sometimes used to demonstrate the hemosiderin deposition.

Cutaneous T-cell lymphoma (CTCL) may begin with clinical lesions that resemble pigmented purpura. In addition, lesions of pigmented purpuric dermatosis may demonstrate clonality. Patients with more widespread lesions above the knee are much more likely to have clonal infiltrates and eventually meet histologic criteria for the diagnosis of CTCL.

In most cases of pigmented purpuric dermatosis, the etiology is unknown. Patients with stasis dermatitis and venous insufficiency may develop lesions that bear a superficial clinical resemblance to Schamberg's disease. Their lesions are more diffuse and do not form well-circumscribed macules. Oral medications can induce PPEs that closely resemble Ducas and Kapetanakis purpura, including acetaminophen, aspirin, glipizide, IFN alfa, and medroxyprogesterone injections. Stopping the medication will lead to resolution of the eruption. Pigmented purpuric contact dermatitis may simulate a PPE. Inciting allergens include nickel sulfate, fragrance mix, and Disperse Blue dyes. Patch testing on the back may be negative, but a positive response may be seen when the causative allergen is applied to a lesion. As with pigmenting drug eruptions, pigmented purpuric contact dermatitis should be suspected when the lesions are more widespread (sites other than the legs) and especially if they have an eczematous character.

Anecdotal reports of benefit from topical corticosteroids make a therapeutic trial for 4–6 weeks reasonable. Oral rutoside, 50 mg twice daily, and ascorbic acid, 500 mg twice daily, may be beneficial. Psoralen plus ultraviolet A (PUVA) and narrow-band UVB have demonstrated efficacy and should be considered when the other modalities fail. Immunosuppressive therapy with cyclosporine and methotrexate has also been effective but is usually not warranted given the lack of significant symptoms. If immunosuppression is considered, CTCL must be excluded, and patch testing and drug withdrawal should be undertaken.

PURPURIC AGAVE DERMATITIS

Agave americana is a large, thick, long-leaved, subtropical plant with a striking blue-gray color. It is often used in ornamental beddings in the southwestern United States. The plant grows up to 2 m (6½ feet) in diameter and may overgrow the surrounding landscape. These plants are deep rooted and difficult to remove, and some individuals attempt removal using a chainsaw. A striking purpuric dermatosis occurs in a pattern corresponding to the splatter of the plant's sap. Histologically, there is vascular damage at the level of the capillary and postcapillary venule, with a sparse infiltrate of neutrophils and karyorrhectic debris, suggesting low-grade leukocytoclastic vasculitis. Papulovesicular lesions have also been described. The plant's sap contains calcium oxalate crystals, as well as various acrid oils and saponins. The causative component is unknown.

VASCULITIS

Vasculitis is a clinicopathologically defined process characterized by inflammation and necrosis of blood vessels. Because the clinical morphology correlates with the size of the affected blood vessel(s), these disorders are classified by the vessel(s) affected. Diseases may involve vessels of overlapping size. In general, small-vessel disease (affecting postcapillary venules) causes urticarial lesions and palpable purpura; small-artery disease manifests with subcutaneous nodules; medium-sized arteries with necrosis of major organs, livedo, purpura, and mononeuritis multiplex; and large-vessel disease with symptoms of claudication and necrosis.

Classification

Numerous vasculitis classification schemes have been proposed, most recently the 2012 Revised International Chapel Hill Consensus Conference Nomenclature of Vasculitides; all have limitations. It is important to remember that infectious and thrombotic conditions, which "classically" show thrombosis of vessels histologically, at times may also show true leukocytoclastic vasculitis. Therefore, infectious, embolic, and thrombotic causes of vessel damage must always be considered before unequivocally diagnosing a case as an "inflammatory" vasculitis. Leukocytoclastic vasculitis is also frequently seen adjacent to suppurative folliculitis and at the base of chronic ulcers. The discovery of the association of some forms of small-vessel and medium-vessel vasculitides with positive ANCAs has made their diagnosis and classification much easier (Box 35-1).

Grzeszkiewicz TM, Fiorentino DF: Update on cutaneous vasculitis. Semin Cutan Med Surg 2006; 25:221.

Box 35-1 Classification of vasculitis

I. Cutaneous small-vessel (postcapillary venule)
- **A.** Idiopathic cutaneous small-vessel vasculitis
- **B.** Henoch-Schönlein purpura
- **C.** Acute hemorrhagic edema of infancy
- **D.** Urticarial vasculitis
- **E.** Cryoglobulinemic vasculitis
- **F.** Erythema elevatum diutinum
- **G.** Granuloma faciale
- **H.** Other diseases with leukocytoclastic vasculitis: drug-induced vasculitis, malignancy (lymphoreticular more common than solid tumor), connective tissue diseases, hyperglobulinemic purpura, inflammatory bowel disease, bowel-associated dermatitis–arthritis syndrome (bowel bypass), HIV infection, and neutrophilic dermatoses (Behçet; Sweet; erythema nodosum leprosum; septic vasculitis; autoinflammatory conditions–familial Mediterranean fever, and serum sickness)

II. Medium-vessel
- **A.** Polyarteritis nodosa
  - **1.** Benign cutaneous forms
  - **2.** Systemic form

III. Mixed size (medium and small) vessel disease
- **A.** Connective tissue disease associated (usually rheumatoid vasculitis)
- **B.** Septic vasculitis
- **C.** ANCA associated
  - **1.** Microscopic polyangiitis
  - **2.** Wegener's granulomatosis
  - **3.** Allergic granulomatosis (Churg-Strauss)
  - **4.** Occasional drug-induced (most are postcapillary venule only)

IV. Large-vessel vasculitis
- **A.** Giant cell arteritis
- **B.** Takayasu arteritis

SMALL-VESSEL VASCULITIS

Cutaneous small-vessel vasculitis (cutaneous leukocytoclastic vasculitis)

The vast majority of cases of cutaneous leukocytoclastic vasculitis (LCV) follow an acute infection or exposure to a new medication. Palpable purpura is the hallmark of this disease, with lesions ranging from pinpoint to several centimeters in diameter (Fig. 35-18). Annular, vesicular, bullous, or pustular lesions may develop. Small ulcerations may develop, but when ulceration is prominent, one must suspect either a vasculitis of larger vessels (small to medium arterioles) or the presence of both a vasculitis and a hypercoagulable state. Lesions of LCV predominate on the ankles and lower legs, affecting mainly dependent areas or areas under local pressure. Edema, especially of the ankles, is usually noted. In the hospitalized or bedridden patient, the buttocks and posterior thighs are dependent areas and may be the initial or primary site of involvement. Mild pruritus, fever, and malaise may occur. Arthralgias or less often frank arthritis may be seen. Other systemic involvement is rare and should lead to consideration of another diagnosis. Although in general, systemic involvement is not found or is minimal, serious systemic disease can accompany cutaneous LCV and should be sought in every patient.

Fig. 35-18 Leukocytoclastic vasculitis, palpable purpura.

The lesions usually resolve in 3–4 weeks, with residual postinflammatory hyperpigmentation. Ten percent of cutaneous LCV patients may have recurrences. A persistent underlying cause must be sought in chronic or recurrent cases.

Histology

There is angiocentric segmental inflammation of the postcapillary venule, with expansion of the vessel wall, fibrin deposition, and infiltration by neutrophils that show fragmentation of their nuclei (karyorrhexis or leukocytoclasia). Endothelial cell swelling is common, and fibrinoid necrosis of the vessel walls is seen. Vascular thrombosis may be present. The presence of tissue eosinophilia favors a medication as the cause. Immunofluorescence and ultrastructural studies have shown the presence of immunoglobulins, complement components, and fibrin deposits within postcapillary venule walls, if the biopsy is taken within the first 24 hours. Later, fibrin is prominent, but immunoglobulin deposits may have been destroyed. An important exception is Henoch-Schönlein purpura, which usually demonstrates prominent IgA deposits even in more advanced lesions.

Pathogenesis

Cutaneous small-vessel vasculitis is thought to be caused by circulating immune complexes. These complexes lodge in vessel walls and activate complement. Various inflammatory mediators are produced, contributing to endothelial injury.

Etiology

In most series, the majority of cutaneous LCV cases are idiopathic. Of the remaining 50% of cases, most are either drug induced or postinfectious. Drugs in virtually every class have been reported as causing LCV, and the time from start of the medication to onset of the eruption may be hours to years, making any ingested agent a possible cause. A host of infectious agents, such as β-hemolytic *Streptococcus* group A, *Mycoplasma,* and rarely *Mycobacterium tuberculosis,* may cause palpable purpura. Cutaneous LCV can occur in association with a connective tissue disease or as its presenting sign. Patients with lymphoproliferative neoplasms, as well as solid tumors (lung, colon, genitourinary, and breast cancer), may experience cutaneous small-vessel vasculitis at some time during the course of their disease. A recurrence of the LCV may mark the return of a treated malignancy. Cutaneous LCV may also be the initial manifestation of mixed small-vessel and medium-vessel vasculitis.

Clinical evaluation

The clinical evaluation is critical in separating cases of benign cutaneous vasculitis (usually following an infection or induced by a medication) from those cases associated with more serious underlying disease or that have significant systemic involvement. It may not be possible on initial physical examination to make this distinction. The history should focus on possible infectious disorders, prior associated diseases, drugs ingested, and a thorough review of systems. Screening laboratory tests may help to elucidate the underlying cause or extent of organ involvement. When the history suggests a recent drug and the patient is clinically well, nothing more than a urinalysis may be required. A CBC, basic metabolic panel, urinalysis, strep throat culture or ASO titer, hepatitis B and C serologies, and ANA and RF are a reasonable initial screen for patients with no obvious cause for their vasculitis. Serum protein electrophoresis, serum complements, ANCAs, and cryoglobulins may be required in some cases. A skin biopsy should be performed to confirm the diagnosis of LCV. DIF should be performed to identify IgA vasculitis (Henoch-Schönlein purpura).

Treatment

The initial treatment of most cases of LCV in patients who are clinically well and have a normal urinalysis should focus on symptom management and should not be aggressive, since the majority of cases are acute and self-limited, affect only the skin, and do not threaten progressive deterioration of internal organs. Rest and elevation of the legs will likely be helpful. Analgesics and avoidance of trauma and cold are prudent general measures. An identified antigen or drug should be eliminated and any identified infectious, connective tissue, or neoplastic disease treated.

A variety of systemic treatments may be required for severe, intractable, or recurrent disease, especially if significant organ involvement is present. For disease limited to the skin, NSAIDs can be considered for arthralgias. Colchicine, 0.6 mg two or three times daily, or dapsone, 50–200 mg/day, may be useful for chronic vasculitis. Low doses of colchicine and dapsone may be combined if either medication alone is unsuccessful or effective doses of either drug cannot be tolerated. Although one controlled trial (the only such trial for cutaneous small-vessel vasculitis) suggested colchicine was ineffective for LCV, some of the patients did respond and flared when the drug was stopped. Oral antihistamines, by blocking the vasodilation induced by histamine, may reduce immune complex trapping and improve LCV. Systemic corticosteroids, in doses ranging from 60 to 80 mg/day, are recommended for patients with serious systemic manifestations or necrotic lesions. Usually, a brief course leads to resolution, and chronic treatment is rarely required. Unfortunately, systemic corticosteroids are not good long-term options for patients with chronic LCV. For those with chronic or refractory disease in whom colchicine or dapsone is ineffective, immunosuppressive agents, such as MMF, 2–3 g/day; methotrexate, 5–25 mg/week; or azathioprine, 50–200 mg/day (2–3.5 mg/kg/day), may be considered. Azathioprine dosing is based on thiopurine methyltransferase (TPMT) levels. In more difficult cases, cyclophosphamide, monthly IV pulses of steroids or cyclophosphamide, or cyclosporine, 3–5 mg/kg/day, may be effective. The tumor necrosis factor (TNF) blockers, especially infliximab and to a lesser degree etanercept, may be effective in cutaneous small-vessel vasculitis. However, these agents may also cause vasculitis. Rituximab has been effective in refractory cases.

Cutaneous vasculitis and connective tissue disease

Patients with various connective tissue diseases (SLE, Sjögren's syndrome, rheumatoid arthritis [RA], dermatomyositis) may develop cutaneous vasculitic lesions. Vasculitis in the patient with connective tissue disease may be associated with significant internal organ involvement, especially of the peripheral and central nervous systems and the kidneys (glomerulonephritis). Ischemic digital infarcts are seen in addition to

palpable purpura. Ulceration of vasculitic lesions can occur and may be particularly difficult to manage in patients with RA. The prevalence of vasculitis in patients with RA has decreased with improved treatment of RA, but this complication remains a significant source of morbidity and mortality for affected patients. Treatment is the same as for cutaneous LCV, along with management of the underlying connective tissue disease.

Subtypes of small-vessel vasculitis

IgA vasculitis (Henoch-Schönlein purpura)

The term IgA vasculitis (IgAV) replaces the Henoch-Schönlein purpura eponym in the most recent vasculitis consensus criteria. IgAV is characterized by purpura, arthralgias, and abdominal and renal disease. Typically, mottled purpura appears on the extensor extremities, becomes hemorrhagic within 1 day, and starts to fade in about 5 days (Fig. 35-19). New crops may appear over a few weeks. Urticarial lesions, vesicles, necrotic purpura, and hemangioma-like lesions may also be present at some stages. There is a male predominance of cases. The disease occurs primarily in children (~75% of cases), with a peak age between 4 and 8 years; however, adults may also be affected. A viral infection or streptococcal pharyngitis is the usual triggering event. *Helicobacter pylori* infection has been implicated in some childhood and adult cases. Medication exposure can also trigger IgAV.

In about 40% of cases, the cutaneous manifestations are preceded by mild fever, headache, joint symptoms, and abdominal pain for up to 2 weeks. Once the vasculitis is fully established, skin lesions occur in all patients. GI symptoms are also common, occurring in about 65% of patients. Abdominal pain and GI bleeding may occur at any time during the disease; severe abdominal pain may even suggest—or portend—an acute surgical abdomen. Paralytic ileus may occur. Vomiting, rebound tenderness, and distention are other manifestations. GI radiographs may show "spiking" or a marbled "cobblestone" appearance. Arthralgia progressing to arthritis produces periarticular swelling around the knees and ankles; about 63% of patients have joint symptoms. Renal involvement manifests as microscopic or even gross hematuria and may occur in 40% or more of patients; usually it is mild.

Fig. 35-19 Henoch-Schönlein purpura.

Pulmonary hemorrhage may occur and can be fatal. The long-term prognosis is generally favorable but is largely dictated by the severity of renal involvement. Children with gross hematuria usually do well; however, progressive glomerular disease and renal failure may develop in a small percentage, so careful follow-up is necessary for those with hematuria. Renal insufficiency is more common in adults, so the rate of long-term sequelae is higher in this population. Purpura above the waist may be a marker of renal involvement. Overall, persistent, usually mild nephropathy occurs in only 8% of patients. Relapses in disease activity, however, are common for months after initial diagnosis. IgA, C3, and fibrin depositions have been demonstrated in biopsies of both involved and uninvolved skin by immunofluorescence techniques. Abnormal IgA deposits in vessel walls are the defining pathophysiologic feature of IgAV (thus the name change) and may result from abnormal IgA1 glycosylation, leading to IgG-IgA1 immune complex deposition and resulting inflammation. In patients with abdominal pain suggestive of IgAV but with no skin lesions, histamine (as used as a control by allergists) can be injected into the skin and the area biopsied 4 h later. This "histamine trap test" may identify IgA in vessels and confirm the diagnosis. The presence of IgM in lesional skin may be an indication of renal involvement.

In adult patients with IgAV and upper GI symptoms (gastritis), a search for *H. pylori* infection should be undertaken. If an association with *H. pylori* can be confirmed, treatment of the GI infection may lead to resolution. IgAV in adults can be associated with an underlying malignancy. Males represent 90% or more of malignancy-associated IgAV cases. Solid tumors are seen in more than half of patients, especially non–small cell lung cancer, prostate cancer, and renal cancer. About 40% have a hematologic malignancy. About half of patients present within 1 month of diagnosis of the malignancy.

Treatment is primarily supportive. The usual duration of illness is 6–16 weeks, and no therapy appears to shorten that duration significantly. Between 5% and 30% of patients will have persistent or recurrent disease. Close follow-up, including urinalysis and blood pressure monitoring, should be continued for at least 6 months. Dapsone, 50–200 mg/day, or colchicine, 0.6 mg/day to 1.2 mg twice daily, can be used initially if treatment is required and skin lesions are the primary concern. For abdominal pain, an H2 blocker and corticosteroids (prednisone at 1 mg/kg/day) can be effective. Corticosteroids are more effective for abdominal pain than analgesia. The value of systemic corticosteroids in the treatment of renal disease is controversial, but steroids may be used preventively or to treat active nephritis. Data from randomized trials unfortunately have not shown significant benefit to this or other therapies in decreasing the risk of long-term renal sequelae. IVIG can be used in refractory skin disease and persistent abdominal pain and to arrest rapidly progressive glomerulonephritis. Cyclophosphamide is also used and may be effective for renal disease. NSAIDs are best avoided because they may cause renal or GI complications.

Acute hemorrhagic edema of infancy

Also known as Finkelstein disease, Seidlmayer syndrome, medallion-like purpura, infantile postinfectious irislike purpura and edema, and purpura en cocarde avec oedème, acute hemorrhagic edema (AHE) of infancy affects children younger than 2 years with a recent history of upper respiratory illness (75%), a course of antibiotics, or both. The children are often nontoxic in appearance. There is abrupt onset of large purpuric lesions involving the face, ears, and extremities (Fig. 35-20). Cockade, annular, or targetoid morphologies may be present. Scrotal purpura may also occur. Early in the course, there may first be acral edema, with subsequent proximal spread. The edema is nontender and may be asymmetric. A low-grade fever is common, and involvement of internal organ systems (joint pains, GI symptoms, renal involvement) is rare. Routine laboratory tests are unremarkable. Spontaneous recovery without sequelae occurs within 12–20 days. The differential diagnosis includes IgAV (Henoch-Schönlein purpura), meningococcemia, erythema multiforme, urticaria, and Kawasaki disease. Some similarities exist between IgAV and AHE (postinfectious, seasonal, male predilection), but AHE is different in that it favors younger children (<2 years), resolves more quickly, lacks IgA on DIF in most cases, and is rarely associated with systemic symptoms. In one family, a child younger than 4 years developed AHE while the sibling age 16 developed IgAV after the same pharyngitis. From a clinical point of view, the most urgent need is to exclude septicemia, especially meningococcemia. Topical and systemic corticosteroids, as well as antihistamines and dapsone, have been reported as beneficial for relief of symptoms and rare complications of AHE of infancy.

Urticarial vasculitis

A significant percentage of patients (reportedly as high as 5–10%, but probably less) with fixed urticarial lesions will have vasculitis histologically. This is termed "urticarial" vasculitis (Fig. 35-21). This urticarial morphology is maintained throughout the course of the illness. Microscopic hemorrhage into the urticarial plaques may occur, resulting in a bruiselike appearance as the lesions fade. Determination of the serum complement levels (CH50, C3, C4, and anti-C1q precipitins) is critical in the evaluation of urticarial vasculitis. Patients with normal complement levels usually have an LCV, which is idiopathic, limited to the skin, self-resolving, and best considered a subset of cutaneous small-vessel vasculitis. Hypocomplementemic urticarial vasculitis is a distinctive syndrome seen virtually always in women. Clinical features include arthritis (50%), arthralgias, angioedema, eye symptoms, asthma and obstructive pulmonary disease (20%), and GI symptoms (20%). Glomerulonephritis may be present. A rare subset of patients with hypocomplementemic urticarial vasculitis has Jaccoud arthropathy and serious valvular heart disease.

Underlying diseases associated with all forms of urticarial vasculitis include gammopathies (IgG and IgM gammopathy), SLE, Sjögren syndrome, serum sickness, and viral infections, especially hepatitis C. Patients with hypocomplementemic

Fig. 35-20 Acute hemorrhagic edema.

Fig. 35-21 Urticarial vasculitis.

urticarial vasculitis can have anti-C1q antibodies directed against the collagenlike region of that molecule, a feature used to define the disease. Patients with SLE may also have these autoantibodies. Many patients with hypocomplementemic urticarial vasculitis will have positive ANAs, and up to one-quarter will have positive anti-dsDNA antibodies. The vast majority (96%) will have a positive "lupus band test." Over time, more than 50% will meet the criteria for the diagnosis of SLE. For this reason, some consider hypocomplementemic urticarial vasculitis a form of SLE. Patients with HCV infection may develop hypocomplementemic or normocomplementic urticarial vasculitis without a detectable cryoglobulin.

The following three clinical features distinguish the skin lesions of urticarial vasculitis from true urticaria:

1. The lesions are often burning or painful, rather than pruritic.
2. The lesions last longer than 24 h and are fixed, rather than transient and migrating.
3. On resolution, there is postinflammatory purpura or hyperpigmentation.

More difficult is the distinction of urticarial vasculitis from neutrophilic urticaria, because patients with the latter condition can have painful, more persistent lesions. Histologic evaluation is critical.

Histologically, patients with hypocomplementemic urticarial vasculitis will show both LCV and diffuse interstitial neutrophils. Eosinophils are more likely to be seen in patients with neutrophilic urticaria or normocomplementemic urticarial vasculitis. Sweet syndrome shows a more intense dermal infiltrate with marked upper dermal edema. Sweet syndrome and vasculitis share the presence of karyorrhexis. Whereas virtually all biopsies of idiopathic urticaria demonstrate neutrophils, karyorrhexis is usually distinctly absent. In neutrophilic urticaria, neutrophils will be found in the dermis and in the vessel walls (moving from the vascular compartment into the skin). Finding neutrophils in the vessel walls alone without fibrinoid necrosis of vessel walls and leukocytoclasia is insufficient to make the diagnosis of urticarial vasculitis. Most patients with urticarial lesions with neutrophilic infiltrates and normal complements have neutrophilic urticaria rather than urticarial vasculitis.

Other neutrophilic disorders in the differential diagnosis of urticarial vasculitis include mixed cryoglobulinemia, Schnitzler syndrome, the autoinflammatory syndromes (*CIAS1/NALP3* mutations), and neutrophilic dermatosis associated with connective tissue disease. Mixed cryoglobulinemia will be seen most frequently in the context of HCV infection and may present with urticarial, purpuric, or even necrotic/ulcerative lesions. Vasculitis should be seen on biopsy. The other three conditions all can have cutaneous lesions that are urticarial and clinically similar. They tend to have less dermal edema than is typical of either urticaria or Sweet syndrome. Histologically, these conditions lack vasculitis but show tissue neutrophilia with leukocytoclasia. Schnitzler syndrome is diagnosed by the finding of an IgM monoclonal gammopathy. The autoinflammatory syndromes are diagnosed by their characteristic features and genetic testing. In some patients with adult-onset Still's disease or SLE, transient macules and papules coalescing into plaques may be seen. This condition has been termed "neutrophilic urticarial dermatosis," but its pathogenesis remains unknown. In patients with such neutrophilic urticarial lesions, ferritin measurement and a workup for SLE are appropriate.

The treatment of hypocomplementemic urticarial vasculitis is directed at the symptomatology and severity of the disease. Indomethacin has been particularly effective. Antihistamines, dapsone, and colchicine may be tried. The addition of pentoxifylline to dapsone may be effective. Antimalarials can be beneficial, as would be expected in this autoimmune connective tissue disease. Immunosuppressive therapy with prednisone and steroid-sparing agents such as MMF, azathioprine, rituximab, and canakinumab can be considered in refractory and severe cases.

Cryoglobulinemic vasculitis

About 15% of patients with a circulating cryoprecipitable protein are symptomatic and have cryoglobulinemic vasculitis. They typically have mixed (type II or III) cryoglobulinemia. Mixed cryoglobulinemia follows a benign course in half the cases, but in about one-third, hepatic or renal failure occurs. About 15% of patients develop malignancy, usually B-cell lymphoma, and less frequently, hepatocellular or thyroid cancer. By far the most common cause of cryoglobulinemic vasculitis is HCV infection, but lymphoproliferative disorders and autoimmune diseases can also be associated. Cryoglobulinemic vasculitis usually presents with macular or palpable purpura, typically confined to the lower extremities. Lesions may be limited or severe. Two thirds of patients show confluent areas of hemosiderosis of the feet and lower legs, characteristic of prior episodes of purpura. Although only 30% of patients report an exacerbation with cold exposure, up to 50% will have Raynaud phenomenon and cold-induced acrocyanosis of the ears. Other morphologies include

ecchymoses, livedo reticularis, urticaria, and ulcerations. Neuropathy and other neurologic complications occur in 40% of patients. Arthralgias, xerostomia, and xerophthalmia are frequent complaints. Renal disease occurs in about 25% of patients; widespread systemic vasculitis occurs in about 10%. These complications can be significant and life threatening, as can therapy-related infections. Laboratory evaluation will reveal a cryoglobulin, hypocomplementemia (90%), and a positive RF (70%). ANCAs are rarely positive. A skin biopsy will show LCV.

The treatment of cryoglobulinemic vasculitis is the treatment of the underlying disease, if possible. With HCV infection, this may be IFN alfa plus ribavirin, or any of a number of newer agents available for this condition. Cryoglobulinemic vasculitis associated with HCV may also flare with IFN treatment. Colchicine, dapsone, IVIG, infliximab, and rituximab (anti-CD20 monoclonal antibody) can be attempted. In severe cases, plasmapheresis may be beneficial.

Macular lymphocytic arteritis (lymphocytic thrombophilic arteritis)

Macular lymphocytic arteritis is a rarely reported condition that affects predominantly non-Caucasian females. It presents with multiple, poorly defined brown macules on the lower legs resembling postinflammatory hyperpigmentation. Histologically, a vessel in the subcutaneous fat is infiltrated with lymphocytes, but usually without destruction of the vessel. Neutrophils are absent. Recent reports suggest this condition may actually represent an indolent form of cutaneous polyarteritis nodosa with potential for ulceration.

Golfer's and exercise-related "vasculitis"

This syndrome occurs mostly in hot weather and affects primarily older men (>50). Golfing or exercise with prolonged walking is the trigger. The syndrome is characterized by asymptomatic or pruritic, burning, or stinging, purpuric, macular or slightly raised papules and plaques, predominantly just above the sock line near the ankles. Mild ankle swelling may be present. The lesions resolve in under 3 days in most patients. Histologically, true LCV is not seen, but erythrocytes and neutrophils are present in the affected tissue. About half the patients are taking antithrombotic agents. This syndrome probably represents a form of purpura caused by anticoagulation and prolonged erect posture rather than a true vasculitis.

Erythema elevatum diutinum

A rare condition, erythema elevatum diutinum (EED) is considered to be a chronic fibrosing leukocytoclastic vasculitis. Classically, multiple orange to yellow papules and plaques develop over the joints (Fig. 35-22), particularly the elbows, knees, hands, and feet. Lesions may also involve the buttocks and areas over the Achilles tendon. Petechiae and purpura can be associated with early lesions. More rarely, large plaques with nodules at the periphery may affect the trunk and extremities. Scattered nodules on the trunk with no acral lesions constitute another rare variant. With time, the papules take on a doughy to firm consistency and develop a red or purple color. In HIV infection, skin-colored or red nodules affect the soles, producing lesions resembling keloids, Kaposi sarcoma, or bacillary angiomatosis. Pruritus, arthralgias, and pain have been reported; however, most patients are

Fig. 35-22 Erythema elevatum diutinum.

asymptomatic. Some patients with EED will develop Sweet syndrome or pyoderma gangrenosum–like ulcerations, which in one patient presented as a phagedenic penile ulceration. Systemic complications are rare, but an unusual and potentially rapidly destructive keratitis can lead to blindness. EED has been associated with HIV infection, SLE, Sjögren syndrome, lymphoma, breast cancer, lymphoepithelioma-like carcinoma, dermatitis herpetiformis, and celiac disease. IgA monoclonal gammopathy may be detected. Chronic and recurrent streptococcal infections cause exacerbations of the disease in some patients. These may all represent conditions with persistent circulating immune complexes that might trigger a chronic vasculitis. Pathogenically, ANCAs (60% IgA and 33% IgG) are found in EED. ANCA-positive vasculitides, such as granulomatosis with polyangiitis and microscopic polyangiitis, have rarely been reported to have EED-like lesions.

Histologically, early lesions are an LCV, but with prominent interstitial neutrophils. Well-formed lesions are composed of nodular and diffuse mixed infiltrates of neutrophils and nuclear dust, eosinophils, histiocytes, and plasma cells that often extend into the subcutaneous fat. The prominence of eosinophils; the chronicity of the process, which results in an onion skin–like perivascular fibrosis; and the admixture of plasma cells and many lymphocytes are the hallmarks of EED. Erythrocyte extravasation may lead to extracellular cholesterol crystals in long-standing cases.

Dapsone is the treatment of choice for EED. Patients with celiac disease may respond to a gluten-free diet. Tetracycline and nicotinamide, sulfapyridine, colchicine, antimalarials, intralesional or systemic corticosteroids, topical dapsone, and surgical excision have all been reported as effective in a limited number of cases. Intermittent plasma exchange has been used successfully in patients with IgA paraproteinemia. The interstitial keratitis also responds to dapsone. Unfortunately, the late nodular lesions may not resolve with dapsone treatment.

Fig. 35-23 Granuloma faciale.

Granuloma faciale

Characterized by brownish red, infiltrated papules, plaques (Fig. 35-23), and nodules, granuloma faciale involves the facial areas, particularly the nose. Healthy, middle-age (mean 53 years) white men (male/female ratio 5:1) are most often affected. Childhood cases have been reported. Extrafacial disease occurs in up to 20% of patients, usually affecting the upper trunk and extremities. The pathology of granuloma faciale is similar to that of EED, with focal LCV, diffuse dermal neutrophilia with leukocytoclasia, tissue eosinophilia, and perivascular fibrosis. Some histologic features, including an abnormal content of IgG4 plasma cells, may be similar to those of IgG4-related sclerosing diseases. A variety of treatment options are available. Intralesional corticosteroids are the recommended first approach. Cryotherapy in combination with intralesional corticosteroids has been shown to be very effective. Topical corticosteroids or tacrolimus may also be useful. Although controlled clinical trials are lacking, dapsone, colchicine, or antimalarials could be considered if the patient remains unresponsive. Pulsed dye or carbon dioxide (CO_2) laser therapy has been effective in multiple cases, making it a reasonable consideration as first-line treatment.

Fig. 35-24 Polyarteritis nodosa with multiple leg ulcerations.

POLYARTERITIS NODOSA

Polyarteritis nodosa (PAN) is characterized by necrotizing vasculitis affecting primarily the small to medium-sized arteries. There are two major forms, the benign cutaneous and the systemic, although even long-standing benign cutaneous PAN can evolve into systemic disease. In 1990, the American College of Rheumatology selected the following 10 features of systemic PAN, at least three of which should be present for diagnosis:

1. Livedo racemosa
2. Polymorphonuclear arteritis
3. Leg pain/myopathy/weakness
4. Mononeuropathy/polyneuropathy
5. Positive hepatitis B virus (HBV) serology
6. Weight loss >4 kg
7. Testicular pain/tenderness
8. Diastolic blood pressure >90 mm Hg
9. Elevated BUN/creatinine
10. Arteriographic abnormality

Systemic PAN shares some clinical features with microscopic polyangiitis (MPA), but the strong association of MPA with ANCA positivity, the involvement of renal glomeruli and pulmonary capillaries, and the presence of vasculitis in arterioles, venules, and capillaries help distinguish MPA from PAN.

The mean age of presentation is 45–50 years, and PAN is two to four times more common in men than women. A cutaneous vasculitis identical to PAN has been seen in IV drug abusers (see later) and in association with SLE, inflammatory bowel disease, hairy cell leukemia, familial Mediterranean fever, and Cogan syndrome (nonsyphilitic interstitial keratitis and vestibuloauditory symptoms). Reported infectious associations include hepatitis B, hepatitis C, antecedent streptococcal infection, and many others. Vascular-based tuberculids (erythema induratum, nodular tuberculid) may have histology identical to PAN. The proportion of PAN cases associated with HBV was previously higher but is currently about 5–7% of cases overall and decreasing with HBV immunization. The identification of associated hepatitis virus infection has therapeutic and prognostic implications.

The skin is involved in up to 50% of patients with the systemic form of PAN, with wide-ranging findings. The most striking and diagnostic lesions (15% of patients) are 5–10 mm subcutaneous nodules occurring singly or in groups, distributed along the course of the blood vessels, above which the skin is normal or slightly erythematous (macular arteritis). These nodules are often painful and may pulsate and over time ulcerate (Fig. 35-24). Common sites are the lower extremities, especially below the knee. Ecchymoses and peripheral gangrene of the fingers and toes may also be present. Livedo reticularis in combination with subcutaneous nodules strongly suggests the diagnosis of PAN. Palpable purpura with histologic features of cutaneous LCV may be seen in 20% of PAN patients. Urticaria is present in 6%. HBV-associated PAN is associated with cutaneous findings in only 30% of patients.

Classic systemic PAN may involve the vessels throughout the entire body. It has a particular predilection for the skin, peripheral nerves, GI tract, and kidneys. Hypertension (from renal involvement in 80%), tachycardia, fever, edema, and weight loss (>70%) are cardinal signs of the disease. Arthralgia/arthritis (up to 75%), myocardial and intestinal infarctions, and peripheral neuritis (75%) are also seen. Mononeuritis multiplex, most often manifested as footdrop, is a hallmark of PAN. Involvement of the meningeal, vertebral, and carotid arteries may lead to hemiplegia and convulsions. The lungs and spleen are rarely involved. Aneurysms develop, which may result in multiorgan infarcts. A Five Factor Score (FFS) has been validated, with 1 point each for proteinuria (>1 g/d), renal insufficiency (serum creatinine >1.58 mg/dL), GI tract involvement, CNS involvement, and cardiomyopathy. The 5-year survival for patients with FFS of 0, 1, and more than 2 are 88%, 75%, and 54%, respectively. Among survivors, relapses remain common. Before the use of systemic immunosuppressives, the mortality for systemic PAN exceeded 90%.

A leukocytosis of as high as 40,000/mm^3 may occur, with neutrophilia up to 80%; thrombocytosis, progressive normocytic anemia, and elevated ESR and C-reactive protein (CRP) may also be found. Hepatitis B and C studies should be performed. Urinary abnormalities, such as proteinuria, hematuria, and RBC casts, are present in 70% of patients. ANCA positivity in PAN is rare (if present, most often p-ANCA), whereas the more specific proteinase-3 and myeloperoxidase antibodies are negative.

The histology is that of an inflammatory necrotizing and obliterative panarteritis that affects the small and medium-sized arteries. Focal vasculitis forms nodular swellings that become necrotic, producing aneurysms and rupture of the vessels. Hemorrhage, hematoma, and ecchymosis may result. Obliteration of the lumen may occur, with ischemic necrosis of surrounding tissue. Characteristically, the arteries are affected at their branching points. Biopsy samples of skin nodules or ulcers must be sufficiently deep to include affected vessels in the deep dermis or subcutis.

The mainstay of diagnosis is the presence of these histologic features and the constellation of clinical findings. The preferable site for biopsy is an accessible area such as skin, muscle, or testis. If these are not involved, angiography may detect aneurysmal dilations as small as 1 cm wide in the renal, hepatic, or other visceral vessels; the angiographic appearance of these aneurysms is characteristic, if not pathognomonic.

Treatment

Untreated classic PAN can be fatal, usually from renal failure or cardiovascular or GI complications. Death generally occurs early in the course of the disease, within weeks to months, highlighting the importance of early diagnosis and treatment. Patients with HBV- or HCV-associated PAN should receive appropriate antiviral treatments as part of their initial therapy. For PAN not associated with HBV or HCV, treatment with corticosteroids and cytotoxic agents has increased 5-year survival to more than 75%. Corticosteroids, in the range of 1 mg/kg/day of oral prednisone, are given initially. Once the disease remits, the dose should be reduced. After an average of 3–6 months, if the patient remains in remission, the corticosteroids are slowly tapered to discontinuation.

Cyclophosphamide is recommended for those with serious systemic involvement or steroid-refractory disease. It is given with corticosteroids or sometimes alone. Initially, 2 mg/kg/day as a single dose is recommended. Twice this amount may be required for severely ill patients. The oral cyclophosphamide dose is then adjusted to maintain the white blood cell (WBC) count between 3000 and 3500 cells/mm^3 and neutrophil count above 1500 cells/mm^3. When the disease has been quiescent for at least 1 year, the cyclophosphamide may be tapered and stopped. On average, 18–24 months of therapy are required. Pulsed IV cyclophosphamide is associated with a lower incidence of toxicity, especially the long-term risk of malignancy. Plasma exchange may be used for acute crises or treatment failures with corticosteroids and cyclophosphamide. Ulcerations in PAN can be very painful because of the associated neuropathy and should be managed as nonhealing leg ulcers.

Cutaneous polyarteritis nodosa

About 10% of patients present with PAN localized to the skin and have limited systemic involvement. Neuropathy occurs in 20%. Subcutaneous nodules (80%), livedo (70%), and ulceration (44%) are the characteristic cutaneous features that should lead to suspicion of cutaneous PAN. Atrophie blanche–like lesions on the ankles may be the sole manifestation. Plaques on the trunk and proximal extremities, expanding slowly and centrifugally, are another manifestation. At the periphery of the plaques is a ring of 1–2 cm subcutaneous nodules. Cutaneous PAN has a better prognosis and requires less aggressive therapy. Patients rarely develop the systemic renal, GI, and cardiovascular complications of systemic PAN. This form of PAN is the most common childhood pattern of PAN. Whether there are two clear subsets of patients, with cutaneous or systemic PAN, or whether they exist on a spectrum, is controversial. Patients with "cutaneous" PAN must be followed carefully and regularly evaluated to exclude the development of systemic involvement, which may appear as long as two decades after the initial diagnosis.

The diagnosis of cutaneous PAN is made by biopsy of a subcutaneous nodule. An excisional biopsy is recommended because the vasculitis is focal. The affected arteriole is at the junction of the dermis and subcutaneous tissue or in the subcutaneous fat. Adjacent to the affected vessel, there is an inflammatory panniculitis, and inadequate evaluation of the biopsy or too small a sample may lead to the erroneous diagnosis of a panniculitis. Also distal to the affected arteriole, thrombosis usually occurs. If the biopsy is inadequate in depth or size, this bland thrombosis without inflammation is seen, and the erroneous diagnosis of a "vasculopathy" will be made. Cutaneous PAN has been associated with HBV surface antigenemia, HCV infection, Crohn's disease, Takayasu arteritis, relapsing polychondritis, streptococcal infections, tuberculosis, and medications (minocycline). Typically, the only laboratory abnormality is an elevated ESR or CRP. In some cases, a p-ANCA may be present. Most patients respond well to aspirin, NSAIDs, prednisone, pentoxifylline, sulfapyridine, colchicine, dapsone, methotrexate, or MMF alone or in some combination. In childhood cutaneous PAN, since streptococcal infection is common, penicillin treatment may be used. In refractory cases, IVIG may be given.

ANCA-POSITIVE VASCULITIDES

Antineutrophil cytoplasmic antibodies (ANCAs) are an important laboratory finding used in the diagnosis and prognosis of systemic vasculitis. ANCAs occur in three patterns: cytoplasmic (c-ANCA), perinuclear (p-ANCA), and atypical ANCA. The initial screening is performed using indirect immunofluorescence, then confirmed using ELISA for characterization of target antigens. c-ANCA is associated with antibodies directed against proteinase 3 (PR3). Antibodies against myeloperoxidase (MPO) result in the p-ANCA pattern, but antibodies against other antigens may also give this pattern. Only ANCAs against PR3 or MPO are associated with primary vasculitic

syndromes; atypical ANCAs are directed against neither. Most laboratories now perform specific tests to determine whether positive ANCAs are reactive against MPO or PR3. Anti-PR3 antibodies are relatively specific for granulomatosis with polyangiitis (Wegener's granulomatosis) and microscopic polyangiitis. Antibodies against MPO are less specific and can be found in microscopic polyangiitis, eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome), and drug-induced vasculitis. Usually, either anti-MPO or anti-PR3 antibodies are found, but not both. If both patterns are found, drug-induced vasculitis should be suspected.

The ANCA-associated vasculitides—microscopic polyangiitis (MPA), granulomatosis with polyangiitis (GPA), and eosinophilic granulomatosis with polyangiitis (EGPA)—have overlapping features, characteristically demonstrating pulmonary hemorrhage and/or necrotizing glomerulonephritis (pulmonary-renal syndrome). Conversely, 60% of patients with the pulmonary-renal syndrome will have ANCA-associated vasculitis. With ANCA testing, these diseases can be diagnosed with 85% sensitivity and 98% specificity. However, although ANCAs are usually negative in Takayasu arteritis, giant cell arteritis, Kawasaki disease, and Behçet's disease, positive ANCAs can be found in cryoglobulinemia and other forms of skin-limited vasculitis, SLE, RA, inflammatory bowel disease, and certain infectious diseases. ANCAs are most useful, therefore, when confirmed by ELISA testing in the setting of vasculitis with systemic features or in situations where the clinical findings suggest ANCA-associated vasculitis. ANCA testing, when used appropriately, is highly sensitive and specific, but it does not replace these clinical features, other relevant laboratory tests, or histologic confirmation of the presence of vasculitis.

Microscopic polyangiitis

With the advent of ANCA serologies and clarification of the features of MPA, this diagnosis is becoming increasingly more common. There is a north-south gradient in incidence, with southern European countries having three to four times as many cases. Most patients with MPA have systemic symptoms, such as fever, weight loss, myalgias, and arthralgias, which can present with an acute flulike illness or evolve for months to years before a more explosive phase of the disease. These cases have been termed "slowly progressive MPA." Most patients with MPA will have or develop segmental necrotizing and crescentic glomerulonephritis (80–90%), with pulmonary involvement in 25–65%. Pulmonary capillaritis, which can be complicated by hemorrhage, occurs in 12–29% of MPA patients. The skin is involved in 44%. Purpuric papules and macules are most common, and livedo reticularis, retiform purpura, cutaneous ulcers, and digital ischemia are also seen. Urticarial lesions occur in 1% of cases. Patients with MPA may present with skin lesions as their initial clinical findings. Livedo is seen in two thirds of such patients. Biopsies of macules, papules, petechiae, or sites adjacent to ecchymoses may reveal a necrotizing LCV in the reticular dermis.

