Case Based Pediatrics For Medical Students and Residents - Contributors

Keith K. Abe, MD, MS
Clinical Instructor in Pediatrics, University of Hawaii John A. Burns School of Medicine.
Resident in Pediatrics (Graduating 2004), Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Reina M. Ahern, MD
Clinical Instructor in Obstetrics/Gynecology, University of Hawaii John A Burns School of Medicine.
Resident in Obstetrics/Gynecology (Graduating 2007), Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Kenneth Ash, MD, FAAP
Associate Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Medical Director of Neonatal/Pediatric Transport, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Melinda J. Ashton, MD, FAAP
Pediatrician in Private Practice.
Clinical Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Medical Director, Physicians Health Hawaii, Inc., Honolulu, Hawaii.

Venkataraman Balaraman, MBBS, FAAP
Associate Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Medical Director, Neonatal Special Care Unit, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Teresa M. Bane-Terakubo, MD, FAAP
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Pediatrician, Queen Emma Clinic, Queen's Medical Center, Honolulu, Hawaii.

Janet M. Berreman, MD, FAAP
Clinical Assistant Professor of Pediatrics, University of Hawaii John. A. Burns School of Medicine.
Attending Pediatrician, Waianae Coast Comprehensive Health Center, Waianae, Hawaii.

Robert J. Bidwell, MD, FAAP
Associate Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Adolescent Medicine Specialist, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

David W. Boldt
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2005), Honolulu, Hawaii.

Leticia P. Borja, MD
Clinical Instructor in Pediatrics, University of Hawaii John A. Burns School of Medicine.
Chief Resident in Pediatrics, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Andrée M. Bouterie, MD
Clinical Instructor, Department of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Fellow in Child Psychiatry, Department of Psychiatry, University of Hawaii John A. Burns School of Medicine.

Rodney B. Boychuk, MD, FAAP
Professor of Pediatrics and Surgery, University of Hawaii John. A. Burns School of Medicine.
Past Chief of Staff, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Jason H. Brown
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2005), Honolulu, Hawaii.

Charles W. Callahan, DO, FAAP, COL, MC, USA
Chief of Pediatrics and Pediatric Pulmonology, Tripler Army Medical Center.
Clinical Professor of Pediatrics, University of Hawaii John A Burns School of Medicine, Honolulu, Hawaii.
Professor of Pediatrics, Uniformed University of the Health Sciences, Bethesda, Maryland.

Robert G. Carlile, MD
Clinical Assistant Professor of Surgery, University of Hawaii John. A. Burns School of Medicine.
Urologic Surgeon in Private Practice, Honolulu, Hawaii.

Corinne C. Chan-Nishina, MD, FAAP
Clinical Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Developmental-Behavioral Pediatrician in Private Practice, Honolulu, Hawaii.

Grant L.Y. Chen, MS
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2004), Honolulu, Hawaii.

Selina S.P. Chen, MD, MPH
Clinical Instructor in Pediatrics and Internal Medicine, University of Hawaii John A. Burns School of Medicine.
Former Resident in Pediatrics and Internal Medicine (Graduated 2003), Queen's Medical Center & Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Dominic C. Chow, MD, MPH, FAAP
Assistant Professor of Pediatrics and Medicine, University of Hawaii John A. Burns School of Medicine.
Associate Director, Internal Medicine/Pediatrics Residency Program, University of Hawaii John A. Burns School of Medicine.
Attending Physician, Queen Emma Clinics, Honolulu, Hawaii.

John J. Chung, MS, MPH
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2005), Honolulu, Hawaii.

Sze Mei Chung
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2004), Honolulu, Hawaii.

Dennis A. Conrad, MD
Professor of Pediatrics and Deputy Chairman for Children's Hospital Affairs, University of Texas Health Science Center at San Antonio, San Antonio, Texas.
Consultant in Pediatric Infectious Diseases, Christus Santa Rosa Children's Hospital, San Antonio, Texas.

Steven C. Crook, MD
Clinical Instructor in Pediatrics, University of Hawaii John A. Burns School of Medicine.
Resident in Pediatrics (Graduating 2004), Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

David F. Crudo, MD, FAAP
Colonel, Medical Corps, Pediatric Endocrinology, US Army Health Clinic, Schofield Barracks, Hawaii.
Clinical Associate Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine, Honolulu, Hawaii.
Clinical Assistant Professor of Pediatrics, Uniformed Services University of the Health Sciences, Bethesda, Maryland..

Robert C. Durkin, MD
Clinical Assistant Professor of Surgery and Pediatrics, University of Hawaii John A. Burns School of Medicine.
Pediatric Orthopedic Surgeon in Private Practice, Honolulu, Hawaii.

Paul J. Eakin, MD
Clinical Instructor in Pediatrics, University of Hawaii John A. Burns School of Medicine.
Former Resident in Pediatrics (Graduated 2003), Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.
Fellow in Pediatric Emergency Medicine, University of Texas Southwestern Medical School, Children's Medical Center of Dallas, Dallas, Texas.

Guliz Erdem, MD
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Pediatric Infectious Disease Consultant, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Dianne Fochtman, RN, MN, CPNP, CPON
Pediatric Oncology Nurse Practitioner, Kapiolani Medical Center For Women And Children.
Clinical Associate Professor of Nursing, University of Hawaii School of Nursing, Honolulu, Hawaii.

Edward W. Fong, MD
Pediatric Pulmonology Fellow, University Medical Center, University of Arizona School of Medicine, Tucson, Arizona.

Brian T. Garcia
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2004), Honolulu, Hawaii.

Francisco J. Garcia, MD, FAAP
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Pediatric Emergency Physician, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Darryl W. Glaser, MD, FAAP
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Pediatric Hematologist/Oncologist, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Jose L. Gonzalez, MD, MSEd, JD, FAAP
Associate Professor of Pediatrics and Director of Pediatric Medical Education, Texas A&M College of Medicine.
Pediatric Endocrinologist, Scott & White Hospital, Temple, Texas.

Chia Sonia Granda
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2005), Honolulu, Hawaii.

Anthony P. S. Guerrero, MD, FAAP
Associate Professor of Pediatrics and Psychiatry, Associate Director, Division of Child and Adolescent Psychiatry, Director of Psychiatric Medical Student Education, University of Hawaii John A. Burns School of Medicine.
Medical Director, Kapiolani Behavioral Health Service, Kapiolani Medical Center for Women and Children.
Attending Pediatrician, Queen Emma Clinics, Honolulu, Hawaii.

Sherrel L. Hammar, MD, FAAP
Professor and Former Chairman of Pediatrics, Former Dean, University of Hawaii John A. Burns School of Medicine.
Chairman of Kapiolani Medical Specialists, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

M. Scott Hickman, MD
Resident in Internal Medicine, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, New York.
Resident in Ophthalmology (2005), University of Missouri – Kansas City School of Medicine, Kansas City, Missouri.
University of Hawaii John A. Burns School of Medicine, Class of 2003.

Kevin H. Higashigawa, MD
Clinical Instructor in Orthopedic Surgery, University of Hawaii John A Burns School of Medicine.
Resident in Orthopedic Surgery, Queen's Medical Center, Honolulu, Hawaii.

Carol Hirai, MD
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Staff Neonatologist, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Greigh I. Hirata, MD
Medical Director, Fetal Diagnostic Center, Ob/Gyn Ultrasound and Medical Genetics, Kapiolani Medical Center For Women and Children.
Assistant Professor of Obstetrics & Gynecology, University of Hawaii John A. Burns School of Medicine, Honolulu, Hawaii.

Edgar C.K. Ho, MD, FAAP
Clinical Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Pediatric Cardiologist, Straub Clinic & Hospital, Honolulu, Hawaii.

Caron M. Hong
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2004), Honolulu, Hawaii.

Alson S. Inaba, MD, FAAP
Associate Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Pediatric Emergency Medicine Attending Physician, Kapiolani Medical Center For Women And Children.
PALS National Faculty, American Heart Association Hawaii Affiliate.
Medical Director, Hawaii Poison Center, Honolulu, Hawaii.

Alan K. Ikeda, MD
Clinical Instructor in Pediatrics, University of Hawaii John A. Burns School of Medicine.
Resident in Pediatrics, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

James H.E. Ireland, MD
Fellow in Nephrology, Mayo Clinic, Rochester, Minnesota.

Julie Won Ireland, MD
Former Resident in Pediatrics (2002), Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.
Fellow in Medical Genetics, Mayo School of Medicine, Rochester, Minnesota.

Erick M. Itoman
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2004), Honolulu, Hawaii.

Lynn M. Iwamoto, MD, FAAP
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Neonatologist, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Daniel C. H. Kidani, MD
Clinical Instructor in Internal Medicine, University of Hawaii John A Burns School of Medicine.
Resident in Internal Medicine, University of Hawaii Affiliated Hospitals, Honolulu, Hawaii.
Resident in Anesthesiology (2004), University of California Irvine Medical Center, Irvine, California.