Vasculitic neuropathy is common (58%), and eye disease may occur. Eosinophilia and asthma are not seen. ANCAs are positive in 70% of cases, p-ANCA more frequently than c-ANCA. MPA is differentiated from PAN by the presence of glomerulonephritis, pulmonary symptoms, and the absence of hypertension and microaneurysms. ANCAs are rarely positive in PAN.

Microscopic polyangiitis is managed similar to other forms of ANCA-associated vasculitis, with systemic corticosteroids and often cytotoxic agents from disease onset. Glucocorticoid monotherapy is associated with lower remission rates. In generalized but non-organ-threatening disease, methotrexate may be added to prednisone, 1 mg/kg/day or equivalent, as initial therapy. For more severe disease, cyclophosphamide is usually given instead with glucocorticoids in the early induction phase of treatment as monthly pulses (vs. daily treatment) for 6–12 months. This regimen has a lower relapse rate compared with the combination of methotrexate and corticosteroids, Rituximab in combination with glucocorticoids is another option for induction of remission shown not to be inferior to combination cyclophosphamide and prednisone for MPA and GPA. Other, less toxic immunosuppressives, such as methotrexate, azathioprine, and MMF, may be used in milder cases or as maintenance therapy. IVIG and anti-TNF agents (infliximab) may be considered in refractory cases. Relapses are frequent. The 5-year survival is about 75%, and 7-year survival is 62%.

Granulomatosis with polyangiitis (Wegener's granulomatosis)

Granulomatosis with polyangiitis (GPA) is a syndrome consisting of necrotizing granulomas of the upper and lower respiratory tract, generalized necrotizing angiitis affecting small and medium-sized blood vessels, and focal necrotizing glomerulitis. By far the most common initial manifestation, present in 90% of patients, is the occurrence of rhinorrhea, severe sinusitis, and nasal mucosal ulcerations, with one or several nodules in the nose, larynx, trachea, or bronchi. Failure to respond to conventional treatment for sinusitis may prompt suspicion of the diagnosis. Fever, weight loss, and malaise occur in these patients, who are usually 40–50 years of age and more often male than female (1.3:1). Obstruction in the nose may also block the sinuses. The nodules in the nose frequently ulcerate and bleed. The parenchymal involvement of the lungs produces cough, dyspnea, and chest pain; 71% of patients have pulmonary infiltrates radiographically. Granulomas may occur in the ear and mouth, where the alveolar ridge becomes necrotic, and ulceration of the tongue and perforated ulcers of

Fig. 35-25 Wegener's granulomatosis, strawberry gingiva.

the palate develop. The combination of nasal and palatal involvement may lead to saddle-nose deformity. The "strawberry gums" appearance of hypertrophic gingivitis is characteristic, and biopsy of these lesions may be diagnostic (Fig. 35-25).

Cutaneous findings occur in 45% of GPA patients. Nodules may appear in crops, especially along the extensor surfaces of the extremities. The firm, slightly tender, flesh-colored or violaceous nodules may later ulcerate. These may be mistaken for ulcerating rheumatoid nodules. The necrotizing angiitis of the skin may present as a palpable purpura, petechial or hemorrhagic pustular eruption, subcutaneous nodules, or ulcers. Livedo reticularis is rare in GPA. Patients may present with pyoderma gangrenosum–like lesions, and several patients have been reported presenting with features of temporal arteritis. The condition previously described as "malignant pyoderma" is now thought to represent GPA.

Limited forms of GPA involving the upper respiratory tract without renal involvement may also occur and have a better prognosis. Cutaneous findings can be associated with limited disease. Focal crescentic necrotizing glomerulonephritis occurs in 85% of GPA patients. It may be fulminant from the outset or may become more severe as the disease progresses. Renal failure was the most frequent cause of death before cyclophosphamide treatment. Other organs frequently involved include the joints (arthralgia in two-thirds); eyes (conjunctivitis, episcleritis, and proptosis) in 58%; and the CNS and heart in 22% and 12% of patients, respectively.

Histologically, the cutaneous lesions may demonstrate an LCV, with or without granulomatous inflammation. Granulomatous vasculitis may be seen. Palisaded granulomas with multinucleated giant cells and a central core of neutrophils and debris are a characteristic finding. Often, if the lesions are ulcerated, they are nonspecific histologically. Biopsy of another affected organ, such as the kidney, lung, or upper respiratory tract, may be required to confirm the diagnosis. The early detection of GPA has improved with the availability of ANCA testing, because almost 100% of patients with active generalized GPA are ANCA positive by either indirect immunofluorescence or ELISA. Almost 90% are c-ANCA (anti-PR3) positive, with the remainder p-ANCA (anti-MPO) positive and very few ANCA negative.

Untreated GPA has a mean survival time of 5 months and a 90% mortality over 2 years. Cyclophosphamide therapy has dramatically changed the prognosis; however, therapy-related adverse events now account for more deaths in the first year after diagnosis than the vasculitis itself. Treatment recommendations are cyclophosphamide, 2 mg/kg/day, and prednisone, 1 mg/kg/day, followed by slow tapering of the prednisone to not less than 15 mg/day during the first 3 months of therapy. Complete remission is achieved in up to 93% of patients and lasts an average of 4 years. Rituximab combined with high-dose glucocorticoids is an alternative to cyclophosphamide for induction therapy and was approved by the FDA in 2011. In more limited disease, patients may respond to methotrexate alone or in combination with prednisone. After initial induction therapy and remission, methotrexate, azathioprine, leflunomide, MMF, or rituximab may be used instead of cyclophosphamide. Treatment should be continued for at least 1 year. Trimethoprim-sulfamethoxazole (TMP-SMX) may decrease the relapse rate and can be considered for long-term treatment of patients with limited upper respiratory tract involvement in remission, in combination with conventional immunosuppressive protocols. The benefit of long-term TMP-SMX results from its reduction of nasal carriage of *Staphylococcus aureus*, a possible trigger of GPA. In refractory cases, plasma exchange, IVIG, and anti-TNF therapy (infliximab) may be used. Tacrolimus, 0.1 mg/kg/day, was successful in treating a pyoderma gangrenosum–like ulceration in a patient with GPA.

Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)

Eosinophilic granulomatosis with polyangiitis (EGPA) occurs in three phases. The initial phase, often lasting many years, consists of allergic rhinitis, nasal polyps, and asthma. The average age of onset of the asthma is 35 years in EGPA (unlike allergic asthma, which often presents in childhood). After 2–12 years, a debilitated asthmatic patient begins to experience attacks of fever and eosinophilia (20–90%), with pneumonia and gastroenteritis caused by eosinophilic infiltration (second phase). After a few more months or years, but on average 3

years after the initial symptoms, a diffuse small-vessel and medium-vessel vasculitis with granulomatous inflammation involves the lungs, heart, liver, spleen, kidneys, intestines, and pancreas. Mononeuritis multiplex is common. Triggers of this third phase have included vaccination, desensitization, leukotriene inhibitors, azithromycin, inhaled fluticasone, and rapid discontinuation of corticosteroids. Renal involvement is less common than in GPA or MPA. A fatal outcome is likely in most untreated patients; congestive heart failure resulting from granulomatous inflammation of the myocardium is the most frequent cause of death. Increased rates of arterial and venous thrombosis are seen in EGPA, perhaps related to the dense infiltrates of eosinophils.

Cutaneous lesions are present in two thirds of EGPA patients. Palpable purpura is seen in almost 50%. Subcutaneous nodules on the extensor surfaces of the extremities and on the scalp are seen in 30%. Firm, nontender papules may be present on the fingertips; these may resemble the lesions seen with septic emboli or atrial myxoma but show vasculitis on biopsy. Urticaria, solar urticaria, and livedo reticularis can occur in EGPA. Plaques with the histologic features of eosinophilic cellulitis (Wells syndrome) can be seen.

Laboratory studies are significant for a peripheral eosinophilia, which correlates with disease severity. ANCAs are frequently positive (55–70%), most often p-ANCA (anti-MPO) and less frequently c-ANCA (anti-PR3), and tend to correlate with disease severity.

Histologically, a small-vessel vasculitis is present that involves not only superficial venules, but also larger and deeper vessels. The tissue is often diffusely infiltrated with eosinophils, and granulomas may be present. Palisaded granulomas differ from those in Wegener's granulomatosis in that they generally lack multinucleated giant cells, and the core contains eosinophils. In some patients, flame figures, similar to those in Wells syndrome, are noted in the dermis.

Corticosteroids alone may be used in patients with EPGA and FFS of 0 (see Polyarteritis nodosa). Cyclophosphamide alone or in combination with corticosteroids should be used in patients with neuropathy, refractory glomerulonephritis, myocardial disease, severe GI disease, and CNS involvement. When treatment is stratified in this way, survival is good, about 90% at 7 years. However, 40% of patients experience one or more relapses, usually with steroid taper. Azathioprine, as well as methotrexate and leflunomide, is used as a steroid-sparing agent, especially to maintain a remission. IFN alfa, MMF, and the anti-TNF agents infliximab and etanercept have also been used successfully in patients with EPGA (Churg-Strauss syndrome).

COCAINE-ASSOCIATED VASCULITIS AND LEVAMISOLE-INDUCED VASCULOPATHY/VASCULITIS

There are numerous reports of various forms of cutaneous vasculitis associated with the intravenous or intranasal use of cocaine. Skin lesions have included typical LCV, as well as larger-vessel vasculitis resembling PAN. Localized nasal lesions with vasculitis resembling GPA (Wegener's granulomatosis) have been observed in patients using inhaled cocaine. This has been termed "cocaine-induced pseudovasculitis" or "cocaine-induced midline destructive lesions" to try to distinguish it from true GPA. In addition, patients using cocaine may develop more widespread cutaneous and systemic vasculitis affecting the kidneys, lungs, and testes. The cutaneous lesions resemble LCV, but ecchymotic lesions (Fig. 35-26) and skin necrosis are more prominent in these patients than in the typical LCV patient. Purpura and necrosis of the earlobe and nose are especially common and characteristic; retiform purpura on the thighs and other areas is frequently seen. Agranulocytosis, not a typical feature of ANCA-positive vasculitis, also occurs. These patients have an elevated c-ANCA, similar to those with true GPA. However, the c-ANCA in patients with cocaine-induced vasculitis reacts with human neutrophil elastase (HNE-ANCA). Patients with GPA and MPA are negative for HNE-ANCA.

Street cocaine is often contaminated with pharmaceutical agents. Levamisole has been found in the cocaine seized by law enforcement in up to 70% of U.S. cases and 100% in Italy. Levamisole is associated with ecchymotic purpura and necrosis, with a predilection for the ears. It also causes agranulocytosis and c-ANCA positivity. It is therefore unclear whether the vasculitic lesions seen in recreational cocaine users are caused by the cocaine or by the levamisole excipient (levamisole-induced vasculopathy/vasculitis), or both. In every patient presenting with a cutaneous or systemic vasculitis, a detailed history of recreational drug use must be obtained, and toxicology screening should be considered in any patient with vasculitis having the features just outlined, especially agranulocytosis or cutaneous necrosis, or failing to

Fig. 35-26 Cocaine-associated vasculitis.

respond to appropriate therapy. Because its half-life is only 5.6 hours, confirming the presence of levamisole in the urine can be difficult. In affected patients, stopping of the drug may lead to a gradual improvement of the vasculitis, although initial immunosuppressive therapy may be required. Treatment to eradicate nasal *S. aureus* should be considered if there are prominent nasal findings.

GIANT CELL ARTERITIS/TEMPORAL ARTERITIS

Giant cell arteritis (GCA) is a systemic disease of people over age 50 (mean age >70), favoring women (2:1). It is uncommon in African Americans and favors whites. Its best-known location is the temporal artery, and it is also known as temporal arteritis, cranial arteritis, and Horton's disease. GCA is characterized by a necrotizing arteritis with granulomas and giant cells, which produce unilateral headache and exquisite tenderness in the scalp over the temporal or occipital arteries in 50–75% of patients. Temporal headaches are characteristically constant, severe, and boring. Ear and parotid pain and mastication-induced jaw claudication may occur. Fever, anemia, and a high ESR (>50) are usually present. Proximal, symmetric, and severe morning and even day-long limb girdle stiffness, soreness, and pain occur in 50% of patients (associated polymyalgia rheumatica). GCA is rarely fatal. Blindness may develop and is the most feared complication of the disease. Many patients who develop visual loss have premonitory symptoms, allowing for diagnosis and intervention, which may prevent permanent visual loss. However, failure to begin treatment within the first 48 hours of the onset of visual symptoms still may lead to permanent damage.

The cutaneous manifestations of GCA may be only inflammatory. The affected artery becomes evident as a hard, pulsating, tender, tortuous bulge under red or cyanotic skin. Another manifestation is necrosis of the scalp (Fig. 35-27). Lesions may begin as ecchymoses. Later, they may become vesicular or bullous and are followed by gangrene. Urticaria, purpura, alopecia, tender nodules, prurigolike nodules, and livedo reticularis may be seen. Lingual artery involvement may cause an accompanying red, sore, or gangrenous tongue. Nasal septal

perforation may develop. Actinic granuloma may be associated. Actinic damage of the arterial elastic tissue of the temporal artery may occur because of its superficial location. The elderly Caucasian is at greatest risk, and when lesions are biopsied, at times only the external half of the artery that received solar radiation is involved. Some posit that temporal arteritis may be an actinically induced disease.

Polymyalgia rheumatica (PMR) has a significant clinical association with GCA. Prompt treatment may forestall serious disease. About 10% of central retinal artery occlusions are caused by GCA. ESR is elevated in more than 90% of patients. Temporal artery biopsy is generally diagnostic, provided at least a 2-cm segment is provided. Even arteries that are normal on palpation may show diagnostic findings. Magnetic resonance angiography and color Doppler and duplex ultrasonography are noninvasive diagnostic methods that may aid in confirming the clinical suspicion and identifying the best site to biopsy, or may even obviate the need for biopsy. Importantly, therapy should never be postponed waiting for a biopsy. Not all patients with arteritis of the temporal artery have GCA, because temporal arteritis may be a manifestation of a systemic vasculitis such as PAN, GPA, or microscopic polyarteritis. Conversely, GCA patients may have involvement of the aorta and its proximal branches, similar to Takayasu arteritis, and are at risk of aneurysm and dissection; it is not clear whether such patients with extracranial large-vessel vasculitis require more aggressive treatment or monitoring. Pathogenically, the presence of TNF polymorphisms in patients with PMR and temporal arteritis suggests a genetic predisposition.

Treatment begins with prednisone, 60 mg/day, and continues for 1 month or until all reversible clinical and laboratory parameters (e.g., ESR) return to normal. GCA is quite steroid responsive, and tapering to a prednisone dose of 7.5–10 mg/day is usually possible. Daily therapy seems to be important and is usually necessary for a minimum of 1–2 years. Most patients achieve complete remission, which is often maintained after therapy is withdrawn. Cyclophosphamide, methotrexate, azathioprine, and anti-TNF agents may be used in refractory cases, but the data are mixed, and relapses occur when treatment is stopped. Corticosteroid therapy is usually required.

Takayasu arteritis

Known also as aortic arch syndrome and pulseless disease, Takayasu arteritis (TA) is a thrombo-obliterative process of the great vessels stemming from the aortic arch, occurring generally in young women (female/male ratio 9:1) in the second or third decade of life. It is more common in Japan, Southeast Asia, India, and South America. Radial and carotid pulses are typically obliterated. Most skin changes are caused by the disturbed circulation. There may be loss of hair and atrophy of the skin and its appendages, with underlying muscle atrophy. Occasional patients with cutaneous necrotizing or granulomatous vasculitis of small vessels have been reported. Erythematous nodules with or without livedo, simulating erythema nodosum or erythema induratum, may rarely occur. Sweet syndrome has also been reported in association with TA. Pyoderma gangrenosum–like ulcerations are well described in Japan; the lesions precede the diagnosis of TA by an average of 3 years. These lesions are more often generalized and in three quarters of cases occur on the upper extremities.

Treatment of TA with prednisone is recommended, 1 mg/kg/day tapered over 8–12 weeks to 20 mg/day or less. Methotrexate may be used for its steroid-sparing effects. The possible effectiveness of biologic therapies, such as the interleukin-6 receptor antagonist tocilizumab, is being actively investigated. With active medical and surgical intervention, the aggressive course of TA can be modified. The pyoderma gangrenosum–like lesions are also treated with systemic corticosteroids, but azathioprine, cyclophosphamide, MMF, cyclosporine, and tacrolimus have also been effective.

MALIGNANT ATROPHIC PAPULOSIS

Papulosis atrophicans maligna, also known as Degos' disease, is a potentially fatal obliterative arteritis syndrome. Some affected patients, perhaps as many as 70%, have a long benign course with skin lesions only, whereas in others, death occurs within a few years. Degos' disease occurs two to three times more frequently in men than in women, often presenting between ages 20 and 40. Familial kindreds are well reported. In patients with the more aggressive variant, survival averages 2–3 years after the disease has developed.

Skin lesions are usually the first sign of the disease. Clinically, Degos' disease is characterized by the presence of pale-rose, round, edematous papules occurring mostly on the trunk. Similar lesions may occur on the bulbar conjunctiva and oral mucosa. Palms, soles, and face are spared, but the penis may be involved. Over days to weeks, the lesions become umbilicated, with an enlarging central depression. The center becomes distinctively porcelain white, while the periphery

becomes livid red and telangiectatic. Central atrophy occurs eventually. The eruption proceeds by crops in which only a few new lesions appear at any one time. One patient was reported to develop panniculitis. Lesions characteristic of Degos' disease may be seen in patients with LE, dermatomyositis, scleroderma, and GPA.

Systemically, ischemic infarcts involve the intestines, producing acute abdominal symptoms, which include epigastric pain, fever, and hematemesis. Death usually results from fulminant peritonitis caused by multiple perforations of the intestine. Less frequently, death occurs from cerebral infarctions.

Wedge-shaped necroses initiated by the occlusion of arterioles and small arteries account for the clinical lesions. Proliferation of the intima and thrombosis constitute the typical histologic picture. The thrombosing process is usually pauciinflammatory, although neutrophils or lymphocytes may be found associated with the thrombosis. The overlying dermis, which is infarcted, contains abundant mucin, especially early in the lesion's evolution. Adnexae are typically necrotic, and the depressed central portion may be noted histologically.

The etiology of malignant atrophic papulosis is unknown, but based on the infarctive nature of the lesions and the universal presence of arteriolar thrombosis, a hyperthrombotic state or endothelial abnormality is suggested. Although most patients have not had abnormalities identified, abnormal platelet aggregation and abnormal coagulation have been identified in some cases. Antiphospholipid antibodies and anticardiolipin antibodies have been discovered in some patients, as has factor V Leiden mutation in one. Parvovirus B19 infection was associated with a fatal case in an adult. Prominent C5b-9 deposits and elevated IFN-α expression have also been described in vessels of the skin, GI tract, and brain, suggesting that complement-mediated vascular injury may play a role.

There is no proven therapy for Degos' disease. Administration of immunosuppressives has been mostly unsuccessful and may even worsen the disease. IVIG has been of therapeutic benefit in one patient, but failed in another. Terminal complement inhibition using the C5 protein inhibitor eculizumab has been attempted. While under investigation, eculizumab apparently has not consistently succeeded in preventing or forestalling systemic manifestations of the disease. Ingestion of low-dose acetylsalicylic acid alone or in combination with dipyridamole (Persantine) has been effective in some patients. Heparin, as described by Degos, has been helpful, and should be considered if antiplatelet therapy is ineffective. Nicotine patches, 5 mg/day, were effective in one patient. Subcutaneous treprostinil was used successfully in a case of eculizumab-resistant Degos' disease. In severe crises, fibrinolytic therapy should be considered. The prognosis is guarded in patients with systemic involvement.

THROMBOANGIITIS OBLITERANS (BUERGER'S DISEASE)

Thromboangiitis obliterans (TAO) is a nonatherosclerotic segmental occlusive disease affecting the arteries of multiple extremities. It is most often seen in men between ages 20 and 40 who smoke heavily. Smoking and rarely the use of smokeless tobacco are intimately tied to Buerger's disease. The various diagnostic criteria proposed usually include age under 45 (or 50); history of tobacco use; distal extremity involvement (infrapopliteal segmental arterial occlusion with sparing of proximal vasculature); frequent distal upper extremity involvement (Raynaud or digital ulcers); consistent angiographic findings; superficial thrombophlebitis; exclusion of autoimmune disease, diabetes mellitus, and hypercoagulable or embolic states.

The vasomotor changes in early cases may be transient or persistent; they produce blanching, cyanosis, burning, and tingling. Superficial thrombophlebitis in the leg and foot occurs in 38% of patients, and 44% may have Raynaud phenomenon. The color of the affected area may change when it is raised or lowered below heart level—red when dependent and white when elevated. Pain is a constant symptom, coming at first only after exercise and subsiding with rest. Instep and foot claudication is the classic complaint. Ultimately, the dorsalis pedis and posterior tibial pulses disappear, followed by others. In TAO, skin supplied by affected arterioles tends to break down, with central necrosis and ulceration and eventual gangrene (Fig. 35-28). GI involvement has been reported. Exposure to cold may cause exacerbations, and more cases are identified in the winter than in any other season.

Arteriography should be done to investigate for central atherosclerotic disease, which may be operable, rather than the inoperable distal damage of Buerger's disease. A characteristic tapering and occlusion of the major arteries with "corkscrew" collateral arteries is found in Buerger's disease on angiography. A vasculo-occlusive syndrome similar to Buerger's disease has been reported in cannabis smokers, but venous thrombophlebitis does not occur. The pathogenic mechanism of the vascular occlusion in Buerger's disease is unknown. In one report, G20210A prothrombin mutations, the majority homozygotic, were found, but these findings have not been reproduced.

The most important therapeutic step is the complete cessation of smoking. Even one or two cigarettes/day, smokeless

Fig. 35-28 Buerger's disease.

tobacco, or nicotine replacement may keep the disease active. IV iloprost (prostaglandin analog) may help the patient with critical limb ischemia get through an acute episode. Oral iloprost is ineffective. Phosphodiesterase type 5 inhibitors have been used successfully. Sympathectomy can provide temporary relief. Implantation of a spinal cord stimulator may be tried. Autologous transplantation of bone marrow mononuclear cells into the calf muscle has benefited patients with TAO and other forms of limb ischemia. G-CSF–mobilized peripheral blood mononuclear cells have had similar efficacy. Endovascular recanalization may be useful in preventing the need for amputation. In patients who stop smoking and do not have gangrene, major amputation is rare. In continued smokers, at least 43% will require amputation.

ARTERIOSCLEROSIS OBLITERANS

Arteriosclerosis obliterans is an occlusive arterial disease most prominently affecting the abdominal aorta, as well as the small and medium-sized arteries of the lower extremities. The symptoms are caused by ischemia of the tissues. Intermittent claudication is manifested by pain, cramping, numbness, and fatigue in the muscles on exercise. These symptoms are relieved by rest. There may be "rest pain" at night when in bed. Also, sensitivity to cold, muscular weakness, stiffness of the joints, and paresthesia may be present. Sexual impotence is common, and there is increased frequency of coronary artery disease.

Reduced or absent pulses (dorsalis pedis, posterior tibial, or popliteal arteries) may be found on physical examination, confirming the diagnosis. The feet, especially the toes, may be red and cold. Striking pallor of the feet with elevation and redness with dependency are compatible findings. Decreased to absent hair growth may be observed on the legs. Ulceration and gangrene may supervene. If present, necrosis usually begins on the toes and is quite painful. Arteriography may be indicated as a preliminary to corrective surgery (arterial grafts). Occasionally, subclavian atherosclerosis may give rise to these signs in the distal upper extremity, producing painful nails and loss of digital skin. Diabetes mellitus, smoking, and hyperlipidemia are risk factors for the development of atherosclerosis.

Claudication and diminished blood pressure in the affected extremity are findings that may lead to earlier diagnosis and thus to curative surgical intervention. Usually, bypass of the affected artery or sympathectomy, or both, are the preferred treatment for arteriosclerosis obliterans. Balloon angioplasty or stent placement may also be effective. Oral beraprost, a prostaglandin I2 analog, appears to improve symptoms of intermittent claudication in these patients. When critical limb ischemia is present, injection of stem cells into the calf muscle may be beneficial.

DIFFUSE DERMAL ANGIOMATOSIS

Diffuse dermal angiomatosis (DDA) is a disorder that preferentially affects women. The most common location is the breast, especially the dependent portion. Affected women tend to have large, pendulous breasts and are usually older than 45. Patients may have had a reduction mammoplasty (often decades earlier), and the disease tends to localize adjacent to the scar from that procedure. The clinical lesions may be reticulated groups of telangiectasias, ischemic (retiform) purpura, ulceration, or some combination. The erythematous/telangiectatic plaques are slightly palpable but not usually indurated. The nipple and areola are spared. The affected patients often have multiple risk factors for a hypercoagulable state or premature atherosclerosis, including a personal history of atherosclerotic cardiovascular disease, obesity, smoking, diabetes mellitus, hypertension, mutations in the thrombolytic

pathway (analogous to those seen in livedoid vasculopathy), and a strong family history for premature atherosclerotic disease-related cardiovascular events. The areas involved are similar to those affected by other prothrombotic disorders (e.g., warfarin necrosis, heparin necrosis)—skin with overly abundant adipose tissue. The breast is most often affected, but the abdomen and medial thighs are also sites of predilection. Usually, only one site is affected, but if the breast is involved, the process can be bilateral. Surgical procedures on the affected area may lead to ulceration that is painful and slow to heal. Because a surgical procedure triggered the ulceration, a mistaken diagnosis of pyoderma gangrenosum may be entertained.

Histologically, a diffuse dermal proliferation of endothelial cells and bland blood vessels occupies much of the dermis. Atypical cells and atypical vascular shapes (as seen in angiosarcoma and Kaposi sarcoma) are not seen. The dermal cells stain for markers of endothelial cells, CD31 and CD34. The pathogenesis is thought to be chronic local ischemia, which may lead to vascular proliferation (angiomatosis) or, if acute and severe, retiform purpura and ulceration. The fatty areas are poorly oxygenated (worse in obese patient), and the pendulous nature of the breasts may stretch or tether the vessels, further compromising the circulation. Inherited and acquired hypercoagulable risk factors (e.g., smoking, atherosclerosis) contribute to the pathogenesis.

The treatment of DDA involves reversing the contributing factors. This includes smoking cessation, weight reduction, and antithrombotic medications such as low-dose aspirin, 81 mg/day, and pentoxifylline, 400 mg twice daily. Reduction mammoplasty may lead to resolution. Atherosclerosis of the arteries serving the affected area may be found, and vascular surgery to enhance circulation may lead to improvement. More than one patient has been successfully treated with isotretinoin. Isotretinoin has fibrinolytic and antiangiogenic effects, which may explain its efficacy.

MUCOCUTANEOUS LYMPH NODE SYNDROME (KAWASAKI DISEASE)

The typical presentation is an irritable, ill-appearing, febrile infant or child younger than 5 years old. Clinical findings in mucocutaneous lymph node syndrome include a skin eruption; stomatitis (injected pharynx, strawberry tongue) and fissuring cheilitis; edema of the hands and feet; nonexudative conjunctival injection; and cervical lymphadenitis. The presence of four of these five cardinal features, plus fever for 5 days or longer, represent diagnostic criteria established by the American Heart Association. The skin eruption is polymorphous and may be macular, morbilliform, urticarial, scarlatiniform, erythema multiforme–like, pustular, or erythema marginatum–like. An early finding (within first week) is the appearance of an erythematous, desquamating perianal eruption in about two thirds of patients. Periorbital edema has been reported. From 15% to 20% of children with Kawasaki disease

Fig. 35-29 Desquamation in Kawasaki disease.

(KD) and fever will not have one or more of the other cardinal features. These cases are termed "incomplete KD." These patients are still at risk for cardiac disease.

Numerous cutaneous and systemic complications have been reported as accompanying or following KD. Pincer nail deformities may appear and resolve spontaneously. Intestinal pseudo-obstruction may occur. Facial nerve paralysis has been described, and a severe peripheral vasculitis with vasospasm, digital ischemia, and gangrene can occur. Numerous children have developed guttate or plaque psoriasis 10–20 days after KD onset. The presumed mechanism is the triggering of psoriasis by the superantigens associated with the acute illness.

The acute illness evolves over 10–20 days. One or 2 weeks after the acute illness, the fingers and toes desquamate, starting around the nails (Fig. 35-29). Coronary artery aneurysms occur in 20–25% of untreated children and 3–5% of treated children. This is the most common cause of acquired cardiac disease in young children. The cardiac involvement can also include decreased left ventricular function, arrhythmias, mitral regurgitation, and pericardial effusion. These complications can be immediate and are the major cause of morbidity and mortality. Over time, those with aneurysms can develop coronary artery stenosis, and as a result, acute cardiac events can occur in young adulthood.

Pathogenesis

A viral or infectious pathogenesis for KD is appealing for the following reasons:

1. Cases were rare before 1950.
2. KD affects children older than 3 months but younger than 8 years.
3. Seasonal peaks occur in the winter and spring.
4. Focal epidemics have been reported.
5. Oligoclonal IgA immune responses are found, suggesting a respiratory portal of entry of an infectious agent.

There are increased superantigens in the stool of children with KD, and a KD-like illness has been described with group A meningococcal septicemia. An infectious pathogenesis, therefore, remains the most plausible etiologic hypothesis; it is less clear whether this is caused by a single unknown agent or whether it represents an immunologic response to a variety of infectious triggers.

It has long been suspected that there is a genetic basis for KD. The disease is 10–20 times more common in persons from Northeast Asia (Japan and Korea), where rates of up to 1 per

150 children are reported. When these Asians move to the United States, they still have this high rate of increased susceptibility. The risk of a sibling developing KD is increased tenfold. Children of parents who had KD in childhood have a twofold increased risk of developing KD. A genome-wide search of almost 1000 KD cases and family members found strong linkage to five genes, three of which form a single functional network. The central gene of this network is *CAMK2D,* which encodes a serine/threonine kinase expressed in cardiomyocytes and vascular endothelial cells. These genes are known to be involved in cardiac and inflammatory pathways. Their transcripts are also greatly suppressed during KD. Other genetic polymorphisms are associated with increased KD susceptibility, including the genes encoding inositol 1,4,5-trisphosphate 3-kinase C *(ITPKC)* and the immunoglobulin G receptor gene *(FCGR2A).*

Kawasaki disease is a systemic vasculitis of medium-sized arteries, of which the coronary arteries are most profoundly and characteristically affected. Coronary artery disease occurs after day 10 of the illness (subacute phase), in combination with thrombocythemia (up to 1 million cells). This combination of an altered endovascular surface and too many platelets, plus abnormal blood flow in the coronary aneurysms, leads to thrombosis and occlusion of the vessels and subsequent cardiac events.

Treatment

The cornerstone of therapy for KD patients is IVIG, given in a single dose of 2 g/kg infused over 10–12 h. Response to treatment is best if given during the first 5–6 days of the illness; however, children with persistent fever beyond this period may benefit from later treatment. Aspirin is used to reduce inflammation and platelet aggregation. The dose is 80–100 mg/kg/day in four divided doses. Once the child has been afebrile for 3–7 days, the aspirin dose is decreased to a single daily dose of 3–5 mg/kg. If the child remains febrile 36 hours after initial treatment (which may occur in 10–20% of patients), a second 2-g/kg dose of IVIG should be given. Such patients are at significantly higher risk of coronary artery aneurysms. A single dose of infliximab, 5 mg/kg, has been reported to be effective in refractory cases, but response, as with other treatments, is not universal. If there is no response to the second IVIG dose, systemic corticosteroid therapy is usually given. Angioplasty, thrombolytic therapy, or coronary artery bypass surgery may be required for patients with coronary disease. Overall, the rate of long-term adverse cardiovascular events appears to be low, although adult patients with a history of KD may be at increased risk of early atherosclerotic disease.

TELANGIECTASIA

Telangiectasias are fine, linear vessels coursing on the surface of the skin. They may occur in normal skin at any age, in both genders, and anywhere on the skin and mucous membranes. Fine telangiectasias may be seen on the alae nasi of most adults. They are prominent in areas of chronic actinic damage. In addition, persons long exposed to wind, cold, or heat are subject to telangiectasias. Calcium channel blockers may lead to generalized or photodistributed telangiectatic lesions and contribute to the appearance of photoaging. Telangiectasias may also be found on the legs as a result of heredity, varicosities, pregnancy, and OC use.

Telangiectasias can be found in conditions such as radiodermatitis, xeroderma pigmentosum, lupus erythematosus, scleroderma and the CREST syndrome, rosacea, pregnancy, cirrhosis of the liver, AIDS, poikiloderma, basal cell carcinoma, necrobiosis lipoidica diabeticorum, lichen sclerosus et atrophicus, sarcoid, lupus vulgaris, keloid, adenoma sebaceum, kaposiform hemangioendothelioma, angioma serpiginosum, angiokeratoma corporis diffusum, hereditary benign telangiectasia, Cockayne syndrome, ataxia-telangiectasia, and Bloom syndrome.

Altered capillary patterns on the finger nailfolds (cuticular telangiectasias) are indicative of collagen vascular disease, such as LE, scleroderma, or dermatomyositis. These may infrequently be present in RA. These disorders are reviewed in Chapter 8.

Generalized essential telangiectasia

Generalized essential telangiectasia (GET) is characterized by the appearance of telangiectasias over a large segment of the body without preceding or coexisting skin lesions. Lesions

tend to appear first on the legs and progress caudad (Fig. 35-30). Women are more often affected, with the condition starting between age 20 and 50. Characteristic features include the following:

1. Widespread cutaneous distribution
2. Progression or permanence of the lesions
3. Accentuation in dependent areas and by dependent positioning
4. Absence of coexisting epidermal or dermal changes, such as atrophy, purpura, depigmentation, or follicular involvement

The telangiectasias may be distributed over the entire body or localized to some large area, such as the legs, arms, and trunk. They may be discrete or confluent. Distribution along the course of the cutaneous nerves may occur. Systemic symptoms are absent, although conjunctival telangiectasias can also be seen. GET is generally not believed to be associated with an increased risk of epistaxis, but GI bleeding has been reported. Families with this disorder, inherited as an autosomal dominant trait, have been reported. The cause of essential telangiectasia is unknown. Treatment is with vascular lasers, if required.

Cutaneous collagenous vasculopathy, a condition favoring middle-age men, is clinically similar to GET but histologically distinct. Histologically, both disorders exhibit greatly dilated subepidermal vessels. However, in cutaneous collagenous vasculopathy, these blood vessels have thickened vascular walls and perivascular hyaline, whereas in GET, they do not.

Fig. 35-30 Generalized essential telangiectasia.

Unilateral nevoid telangiectasia

In unilateral nevoid telangiectasia (UNT), fine, threadlike telangiectases develop in a unilateral, sometimes dermatomal distribution (or following lines of Blaschko). Spider angiomas may also be present. The most common distribution is unilateral or bilateral involvement of the third and fourth cervical dermatomes. The condition is rare in men; in affected women, it starts in adulthood. The familial form (very rare) favors males, is autosomal dominant, and appears postnatally. UNT is associated with conditions that have increased levels of estrogen or vascular endothelial growth factor (VEGF): puberty, pregnancy, OC use, HCV infection, and cirrhosis, as well as with neurologic disorders such as hypoesthesia of the affected area. Treatment with pulse dye laser can be effective.

HEREDITARY HEMORRHAGIC TELANGIECTASIA (OSLER'S DISEASE)

Also known as Osler-Weber-Rendu disease, hereditary hemorrhagic telangiectasia (HHT) is characterized by small tufts of dilated capillaries scattered over the mucous membranes and the skin. These slightly elevated lesions develop mostly on the lips, tongue, palate, nasal mucosa, ears, palms, fingertips, nailbeds, and soles. They may closely simulate the mat telangiectases of the CREST variant of scleroderma, without the other features of CREST syndrome. Diagnostic criteria have been proposed and include the following:

1. Epistaxis—spontaneous, recurrent nosebleeds
2. Telangiectases—multiple at characteristic sites (lips, oral cavity, fingers, nose) (Fig. 35-31)

Fig. 35-31 Hereditary hemorrhagic telangiectasia.

3. Visceral lesions—GI bleeding; pulmonary, hepatic, cerebral, or spinal arteriovenous malformation (AVM)
4. Family history—one affected first-degree relative

The presence of three of the four criteria indicates a definite diagnosis, and two of four indicates a possible diagnosis. There are at least three variants: HHT1 and HHT2, and a third associated with juvenile polyposis.

Frequent nosebleeds and melena are experienced because of the telangiectasias in the nose and GI tract. Epistaxis is the most frequent and persistent sign. Worsening epistaxis may herald high-output cardiac failure from AVMs. Pregnancy can also exacerbate HHT. GI bleeding is the presenting sign in up to 25% of patients; however, 40–50% develop GI bleeding sometime during the course of their disease. Chronic persistent anemia requiring iron and blood transfusions is characteristic of severe cases. The spleen may be enlarged. Pulmonary and CNS AVMs may appear later in life. Liver failure can result from diffuse intrahepatic shunting—hepatic artery to vein, bypassing the liver parenchyma. Retinal arteriovenous aneurysms occur only rarely. Other sites of bleeding may be the kidney, spleen, bladder, liver, meninges, and brain. The risk of cerebral hemorrhage from cerebral AVMs, cerebral abscesses, and pulmonary hemorrhage from pulmonary AVMs is probably high enough that asymptomatic patients should be screened for the presence of cerebral and pulmonary AVMs. Because of the risk of cerebral abscess, some have advocated antibiotic prophylaxis for dental and contaminated skin procedures.

The telangiectasias tend to increase in number in middle age; however, the first appearance on the undersurface of the tongue and floor of the mouth is at puberty. Pulmonary or intracranial arteriovenous fistulas and bleeding in these areas may be a cause of death.

Osler's disease (HHT) is inherited as an autosomal dominant trait. The vascular abnormalities found in HHT consist of direct arteriovenous connections without an intervening capillary bed. Affected patients have mutations that affect transforming growth factor (TGF)–β signaling. Multiple gene mutations are known; mutations in endoglin (*ENG*) and ALK-1 (*ACVRL1*) together make up 85% of cases. These encode a homodimeric integral membrane glycoprotein, which is a TGF-β receptor. HHT1 is associated with *ENG* mutations, and HHT2 with *ACVRL1* mutations. HHT1 patients have a higher prevalence of pulmonary AVMs, while HHT2 patients tend to have a milder phenotype and later age of onset, but increased liver manifestations. Patients with HHT and juvenile polyposis have mutations in the *MADH4* gene, a downstream effector of TGF-β signaling. TGF-β is a potent stimulator of VEGF production. VEGF leads to disorganized and tortuous vessels, as seen in HHT. VEGF levels are increased in patients with HHT.

Treatment is directed at controlling the specific complications and identifying and treating AVMs before they become symptomatic. The tendency to epistaxis has been reduced by estrogen therapy, and some recommend estrogen preparations or tamoxifen. Dermoplasty of the bleeding nasal septum may be performed by replacing the mucous membrane with skin from the thigh or buttock. Repeated laser treatments of the nasal and GI mucosa are often required. Topical tranexamic acid has been used to control epistaxis. Bleeding episodes are treated supportively with iron and RBC transfusions. Interventional radiology with selective embolization can treat pulmonary and CNS AVMs, avoiding invasive surgeries. In patients with liver failure or high-output heart failure due to liver AVMs, liver transplantation may be required. Blocking VEGF with thalidomide (or more effectively with lenalidomide) can reduce GI bleeding and transfusion dependence. Bevacizumab, a monoclonal inhibitor of VEGF delivered intravenously, has dramatically improved some severely ill HHT patients, reducing the size and flow of their hepatic AVMs, reversing heart and liver failure, and reducing transfusion requirements. It has also been used successfully as a submucosal injection and topical spray for epistaxis.

LEG ULCERS

Leg ulcers are a common medical condition, affecting 3–5% of the population over age 65. The cause of chronic leg ulceration is venous insufficiency alone in 45–60% of cases, arterial insufficiency in 10–20%, diabetes mellitus in 15–25%, or combinations thereof in 10–15%. Smoking and obesity increase the risk for ulcer development and persistence, independent of the underlying cause. Defining the cause of the leg ulceration is important for treatment.

The wound-healing response is complex, involving intricate interactions between different cell types, structural proteins, growth factors, and proteinases. Normal wound repair consists of three phases—inflammation, proliferation, and remodeling—which occur in a predictable sequence.

VENOUS DISEASES OF THE EXTREMITIES

Stasis dermatitis

Stasis dermatitis presents as erythema and a yellowish or light-brown pigmentation of the lower third of the lower legs, especially in the area just superior to the medial malleolus. An associated eczematous dermatitis may occur. The dermatitis may be weepy or dry, scaling or lichenified; it is almost invariably hyperpigmented by melanin and hemosiderin. Varicose veins are usually present, although they need not be numerous or conspicuous. Stasis dermatitis is a cutaneous marker for venous insufficiency. The approach to management should be twofold: relief of symptoms and treatment of the underlying venous insufficiency. Patients with pruritus and an eczematous component should be treated with emollients and topical corticosteroids. The daily use of elevation and support stockings is strongly recommended.

Venous insufficiency and obesity-associated mucinosis

Localized areas of mucin deposition can be observed directly over the perforators on the lower extremity. These present as blushed, red-blue, partially compressible, agminated papules. On biopsy, deposits of dermal mucin against a background of the changes of venous insufficiency are seen. In the setting of morbid obesity and lower extremity edema, pretibial translucent papules can appear and merge into plaques. The plaques are composed of dermal mucin (hyaluronic acid). The diagnosis of "pretibial myxedema" is usually made, but thyroid functions are normal. With weight loss, the lesions improve, suggesting that they were caused by the lower extremity edema and venous insufficiency of obesity.

Venous insufficiency ulceration

Stasis dermatitis and venous ulceration result from increased pressure in the venous system of the lower leg. The most common cause is insufficiency of the valves in the deep venous system and lower perforating veins of the lower leg. With each contraction of the calf, blood should be pumped to the heart via this "muscle pump." Intact valves in the lower leg are required to prevent this "pumped" blood from refluxing out through the perforators into the superficial system. Increased flow through the superficial system results in enlargement of the superficial venous plexus and the appearance of "varicose veins." Increased pressure on the iliac veins from pregnancy or obesity, or simple inactivity may also result in the appearance of "venous insufficiency." The valvular insufficiency results in disorder in the venous and capillary circulation of the leg. Valve insufficiency may occur from prior thrombophlebitis or congenital "weakness." Prolonged standing without walking or contracting the calf muscles, sitting for long periods, anemia, zinc deficiency, and a defective fibrinolytic system may accelerate the process. If a history of thrombophlebitis is present, an evaluation for a hypercoagulable state, such as a deficiency of factor V Leiden, should be considered.