Claudine Kimura, MD
Assistant Clinical Professor of Internal Medicine and Clinical Instructor of Pediatrics, University of Hawaii John A. Burns School of Medicine, Honolulu, Hawaii.

Bryan O. King, MS
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2005), Honolulu, Hawaii.

Christina Keolanani Kleinschmidt
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2005), Honolulu, Hawaii.

David K. Kurahara, MD, FAAP
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Pediatric Rheumatologist, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Myrna I. Kuo
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2005), Honolulu, Hawaii.

Sheree Kuo, MD, FAAP
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Neonatologist, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Todd T. Kuwaye, MD, MS
Attending Pediatrician/Internist, Kaiser Permanente Hawaii Nanaikeola Clinic, Nanakuli, Hawaii.

Douglas K. Kwock, MD, FAAP
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Pediatric Infectious Disease Consultant, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Wade T. Kyono, MD
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Pediatric Hematologist/Oncologist, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Meta T. Lee, MD, MSEd
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Pediatrician, Queen Emma Clinic, Queen's Medical Center, Honolulu, Hawaii.

Winona K. Lee, MD
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Fellow, Native Hawaiian Center of Excellence, University of Hawaii John A. Burns School of Medicine, Honolulu, Hawaii.

Peggy M. Liao, MD
Clinical Assistant Professor of Surgery, University of Hawaii John A. Burns School of Medicine.
Pediatric Ophthalmologist in Private Practice, Honolulu, Hawaii.

Sherry W.H. Loo, MD
Associate Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Neonatologist, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Nu Lu
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2004), Honolulu, Hawaii.

Jhoanna D. Mabutas, MD
Clinical Instructor in Pediatrics and Internal Medicine, University of Hawaii John A. Burns School of Medicine.
Former Resident in Pediatrics and Internal Medicine (Graduated 2003), Queen's Medical Center & Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Jonathan K. Marr, MD
Clinical Instructor in Pediatrics, University of Hawaii John A. Burns School of Medicine.
Former Resident in Pediatrics (Graduated 2003), Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Wendy C. Matsuno, MD
Clinical Instructor in Pediatrics, University of Hawaii John A. Burns School of Medicine.
Resident in Pediatrics (Graduating 2005), Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Wallace J. Matthews, Jr., MD, FAAP
Clinical Associate Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Medical Director of Respiratory Care, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Desiree Medeiros, MD
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Pediatric Hematologist/Oncologist, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Joan Ceccarelli Meister, MD, FAAP
Clinical Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Neonatologist, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Marian E. Melish, MD, FAAP
Professor of Pediatrics, Tropical Medicine and Medical Microbiology.
Chief of Pediatric Infectious Disease, University of Hawaii John A. Burns School of Medicine.
Medical Director of Infection Control, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

M. Stanton Michels, MD, FAAP
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Pediatrician, Queen Emma Clinics, Queen's Medical Center, Honolulu, Hawaii.

Max C. Miranda
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2004), Honolulu, Hawaii.

Richard Y. Mitsunaga, MD, FAAP
Pediatrician in Private Practice.
Medical Director, HMSA QUEST (Medicaid Managed Care Plan).
Clinical Professor of Pediatrics, University of Hawaii John A Burns School of Medicine, Honolulu, Hawaii.

Kathleen A. Morimoto, MD
Clinical Instructor in Pediatrics, University of Hawaii John A. Burns School of Medicine.
Pediatrician in Private Practice, Kaneohe, Hawaii.

Daniel T. Murai, MD, FAAP
Associate Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Neonatologist, Kapiolani Medical Center for Women and Children, Honolulu, Hawaii.

Lori S. Murayama
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2004), Honolulu, Hawaii.

Ken Nagamori, MD, FAAP
Clinical Associate Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Pediatric Gastroenterologist in Private Practice, Honolulu, Hawaii.

Gareth K. Nakasone
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2005), Honolulu, Hawaii.

Mai Anh K. Nguyen, MD
Assistant Professor of Pediatrics and Psychiatry, University of Hawaii John A. Burns School of Medicine, Honolulu, Hawaii.

Kalamaoka'aina Kil Soon Niheu, MD
Clinical Instructor in Family Practice, University of Hawaii John A Burns School of Medicine.
Resident in Family Practice (Graduating 2006), Wahiawa General Hospital, Wahiawa, Hawaii.

Julie K. Nishimura, MD, FAAO
Pediatric Ophthalmologist, Kaiser Permanente Medical Group, Honolulu, Hawaii.

Jason T. Nomura, MD
Resident in Emergency Medicine/Internal Medicine, Christiana Care Health Services, Delaware

Sherloune Normil-Smith, MD
Clinical Instructor in Pediatrics, University of Hawaii John A. Burns School of Medicine.
Former Resident in Pediatrics (Graduated 2003), Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Brent K. Ogawa, MD
Resident in Orthopedic Surgery, University of Southern California School of Medicine, Los Angeles, California.

Jeffrey K. Okamoto, MD, FAAP
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Medical Director of Rehabilitative Services, Kapiolani Medical Center for Women and Children, Honolulu, Hawaii.

Judy T. Okimura, MD
Clinical Instructor in Pediatrics and Internal Medicine, University of Hawaii John A. Burns School of Medicine.
Former Resident in Pediatrics and Internal Medicine (Graduated 2003), Queen's Medical Center & Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Floyd S. Ota, MD
Clinical Instructor in Pediatrics, University of Hawaii John A. Burns School of Medicine.
Fellow in Pediatric Emergency Medicine, University of Texas Southwestern Medical School, Children's Medical Center of Dallas, Dallas, Texas.

Kimberly N. Otsuka, MD
Pediatric Pulmonology Fellow, University of Arizona, Tucson, Arizona.

Potenciano Reynoso Paredes, MD
Clinical Instructor in Pediatrics, University of Hawaii John A. Burns School of Medicine.
Former Resident in Pediatrics (Graduated 2002), Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Leo U. Pascua, MD
Clinical Assistant Professor of Family Practice, University of Hawaii John A. Burns School of Medicine.
Pediatrician in Private Practice. Vice-Chief of Staff, Wahiawa General Hospital, Wahiawa, Hawaii.

Mary Elaine Patrinos, MD, FAAP
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Neonatologist, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Kaipo T. Pau
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2005), Honolulu, Hawaii.

Anita M. Pedersen, MD, FAAP, LTC, MC, USA
Chief, Pediatric Endocrinology, Tripler Army Medical Center.
Clinical Assistant Professor of Pediatrics, University of Hawaii John A Burns School of Medicine, Honolulu, Hawaii.

Donald A. Person, MD, COL, MC, USA, FAAP
Medical Director and Senior Scientist, Department of Clinical Investigation, Tripler Army Medical Center.
Clinical Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine, Honolulu, Hawaii.

Maureen M. Petersen, MD, CPT, MC, USA
Attending Pediatrician, Tripler Army Medical Center, Honolulu, Hawaii.
Clinical Assistant Professor of Pediatrics, University of Hawaii John A Burns School of Medicine, Honolulu, Hawaii.

Robert L. Peterson, MD
Assistant Professor of Surgery, University of Hawaii John A. Burns School of Medicine.
Chairman of Surgery, Kapiolani Medical Center For Women And Children..
Medical Director, Athena Clinics International, Honolulu, Hawaii.

D. Venu Reddy, MD, MPH, FAAP
Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Director, Pediatric Cardiology, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Timur M. Roytman
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2005), Honolulu, Hawaii.

Raul Rudoy, MD, MPH, FAAP
Professor and Chairman, Department of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Pediatric Infectious Disease Specialist, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Joel Ruff, MD
Clinical Instructor in Pediatrics, University of Hawaii John A. Burns School of Medicine.
Former Resident in Pediatrics (Graduated 2003), Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Lu'ukia Ruidas, MD
Clinical Instructor in Family Practice, University of Hawaii John A. Burns School of Medicine.
Resident in Family Practice, Wahiawa General Hospital, Wahiawa, Hawaii.

Nadine Tenn Salle, MD
Clinical Instructor in Pediatrics and Internal Medicine, University of Hawaii John A. Burns School of Medicine.
Practicing Pediatrician and Internist, Honolulu, Hawaii.

Renee L. Sato, MD
Clinical Instructor in Obstetrics/Gynecology, University of Hawaii John A. Burns School of Medicine.
Resident in Obstetrics/Gynecology (Graduating 2006), Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Teresa Han Seo
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2004), Honolulu, Hawaii.

Scott J. Sheets, DO, MAJ, MC, USA
Chief, Pediatric Pulmonology, Tripler Army Medical Center.
Clinical Assistant Professor of Pediatrics, University of Hawaii John A Burns School of Medicine, Honolulu, Hawaii.

Cecilia M. Shikuma, MD
Associate Professor of Medicine, University of Hawaii John A. Burns School of Medicine.
Director, Hawaii AIDS Clinical Research Program, Honolulu, Hawaii

Melanie L. Shim, MD, FAAP
Clinical Instructor, Division of Pediatric Endocrinology, Department of Pediatrics, UCLA School of Medicine.
Attending Pediatric Endocrinologist, Mattel Children's Hospital at UCLA, Los Angeles, California.

Walton K.T. Shim, MD, FACS, FAAP
Professor of Surgery and Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Pediatric Surgeon and Chief of Staff, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Lance K. Shirai, MD, MS, FAAP, FACC
Clinical Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Pediatric Cardiologist, Kaiser Permanente Medical Center, Honolulu, Hawaii.

Miki E. Shirakawa
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2004), Honolulu, Hawaii.

Bruce T. Shiramizu, MD
Associate Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Director, Hawaii HIV and Immunology Laboratory, Honolulu, Hawaii.

Jocelyn M. Sonson
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2005), Honolulu, Hawaii.

Chad S.D. Sparks
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2004), Honolulu, Hawaii.

Cheryl M. Takao, MD
Clinical Instructor in Pediatrics, University of Hawaii John A. Burns School of Medicine.
Resident in Pediatrics (Graduated 2002), Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.
Fellow in Pediatric Cardiology, Children's Hospital of Los Angeles, Los Angeles, California.

Akaluck Thatayatikom, MD
Assistant Professor of Pediatrics, Faculty of Medicine, Thammasat University, Thailand.
Former Fellow in Allergy and Immunology, National Jewish Medical and Research Center, Denver, Colorado.
Former Resident in Pediatrics (graduated 2002), Kapiolani Medical Center for Women and Children, Honolulu, Hawaii.
Fellow in Pediatric Rheumatology, Washington University, St. Louis Children's Hospital, St. Louis, Missouri.

Cynthia H. Tinsley, MD
Pediatric Intensivist, Pomona Valley Hospital, Pomona Valley, California.

Sharon M. Tisza, MD
Clinical Instructor, Department of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Fellow in Forensic Psychiatry, Department of Psychiatry, University of Hawaii John A. Burns School of Medicine, Honolulu, Hawaii.
Attending Child and Adolescent Psychiatrist, Aloha House, Kahului, Hawaii.

Mari Uehara, MD
Pediatrician and Child Development Specialist, Kapiolani Medical Center For Women And Children.
Clinical Instructor of Pediatrics, University of Hawaii John A. Burns School of Medicine, Honolulu, Hawaii.

Annemarie Uliasz
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2004), Honolulu, Hawaii.

Daniel W. Ulrich, MD
Clinical Instructor in Pediatrics, University of Hawaii John A. Burns School of Medicine.
Resident in Pediatrics & Psychiatry, Fellow in Child Psychiatry, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Greg Y. Uramoto, MD
Pediatric Endocrinologist, Central Medical Clinic.
Clinical Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine, Honolulu, Hawaii.

Paula A. Vanderford, MD, FAAP
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Medical Director, Pediatric Intensive Care Unit, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Judy Makowski Vincent, MD, FAAP
Colonel (Ret.), Medical Corps, United States Army, Senior Consultant in Pediatric Infectious Diseases, Tripler Army Medical Center.
Clinical Associate Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine, Honolulu Hawaii.

Catherine Y.H. Wagoner, MD
Pediatrician in Private Practice, Reno, Nevada.

Robert Wilkinson, MD, FAAP
Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Hematologist/Oncologist in Private Practice.
Director, Hawaii Children's Blood and Cancer Group, Honolulu, Hawaii.

Adeline Winkes, MD, FAAP
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Hospitalist Pediatrician, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

David K.M. Wong, MD
Clinical Instructor in Surgery, University of Hawaii John A. Burns School of Medicine.
Resident in Surgery, University of Hawaii Affiliated Hospitals, Honolulu, Hawaii.

Jeffrey J. Wong, MD
Clinical Instructor in Internal Medicine, University of Hawaii John A. Burns School of Medicine.
Resident in Internal Medicine, University of Hawaii Affiliated Hospitals, Honolulu, Hawaii.
Resident in Ophthalmology (2004), New York University, New York, New York.

Kelley A. Woodruff, MD, FAAP
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Pediatric Hematologist/Oncologist, Hawaii Children's Blood and Cancer Group, Honolulu, Hawaii.

Rodney K. Yamaki
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2004), Honolulu, Hawaii.

Franklin Y. Yamamoto, MD, FAAP, FAAAAI
Director, Pediatric Allergy Clinic, Kapiolani Medical Center For Women And Children.
Associate Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine, Honolulu, Hawaii.

Kara S. Yamamoto, MD, FAAP, FACR
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Attending Pediatric Rheumatologist, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Loren G. Yamamoto, MD, MPH, MBA, FAAP, FACEP
Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Pediatric Emergency Medicine Medical Director, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Kelly S. Yamasato
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2005), Honolulu, Hawaii.

Vince K. Yamashiroya, MD, FAAP
Clinical Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Pediatrician in Private Practice, Honolulu, Hawaii.

Cindy W. Yang
Medical Student, University of Hawaii John A Burns School of Medicine (Class of 2005), Honolulu, Hawaii.

Lynette L. Young, MD, FAAP
Assistant Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine.
Pediatric Emergency Medicine Attending Physician, Kapiolani Medical Center For Women And Children, Honolulu, Hawaii.

Chapter I.1. Pediatric Primary Care
Melinda J. Ashton, MD

A six year old male presents to your office for his annual well child visit. He is accompanied by his mother. You have cared for this child since his birth, and he has had regular well child care. You last saw him for his visit prior to entering kindergarten at age five years. Today his mother notes that she has been anxiously awaiting this visit as she has several concerns to discuss:

1. He is having some difficulty in school (now just finishing the first quarter of first grade). He is struggling to learn to read, and has some difficulty with arithmetic. His teacher called his mother yesterday to report that he hasn't been turning in his homework or completing his classroom assignments. His mother indicates that she was very surprised to hear this, as the previous teacher reports have indicated that he was doing adequate work.
2. He has frequent complaints of stomachache. He has a good appetite, but has always been a "picky eater". He enjoys drinking milk.
3. He has been having increasing nasal congestion over the last few months. He has had some sneezing attacks, and seems to clear his throat often. He does cough at night. The cough often sounds "wet" to his mother. He also joins in to tell you that he has a hard time breathing during PE. He has no other regular physical activity, but his mother reports that he is always "busy doing something". His mother reminds you that he was born prematurely at 34 weeks, and had difficulty with wheezing as a younger child, but he has done well in the last year or two and hasn't needed any medications for wheezing.

Exam: VS are normal. Weight 30 kg (66#) (> 95%ile), height 117 cm (46") (50%). In general, he appears to be an overweight, friendly child who is cooperative and who appears to be his stated age. He is active in the exam room, exploring the contents of the drawers and cabinets. He interrupts his mother repeatedly during the interview. He appears to be mouth breathing with significant nasal congestion. His tonsils are large but not inflamed. His heart is regular without murmurs. His pulses are normal. His lungs have clear breath sounds, with transmitted upper airway rhonchi. There are no wheezes, but the I:E ratio is prolonged. His abdominal and neurologic screening exams are normal.

The approach taken by a pediatrician when confronted with this patient with multiple complex complaints will vary considerably depending on factors such as training, availability of appropriate pediatric subspecialists, and past successes (or failures) when managing similar issues. As an example, the patient presented above could be referred to a psychologist for an educational assessment, a psychiatrist to manage possible ADHD, a gastroenterologist to manage his abdominal pain, an allergist, a pulmonologist, and possibly an otolaryngologist to evaluate his respiratory complaints, and a nutritionist or dietitian or weight management program to manage his obesity. It would be a daunting task to coordinate and manage all of these specialists, and it is likely that the parents would be thoroughly confused about how to improve his situation if they did receive input from all of these experts. On the other hand, a thoughtful pediatrician could successfully manage all of these issues without any consultations at all. Most pediatricians would probably develop a plan of care somewhere between these two extremes, using selected specialists to assist in the area of concern that they feel least comfortable managing.

The medical home is a concept in which a primary care provider is the ultimate source of all health care for a child. This would include acute care visits for illnesses and injuries, anticipatory guidance, immunizations, growth and development monitoring, preventive health maintenance, and especially for children with special health care needs; the coordination of care among other medical and nonmedical specialists (audiology, speech therapy, child development programs, school programs, etc.).