Edema and fibrosis develop in the skin over the medial aspect of the ankle and lower third of the shin (Fig. 35-32). Following minor trauma, a macular hemorrhage appears. This is the premonitory sign of an impending ulceration. Venous ulcers usually occur on the lower medial aspect of the leg. They may appear on the background of stasis dermatitis with lipodermatosclerosis (Fig. 35-33). Venous ulcerations can be

Fig. 35-32 Stasis dermatitis, venous insufficiency.

Fig. 35-33 Venous leg ulcer.

painful, but not as painful as pyoderma gangrenosum or arterial or embolic ulcerations. The ulcer tends to be round or oblong and has a characteristic yellow, fibrinous base. Multiple lesions may occur.

In most cases, the diagnosis of a venous ulceration can be made on clinical grounds. If there is no clear history or physical findings of venous insufficiency, venous rheography can be performed. An ABI (ankle:brachial index, or ratio of blood pressure in the leg to the arm) should be performed, especially in cases where peripheral pulses are diminished and hair on the lower legs is lost. This will identify coexistent arterial disease. More extensive vascular studies may be necessary to identify the presence and extent of arterial disease or focal venous valvular incompetence or congenital absence. In leg ulcers of the lower medial leg, even if cutaneous findings of venous insufficiency are absent, venous insufficiency will still be the most common cause of the ulcer. Lesions in atypical locations, those that do not respond appropriately to therapy, and those in which venous rheography is normal may require a biopsy to exclude other causes, including a cutaneous neoplasm. Additional workup may also be required to identify other, less common causes of leg ulcers, such as cholesterol emboli, atherosclerotic disease, diabetes mellitus, sickle cell disease, vasculitis, infection, and pyoderma gangrenosum.

Despite extensive research and the marketing of many new products and devices for the treatment of leg ulcers, little has changed in their management over the last decades. Treatment is primarily to improve venous return and reduce edema. Compression therapy is the mainstay of treatment. This involves, preferably, the use of inelastic/short-stretch bandages or multilayer compression dressings such as Unna boots, versus elastic/long- stretch bandages such as Coban or ACE wraps, which are significantly less effective at reducing venous hypertension and edema. Elevation of the leg above the heart, for as much of the time as possible (at least 2 h twice daily), is also beneficial. Elastic support of the legs must be continued after the ulcer heals. Other causes of edema, such as cardiac failure, must be addressed. The avoidance of long, cramped sitting (in airplanes or vehicles) or prolonged standing is advisable. Diuretics are overused and not proven to be of benefit. If there is a central cause of fluid retention (cirrhosis, heart failure, renal failure), diuretics may be beneficial, but otherwise they should be avoided. Avoidance of trauma is important. Pentoxifylline, 400–800 mg three times daily, in addition to compression, is beneficial in healing refractory venous ulcerations. A cooperative patient and a patient physician are necessary in the long-term management of venous disease. Topical anti-infectives are usually not necessary (except metronidazole gel to prevent anaerobic overgrowth). There is a high risk of allergic contact dermatitis from other topical antibiotics. Oral antibiotics should only be used to treat associated invasive infection. A rim of erythema usually surrounds an ulcer. Expanding erythema, an enlarging ulcer, or increasing pain or tenderness may be signs of infection. Surface cultures and Gram stains may demonstrate colonizing, but not pathogenic, bacteria. Biopsy for histology and tissue homogenate culture is the most effective way to demonstrate a true invasive pathogen.

Many treatment options have been developed for chronic ulcers. Unfortunately, conclusive comparative studies between the various treatment alternatives are lacking. All are to be used in combination with compression treatment, which by itself leads to healing in 73% of cases without other interventions. Occlusive and semipermeable biosynthetic wound dressings can be very effective when combined with compression. They can speed healing, reduce pain, make dressing changes infrequent, and help debridement. If a hard eschar is present over the ulcer when first seen, a dressing will assist in its removal. Early in the treatment of an ulcer, a highly inflammatory and exudative phase occurs. This will often wash off the semipermeable dressing and may require the use of fenestrated dressings and even the application of absorbent padding over the dressing for the first few weeks. The patient will interpret this increased wound exudate, which is normal and indicates the conversion of a nonhealing to a healing wound, as an infection, and should be appropriately educated before such dressings are applied. Dressings containing dilute acetic acid or silver may help reduce bacterial overgrowth in the wound but fail to decrease the time to healing. However, metronidazole gel 0.75% instilled into the wound will help to reduce the amount of wound exudate and remove unpleasant odor by eliminating anaerobic bacteria. The smell of a chronic leg ulcer may reduce the patient's quality of life. Topical growth factors applied to the wound bed, such as platelet derived growth factor and epidermal growth factor, can promote wound healing but are limited by high cost. Granulation tissue formation is enhanced, so they may be useful in wounds that are unable to develop a granulation tissue base despite local care and conservative debridement. Weekly debridement of the anesthetic, dead fibrinous tissue can be useful in stimulating granulation tissue at the base of slow-to-heal venous ulcerations. Injection of granulocyte-macrophage colony-stimulating factor (GM-CSF) into the ulcer base may also stimulate refractory ulcers to heal, but is very expensive. Grafts and skin substitutes can be considered for refractory ulcers that have failed conservative therapy. Bilayer artificial skin grafts, in conjunction with compression, increases venous ulcer healing compared with compression plus dressing alone.

In more than 90% of patients, only simple but persistently applied measures are required. Enhanced compliance, longer elevation, and removal of leg edema are the first steps in attempting to heal refractory leg ulcers. If these are not optimized, expensive dressing and medications will not lead to healing. The role of vascular surgery or venous ablation in the healing of leg ulcers is controversial. Vascular surgery does not impact wound healing significantly compared with compression alone, but it appears to diminish rates of recurrence.

Risk factors that predict failure to heal within 24 weeks of limb compression therapy include a large wound area, history of venous ligation or stripping, history of hip or knee replacement, ABI less than 0.80, fibrin on 50% or more of the wound surface, and presence of the ulcer for an extended time. For every 6 months of duration, the ulcer healing time doubles.

ARTERIAL INSUFFICIENCY (ISCHEMIC) ULCER

Ischemic ulcers are mostly located on the lateral surface of the ankle or the distal digits. The initial red, painful plaque breaks down into a painful superficial ulcer with a surrounding zone of purpuric erythema. Granulation tissue is minimal, little or no infection is present, and a membranous inactive eschar forms over the ulcer. Patients at risk are those with long-standing hypertension, smokers, diabetic patients, and those with hyperlipidemia. The presence of an arterial ulceration identifies patients at increased risk for limb loss.

Signs and symptoms indicating that arterial disease is the cause of the ulceration include thinning of the skin, absence of hair, decreased or absent pulses, pallor on elevation, coolness of the extremity, dependent rubor, claudication on exercise, and pain on elevation (especially at night) relieved with dependency. In progressive disease, the diagnosis of thromboangiitis obliterans, or Buerger's disease, should be considered. Patients with arterial insufficiency are also at risk

for cholesterol emboli, another arterial cause of lower leg ulceration. Eosinophilia, palpable peripheral pulses, sudden onset, and associated renal insufficiency are clues to the diagnosis of cholesterol emboli.

The diagnosis of arterial insufficiency can usually be confirmed by physical examination and careful palpation of the leg pulses. For more accurate evaluation, the blood pressure in the arm and leg is taken, which should be almost identical. The ratio of the popliteal to brachial pressure is called the ABI; if less than 0.75, arterial insufficiency exists, and if less than 0.5, the insufficiency is substantial.

Surgical intervention may be required to heal the ulceration. If the blood supply cannot be improved, little can be done, except to prevent infection by the measures described for venous ulcers. The area should be protected from injury and cold, and smoking and tight socks should be avoided. Hyperbaric oxygen may be of some use but is limited by availability and cost. A recent Cochrane review highlighted the dearth of high-quality studies but suggested hyperbaric oxygen improves ulcer healing in the short term but not the long term.

NEUROPATHIC ULCERS

Foot ulcers in diabetic patients are usually related to sensory neuropathy. Offloading the ulcer is the primary principle of management. Necrotic tissue should be debrided back to bleeding, viable tissue. Because the foot is typically insensate, this can be done in the office without the need for anesthetic. Associated osteomyelitis is best treated by removal of the infected bone. Consultation with or referral to a podiatrist or orthopedic surgeon may be indicated. Various shoes and padded boots can be used to offload different areas of the foot. An orthotics consultation is usually indicated. Clinical infection should be treated, but simple colonization typically does not require treatment. After the ulcer heals, a shoe of appropriate depth and width will help to prevent recurrence. Frequent foot inspections for the presence of "hot spots," as well as debridement of dystrophic nails, are important facets of prevention of leg ulcers in diabetic patients.

LYMPHEDEMA

Lymphedema is the swelling of soft tissues in which an excess amount of lymph has accumulated. Chronic lymphedema is characterized by long-standing, nonpitting edema. Box 35-2 provides a working classification of lymphedema.

The most prevalent worldwide cause of lymphedema is filariasis. In the United States, the most common cause is postsurgical. If lymphedema is long-standing, a verrucous appearance to the affected extremity develops (elephantiasis verrucosa nostra).

Lymphedema of the lower extremity must be distinguished from "lipedema." This syndrome is characterized by bilateral, symmetric lower extremity enlargement caused by subcutaneous fat deposition. The buttocks to the ankles are affected in women, starting at puberty with gradual progression. The feet are spared in lipedema but usually involved in lower extremity lymphedema. Lipedema does not respond to compression therapy. The skinfold at the base of the second toe is too thick to pinch in lymphedema but normal in lipedema (Stemmer's sign). Verrucous changes do not occur in lipedema but do occur in lymphedema. Women with lipedema will have tenderness to pressure on the affected area. There is frequently a family history of lipedema. Magnetic resonance imaging (MRI) will separate the two entities if the diagnosis cannot be confirmed on a clinical basis.

Types

Lymphedema is classified by clinical type (Box 35-2). Primary types include congenital and early-onset and late-onset lymphedema. Other primary types of lymphedema are associated with characteristic features or syndromes. Some cutaneous disorders are associated with, or a complication of, primary lymphedema. Secondary lymphedema can occur from numerous causes, including neoplasia and its treatment, infections, and physical factors.

Lymphedema praecox

Lymphedema praecox accounts for the majority of primary lymphedema cases; it usually develops in females between

Complications of lymphedema

- Cellulitis of lymphedema
- Elephantiasis nostra verrucosa
- Ulceration
- Lymphangiosarcoma

ages 9 and 25. Swelling appears around the ankle and then extends upward to involve the entire leg; the condition is unilateral in 70% and affects the left leg more often than the right. With the passage of time, the leg becomes painful, with a dull, heavy sensation. Once this stage has been reached, the swollen limb remains swollen, since fibrosis has occurred. These changes are caused by a defect in the lymphatic system. Lymphangiography demonstrates hypoplastic lymphatics in 87% of patients, aplasia in approximately 5%, and hyperplasia with varicose dilation of the lymphatic vessels in 8%. Because the condition typically occurs in women around menarche, estrogen may play a pathogenic role.

Nonne-Milroy-Meige syndrome (hereditary lymphedema)

Milroy hereditary edema of the lower legs is characterized by a unilateral or bilateral lymphedema present at, or soon after, birth and is inherited as an autosomal dominant trait. The edema is painless, pits on pressure, is not associated with any other disorder, and persists throughout life (Fig. 35-34). It may involve the genitalia and produce lymphangiectasias superficially. Chylous discharge can occur. The face and arm may also be involved. Most frequently, the lymphedema is bilateral, and females are predominantly affected.

Fig. 35-34 Milroy's disease. (Courtesy of Dr. Lawrence Lieblich.)

Treatment of this particular type of edema is extremely difficult, since the disease is an anomaly of the lymph-draining vessels. Decongestive physiotherapy can be considered. In some cases, surgical procedures to remove affected tissue can be performed. This condition may be linked to a mutation in *FLT4,* the gene for VEGFR3, which is expressed in lymphatic endothelial cells and is necessary for normal lymphatic function.

Lymphedema-distichiasis syndrome

The association of distichiasis (double row of eyelashes) and late-onset lymphedema is a form of hereditary lymphedema called lymphedema-distichiasis syndrome, or Meige syndrome. It is an autosomal dominant syndrome with the appearance of bilateral lymphedema, beginning between ages 8 and 10 in affected boys, and between 13 and 30 in affected girls. Lymphatic vessels are increased (not hypoplastic or absent, as in other forms of congenital lymphedema) in the affected legs, but lymphatic valves are aplastic. Associated findings are varicose veins in 50% by age 64; congenital ptosis (31%); and congenital heart disease (6.8%), cleft palate (4%), scoliosis, and renal abnormalities. There may be phenotypic heterogeneity in this syndrome, because different mutations may lead to slightly different phenotypes, especially in regard to the ancillary features associated with the syndrome. This syndrome is caused by a gene mutation in the FOXC2 transcription factor. This factor is expressed in developing eyelids, lymphatics, lymphatic valves, and other tissues with abnormalities in this syndrome.

Emberger syndrome

Emberger syndrome is primary lymphedema associated with myelodysplasia. This genetic syndrome presents with lymphedema of one or both lower limbs and often the genitalia between infancy and puberty. Myelodysplastic syndrome and

acute myeloid leukemia developing in adolescence or childhood are preceded by pancytopenia with a high incidence of monosomy 7 in the bone marrow. Associated features include mild skeletal abnormalities, deafness, and multiple warts. This syndrome is associated with gene mutations in GATA2, a hematopoietic transcription factor.

WILD syndrome (warts, immunodeficiency, lymphedema, anogenital dysplasia)

Lymphedema appears in early childhood and may progress to involve all four extremities and the genitalia. Widespread flat warts appear during childhood, resembling the numerous flat warts seen in epidermodysplasia verruciformis. The anogenital region develops numerous warts and anogenital dysplasia. Helper T cells are reduced.

Hypotrichosis-telangiectasia-lymphedema syndrome

Lymphedema appears in childhood. Vascular dilations and telangiectasias appear on the palms and soles. Both autosomal recessive and autosomal dominant patterns of inheritance occur, but both forms are caused by mutations in the gene for SOX18.

Primary lymphedema associated with yellow nails and pleural effusion (yellow nail syndrome)

Lymphedema is confined mostly to the ankles and occurs in about 60% of patients with yellow nail syndrome. The nails show a distinct yellowish discoloration and thickening. Recurrent pleural effusion or bronchiectasis may be a feature.

Secondary lymphedema

In some malignant diseases, involvement of the axillary or pelvic lymph nodes will produce blockage and lymphedema. Malignant disease of the breast, uterus, prostate, skin, bones, or other tissues may cause such changes. Hodgkin disease and especially Kaposi sarcoma may be accompanied by significant lymphedema well beyond the amount expected from the degree of skin involvement. Such patients require chemotherapy; lymphedema is the hallmark of lymphatic involvement. Chronic lymphedema is seen in more than one in five women after mastectomy and removal of the axillary nodes; it may occur after varying time periods.

Postmastectomy lymphangiosarcoma (Stewart-Treves syndrome)

This type of vascular malignancy usually arises in chronic postmastectomy lymphedema. The lesions are bluish or reddish nodules arising on the arm. Similarly, primary or secondary lymphedema of the lower extremity may be complicated by angiosarcoma. Angiosarcoma arising in a lymphedematous extremity often presents with multiple lesions. Metastasis and death frequently result. Early, aggressive surgical treatment with amputation may be lifesaving. The treatment of breast cancer with lumpectomy and local radiation therapy may be complicated by angiosarcoma of the breast with minimal or no associated lymphedema. This is called "cutaneous postradiation angiosarcoma of the breast." This form of angiosarcoma also frequently results in metastasis and death.

Obesity-related lymphedema

Morbid obesity may impair lymphatic return, resulting in lymphedema. It is also an independent risk factor for developing lymphedema after surgery or cancer therapy. A recently-described entity called "massive localized lymphedema" occurs in morbidly obese patients, presenting with a painless mass, usually on the medial thigh, characterized by typical cutaneous clinical and histologic changes of chronic lymphedema.

Postinflammatory lymphedema

The lymphedematous extremity may be caused and worsened by repeated bacterial cellulitis or lymphangitis. These recurrent infectious episodes, when they complicate filariasis, cause the elephantiasis. Streptococcal cellulitis after venectomy in patients who have undergone coronary bypass surgery is a well-documented cause. However, almost any chronic or recurrent infection can cause lymphatic damage. Chronic antibiotic therapy can halt the progression by preventing the attacks of bacterial cellulitis.

Bullous lymphedema

Frequently misdiagnosed as an immunobullous disease, bullous lymphedema usually occurs with poorly controlled edema related to heart failure and fluid overload. Compression results in healing.

Factitial lymphedema

Also known as hysterical edema, lymphedema can be produced by wrapping an elastic bandage, cord, or shirt around an extremity, and/or holding the extremity in a dependent and immobile state. Self-inflicted causes of lymphedema are usually difficult to prove and may occur in settings of known causes of lymphedema, such as postphlebitic syndrome or surgical injury to the brachial plexus. Factitial lymphedema caused by blunt trauma localized to the dorsum of the hand or forearm is referred to as Secretan syndrome or l'oedème bleu, respectively. It often is unilateral, and significant purpura may occur. Effective care of such patients requires psychiatric intervention. Occupational causes must be excluded.

Podoconiosis

Podoconiosis, or mossy foot, is a noninfectious form of lymphedema. It is restricted to tropical regions in Central Africa, Central America, and North India. It occurs in persons walking barefoot in soil of volcanic origin. This soil has high concentrations of aluminum, silicon, beryllium, zirconium, magnesium, and iron. Colloid-sized particles of the dust penetrate the sole, are ingested by macrophages, and migrate to lymph nodes. Lymphatic drainage is impaired by fibrosis of lymphatic channels induced by microscopic deposits of the substances. Males and females are equally affected, and in endemic areas, up to 5% of the population can develop the disease. Moving into an endemic area from a nonendemic area can lead to the condition appearing over the next 5 years. Podoconiosis begins in childhood or adolescence with mild swelling of the feet. Burning of the feet occurs at night. The dorsal surface of the foot itches, is rubbed, and becomes lichenified. Increased skin markings result, and finally, marked hyperkeratosis caused by repeated infections. This closely resembles elephantiasis verrucosa cutis. The condition is usually asymmetric. Podoconiosis is prevented by wearing shoes. Elevation, compression, and local wound care all aid in treating this condition. Extensive surgery, as done for filariasis, has had disappointing results.

Occupational hand edema

Occupational persistent hand edema in divers can occur, related to the constrictive action of the divers' suits and pricks from sea urchin spines.

Evaluation

The diagnosis of lymphedema is usually based on a classic presentation; in the early stages, however, the disease may require further investigation. Considerations include isotopic lymphoscintigraphy, fluorescence microlymphography, MRI, computed tomography, and ultrasonography. These imaging modalities have replaced lymphangiography, a more invasive technique that can cause further damage to remaining lymphatics.

Treatment

Most patients with lymphedema are treated conservatively by means of various forms of compression therapy, complex physical therapy, pneumatic pumps, and compressive garments. Chronic antibiotic treatment may be beneficial in patients with repeated episodes of erysipelas or cellulitis. In diabetic patients with insensate feet, the frequency of infection can be reduced by wearing properly fitting shoes. Volume-reducing surgery and lymphatic microsurgery are rarely performed, although a few centers consistently report favorable results. It is best to refer these patients to a center versed in the treatment of these complicated conditions, to optimize patient compliance and customize therapy to the patient's lifestyle.

36 Disturbances of Pigmentation

The visible pigmentation of the skin or hair is a combination of the amount of melanin, type of melanin (eumelanin vs. pheomelanin), degree of vascularity, presence of carotene, and thickness of the stratum corneum. Other materials can be deposited abnormally in the skin, leading to pigmentation. Eumelanin is the primary pigment producing brown coloration of the skin. Pheomelanin is yellow or red and is also produced solely in melanocytes. Melanin is formed from tyrosine, through the action of tyrosinase, in the melanosomes of melanocytes. A multitude of genes are expressed only in melanosomes and apparently are important in melanin production and delivery. Melanosomes are lysosome-related organelles. Melanosome formation and the end result, pigmentation, require both the adequate manufacture of melanin and the appropriate transport of melanosomes within the melanocyte. The melanosomes are transferred from a melanocyte to a group of 36 keratinocytes called the epidermal melanin unit, to which they provide melanin. The variations in skin color between persons and races are related to the degree of melanization of melanosomes, their number, and their distribution in the epidermal melanin unit. Disorders of loss or reduction of pigmentation may be related to loss of melanocytes or the inability of melanocytes to produce melanin or transport melanosomes correctly. Wood's light examination is often performed to evaluate lesions of hyperpigmentation or hypopigmentation. Hyperpigmented lesions that enhance with Wood's light usually have increased epidermal melanocyte number or activity. If the lesions do not enhance, the melanin is located in the dermis. Wood's light will greatly enhance depigmented lesions (complete loss of pigment) but does not enhance lesions with partial pigment loss (hypopigmentation).

Yaar M, et al: Cutaneous pigmentation in health and disease: novel and well-established players. J Invest Dermatol 2013; 133:11.

PIGMENTARY DEMARCATION LINES

Pigmentary demarcation boundaries of the skin can be classified into groups based on their anatomic location, orientation, and degree of pigmentation (hyperpigmentation or hypopigmentation):

1. Group A: lines along the outer upper arms with variable extension across the chest
2. Group B: lines along the posteromedial aspect of the lower limb (Fig. 36-1)
3. Group C: paired median or paramedian lines on the chest, with midline abdominal extension
4. Group D: medial, over the spine
5. Group E: bilaterally symmetric, obliquely oriented, hypopigmented macules on the chest
6. Groups F, G, and H: facial pigmentary demarcation lines

More than 70% of black patients have one or more lines, which are much less common in white patients. Group B lines often appear for the first time during pregnancy.

The term "acquired, idiopathic, patterned facial pigmentation" (AIPFP) has been used to encompass pigmentary demarcation lines of the face as well as idiopathic periorbital and perioral pigmentation. These are patterned, bilateral, and homogeneous and have various shades of brown with a variable gray undertone. Periorbital and perioral hyperpigmentation occur in the late teens and early twenties. Other forms of facial hyperpigmentation occur later (average age >30). Periorbital pigmentation usually is demarcated by a band of normal skin beneath the upper eyebrow superiorly and the orbital rim inferiorly. It may extend outward onto the lateral cheek or over the root of the nose. One third of patients with perioral pigmentation have a family history. These patterns of facial pigmentation may represent variations of embryologic pigmentation.

Pigmentary demarcation lines must be distinguished from the much rarer condition, acquired dermal melanocytosis (ADM). This primarily affects Asian and Hispanic women (male/female ratio 1:17). The face is the most common location, and it includes the entities bilateral and unilateral nevus of Ota–like macules (Hori and Sun nevus, respectively). ADM can first appear during pregnancy or therapeutic use of estrogen/progesterone. Lesions present as blue-gray patches, with superimposed brown macules. Infrequently, the trunk or extremities may be affected. Lesions do not enhance with Wood's light. They may be localized (after trauma) or may be more diffuse. Ultraviolet (UV) light and psoralen plus UVA (PUVA) therapy are possible precipitants. Biopsy shows melanocytes in the dermis, similar to the findings in mongolian spot, nevus of Ota, and nevus of Ito. The lesions appear to represent activation of melanin production by residual dermal melanocytes because biopsies in "normal" skin adjacent to the pigmented lesions show dermal melanocytosis.

ABNORMAL PIGMENTATION

Hemosiderin hyperpigmentation

Pigmentation resulting from deposits of hemosiderin occurs in purpura, hemochromatosis, hemorrhagic diseases, and stasis dermatitis. Clinically, hemosiderin hyperpigmentation is distinguished from postinflammatory dermal melanosis by a golden-brown hue, unlike the brown or gray-blue pigmentation of epidermal or dermal melanin, respectively. At times, a biopsy is required to distinguish melanin-induced from hemosiderin-induced hyperpigmentation. Some medications, including minocycline, deposit in the skin and complex with both iron and melanin, making uniquely colored (usually blue-gray) deposits. Extravasation of iron into the soft tissue from a poorly functioning venous catheter can cause local hemosiderosis of a limb. Multiple transfusions (>20) can result in cutaneous iron deposits in about 20% of patients. Drinking tea while ingesting an iron-containing solution can result in iron staining of the tongue and teeth, simulating black hairy tongue.

Postinflammatory hyperpigmentation (postinflammatory pigmentary alteration)

Any natural or iatrogenic inflammatory condition can result in hyperpigmentation or hypopigmentation. Postinflammatory dyspigmentation is more common in persons with Fitzpatrick skin types IV, V, and VI, especially types IV and V. It is more likely to occur after laser treatment when performed in premenstrual women. It affects both genders equally.

Hyperpigmentation may result from the following two mechanisms:

1. Increased epidermal pigmentation via increased melanocyte activity

Fig. 36-2 Postinflammatory hyperpigmentation from varicella.

2. Dermal melanosis from melanin dropout from the epidermis into the dermis

Wood's light examination will distinguish these two patterns of postinflammatory hyperpigmentation. Lesions of hyperpigmentation tend to be tan to brown (Fig. 36-2) and may have a gray hue, caused by dermal melanin.

Hypopigmented lesions are prominently lighter than the surrounding area. Histologically, there is melanin in the upper dermis and around upper dermal vessels, located primarily in macrophages (melanophages). The pattern of the dermal melanosis does not predict whether the lesion will be lighter or darker as a result of the prior inflammatory process—thus the tendency of pathologists to provide a diagnosis of "postinflammatory pigmentary alteration" (PIPA) in such cases.

Postinflammatory dyspigmentation is addressed initially by treating the underlying skin disease, if possible. The resolution of pityriasis alba with mild topical corticosteroids and moisturizers is an example of resolution of postinflammatory hypopigmentation by treating the cause. This should be the sole approach in hypopigmented lesions after inflammation. For hyperpigmented lesions, hydroquinone may be used in cases that enhance with Wood's light. Tretinoin application may enhance the effect of hydroquinone. Laser treatments and chemical peels must be done with extreme caution, because results are unpredictable and increased pigmentation may result.

MELASMA (CHLOASMA)

Melasma is a common disorder, with two predisposing factors: sun exposure and sex hormones. It tends to affect darker-complexioned individuals, especially East, West, and Southeast Asians, Hispanics, and black persons who live in areas of intense sun exposure and who have Fitzpatrick skin types IV and V. Subtle melasma, as identified by UV light examination, may be seen in up to 30% of middle-age Asian females. Men are also affected, especially those from Central America, who may have prevalence rates as high as 35%. Guatemalan men seem to be at greater risk than Mexican men, and speaking a native tongue is also a risk factor, suggesting a genetic component associated with indigenous heritage.

The pathogenesis of melasma is not known. However, many observations strongly suggest that sun exposure is the primary trigger. Melasma affects the face, a sun-exposed area, and worsens in the summer. Melasma patients have a lower minimal erythema dose (MED) to UV light, and pigment more easily with UV exposure. An association exists between the number of melanocytic nevi and the development of melasma. The prevalence of melasma increases with age in both men and women. Solar elastosis is more marked in areas of melasma than unaffected facial skin. Melasma-affected skin has reduced WIF-1 (Wnt antagonist) expression and resultant increased Wnt expression; Wnt stimulates melanogenesis.

After sun exposure, the second most important trigger for melasma is female hormones. Melasma is more common and severe in women than men. It occurs frequently during pregnancy, with oral contraceptive (OC) use, or with hormone replacement therapy (HRT) at menopause. Discontinuing OC use or HRT rarely clears the pigmentation, which still may last for many years. In contrast, melasma of pregnancy usually clears within a few months of delivery. Melasma may be seen in other endocrinologic disorders, as well as with phenytoin and finasteride therapy.

Melasma is characterized by brown patches, typically on the malar prominences and forehead. The forearms may also be affected. There are three clinical patterns of facial melasma: centrofacial, malar, and mandibular. The centrofacial and malar patterns constitute the majority (Fig. 36-3), but most patients have multiple types, so this classification is not very useful therapeutically. The pigmented patches are usually sharply demarcated. Although melasma has classically been classified as epidermal or dermal, based on the presence or absence of Wood's light enhancement, respectively, most cases show both epidermal and dermal melanin. Dermal melanophages are a normal finding in sun-exposed Asian skin. Independent of Wood's light findings, a therapeutic trial of some form of hypopigmenting agent should be recommended if the patient requests it.

Fig. 36-3 Melasma of the cheek.

Therapeutically, a sunblock with broad-spectrum UVA (even visible light) coverage should be used daily; it will modestly improve the melasma, but more importantly, will enhance the efficacy of bleaching creams. Bleaching creams with hydroquinone are the gold standard and are moderately efficacious, containing 2% (available over the counter) to 4% hydroquinone. Tretinoin cream may be added to increase efficacy. Tretinoin alone may reduce melasma, but it is not as effective as hydroquinone. The combination of hydroquinone and tretinoin, administered with a topical corticosteroid, has been called "Kligman's formula" and is the most effective topical regimen available to treat melasma. Twice-weekly application of the triple combination can be effective for maintenance. Overuse can lead to fixed erythema and telangiectasias, acneiform eruptions, and hypertrichosis. When 4% hydroquinone is ineffective, higher concentrations may be recommended. Satellite pigmentation and local ochronosis are potential complications from use of these higher-concentration preparations. Methimazole, azelaic acid, kojic acid, vitamin C, and arbutin are other therapies with minimal to moderate efficacy. Many of these agents are added to cosmetic products for skin lightening and may be combined, because they act on different steps of melanogenesis. All these topical agents are generally less effective than 4% hydroquinone but may be used in the patient intolerant of hydroquinone. Oral tranexamic acid may play a role as a systemic agent in treating refractory melasma.

Various surgical procedures, such as peels and light-based treatments, have been proposed as effective for melasma, but results are mixed. Peels with glycolic acid, salicylic acid, trichloroacetic acid (TCA), and tretinoin 1% have not reproducibly enhanced the efficacy of 4% hydroquinone and can cause hyperpigmentation if irritation ensues. The use of light-based modalities for the treatment of melasma should be approached with caution. These therapies may be complicated by hyperpigmentation, irritation, hypopigmentation, and even scarring, if not used appropriately. Intense pulse light (IPL) can improve melasma, but there is a high relapse rate. Pulse dye laser may enhance combination topical treatment, and improvement may continue after therapy is discontinued. Q-switched neodymium:yttrium-aluminum-garnet (Nd:YAG) laser therapy can lead to increased pigmentation.

RETICULATE PIGMENT DISORDERS OF THE SKIN

This group of disorders is linked by similar clinical features: reticulate pigmentation of various skin sites and characteristic histology—adenoid pigmented proliferations of the rete ridges of the interfollicular and infundibular follicular epidermis, at times with focal acantholysis. Patients may have overlapping features of several different syndromes, making specific classification of an individual patient or family difficult.

Dyschromatosis symmetrica hereditaria (reticulate acropigmentation of Dohi)

Originally described and still reported primarily in the Japanese, acropigmentation of Dohi has been found to affect individuals from Europe, India, and the Caribbean region. It is also referred to as dyschromatosis symmetrica hereditaria (DSH) or symmetric dyschromatosis of the extremities. It is inherited most often as an autosomal dominant trait, although autosomal recessive kindreds have been reported. Patients develop progressive hyperpigmented and hypopigmented macules, often mixed in a reticulate pattern, concentrated on the dorsal extremities, especially the dorsal hands and feet. The lesions vary in size from pinpoint to pea sized. Frecklelike macules can present on the face. Long hair on the forearms, hypo/hyperpigmented hair, acral hypertrophy, and dental abnormalities also have been reported. Lesions appear in infancy or early childhood and usually stop spreading before adolescence. The pigmentary lesions last for life. The autosomal dominant form of DSH is caused by a mutation in the *DSRAD (ADAR1)* gene, which encodes a double-stranded RNA–specific adenosine deaminase, an RNA-editing enzyme.

Dowlin-Degos disease (reticular pigmented anomaly of flexures)

Reticular pigmented anomaly of the flexures is a rare autosomal dominant pigmentary disorder; it is now more often called Dowling-Degos disease (DDD). Pigmentation usually appears at puberty or in early adolescence but may present later in adulthood. The skin lesions primarily affect the intertriginous areas, such as the axillae, neck, genitalia, and inframammary/sternal areas. In some cases, the dorsal hands are involved. The pigmentation is reticular; at the periphery, discrete, brownish black macules surround the partly confluent, central pigmented area. In more mildly affected patients, the pigmentation is dappled. The pigmentation progresses very gradually. There are frequently acneiform, pitted scars, sometimes pigmented, around the mouth. Comedonal and cystic lesions have been described on the flexures and in the axillae. Hidradenitis suppurativa–like lesions in the groin and axilla may occur. A follicular variant of DDD has been reported. Patients may complain that the condition is worse during hot weather. Squamous cell carcinoma of the buttocks or perianal area has been described.

Histologically, in addition to the typical lentiginous adenoid proliferations of the rete ridges, small horn cysts may be present, so that the pattern resembles that of a reticulated seborrheic keratosis. Comedones may be present. Classic autosomal dominant Dowling-Degos disease is caused by mutations in the keratin 5 gene (*KRT5*). Similar mutations occur in Galli-Galli disease, suggesting that the two conditions represent variants of the same disorder rather than separate diseases. In DDD patients who lack mutation in *KRT5,* mutations have been found in *POGLUT1* and *POFUT1,* both of which are essential regulators of Notch activity. Cases of DDD associated with these gene mutations can have widespread cutaneous lesions.

Galli-Galli disease

Galli-Galli disease is now recognized as an acantholytic variant of Dowling-Degos disease, also caused by mutations in the

Fig. 36-4 Galli-Galli disease.

keratin 5 gene. The skin lesions are 1–2 mm, slightly keratotic, red to dark-brown papules, which are focally confluent in a reticulate pattern (Fig. 36-4). The skin lesions favor skinfolds, although other skin sites may also be involved. The neck, axillae, upper extremities, dorsal hands, trunk, groin, and even the scrotum and lower extremities may be affected. Histologically, there is prominent digitate downgrowth of the rete ridges, identical to that seen in DDD. The characteristic histologic feature is a suprabasilar cleft and suprapapillary thinning of the epidermis. There is no dyskeratosis, as seen in Grover's disease. Ablative laser treatment led to axillary symptom resolution in one patient.

Reticulate acropigmentation of Kitamura

Reticulate acropigmentation of Kitamura (RPK) is a rare autosomal dominant disease that initially was recognized in Japan but now has been seen in many countries, usually in persons

Fig. 36-5 Dermatopathia pigmentosa reticularis.

of color. The characteristic presentation is pigmented, angulated, irregular, frecklelike lesions with atrophy, arranged in a reticulate pattern on the dorsal feet and hands. Lesions start in the first to second decade of life, gradually progress, and slowly darken over time. The axillae and groin may be affected, as can the skin of the trunk and more proximal extremities. Linear irregular breaks in the dermatoglyphics of the palms are characteristic and help to distinguish this disorder from the other "reticulate flexural anomalies." Patients with mixed features of DDD and RPK have been reported. RPK is caused by a loss-of-function mutation in *ADAM10,* the gene product of which is involved in ectodomain shedding of adhesion molecules.

DERMATOPATHIA PIGMENTOSA RETICULARIS

Dermatopathia pigmentosa reticularis (DPR) is an extremely rare dominant ectodermal dysplasia characterized by the triad of generalized reticulate hyperpigmentation (Fig. 36-5), noncicatricial alopecia, and onychodystrophy. Additional associations include loss of dermatoglyphics, hypo/hyperhidrosis, pigmented lesions of the oral mucosa, palmoplantar hyperkeratosis, and nonscarring blisters on the dorsa of the hands and feet. Wiry scalp hair and digital fibromatosis have also been reported. Dental anomalies are not a feature of DPR. Some members of families affected by Naegeli-Franceschetti-Jadassohn syndrome (NFJS) have clinical features identical to DPR. Both NFJS and DPR are caused by mutations in the keratin 14 gene.

Fig. 36-6
Dyschromatosis universalis hereditaria.

Fig. 36-7 Transient neonatal pustulosis.

Dyschromatosis universalis hereditaria, familial progressive hyperpigmentation and hypopigmentation

Dyschromatosis universalis hereditaria (DUH) is a rare autosomal dominant genodermatosis characterized by asymptomatic hyperpigmented and hypopigmented macules in a generalized distribution (Fig. 36-6) on the trunk and limbs and sometimes the face. Lesions are irregular in size and shape and appear in infancy or childhood, often in the first few months of life. The palms, soles, and mucous membranes are usually spared. Most DUH patients do not show other symptoms and are otherwise well. Infrequently reported associations include ocular and auditory abnormalities, photosensitivity, developmental delay, and short stature. Histologically, there are normal numbers of melanocytes in both the lighter and the darker skin, but more melanized, mature melanosomes in the darker areas and empty, immature melanosomes in the hypopigmented areas. A mutation in the *ABCB6* gene (mitochondrial porphyrin transporter localized to outer membrane of mitochondria) has been identified in numerous cases of autosomal dominant DUH (DUH-1). The wild-type protein localizes to the dendrites of melanocytes and is probably involved in melanosome transport. The mutant protein remains in the Golgi complex, which could disrupt melanosome transport.

A much rarer variant of DUH is DUH-2, which is inherited as an autosomal recessive genodermatosis, with a putative gene location on chromosome 12. Familial progressive hyperpigmentation (FPH) is an autosomal dominant genodermatosis characterized by hyperpigmented patches presenting in early infancy and progressing with age. Hypopigmented lesions are absent, distinguishing it from DUH-2, which FPH otherwise closely resembles. Familial progressive hyperpigmentation and hypopigmentation (FPHH) is an autosomal dominant disorder characterized by diffuse, partly blotchy hyperpigmentation, hyperpigmented macules, café au lait macules, and larger hypopigmented ash-leaf macules on the face, neck, trunk, and limbs present at birth or early in infancy. Lesions increase in size and number with age. FPHH and FPH have also been associated with mutations in the same region of chromosome 12 as DUH-2, mapping to the gene *KITLG* (also known as steel factor or mast cell growth factor/stem cell factor), which codes for the ligand of c-KIT. The mutations in FPHH and FPH are gain-of-function mutations.

TRANSIENT NEONATAL PUSTULAR MELANOSIS

Also called transient neonatal pustulosis, this disorder is present at birth. Newborns present with 1–3 mm, flaccid, superficial fragile pustules (Fig. 36-7). Some of the pustules may have already resolved in utero, leaving pigmented macules. Lesions affect the chin, neck, forehead, back, and buttocks, but can occur anywhere. Delayed appearance into the second or third week of life is rarely reported, as are numerous lesions and lesions up to 1 cm in diameter. In dark-skinned infants, pigmented macules may persist for weeks or months after the pustules have healed. Transient neonatal pustular melanosis is observed in 4.4% of black and 0.6% of white newborns and may be more common after vaginal than cesarean delivery.

Histologically, there are intracorneal or subcorneal aggregates, predominantly of neutrophils, although eosinophils may also be found. Dermal inflammation is composed of a mix of neutrophils and eosinophils. The differential diagnosis includes erythema toxicum neonatorum, neonatal acne, and acropustulosis of infancy.

Fig. 36-8 Peutz-Jeghers syndrome, macular pigmentation of lower lip.

PEUTZ-JEGHERS SYNDROME

Peutz-Jeghers syndrome (PJS) is characterized by hyperpigmented macules on the lips and oral mucosa, polyposis of the gastrointestinal (GI) tract, and greatly increased cancer risk. The dark-brown or black macules appear typically on the lips, especially the lower lip, in infancy or early childhood (Fig. 36-8). Similar lesions may appear on the buccal mucosa, tongue, gingiva, and the perianal mucosa; macules may also occur around the mouth, on the central face, and on the backs of the hands, especially the fingers, toes, and tops of the feet. More than two thirds of patients have lesions on the hands and feet, and 95% have perioral lesions. Skin lesions grow in size and number until puberty, after which they begin to regress. Buccal pigmented macules tend to persist. Similar pigmentation may be seen in the bowel.

The diagnosis of PJS is made with any of four major criteria: (1) two or more histologically confirmed PJS polyps; (2) any number of PJS polyps and a family history of PJS; (3) characteristic mucocutaneous pigmentation and a family history of PJS; or (4) any number of PJS polyps and characteristic mucocutaneous pigmentation. In 94% of patients who fulfill these criteria, a mutation in the *STK11* gene will be found. Almost half of patients are "new" mutations, with no family history of PJS.

The associated polyps, which are histologically characteristic, involve the small intestine by preference (64%), but hamartomatous polyps may also occur in the stomach (49%), colon (49%), and rectum (32%). The polyposis of the small intestine may cause repeated bouts of abdominal pain and vomiting. Bleeding is common; intussusception is frequent (47%). Boys with PJS often have evidence of estrogen excess with gynecomastia and advanced bone age.

Patients with PJS have a 10-fold to 18-fold greater lifetime cancer risk (81–94%) than the general population. The greatest risk is for GI malignancy, which is increased 130-fold in PJS patients. These cancers occur in the colon (39% of patients), stomach (29%), and small intestine (13%). Cancers begin to appear about age 30 years. Cancers also occur in extraintestinal sites, especially the breast, genitourinary (GU) tract, and pancreas (100-fold increase in PJS patients). The prevalence of cancers by anatomic site is pancreas (26%), breast (54%, can be bilateral), and ovary (21%). Sertoli-Leydig cell stromal tumors occur in 9% of PJS males, and sex cord tumors with annular tubules can occur in female PJS patients. Given the high risk of cancer in PJS patients, standard screening protocols have been recommended. Since 40% of patients develop significant GI and potentially GU complications by age 6 years, GI screening may need to begin as early as age 4 or 5, with testicular examination in males with PJS. The syndrome is transmitted as a simple mendelian dominant trait, caused in the majority of patients by a germline mutation of the *STK11/LKB1* tumor suppressor gene on chromosome 19p13. The gene product is a serine-threonine kinase involved in signal transduction in the mTOR pathway. Patients have one inactive copy of this gene. Patients with truncation of the gene rather than a missense mutation are more severely affected, suggesting a phenotype/genotype correlation. In Chinese PJS patients, mutations in *OR4C45, ZAN,* pre-microRNAs, and other genes have been identified, suggesting that multiple different genes can cause this syndrome.

Laugier-Hunziker syndrome, Carney syndrome, and Cronkhite-Canada syndrome should be considered in the differential diagnosis of PJS. Laugier-Hunziker syndrome presents with mucosal pigmentation and pigmented nail streaks. Cronkhite-Canada syndrome consists of melanotic macules on the fingers and GI polyposis, as well as generalized, uniform darkening of the skin, extensive alopecia, and onychodystrophy. The polyps that occur are usually benign adenomas and may involve the entire GI tract. A protein-losing enteropathy may develop and is associated with the degree of intestinal polyposis. Onset is typically after age 30 in this sporadically occurring, generally benign condition. Hypogeusia is the dominant initial symptom, followed by diarrhea and ectodermal changes. About 75% of all cases have been reported from Japan. Zinc therapy may improve the hypogeusia and other symptoms. Carney syndrome patients may also develop Sertoli cell tumors and gynecomastia, which in combination with their mucocutaneous pigmentation, may lead to an erroneous diagnosis of PJS.

METALLIC DISCOLORATIONS

Pigmentation may develop from the deposit of fine metallic particles in the skin. The metal may be carried to the skin by the bloodstream or may permeate into it from surface applications. Discolorations from medications containing silver and gold are discussed in Chapter 6.

Arsenic

Acute arsenic poisoning is associated with flushing on day 1 of exposure and facial edema on days 2–5. A morbilliform eruption appears on days 4–6. Hepatic dysfunction occurs simultaneously with the appearance of an eruption of discrete red-brown, erythematous papules in the intertriginous areas (areas of friction) of the lower abdomen, buttocks, and lateral upper chest. It regresses after 2–3 weeks, at times accompanied by acral desquamation. Three months after exposure, Mees' lines, total leukonychia, Beau's lines, and onychodystrophy may be seen. Periungual pigmentation occurs in up to half of acutely poisoned patients at 3 months.

Arsenic is an elemental metal that is ubiquitous, existing in nature as metalloids, alloys, and a variety of chemical compounds. These various forms of arsenic may be deposited into water, soil, and vegetation, producing serious health risks. Certain regions of Pakistan, India (West Bengal and Eastern India), Mongolia, China, Cambodia, and Vietnam have high levels of arsenic in their drinking water, exposing millions of people to levels of arsenic that result in health consequences. Numerous cases of arsenic-induced skin lesions have occurred. In areas of exposure, even young children can demonstrate cutaneous stigmata. Skin lesions usually occur only when arsenic concentrations in drinking water are 50 μg/L or more.

Two characteristic forms of skin disease occur. Cutaneous hyperpigmentation is the most common and earliest side effect. The hyperpigmentation is usually diffuse, most prominent on the trunk. Patchy hyperpigmentation may be accentuated in the inguinal folds, on the areolae, and on palmar creases. This can simulate Addison's disease. Areas of hypopigmentation may be scattered in the hyperpigmented areas, giving a "raindrop" appearance. Focal melanotic macules may also be present. The pigmentation may resolve or persist indefinitely. Punctate keratoses on the palms and soles are characteristic. Diffuse palmoplantar keratoderma may rarely occur. Blackfoot disease—arsenic-induced peripheral vascular disease that can lead to vasospasm and peripheral gangrene—and a severe peripheral neuropathy can also occur with chronic arsenic ingestion.

Risk factors for development of clinically evident arsenic-induced disease include concentration of arsenic contamination in exposure source (usually water) and malnutrition with low body mass index (BMI). There is significant variation in prevalence of skin disease from arsenic exposure among different racial groups and individuals. Evidence indicates that polymorphisms in arsenic-metabolizing (methylation) pathways, specifically converting monomethylarsonic acid to dimethylarsinic acid, may explain these risk differences. Arsenic exposure is also associated with a significant reduction in circulating helper T cells, perhaps contributing to increased cancer risk. One study identified polymorphisms in the *XPD* gene as a risk factor for arsenic-induced skin lesions. Histologically, the arsenical keratosis on the palms and soles shows hyperkeratosis, parakeratosis, acanthosis, and papillomatosis. Approximately 6–7% of hyperkeratotic skin lesions will demonstrate basilar atypia, and about 1% will show cancer. Arsenic exposure leads to the development of nonmelanoma skin cancers. Bowen's disease represents the majority of arsenic-induced skin cancers and may appear on sun-exposed or sun-protected skin. Basal cell carcinomas are frequent, are usually multiple, are most common on the trunk, and can be in sun-protected sites. Squamous cell carcinoma may also occur. Acitretin may improve "arsenical" keratoses. Arsenic exposure results in increased risk for lung, liver, and renal carcinoma.

Lead

Chronic lead poisoning can produce a "lead hue," with lividity and pallor, and a deposit of lead in the gums may occur: the "lead line."

Iron

In the past, soluble iron compounds were used in the treatment of allergic contact and other dermatitides. In eroded areas, iron was sometimes deposited in the skin, like a tattoo. The use of Monsel solution can produce similar tattooing, so aluminum chloride is now preferred. If Monsel is used, to minimize tattooing, it is best applied with a cotton-tipped applicator barely moistened with the solution, then rolled across a wound that has just been blotted dry.

Hemochromatosis

Hemochromatosis is a disorder caused by mutations in at least five different genes involved in iron absorption. It is very common in the white European population, in whom most

Fig. 36-9 Hemochromatosis.

mutations are at two genetic loci, C282Y and H63D in the *HFE* gene. Only a minority of persons with the most common genetic defects causing hemochromatosis will develop disease, perhaps 25% of men and 6% of women. Men are affected more frequently and at an earlier age, usually 30–50. With widespread genetic testing, the age of diagnosis has been decreased, and the number of asymptomatic affected females has dramatically increased. The characteristic cutaneous manifestation is gray to brown mucocutaneous hyperpigmentation. This is enhanced in sun-exposed areas of the forearms, dorsal hands (Fig. 36-9), and face, as well as in the inguinal area. The mucous membranes are pigmented in up to 20% of patients. The percentage of affected males with pigmentation is about 30%, and in women, fewer than 10% of diagnosed patients have skin changes. Other skin changes can include koilonychia and localized ichthyosis. Alopecia is common, and pruritus can occur. Porphyria cutanea tarda may result from inhibition of uroporphyrinogen decarboxylase in the liver by iron overload. In patients with chronic venous insufficiency, the risk of lower leg ulceration is increased sixfold in those also carrying the C282Y mutation, leading some to suggest that this test should be ordered in at-risk patients at the initial stages of venous insufficiency. Biopsy of affected hyperpigmented skin shows dermal iron deposition, but the visible pigmentation is actually increased epidermal melanin in the basal cell layer.

The most seriously affected organ is the liver. Hepatomegaly and elevated liver function tests (LFTs) are signs of hepatic iron overload. Cirrhosis and hepatocellular carcinoma may develop, but are now less common with early diagnosis and treatment. The endocrine system is also affected, with hypogonadism the primary complaint. The association of diabetes mellitus (DM) with hemochromatosis has been questioned. Few patients diagnosed in the 21st century have associated DM, and those who do have a positive family history of diabetes independent of the hemochromatosis, suggesting that development of DM in patients with hemochromatosis is caused by other genetic and environmental factors, and not iron overload. Arthropathy is seen in about 50% of women and 40% of men. Cardiac abnormalities include heart failure and arrhythmias. Consuming alcohol and smoking, as well as coexistent hepatitis C virus (HCV) infection, make it more likely that persons with genetic predisposition will develop clinical disease.

Laboratory evaluation should be pursued in persons with appropriate clinical findings suggesting the diagnosis of hemochromatosis. Levels of plasma iron and the serum iron-binding protein are elevated. The transferrin saturation (TS = serum iron/total iron-binding capacity) is a useful screening measure. A score of 45 or less is normal, except in premenopausal women, in whom greater than 35 may be considered abnormal. High serum ferritin levels are also present. Genotyping is now performed in persons with TS greater than 45 and elevated ferritin level, and confirms the diagnosis. Liver biopsy is reserved for persons with elevated LFTs, ferritin greater than 1000 µg/L, or age over 40.

Four different genes cause autosomal recessive hemochromatosis, and one causes autosomal dominant disease. The most common autosomal recessive form is caused by a mutation in the *HFE* gene, most frequently C282Y (80%), and less often H63D. The incidence of homozygosity for C282Y is 5 in 1000 persons of northern European descent, making it 10 times more common than cystic fibrosis. Compound heterozygotes (C282Y/H63D) also develop disease. Two autosomal recessive forms of juvenile hereditary hemochromatosis are described, caused by mutations in the Hemojuvelin and the Hepcidin gene. Mutations in the transferrin receptor 2 gene lead to a form of autosomal recessive adult-onset hemochromatosis. Ferroportin mutation leads to an adult-onset form of autosomal-dominant hemochromatosis.

All forms of hemochromatosis are treated with phlebotomy until satisfactory iron levels are attained. Vitamin C supplementation must be avoided, because it can worsen the disease. Raw seafood should be avoided because *Vibrio vulnificus* infection may occur. Phlebotomy can prevent cirrhosis. Once cirrhosis is present, phlebotomy does not prevent development of hepatocellular carcinoma, which occurs in 30% of patients.

Titanium

A titanium-containing ointment caused yellowish papules on the penis in a patient. Titanium screws used for orthopedic procedures, if close to the skin, can cause cutaneous blue-black hyperpigmentation. In cases of degeneration of artificial knee joints, periprosthetic black pigment can be seen, resulting from titanium deposition. Rarely, this pigment may migrate to the skin, resulting in dermal blue-gray patches over the shin. Melanin stains are positive, but polarizing foreign material can be seen, and x-ray spectrophotometry reveals titanium in the tissue.

IDIOPATHIC GUTTATE HYPOMELANOSIS (LEUKOPATHIA SYMMETRICA PROGRESSIVA)

Idiopathic guttate hypomelanosis is a common acquired disorder that affects women more frequently than men. It usually occurs after age 40, and its prevalence increases with age, exceeding 90% in Koreans over age 60. The lesions occur chiefly on the shins (Fig. 36-10) and forearms, suggesting that sun exposure plays a role. Widespread lesions have occurred in patients receiving UV phototherapy. Individual lesions are small (average 2–5 mm), hypopigmented macules. They usually number 10–30, but numerous lesions may occur. A few lesions can occur on the face. The lesions are irregularly shaped and sharply defined, similar to depigmented ephelides. Histologically, there is epidermal atrophy and reduced numbers of hypoactive melanocytes. Skin injury with cryotherapy, phenol, and carbon dioxide (CO_2) laser can improve the appearance of the lesions. Topical calcineurin inhibitors, by their stimulation of melanocyte migration and activity, can be therapeutic.

Fig. 36-11 Localized vitiligo.

VITILIGO

Vitiligo usually begins in childhood or young adulthood, with a peak onset between ages 10 and 30. About half of cases begin before age 20. The prevalence ranges from 0.5% to 1% in most countries, but more than 8% in some regions of India. Although females are disproportionately represented among patients seeking care, it is not known whether they are actually more frequently affected or simply more likely to seek medical care. Vitiligo does begin at a younger age in females. Vitiligo has developed in recipients of bone marrow transplant or lymphocyte infusions from patients with vitiligo.

Clinical features

Vitiligo is an acquired pigmentary anomaly of the skin manifested by depigmented white patches surrounded by a normal or a hyperpigmented border. There may be intermediate tan zones or lesions halfway between the normal skin color and depigmentation, so-called trichrome vitiligo. Blue-gray hyperpigmented macules representing melanin incontinence may be present focally. The hairs in the vitiliginous areas usually become white as well. Rarely, the patches may have a red, inflammatory border. The patches are of various sizes and configurations, but the margins are usually smooth and convex, except in segmental vitiligo, which has a much more irregular contour.

Six types of vitiligo have been described, according to the extent and distribution of the involved areas: localized (Fig. 36-11) or focal (single or a few macules in one anatomic area, often the trigeminal area, especially in children); segmental; generalized (common symmetric); universal (Fig. 36-12); acrofacial; and mucosal. The generalized pattern is most common. Involvement is symmetric. The most commonly affected sites are the face, upper part of the chest, dorsal aspects of the hands, axillae, and groin. The skin around orifices tends to be affected: the eyes, nose, mouth, ears, nipples, umbilicus, penis, vulva, and anus. Lesions appear at areas of trauma, so vitiligo favors the elbows and knees. Universal vitiligo applies to cases where the entire body surface is depigmented. The acrofacial type affects the distal fingers and facial orifices (lips and tips). Focal vitiligo may affect one nondermatomal site, such as the glans penis (Fig. 36-13), or asymmetrically affect a single region. Focal vitiligo is to be distinguished from the segmental form of vitiligo, which resists treatment, has an earlier onset, and is less often associated with other autoimmune phenomena. Segmental vitiligo represents 5% of adult and 20% of childhood cases and often has a dermatomal or quasidermatomal distribution.

In patients with vitiligo, local loss of pigment may occur around melanocytic nevi and melanomas, the so-called halo phenomenon. Vitiligo-like leukoderma occurs in about 1% of melanoma patients. In those with previously diagnosed

Fig. 36-12 Vitiligo, generalized.

Fig. 36-13 Penile vitiligo.

melanoma, this suggests metastatic disease. Paradoxically, however, because the reaction indicates an autoimmune response against melanocytes, patients who develop it have a better prognosis than patients without leukoderma. Lesions of vitiligo are hypersensitive to UV light and burn readily when exposed to the sun. With repeated sun exposure, lesions of vitiligo can tolerate additional UV exposure (photoadaptation), allowing for increasing doses of therapeutic UV phototherapy.

Ocular abnormalities are increased in patients with vitiligo, including iritis and retinal pigmentary abnormalities. Patients have no visual complaints. Eight percent of patients with idiopathic uveitis have vitiligo or poliosis. The conditions most frequently associated with vitiligo are other "autoimmune" diseases. Autoimmune thyroid disease is the most common autoimmune association and should be screened for in every vitiligo patient. Other autoimmune conditions include type 1 DM, pernicious anemia, Addison's disease, and alopecia areata. Additional screening should be directed by signs and symptoms. Vitiligo occurs in 13% of patients with the autoimmune polyendocrinopathy-candidiasis–ectodermal dystrophy (APECED) syndrome, caused by mutations in the autoimmune regulator gene *(AIRE)*. Polymorphisms in *AIRE* are found more often in vitiligo patients than controls.

Although familial aggregation of vitiligo is seen—up to 30% of vitiligo patients have an affected relative—it is not inherited as an autosomal dominant or recessive trait, but rather seems to have a multifactorial genetic basis. In addition to the autoimmune pathogenic hypothesis, which is most likely, oxidant/antioxidant and neural theories have been proposed. The psychological effect of vitiligo should not be underestimated. Patients are frequently anxious or depressed because of the appearance of their skin and the way it affects their social interactions. This is true for both children and adults. Determining how the vitiligo psychosocially impacts the patient (if it does) should be documented in the record and could be used as a metric to guide therapy. It is important to treat children who may not be having a psychological complication, since when they become young adults, they frequently develop quality-of-life impairment because of their vitiligo. Referring the patient to a mental health professional or the National Vitiligo Foundation (www.nvfi.org) may be helpful in this situation.

Histopathology

There is complete absence of melanocytes. Usually, there is no inflammatory infiltrate, but lichenoid or spongiotic inflammation may be detected at the edge of vitiligo lesions. This explains the scaling or hyperpigmentation sometimes observed around lesions of vitiligo.

Differential diagnosis

Vitiligo must be differentiated from morphea and lichen sclerosus, both of which are hypopigmented but associated with a change in the skin *texture*. Pityriasis alba has a fine scale, is slightly papular, and is poorly defined. Tinea versicolor favors the center back and chest and has a fine scale; yeast and hyphal forms are demonstrable with potassium hydroxide (KOH) examination. The tertiary stage of pinta might easily lead to diagnostic confusion, but a travel history and serologic testing will help elucidate the diagnosis. Patients with severe chronic actinic dermatitis may develop vitiligo-like depigmentation. Chemical leukoderma may closely resemble vitiligo (see later section).

Treatment

Vitiligo can be a frustrating condition to treat. Spontaneous repigmentation occurs in no more than 15–25% of cases. Response is typically slow, taking weeks to months to see results. Segmental vitiligo is the least responsive form. Treatment of vitiligo can be approached in two steps: (1) stopping progression and (2) repigmenting the depigmented areas. Many treatments may stop the progression, but fewer lead to durable repigmentation. For rapidly progressive, generalized vitiligo, a short course of systemic corticosteroids can be considered. Because early treatment may result in better response, the duration and stability of the vitiligo should be factored into any treatment decision. Specifically, if one hopes to recruit melanocytes from hair follicles in the affected area, if the hair is still pigmented in the vitiligo-affected skin, the likelihood of response may be higher. Some forms of treatment, such as phototherapy, may actually worsen the appearance of the vitiligo initially by pigmenting surrounding normal skin, accentuating the depigmented areas. This is particularly true in persons of lower Fitzpatrick phototypes (I and II). The

anatomic location of the lesion predicts the likelihood of response and the rate of response, independent of the modality used for therapy. Facial vitiligo has an excellent prognosis, with many patients achieving cosmetically significant improvement. The dorsal hands and feet, by contrast, respond to most forms of treatment only about 10–20% of the time. Truncal vitiligo demonstrates an intermediate response.

The major problem for the vitiligo patient is appearance. For vitiligo in persons of low Fitzpatrick phototypes (I and II) and for long-term, stable vitiligo, nontreatment is an option. These patients are treated with sun protection, supplemented with cosmetic camouflage as required. The newer self-tanning creams are useful for light-skinned and olive-complexioned patients with acral lesions. Phototherapy may more dramatically increase the risk of skin cancer in those with lower Fitzpatrick phototypes, suggesting that alternative approaches should be considered. In addition, mucosal vitiligo (of the lips) and periungual and dorsal hand vitiligo currently have essentially no reproducibly effective form of medical therapy. Camouflage is therefore an important therapeutic modality for the vitiligo patient. Dihydroxyacetone is a brown dye that stains the skin. In lower concentrations, it can be used in persons with lower phototype, since it is a golden or tan color (self-tanning products). In high concentrations, it is dark brown and can be used in patients with type V and VI phototypes to camouflage their lesions. Dihydroxyacetone is a stain, so it does not rub off, but rather needs to be reapplied because it is sloughed off from the epidermis (every 5–10 days). Numerous cosmetic products are available and can be amazingly effective in making the vitiliginous skin blend completely into the normal surrounding skin. However, it is technically difficult for patients to match their skin color without instruction. In the beginning, vitiligo patients using these products will benefit by consulting an aesthetician trained in medical camouflage. Once applied, the products tend to rub off. Application of Cavilon "No Sting Barrier Film" as a spray over the camouflage cosmetic may prevent the product from rubbing off during daily activities.

Topical treatment is appropriate for limited skin areas (<10–20% body surface area [BSA]). Occlusion of all forms of topical therapy may enhance efficacy. Topical potent to superpotent corticosteroids are used for a 2-month trial. Up to 80% of patients with facial vitiligo will achieve more than 90% repigmentation. This usually occurs diffusely, not perifollicularly, as occurs on the trunk. On the trunk, only 40% of patients achieve greater than 90% repigmentation. Treatment should be limited to 4–6 months, and the patient must be monitored for acne, atrophy, and telangiectasias. Although rarely studied, monthly intralesional triamcinolone acetonide, 3 mg/mL, has achieved 80–90% repigmentation in a limited number of patients. The response is reported to be durable and remains after the injections are stopped.

Topical pimecrolimus cream and tacrolimus ointment 0.1% have been particularly efficacious in treating facial vitiligo. In some series, these have been as effective as superpotent topical corticosteroids and avoid the steroid-induced complications of atrophy and acne. Patients who initiate treatment in the summer have a higher rate of response. Continual application may be required; patients who discontinue treatment may develop new lesions. With topical therapies, new areas of vitiligo appear in untreated areas, suggesting there is no systemic effect. Topical pimecrolimus may enhance the efficacy of narrow-band (NB) UVB in repigmenting facial, but not other, vitiligo. Topical calcipotriene and other vitamin D analogs have had variable results. Alone, these agents lack efficacy. When they are used in combination with other treatments, some studies have demonstrated additive benefit and others no benefit. Therefore, these agents cannot be recommended.

Use of NB-UVB two to three times weekly has become the preferred form of phototherapy to treat vitiligo. It avoids the need for prolonged eye protection and the occasional psoralen-induced nausea associated with PUVA. About half of patients will achieve more than 75% repigmentation of the face, trunk, proximal arms, and legs. Hand and foot lesions repigment in less than 25% of patients. Children may have slightly higher response rates than adults. In patients with greater than 20% BSA involvement, only about 5% will show complete repigmentation with phototherapy. Long courses of treatment may be required. PUVA therapy can also be used to treat vitiligo but is less effective than NB-UVB. Repigmentation from phototherapy may begin after 15–25 treatments; however, significant improvement may take as many as 100–200 treatments (6–24 months). On average, maximum improvement is seen after about 9 months of therapy. If follicular repigmentation has not appeared after 3 months, phototherapy should be discontinued. Home phototherapy is a good option in UV-responsive vitiligo patients. Known photosensitivity, porphyria, and systemic lupus erythematosus are contraindications to phototherapy. Excimer laser phototherapy can be as effective as or more effective than NB-UVB, and the response is more rapid. It can be used on limited areas, avoiding whole-body UV exposure. Whereas 25% of treated patches repigment completely, treatment-resistant areas (elbows, knees, wrists, dorsal hands and feet) have only a 2% rate of at least 75% repigmentation. The addition of topical corticosteroid to excimer laser treatment will enhance efficacy. Afamelanotide, a synthetic melanocyte-stimulating hormone analog delivered by monthly implant, may enhance the efficacy of NB-UVB treatment. Oral khellin or L-phenylalanine and antioxidants greatly enhance the response to phototherapy for some investigators, but the results are not reproducible.

Topical application of 8-methoxypsoralen at a concentration of 0.01–0.1%, followed by UVA exposure, may lead to repigmentation. Topical PUVA is used for focal or limited lesions. Inadvertent burns with blistering are frequent complications during treatment in the United States, even when the patient is treated by professionals. For this reason, topical PUVA therapy has been difficult for patients to perform at home. Topical PUVA, however, is widely used in India with success, suggesting that, in the right hands, this treatment can be effective.

In certain situations, use of systemic immunosuppressives may be appropriate in the treatment of vitiligo. This is usually in the setting of rapidly progressive disease, with the goal of reducing the total amount of pigment loss. Systemic corticosteroids are usually used and are tapered over several months. Twice-weekly dexamethasone, at a dose of 10 mg, is one such regimen. Once the disease is arrested, the patient can be converted to phototherapy. The long-term use of systemic immunosuppressives is not recommended. These initially may control the disease, but with chronic use, unacceptable toxicity often develops.

Surgical treatments can be applied to limited lesions if the previous methods do not prove beneficial, but these are time-consuming. Surgery is recommended primarily in patients with treatment-resistant vitiligo, specifically segmental vitiligo, which does not reactivate with injury. Patients must have stable disease (no new lesions or expansion of lesions for 1 year). Surgical procedures are not effective in patients who exhibit Koebner phenomenon or have active vitiligo. Given its expense, surgical treatment should be reserved for exposed skin sites covering less than 2–3% of BSA. Minigrafting, transplantation of autologous epidermal cell suspension, and ultrathin epidermal grafts have all been used. UV phototherapy is often given after the surgical procedure. In some patients with refractory head and neck lesions of vitiligo, skin injury with various lasers combined with sunlight may lead to repigmentation.

Total depigmentation

If more than 50–80% of BSA is affected by vitiligo, the patient can consider depigmentation. This form of treatment should be considered permanent, and the goal is total depigmentation. Limited areas, such as those exposed daily, may be treated, but satellite and distant depigmentation may occur, so the action of the medication cannot be limited to the applied area. Monobenzone (monobenzyl ether of hydroquinone) 20% is applied twice daily for 3–6 months to residual pigmented areas. Up to 10 months may be required to complete the treatment. About one in six patients treated experiences acute dermatitis, usually confined to the still-pigmented areas, but this rarely limits treatment. Once a uniform depigmented appearance is achieved, the patient is very satisfied. Topical 4-methoxyphenol 20% cream (mequinol, monomethylether of hydroquinone) can also be used for depigmentation. The Q-switched laser selectively destroys melanocytes and can also achieve depigmentation. Laser can be combined with a topical depigmenting agent for added efficacy.

CHEMICAL LEUKODERMA (OCCUPATIONAL VITILIGO)

Chemical leukoderma is an acquired, depigmented dermatosis caused by repeated exposure to chemicals. It is frequently misdiagnosed as vitiligo. Patients with vitiligo or a family history of vitiligo are at much greater risk of developing chemical leukoderma. The diagnostic criteria follow:

1. Acquired, vitiligo-like depigmented lesions
2. History of repeated exposure to a specific chemical compound
3. Patterned, vitiligo-like macules conforming to site of exposure
4. Confetti macules

The majority of cases are caused by exposure to aromatic or aliphatic derivatives of phenols and catechols, including paratertiary butylphenol (adhesive in shoes), amylphenol, butylcatechol, and alkyl phenols. However, sulfhydryls, mercurials, arsenics, cinnamic aldehyde, *p*-phenylenediamine, chloroquine, and azelaic acid have also been implicated. Some of these compounds have a structure similar to tyrosine and may be converted by tyrosine-related protein-1 to compounds toxic to the melanocyte. This process is considered to be different from depigmentation following allergic contact dermatitis. The clinical pattern may be similar to idiopathic vitiligo, but lesions tend to be concentrated in areas of repeated contact with the substance. The first recognized cases of occupational vitiligo occurred in individuals who worked in rubber garments or wore gloves that contained monobenzyl ether of hydroquinone. Phenolic antiseptic detergents used in hospitals and in industrial cleaners have caused chemical leukoderma in janitorial and housekeeping employees. Adhesives and glues containing incriminated chemicals may be found in shoes, wristbands, adhesive tape, and rubber products used in brassieres, girdles, panties, or condoms. Self-sticking bindis (cosmetic used by many Indian women on forehead) have been reported to induce leukoderma from the adhesive material. Also, electrocardiograph electrodes may cause similar round, hypopigmented spots at the site of contact. Radiation therapy and imiquimod application for genital wart treatment can also cause cutaneous depigmentation resembling vitiligo.

The most common location for chemical leukoderma is the face (40% of cases), followed by the hands and feet. The scalp is rarely affected. Hair dye (at rim of scalp but not on scalp), deodorant (axilla), detergent, adhesives (face, bindis), rubber sandals (feet), black socks and shoes (feet), and rubber condoms (penis) are the exposures associated with lesions in various anatomic regions. Pruritus occurs in more than 20% of patients (rare complaint in vitiligo patients). The clinical lesions are sharply marginated macules and patches, often with "confetti" or pea-sized macules seen at the periphery. This clinical pattern is atypical for idiopathic vitiligo and should suggest the diagnosis of chemical leukoderma. More than 25% of patients have lesions outside the area of contact with the implicated chemical. In about 10% of patients, new vitiliginous lesions will continue to develop, even after exposure to the chemical is stopped. Treatment is avoidance and measures used for idiopathic vitiligo. Chemical leukoderma in a person without vitiligo has a good prognosis, with repigmentation in up to 75% of cases. If a person with vitiligo develops a chemical leukoderma, repigmentation occurs in only 20% of patients. Histologically, the vitiliginous areas of a chemical leukoderma show an absence of melanocytes identical to lesions of true vitiligo.

VOGT-KOYANAGI-HARADA SYNDROME

Vogt-Koyanagi-Harada syndrome (VKHS) is a rare multisystem disease which affects the eyes, skin, auditory system, and central nervous system (CNS). It affects primarily pigmented races and is rare in white persons. It is twice as common in females and affects all ages. The disease occurs in four phases. First is the prodromal phase or meningoencephalitic phase, with fever, malaise, headache, nausea, and vomiting. The CNS involvement can include meningismus, headaches, mental status changes, cerebrospinal fluid pleocytosis, tinnitus, and dysacusis. Recovery is usually complete. The second, uveitic phase is characterized by anterior and/or posterior uveitis and inflammation of many other parts of the eye. The third, convalescent phase begins 3 weeks to 3 months after the uveitis appears, usually as it begins to improve. This stage is characterized by noncicatricial alopecia, vitiligo-like depigmentation, and poliosis of scalp, eyebrows, eyelashes, and hairs of the axillae. The vitiligo-like lesions occur in only 20–60% of patients with VKHS. The skin of the back or buttocks seems to be the initial or only anatomic area involved. The skin lesions must begin after the ocular symptoms to be considered diagnostic. The fourth phase is one of recurrent attacks of uveitis. Most ocular complications result from this stage of the disease, including permanent decreased visual acuity, cataracts, and glaucoma.

Vogt-Koyanagi-Harada syndrome is a cell-mediated autoimmune disease, with the autoantigen(s) thought to be expressed solely in melanin-containing cells. The target antigens may be the tyrosinase family proteins; immunization of mice with several of these proteins can induce a syndrome similar to VKHS. Supporting this hypothesis are the rare observations that vitiligo, interferon therapy for hepatitis C, and melanoma can all be associated with the appearance of VKHS. Aggressive immunosuppressive therapy with systemic corticosteroids and immunomodulatory medications (cyclosporine, azathioprine, mycophenolate, tacrolimus, infliximab) may preserve ocular function and prevent ocular complications. Th17 CD4+ cells stimulated by high levels of interleukin (IL)–23 and secreting IL-17 are present in VKHS patients with active uveitis. At least 10 patients with psoriasis and VKHS have been reported. They present at an older age than VKHS patients without psoriasis, and they often have HLA genotypes that have been associated with both VKHS and psoriasis (DR4, Cw6).

LEUKODERMA

Postinflammatory leukoderma may result from many inflammatory dermatoses, such as pityriasis rosea, psoriasis, herpes zoster, secondary syphilis, and morphea. Sarcoidosis, tinea versicolor, mycosis fungoides, scleroderma, and pityriasis lichenoides chronica may all present with hypopigmented lesions (only rarely are these actually depigmented), as may Hansen's disease. Burns, scars, postdermabrasion, and intralesional steroid injections with depigmentation are other examples of leukoderma. IL-17and tumor necrosis factor (TNF)–α synergistically suppress pigmentation related signaling and melanin production, partly through induction of β-defensin 3, an antagonist for melanocortin 1 (MC1R), and may represent the mechanism by which psoriasis and other inflammatory dermatoses are complicated by hypopigmentation.

Melanosomes are members of the lysosome-related organelle (LRO) family. Congenital disorders of hypopigmentation can be caused by four groups of genetic defects: (1) mutations in genes controlling melanoblast migration (Waardenburg syndrome); (2) mutations in genes controlling enzymes involved in melanin synthesis (oculocutaneous albinism); (3) mutations in genes of melanosome structural proteins (genes controlling melanosome cell membrane or scafforling on which melanins are deposited within melanosome—-Chédiak-Higashi and Hermansky-Pudlak syndromes); or (4) mutations in genes controlling melanosome-trafficking proteins (surface proteins on melanosome that direct melanosome movement from Golgi complex to melanocyte periphery—Griscelli syndrome). Clinically, this group of disorders can be characterized as generalized (systemic) or localized. Within each of these subgroups are those conditions with associated comorbidities and those without comorbidities (Box 36-1).

Box 36-1 Classification of hypopigmentation disorders

- **I. Systemic hypopigmentation (generalized hypopigmentation)**
  - **A.** Without comorbidities
    - **i.** Oculocutaneous albinism types 1–4
    - **ii.** Griscelli syndrome type 3
  - **B.** With comorbidities
    - **i.** Bleeding: Hermansky-Pudlak syndrome

OCULOCUTANEOUS ALBINISM

Oculocutaneous albinism (OCA) is an autosomal recessively inherited trait with reduction or absence of melanin in skin, hair, and eyes. Eye problems are frequently present, including moderate to severe impairment of visual acuity, nystagmus, strabismus, and photophobia. The cutaneous phenotype of the various forms of albinism is broad, but the ocular phenotype is reasonably constant in most forms.

The most serious sequelae of albinism are gross visual disturbances and increased risk for development of skin cancer. A number of syndromes associated with albinism can also cause premature mortality from impaired functioning of other involved organs and systems.

Disorders of melanin synthesis

The seven genetic forms of nonsyndromal OCA are all caused by disruption of melanin synthesis and are all autosomal recessive disorders. Their prevalence varies widely around the world but is estimated at about 1 in 17,000. This means that about 1 in 70 persons carries a gene for OCA. Given the phenotypic overlap of the various forms of OCA, genetic testing is recommended to establish the diagnosis. Since both parents are obligate carriers and two thirds of healthy siblings are at risk for being carriers, genetic counseling is recommended. Carriers are asymptomatic. All persons with OCA and their parents should be educated regarding aggressive sun protection with sunscreens, appropriate clothing, and sun avoidance. Vitamin D supplementation may be required. As adults, patients should be examined for skin lesions suspicious for melanoma and nonmelanoma skin cancer.

Oculocutaneous albinism 1

OCA1 results from mutations in the tyrosinase gene and accounts for approximately 40% of OCA worldwide. It is the most severe form of albinism and is the most common type of albinism in Japanese, non-Hispanic Caucasians, and a mixed-race European population, with a prevalence of about 1 in 40,000. Affected patients are homozygous for the mutant gene or are compound heterozygotes for different mutations in the tyrosinase gene *(TYR)*. OCA1 is divided into two forms: OCA1A and OCA1B. At birth, these are indistinguishable. OCA1A is the most severe form, with complete absence of tyrosinase activity and of melanin in the skin and eyes. Visual acuity is decreased to 20/400. The hair, eyelashes, and eyebrows are white, and the skin is white and does not tan. Irises are light blue to pink and fully translucent. Amelanotic nevi may be present. In OCA1B, tyrosinase activity is greatly reduced but not absent. Affected patients may show an increase in skin, hair, and eye color beginning at age 1–3 years, and they can tan. Iris color may also darken over time. OCA1B was originally called "yellow mutant" albinism. Temperature-sensitive OCA (OCA1-TS) is considered a variant of OCA1B; it results from mutations in *TYR* that produce an enzyme with limited activity below 37°C (98°F) and no activity above this temperature. Affected patients have white hair, skin, and eyes at birth. At puberty, dark hair develops in cooler acral areas: legs, arms, and chest. Visual acuity is not as severely affected in OCA1B.

Oculocutaneous albinism 2

OCA2 has a prevalence of 1 in 36,000 in white Europeans, but as much as 1 in 4000 in some parts of Africa. It is the most common form of OCA, accounting for approximately 50% of OCA worldwide. OCA2 was formerly called "tyrosinase-positive" albinism, or "brown OCA." Inheritance is autosomal recessive and results from mutations in the OCA2 gene, formerly known as the P-gene. The OCA2 gene encodes an integral melanosomal protein that is important for normal biogenesis of melanosomes and normal processing and transport of melanosomal proteins such as tyrosinase and tyrosinase-related protein 1 (TYRP1). The cutaneous phenotype of OCA2 patients is broad, ranging from near-normal pigmentation to virtually no pigment. Newborns have pigmented hair. Nevi and ephelides are common. Pink irises are usually not seen. Visual defects are not as severe as in OCA1. Pigmentation increases with age, and visual acuity improves from infancy to adolescence. Prader-Willi and Angelman syndromes are caused by deletions in the chromosomal region contiguous to and sometimes including the OCA2 gene. About 1% of patients with these syndromes also have OCA2.

Oculocutaneous albinism 3

OCA3 is caused by mutations in the *TYRP1* gene. TRYP1 is involved in the maintenance of melanosome structure and affects melanocyte proliferation and cell death. It also is an essential cofactor for tyrosinase activity. This form of OCA has been most frequently found in African patients and was called "rufous" or red OCA. Patients have red hair and reddish brown skin. Visual abnormalities may not be detectable.

Oculocutaneous albinism 4

OCA4 is caused by mutations in the *MATP* (also known as *SLC45A2*) gene encoding a membrane-associated protein, predicted to span the membrane 12 times and to function as a transporter. Patients are hypopigmented to a variable degree and are phenotypically identical to patients with OCA2. Visual acuity is decreased, and nystagmus is found in many but not all patients. This has also been reported in a Turkish patient, as well as German, Japanese, and Korean OCA patients.

Oculocutaneous albinism 5

OCA5 has been mapped to the 4q24. It has been described in a Pakistani family with golden hair, white skin, nystagmus, photophobia, and impaired visual acuity.

Oculocutaneous albinism 6

OCA6 is caused by mutations in *SLC24A5,* the gene product of which is a solute carrier protein important in melanosomal architecture, linking closely the structure of the melanosome to melanin synthesis. This form of OCA is found in diverse ethnicities, and the phenotype is heterogeneous with hair color from white to blond to dark brown. Most mutations occur in position 111 of the gene, with a Thr111 mutation in European or American OCA6 and Ala111 in African or Asian OCA6.

Oculocutaneous albinism 7

OCA7 is caused by mutation in the C10 or Fll gene, the gene product of which is a member of the leucine-rich repeat proteins.

Disorders of melanosome formation and trafficking

These multisystem syndromes are associated with albinism and are caused by genes that function in intracellular organelle formation and movement in a variety of specialized cell types, such as melanocytes, neurons, immune cells, monocytes, platelets, and type II epithelial cells in lungs. The silver hair associated with some of these syndromes may demonstrate pigment clumping, allowing the diagnosis to be suspected.

Chédiak-Higashi syndrome

Chédiak-Higashi syndrome (CHS) is a progressively degenerative, fatal disease characterized by partial oculocutaneous albinism (decreased skin, eye, and hair pigment), giant intracellular granules, pigment clumping in hair shafts, and a bleeding diathesis caused by absent or reduced platelet-dense bodies. It presents in childhood, usually with infections of the skin, gut, and lungs. Common pathogens are *Staphylococcus aureus,* streptococcus, gram-negative organisms, *Candida,* and *Aspergillus*. Immunoglobulins, antibody production, and phagocytosis are normal, but neutropenia is common and leukocytes display impaired migration. Natural killer cells are decreased in function, and cytotoxic T-lymphocyte (CTL) cytotoxicity is impaired. The hair of these patients is blond and sparse. The ocular albinism is accompanied by nystagmus and photophobia. In darker-skinned races, affected patients are lighter-skinned than their parents and siblings and may have speckled hyperpigmentation and hypopigmentation.

Chédiak-Higashi syndrome results from mutations in the *LYST or CHS1* gene, the exact biologic function of which is unknown. The gene must be important in lysosome and lysosome-related organelle trafficking or size regulation. Melanosomes are giant, and platelets, eosinophils, basophils, and monocytes have giant intracellular granules that are azurophilic.

About 85% of CHS patients develop hemophagocytic lymphohistiocytosis (HLH), referred to as the "accelerated phase." This occurs during infancy or childhood and can be fatal. It is caused by the unfettered proliferation of lymphocytes creating a lymphomalike condition with fever, anemia, neutropenia, hepatosplenomegaly, and lymphadenopathy. The likelihood of developing HLH is related to the degree of deficiency of CTL cytotoxicity, independent of genotype. Hematopoetic stem cell transplantation (HSCT) before the onset of this phase may be lifesaving, and it also prevents the infections. Unfortunately, even with HSCT, if CHS patients survive into adulthood, they develop progressive neurologic involvement, including dementia, spinocerebellar impairment, parkinsonism, and spastic paraparesis.

Hermansky-Pudlak syndrome

Hermansky-Pudlak syndrome (HPS) is an autosomal recessive disorder consisting of oculocutaneous albinism, a hemorrhagic diathesis secondary to the absence of dense bodies in platelets. There is progressive accumulation of a ceroidlike material in the reticuloendothelial system and visceral organs. It is hypothesized but not confirmed that this ceroid material can lead to interstitial lung disease (HPS-ILD) and inflammatory bowel disease (HPS-IBD). The hypopigmentation is caused by impaired melanosome trafficking. Patients with this disorder have a history of easy bruisability, epistaxis, gingival bleeding, hemoptysis, and bleeding after various surgical procedures and childbirth. Major bleeding occurs in 40% of HPS patients.

Currently, nine human genes (for HPS1, *AP3B1* gene, and for HPS 3–9) have been identified, which, when independently mutated, lead to a clinical picture consistent with HPS. All these genes form protein complexes that regulate vesicle trafficking in the endolysosomal system (LROs). These proteins complex together to form various lysosomal-trafficking protein complexes: AP-3, BLOC-1, BLOC-2, and BLOC-3. Although many of the HPS subtypes share the clinical signs and symptoms previously noted, a few subtypes either lack some of

Fig. 36-14 Hermansky-Pudlak syndrome; freckling of V of neck and basal cell carcinoma in Puerto Rican man.

these or have additional unique features that serve to distinguish them from the other HPS subtypes. Mutations in any gene that produces a protein that contributes to a specific BLOC tend to create a similar clinical phenotype. For example, in mice and men, HPS1 and HPS4 (BLOC-3 proteins) and HPS 3, 5, and 6 (BLOC-2 proteins) have relatively similar phenotypes. The most common subtype is HPS1, which, together with HPS4, accounts for 50% of the known worldwide cases of HPS. One in 21 Puerto Ricans has a mutation (usually 16–base pair [bp] duplication) in the HPS1 gene. HPS accounts for 80% of albinos in Puerto Rico, and 1 in 1800 Puerto Ricans in the northwest region of the country has HPS. HPS1 and HPS4 are clinically similar because together they form the BLOC-3 complex (Fig. 36-14). These are the two most severe forms of HPS. Skin pigmentation can vary from total lack of pigment to lighter hair and skin coloring than in other members of the family. Ocular changes similar to those of OCA can occur, including iris transillumination, hypopigmented retina, visual impairment, horizontal nystagmus, and strabismus. Atypical nevi, acanthosis nigricans–like lesions in the axillae and neck, and trichomegaly also occur. Solar damage, as evidenced by solar lentigines, actinic keratoses, and nonmelanoma skin cancers, occurs in 80% of patients with the 16-bp duplication in HPS1. Interstitial pulmonary fibrosis, IBD, renal failure, and cardiomyopathy are late complications and can cause premature mortality between ages 20 and 50. About 60% of patients with HPS have pulmonary symptoms, starting at a mean age of 35 years. Pirfenidone, an antifibrotic agent, can slow the progression of pulmonary fibrosis in HPS1 patients with significant residual lung function (initial forced ventilatory capacity >50%). Lung transplantation can be considered.

Hermansky-Pudlak syndrome type 2 is caused by a mutation in the gene *(AP3B1)* coding for the 3βA subunit of AP3, a molecule necessary for normal protein trafficking to the lysosome. HPS2 is notable for immunodeficiency and persistent neutropenia, with recurrent bacterial infections of the upper respiratory system and middle ear, possibly caused by the lack of antigen presentation by the CD1b molecule, since CD1b fails to gain access to the lysosome. Initially, patients may be misdiagnosed as having CHS resulting from pigment dilution and recurrent infections. However, the large intracellular granules of CHS are absent. Mild pulmonary fibrosis and a mild hearing defect can be associated with HPS2.