Although acute care office visits for illnesses and injuries are an important part of what pediatricians do, a significant component of pediatric primary care consists of anticipatory guidance, immunizations, growth and development monitoring, and preventive health maintenance (1). Coordination of care and providing after hours care are areas where there is a large amount of variation in approach. This variation is partly a result of personal style and choices, but it is also significantly influenced by location and type of practice. For example, a solo rural pediatrician would not be able to limit his/her availability after hours for emergencies in the same way that a pediatrician employed by a large group that provides full after hours coverage for emergencies, newborns and telephone triage would be able to. Even in urban areas with lots of coverage for emergency care and newborns, pediatricians vary in their accessibility to their patients. Some parents are told not to call their pediatrician after hours "unless it is an emergency", while others work with pediatricians who provide their home phone number and are easily accessible through an answering service for after hours concerns. Those pediatricians find that while many families feel comforted by the knowledge that they could reach their doctor easily if they needed to, not many families abuse the privilege.

Another area of after hours care with great variability is the use of the emergency room to manage illness when the office is closed. Some pediatricians are not available to their patients for after hours advice at all, with their answering machine directing parents with concerns to take the patient to the nearest emergency room. Most pediatricians will discuss concerns that a parent may have after hours; the difficulty then is that you must offer advice about whether to seek care in the emergency room or wait until the office is again open. Concern about liability may cause some physicians to send most patients to the emergency room, particularly if there is another physician there who will see the child (so that they do not have to go in themselves). That will then transfer the problem to someone else, and an exam will be performed so that you are no longer accepting the parental observations as your only source of information. Unfortunately this is a very expensive way to provide care, so many pediatricians try to refer only those patients who sound like they might benefit from emergency care. Determining which patients should go becomes even more difficult when covering for a colleague after hours. Part of the decision making often includes knowledge of prior interactions with the parents. When the parents are strangers, it is more likely that they will be sent to the ER if they call with concerns.

As primary care physicians, pediatricians are the first to be consulted by many parents for a wide range of concerns. It is useful to have a basic management plan (or algorithm) for the most common complaints that come in, including an assessment of when referral to a specialist might make sense. In developing such an algorithm, a primary consideration will be the local availability of pediatric subspecialists. For example, it is not useful to decide that any child presenting with a heart murmur will be evaluated by a pediatric cardiologist, if the nearest available pediatric cardiologist is hundreds of miles away. The varying availability of subspecialty care is one of the factors involved in the observed variability in the medical care provided in one locale compared to another.

If a pediatric subspecialist is not available locally, the choices for a general pediatrician then become: a) evaluate and manage yourself, b) use a specialist who does not have pediatric subspecialty training, or c) send the patient to the specialist regardless of the

distance/expense/inconvenience involved. In some locations, you may also have the option of managing the patient using a specialist available to you by telemedicine, but this is not a widespread practice yet.

Certification is available from the American Board of Pediatrics in the following pediatric subspecialties: adolescent medicine, clinical and laboratory immunology, medical toxicology, pediatric cardiology, pediatric critical care medicine, pediatric emergency medicine, pediatric endocrinology, pediatric gastroenterology, pediatric hematology/oncology, pediatric infectious diseases, pediatric nephrology, neonatal-perinatal medicine, pediatric pulmonology, pediatric rheumatology, developmental-behavioral pediatrics, neurodevelopmental disabilities and sports medicine (2).

Subspecialty certification (from other specialty Boards) is also available in: pediatric otolaryngology, child and adolescent psychiatry, pediatric radiology, pediatric surgery, and pediatric pathology (3). Other specialties may offer additional pediatric training to their fellows to allow them to be designated as subspecialists. For example, pediatric orthopedists and pediatric ophthalmologists have additional training and skills necessary for the appropriate care of children.

Under traditional fee for service payment arrangements (doctors are paid for services that they deliver), access to pediatric subspecialty care was primarily limited by geographic availability. "Capitation" refers to a system in which physicians are paid a fixed amount per patient per month regardless of whether the patient is seen 20 times during the month or not at all. Capitation is risky in that physicians will not be adequately reimbursed for severe or chronically ill patients, but on average, this is offset by healthy patients who do not use the service. With other insurance payment arrangements covered under the umbrella of "managed care" (which may be pure capitation or a combination of capitation and fee for service), the access to pediatric subspecialty care may also be limited by the network of physicians who participate with (or are employed by) the health maintenance organization. A pediatrician who is deciding whether to contract with, or become employed by, a health maintenance organization may want to consider what degree of access to pediatric subspecialty care his/her patients will be able to count on. As access to subspecialists becomes more difficult, the primary care pediatrician will need to be able to provide more complex care for at least some of the patients in his/her panel.

The American Academy of Pediatrics has addressed these issues in several policy statements. For example, in "Guiding Principles for Managed Care Arrangements for the Health Care of Newborns, Infants, Children and Young Adults" (4), some major principles were outlined including:

1. Access to Appropriate Primary Care Pediatricians:

a. Choice of primary care clinicians for children must include pediatricians.

b. Primary care pediatricians (PCPs) should serve as the child's medical home and ensure the delivery of comprehensive preventive, acute, and chronic care services. They should be accessible 24 hours a day, 7 days a week, or have appropriate coverage arrangements.

c. The PCP should assume the role of the care coordinator (i.e., the physician who ensures that all referrals are medically necessary). The function of the PCP might be transferred to a pediatric medical subspecialist for certain children with complex physical and/or mental health problems (e.g., those with special health care needs, such as children with cystic fibrosis, juvenile rheumatoid arthritis) if the specialist assumes responsibility and financial risk for primary and specialty care. For certain physical, developmental, mental health, and social problems, the PCP may seek the assistance of a multidisciplinary team with participation by appropriate public programs (e.g., Title V Program for Children with Special Health Care Needs).

d. Families should receive education at the time of enrollment to help them understand fully how managed care arrangements work for their individual policies.

2. Access to Pediatric Specialty Services:

a. When children need the services of a physician specialist or other health care professionals, plans should use clinicians with appropriate pediatric training and expertise. Pediatric-trained physician specialists, including pediatric medical subspecialists and pediatric surgical specialists, should have completed an appropriate fellowship in their area of expertise and be certified by specialty boards in a timely fashion if certification is available. These physicians and other health care practitioners should be engaged actively in the ongoing practice of their pediatric specialty and should participate in continuing medical education in this area.

b. There should be no financial barriers to access for pediatric specialty care above and beyond customary plan requirements for specialty care.

c. Plans should contract with the appropriate number and mix of geographically accessible pediatric-trained physician specialists and tertiary care centers for children.

d. Referral criteria for pediatric specialty clinicians should be developed. These criteria may include age of the patient, specific diagnoses, severity of conditions, and logistic considerations (e.g., geographical access and cultural competence).

e. Processes for approving referrals to pediatric medical subspecialists and pediatric surgical specialists should be developed by health plans working collaboratively with PCPs and pediatric medical subspecialists and pediatric surgical specialists.

There is particular concern about pediatric specialty care for children with special health care needs. As stated in the AAP policy statement "Managed Care and Children with Special Health Care Needs: A Review" (5): Children with disabilities differ from adults with disabilities in a managed care environment in a variety of ways. Three major differences include the following: 1) The changing dynamics of child development affect the needs of these children at different developmental stages and alter their expected outcomes. Illness and disability can delay, sometimes irreversibly, a child's normal development. 2) The epidemiology and prevalence of childhood disabilities, with many rare or low incidence conditions and few common ones, differ markedly from that of adults, in which there are few rare conditions and several common ones. 3) Because of children's need for adult protection and guidance, their health and development depend greatly on their families' health and socioeconomic status.

This policy also states, "Children with disabilities and other chronic conditions that may lead to disability require the services of pediatric subspecialists in addition to primary care pediatricians. Access and availability of pediatric subspecialty services must not be significantly impeded by managed care arrangements. Although it is ideal for the primary care physician to manage and coordinate the care for a child's health needs, the complex or rare nature of a particular child's condition may make it difficult for the primary care physician to meet all of the needs of the child and family adequately without additional expertise" (5).

A good pediatric primary care physician should also work with non-physician partners. Interactions with school personnel, public health nurses, social workers, various therapists (such as speech/language therapists, occupational therapists, physical therapists), early

childhood educators or daycare providers are a common part of pediatric practice today. Learning to interact appropriately with these individuals, and to gain from their expertise, is an important part of pediatric training.

Primary care pediatrics can be very challenging. Although there is a perception that office based pediatrics is largely limited to runny noses and ear infections, in fact there is a wide realm of issues and problems that a pediatrician may become involved in. The nature of the practice will depend to some extent on the ease of availability of subspeciality care, but will also depend on personal characteristics of the pediatrician that determine the practice style he or she is most comfortable with.

Questions

1. True/False: When caring for pediatric patients, it is always more appropriate to use pediatric subspecialists than specialists who may be primarily trained to work with adults.