Patients with HPS3, HPS5, and HPS6 have mild clinical findings, without reported pulmonary or GI involvement. These types are caused by mutations in three proteins that make up BLOC2. HPS7 and HPS8 are very rare and present with a phenotype of oculocutaneous albinism and a bleeding tendency caused by platelet dysfunction. The HPS7 gene *(DTNBP1)* encodes dysbindin; the HPS8 gene is *BLOC1S3*, both BLOC-1 subunits.

Disorders of melanocyte transport

Griscelli syndrome

The myosin-5a/RAB27A/melanophilin tripartite protein complex is required to capture mature melanosomes in the peripheral actin network for subsequent transfer to keratinocytes. Mutation in each of these genes causes one type of Griscelli syndrome (GS), with a distinct clinical phenotype with features unique to each type. All types of GS are rare, autosomal recessive inherited, and characterized by mild skin and hair hypopigmentation. GS patients do not have a bleeding tendency, distinguishing them clinically from HPS. GS1 is caused by mutations in the *MYO5A* gene encoding the actin-associated myosin Va motor protein. Patients have primary neurologic dysfunction but no immunologic disease. They have silver hair. GS1 and Elejalde syndrome are thought to be the same disease. GS2 is caused by mutation in the *RAB27A* gene. Patients have silver hair, infections, and hemophagocytic lymphohistiocytosis (HLH), usually triggered by viruses. Leukocytes infiltrating the brain can cause secondary neurologic disease, but patients have no primary neural defects. GS3 is caused by mutations in melanophilin *(MLPH)* and results only in cutaneous hypopigmentation.

Disorders of melanoblast migration and survival

These disorders cause "spotting," with patches of white hair and unpigmented skin.

Waardenburg syndrome

Four types of Waardenburg syndrome (WS) exist, with overlapping phenotypic features; three are autosomal dominant, and type IV is autosomal recessive. Six genes are associated with WS. Types I and III are caused by mutations in the *PAX3* gene, encoding a transcription factor. Most cases of WS type II are caused by mutations in the *MITF* gene; however, some, more mildly affected patients with mutations in *SOX10, EDN3, EDNRB,* and *SNA12* may present as WS type II. WS type IV is caused either by a heterozygous mutation in the *SOX10* gene or by homozygous mutations in the endothelin-3 *(EDN3)* or the endothelin B receptor *(EDNR3)* gene. These mutations impair the ability of melanoblasts to reach their final target sites (inner ear, eye, skin) during embryogenesis.

Patients with WS have features of piebaldism, with a white forelock, hypopigmentation, and premature graying, caused by absence of melanocytes in affected areas. Other characteristic findings include synophrys (eyebrows growing together), lateral displacement of the medial canthus (dystopia canthorum), congenital deafness, and ocular changes, including heterochromia iridis (Fig. 36-15). Types I and III are both characterized by dystopia canthorum; in WS type I, white forelock and depigmented skin patches are more frequent; while in WS type III, musculoskeletal anomalies (flexion contractures, muscle hypoplasia of the upper limbs, and camptodactyly occur. In WS type II, no dystopia canthorum is observed, but hearing loss and heterochromia iridis are more frequently found. WS type IV is identical to type I, except for its association with Hirschsprung disease (congenital megacolon), since the migration of neural crest cells into the Auerbach plexus requires *EDN3/EDNRB* and *SOX10. SOX10* mutations are associated with neurologic defects, and there is a poor phenotype/genotype correlation in *SOX10*-associated WS. Developmental delay occurs in the many of these patients, suggesting that other genes required for neural development may influence *SOX10* mutation–associated phenotype. This association between WS type IV caused by *SOX10* and neurologic disease has been termed PCWH (peripheral demyelinating neuropathy, central demyelinating leukodystrophy, Waardenburg syndrome, Hirschsprung disease).

Fig. 36-16 Piebaldism, vitiligo-like depigmentation.

Piebaldism

Piebaldism is a rare, autosomal dominant syndrome with variable phenotype, presenting at birth. The characteristic clinical features are a white forelock and patchy absence of skin pigment (Fig. 36-16). The depigmented lesions are static and characteristically occur on the anterior and posterior trunk, midupper arm to wrist, midthigh to midcalf, and shins. A characteristic feature of piebaldism is the presence of hyperpigmented macules within the areas lacking pigmentation and also on normally pigmented skin. The depigmented lesions may repigment spontaneously, or especially after injury. The white forelock is a triangular or diamond-shaped midline white macule on the frontal scalp or forehead, and it is the only manifestation in 80–90% of patients. The medial portions of the eyebrows and eyelashes may be white. Histologically, melanocytes are completely absent in the white macules.

Piebaldism is caused by mutations in the *KIT* gene. The phenotypic differences between families are caused by different locations of mutations in the gene. A mild phenotype occurs in cases associated with haploinsufficiency or a truncated mutation in the TK domain. Severe phenotypes are associated with dominant-negative inhibition caused by a missense mutation in the TK domain. The white lesions may respond to camouflage cosmetics or surgical corrections (see Vitiligo). Rarely, Hirschsprung disease and neurofibromatosis type I have been associated with piebaldism.

37 Dermatologic Surgery

Dermatology has always been a surgically oriented specialty. Although procedures such as curettage, biopsy, destruction, and excision have been key components of the field, the practice has evolved to include a greater number and extent of surgical procedures. This progression can be attributed to a variety of factors. Dermatologists have a greater understanding of cutaneous pathology, which places them in a unique role to manage complex surgical procedures that arise in the skin. In addition, outpatient dermatologic surgery has been shown to be cost-effective, safe, and efficacious, delivering a greater degree of patient convenience, particularly compared with other fields. The American Board of Dermatology therefore mandates surgical exposure and experience for all residents in dermatology residency programs. Furthermore, with the Accreditation Council for Graduate Medical Education (ACGME) accreditation of Procedural Dermatology fellowships, dermatologic surgery has become recognized as a mainstream medical option for patients. This chapter and Chapters 38 and 39 provide a survey of procedures, indications, and appropriate management within the spectrum of the dermatologic surgery field.

PREPARATION FOR SURGERY

A thorough and complete preoperative evaluation is required before performing any surgical procedure. A detailed medical history must be obtained, including information on drug allergies, current medications (including herbal or natural supplements), presence of a pacemaker or implantable cardioverter/defibrillator, recently implanted prosthetic devices, history of prior wound infection or perioperative bleeding, and history of endocarditis or cardiac valvular or congenital malformation.

Anticoagulants

Much has been written regarding the role of antiplatelets and anticoagulants and surgical bleeding. Dermatologists are frequently presented with the dilemma of whether to discontinue blood thinners in the setting of surgery. Data and multiple reviews have shown that continuous treatment with blood thinners perioperatively in patients undergoing Mohs and cutaneous surgery is not associated with an increase in surgical complications leading to significant morbidity. In contrast, discontinuation of these medications may increase the risk of catastrophic cerebral and cardiovascular complications. Kovich and Otley reported a series of thrombotic complications in a group of patients who had discontinued aspirin or warfarin before surgery; these included cerebrovascular accident (stroke), transient ischemic attack, myocardial infarction, pulmonary embolus, and death. Multiple authors believe that the potential adverse effects of discontinuing essential medical blood thinners far outweigh the potential side effects of surgical bleeding (e.g., managing a postoperative hematoma). In fact, despite some surgeons' claims to the contrary, studies have demonstrated that blinded surgeons are unable to identify intraoperatively which patients are taking anticoagulation medication based on the subjective amount of surgical oozing. As such, it is recommended that patients be maintained on all medically necessary blood thinners during cutaneous surgery. In contrast, patients taking aspirin for primary prevention may discontinue use 2 weeks before any surgical procedure.

Herbal supplements are becoming increasingly popular with patients who are looking for a "natural" option to traditional medication. Patients may not readily volunteer that they are taking these supplements, either because they do not characterize supplements as medication or because they are concerned that physicians will not be accepting of alternative treatments. Therefore, physicians should ask patients specifically if they are taking any supplements. Ginkgo, garlic, ginseng, ginger, and vitamin E may increase the risk of perioperative bleeding. These herbal supplements are not medically necessary, so patients should discontinue them for several weeks before undergoing dermatologic surgery.

Antibiotic prophylaxis

Dermatologists performing cutaneous surgery are often faced with the decision of whether to prescribe prophylactic

antibiotics. The main issues surrounding antibiotic prophylaxis are prevention of surgical site infections and reduction of the risk of endocarditis or contamination of prosthetic devices in high-risk patients. Despite the trend in medicine toward evidence-based approaches, many dermatologists overlook this when approaching antibiotic prophylaxis. Although reducing infection is one objective in the use of antibiotics, dermatologists must consider the risks of such treatment, including adverse drug reactions, serious drug reactions, drug interactions, development of resistant strains of bacteria, and increased cost.

Surgical site infection

Determining the indications for antibiotic prophylaxis for surgical site infections requires an understanding of the various types of wound that the dermatologist may encounter. Wounds can be categorized into the following four groups:

1. Clean wounds (class I) are created on normal skin using clean or sterile technique. Examples include excision of neoplasms, noninflamed cysts, biopsies, and most cases of Mohs surgery. The majority of dermatologic surgery falls into this category. The infection rate of these wounds is less than 5%. Of note, this incidence is based on general surgery cases, which are often of longer duration and a greater extent than most dermatologic procedures. This explains the lower actual infection rate in dermatologic surgery, which is in the 1–3% range.
2. Clean-contaminated wounds (class II) are created on contaminated skin or any mucosal or moist intertriginous surface, such as the oral cavity, upper respiratory tract, axilla, or perineum. The infection rate of these wounds is 10%.
3. Contaminated wounds (class III) involve visibly inflamed skin with/without nonpurulent discharge and have an infection rate of 20–30%. Examples included inflamed cysts or traumatic wounds.
4. Infected wounds (class IV) have contaminated foreign bodies, purulent discharge, or devitalized tissue. Examples included necrotic tumors, ruptured cysts, or active hidradenitis suppurativa. These wounds have an infection rate of 40%.

Clean (class I) wounds, which constitute the vast majority of dermatologic surgery procedures, do not require antibiotic prophylaxis.

Although antibiotic prophylaxis in clean-contaminated (class II) wounds is not a clear issue, most cases do not require routine antibiotics. It is preferable to treat infections should they arise (because these are not a common occurrence, even in class II wounds), rather than expose all patients to antibiotics and the increased rate of drug-related adverse events. Some exceptions to this that have been advocated include surgical cases that violate mucosal membranes (oral, nasal, anogenital) and patients with heavily colonized skin (atopic dermatitis, infected skin), as well as those in whom a wound infection would result in significant morbidity. However, dermatologic surgeons do not universally agree on these exceptions, and the role for antibiotic prophylaxis is still debated.

In contaminated (class III) and infected (class IV) wounds, antibiotics serve a therapeutic, rather than a prophylactic, role and should be used routinely in these cases.

Antibiotic selection and timing

To achieve optimal prophylaxis, antibiotics should be in the bloodstream, and thus at the surgical site, at the time of incision. Antibiotics given at the conclusion of the procedure are not as effective in preventing infection, because they are not incorporated into the coagulum of the wound. Once the surgical wound is closed, the risk of infection decreases significantly. Most dermatologic procedures are of short duration, so a single preoperative dose of antibiotics 1 hour before the start of the case is sufficient. In rare cases with an extended dermatologic procedure, a second dose of antibiotics can be administered 6 hours postoperatively.

Table 37-1 Antibiotic prophylaxis for heavily colonized or high-risk patients

Surgical site	Antibiotic	Regimen (single dose 1 hour preoperatively)
Skin	Cephalexin Dicloxacillin Clindamycin Vancomycin	1 g orally 1 g orally 300 mg orally 500 mg intravenously
Oral and respiratory mucosa	Cephalexin Amoxicillin Clindamycin	1 g orally 1 g orally 300 mg orally
Gastrointestinal and genitourinary mucosa	Cephalexin Trimethoprim-sulfamethoxazole Ciprofloxacin	1 g orally 1 double-strength tablet orally 500 mg orally

The choice of antibiotic is based on the most likely causative organism at the surgical site (Table 37-1). *Staphylococcus aureus* is the most common wound infection in cutaneous surgery. Other pathogens to consider in some situations include *Streptococcus viridans* (oral mucosa) and *Escherichia coli* (perineal and genital location).

First-generation cephalosporins are an ideal initial choice for the treatment of wound infection because of their coverage of staphylococcal organisms, common gram-negative organisms such as *E. coli,* and certain *Proteus* species. Cephalosporins are rapidly absorbed when taken orally and have good tissue penetration. Their estimated cross-reactivity in penicillin-allergic patients is 5–10%.

Isoxazolyl penicillins, such as dicloxacillin and nafcillin, can also be used because they provide coverage for most strains of streptococci and β-lactamase–producing bacterial strains, such as *S. aureus.* Aminopenicillins, such as ampicillin and amoxicillin, have better gram-negative, enterococcal, and group A streptococcal coverage. However, aminopenicillins are not effective against β-lactamase–producing bacteria and thus are used more often in procedures involving oral mucosa.

Clindamycin, macrolides (e.g., erythromycin, azithromycin), trimethoprim-sulfamethoxazole (TMP-SMX), and ciprofloxacin can all be considered in patients with a penicillin or cephalosporin allergy, with the specific choice based on the site of surgery and thus the presumed causative organism. Vancomycin is generally limited to those cases where methicillin-resistant *Staphylococcus aureus* (MRSA) is suspected, because it requires intravenous administration and adjustment in patients with impaired renal function.

Treatment of wound infection

Postoperative surgical site infection is quite uncommon in dermatologic surgery procedures, with an incidence of 1–3%. Infections typically present 4–7 days after surgery with

increased erythema, tenderness, warmth, and purulent drainage. Sutures can be removed to allow for drainage of exudate. In cases where infection leads to dehiscence, the wound can be packed or allowed to heal by second intention. Scar revision can be performed at a later date should that be necessary. A culture should be performed before initiating empiric antibiotics to determine sensitivities.

Staphylococcus aureus is the most common pathogen, and cephalexin or dicloxacillin is an appropriate first-line treatment. Patients with a penicillin allergy can be treated with clindamycin. Although this antibiotic has been associated with colitis, the short courses of clindamycin typically used with surgical site infection generally do not present a problem. In communities or institutions with a high incidence of MRSA, antibiotic choice can be modified based on community sensitivities (e.g., doxycycline, TMP-SMX). Ciprofloxacin can be used for infections with a higher likelihood of gram-negative or *Pseudomonas* organisms (e.g., ear). Antibiotic choice should be modified based on culture results.

Endocarditis prophylaxis

The American Heart Association (AHA) updated its recommendations on infective endocarditis (IE) prophylaxis in 2007. The overall conclusions were that bacteremia from daily activities is much more likely to cause IE than bacteremia associated with dental procedures, and that far fewer patients are now recommended to have antibiotic prophylaxis. Antibiotic prophylaxis has been limited to patients with the conditions listed in Box 37-1. All other cardiac conditions, including mitral valve prolapse and other forms of congenital heart disease, no longer require prophylaxis for any procedure.

Antibiotic prophylaxis is reasonable when procedures involve manipulation of gingival tissue, perforation of oral mucosa, or incision or biopsy of the respiratory mucosa, or when performed on infected skin, but only in patients with underlying cardiac conditions associated with the highest risk of adverse outcome, as outlined in Box 37-1. Antibiotic prophylaxis solely to prevent IE is not recommended for gastrointestinal or genitourinary procedures. The AHA reaffirmed its 1997 statement regarding medical procedures, including incision or biopsy of surgically scrubbed skin, that do not require antibiotic prophylaxis. Antibiotic prophylactic regimens for those select high-risk patients should be a single dose of antibiotic administered 1 hour before the procedure (Table 37-2).

There are no formal guidelines regarding the use of antibiotics in patients with orthopedic prosthetic devices undergoing dermatologic surgery. However, guidelines for dental procedures in patients with joint replacement can be extrapolated to certain procedures. Patients with joint replacement probably do not need prophylactic antibiotics for clean wounds. If mucosa is invaded, prophylaxis may be appropriate and reasonable in the small number of patients who might be at high risk of joint infection. Consultation with orthopedic surgery is appropriate in determining whether antibiotic prophylaxis is necessary.

Preoperative antisepsis

Many surgical preparations are available for preoperative antisepsis. Alcohol is frequently used for minor clean procedures, such as biopsies. However, since it has only weak antimicrobial activity, alcohol is not recommended for more extensive procedures.

Chlorhexidine has a broad spectrum against gram-positive and gram-negative organisms, a rapid onset of activity, and sustained residual activity even after being wiped off, and it is nonstaining. Chlorhexidine has been reported to cause both ototoxicity and keratitis from direct tympanic or ocular contact. However, this is mainly in patients under general anesthesia who cannot respond to immediate irritation associated with ocular contact, a problem that is avoided in most dermatologic procedures performed under local anesthesia.

Betadine (povidone-iodine) and all iodine-containing preparations have an excellent bactericidal activity within several minutes of application. However, these agents are often irritating to the skin, leave a residual color, can be absorbed in premature infants, and must dry before the procedure if they are to act as an effective antimicrobial agent.

Hexachlorophene is not bactericidal against many gram-negative organisms. It has the potential for neurotoxicity in children and teratogenicity in pregnancy. Hydrogen peroxide has no significant antiseptic properties, and thus it is not suitable for sterile skin preparation.

If hair must be removed before surgery, this should be done in a manner that does not leave open skin (cuts or scratches), which can serve as a conduit for infection. Preoperative shaving has been associated with a higher rate of bacterial infection secondary to cutting of the skin surface.

Anesthesia

Anesthetics work by blocking sodium influx into neurons and preventing depolarization and blockage of action potential. Small, unmyelinated C fibers, which carry pain and temperature sensation, are more easily blocked than larger, myelinated A fibers, which carry pressure sensation and motor function. This difference translates clinically, with patients under local anesthesia not experiencing pain from the sharp incision, but still maintaining the sensation of pressure during the procedure.

All local anesthetics have a similar structure, consisting of three parts: an aromatic hydrophobic ring, intermediate chain, and amine end. The aromatic hydrophobic portion is lipophilic and facilitates diffusion through nerve cell membranes, correlating to the potency of the anesthesia. The hydrophilic amine end contributes to the aqueous solubility of the anesthetic and is involved in binding of the molecule to the sodium channel. The intermediate chain consists of either an amide or an ester. Amides are metabolized by hepatic microsomal enzymes, and esters are metabolized in plasma by pseudocholinesterase and excreted by the kidney.

The choice of anesthetic is based on a variety of factors, including patient allergy, renal or hepatic impairment, and type of procedure being performed. The "workhorse" anesthetic of dermatologic surgery is lidocaine, because of to its rapid onset of action and intermediate duration of action. Longer-acting anesthetics, such as bupivacaine, have a delayed onset of action, but can be used in special procedures or in combination with lidocaine to maximize duration of anesthesia.

All local anesthetics, with the exception of cocaine and prilocaine, cause vasodilation from relaxation of smooth muscle. As a result, patients experience increased surgical bleeding and shorter duration of action as the anesthesia is cleared from the surgical site because of vasodilation. Epinephrine, which causes vasoconstriction, is often added to local anesthetics to decrease bleeding, increase duration of anesthesia, and reduce systemic side effects caused by systemic absorption. Concentrations of 1:100,000 to 1:400,000 are typically used, with lower concentrations having fewer side effects while still maintaining clinical efficacy. The vasoconstrictive effect of epinephrine takes 15 min for onset, so the surgeon must allow adequate time before starting the procedure. Epinephrine is a strong α- and β-adrenergic receptor agonist and has an absolute contraindication in hyperthyroidism and pheochromocytoma. Large amounts of epinephrine must be used cautiously in patients with severe hypertension or narrow-angle glaucoma, as well as in pregnancy. Patients taking β-blockers, monoamine oxidase inhibitors, tricyclic antidepressants, and phenothiazines are more sensitive to epinephrine. Although the subject of much controversy, epinephrine is safe to use in well-vascularized areas, such as the ear, nose, and genitals. Reports of necrosis are likely the result of excessive volume being placed, which can cause a physical tamponade of vessels, rather than being a direct result of epinephrine.

Sodium bicarbonate (8.4%) can be added (1:10 ratio) to reduce the pain and burning associated with the lower pH of lidocaine with epinephrine. However, sodium bicarbonate can reduce epinephrine activity with time, thus requiring freshly mixed preparations on a regular basis.

Side effects

The most common side effect of local anesthetic is injection site pain. Buffering with sodium bicarbonate, using a small-gauge needle (e.g., 30 gauge), using ice or vibratory distraction at the injection site, injecting slowly into the subcutaneous tissue (rather than the dermis), warming the anesthesia, minimizing the number of injections, and placing subsequent injections in an already-anesthetized location can minimize the pain associated with local anesthesia. Vasovagal reactions are common during anesthesia administration. Patients should lie flat during the injection to reduce this occurrence. Cold compresses and placing the patient in a Trendelenburg position can help if symptoms occur.

Maximum dosage of anesthesia has traditionally been accepted as 5 mg/kg of 1% plain lidocaine and 7 mg/kg of 1% lidocaine with epinephrine. These numbers have been based on traditional industry-based studies, not found in the medical literature. Experience with tumescent liposuction has taught that dosages up to 55 mg/kg are well tolerated and safe in certain clinical situations. Bupivacaine has a greater risk of cardiac toxicity than lidocaine because of its longer duration of action.

Most true allergic reactions to local anesthetics have been reported with esters. The metabolite *p*-aminobenzoic acid (PABA) is responsible for ester allergies. There is no cross-reactivity between ester and amide classes of anesthetics, so allergy to one type does not preclude the use of the other. True systemic amide allergy is extremely rare. Thorough questioning of patients who report allergy often reveals a vasovagal reaction or epinephrine sensitivity. If local anesthetic use is precluded, intradermal injection with diphenhydramine can be used. Drowsiness can be a side effect when large doses of this agent are used. Bacteriostatic saline, with the benzyl alcohol preservative acting as the anesthetic agent, is often sufficient to provide the brief anesthesia needed to perform small procedures.

Topical anesthetics can be effectively used for many laser procedures, as well as decreasing pain associated with pinpricks of local anesthesia. These products require an extended time of application and/or occlusion to penetrate the stratum corneum and work effectively. The level of anesthesia obtained with these agents is often inconsistent. Topical anesthetics are more effective on mucosa because of the absence of the corneal barrier. There are numerous lidocaine-containing products in a variety of preparations. Eutectic mixture of 2.5% lidocaine and 2.5% prilocaine has also been used extensively. Prilocaine-induced methemoglobinemia has been reported in children from the increased systemic absorption of prilocaine from certain topical products.

Direct application of ice can reduce injection site pain. Ethyl chloride spray rapidly chills the skin and can be used for minor curettage procedures or needle insertion. Refrigerated forced air or water-chilled sapphire crystals can help reduce pain associated with laser procedures. Ophthalmic solutions of proparacaine 0.5% or tetracaine 0.5% can provide rapid anesthesia and are useful when placing corneal shields.

Anatomy

A thorough understanding of anatomy is critical when performing dermatologic surgery. The vascular supply, sensory and motor innervation, and muscles of facial expression all play a role in the successful surgical outcome (Figs. 37-1 to 37-3 and Box 37-2).

Several key danger zones are worthy of mention. The temporal branch of the facial nerve is at greatest risk for injury when it runs superficial to the deep temporalis fascia as it crosses the zygomatic arch. Care must be taken to undermine bluntly in a plane above the SMAS (superficial muscular aponeurotic system). Injury to the temporal nerve results in brow ptosis and inability to raise the eyebrow. The danger zone for the marginal mandibular nerve lies where it crosses over the body of mandible, just anterior to the masseter muscle. Injury to the marginal mandibular nerve causes asymmetric ipsilateral lip elevation and inability to show the lower teeth. The spinal accessory nerve is at risk in a region of the neck delineated by the clavicle inferiorly, sternocleidomastoid muscle

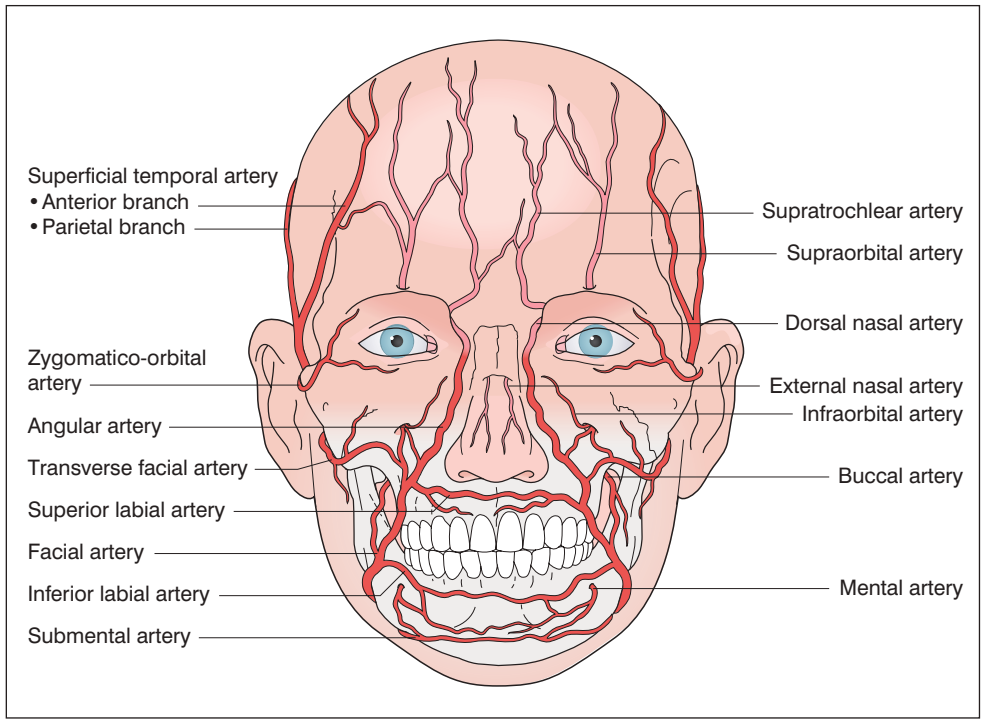

Fig. 37-1 Arterial supply of the face. Light pink designates arteries derived from the internal carotid artery; dark pink, from the external carotid artery.

anteriorly, and trapezius muscle laterally and posteriorly. Damage to the nerve causes a winged scapula, inability to shrug the shoulder, difficulty abducting the shoulder, shoulder drop, and chronic shoulder pain.

Equipment

The choice of instruments and suture depends on the procedure being performed. Most simple, in-office biopsies are performed in a "clean" rather than sterile manner and require minimal instrumentation. More complex excisional and reconstructive surgery is generally performed with sterile technique and employs a surgical tray with a wider range of instruments (Box 37-3).

For procedures requiring sutures, absorbable material is used for deeper, layered closures, whereas surface sutures are generally nonabsorbable or fast-absorbing (Table 37-3). The large number of suture choices relates to both the type of procedure performed and the anatomic location treated. Choices include absorbable and nonabsorbable, synthetic and nonsynthetic, monofilament and braided. The surgeon must consider a variety of other characteristics when choosing which suture to use. Memory is the ability of the suture to return to its original shape after deformation, which results in poor handling and decreased knot security. Plasticity is the ability of the suture to retain its new shape after it has been stretched. Elasticity is the ability of a suture to return to its original length and shape after stretching, an important factor to consider in relation to the resulting edema associated with surgery. The

Polybutester (Novafil)	monofilament

coefficient of friction is the ease with which the suture slides through tissue and is directly related to knot security. Capillarity is the ability of the suture to wick away fluid, with braided sutures having an increased tendency to trap fluid and bacteria. All have appropriate applications.

In general, for procedures requiring buried suture, a synthetic braided suture is a common choice. The 50% tensile strength for this class of suture is about 3 months, and this suture is less palpable under the skin. For these reasons, synthetic braided sutures are often used across all anatomic locations. For procedures on the trunk and extremities (i.e., areas under tension), a monofilament absorbable suture may be considered, because the tensile strength may last longer than with synthetic braided suture, and reports indicate decreased incidence of "spitting" suture. The thicker skin in the trunk and extremities may hide the palpability of monofilament absorbable suture, making it more acceptable to patients. Epidermal approximation in more delicate areas is more appropriately closed with smaller, 5-0 or 6-0 sutures, whereas 4-0 or 3-0 sutures are used in more high-tension areas (e.g., trunk, extremities). Absorbable sutures (e.g., gut) may be considered in sensitive areas where suture removal may be painful or difficult (e.g., eyelids) or in children. Facial sutures are often taken out in 4–7 days to decrease the risk of forming track marks from epithelialization of the suture puncture site, whereas sutures on the scalp, neck, and body are often left in for about 2 weeks. Running subcuticular sutures can be left in for 3 weeks to add tensile strength to wounds without the risk of suture marks. Surgical staples can be used on locations such as the scalp to accommodate the higher tension and avoid pulling hair into the wound. Staples can be applied more quickly than traditional suturing and can provide good wound eversion to facilitate healing.

Cyanoacrylates are liquid tissue adhesives that rapidly polymerize when applied to the skin. These adhesives are easy to apply, avoid suture marks, minimize postoperative wound care, and eliminate the need to return to the clinic for suture removal. *N*-butyl-2-cyanoacrylate (Indermil; Syneture, Norwalk, CT) and octylcyanoacrylate (Dermabond; Ethicon, Bridgewater, NJ) are the more frequently used adhesives. The longer length of the side chain of octylcyanoacrylate has been

shown to be stronger and more flexible when applied. Studies report various results compared with traditional sutures. As such, care must be taken in choosing the right clinical situations to use these products.

BIOPSIES

When performing a skin biopsy, the clinician should consider the lesion characteristics, reason for biopsy (diagnostic vs. cosmetic), and site. Shave biopsies can range from a superficial scissor snip of an epidermal growth to deep shave excisions of papillary dermal processes. Punch biopsies are most often used for dermal lesions, sampling deeper than shave biopsies, but requiring sutures. Excisional biopsies remove an entire clinical lesion and are the biopsy of choice for pigmented lesions suspicious for melanoma. Incisional biopsies remove a portion of a clinical lesion and are often performed on larger plaques or patches when an excisional biopsy is not cosmetically acceptable or feasible. A wedge biopsy is a deep incisional biopsy that can sample pathologic tissue and adjacent normal tissue; it is especially useful for pathologic diagnosis of certain inflammatory conditions (e.g., panniculitis, fasciitis).

Shave biopsies are best suited for pedunculated, papular, or otherwise exophytic lesions (see Video 37-1). Using a deep or rolled shave, samples can also be obtained of macular or indurated lesions, provided the necessary histologic changes reside in the epidermis or papillary dermis. Infiltration of local anesthesia distends and elevates the lesion, increases skin turgor, affords greater resistance to the blade, and facilitates undercutting the lesion. Using either a No. 15 blade scalpel or a razor blade, which can be flexed to achieve the desired depth, a horizontal incision is made and the lesion removed with sweeping strokes (Fig. 37-4). Hemostasis is typically attained with topical application of 35% aluminum chloride solution.

Fig. 37-4 Shave biopsy. Lesion is pinched up with thumb and finger and biopsy performed with sweeping strokes.

Sharp scissor biopsy is best suited for pedunculated lesions. Iris or Gradle scissors are used to snip the base of the lesion. In many cases, this can be done without anesthesia. Chemical hemostasis, electrocautery, or simple pressure can be used to control bleeding.

The dermatologic punch is frequently used for both excisional and incisional biopsies (Fig. 37-5; also see Video 37-2). When performing a punch biopsy, the skin should be stretched perpendicular to the relaxed skin tension lines. The elliptical wound resulting from the release of the tension can be suture-closed in a linear fashion, without redundancy or puckering associated with circular wounds. The punch is placed on the skin perpendicular to the surface. While the surgeon applies gentle pressure, it is rotated back and forth and advanced to the hub. The specimen is carefully grasped to avoid crush artifact, and the base is cut. Sutures are typically placed to achieve hemostasis, but punch sites that are allowed to heal by second intention have been shown to heal with a similar cosmetic outcome.

A variation of the punch biopsy can be used to remove larger subcutaneous nodules. Narrow-hole extrusion is a surgical technique that uses a punch biopsy to make a small cutaneous portal through which larger benign growths (e.g., lipoma) can be extruded (Fig. 37-6; also see Video 37-3). This technique allows the evacuation of large subcutaneous growths with a relatively small surface incision.

Suture technique

Proper suture placement is essential to obtain the desired final result. Sutures are used to close any dead space, reduce bleeding, provide tensile strength and minimize tension to facilitate wound healing, and achieve epidermal wound approximation to maximize cosmetic outcome. Instrument-tied knots are the most common sutures used in dermatologic surgery. Various suturing techniques can be employed, based on factors such as size, anatomic location, and thickness of the surgical wound.

Buried subcutaneous sutures are used for larger or deeper wounds to reduce the risk of wound dehiscence. Proper placement is key to achieving eversion of the wound edges and decreasing tension (Fig. 37-7). The stitch is in the dermis and fat, with the knot cut short and buried to reduce tissue reaction and "spitting" sutures.

Simple epidermal interrupted sutures are one of the most versatile stitches used in dermatology. These are best used for closure of small punch biopsies or for larger, layered excision or flap repairs. Interrupted sutures are especially useful in high-tension wounds; a single suture can be removed, and the surgeon can assess the wound for any dehiscence. For wound edges with a step-off from the opposing epidermal edges, the surgeon places the suture more superficially at the higher side and deeper on the lower side to even the edges (Fig. 37-8).

The vertical mattress suture is useful for reducing tension, closing dead space, and achieving wound eversion (Fig. 37-9). It can function as both the buried and the superficial suture. Because it tends to leave track marks and strangulate the skin, the vertical mattress suture must be used strategically and removed sooner than traditional sutures.

The horizontal mattress suture reduces tension and can be used as a retention suture when attempting to close larger wounds (Fig. 37-10). It can cause strangulation and necrosis of poorly vascularized tissue and should be used with caution when closing flaps.

Running sutures can be used for epidermal closure in wounds under minimal tension and with closely approximated wound edges. Placement is much faster than with simple interrupted sutures because knots are only used at each

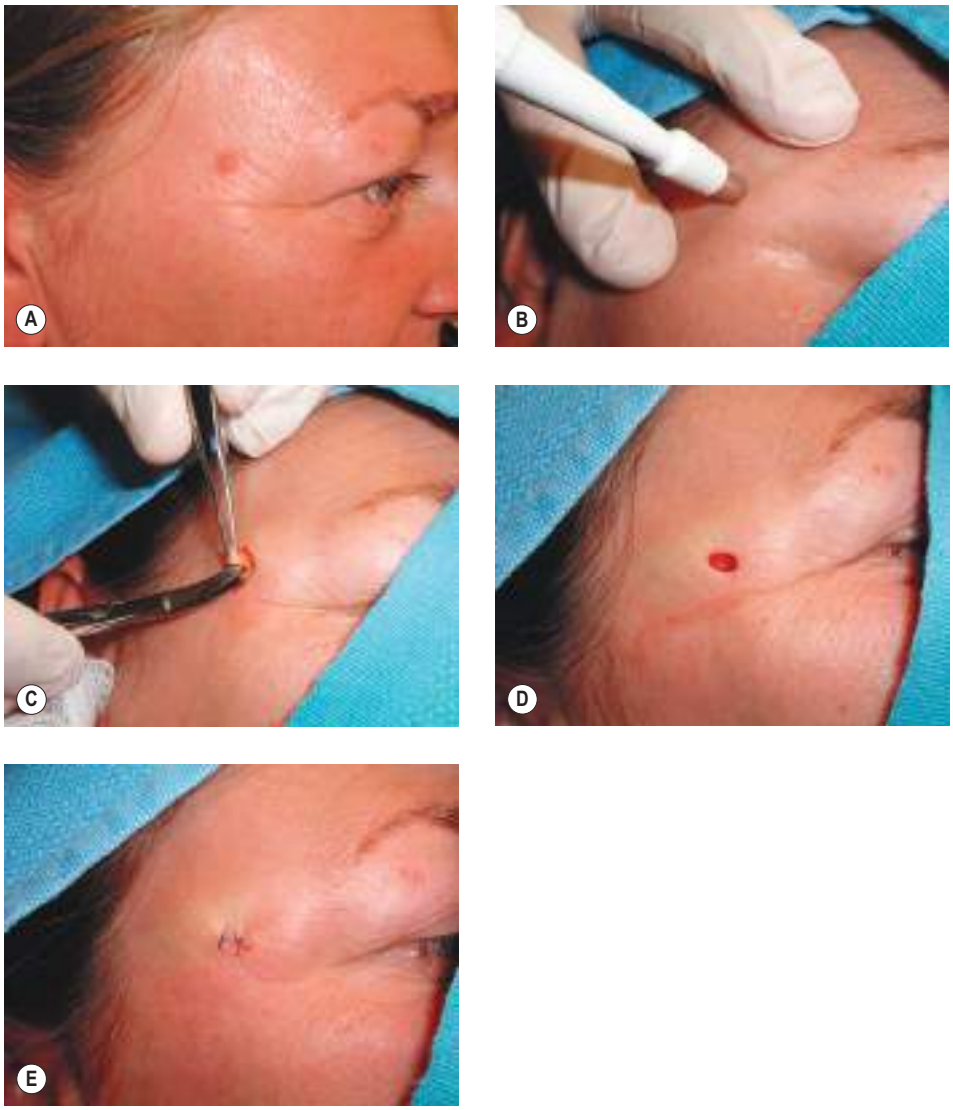

Fig. 37-5 Punch biopsy. A, Lesion to be removed. B, Skin stretched perpendicular to relaxed skin tension lines and punch inserted with twisting motion. C, Specimen is carefully grasped and removed. D, Resultant elliptical defect. E, Sutures in place.

end of the wound. The running locked suture is a variant of the simple running suture and involves passing the needle through the previous loop (Fig. 37-11). This technique creates pressure along the wound edge and can be used in highly vascularized regions for additional hemostasis.

Running subcuticular sutures typically use a nonabsorbable suture and are used for trunk and extremity closures where sutures are left for 2–3 weeks. Since the suture is buried, it can be left in place for a longer period without developing cross-hatch marks (Fig. 37-12). A single loop coming out in the middle of larger wounds can help facilitate removal of the suture. Alternatively, absorbable suture can be used and can eliminate the need for removal.

CRYOSURGERY

Cryosurgery is used for the treatment of numerous benign, premalignant, and malignant skin lesions. Most dermatologists employ cryosurgery extensively because it is easy to use, cost-effective, and versatile. Postoperative wound care is relatively simple, and complications are uncommon. Although a number of cryogens have been used (e.g., ethyl chloride, CO_2, NO), liquid nitrogen, with a boiling point of –195.6°C, is most widely utilized.

The mechanism of injury in cryosurgery is the result of multiple factors, including mechanical damage to cells resulting from intracellular and extracellular ice crystal formation, exposure to high electrolyte concentrations in surrounding nonfrozen or thawing fluid, recrystallization patterns during thaw, and ischemia caused by vascular stasis and damage. Rapid freezing causes intracellular ice crystals that are more destructive than the extracellular crystals formed during slow freezing. Tissue damage is maximized with a slow thaw time, which causes increased solute gradients and greater cell destruction. Multiple freeze-thaw cycles can further increase damage to the target lesion.

There are several techniques for cryosurgery. The simplest is the use of a cotton-tipped applicator. Varying the amount of pressure applied and duration of contact of the applicator to the skin can control the depth of freeze. Additionally, the volume of liquid nitrogen can be increased or decreased by adding or removing cotton from the applicator tip. Viruses have been shown to survive in liquid nitrogen, so cotton-tipped applicators should never be reintroduced to the storage container. Rather, a small amount of liquid nitrogen

should be transferred to an individual container and discarded after use.

Spray application is one of the most common methods of cryosurgery. This technique uses a handheld liquid nitrogen spray unit with an adjustable nozzle to vary the size of the stream delivered. An insulating cone or a disposable otoscope speculum can be used to focus the delivery of liquid nitrogen, resulting in a deeper freeze and finer control with less damage to uninvolved skin (Fig. 37-13).

Basal cell carcinomas (BCCs) can be treated with cryosurgery. However, alternative surgical options are more routinely performed for the treatment of BCCs given the cure rates obtained, tolerance of the procedure, and aesthetic outcomes achieved. Freezing to reach a target temperature of approximately –50°C, as measured by a thermocouple, is appropriate for management of these tumors. This translates to a thaw time of approximately 60 sec, with a freeze margin of approximately 5 mm (Fig. 37-14). It is important to recognize that the pain associated with such treatment requires local anesthesia. Kokoszka and Scheinfeld found a recurrence rate of less than 10% for primary small, noninfiltrating (superficial and nodular) BCC treated with cryosurgery. Some have suggested that initially treating the tumor with curettage, followed by cryosurgery, can lead to cure rates consistent with curettage and electrodesiccation. However, Kuijpers et al. suggested that standard excision provides higher cure rates than curettage and cryosurgery and recommend that excision be used as the preferred treatment for BCC, because of the higher cure rate, better cosmetic outcome, and faster healing.

Side effects of cryosurgery are similar to those of other ablative procedures (e.g., curettage and electrodesiccation) and include blistering, crusting, pain, a 3- to 4-week healing period, and scarring. Because melanocytes are more susceptible to thermal damage than keratinocytes, hypopigmentation can often be seen, especially in individuals with darker skin tones. Although more frequently seen with longer freeze-thaw times, pigment alterations can be observed even with very brief treatment cycles. A self-limited hyperplastic or pseudoepitheliomatous healing response may occur approximately 2–4 weeks after freezing. Nerve injury can occur during cryosurgery. Anatomic locations with superficial nerves (e.g., lateral aspects of fingers, ulnar groove of elbow, preauricular and postauricular skin) are especially susceptible to this complication. Techniques to limit this risk include tenting the skin up and away from the nerve, ballooning the skin with lidocaine, or sliding the skin back and forth over the underlying fascia during treatment to limit exposure to the underlying nerve. Alopecia can occur when treating hair-bearing areas. Both atrophic and hypertrophic scars can be seen after cryosurgery.

CURETTAGE

The curette has long been a standard tool in the dermatologist's surgical management of neoplasm. This round, semisharp knife is available in sizes from 0.5 to 10 mm, allowing for the removal of a variety of lesions. Since it is not as sharp as a scalpel, the curette does not easily cut through normal skin. Therefore, it is best suited for use on soft or friable lesions,

Fig. 37-14 Cryosurgery. A, Basal cell carcinoma on the posterior helix. B, Cryosurgery to neoplasm. C, One week later, with necrosis and sloughing of treatment area. D, Final result several months later.

such as warts, seborrheic and actinic keratoses, the papules of molluscum contagiosum, and select BCCs and squamous cell carcinomas (SCCs). The proper selection of lesion, location, and size of the curette, combined with the surgeon's technique, all play a role in both the therapeutic and the cosmetic outcome.

The skin should be stabilized with the nondominant hand while the curette is held like a pencil. Curettage should be performed in a centripetal manner (from the outside in) to avoid stripping sun-damaged skin and creating a larger wound. To ensure complete destruction, curettage should be performed in multiple directions to produce symmetric wound margins. A large curette can be used for initial debulking, followed by a smaller curette to remove any residual foci or extensions. Curettage is complete when the "gritty," firm sensation of normal dermis is felt, and slight punctate dermal bleeding occurs.

Curettage combined with electrodesiccation (C&E) is widely used for the treatment of BCC and SCC (Fig. 37-15). Silverman et al. reviewed the cure rates of primary BCC treated with C&E over a 27-year period at New York University, stratifying low-, middle-, and high-risk anatomic locations and the risk of recurrence after C&E of primary BCC. Low-risk anatomic sites (neck, trunk, and four extremities) had a 5-year recurrence rate of 3.3%. Middle-risk sites (scalp, forehead, pre-/postauricular, and malar areas) had an overall recurrence rate of 12.9%, but this was reduced to 5% when limited to noninfiltrative carcinomas of less than 1 cm. High-risk sites (nose, paranasal, nasolabial groove, ear, chin, mandibular, perioral, and periocular areas) had an overall recurrence rate of 17.5%, but a more acceptable 5% recurrence rate was achieved when treatment was limited to lesions of less than 6 mm.

In addition to size and anatomic location, the histologic subtype is an important factor in the effectiveness of C&E. Infiltrative and micronodular BCCs are not appropriate for C&E, whereas it can be considered a therapeutic option in superficial and nodular subtypes. Blixt et al. demonstrated that tumors with high-risk histologic subtypes (e.g., infiltrating, micronodular, desmoplastic) had overall recurrence rates of 27% when treated with C&E alone. SCC in situ may be appropriately treated with C&E, although in most circumstances, invasive SCC would not typically be amenable to this modality.

There is little agreement regarding the requisite number of cycles of C&E. In fact, treating all lesions identically with a particular number of cycles may lead to overtreatment of some lesions and undertreatment of others. In general, accepted therapy employs three cycles to treat most malignant lesions. However, smaller superficial malignancies may be treated with fewer cycles; the rationale is to improve cosmetic outcome while still achieving acceptable cure rates. Nonetheless, the success of C&E relies on the surgeon's ability to identify by feel and appearance the tissue to be ablated. Finally, C&E should be replaced by excision if curettage extends into subcutaneous tissue. As such, lesions previously biopsied using a punch that has extended into the subcutaneous fat may be less amenable to C&E.

ELECTROSURGERY

Electrosurgery comprises a variety of surgical techniques, applications, and apparatuses. In general, the tissue effect is created by heat delivered to or generated in the tissue as a result of an electric current. Various forms of electrosurgery are routinely used by dermatologists for applications such as destruction, hemostasis, excisions, and cosmetic procedures. An understanding of the different modalities and their applications can improve surgical outcome (Fig. 37-16).

Electrocautery

Electrocautery is most often performed today with battery-powered, handheld, disposable units. Direct current is passed through a metal treatment tip. Resistance to the flow of current causes heat to be generated, which can be adjusted by the intensity of the current. Hemostasis is achieved by direct heating of the tissue; no electric current passes through the patient. Therefore, this device may be considered in patients with implantable cardiac devices sensitive to electric current.

Electrodesiccation and electrofulguration

Electrodesiccation (desiccate, "dry up") and electrofulguration (*fulgur,* "lightning") represent the most common uses of electrosurgery in dermatology. In electrodesiccation, the electrode tip is in contact with the tissue; with electrofulguration, a 1–2 mm separation between the tip and the tissue produces a spark. Electrodesiccation causes a deeper wound, whereas electrofulguration is more superficial.

A highly damped (decreasing amplitude) waveform of high voltage and low amperage is produced by a spark-gap generator. This is a monoterminal current, so a grounding electrode on the patient is not required. Electrodesiccation/fulguration produces superficial destruction, because the carbonization on the treated surface limits damage to deeper tissue.

This type of electrosurgery has numerous applications in the daily practice of dermatology. Superficial, small dermal tumors, such as syringomas or seborrheic keratoses, may be treated with electrodesiccation. Insertion of the fine, epilating needle into the tumor is followed by the application of low current until a surface bubbling occurs. The small amount of char is then removed with a curette, resulting in a smooth surface appearance. In addition, skin tags, warts, and fine telangiectases may all be effectively removed by this technique. Electrodesiccation or fulguration is typically employed in treatment of many BCCs and SCCs (see Curettage). It is also useful in excisional surgery to obtain hemostasis. The field must be dry, because the destruction by this current is superficial and will not be transmitted through blood.

Electrocoagulation

Electrocoagulation employs moderately damped current with a lower voltage and higher amperage. The patient is incorporated into a biterminal circuit. Electrocoagulation causes greater tissue damage and deeper penetration than electrodessication or electrofulguration.

Electrosection

Electrosection employs an undamped, low-voltage, high-amperage current in a biterminal manner. This technique has the advantage of cutting with simultaneous hemostasis. As such, it is used for bloodless excisional surgery of protuberant masses and growths, such as rhinophyma. There is vaporization of tissue with minimal heat spread. Extra care must be taken with this technique; maintaining an appropriate depth can be difficult, given the ease with which the device can cut through skin. When the device is properly used, fine surgical excisions can be produced, with minimal trauma to surrounding tissue and excellent hemostasis. Various handpiece attachments, including scalpels, needles, wire loops, and balls, can further adapt the instrument to the specific procedure.

Special care must be taken when using electrosurgery in a patient with a pacemaker or implantable cardioverter-defibrillator, especially if the procedure is performed within a few centimeters of the device. Although modern devices are better shielded and less likely to respond to external electrical interference, it is always prudent to deliver current in short bursts. The physician should also consider the use of electrocautery (heat only, no electrical transmission) or a bipolar device (current transmitted between two tips) when treating these patients. Yu et al. reviewed the use of electrosurgery in patients with cardiac devices.

EXCISIONAL TECHNIQUE

The fusiform or elliptical excision is the workhorse procedure used to treat invasive skin cancers, as well as benign skin lesions needing extirpation (Fig. 37-17; also see Videos 37-4 and 37-5). The basic principle of the fusiform ellipse is excision of a specimen oriented with its longest axis along skin tension lines and its width not exceeding one third of its length. The ellipse can be curved in a crescentic or "lazy S" pattern to align the final scar better with skin tension lines. If the procedure is performed with the correct dimensions (usually a length/width ratio of 3:1) and a 30-degree angle at each pole, standing cutaneous cones at the two extremes of the excision are generally avoided. Standing cutaneous cones represent excess tissue bunching at the poles of a skin closure and should be "sewn out" or excised by triangulation or M-plasty, if needed. Undermining, using sharp or blunt dissection of the skin from underlying subcutaneous tissue, reduces wound tension and helps with wound edge eversion.

SKIN FLAPS AND GRAFTS

Choosing whether to close a wound by linear closure, local skin flap, or skin graft or to allow it to heal by second intention can be complex. Important considerations include patient concerns and ability to perform required wound care, local tissue movement, adjacent anatomic structural preservation and function, and cosmesis.

Healing by second intention

Wound healing by second intention yields excellent results in select clinical settings. Because contraction occurs in wound healing, wounds adjacent to a free margin may result in a pull and distortion. This may affect surrounding anatomic structures (e.g., pull on a nasal rim or eyelid). The wounds may heal with hypertrophic or pigmentary changes. In some areas and situations, however, allowing a wound to heal by second intention is appropriate. These include superficial wounds in concave areas (e.g., medial canthus, conchal bowl, junction between nose and cheek), partial-thickness wounds involving the mucosa of the lip, or certain clinical situations, such as elderly or frail patients with decreased cosmetic concerns (Fig. 37-18). Wound care is straightforward, and postoperative restrictions are minimal.

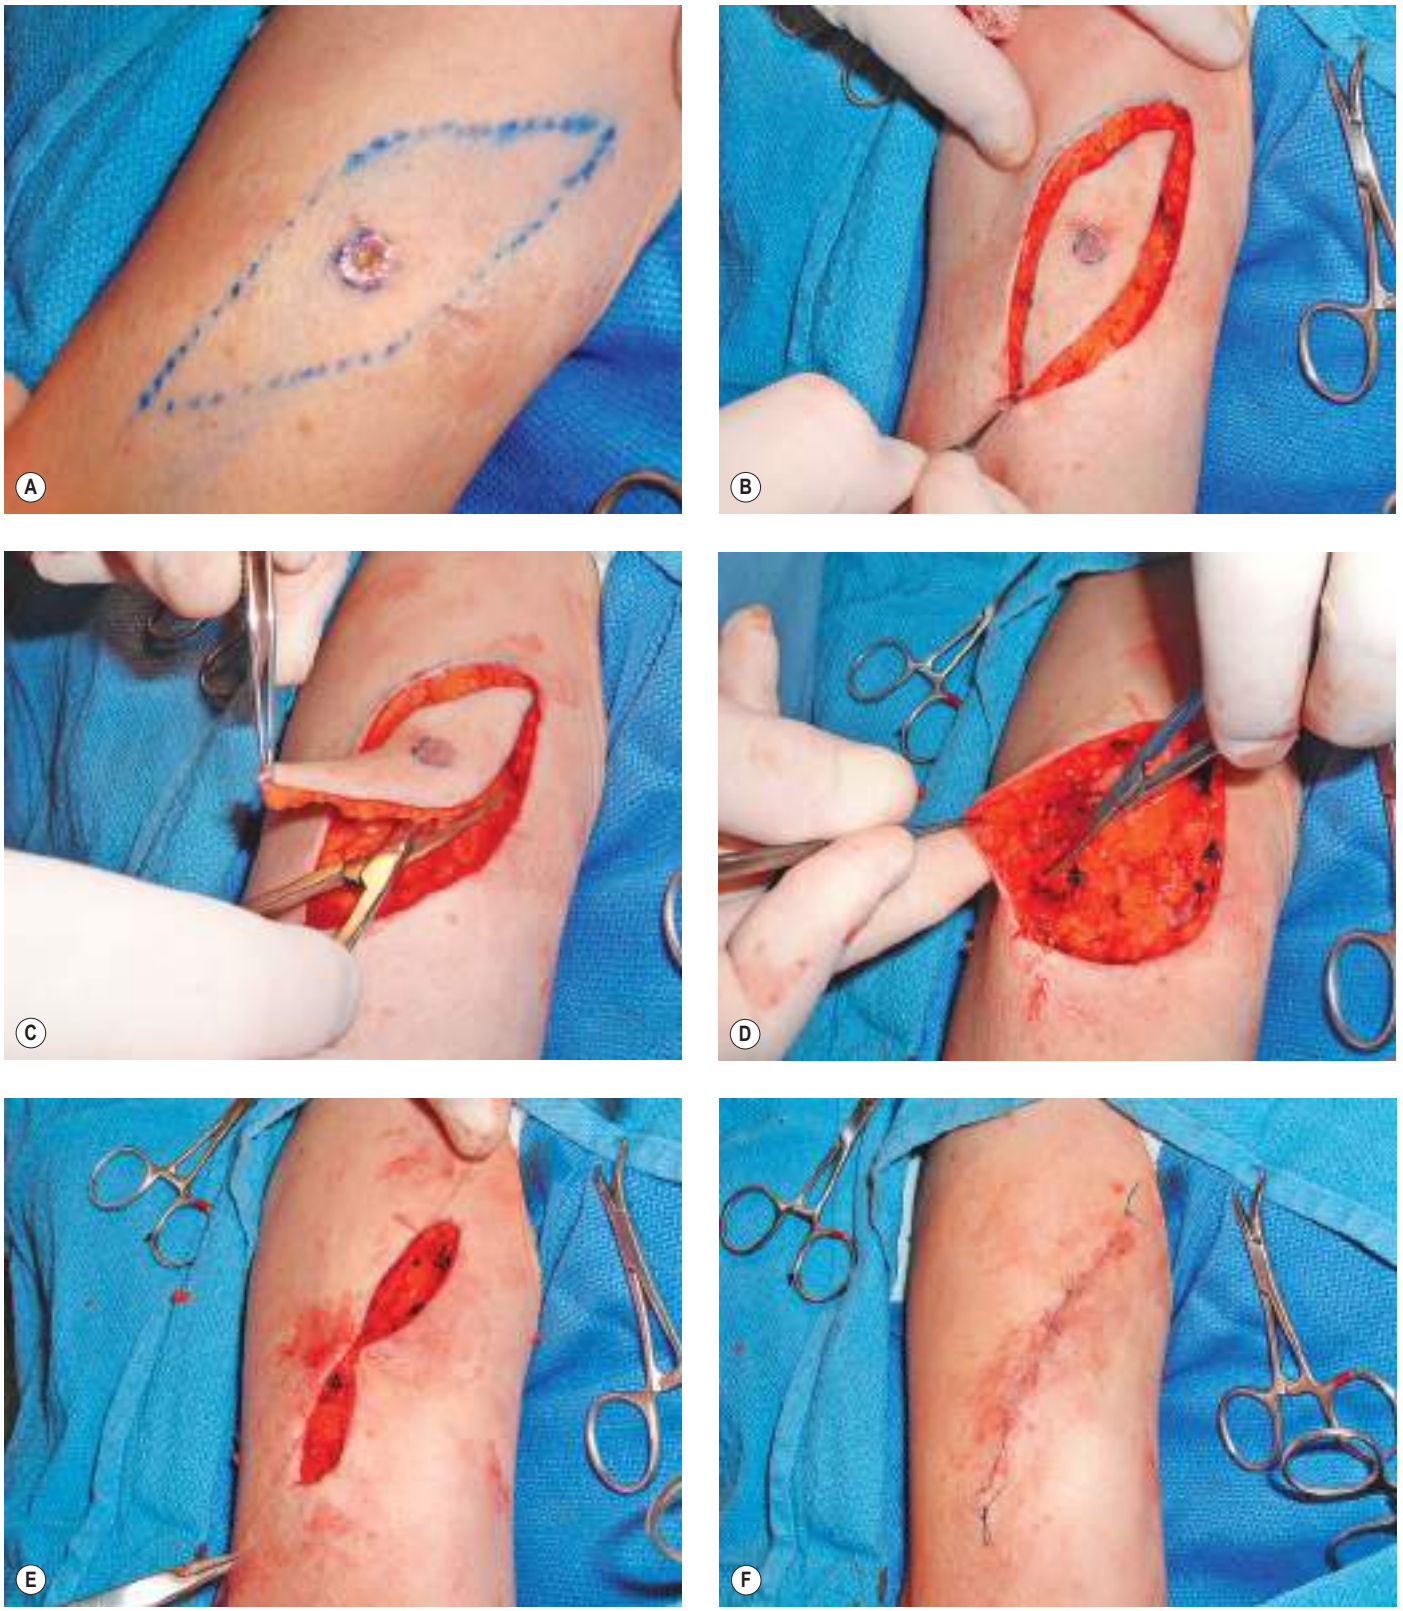

Fig. 37-17 Elliptical excision. A, Ellipse is designed along relaxed skin tension lines with a 3:1 length/width ratio. B, Incision made into subcutaneous tissue. C, Removal using tissue scissors in even plane. D, Blunt undermining of skin edges using skin hook. E, Buried interrupted tension-bearing absorbable sutures placed. F, Epidermal approximation using nonabsorbable running subcuticular sutures, with interruption in center of wound for easier removal.

Flaps

Local skin flaps are geometric segments of tissue contiguous with a skin defect that are advanced, rotated, or transposed to close a wound. Advantages of flaps include better approximation of skin texture and color, hiding incision lines, redirecting tension vectors, and covering exposed cartilage and bone. Flap survival is based on the preservation of the random blood supply along the pedicle. Consideration of both the primary movement of the flap (actual movement of flap into defect) and secondary movement (movement of surrounding tissue in reaction to flap movement) is critical when designing the repair (Fig. 37-19).

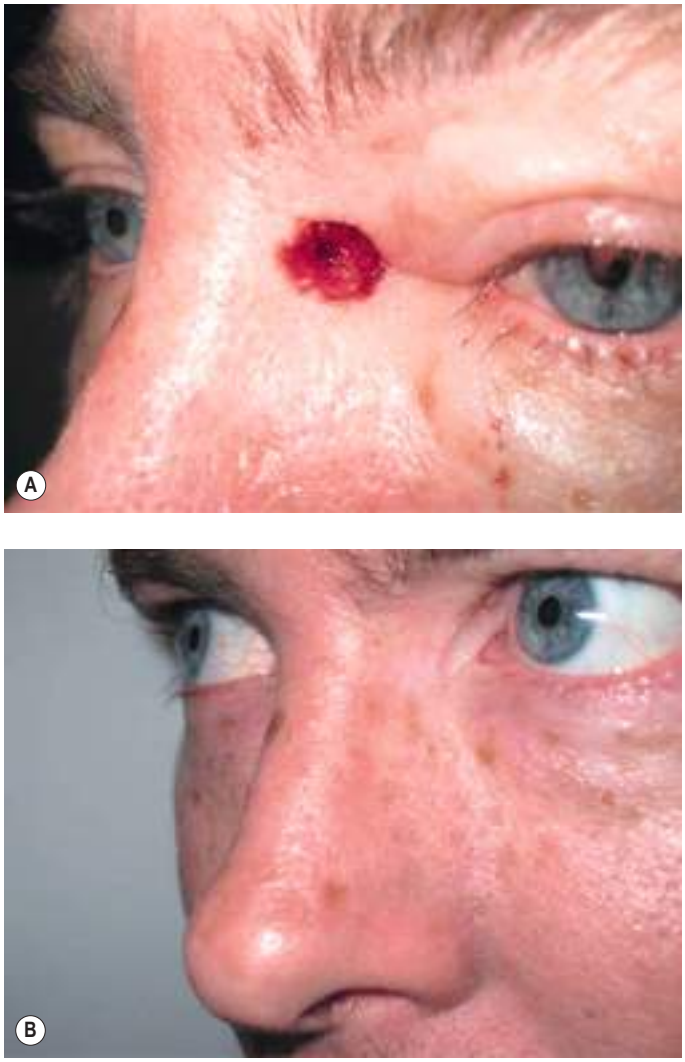

Fig. 37-18 Healing by second intention. A, Mohs defect. B, Final result, 1 year later.

Advancement flap

An advancement flap moves almost entirely in one linear direction (Fig. 37-20). The classic advancement flap involves the creation of a rectangular pedicle, which slides into position over the primary surgical defect. The key suture advances the flap and closes the primary defect. Tissue redundancies at the base of the flap can be removed by triangulation. Survival of the distal tip of the flap depends on blood supply from the base, and thus a maximum length/width ratio of 3:1 should be designed.

If insufficient movement is obtained with a single advancement flap, a bilateral advancement (O-H) can be employed, such that each flap advances to cover half the defect. This repair can be used in eyebrow or helical rim repairs. Single arm advancement flaps (O-L) and bilateral single arm advancement flaps (O-T) are similar to classic advancement flaps, except that only a single incision is made and the standing cone is removed by triangulation. These flaps have the advantage of a larger pedicle providing blood supply and allow a linear portion of the flap to be hidden in an existing rhytid for better cosmetic outcome. Common sites for single arm advancement flaps include the nasal side wall, helical rim, upper lip, forehead, and eyebrow.

The island pedicle flap is a specific variant of an advancement flap (Fig. 37-21). This flap depends on a subcutaneous vascular pedicle for its blood supply and has all the epidermal connections severed by incisions. Care must be taken in designing island pedicle flaps because the incision lines surrounding the flap can result in a patchlike appearance in the final outcome. The best cosmetic results are achieved when at least one of the incision lines can be hidden in an existing rhytid or anatomic boundary.

Rotation flap

The rotation flap can conceptually be considered a variation of the advancement flap, in that it slides into position in much the same way, although in an arcuate manner. Tension vectors from this pulling action are directed along the arc of rotation in reverse fashion (Fig. 37-22). Rotation flaps are often used to close large defects when there is insufficient tissue laxity (Fig. 37-23). The flap has the advantage of good survival secondary to the large pedicle and the ability to recruit skin from a great distance. A back cut can be used to reduce pivotal restraint and provide greater tissue movement, but this may compromise the vascular pedicle. Variations include bilateral rotation flap (O-Z) (Fig. 37-24) or dorsal nasal rotation flap (Fig. 37-25).

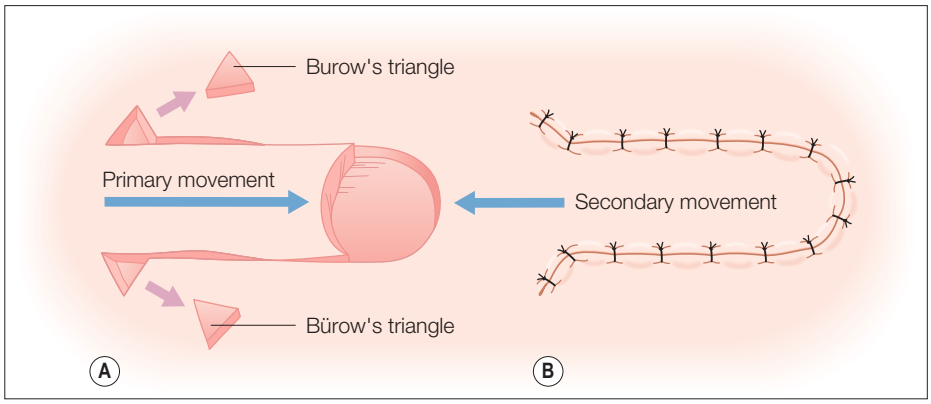

Fig. 37-19 Advancement flap movement.

Fig. 37-20 Single arm advancement flap. A, Advancement flap designed on nasal side wall. B, Final wound closure. C, Three months postoperatively.

Transposition flaps

In the case of the transposition flap, the flap is elevated, transposed over intervening tissue, and sutured into the primary defect. The tension vector is redirected across the closure of the secondary defect (i.e., area originally occupied by flap). This is especially helpful for defects that are adjacent to anatomic free margins. The key suture closes the secondary defect, and the flap is then lifted and transposed into position over the primary defect. The prototype of this flap is the rhombic flap (Fig. 37-26). Other examples include bilobed flaps (Fig. 37-27), nasolabial/melolabial flaps, banner flap, Z-plasty, and Webster's 30-degree flap (Fig. 37-28; also see Video 37-6).

Choice of a particular type of flap involves multiple factors, including location of defect, availability of tissue movement, surrounding structures, effects of tissue movement, and blood supply. Full discussion of flaps is beyond the scope of this chapter and is available in multiple referenced texts. The successful design and execution of flap repairs can be complex and requires appropriate and extensive training.

Z-plasty

The Z-plasty is useful for any reconstructive surgeon, especially as part of scar revision. When used properly, the Z-plasty alters the direction of the scar, lengthens the contracted scar, and changes a linear scar into geometric, broken lines. Z-plasty can thus redirect a scar into the relaxed skin tension lines or can reduce anatomic distortion resulting from scar contracture by lengthening the scar.

In the classic Z-plasty, the scar is the central diagonal, and two symmetric limbs are taken from the end of the scar, resulting in a "z" appearance. The length and angle of these peripheral arms determine the degree of wound lengthening and redirection. In a classic 60-degree Z-plasty, the scar is redirected 90 degrees and the wound lengthened by 75% (Fig. 37-29). Smaller angles result in a less dramatic gain in length. Once the limbs are incised, the two triangular flaps are "flip-flopped" into position and sutured into place. One disadvantage of Z-plasty is the increase in incisions, which often are more difficult to camouflage.

Skin grafts

Skin grafts are employed when primary closure or flap closure is not an available option. By definition, a graft is completely excised from the donor site and is devitalized (i.e., no intrinsic blood supply). Success is predicated on the reattachment of vascular supply to the graft from the defect. Grafts offer the advantage of fewer incision lines compared with local flaps. However, the lack of color and texture match resulting

from the remote donor location of grafts is a potential disadvantage.

Grafts can be categorized as full, split, or composite; when to use each depends on the depth of the defect, vascular supply, and concern about skin cancer recurrence. Full-thickness skin grafts have a full dermis and are the most common grafts used in dermatologic surgery. The graft is defatted, trimmed to fit the defect, anchored in place with peripheral and basting sutures, and secured with a tie-over dressing. Common donor sites include preauricular cheek, postauricular crease, conchal bowl, upper eyelid, upper inner arm, and clavicle. Full-thickness grafts can produce an excellent cosmetic result if executed properly (Fig. 37-30). However, the increased skin thickness results in an increased metabolic demand and a higher rate of necrosis and failure.

Imbibition occurs during the first 24–48 h after graft placement. The graft is sustained by passive diffusion of nutrients

from the wound bed during this stage. It becomes edematous, and the fibrin network attaches the graft to the bed. Inosculation is the next stage, with revascularization resulting from linkage of dermal vessels in the graft to the wound bed. Neovascularization occurs from capillary ingrowth to the graft from the recipient base and side walls. Full circulation can be restored in 7 days and depends on graft thickness and vascularity of the wound bed.

Split-thickness skin grafts have only a partial dermis and are useful for covering large areas or improving surveillance in tumors with a high risk of recurrence (see Video 37-7). Small grafts can be harvested freehand with No. 15 blade or with a handheld Weck blade, using various guards to determine graft thickness (Fig. 37-31). Larger grafts can be obtained using a power dermatome (Fig. 37-32). Grafts can be meshed to provide coverage for larger defects. Compared with full-thickness skin grafts, split-thickness grafts have a higher rate of survival and shorter healing time, do not require repair of the donor site, and are a good choice for areas that are poorly vascularized because of lower metabolic demand. However, split-thickness grafts have a higher degree of contraction, lack skin appendages, and provide a poorer cosmetic match than full-thickness grafts.

Composite grafts usually consist of skin and underlying structure (e.g., cartilage) and are predominantly used to repair such wounds as full-thickness alar rim defects. These grafts have an increased nutrient requirement and thus are more likely to fail. Free cartilage grafts can be used for reconstruction of the ear and nasal ala or tip.

MOHS MICROGRAPHIC SURGERY

Frederic Mohs initially developed this technique at the University of Wisconsin in the 1930s as a means for margin control during surgical excision of skin cancer. The original technique used zinc chloride paste to fix tissue in vivo, followed by surgical excision. Drs. Tromovitch and Stegman in San Francisco modified Mohs technique in the 1970s to a fresh frozen tissue variant that continues to be used today. The basic surgical principles in Mohs micrographic surgery are similar to those used in standard excision, although unique challenges are encountered with Mohs surgery. A complete understanding of pathology, anatomy, cutaneous oncology, advanced surgical reconstruction, and management of surgical complications is critical to a successful patient outcome. Any dermatologist performing Mohs micrographic surgery should be well trained in this technique and all the accompanying challenges of surgical and postoperative care.

Mohs micrographic surgical excision is a tissue-sparing technique that employs frozen-section control of 100% of the surgical margin (see Video 37-8). This evaluation of the entire surgical margin using horizontal sections (not vertical, as used in standard sectioning) combined with precise mapping allows for the highest cure rate of cutaneous neoplasms (Fig. 37-33). In addition, the sparing of normal adjacent tissue can improve cosmesis and decrease the risk of functional defects in a sensitive anatomic location. Any tumor that has a contiguous growth pattern is a candidate for Mohs micrographic surgical excision. Immunohistochemical stains can be used in specific cases to help identify residual tumor.

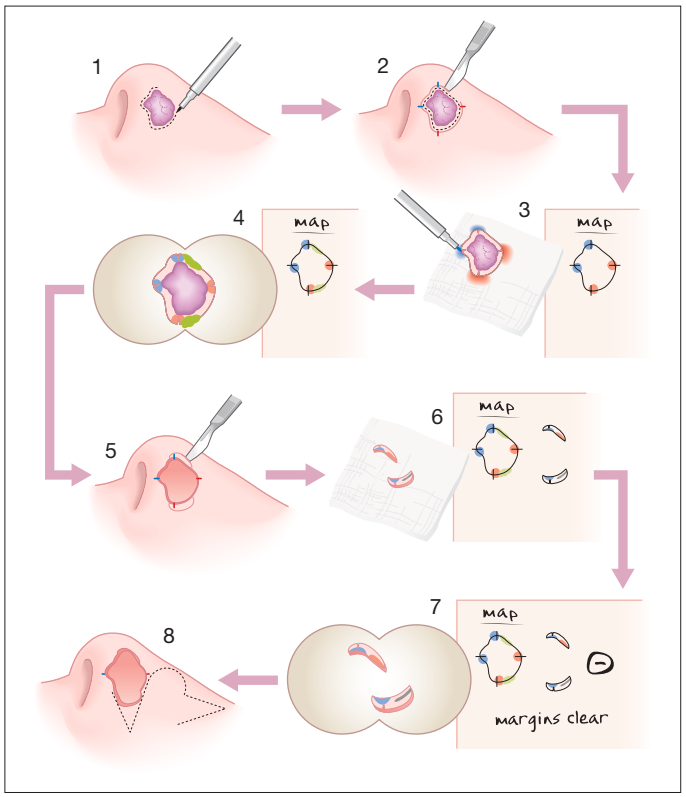

Fig. 37-33 Mohs micrographic surgery process.

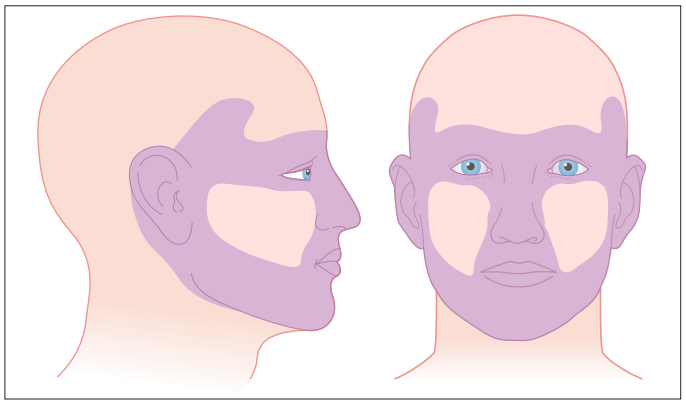

Fig. 37-34 H-zone of the face.

Multiple indications exist for Mohs micrographic surgical excision (Fig. 37-34 and Box 37-4). In an effort to help identify which patients and tumors are appropriate for treatment with Mohs surgery, a joint task force has established guidelines for appropriate-use criteria. These guidelines should be followed to prevent overuse of Mohs surgery for inappropriate clinical situations. A smartphone "app" is available for reference when evaluating patients in the clinic. Mohs surgery provides cure rates of 99% for primary BCCs and 95% for recurrent BCCs. SCCs on the skin and lip treated with Mohs surgery have a 5-year recurrence rate of 3.1% (vs. 10.9% for other modalities). SCC on the ear treated with Mohs surgery has a 5-year recurrence rate of 5.3% (vs. 18.7% for other modalities). Locally recurrent SCC also has reduced recurrence when treated with Mohs surgery compared with other modalities (10% vs. 23.3%). Other tumors that can be successfully treated by Mohs surgery include dermatofibrosarcoma protuberans, atypical fibroxanthoma, and microcystic adnexal carcinoma. Mohs micrographic surgical excision of melanoma continues to be debated. Several studies have demonstrated comparable local recurrence, metastasis, and disease-specific survival rates in head and neck melanomas treated with Mohs micrographic surgery when compared with standard excision. In contrast, Walling et al. showed that staged excision for melanoma resulted in lower recurrence rates and similar-sized defects compared with Mohs surgery.

Box 37-4 Indications for Mohs surgery

- Recurrent or incompletely excised nonmelanoma skin cancer
- Tumors with aggressive histologic subtypes (infiltrative, morpheaform, micronodular, perivascular, or perineural involvement)
- Tumors with poorly defined clinical margins
- High-risk location >0.4 cm (H-zone of the face, eyes, ears, nose)
- Large tumors (>1.0 cm on face; >2.0 cm on trunk or extremities)
- Cosmetically and functionally important areas, including genital, anal, perianal, hand, foot, and nail units
- Tumors arising in immunosuppressed patients
- Tumors arising in previously irradiated skin or scar
- Genetic conditions with increased risk of neoplasms (basal cell nevus syndrome or xeroderma pigmentosa)

PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) involves the activation of a photosensitizer by visible light in the presence of oxygen, resulting in the creation of reactive oxygen species, which selectively destroy the target tissue. The first requirement for PDT is delivery of either a systemic or a topical photosensitizing drug. Systemic photosensitizing molecules are large, lipophilic molecules that require intravenous administration to reach the target site. One of the major disadvantages of these systemic drugs is the prolonged period of phototoxicity. Examples include porfimer sodium and hematoporphyrin derivative. The benzoporphyrin derivative monoacid ring A (verteporfin) has a shorter period of photosensitivity (<72 h) than other systemic agents.

Topical agents offer the advantage of limiting photosensitivity to the application site and have become widely used in dermatology. Delta-aminolevulinic acid (ALA) is the most common photosensitizing agent used in dermatology. It is applied and left on the skin for a sufficient period to allow for accumulation within the target cells. ALA is subsequently converted to the photosensitizer protoporphyrin IX (PpIX), which can then be stimulated through the controlled use of a light source. Tumor cells are thought to be selectively targeted by increased penetration of ALA through the abnormal epidermis overlying the tumor cells. In addition, the iron-deficient, rapidly proliferating tumor cells have an increased production of PpIX compared with normal epidermal cells, resulting in selective photosensitivity and damage to the target site. Methyl aminolevulinate (mALA) is also used as a topical photosensitizing agent. Gentle scraping or curettage before application is performed to increase penetration. Once absorbed, mALA is converted to ALA within the target tissue.

The second requirement of PDT is an appropriate light source to activate the photosensitizer. The light source must match the absorption peak of the photosensitizer. Lasers, intense pulsed-light devices, or an incoherent light source can be used. Red light uses the 630-nm peak of PpIX as its target and has deeper penetration, which is appropriate for dermal processes. Blue light targets the 417-nm peak and has a more superficial penetration, making it an appropriate choice for the treatment of epidermal lesions such as actinic keratoses.

Following absorption of light, the photosensitizer is converted from a stable ground state to an excited triplet state. The excited-triplet-state electrons interact with tissue oxygen, creating singlet oxygen. Singlet oxygen causes oxidative damage to cellular membranes (mitochondria and other cellular organelles) and direct cell death, the key mechanism of action in topical PDT. This entire process occurs over microseconds. In comparison, PDT using systemic photosensitizers predominantly causes destruction of target sites through vascular injury that leads to tissue ischemia.

Actinic keratosis

Numerous studies have demonstrated the efficacy of PDT in the treatment of actinic keratoses, with overall clearance rates ranging from 50% to 70% for a single treatment and up to 90% with additional treatment sessions. Facial lesions tend to respond better than acral or extremity lesions. Initial studies used an extended application of topical ALA for 14–18 h, followed by activation with a variety of light sources (e.g., blue light, red light, pulsed dye laser, intense pulsed light). This protocol resulted in an effective treatment for actinic keratoses on the scalp and face. However, recent studies and clinical practice show that short incubation periods of 1–3 h with ALA are an effective protocol for the treatment of actinic keratoses, vastly improving the convenience of this therapy.

Methyl ALA may offer several advantages over δ-ALA, including improved skin penetration from mALA's increased lipophilic quality, greater selectivity for neoplastic cells, and possibly less pain and discomfort associated with treatment. However, there are no comparative studies for ALA and mALA PDT in the treatment of actinic keratosis. Pariser et al. showed that mALA applied for 3 h, followed by noncoherent red light, resulted in an almost 90% response rate in actinic keratosis. Given the absence of stratum corneum on the lips and the increased penetration of topical ALA, PDT has been used effectively for actinic cheilitis. This may be an option in patients with recalcitrant disease.

Basal cell carcinoma

Studies suggest that topical PDT for the treatment of BCC can have initial clearing and excellent cosmetic results, with cure rates ranging from 64% to 97%. However, despite the initial success, BCCs treated with PDT often have a higher recurrence rate on long-term follow-up. In addition, comparative studies of PDT and traditional surgical treatments (e.g., excision or Mohs surgery) are limited or lacking.

Superficial BCC tends to have better response rates than nodular BCC, likely caused by the limited penetration of both the ALA and the activating light into the deeper portion of the dermis for nodular tumors. Pretreatment with curettage for thicker lesions may help to facilitate penetration of ALA and may result in improved cure rates. Infiltrative tumors have an even higher recurrence rate, suggesting that PDT should not be considered a first-line treatment for this histologic subset of BCC.

Arits et al. compared PDT, topical 5-fluorouracil (5-FU), and imiquimod for the treatment of superficial basal cells. Although all modalities were effective, imiquimod was demonstrated to have higher success rate. Both PDT and 5-FU had similar cure rates over 1-year follow-up. However, individual patient factors must be considered when choosing a treatment option.

Subsets of patients with numerous and extensive BCCs (e.g., basal cell nevus syndrome) may be unique cases in whom PDT can be considered for nodular or more extensive tumors, because of the tissue-sparing and chemopreventive advantages over traditional surgical treatments.

Squamous cell carcinoma in situ

In situ SCC is quite responsive to PDT. Multiple studies demonstrate an initial cure rate of 54–100%, with variable long-term efficacy. Red light should be used instead of blue light because it penetrates more deeply and thus more effectively treats adnexal extensions. Truchuelo et al. demonstrated a 76% clearance of Bowen's disease after two mALA PDT sessions. Calzavara-Pinton et al. used mALA PDT for SCC in situ and reported cure rates of 87.8% at 3 months and 70.7% at 24 months. These patients had good cosmetic outcomes and tolerated the procedure well. In contrast, patients with invasive SCC fared much more poorly with mALA PDT, with a 45.2% cure rate at 3 months falling to 25.8% at 24 months.

Few reports detail the use of PDT for invasive cutaneous SCC. Given the limited success in treating these tumors and the potential for metastatic spread, PDT is not recommended as standard therapy for invasive SCC.

RADIATION THERAPY FOR SKIN CANCER

Radiation therapy (x-ray therapy, XRT) has a long history of use for treatment of both benign and malignant skin conditions. The use of ionizing radiation in dermatologic therapy of benign conditions has decreased greatly, because of highly effective medical therapies and the potential genetic and somatic hazards of radiation. However, XRT for malignant skin conditions remains an important primary and adjuvant therapeutic modality. When used in the proper clinical situation, XRT can provide effective treatment while sparing normal tissue and eliminating the need for surgical reconstruction.

Radiation is an appropriate primary treatment for skin cancer in patients who refuse surgery or who are not optimal surgical candidates. In contrast, patients who are relatively young are less ideal candidates for XRT because of the increased risk of developing additional primary tumors within the radiation field, as well as the long-term cosmetic complications associated with this therapy. Tumors located on the eyelids, nose, ears, and lips can be treated with excellent cosmetic outcomes with XRT, whereas lesions on the extremities are frequently treated by excision because of the larger surgical area that can be easily achieved. Treatment of primary BCC with XRT can produce cure rates greater than 90%, although primary SCC may have slightly lower cure rates. It is important to stress that Mohs micrographic surgical excision of primary tumors can achieve cure rates of 97–99%, often with excellent long-term cosmetic outcomes. Furthermore, Mohs surgery can generally be completed in a single day, whereas XRT is routinely fractionated over weeks.

Recently, superficial XRT and electronic surface brachytherapy have been presented as alternative nonsurgical methods to treat skin cancer. These technologies differ from traditional XRT and classic forms of radionuclide-based brachytherapy. Superficial XRT is "low-energy" therapy. In contrast to other XRT types, where the goal is usually to treat tumors that extend deeply beneath the skin surface, superficial x-rays have very limited penetration and thus primarily target the skin. Electronic surface brachytherapy delivers radiation without using an isotope using a miniaturized x-ray tube. This form of treatment contains no actively radioactive isotope components, so it is subject to much less regulation and offers the advantage of less shielding requirements for patients and staff. Both superficial XRT and brachytherapy have been used for skin cancer increasingly over the past few years. In a retrospective analysis of 1715 BCCs and SCCs treated with superficial XRT, Cognetta et al. reported cumulative recurrence rates of all tumors at 2 and 5 years of 1.9% and 5.0%, respectively. Long-term outcomes for electronic brachytherapy are not yet available, but many centers have reported initial cohorts with good short-term cosmesis. At present, additional research is needed for these modalities to determine their proper role in the treatment and management of cutaneous malignancies.

Radiation therapy may also be considered if surgical margins show microscopic evidence of residual tumor after excision. XRT can be used for recurrent BCC and SCC previously treated with nonradiologic methods, although not with the same success as primary tumors. Caccialanza et al. demonstrated an 84% 5-year cure rate for recurrent BCC and SCC in a group of about 250 recurrent tumors, with almost all having an acceptable cosmetic result. Locke et al. showed that primary tumors treated with radiation had a response rate of 93%, versus 80% for recurrent neoplasms. Mohs micrographic surgical excision of recurrent nonmelanoma skin cancer (NMSC) produces higher cure rates (95%), but if cancers have recurred multiple times, consideration should be given to addition of adjuvant XRT based on negative pathologic features.

Several studies indicate that recurrence of NMSC after primary XRT may be more aggressive and invasive than recurrence after primary surgical treatment. Smith et al. demonstrated that BCCs recurring after primary XRT had deeper

subcutaneous tissue invasion and a larger percentage increase between clinical preoperative tumor area and final postoperative defect area than recurrent tumors that had initially been treated with other modalities. Therefore, salvage surgeries for post-XRT recurrences generally should be undertaken with large clinical margins.

Radiation therapy offers a valuable adjunctive treatment option for particularly aggressive perineural SCC and BCC. Detection of single-cell tumor spread may be particularly difficult after excisional surgery. In addition, perineural carcinoma may spread more rapidly along nerve sheaths than by contiguous growth. With either primary surgery or primary radiation, overall control rates are lower for tumors with perineural invasion. Given the increased risk of metastasis and recurrence in this group of tumors, adjuvant XRT should be considered as prophylactic treatment after surgical excision.