2. True/False: There is a standard for after hours accessibility that all pediatricians adhere to.

3. True/False: There is variability in the use of pediatric subspecialty care that results from factors other than availability of specialists.

4. If a pediatric subspecialist is not available, the pediatrician has the following choices:
   a. Evaluate and manage the patient without referral.
   b. Use a specialist who does not have pediatric subspecialty training.
   c. Send the patient to a pediatric subspecialist regardless of cost and inconvenience.
   d. All of the above.

5. Pediatricians may be concerned about giving after hours telephone advice to parents who call. This concern may be dealt with by:
   a. Refusing to talk with parents after hours.
   b. Referring all parents who call to take their child to the ER.
   c. Only giving advice to parents who are familiar and reliable.
   d. Ignoring concerns and giving advice to any parent who calls.
   e. All of the above may be considered appropriate.

Answers to questions

1. False. Proximity to the patient is also an important factor. A general surgeon practicing in a small town might be the best person to handle a suspected case of appendicitis, for example.
2. False. Although some third party payors have standards written into their contracts with physicians, and the American Academy of Pediatrics has created a standard, not all pediatricians adhere to these standards.
3. True. Many factors are involved, including the training of the primary care pediatrician and past experience with similar cases.
4. d
5. e

Chapter I.2. Growth Monitoring
Vince K. Yamashiroya, MD

A 4 month old Asian female comes to your office for her scheduled well baby checkup. She was born at 39-4/7 weeks gestation by normal spontaneous vaginal delivery without any complications. At birth, her weight was 3856 g, length 53 cm, head circumference 34 cm, and chest circumference 35.5 cm. She was discharged from the nursery at 48 hours of life. She has been breast-fed since birth, although her mother started to also use formula between one to two months of age. She is now being breast-fed once a day, given pumped breast milk in a bottle two to three times a day, and formula the rest of the time (about 16 oz or 480 ml per day). She has 2 to 3 bowel movements a day with many wet diapers. Her past medical history is otherwise significant for a vibratory heart murmur heard from the second week of life, which was thought to be innocent. Parents have no concerns.

Exam: VS are normal. Weight 7.4 kg (95%tile), length 64 cm (90%tile), head circumference 43 cm (90%tile), and chest circumference 41 cm. She is a robust, active and healthy appearing infant. Her heart murmur has resolved and the rest of her examination is otherwise normal.

The monitoring of a child's growth is probably the most important job for a pediatrician. It is not only essential for the general pediatrician, but for other subspecialties as well. An aberration in growth patterns is often the first clue that there is something wrong with the child. Often, the growth of the child is used in conjunction with other signs and symptoms, to help the physician determine what the problem might be. An older child who is not gaining weight could be the first clue to inflammatory bowel disease. A girl who is short in stature may have Turner syndrome. A baby with an abnormally increasing head size might have hydrocephalus.

The most important tool for assessing and monitoring a child's growth is the growth chart which plots height (length), weight and head circumference. There are different growth charts for boys and girls. There are two age group specific growth charts, one for children from birth to 36 months of age, and another from 2 years to 20 years of age.

The National Center For Health Statistics (HCHS) of the Centers for Disease Control and Prevention, recently released new standard growth charts in 2000 that remedy many of the deficiencies present in older growth charts. The new growth charts are based on a national representative sample collected from 1988 to 1994 as part of the National Health and Nutrition Examination Survey (NHANES-III), and they better represent the combined growth patterns of breast-fed and formula-fed infants. The larger, pooled data sets used to create the revised charts eliminate the problem of differing percentiles when making the transition from recumbent length to stature height. Lastly, the weight for height curves have been replaced by body mass index (BMI) curves. Other new features of the new growth charts are the extension to 20 years because of sufficient data being available and its desirability for general populations, particularly for clinics dealing with endocrine disorders and congenital abnormalities (1).

It should be noted that these growth charts are reflective of the population who are healthy and born at term. There are other growth charts available for children with various conditions, such as Turner, Klinefelter and Down syndromes and achondroplasia (2). Special growth charts for premature babies are also available by Babson and Benda that are based on gestational rather than chronological age, beginning at 26 weeks of gestation (3). Unfortunately, these charts are based on a relatively small, possibly non-representative sample (4). If the NCHS growth charts are used, however; the child's growth parameters (weight, height, head circumference) should be adjusted for prematurity until 24 months of age or up to three years for infants born at less than 1500 grams (5). Very low birth weight (VLBW < 1,500 g) infants may continue to show catch-up growth through early school age.

It is essential to look at the trajectory of the child's growth curve. Typically, infants and children stay within one or two growth percentile channels, which is due to the control that genes exert over body size. A growth channel is the area between the percentile lines. A normal exception occurs during the first two years of life. For full term infants, size at birth reflects the influence of the uterine environment. Size at age 2 years correlates with mean parental height, reflecting the influence of genes. Therefore, from birth through 18 months, small infants will often shift percentiles upward toward their parents' mean percentile, and large infants will shift downwards (4). A formula can be used to calculate the estimated adult height by taking the mid-parental height (mother's height + father's height, divided by 2), and adding 6.5 cm for males, and subtracting 6.5 cm for females, with a range of 2 standard deviations (one standard deviation is about 5 cm) (6). Growth is influenced by many factors, including nutrition, chronic disease, etc., therefore this formula is based purely on genetic potential.

In adolescents, normal variations in the timing of the growth spurt can lead to a misdiagnosis of growth abnormalities. In primary care, it is important to know the relationship between sexual maturity and growth, which is beyond the scope of this chapter. However, a few general rules can be kept in mind. Before the onset of puberty, the average height velocity is about 5 to 6 cm per year. In females, peak height velocity occurs about 2 years after the growth spurt begins and averages about 9 cm per year. This is also around the time when the nipple and areola have developed but before any other significant breast development (7), and about 6 to 12 months prior to menarche. After menarche, females will usually not grow more than 5 cm, with epiphyseal closure occurring about 2 years after. In males, peak height velocity occurs later and averages about 10 cm per year. This is about the time that the male's genitalia are fully developed. Males are taller because of this greater velocity of height in addition to having about 2 more years of prepubescent growth over females (8).

The growth curve is not linear but rather sigmoidal. Growth normally starts to slow down at about 12 to 15 months of age, which is reflected in the growth chart. The periods of rapid growth occur during the first 12 months of age, and from puberty until adulthood. The growth chart is an essential tool to diagnose failure to thrive (FTT) or growth failure. Although there are no universal criteria for FTT, most consider the diagnosis if the child's weight is below the 5th percentile or drops more than two major percentile lines. Calculation of weight gain in grams per day also allows more precise estimation of growth rate as can be seen in the table below. Neonates should gain weight at a rate of 15 g/kg/day (9).

Age	Approximate Daily Weight Gain	Approximate Monthly Weight Gain
0-3 mos	30 g	1 kg (2 lb)
3-6 mos	20 g	0.6 kg (1.25 lb)
6-9 mos	15 g	0.5 kg (1 lb)
9-12 mos	12 g	0.4 kg (12 oz)
1-3 yrs.	8 g	0.25 kg (8 oz)
4-6 yrs.	6 g	0.18 kg (6 oz)

Note: 30 g = 1 oz.

When curves are outside the 5th and 95th percentiles, it is useful to mention the age at which the growth parameter is at its median value (50th percentile). For example, if a 10 year old female weighs 18 kg, this weight is below the 5th percentile for a 10 year old; and, it is at the 50th percentile for a 5 year old. One could state that her weight age is 5 years, which is a better quantitative description of the growth abnormality.

The weight for height curves exceeding 120% of the median weight for height can also be an indicator for obesity. The problem with the weight for height curves is that they are applicable only from 2 years to 11.5 years for males and up to 10 years for females because of weight for height changes occurring with age after pubescence. The new growth charts remedy this by including the body mass index (BMI), which is weight in kilograms divided by the square of the height in meters. In adults, a BMI value greater than 25 units is widely accepted as being overweight and a value larger than 30 units is accepted as obesity. However, since the cutoff values for children differ with age and sex, they therefore must be based on percentiles, with the 85th percentile being suggested as the cutoff point for being overweight. This percentile is also justified by studies showing that the risk of large BMI values in adulthood and the prevalence of cardiovascular and other diseases increase dramatically for children ages 8 years and older who are over the 85th percentile for BMI. BMI values decrease from 2 years to 5 years of age, after which there is an increase to 20 years of age. The changes with age in BMI reference values reflect normal alterations in total body fat and fat-free mass. Fat-free mass increases with age in both sexes, but increases are more rapid in boys than in girls after age 13. Likewise, total body fat increases from 8 to 18 years in girls but decreases after age 14 in boys. Another interesting point is the time of rebound, or the point when the BMI values change from decreasing to increasing. It has been observed that individuals who rebound earlier than 5 years of age have higher BMI compared to those who rebound later after 5 years of age. This helps predict those individuals who are at risk for obesity later in childhood and adulthood. The disadvantage of using BMI is that it does not provide an accurate index of adiposity since it does not differentiate between lean tissue and bone from fat. However, BMI values correlate with total body fat, fat as a percentage of body weight (percent body fat), and the mass of all lean tissues (fat-free mass). Although percent body fat is the best measure of obesity, its measurement requires complex laboratory procedures. When BMI is used to identify obese children, there are many false negatives (obese children not identified) but few false positives (non-obese children classified as obese). Therefore, for the easy recognition of obese children, BMI is preferred over triceps skinfold thickness in girls, but triceps skinfold thickness may be more useful in boys (1).