Cutaneous Laser Surgery 38

Cutaneous laser surgery is a continually evolving area of dermatology. Development of new lasers, as well as improvements in existing lasers, continues to advance the field. As a result of this progress, laser surgery has become an extremely effective therapeutic modality for a multitude of dermatologic conditions.

LASER PRINCIPLES

"Laser" is an acronym for light amplification by stimulated emission of radiation. The first laser, a ruby laser, was operated in 1960 by Theodore Maiman. Medical applications were quickly recognized, and Leon Goldman pioneered their dermatologic use.

Although technology has advanced through the years, several distinctive characteristics have remained in all lasers. Compared with other light sources, laser light is defined as monochromatic (i.e., a single wavelength), collimated (i.e., nondivergent), and coherent (i.e., in phase, with peaks and troughs of the light all aligned) (Fig. 38-1). Laser energy is measured in joules (J). Fluence is defined as the amount of energy delivered per unit area (J/cm^2). Power is the rate at which energy is delivered and is measured in watts (1 watt is defined as 1 J/sec).

The wavelength is determined by the active medium of each particular laser. Active medium can consist of a gas (e.g., argon, CO_2), liquid (e.g., dye), or a solid (e.g., ruby, yttrium-aluminum-garnet crystal) (Table 38-1). The choice of wavelength is determined by the target tissue and depth of penetration required (Fig. 38-2).

Continuous-wave lasers emit a beam of light whose output power is constant over time, resulting in a long, continuous exposure. Quasi–continuous-wave lasers shutter the continuous beam into short segments, producing interrupted emissions of constant laser emission. Pulsed lasers produce short, high-energy pulses of light. Q-switched (quality-switched) lasers are able to generate extremely high-energy pulses over very short (nanoseconds or picoseconds) pulse durations and are used primarily for treating pigmented lesions.

Light can interact with incident targets in one of several ways: reflected, transmitted, scattered, or absorbed (Fig. 38-3). Approximately 5% of laser light is reflected from the epidermis and not absorbed. Transmitted light passes unaltered through the tissue. Light is scattered by the various skin structures, molecules, and cells, thus limiting its depth of penetration and effect on tissue. When reflected, transmitted, or scattered, the light has no effect on the target tissue. When absorbed, however, the light energy is transformed into heat. In most cases of laser therapy, it is the heat generated by absorption that produces the desired therapeutic effect.

The concept of selective photothermolysis, originally promoted by Parish and Anderson, is the basis for all laser-tissue interactions. Lasers in cutaneous surgery are selected by matching their particular wavelength with the absorption spectrum of a desired target. The target structures that absorb laser light are defined as chromophores, with the most common in the skin being water, hemoglobin, and melanin (Fig. 38-4). The goal is to deliver a wavelength that is specifically absorbed by the chromophore, inducing heat buildup and the resultant destruction of that target. In an ideal situation, this wavelength would have little or no absorption by surrounding structures. By controlling exposure times and energy delivered (fluence), the amount of heat buildup can be confined to the desired target with minimal or no collateral damage to surrounding structures from heat dissipation, a property defined as thermal relaxation. A target's thermal relaxation time (TRT) is defined as the time required for the heated target tissue to dissipate half the absorbed heat and is related to the size and shape of the target structure. Selective photothermolysis is achieved by ensuring that the laser pulse duration is equal to or less than the TRT of the target tissue. Thus, larger structures (e.g., hair follicles) have a longer TRT and are best treated with longer pulse widths. Smaller structures (e.g., melanosomes) have a shorter TRT and can be treated with much shorter pulse durations (Table 38-2).

The beam diameter of the laser, or spot size, is a factor in depth of laser penetration. Small spot sizes produce significantly more scatter of the laser outside the effective beam, thus resulting in smaller effective treatment areas. In contrast, larger spot sizes produce more photons that remain within the beam diameter, resulting in higher fluences at a given depth. Therefore, with any given wavelength, a larger beam diameter results in a deeper level of penetration (Fig. 38-5).

Epidermal melanin and heat transfer from dermal structures can result in inadvertent epidermal heating and injury. By selectively cooling the overlying skin, while still maintaining sufficient dermal heat to damage the target, the laser surgeon can reduce the chances of epidermal injury. Precooling, parallel cooling, and postcooling have all been used to protect the skin. Dynamic cooling devices use a cryogen spray to cool the skin before and after laser exposure. Contact cooling with a chilled sapphire tip can be used throughout the treatment and is especially useful for parallel cooling. Forced cooled air provides less effective cooling than other methods but can be useful in reducing pain associated with laser treatment. Direct application of ice can also be used for postcooling.

The laser is a technologically advanced instrument that has been used effectively and safely for a wide variety of dermatologic conditions. However, as with any surgery or therapeutic intervention, side effects and complications can occur. Short-term side effects include purpura, edema, and crusting. More concerning, long-term adverse events include scarring (both atrophic and hypertrophic), dyspigmentation, infection, and persistent erythema. Although not a complication, lasers sometimes show a lack of efficacy even when used properly

in appropriate clinical settings. Detailed informed consent is critical before performing any laser treatment. Appropriate instruction and supervision in the use of lasers must be obtained by dermatologic surgeons to ensure optimum safety and surgical outcome. Adverse outcomes in laser-treated patients have a significant medicolegal impact, with nonphysician operators accounting for a significant proportion of these cases. Caution is required for any physician who is supervising these providers when performing laser treatment.

LASER TREATMENT OF VASCULAR LESIONS

A number of congenital and acquired vascular lesions can be effectively treated with laser. Given the variety of choices available, the laser surgeon must have a complete understanding of the inherent differences in wavelengths, pulse durations, and the vessel size of the particular lesion being targeted. Over the years, lasers have become more selective and the treatment of vascular lesions more effective.

Pulsed dye laser

The pulsed dye laser (PDL) was the first laser developed specifically to take advantage of selective photothermolysis. The laser medium is a rhodamine dye, which initially was developed to deliver a wavelength of 577 nm, coinciding with a specific hemoglobin absorption peak. Older lasers used a wavelength of 585 nm, but for various technical and clinical reasons, the wavelength has evolved in the current generation of PDL to be 595 nm. Initial pulse durations were about 500 microsecond (μs)/pulse. This was based on calculations that the target, hemoglobin, had a TRT of 1 millisecond (ms) or less. These parameters resulted in immediate postoperative purpura lasting up to 2 weeks.

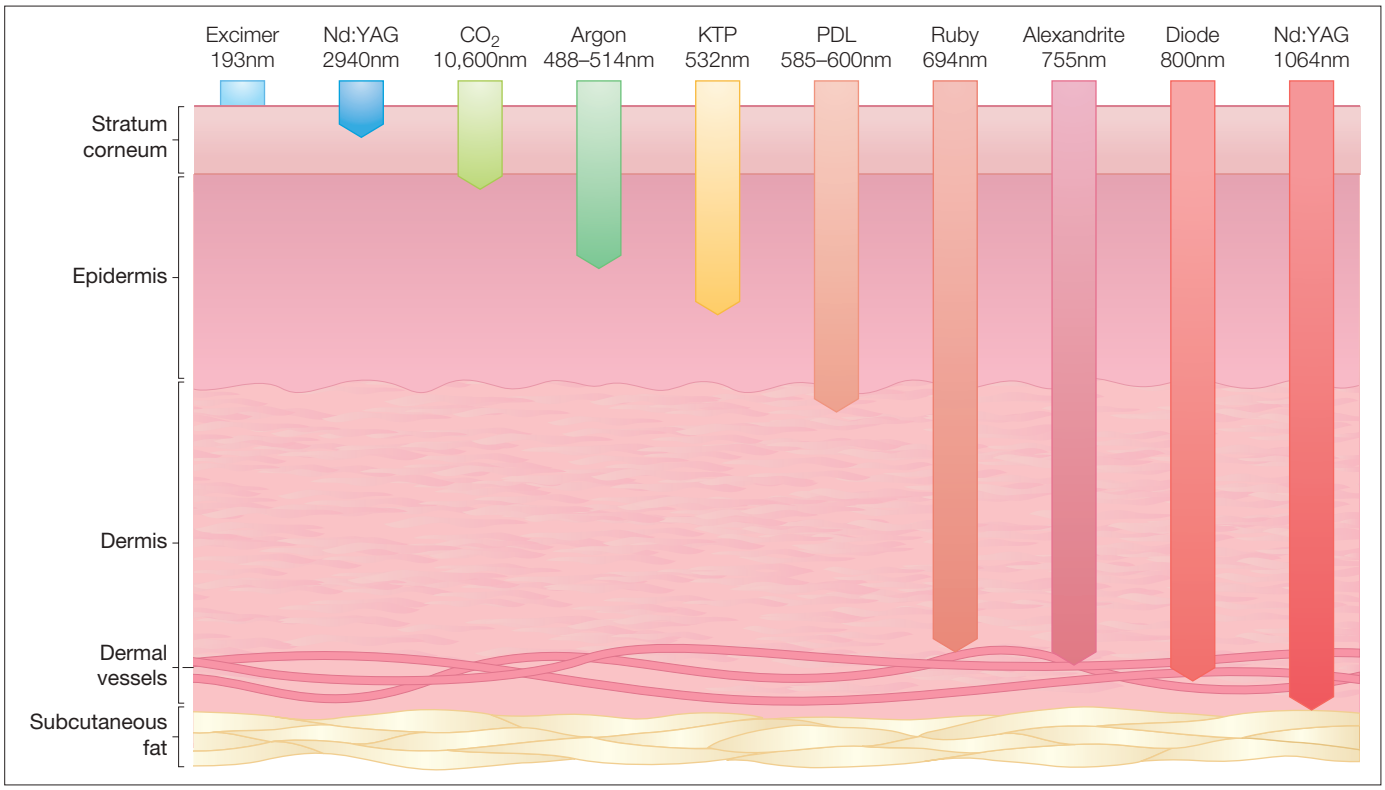

Fig. 38-2 Laser penetration.

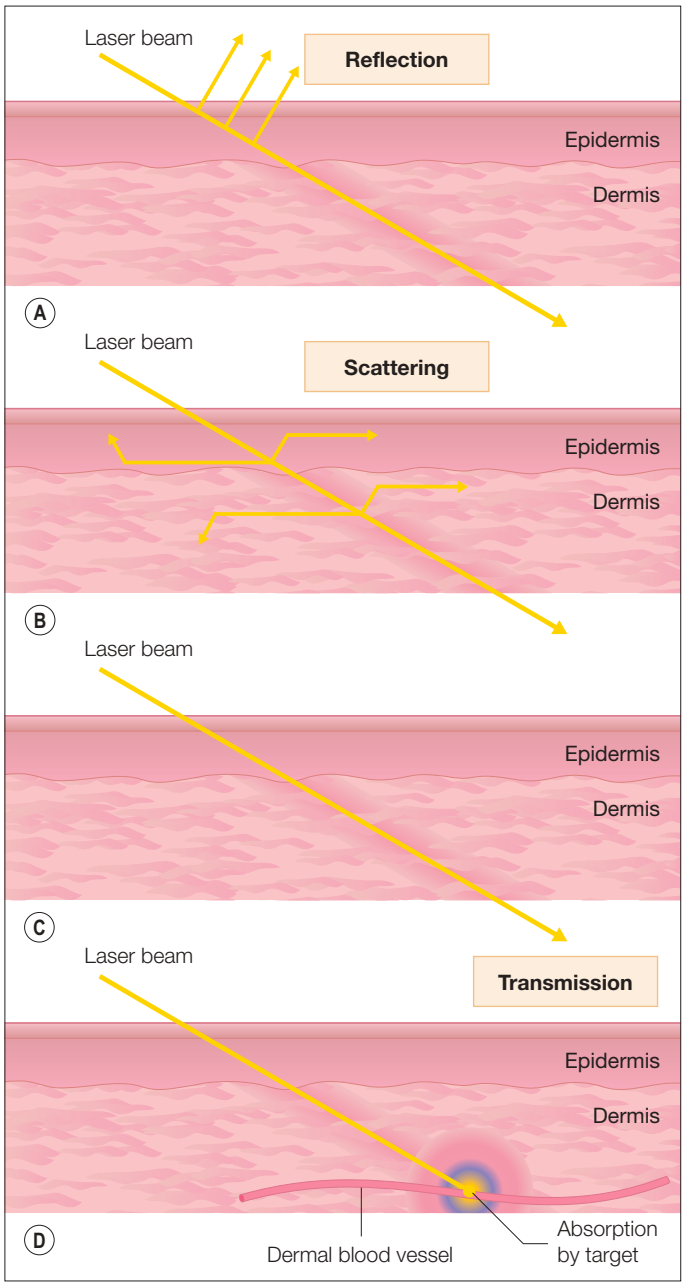

Fig. 38-3 Laser interaction with skin.

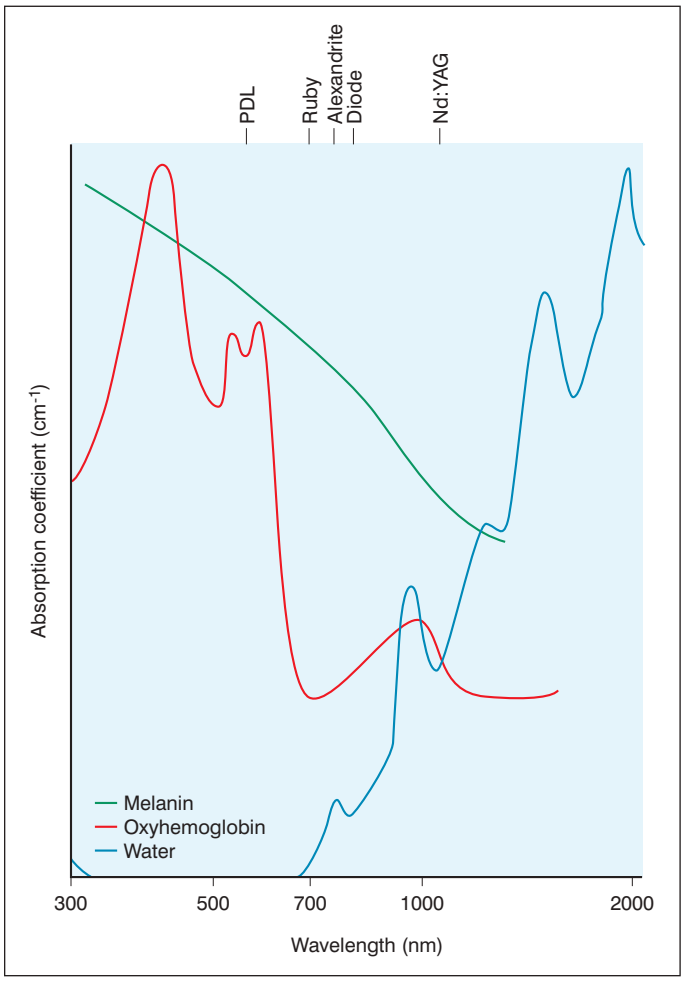

Fig. 38-4 Absorption spectra. The heterogeneous absorption spectra of chromophores allow selective photothermolysis to work.

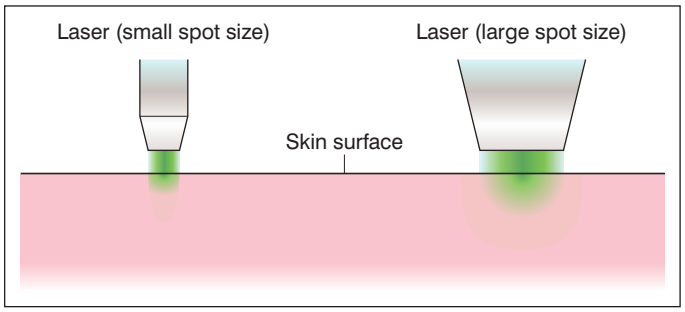

Fig. 38-5 Effects of spot size on scattering. The larger spot size allows more photons to remain within a beam's diameter, whereas with a smaller spot size, a greater fraction of photons scatters outside the beam and is ineffective. Thus, a beam of a given wavelength penetrates to a deeper level with a larger spot size.

Newer configurations of the laser allow for pulse durations from 0.45 to 40 ms, based on newer understandings of TRTs in the context of the size of the target (e.g., capillaries vs. larger vessels) and clinical effects (purpuric vs. nonpurpuric treatment). By using longer pulse durations, gentler and more uniform heating results in reduced or absent posttreatment purpura (more acceptable to patients) than the earlier PDL configurations, while still maintaining clinical efficacy.

The PDL is an extremely useful instrument for the treatment of vascular lesions. These lasers have traditionally been used for port wine stains, telangiectasias, erythematotelangiectatic rosacea, and hemangiomas. The risk of scarring and pigment change is very slight with this technology. PDL is used in a wide range of patients, including newborns. The newer, long-pulsed and longer-wavelength lasers allow for treatment of larger and deeper vessels. By combining these treatments with surface-cooling devices, the epidermis can be protected, which allows for the delivery of greater energy in a safer and less painful manner.

The PDL is the treatment of choice for port wine stains. A series of treatments every 4–6 weeks is required for maximum benefit, with gradual improvement after each session. Although most patients will show improvement, total clearance of lesions is extremely rare (Fig. 38-6). Rate of improvement is related to anatomic location, with lesions on the extremity responding less than facial lesions. Size also plays a role in the response rate of port wine stains. Smaller lesions have greater rate of improvement than larger lesions. Treatments are typically performed with short pulse durations, with resulting purpura lasting for 10–14 days. When the

Table 38-1 Dermatologic lasers

Laser/system	Wavelength (nm)	Color	Applications
Argon	488–514	Blue-green	Vascular lesions
Intense pulsed light (IPL)	515–1200	Green-red and infrared	Vascular lesions, pigmented lesions, epilation, photodamage
Potassium titanyl phosphate (KTP)	532	Green	Vascular lesions, pigmented lesions
QS Nd:YAG (frequency doubled)	532	Green	Vascular lesions, pigmented lesions; tattoo—red
Copper vapor	578/511	Yellow-green	Vascular lesions, pigmented lesions
Flashlamp-pumped pulsed dye (PDL)	585–600	Yellow	Vascular lesions

Table 38-2 Pulse durations and targets of selective photothermolysis

Chromophore	Diameter	TRT	Typical laser pulse duration
Tattoo ink particle	0.1 μm	10 ns	10 ns
Melanosome	0.5 μm	250 ns	10–100 ns
Port wine stain vessels	30–100 μm	1–10 ms	0.4–20 ms
Terminal hair follicle	300 μm	100 ms	3–100 ms
Leg vein	1 mm	1 s	0.1 s

TRT, Thermal relaxation time; ns, nanoseconds, ms, milliseconds; s, second.

treatment is performed with proper cooling and appropriate technique, the risk of atrophic scarring and pigmentary alterations is extremely low. Redarkening of treated port wine stains after treatment with PDL has occurred over time and may necessitate repeat treatments years later.

Ulcerated hemangiomas have been successfully treated by PDL. In addition, following spontaneous resolution of infantile hemangiomas, PDL can be used for any persistent telangiectasias. PDL has a limited depth of penetration, however, and thus is not effective in the treatment of deeper components of hemangiomas, which are likely to continue to proliferate despite laser therapy. The use of PDL for superficial hemangiomas in the proliferative phase remains controversial. Some studies have demonstrated that early treatment with PDL results in improved clearing. However, other authors have advocated that the natural course of hemangiomas is of regression, and that potential risk of ulceration and atrophy from PDL treatment is not warranted for uncomplicated lesions.

Erythematotelangiectatic rosacea is a common condition characterized by persistent facial erythema, telangiectasias, and flushing. PDL has been shown to be an effective and safe treatment option (Fig. 38-7). The long-pulsed PDL has the advantage of purpura-free treatment, which is better tolerated by patients desiring cosmetic improvement.

The PDL has been effectively used for the treatment of warts, producing similar cure rates as traditional therapy. Several reports address the use of PDL for hypertrophic scars. Manuskiatti and Fitzpatrick demonstrated that PDL, intralesional corticosteroid, and 5-fluorouracil (5-FU) produced similar beneficial effects in the treatment of hypertrophic sternotomy scars. The mechanism of action in warts and hypertrophic scars is not clear but may be related to injury to vessels supporting the lesions or simply to heat-related injury. As with other treatment modalities for these two conditions, results are variable.

Potassium titanyl phosphate laser

The potassium titanyl phosphate (KTP) laser produces a visible green beam of 532 nm. Because there is significant hemoglobin and melanin absorption of this wavelength, the KTP laser can be used to treat both vascular and superficial pigmented lesions. The KTP laser is actually an Nd:YAG laser that emits a wavelength of 1064 nm. The beam is passed through a crystal of KTP that reduces the wavelength by 50%, producing the 532-nm wavelength.

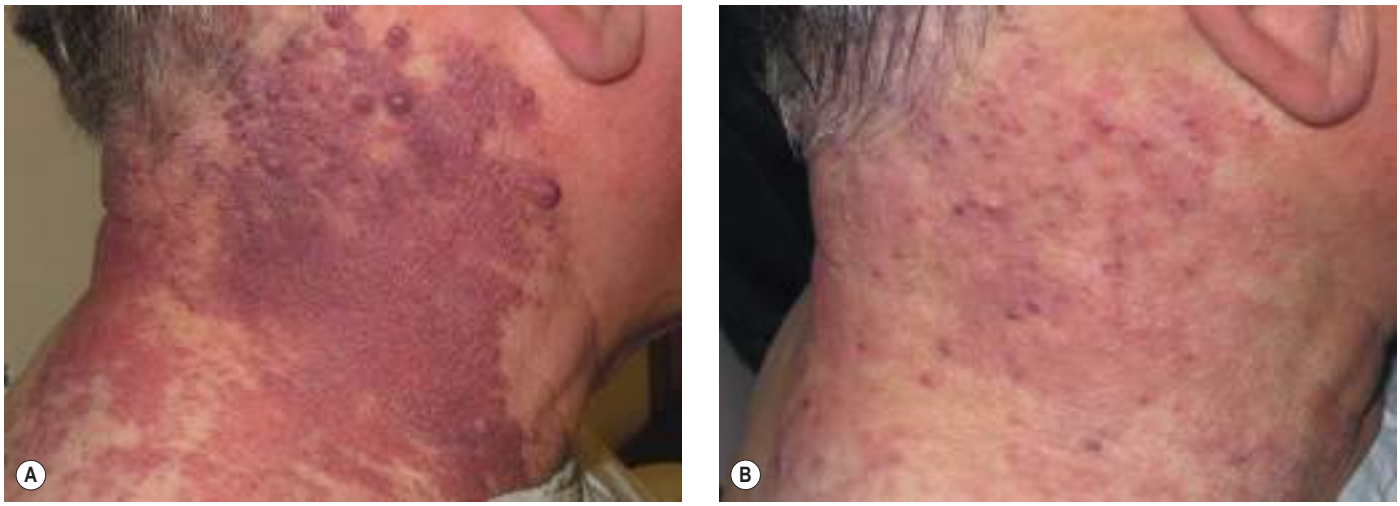

Fig. 38-6 Laser treatment of port wine stain. A, Before treatment. B, After eight treatments with pulsed dye laser.

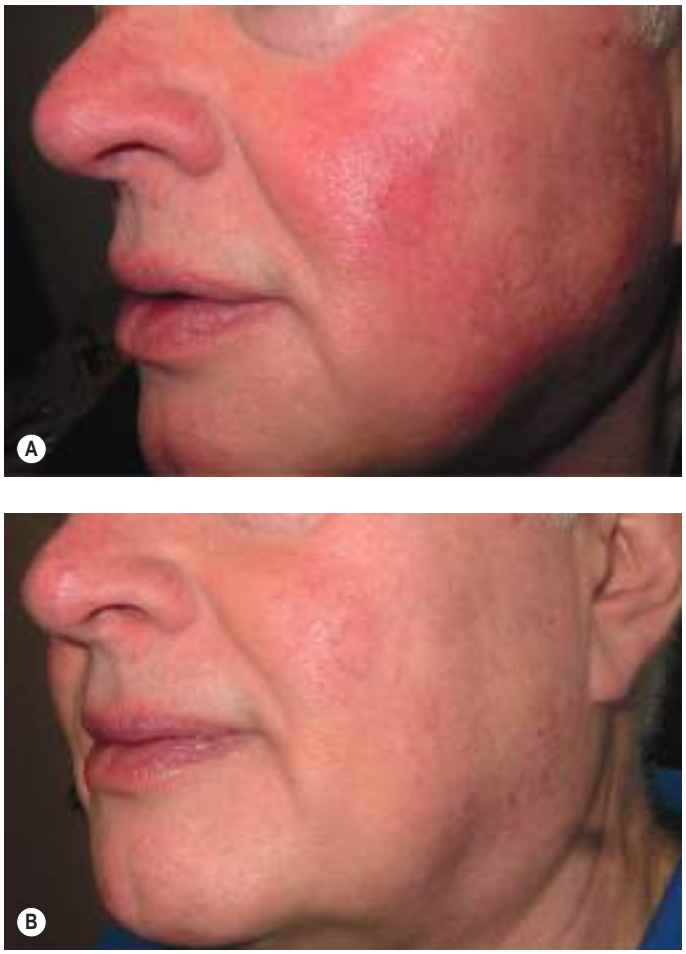

Fig. 38-7 Laser therapy for rosacea. A, Before treatment. B, After two treatments with subpurpuric pulsed dye laser.

Pulsed KTP lasers have pulse durations ranging from 1 to 100 ms. The advantage of these lasers is the strong absorption of their wavelength by hemoglobin. In addition, purpura is not present with the longer pulse widths. The 532-nm wavelength has a limited depth of penetration, making it an excellent choice for the treatment of fine facial vessels. However, it can be absorbed by epidermal pigment to a greater degree than other, longer-wavelength vascular lasers, which increases the risk of pigmentary complications. KTP lasers can be quite compact, allowing for easy transport between various locations. With few moving parts, they are also relatively maintenance free.

The KTP lasers are suited to treatment of individual telangiectasias of the face, cherry angiomas, and small spider angiomas. Since individual vessels must be traced out using a narrow beam diameter, the number of vessels treated in any given session is limited when using certain KTP lasers with smaller spot sizes. However, models with larger spot size and cooling can be effectively used for the treatment of erythematotelangiectatic rosacea and port wine stain.

Long-pulsed infrared lasers

Lasers are now being used to take advantage of the broad oxyhemoglobin absorption band in the near-infrared range. Long-pulsed lasers include the alexandrite (755 nm), diode (800 nm, 940 nm), and neodymium:yttrium-aluminum-garnet (Nd:YAG; 1064 nm). These lasers are best used for larger and deeper vessels, such as large-vessel venous malformations, vascular blebs in port wine stains, blue reticular veins, venous lakes, and lower extremity spider veins (Fig. 38-8).

Intense pulsed light

The intense pulsed light (IPL) system, although technically not a laser, uses a flashlamp that emits a noncoherent broad spectrum of light (400–1200 nm) at various pulse durations and intervals. By employing filters to eliminate the lower wavelengths, light from 560 nm and above can be used to treat various cutaneous conditions. IPL technology has the advantage of treating more than one specific chromophore at a time and is especially useful in improving both vascular and pigmentary changes typically seen in photodamaged skin (see later discussion). In addition, IPL has a relatively large beam size and rapid pulse rate, allowing for the treatment of a large area in a relatively short amount of time. IPL has been used for the treatment of facial telangiectasia and rosacea. There is generally no purpura when appropriate settings are used, but care must be taken to avoid dyspigmentation and blistering in darker skin types. As with other light sources, a series of treatment sessions spaced out every 4–6 weeks is typically required for maximum improvement with IPL systems.

LASER TREATMENT FOR PIGMENTED LESIONS

Highly pigment-selective Q-switched (QS) lasers are used extensively in the treatment of both epidermal and dermal pigmented lesions. In most cases, the target chromophore is the melanosome. These tiny structures have a very short TRT (250–1000 ns), and the development of Q-switching allows for production of extremely high energies and short, nanosecond (ns) pulse durations. As a result, these lasers can produce damage to the selected target while minimizing injury to surrounding tissue.

Q-switched lasers are used to treat epidermal pigmented lesions and tattoos. The delivery of tremendous amounts of energy over a very short period (nanoseconds or picoseconds) produces pressure waves. This photoacoustic effect results in shock waves that shatter the larger ink particles into smaller fragments. Repeated treatments are necessary for complete response. QS lasers include the ruby (694 nm), alexandrite (755 nm), and Nd:YAG, in both a frequency-doubled (532 nm) and standard (1064 nm) mode (Table 38-3). Because of the longer wavelength, the Nd:YAG laser penetrates much more deeply and therefore is more useful in treating more deeply seated or thicker lesions compared to shorter-wavelength QS lasers.

Less pigment-selective lasers can be used in some clinical settings. The variable-pulsed KTP laser can be used to treat epidermal pigmentation, such as lentigines, ephelides, thin seborrheic keratoses, and dermatosis papulosis nigra. Because the KTP laser has a limited depth of penetration, it is not effective in the treatment of deeper dermal lesions. Long-pulsed ruby, alexandrite, and Nd:YAG lasers can also be used to treat

pigmented lesions, but are not as effective as their QS counterparts.

Non-pigment-specific ablative lasers have been used in the treatment of pigmented lesions and tattoos. Carbon dioxide (10,600 nm) and erbium:YAG lasers (2940 nm) target water. They nonselectively remove the entire epidermis and a variable level of dermis tissue, as well as any associated pigment present.

Epidermal pigmented lesions

Lentigines are hyperpigmented macules composed of an increased number of basal melanocytes. These lesions can be effectively treated with a variety of laser and light sources because of their superficial position in the skin. QS lasers can be used to treat solar lentigines and those associated with certain syndromes (e.g., Peutz-Jeghers) (Figs. 38-9 and 38-10). Variable-pulsed KTP provides effective treatment. IPL is an excellent choice for patients with widespread photodamage consisting of both vascular and pigmentary changes.

Café au lait macules and Becker's nevus can be treated with QS lasers. Unfortunately, treatment often results in variable clinical efficacy. Short-term lightening or clearing with multiple treatments is frequently seen, but recurrence is common.

Dermal pigmented lesions

Nevus of Ota and nevus of Ito are dermal melanocytoses that can be effectively treated with QS lasers. A series of treatments can significantly improve or even clear the lesion (Fig. 38-11). These treatments are generally well tolerated and the results long-lasting.

Melasma is an acquired hypermelanosis that is often associated with sun exposure, pregnancy, and oral contraceptives. First-line treatment includes strict sun protection, discontinuing any offending systemic medication, and the use of topical agents such as hydroquinone and retinoids. Laser treatment is often ineffective, and recurrence is frequently seen in patients with initial improvement.

Postinflammatory hyperpigmentation does not generally respond to QS laser. Recurrence or worsening is typically seen because of additional epidermal injury associated with laser treatment.

Tattoos

Pigmentation to mark the skin for decorative purposes has been used by humans for thousands of years and remains a popular practice today. As a result of the increasing number

Fig. 38-12 Laser therapy for tattoo removal. A, Before treatment. B, After six treatments with QS ruby and QS Nd:YAG laser.

of people with tattoos, it should come as no surprise that many patients desire removal. Regardless of the type of tattoo—cosmetic, medical, or traumatic—effective treatment can be frequently offered.

In the past, tattoos were removed by a variety of nonselective destructive techniques, including excision, dermabrasion, cryosurgery, and ablative laser. Although effective in eliminating the ink, these techniques produced significant scarring. With the advent of newer technology that is more specific and less traumatic, these destructive modalities are not generally employed today.

Currently, QS lasers are the first-line treatment for tattoo removal. The delivery of high energy in very short pulse durations causes fragmentation of the tattoo ink particle, which is then eliminated from the body by phagocytosis of macrophages and lymphatic drainage. Repeat treatments are required to achieve maximum benefit (Fig. 38-12).

Patients frequently inquire as to the number of treatment sessions needed for maximum improvement. Unfortunately, a precise answer is difficult to provide and depends on the amount of ink in the tattoo, size of tattoo, location, and color being treated. Traumatic tattoos typically respond extremely well with a short course of treatments. Amateur tattoos typically have less ink and generally have a good response to laser

Fig 38-13 Traumatic tattoo. A, Before laser treatment. B, After two treatments with QS Nd:YAG laser.

treatment. Traumatic tattoos from an injury typically respond very well with a limited number of treatments (Fig. 38-13). In contrast, multicolored professional tattoos have a more unpredictable response and require more treatments, sometimes 10–15 or more, to achieve maximum benefit. The choice of which laser to use depends on the specific tattoo color being targeted (Table 38-4).

Tattoo complications

Textural changes can occur as a result of the repetitive injury associated with laser treatment (Fig. 38-14). Epidermal injury can be seen with excessive fluences and with short treatment intervals. By spacing out treatment sessions, lowering fluences, and using longer wavelengths to protect the epidermis, this can often be avoided.

Hypopigmentation is sometimes seen in patients with darker skin types (Fig. 38-15). Similar to textural changes, pigmentary changes are more common with shorter wavelengths (ruby and alexandrite), which can cause more epidermal damage. Similar precautions can be used to minimize these changes.

Paradoxical darkening of flesh, brown, or white tattoos (with red and yellow ink less frequently) can occur immediately following treatment with QS lasers. The reduction of rust-colored ferric oxide to black-colored ferrous oxide or the white-colored titanium^{4+} dioxide to blue titanium^{3+} dioxide is thought to be responsible for the color change. This reaction

Table 38-4 Tattoo colors and pigments, with lasers used for treatment

Color/etiology	Pigment	Laser
Traumatic	Lead, asphalt, carbon, gunpowder	QS ruby; QS alexandrite; QS Nd:YAG (1064 nm)
Amateur black	India ink, carbon	QS ruby; QS alexandrite; QS Nd:YAG (1064 nm)

is typically seen is cosmetic tattoos used for lip liners and eyebrows. However, many brightly colored tattoos have some white mixed in with them, so caution must be taken in these circumstances (Fig. 38-16). A test treatment in a limited area should be done if paradoxical darkening is possible. The darkened tattoo can be treated with the appropriate QS wavelength, but response is unpredictable and requires numerous treatments.

Despite appropriate treatment, tattoos may not respond completely. This may result from the color, ink density, anatomic location, or age of the tattoo. Appropriate preoperative counseling is required before embarking on any treatment course.

Treatment of gunpowder traumatic tattoos can result in microexplosions and scars. Care must be taken when treating these patients.

LASER HAIR REMOVAL

Laser hair removal is widely used for the permanent reduction of hair and is one of the most popular laser procedures performed. Hair removal lasers target the melanin within the follicle, and given the size of the target chromophore, longer pulse durations are required to generate enough heat to damage the bulbar stem cells. Patients with dark hair and lightly pigmented skin are the best candidates for treatment. In contrast, white, blond, and gray hairs generally respond poorly given their absence of a sufficient pigment target.

Patients must avoid waxing, electrolysis, or plucking of hairs before laser treatment, because hair is required to be present as a target. Shaving before laser treatment is acceptable and will not interfere with efficacy. Shaving is mandatory immediately before treatment to avoid epidermal injury from absorption of the laser by hairs on the surface of the skin. Only hairs in the anagen growth phase are permanently injured. Therefore, sufficient time must elapse between treatments for hair to regrow and provide an appropriate chromophore for subsequent laser treatment, generally 6–8 weeks.

Devices currently used for hair removal include the long-pulsed ruby, alexandrite, diode, and Nd:YAG lasers and IPL. Multiple treatments are required for maximum benefit. In addition, these longer-pulsed lasers can produce a significant reduction in both hair and papules/pustules in patients with pseudofolliculitis barbae, acne keloidalis nuchae, or folliculitis decalvans.

Complications are rare with proper patient selection and treatment parameters. Excessive fluences or insufficient cooling can result in epidermal injury (Fig. 38-17). Caution must be employed in treating patients with increased skin pigmentation caused by sun tanning, because pigmentary changes and cutaneous burns can occur. Since melanin is the target for these lasers, care must be taken in treating more darkly pigmented patients to avoid epidermal damage. In this patient population, the longer-pulsed Nd:YAG laser has allowed safe treatment with fewer complications, because of the deeper penetration and reduced melanin absorption of this wavelength. Paradoxical hypertrichosis as a result of laser hair treatment has been reported. The etiology is unclear, but the condition seems to occur more frequently in darker skin types. Rarely, atypical cutaneous infections have been reported. Interestingly, studies have shown that laser hair removal is the most common litigated laser procedure, with nonphysician providers accounting for a significant proportion of these cases.

ABLATIVE LASER RESURFACING

Both carbon dioxide (CO_2) and erbium:YAG (Er:YAG) lasers are absorbed by water. Since water makes up 72% of the skin, these lasers effectively ablate the skin to varying depths depending on the energy delivered. Ablative lasers can be used therapeutically to treat conditions such as warts, adnexal tumors, and actinic damage. In addition to these medical indications, ablative lasers can also be employed to remove very superficial external layers and resurface the skin for cosmetic enhancement (e.g., acne scarring, photorejuvenation [see Video 38-1]). Despite all the efforts to produce nonablative resurfacing technology, ablative lasers remain unparalleled in producing meaningful and dramatic rejuvenation.

Early systems employed a continuous-wave mode of emission, which led to a greater degree of thermal damage and risk of scarring. Newer, high-energy, ultrapulsed and computerized scanning systems have allowed a greater degree of control with laser ablation, resulting in more predictable outcomes.

Carbon dioxide lasers

The CO_2 laser emits an invisible infrared beam of 10,600 nm and can be used in continuous-wave or superpulsed mode. Water nonselectively absorbs laser energy, turning it instantly into steam, and producing ablative and thermal damage. Used in the superpulsed mode, the laser beam can be delivered in short bursts, allowing thermal destruction of the epidermis and papillary dermis while limiting deeper thermal damage. Delivery in this mode is more uniform and much faster when the optomechanical scanner is employed. Superpulsed CO_2 lasers are extremely effective for the treatment of actinic damage and photoaging. The thermal injury causes conformational changes within the collagen, leading to clinical tightening. As such, ablative laser resurfacing produces significant improvement in wrinkling, scarring, and skin tone.

Ablative laser surgery can be performed safely and comfortably under local anesthesia in the outpatient setting. Oral anxiolytics are routinely employed before starting the procedure. Regional blocks and local infiltration of anesthesia can provide effective pain control. Metal eye shields and anesthetic eye drops (e.g., proparacaine) should be used to provide eye protection. Wet towels are placed around the treatment site to prevent fire or heat injury.

Side effects include postinflammatory pigmentary changes, especially in patients with Fitzpatrick skin types III–VI. Treatment with hydroquinone at the first sign of hyperpigmentation can effectively reduce the hyperpigmentation. Hypopigmentation is frequently seen after resurfacing and is often caused by the contrast between treated and untreated skin. To minimize the aesthetic impact, the entire face should be treated or, if this is not possible, regional subunits to avoid a clear line of demarcation. Scarring and textural changes can rarely be seen. Prolonged erythema can last 3–10 months. Bacterial, viral, and fungal infections have all been reported with resurfacing but have a relatively low incidence. Prophylactic antiviral agents are typically started on the day of the procedure, even in patients with no history of orolabial herpes simplex virus (HSV) infection. There is no role for universal antibiotic or antifungal prophylactic treatment in patients undergoing resurfacing. Rather, treatment can be started empirically if patients develop infection, then tailored based on culture results. Given the morbidity of the postoperative course and prolonged recovery associated with ablative resurfacing, patients must be properly counseled during the preoperative visit.

Used in the quasi–continuous-wave mode, the CO_2 laser is an excellent therapeutic choice for very large plantar and periungual warts that have failed to respond to routine office modalities. Both a cutting mode and a defocused ablative mode can be used with these systems to excise the visible verrucae effectively and to treat any residual human papillomavirus in surrounding skin.

The CO_2 laser is also a treatment option for refractory keloids. Other benign lesions amenable to CO_2 laser ablation include xanthelasma, rhinophyma, and syringomas. Various malignant and premalignant lesions are also effectively treated by laser ablation, including actinic cheilitis and superficial basal and squamous cell carcinomas.

Erbium:yttrium-aluminum-garnet laser

The Er:YAG laser emits an invisible near-infrared beam of 2940 nm, resulting in significantly more efficient absorption by water (16 times) and a more explosive ablative effect than with the CO_2 laser. As such, the Er:YAG laser results in tissue ablation with less surrounding thermal damage. In addition, this wavelength is close to a collagen absorption peak, thus allowing for greater collagen ablation than the CO_2 laser. The decreased thermal injury and collagen ablation is an advantage for treatment of scars, photodamaged skin, rhytids, and rhinophyma (Figs. 38-18 and 38-19). Some maintain that healing may be slightly faster, with less risk of prolonged erythema and scarring. Nonetheless, the depth of injury produced (regardless of technology used) is the primary determinant for the healing process and incidence of side effects, not the laser used.

Compared with the photocoagulation effects of the CO_2 laser, the decreased thermal damage produced by the Er:YAG laser can result in poor hemostasis. To address this limitation, certain Er:YAG systems have a programmable coagulation

mode to limit the amount of intraoperative bleeding. In addition, the collagen-tightening effect may not be as pronounced as with the CO_2 laser. However, when similar clinical injuries and depth are achieved, studies have shown that the Er:YAG and CO_2 lasers have comparable photorejuvenating effects, as well as similar postoperative healing times and complication profiles.

Fractional resurfacing

In fractional photothermolysis, an ablative laser is administered in a pixilated pattern over a grid. These lasers created small columns of thermal injury, or microthermal zones (MTZ), which are separated by areas of untreated skin. Only 15–25% of the skin surface is typically ablated during a treatment session, so this technique allows for more rapid reepithelialization, compared with the confluent patch of laser-induced injury typically created with traditional ablative resurfacing. The injury created by MTZ results in the stimulation of collagen synthesis and cutaneous remodeling, much in the same manner as traditional resurfacing, but to a proportionately lesser degree.

Fractional resurfacing has been used for the treatment of photoaging, with the advantage of more rapid healing, reduced erythema and swelling, and fewer side effects. Fractional resurfacing has also been used for such indications as acne scars, residual hemangioma residuum, and pigmentary disorders. An additional advantage of this technology is the ability to treat any anatomic location, including hands, chest, neck, and arms. However, patients often need multiple treatment sessions to achieve maximum benefit, and the final result is not nearly as impressive as with traditional ablative resurfacing. In addition, the cumulative downtime required with multiple treatments may exceed that of a single ablative resurfacing treatment, thus negating the perceived benefit of fractional resurfacing.

Fractional ablative resurfacing has been used for the treatment of acne scarring. It has also been used for residual hemangioma and pigmentary disorders such as melasma.