Common student and board examination questions include the growth chart patterns for various diseases and conditions such as constitutional growth delay, familial short stature, nutritional insufficiency, and congenital pathologic short stature. The following list describes the characteristics of each (4).

1. Congenital pathologic short stature: These infants are born small and growth gradually tapers off throughout infancy. These babies are born with intrauterine growth retardation (IUGR), and are small for gestational age (SGA). Examples are chromosomal abnormalities, TORCH infections, teratogens, extreme prematurity, maternal smoking, etc.
2. Constitutional growth delay: In this type of delay, these patients enter puberty later; therefore, their growth spurt occurs later in adolescence. The growth curve has the following appearance: weight and height drop in their percentiles near the end of infancy, parallel the norm through middle childhood, and accelerate toward the end of adolescence. Adult size is normal or often taller than average because their duration of growth is longer than others. Frequently, one or both parents may have a history of short stature during childhood, delayed puberty, and eventual normal adult height. Delayed puberty can be identified by asking about age of menarche in mother and age at which father first started shaving. Tanner staging is also useful in evaluating these patients because of their delayed puberty.
3. Familial short stature: Infant and parents are small. Growth runs parallel to and just below the normal curves.
4. Nutritional insufficiency: In this condition, weight declines before length. Body mass index is also low.

Questions

1. What is the formula for calculating BMI?
2. At what age does the uterine environment play a role in the growth of a child versus the influence on growth by the genetic makeup?
3. What are two ways failure to thrive are recognized in a growth chart?
4. What percentile of BMI is considered the cutoff point for being overweight?
5. What is the approximate weight gain in grams per day for a healthy term infant from birth to 3 months of age?
6. At what age does rebound occur in BMI? If a child rebounds early, what is this predictive of?
7. What is a weakness of using BMI to identify obesity?
8. How do the growth curves for congenital pathologic short stature, constitutional growth delay, and familial short stature look like?
9. What is the formula used to estimate a child's adult height (Tanner's height prediction formula)?

Answers to questions

1. BMI (kg/m2) = weight in kilograms divided by the square of the height in meters.
2. First 18 months of life.
3. a) If the child's weight is below the 5th percentile, or b) if weight drops more than two major percentile lines.
4. 85th percentile.
5. 30 grams, or 1 oz per day.
6. At 5 years of age. Those who rebound before 5 years have a higher risk of obesity in childhood and adulthood.
7. It does not provide an accurate index of adiposity since it does not differentiate between lean tissue and bone from fat.
8. Congenital pathologic short stature: infant born small and growth gradually tapers off throughout infancy. Constitutional growth delay: weight and height drop in their percentiles near the end of infancy, parallel the norm through middle childhood, and accelerate toward the end of adolescence. Adult size is normal. Familial short stature: Infant and parents are small. Growth runs parallel to and just below the normal curves.
9. Predicted adult height = (mother's height + father's height) divided by 2, and adding 6.5 cm for males, and subtracting 6.5 cm for females, with a range of 2 standard deviations (one standard deviation is about 5 cm).

Chapter I.3. Developmental Screening of Infants, Toddlers and Preschoolers

Jeffrey K. Okamoto, MD

Three 18 month old children with their respective families have been seen at the outpatient pediatrics clinic since birth. All three children superficially appear normal, growing well on their growth curves. The children have no dysmorphic features or other abnormal signs on physical exam. They have not had any serious illness or hospitalization. The physicians in the clinic are mandated to do a check of development but they do this somewhat differently from physician to physician. One physician uses a Denver II Developmental screen on selected visits. One physician uses a Parent Questionnaire (a particular one called the PEDS) routinely. Another physician asks questions to her parents but does not use any formal developmental screening instrument.

In actuality all three children have autism. All three families do not know their children have this.

The first child shows delays on the Denver II screen in the personal social area. With the Denver II, the parents are asked certain questions, and they relate he doesn't play pat-a-cake, indicate wants, wave bye-bye, imitate activities or help in the house at 18 months of age. On direct observation with the Denver II he doesn't play ball with the examiner. Also he is not saying any words including "mama" or "dada" at 18 months of age. In the gross and fine motor areas his development appears normal. He is referred to an early intervention program and is diagnosed with autism.

The mother of the second child answers "Yes" to three of the questions on the PEDS (Parents' Evaluation of Developmental Status) parent questionnaire: 1) Do you have any concerns about how your child understands what you say?, 2) Do you have any concerns about how your child behaves? and 3) Do you have any concerns about how your child gets along with others?. The mother answers "no" to the other questions on the questionnaire. On further questioning the child's family relates how she likes to play by herself, and is easy to care for as she doesn't need too much attention. They are worried that she doesn't talk as much as other children, with words being spoken but in ways that do not make sense. She is suspected to have autism, and is referred to a Developmental Behavioral Pediatrician who confirms the diagnosis after more elaborate evaluation. She is referred to an early intervention program.

The physician who asks questions directly to families, finds the parents of the third child slightly worried at the 18 month visit about the child not being cuddly and not seemingly not very attached to them. They are told to interact more at home with their toddler. Later at three years of age, the parents are very worried about the child's language but are told that many children are "late talkers". When the child is five years of age the school notes the child's aloofness, poor receptive and expressive language, and nonexistent social skills. The school psychologist evaluates the child and relates to the parents their child has autism. The parents become angry as they find that many characteristics they have seen in the past two to three years are noted by the school psychologist as signs of autism. They tell the psychologist that they feel that their physician should have figured this out earlier.

An important aspect of caring for children in a medical context is that they grow in multiple ways over time. There is an expectation that they will grow physically in size. They also develop cognitively, behaviorally, socially and motorically.

Unfortunately, there are a variety of medical conditions that are derangements in proper child development. These include common diagnoses such as mental retardation and language disorders. There are many more problems that are rare, such as most of the developmental disabilities with genetic etiologies. Other medical conditions, such as cancer, may impact child development because of the effects of chemotherapy on the brain, or because of child and parental stress. Developmental or behavioral conditions are thought to occur in 12 to 16% of children in the United States (1). Families expect physicians to identify developmental problems in their children and then help manage these concerns (2).

It is therefore particularly important for physicians to carefully and routinely evaluate children for problems in development and behavior. Physicians such as pediatricians and family practitioners have essential roles because of their frequent contact with children and their families. They have knowledge of normal and abnormal development unlike other professionals who are in touch with families.

Physicians commonly encounter children in well child visits, in the emergency room, and in the hospital. All of these contexts allow for some monitoring of a child's development, but the best time to do developmental screening is in a primary care context. In the emergency room or in the hospital, a child may show developmental regression. Directly observed developmental behavior may be different than when the child is well (3). Attention is focused on acute illness during ER and hospital conditions, which makes families less receptive to other aspects of child health and development. Families also have more trust with someone who gets to know their child and family well. They prefer hearing any bad news from their regularly seen provider (4).

Identifying children with cognitive, behavioral, social or motor problems can be difficult. Problems in development may be subtle. Glancing at a child in the clinic may not identify these problems. Obvious and severe problems are actually rare compared to more commonly seen but subtle problems. Also, children sometimes do not cooperate with assessments. Lastly, developmental expectations change with age. Risk factors change with time. A child that appears completely normal as an infant or toddler may not develop skills expected in the preschool or school age group periods.

But because a moderate percentage of children have developmental or behavioral problems, a physician requires solid strategies for determining if a child has an important lag or problem in development. The majority of children with developmental problems are not detected without standardized screening tests. Informal "eyeballing" of children and informal questioning of parents do not work well. There is a good chance of missing problems because of the need of looking at multiple domains in development. A physician asking about walking and other motor skills may miss language and other cognitive deficits. Research from Great Britain where clinical impression is used rather than screening tests is revealing. It has been found that only about half the children who need to be identified are found using physician clinical impression without a developmental screening instrument (5). Also, asking questions about developmental milestones without a screening tool finds less than 30% of children with developmental conditions (6).

Therefore several instruments have been developed to increase identifying children with problems. These tools should be used on whole populations of children as to not miss children with subtle (and sometimes not so subtle) problems. Children need to be identified early so that problems can be managed properly. Goals of early management include optimizing the child's development, and supporting families with these children well.

The Denver II is a very popular screening tool used in the United States and worldwide. It was developed by Dr. William Frankenburg at the University of Colorado Health Sciences Center in Denver. It is an example of a "hands on" screening tool that also allows for parental report for selected items. However, most of the items require direct observation of the child trying to do certain tasks. There are 125 tasks arranged in four domains: personal-social, fine motor-adaptive, language and gross motor. However, only a few items in each domain are required to screen a particular child at a selected age. It has several advantages including ease of administration, coverage of a good range of age groups to screen (from birth to about 6 years of age), and a normative sample that includes diversification of race, place of residence (urban, suburban, rural) and the mother's educational level (7). There are also very few screening tests that take less time (although clinicians still balk at the 20 minute administration time).

One type of screening that is growing in popularity, and bolstered by recent research findings is a standardized parent questionnaire. Parents' concerns about children are important. Some concerns, particularly with parental worries regarding speech-language, emotional, behavioral, fine motor and global problems were highly predictive of true problems (5). Concerns about the accuracy and bias of parent reporting, parent reading level, and their understanding of concepts regarding the standardized parent screening tools have not been shown to be major problems after research has been done regarding these tools. (6).

The PEDS (Parents' Evaluation of Developmental Status) is a recently developed and well researched example of a standardized parental questionnaire. Parents complete the 10 item questionnaire in the waiting room. It takes about two minutes for the clinician to interpret the questionnaire. The PEDS can guide the clinician in getting particular history from the parents and guide what elements to include on the exam. The interpretation also helps guide the clinician in whether to use a hands-on screening tool, give parental reassurance, monitor the child, or make specific referrals to other specialists (6).

There are common problems in using developmental screening tests. A very common problem is not administering the screen as it was intended. This is often done secondary to poor training in the screening tool or to save time. The Denver II takes about 20 minutes to administer and score (8). Parental questionnaires are often quicker as they can be given to the parents while they are in the waiting room, and then scored when they interact with the physician (7).

Another problem is to assume that the screening test done at one point in time will discover all children with every type of developmental problem (8). Because development is ongoing with time, and because measuring development at very young ages cannot evaluate the full complexity of the various developmental domains at later ages, it is important to continue to assess children using tools appropriate for their age throughout their entire development.

Fortunately the child attending school usually has such assessments administered by the school on a periodic basis. The job of the physician in developmental screening is especially important prior to the school years. Physicians can access early intervention services until 3 years of age and then special education programs from ages 3 to 5 years for their children with developmental concerns.

Questions

1. Developmental and behavioral conditions occur in approximately what percentage of children?
   a. 0.15%
   b. 1.5%
   c. 15%
   d. 50%
   e. 80%

2. What is the best clinical situation to try to identify children with developmental disorders from developmentally normal children?
   a. Primary care clinic
   b. Emergency room
   c. Hospital ward
   d. Pediatric intensive care unit
   e. All of the above are "best places"

3. Which of these following methods of identifying children with developmental or behavioral concerns has the worst sensitivity?
   a. "Hands on" developmental screening tool (such as the Denver II).
   b. Parent answered developmental questionnaire.
   c. Physician clinical impression about development, without a screening tool.
   d. Flagging all children in the Neonatal Intensive Care Unit (NICU) that have risk factors for disability.
   e. All have about equal sensitivity.

4. Which of the following have been proven problems regarding the standardized parent developmental screening tools?
   a. Concerns about the accuracy of parent reporting.
   b. Concerns about the bias of parent reporting.
   c. The tools are time consuming for the clinician to use.
   d. Understanding of concepts by parents.
   e. All of the above are not problems according to research.

5. Common problems in using developmental screening tests include all of the following EXCEPT:
   a. Not administering the screen as it was intended.
   b. An assumption that the screening test done at one point in time will discover all children with every type of developmental problem.
   c. Screening tests can be time consuming for the clinician.
   d. Children are not amenable to screening between birth and three years of age.
   e. Training is necessary for the proper use of these tools.

6. When is the best age (out of the following suggestions) for a physician to administer a developmental screening tool?
   a. In utero
   b. 2 years
   c. 6 years
   d. 10 years
   e. 17 years

Chapter I.4. Immunizations
Dennis A. Conrad, MD

A four year old boy presents to your office for the first time with a chief complaint of deficient immunizations. His mother, who in prior generations would have been characterized most accurately as an aging hippie, tells you, "He needs his shots to get into school, and he doesn't have any." You confirm that he has not received a single immunization prior to this time. When you ask why he hasn't been immunized, his mother replies that she "hasn't gotten around to it yet," and furthermore, that she "read on the Web and saw on TV that vaccines can hurt you." She then inquires of you, "What shots does a kid actually need, what are vaccines actually made of, and how safe are those immunizations, anyway?"

You perform a physical examination that reveals a healthy boy who is height and weight proportionate and developmentally appropriate for age, has no evidence of concomitant illness, and no abnormal findings upon thorough evaluation.

You then roll your eyes, sigh, and tell your nurse to reschedule your afternoon appointments. You attempt to address the mother's questions and concerns. Following your informative and comprehensive discourse, you obtain informed consent from the mother, then immunize the child using an accelerated schedule to "catch-up" the deficient immunizations. The child tolerates the vaccines without any significant adverse event occurring. After having been provided the remaining required immunizations during subsequent office visits, he begins school the autumn of his 5th year of life protected from vaccine-preventable diseases and meeting the statutory requirements for school entry. He does not acquire a vaccine-preventable disease throughout the remainder of his full and successful life as a professional surfer.

Immunizations children routinely receive currently during childhood are those that protect against hepatitis B, diphtheria, pertussis, tetanus, polio, Haemophilus influenzae type b, Streptococcus pneumoniae, measles, mumps, rubella, and varicella (1). In addition, selected populations receive immunization to protect against hepatitis A and seasonal influenza viruses. The number and ages of administration for these vaccines differ, but the goal of the recommended schedule for childhood immunizations is to provide full protection against vaccine-preventable diseases.

Immunization policy has established the practice of universal childhood immunization to provide vaccines at a time (childhood) an individual is more likely to have contact with health care providers (to increase convenience and minimize delivery costs), to protect children from vaccine-preventable diseases, to establish the foundation for an immune adult population, and to have a enforcement mechanism in order to ensure compliance (required for school entry).

Hepatitis B virus (HBV) vaccine is a recombinant subunit vaccine containing purified Hepatitis B surface antigen, synthesized by insertion of a plasmid encoding for the Hepatitis B surface antigen protein into baker's yeast (2). Hepatitis B vaccine exists as monovalent vaccine (RecombivaxHB, Engerix-B), in combination with Haemophilus influenzae type b vaccine (Comvax), and in combination with Hepatitis A vaccine (Twinrix).

The monovalent Hepatitis B vaccines are administered as a 3 dose series, with the first dose given between birth and 2 months of age, the second dose between 2 months and 4 months of age, and the third dose between 6 months and 18 months of age. Comvax should not be given before 6 weeks of age due to the Haemophilus influenzae type b component, and Twinrix is not yet approved in the United States for use in persons less than 18 years old.

Universal immunization of infants with hepatitis B vaccine is recommended to provide global protection of that birth cohort against hepatitis B infection, to provide vaccine at a time health care visits are otherwise being made, and to afford protection to infants born to mothers who have chronic hepatitis B infection. If hepatitis B vaccination is not provided in infancy at the recommended ages, then at least a 1 month interval should separate administration of the first and second vaccine doses, and at least a 5 month interval should separate the second and third vaccine doses.

The most common adverse reactions to hepatitis B immunization are fever and local reactions at the injection site. Allergic reactions occur infrequently. No causal association with multiple sclerosis or sudden infant death syndrome has been demonstrated.

Diphtheria (D; d) vaccine is a toxoid vaccine that provides formalin-inactivated diphtheria toxin, derived from a potent exotoxin produced by Corynebacterium diphtheriae (3). A "toxoid" is a denatured (nonpathogenic) toxin which stimulates an immune response against the toxin but not necessarily the organism as a whole. Immunization promotes an antibody response that neutralizes the exotoxin, protecting against the cardiotoxic and neurotoxic effects of the exotoxin which is produced during infection. Diphtheria toxoid is combined with tetanus toxoid in a pediatric (DT) and adult (dT) formulation that differs by amount of diphtheria antigen. Diphtheria and tetanus toxoids are also combined with acellular pertussis vaccine (DTaP) for use during routine childhood immunization.

DTaP is given by intramuscular injection as a primary 3 dose series at 2 months, 4 months, and 6 months of age, and as a 2 dose booster series at 12-18 months and 4-6 years. A reduced diphtheria-antigen adult formulation booster (dT) is administered at 11-12 years, and subsequent boosters are then administered at 10 year intervals throughout life.