Cosmetic Dermatology 39

Dermatologists have been leaders in the field of cosmetic surgery. Many procedures, products, and technologies in cosmetic dermatologic surgery have been developed and researched by dermatologists. Patients are increasingly turning to dermatologists for the management of cosmetic issues. As a result, the specialty must continue to be at the forefront of cosmetic procedures and remain committed to advancing the field through innovation and scientific progress.

SOFT TISSUE AUGMENTATION

Soft tissue augmentation has been gaining in popularity in recent years as patients seek cosmetic improvement without undergoing invasive procedures. Numerous fillers are available to correct soft tissue contour abnormalities and provide cosmetic enhancement. Although they provide numerous advantages over surgical techniques, the temporary nature of most fillers requires repeated treatment to maintain a desired outcome. Some patients find that the temporary nature of these agents is less than ideal, but one must also consider that undesired outcomes of treatment are also temporary. In the last few years, the number of available agents has increased. In Europe, there are as many as 30 different filler choices. The U.S. Food and Drug Administration (FDA) has approved fewer fillers, although several new products have recently become available.

Bovine collagen

Bovine-derived collagen has been used for more than 20 years and is the gold standard against which all filler substances are compared. There are currently three FDA-approved brand-name products for use in soft tissue augmentation: Zyderm I, Zyderm II, and Zyplast (Allergan, Irvine, CA). The source for all three bovine types is a closed herd in the United States, and there have been no cases of bovine spongiform encephalopathy associated with these products. All are composed of 95% type I collagen and the remainder of type III collagen, suspended in buffered saline and 0.3% lidocaine. Zyderm I consists of 35 mg/mL of collagen, and Zyderm II has a higher concentration of 65 mg/mL. Zyplast is cross-linked with glutaraldehyde, making it more resistant to proteolytic degradation, which provides longer duration. All three products come preloaded into syringes and are stored at 4°C.

Bovine collagen hypersensitivity occurs in about 3% of the population, making skin testing a requirement before using these products. Additionally, 1–2% of patients with a negative skin test will subsequently develop an allergic reaction after treatment. Therefore, many dermatologists recommend a second skin test after an initial negative test. Patients may also develop allergy after multiple treatments. Therefore, in patients with a span between treatments of more than 2 years, repeated skin testing is indicated.

Zyderm I and Zyderm II are injected into the superficial dermis, whereas Zyplast is placed deeper. A combination of threading, fanning, and serial puncture injection techniques with a 30-gauge needle can be used. Anesthesia may not be required because the product already contains lidocaine; however, regional nerve blocks may be helpful in sensitive patients or when injecting the lips. Slight overcorrection is recommended with bovine collagen because it tends to reduce in volume due to the amount of water in the product.

Patients can expect 2–5 months of improvement, depending on the location of placement. Dynamic rhytids (e.g., caused by muscular activity) have a shorter duration of correction, unlike more static conditions (e.g., acne scars). Zyplast may have a longer duration because of its relative protection from enzymatic degradation. However, it must be placed deeper in the dermis to avoid a beaded surface appearance and is therefore less useful for correction of superficial rhytids.

Complications with bovine collagen include delayed hypersensitivity reactions. Although rare, allergic reactions can occur in 1% of patients who have had two negative skin tests. This presents as swollen granulomas or sterile abscesses at the treatment site. Although self-limiting, these reactions can take up to 1 year to resolve. Intralesional steroid injections, antibiotics, and systemic anti-inflammatory drugs can be considered for treatment. Zyplast placed in the glabellar complex has resulted in vascular occlusion and necrosis. This may be caused by the deeper placement required with this product and the associated adverse pressure-related effects on cutaneous vasculature.

Human collagen

One of the main shortcomings of bovine collagen is the risk of hypersensitivity reaction. Synthetic human collagen has been developed as an alternative that does not require multiple skin testing and can be administered immediately. There has been no documented cross-reaction between bovine and bioengineered human collagen, allowing patients with a documented allergy to bovine collagen to be treated safely with human collagen.

Cosmoderm 1 and 2 and Cosmoplast (Allergan) are FDA-approved bioengineered human collagen derived from neonatal foreskin. Synthetic human collagen has a very similar formulation to its bovine counterpart and is packaged in similar concentrations. Cosmoderm 1 has a concentration of 35 mg/mL and is in phosphate-buffered saline with 0.3% lidocaine. Cosmoderm 2 has a concentration of 65 mg/mL. Cosmoplast has 35 mg/mL of human-derived collagen and is

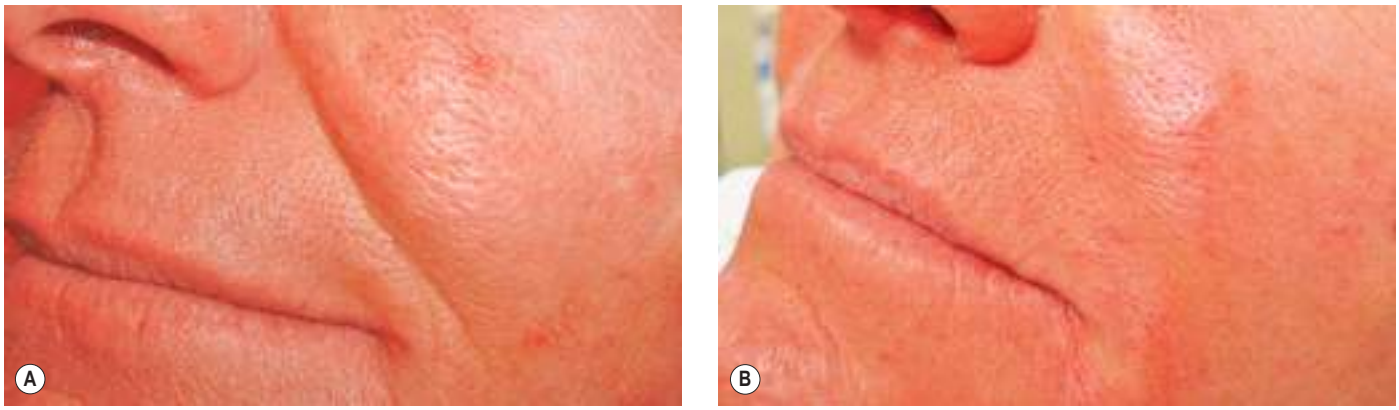

Fig. 39-1 Hyaluronic acid filler, nasolabial fold. A, Before treatment. B, Immediately after placement of hyaluronic acid, with marked improvement and reduction of rhytids.

cross-linked with glutaraldehyde. All products have the same indications, are injected in a similar manner to their bovine counterparts, and have similar cosmetic results and longevity.

The clinical use of collagen has been declining as manufacturers have decreased production and transitioned to the manufacturing and promotion of hyaluronic acid fillers.

Hyaluronic acid

Hyaluronic acid, a polysaccharide, is a natural component of human connective tissue. A member of the family of glycosaminoglycans, hyaluronic acid is composed of repeating disaccharide units. This molecule has the advantage of being identical across all species. As such, hypersensitivity reactions should not occur, and skin testing is not required before treatment. However, early formulations of hyaluronic acid did produce rare hypersensitivity reaction, although the incidence has declined with the introduction of a more purified product. Granulomatous foreign body reactions have been described in case reports.

Hyaluronic acid avidly binds water, and patients may experience redness, swelling, and bruising in the first few days after treatment. Most of the volume is maintained after placement, making overcorrection unnecessary when injecting. Hyaluronic acid products consist of a clear gel in a prepackaged syringe. Early products did not contain lidocaine, often necessitating the use of local anesthesia and regional blocks for patient comfort. However, many current preparations of hyaluronic acid now include lidocaine, thus eliminating the need for adjuvant anesthesia and making them significantly more comfortable for patients. Hyaluronic acid fillers can produce a more durable aesthetic improvement than collagen, often lasting from 5 to 8 months (Fig. 39-1; also see Video 39-1).

The two types of hyaluronic acid filler substances are streptococcal derived and animal (i.e., rooster comb) derived. Streptococcal-derived filler is by far the most common as manufacturers and consumers moved away from animal-derived products due to lack of longevity. There are numerous evolving proprietary formulations, including Restylane and Perlane (Medicis, Scottsdale, AZ), with the "L" designation for the lidocaine-containing formulation; Juvederm and Voluma (Allergan), with the "XC" designation for the lidocaine-containing formulation; and Belotero Balance (Merz; Greensboro, NC). All these fillers come in prepackaged syringes and do not require refrigeration.

The characteristics and viscosity of the different products are largely determined by the size and concentration of the molecule within each preparation. Restylane contains 20 mg/mL of hyaluronic acid, with a particle size of 100,000/mL, and is injected with a 30-gauge needle. Perlane also has a concentration of 20 mg/mL, but a much larger particle size of 8000/mL, and is appropriate for deeper contour abnormalities. Juvederm is available in two formulations, Ultra and Ultra Plus ("XC" indicates lidocaine-containing product). Both have a concentration of 24 mg/mL, with Ultra Plus being about 20% thicker, making it more appropriate for deeper folds. Voluma is indicated for cheek augmentation or to correct age-related volume loss in the midface. Belotero can be used for fine superficial lines, such as perioral rhytids.

Hyaluronic acids tend to produce more swelling and bruising than collagen. Proper preoperative consultation is necessary to ensure that the patient understands this and does not have upcoming social engagements. Improper placement of hyaluronic acid too superficially can result in a blue discoloration or nodule on the skin surface, known as the Tyndall effect. An incision with a large-gauge needle or No. 11 blade and expression of the product can be performed. Hyaluronidase injections can dissolve the product if either a reaction or unevenness results, a considerable advantage over other filler substances.

Poly-L-lactic acid

Microparticles of poly-L-lactic acid (Sculptra; Valeant, Bridgewater, NJ) are used as an injectable implant to replace diffuse volume loss, rather than the small-volume injections of other fillers. This product is currently FDA approved for correcting facial lipoatrophy in patients with human immunodeficiency virus (HIV) infection and for aesthetic treatment of lines and contour deficiencies.

Poly-L-lactic acid is a biodegradable, biocompatible, and immunologically inert product that does not require skin testing. Polylactic acid has been used as absorbable suture material (e.g., Vicryl). Polylactic acid is absorbed gradually in the skin, inducing a fibroblastic response and de novo collagen synthesis. Multiple treatment sessions at intervals of 4–6-weeks are often required to achieve the final result (Fig. 39-2). Since correction depends on the formation of new collagen, patients must be counseled that an immediate effect does not occur with this product. Results can last for up to 2 years.

Poly-L-lactic acid comes packaged as a freeze-dried powder and must be reconstituted for a minimum of 4 hours before injection to ensure adequate hydration of the particles. Lidocaine can be added to the vial to reduce injection pain. The product is injected using a 25-gauge needle at the level of the

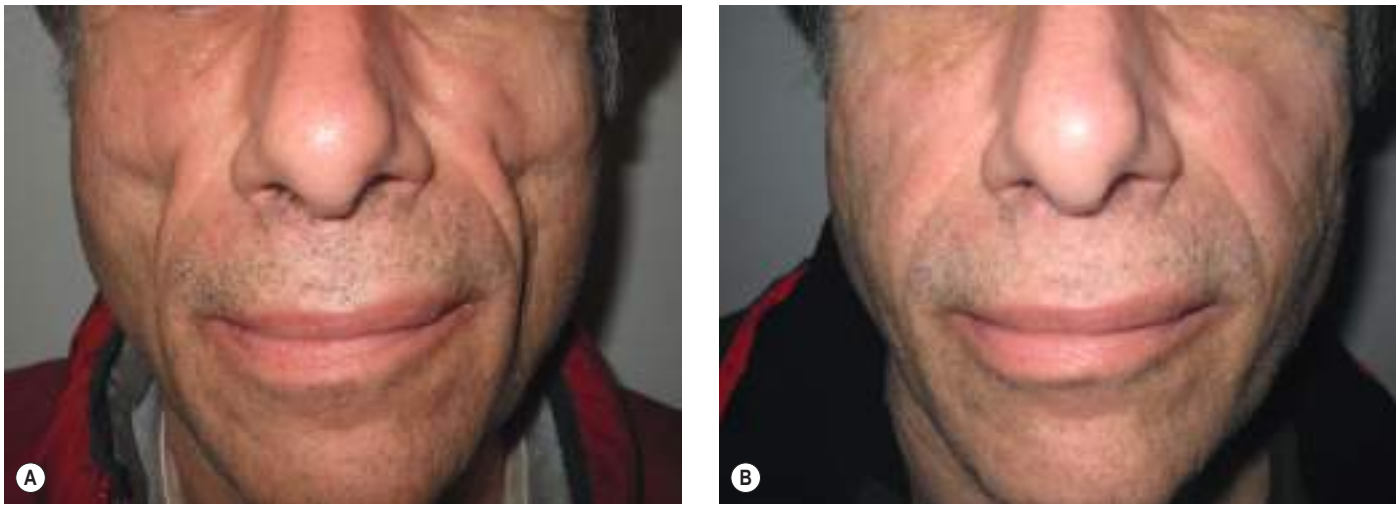

Fig. 39-2 Poly-L-lactic acid for HIV lipoatrophy. A, Before treatment. B, After five treatments.

deep dermis and subcutaneous junction in a fanning or crosshatch fashion. Postinjection massage for several days can help reduce nodules.

Side effects include delayed foreign body granulomas at injection sites. Intralesional 5-fluorouracil (5-FU) or triamcinolone, 10 mg/mL, may be used for the treatment of these papules.

Calcium hydroxylapatite

Calcium hydroxylapatite (Radiesse; Merz, Greensboro, NC) consists of fine particles (25–45 μm) of material traditionally used to reconstruct bone. Once injected into the dermal–subcutaneous junction, the particles act as scaffolding for autologous collagen synthesis. The ensuing fibrotic reaction results in soft tissue correction that can last for 9–12 months. It is FDA approved for correction of moderate to severe folds and wrinkles, such as nasolabial folds, and for HIV facial lipoatrophy.

Injections can be quite painful, and local anesthesia is generally used. Calcium hydroxylapatite is injected into the deep dermis and subcutaneous junction with a threading technique using a 27-gauge needle. It comes prepackaged in syringes and can be stored at room temperature.

Nodules are more often seen when calcium hydroxylapatite is injected into the lips, thus discouraging its use in the treatment of hypolabium. Caution must be exercised; any product that requires a fibrotic reaction to be effective can result in a granulomatous reaction and an untoward result. Since calcium is radiopaque, the product may be detected and may interfere with radiologic imaging.

Silicone

Silicone has been used in the past for soft tissue augmentation by dermatologists. This product was never FDA approved, and issues of purity and safety limited its widespread use. In 1994, the FDA removed silicone from the market. Recently, however, the FDA approved 1000-centistoke liquid silicone (Silikon 1000; Alcon Labs, Fort Worth, TX) for the treatment of retinal detachment. It is currently being used off-label as permanent filler for HIV-associated facial lipoatrophy, scars, and rhytids.

The potential for delayed and severe complications with this permanent filler, as well as legal concerns and restrictions, has limited use of silicone. Adverse reactions associated with silicone injections include granuloma formation and migration of implant, which are compounded by the permanent nature of the product. Many of the past reported complications of silicone injection were the result of using either an impure, nonmedical-grade substance or an improper technique with large-volume injections. A multisession, microdroplet technique, placing multiple depot injection of 0.01 mL of product into the deep dermis in 1–3 mm intervals, significantly reduces the complication rate. An additional consideration is that the current FDA-approved product is more concentrated than the previous silicone products. Further study is needed to evaluate the long-term safety and efficacy of silicone oil injections for correction of soft tissue contour deficiencies.

Polymethylmethacrylate

Artefill (Suneva Medical, San Diego), named Artecoll in Europe, is an FDA-approved suspension containing 20% polymethylmethacrylate (PMMA, commonly known as Lucite) microspheres of 30–40 microns (μ) in diameter, suspended in 80% bovine collagen, for soft tissue augmentation. The carrier collagen provides initial correction and is degraded over several months, leaving the PMMA microspheres. PMMA is nondegradable and serves as a permanent framework for connective tissue deposition and can produce long-term correction.

Technique is critical to successful outcomes. If injected too deeply, the implant is ineffective; superficial placement can cause prolonged erythema. Granuloma formation and hypertrophic scarring can occur and have been reported as a delayed reaction. Intralesional triamcinolone can be used for treatment of these reactions. One patient who developed a delayed foreign body granuloma 6 years after injection with PMMA was successfully treated with a 24-week course of 600 mg/day of allopurinol. Intralesional triamcinolone has also been used as a treatment for granulomas. Because the product contains bovine collagen, skin testing is required before use. Early indications suggest efficacy of triamcinolone treatment for acne scarring.

Expanded polytetrafluoroethylene

Expanded polytetrafluoroethylene (ePTFE) is a synthetic solid material that is soft and pliable, is not degraded, and

has the advantage of being permanent. The material is placed through a small skin incision and positioned in the desired location. Areas typically treated include lip margins or the muscular portion of the vermillion for enhancement, nasolabial folds, and soft tissue depressions. Complications associated with ePTFE include extrusion, migration, shrinkage, and hardening.

Autologous fat transplantation

Autologous lipotransfer allows for soft tissue augmentation without the risk of allergy, rejection, or infectious transmission. Unlike other filler techniques, fat transfer is truly a grafting procedure. As such, its success is predicated on the survival of the transferred adipocytes. Fat is harvested from a choice of donor sites, typically the abdomen, buttock, thigh, or knee. There is no consensus as to the advantages of harvesting with a liposuction cannula, syringe extraction with a large-bore needle, or open surgical method. The fat is then separated from anesthetic fluid and blood and injected through a large-bore needle (16–18 gauge) into the desired location. Any remaining fat can be frozen at –70°C for use later, with varying claims regarding loss of efficacy.

The variable rate of graft survival, the recipient site reaction (bruising, swelling), and the added morbidity of a donor site are limiting factors in patient satisfaction with this technique. In some cases, partial survival results in uneven correction that may require additional treatments. Some argue that multiple smaller-volume injections spaced over two or three treatments are more effective than single, large-volume lipotransfer. If the fat survives, it can provide a very natural correction. However, local factors such as motor activity and gravitational effects will mitigate against permanent correction. This technique is not useful for the correction of superficial rhytids and mainly corrects deeper defects such as nasolabial folds, hypolabium, buccal depression, and deep scars.

BOTULINUM TOXIN

The use of botulinum toxin (BTX) in dermatology has increased rapidly over the years, and at present, it is one of the most common cosmetic procedure performed in the United States. In 2002, the FDA approved onabotulinumtoxinA for the treatment of dynamic glabellar frown lines. Although BTX is most frequently used for relaxation of dynamic rhytids in the upper third of the face, advanced aesthetic treatment techniques for additional anatomic sites have been developed and are currently used off-label.

Produced by *Clostridium botulinum*, there are seven different serotypes of BTX: A, B, C1, D, E, F, and G. These serotypes inhibit the release of acetylcholine from the presynaptic motor neuron, resulting in chemodenervation and paralysis of the treated muscle. Over time, new nerve terminals form and create new neuromuscular junctions with the muscle fibers, which gradually restore motor function.

BTX type A (Botox Cosmetic [onabotulinumtoxinA], Allergan; Dysport [abobotulinumtoxinA], Medicis); Xeomin (incobotulinumtoxinA; Merz) is the most common serotype. Its mechanism of action is through the cleavage of SNAP-25, a presynaptic membrane protein required for fusion of neurotransmitter-containing vesicles. Effect is generally noted 2–5 days after treatment with BTX-A, but the delay can be as long as 2 weeks in some cases. Results can last 2–5 months. In addition to aesthetic indications, onabotulinumtoxinA is FDA approved for the treatment of blepharospasm, strabismus, cervical dystonia, upper limb spasticity, chromic migraine, urinary incontinence, and axillary hyperhidrosis.

Each of these BTX-A products has a similar mechanism of action, but each formulation also has unique characteristics. For dosing purposes, onabotulinumtoxinA and incobotulinumtoxinA have a similar potency (clinical equivalency ratio of 1 unit = 1 unit). AbobotulinumtoxinA has equivalency of 3:1 compared with the other formulations. Therefore, it is critical that physicians perform appropriate dosage conversions when switching among different products. AbobotulinumtoxinA appears to have greater spread once injected into the skin. IncobotulinumtoxinA is unique in that it is

formulated with no complex proteins and thus, in theory, may have a lower risk of neutralizing antibody formation (although the risks of this occurring in aesthetic use is exceedingly low with all current formulations of BTX-A). In addition, incobotulinumtoxinA has the advantage of being able to be stored refrigerated or at room temperature, whereas the other products require refrigeration.

The only other serotype that is currently available commercially is BTX type B (Myobloc [rimabotulinumtoxinB]; Solstice Neurosciences, Malvern, PA). Its mechanism of action is through the cleavage of a vesicle-associated membrane protein (VAMP), also known as synaptobrevin. This serotype has more rapid onset of effect than BTX-A. In addition, differences in potency suggest that approximately 100 units of Myobloc are equivalent to 1 unit of Botox. It currently has FDA approval for the treatment of cervical dystonia.

BTX-A is distributed in vials as a vacuum-dried powder, which is reconstituted with 1.0–5.0 mL of saline. Many physicians think that the dilution of BTX does not a make a significant difference in patient outcome, and studies appear to confirm this. Others argue that higher concentrations with smaller injection volumes reduce the amount of unintended diffusion. It is more important to use the same dilution every time to ensure that the physician does not need to do "mental math," and to reduce confusion with each new vial of BTX.

Despite package insert recommendations, experience suggests that there is little loss of potency over several weeks following reconstitution with preserved saline. The use of preserved saline for reconstitution reduces the burning and pain associated with injection from the anesthetic properties of the benzyl alcohol in preserved saline.

BTX-A is predominantly used in dermatology for treatment of dynamic rhytids on the upper third of the face. The key to successful treatment is understanding the anatomy involved in facial expression, rather than performing the procedure by rote. Having the patient frown, squint, and raise the brows before treatment helps identify the active target muscles and serves as a guide for proper placement.

Glabellar frown lines

Currently, treatment of glabellar frown lines is the only FDA-approved cosmetic indication for BTX-A. These lines result from contraction of the corrugator supercilii muscle, which pulls the brows medially, and the procerus muscle, which pulls the brow inferiorly. In addition, by inactivating the brow depressors, unopposed action of the brow elevators (e.g., frontalis muscle) can result in a slight but noticeable brow lift.

Approximately 20–35 units of onabotulinumtoxinA (or equivalent if using different product), are typically injected into the corrugators and procerus in a five-point injection method (Fig. 39-3; also see Video 39-2). Male patients and those with larger muscle mass may require a higher number of units (30–50). By having the patient furrow the brow, one can identify the origin and insertion of the corrugator supercilii. By grasping with the thumb and index finger, the physician can isolate the muscle and ensure accurate toxin placement.

If toxin diffuses through the orbital septum into the orbit, weakening of the levator palpebrae muscle can result in upper lid ptosis. Care should be taken to inject 1 cm above the superior bony orbital rim to reduce risk of diffusion of toxin and the resulting complication. The use of α-adrenergic agonist eye drops, such as apraclonidine 0.5% or phenylephrine 2.5%, can stimulate Müller's muscles in the lid, providing some relief until the effects of the BTX-A dissipate.

Horizontal forehead lines

Horizontal forehead lines are caused by contraction of the frontalis muscle, which produces elevation and movement of the eyebrows. Care must be taken when treating this area with BTX-A to avoid ptosis or "heaviness" of the brow. Extra caution should be used in men with low-set brows or older patients who use their frontalis to raise their eyebrows to assist with vision.

Since the lower portion of the frontalis is primarily responsible for brow elevation, injections are often limited to the upper half or two thirds of the muscle. Between 10 and 25 units of onabotulinumtoxinA (or equivalent if using different product), delivered in multiple superficial injections across the forehead, is typically used for this area (see Video 39-3).

If upper lateral fibers of the frontalis remain totally untreated, the increased resting muscle tone will raise the lateral edge of the eyebrow, creating a quizzical look (Fig. 39-4). Injecting a small amount of BTX-A in the upper lateral brow can help correct this.

Crow's feet

Crow's feet are rhytids that extend radially from the lateral canthus and are produced by contraction of the lateral orbicularis oculi. Even with successful treatment with BTX-A, rhytids may still persist because of the upward motion of the cheek when the patient smiles. Proper preoperative counseling is required to prevent frustrated patients.

Superficial blebs are raised approximately 1 cm lateral to the lateral canthus (Fig. 39-5). Between 8 and 12 units of onabotulinumtoxinA (or equivalent if using different product) are placed around each orbit. Care should be taken to orient the needle away from the globe as a safety precaution, in case the patient moves unexpectedly.

Bruising is common in this location because of the thinness of the skin and the presence of numerous periocular superficial veins. Purpura can be minimized by injecting superficially, ensuring proper illumination and stretching of the skin to help identify the veins, and limiting the total number of injections. Diffusion into the zygomaticus major and minor muscles, leading to ipsilateral lip ptosis and asymmetric smile, can occur with overzealous treatment of the inferior portion of the orbicularis oculi muscle.

Other locations

Other sites that can be treated with BTX-A include platysmal bands, diagonal creases along the nasal side wall ("sniff lines" or "bunny lines"), mental crease, and depressor anguli oris muscle (for frowning of lateral corners of mouth). Care must be taken when treating the lower third of the face to avoid complications with mouth and lip control. Excessive or misplaced BTX-A in the platysmal bands can cause dysphagia, dysphonia, and neck weakness.

Hyperhidrosis

In addition to cosmetic uses, onabotulinumtoxinA is FDA approved for the treatment of axillary hyperhidrosis. Before treatment, a Minor's starch-iodine test is used to document both the severity and the location of excessive sweating (Fig. 39-6; also see Video 39-4). Effective treatment can be achieved with doses of 50 units/axilla, although some patients do require higher doses. Intradermal injections are spaced in a grid 1 cm

Fig. 39-3 Botulinum toxin injection technique for glabellar frown furrow. A, Glabellar lines with frowning. B, As patient frowns, the muscle is grasped between thumb and index finger; the injection is placed directly into the belly of the corrugator supercilii muscle. C, Injection into the procerus muscle. Fig. 39-7 Starch-iodine test; partial response to botulinum toxin.

apart over the entire area. Anhidrosis is achieved within 1 week and typically lasts for 4–12 months (see Video 39-5). Side effects are generally limited to injection site bruising.

Treatment of palmar hyperhidrosis with BTX-A is more complicated than treating the axilla. Higher doses, typically 100–150 units/palm, are required because of the greater surface area involved and the limited diffusion of the toxin in acral skin. Pain is more significant when treating the palm and typically requires the use of wrist nerve blocks. Lastly, a slight muscle weakness of the hands, manifested by the loss of fine motor movement, is typically seen for several weeks after treatment.

Frequently, there are focal areas of activity after treatment for hyperhydrosis. However, since the sweat diffuses over the entire surface, patients often describe a false sensation of severe sweating and complain that the treatment "didn't work." By repeating the starch-iodine test, the focal areas of activity can be identified and directed touch-up performed (Fig. 39-7). Repeated treatments over time appear to increase the duration of efficacy for resulting injections.

VARICOSE AND TELANGIECTATIC VEINS

Sclerotherapy

Patients frequently seek treatment of telangiectasias and reticular veins in the lower extremities. Historically, the treatment of choice for telangiectatic and reticular veins has been sclerotherapy (Fig. 39-8; also see Video 39-6). However, some studies suggest that laser treatment for lower extremity telangiectasia can be as effective as sclerotherapy. In addition, laser therapy can be considered in patients who failed to respond to sclerotherapy or had significant complications from sclerotherapy. However, many believe that sclerotherapy should be first-line treatment for vessels that can be cannulated with a needle.

Sclerosing solutions

There are three broad classes of sclerosing agent available to dermatologists: hyperosmotic agents, detergents, and chemical irritants (Table 39-1). Hyperosmotic agents cause endothelial cell damage through dehydration; detergents disrupt the

Fig. 39-8 Sclerotherapy; injection technique using fine needle to cannulate vein.

Fig. 39-9 Sclerosing foam. Sodium tetradecyl sulfate (STS) foam is made by mixing air with liquid using a three-way stopcock and two syringes.

Table 39-1 Sclerotherapy agents

Agent	Class	FDA approved	Comments
Hypertonic saline	Hyperosmotic	Yes	No allergenicity; painful
Hypertonic saline (10%) plus dextrose (25%)	Hyperosmotic	No	Lower allergenicity; painful
Sodium tetradecyl sulfate	Detergent	Yes	Can be used as foam; painless except with extravascular injection
Polidocanol	Detergent	Yes	Painless; can be used as foam
Sodium morrhuate	Detergent	Yes	High risk of allergic reaction
Chromated glycerin	Chemical irritant	No	Weak agent
Polyiodinated iodine	Chemical irritant	No	Highly caustic

cellular membrane; and chemical irritants act as a corrosive and lead to endothelial injury.

Hypertonic saline is an FDA-approved agent frequently used in sclerotherapy. At concentrations of 10–30%, this agent has the advantage of a complete lack of allergenicity when used alone. The disadvantage of hypertonic saline is pain associated with injections and ulcerogenic potential. Often, anesthetic agents such as lidocaine are added to the mixture to minimize the discomfort involved, by decreasing the concentration of the saline and through the direct anesthetic effect.

Hypertonic saline (10%) mixed with dextrose (25%) is another hyperosmolar agent that has been used in vein sclerosing. This agent has the advantages of low allergenicity and decreased pain compared with higher concentrations of plain hypertonic saline. However, this mixture is currently not FDA approved and is a relatively weak sclerosant compared to other options available.

Sodium tetradecyl sulfate (STS) or Sotradecol (AngioDynamics, Latham, NY) is a detergent sclerosant that has been FDA approved for 55 years. Typical concentrations used for superficial telangiectasias are 0.1–0.2%, and reticular veins can be treated with 0.2–0.5%. One advantage of STS is the lack of pain with injections; however, extravascular injection can be painful.

Polidocanol (Asclera; Merz Aesthetics, San Mateo, CA), a detergent, is FDA approved for use in sclerotherapy and comes in 0.5% (for vessels <1 mm in diameter) and 1% concentrations (for reticular veins <3 mm). It possesses many of the same advantages as STS, including lack of pain with injection and the ability to be used as foam. Goldman demonstrated comparable efficacy and a similar adverse event profile between polidocanol and STS.

As detergents, both STS and polidoconol can be made into foam. This is typically done with a three-way stopcock and a syringe filled with air (Fig. 39-9; also see Video 39-7). Foam can increase contact between the agent and the vessel wall, can result in more effective sclerosis at a lower concentration, and allows treatment of larger-caliber vessels. Foam tends to degrade fairly quickly (1–2 min), so it should be mixed immediately before injection. The bubble size created correlates to the stability of the foam created, with microfoam (<50 μ) being more stable than larger foam (>100 μ). Foam technique has historically been an off-label use of polidocanol or STS but has been used widely with successful results and a high degree of safety. However, Varithena (BTG, London) is a polidocanol injectable nitrogen foam product approved by the FDA in 2013 and is indicated for the treatment of incompetent great saphenous veins, accessory saphenous veins, and visible varicosities of the great saphenous vein system above and below the knee.

Sodium morrhuate is a detergent approved by the FDA for treatment of varicose veins. However, this sclerosing agent is not generally used for the treatment of cutaneous telangiectasias because of its highly caustic nature and higher anaphylaxis potential.

Glycerin and polyiodide iodine are chemical irritants used as sclerosing agents. Although not FDA approved for sclerotherapy, these act as corrosive agents and cause a direct injury to the vessel endothelium. Leach and Goldman report a significant decrease in bruising, swelling, and postprocedural hyperpigmentation with glycerin compared with STS.

Fig. 39-10 Ambulatory phlebectomy. A, Hook used to secure the vein. B, Vein is clamped on either side and severed. Clamp is then used to remove the vein using a rolling and pulling technique. C, Removed vein segment. The distal end can be tied off using absorbable suture, or additional segments can be removed using the same technique.

Complications

Side effects and complications of sclerotherapy can be associated with all types of sclerosing agent. Ulceration can occur despite the meticulous technique of the dermatologist and regardless of the sclerosing agent used. Extravasation of sclerosing solution from the vein may occur, or injection into a dermal arteriole or arteriovenous anastomosis may result in cutaneous necrosis. If extravasation is suspected, injection of normal saline to dilute the sclerosing agent may prevent ulceration. Alternatively, application of 2% nitroglycerin ointment may prove beneficial. If ulceration does occur, conservative wound management should be undertaken until healed.

Hyperpigmentation along the course of treated veins has been reported to occur in 10–30% of patients. This pigmentation is caused by hemosiderin deposition and has been reported with a variety of sclerosing agents, including hypertonic saline, polidocanol, and STS. Pigmentation often improves with time, with approximately 70% improvement over a 6-month period. Treatment options include trichloroacetic acid, hydroquinone, retinoic acid cream, intense pulsed light, and laser treatments. Tafazzoli et al. report excellent results with the Q-switched ruby laser.

Telangiectatic matting is the appearance of fine telangiectatic blush at the site of previously treated veins. This has been reported in 10–15% of patients treated with sclerotherapy. Risk factors associated with this include estrogen therapy, obesity, and a family history of telangiectasia. Low injection pressures and limiting the amount of sclerosant per injection site may help reduce the incidence of telangiectatic matting. Spontaneous resolution often occurs in 3–12 months. Treatment options include intense pulsed light, pulsed dye laser, and injection of sclerosant into the matted vessels.

Arterial injection of sclerosant is the most serious complication of vein sclerosing. Although rare, it has considerable associated morbidity and necessitates timely action. Classically, the patient reports significant pain immediately after injection, accompanied by pallor and cyanosis. If arterial injection occurs, the physician should immediately apply ice and attempt to dilute the vessel with injections of normal saline. Procaine can be used to inactivate STS. Intravenous heparin and thrombolysis should be considered.

Ambulatory phlebectomy

Ambulatory phlebectomy is an outpatient procedure used to remove varicose veins, employing skin hooks through a series of stab incisions along the course of the varicosity. Tumescent anesthesia is often used during this technique and has the added benefit of compression of the vein and reduction of blood loss. Various hooks and clamps are used to remove the vein (Fig. 39-10). Incision sites heal with minimal scarring. Adverse effects are generally limited and consist of minor pain and bruising. Infection and nerve damage are extremely rare.

Endovenous ablation

Endovenous ablation should be considered in patients with greater saphenous incompetence and is rapidly replacing traditional vein stripping. In patients with lower extremity telangiectasia and reticular veins, prior assessment of underlying saphenous reflux is necessary to prevent recurrence following treatment of the visible varicosities.

Radiofrequency or laser (using 810 nm or 1320 nm) can be used to heat and damage veins. Either method results in vein wall shrinkage and subsequent vessel thrombosis and occlusion. Tumescent anesthesia allows the procedure to be performed painlessly, surrounds and compresses the vein for greater contact between the catheter and vessel wall, and distends the skin away from the heat source, preventing cutaneous damage. A catheter is placed under ultrasound guidance and guided to the saphenofemoral junction. The catheter is slowly withdrawn along the length of the vein, and the thermal injury leads to vessel occlusion.

The most common complications include ecchymosis and pain. Thermal burns of the skin are infrequently seen when tumescent anesthesia is properly used. Nerve injury is uncommon, and paresthesias are often temporary. Deep vein thrombosis has been documented, but pulmonary embolism is extremely rare when the technique is performed properly.

LIPOSUCTION

Liposuction is used for the removal of local areas of adipose and to improve body contour. It is not a treatment for obesity and should not be used as a weight loss mechanism. The most common areas treated are the abdomen and thighs, neck, jowls, knees, ankles, and breasts (Fig. 39-11). Additional conditions, such as gynecomastia, buffalo hump, lipoma, lipodystrophy, and axillary hyperhidrosis, can be treated by liposuction.

The most common technique employed by dermatologists involves infiltrating the treated area with dilute anesthesia and aspirating the fat through cannulas attached to a vacuum. The choice of cannula can determine the amount of fat aspirated, with more aggressive cannulas having a larger bore, being pointier, and having multiple, larger holes placed near the tip. Tumescent anesthesia typically consists of 0.05–0.1% lidocaine with 1:1 million epinephrine and sodium bicarbonate. The total safe concentration of lidocaine that can be used is 55 mg/kg. The benefits of tumescent anesthesia are the ability to perform the procedure comfortably under local anesthesia, hemostasis, and hydrodissection of adipocytes, which facilitates aspiration. Laser-assisted lipolysis has not been shown to be superior to traditional tumescent liposuction.

Much discussion surrounds the safety of office-based liposuction. It is important to stress that the serious complications seen in liposuction are associated with general anesthesia, not with procedures performed with local tumescent anesthesia. Although deaths have been reported during liposuction, none has occurred when patients were treated with tumescent anesthesia alone. Office-based tumescent liposuction performed by dermatologic surgeons is safe and has a lower complication rate than hospital-based procedures.

CHEMICAL PEELS

Superficial peel

Peels are categorized by the level of injury they cause. Superficial peels cause wounding to the epidermis and may reach the papillary dermis. These peels are well tolerated by patients who require limited "downtime" after treatment. Superficial peels are used in the treatment of photoaging, acne, actinic keratoses, solar lentigines, and pigmentary dyschromias. Given the limited nature of the injury induced by these peels, patients often need multiple treatments on a weekly or monthly basis to reach a desired result. However, patients need to be properly counseled regarding the limited benefit of superficial peels, which cannot provide the improvement in wrinkles and

deep furrows that may be possible with deeper injury peels. Repeated superficial peels cannot produce the same results as a single, deeper peel.

Alpha-hydroxy acids (AHAs), naturally occurring agents that are typically derived from foods, include glycolic acid (sugarcane), lactic acid (sour milk), malic acid (apples), and citric acid (citrus fruits). Glycolic acid has the smallest molecular size and thus the greatest bioavailability, making it one of the most frequently used AHAs. The depth of injury is determined by the pH, concentration of the acid, amount applied, and length of treatment time. Glycolic acid, in concentrations up to 70%, is often used for melasma, acne, and photoaging. Following rapid application to the entire face, it must be neutralized with sodium bicarbonate or plain water. Glycolic acid has been used in combination with 5-FU for the treatment of actinic keratoses.

Salicylic acid, a β-hydroxy acid, can be used in concentrations of 20–30% for the treatment of acne and mild photoaging. It is especially useful as an adjunctive treatment for acne because of both the keratolytic and the comedolytic properties of salicylic acid. It is also used in combination with other agents as part of Jessner's solution. Salicylic acid tends to be less inflammatory than other superficial chemical peels. After application, patients experience some mild stinging and discomfort. A whitening of the skin, termed frosting, from the precipitation of salicylic acid crystals is noted within several minutes of application. Salicylic acid does not require neutralization, although cool compresses after application can soothe the skin.

Trichloroacetic acid (TCA) in concentrations of 10–25% is used extensively as a superficial peel. The depth of injury is related to the concentration and the number of applications, with repeated coats of a low-concentration TCA leading to greater penetration. The agent is applied, and erythema and a white frost are noted within 1 minute. Patients experience a burning sensation. Handheld fans and postprocedural cool compresses can reduce discomfort. TCA does not require neutralization after application.

Jessner's solution combines resorcinol, salicylic acid, and lactic acid in ethanol (Table 39-2). This superficial peel has keratolytic activity and is typically used for acne or hyperkeratotic lesions. It is self-neutralizing, and multiple applications can be performed to obtain a deeper injury.

Solid CO_2 (dry ice) has been used alone and in combination with TCA to obtain a deeper peel. It has been proposed as an effective treatment for acne scars and as a way to potentiate the effect of TCA to achieve a deeper peel.

Medium-depth peel

Medium-depth chemical peeling is defined as a controlled wound through the epidermis and down to the deep papillary dermis. In contrast to the multiple treatments that are often performed with superficial peels, medium-depth peels are generally done as a single procedure because of the more significant injury produced and more robust clinical response. These peels cause epidermal necrosis and dermal injury, which result in increased collagen production during the wound-healing process over the next several months. Medium-depth peels are indicated for the treatment of mild to moderate photodamage, rhytids, pigmentary dyschromias, actinic keratoses, solar lentigines, and other epidermal growths.

The classic medium-depth peel is 50% TCA. However, it is generally not used currently as a single-agent peel because of its unpredictable results and increased incidence of scarring and dyspigmentation. Rather, combining 35% TCA with an initial application of another agent, such as Jessner's solution or glycolic acid, can produce a medium-depth injury without the complications associated with higher concentrations of TCA alone. As a result of the damage to the epidermis produced with the initial peel, the lower-strength TCA is able to penetrate deeper and produce a more significant and even result.

Antiviral prophylaxis should be used in any full-face medium-depth peel because of the potential risk of herpes simplex virus (HSV) activation. Acyclovir, 400 mg three times daily, or valacyclovir, 500 mg twice daily, can be started at the time of peel and continued until complete reepithelialization has occurred, typically 7–10 days. Prophylactic antibiotic therapy has no role in these full-face peels.

Deep peel

Deep chemical peels are defined as those that cause an injury down to the midreticular dermis. These peels are indicated for patients with moderate to severe photodamage and advanced rhytids. Deep peels produce significant injury, and patients have an extended period of postoperative healing.

Baker-Gordon formula phenol peel is the traditional deep peel (Fig. 39-12). Undiluted 88% phenol does not produce a deep or consistent injury because it causes complete coagulation of epidermal keratin proteins, thus blocking further penetration. The Baker-Gordon formula reduces the concentration of phenol to 55%; the croton oil acts as a keratolytic and potentiates the depth of penetration of the phenol (Table 39-3). Cardiac monitoring is required because phenol can produce arrhythmias. Intravenous fluids are given before and during the peel to limit the serum concentrations of phenol and any potential renal complications. In addition, the face is divided into smaller cosmetic units, which are treated individually. A 15-minute wait is required between treating each subunit, spreading the entire procedure over 1–2 hours, thus further limiting the systemic concentration of phenol. Following application, occlusive tape can be applied if a deeper wound is desired. The patients are managed conservatively in the postoperative period with petrolatum and wound care until the skin heals. In addition to the cardiac and systemic concerns associated with deep peels, other risks include

Table 39-2 Jessner's solution

Agent	Amount
Resorcinol	14 g
Salicyclic acid	14 g
85% lactic acid	14 g
95% ethanol qs ad	100 mL

Table 39-3 Baker-Gordon formula

Agent	Amount
88% liquid phenol, USP	3 mL
Tap water	2 mL
Septisol liquid soap	8 drops
Croton oil	3 drops

hypopigmentation, textural abnormalities, and scarring. If any of the phenol solution accidentally contacts the eyes, mineral oil should be used to flush, because water can potentiate the effect of the phenol. Antiviral prophylaxis should be administered.