Tetanus (T) vaccine is a toxoid vaccine that provides formalin-inactivated tetanus toxin, derived from the neuromuscular toxin tetanospasmin produced by Clostridium tetani (3). Immunization promotes an antibody response that neutralizes the toxin. Tetanus vaccine may be monovalent (TT), or combined with either diphtheria toxoid (DT or dT) or with diphtheria toxoid and acellular pertussis (DTaP).

Persons who sustain injuries more likely to become infected with Clostridium tetani (crush wounds with devitalized tissue, deep puncture wounds, wounds contaminated with soil or vegetative matter) should receive a booster dose of tetanus vaccine if at least 5 years have passed since last receiving a tetanus vaccine booster. The most common adverse reactions to tetanus immunization are fever and local reactions at the injection site. Severe allergic reactions, Guillain-Barre syndrome, and brachial neuritis occur rarely.

Three acellular pertussis (aP) vaccines are currently licensed and available for use in the United States (Tripedia, Infanrix, Daptacel). These vaccines are called acellular, to distinguish this formulation from the older whole-cell pertussis vaccine. Whole-cell pertussis vaccine consisted of inactivated ("killed") but otherwise complete Bordetella pertussis bacteria. Administration provided protection against disease but was associated with the potential for adverse effects that occurred frequently and could be quite severe on rare occasion. In order to provide a vaccine that was better tolerated, individual bacterial components that contributed to organism virulence and pathogenicity were identified and purified as individual cell-free (acellular) antigens that comprise the current acellular pertussis vaccines (3,5).

DTaP is given by intramuscular injection as a primary 3 dose series at 2 months, 4 months, and 6 months of age, and as a 2 dose booster series at 12-18 months and 4-6 years. Whole-cell pertussis vaccine was not provided to persons beyond 7 years old, due to the

increased incidence of adverse reactions associated with immunization. Currently, acellular pertussis vaccine is not recommended for immunization of persons older than 7 years of age due to the prior experience of whole-cell pertussis vaccine in this age group, although research is currently being conducted to see if adults may safely receive booster doses of the less reactogenic acellular pertussis vaccine to enhance and extend immunity to pertussis.

The most common adverse reactions to acellular pertussis immunization are fever and local reactions at the injection site. Allergic reactions occur infrequently. Rare but potentially serious reactions, including high fevers, prolonged crying, hypotonic-hyporesponsive episodes, and seizures have occurred, but at significantly lower frequency than was true for whole cell pertussis vaccine.

Inactivated polio vaccine (IPV) is a trivalent killed virus vaccine (Salk vaccine; IPOL) that contains formalin-inactivated poliovirus 1, poliovirus 2, and poliovirus 3, which are the three neurovirulent strains. Improvement in manufacturing techniques has enhanced the immunogenicity of inactivated polio vaccine (eIPV). Immunization effectively protects against paralytic poliomyelitis, but may not protect against subclinical enteric infection due to lack of secretory antibody response to inactivated polio vaccine (6).

Inactivated polio vaccine is administered as a 4 dose regimen by intramuscular injection at 2 months, 4 months, between 6 months and 15 months (3 dose primary series), and between 4 years and 6 years of age (booster dose). The most common adverse reactions to inactivated polio immunization are fever and local reactions at the injection site. Allergic reactions occur infrequently. Inactivated polio vaccine cannot cause vaccine associated paralytic poliomyelitis.

A second formulation of polio vaccine, trivalent oral live attenuated polio vaccine (tOPV; Sabin vaccine; Orimune), also provides protective immunity against paralytic poliomyelitis. In addition, oral polio vaccine uniquely protects against enteric infection by promoting mucosal immunity and offering the benefit of herd immunity by secondary immunization of susceptible persons exposed to asymptomatic shedding of vaccine strain virus from vaccine recipients. Unfortunately, as paralytic poliomyelitis due to wild-type virus was eradicated in the United States by effective immunization programs, the rare risk of paralytic poliomyelitis due to vaccine strain virus (3 to 12 cases annually) ultimately has become greater than the risk due to wild-type poliovirus. Therefore, only inactivated polio vaccine is used in the United States currently, whereas the effective, economically favorable, convenient trivalent oral polio vaccine continues to be used in wild-virus polio endemic regions in an attempt to eradicate paralytic poliomyelitis worldwide.

A vaccine containing DTaP, HBV, and IPV (Pediarix) has recently been licensed for use in the United States to provide the primary series of immunizations (first 3 doses) for children 6 months to 7 years old. This combination vaccine may be used for all 3 vaccine doses, or used to complete the primary series in infants who have already received 1 or 2 doses of DTaP, HBV, or IPV. The combination vaccine was developed to reduce the number of injections infants receive during routine childhood immunization, and provides the same vaccines that have previously existed individually (Infanrix, IPV, and Engerix-B).

Haemophilus influenzae type b (Hib) vaccine is a conjugated vaccine containing the Haemophilus influenzae type b capsular polysaccharide polyribosylribitol phosphate (PRP), which is the major virulence factor, conjugated with a carrier protein to enhance immunogenicity (7). Infants less than 6 weeks old should not be exposed to vaccines containing Haemophilus influenzae type b PRP antigen, as premature exposure may create immune tolerance, causing suboptimal antibody response upon subsequent antigen exposure and resulting in failure to develop protective antibody concentrations.

The four monovalent conjugated Haemophilus influenzae type b vaccines currently available are differentiated by their respective carrier proteins. Infants receive either a 2 dose or 3 dose series of Haemophilus influenzae type b vaccine during the first year of life (predicated by specific vaccine brand utilized), and a single booster dose between 12 months and 15 months of age (resulting in either a 3 dose or 4 dose regimen to completely immunize the child).

The number of conjugated Haemophilus influenzae type b vaccine doses required to immunize older children not receiving vaccine in infancy diminishes due to brisker antibody response seen when older children receive conjugated Haemophilus influenzae type b vaccine. If the first dose of vaccine is not administered until the child is between 7 months and 11 months of age, then only 3 doses are required to complete the regimen. If the first dose of vaccine is not administered until the child is between 12 months and 14 months of age, then only 2 doses are required to complete the regimen. If the first dose of vaccine is not administered until the child is between 15 months and 59 months of age, then only a single dose is required to complete the regimen. Non-immunized children 5 years old and older do not require Haemophilus influenzae type b vaccine unless they possess underling risk factors (impairment in immunity) that would increase their risk for invasive disease.

The most common adverse reactions to conjugated Haemophilus influenzae type b immunization are fever and local reactions at the injection site. Allergic reactions occur infrequently.

Conjugated Streptococcus pneumoniae (PCV) vaccine is a conjugated heptavalent vaccine (Prevnar) containing the capsular polysaccharides of the 7 strains of Streptococcus pneumoniae responsible for 80% of all cases of invasive pneumococcal disease occurring in children in the United States (8). Each specific polysaccharide is conjugated with a nontoxic mutant diphtheria toxin to enhance immunogenicity when administered to infants. Capsular polysaccharide is an important virulence factor for Streptococcus pneumoniae, existing in antigenically distinct permutations that confer type specificity to the individual bacterium, and requiring a type-specific host immune response to protect against disease.

Nonconjugated pneumococcal polysaccharide vaccine (PPV), which was developed before conjugated pneumococcal vaccine, currently exists as a 23-valent vaccine (PNU-IMUNE 23 and Pneumovax 23) that protects against 85-90% of strains causing invasive disease occurring in children and adults in the United States, but is poorly immunogenic in children under 2 years of age. Use of nonconjugated polysaccharide vaccine is indicated for persons at least 2 years of age, and is administered as a single intramuscular injection. Persons at high risk for invasive pneumococcal disease (asplenia, sickling hemoglobinopathy, congenital and acquired immunodeficiency, immunosuppression, spinal fluid leak, chronic cardiac, pulmonary, hepatic, or renal disease) should receive a second dose of unconjugated pneumococcal polysaccharide vaccine, administered between 3 years and 5 years following the initial dose.

Infants receive a 4 dose regimen of conjugated pneumococcal vaccine. The primary series is administered by intramuscular injection at 2 months, 4 months, and 6 months of age, and a fourth (booster) dose is administered between the ages of 12 months and 15 months. The number of conjugated pneumococcal vaccine doses required to immunize older children not receiving vaccine in infancy is reduced due to the brisker antibody response seen when older children receive conjugated pneumococcal vaccine. If the first dose of vaccine is not administered until the child is between 7 months and 11 months of age, then only 3 doses are required to complete the regimen. If the first dose of vaccine is not administered until the child is between 12 months and 23 months of age, then only 2 doses are required to complete the regimen. Routine conjugated pneumococcal vaccination is not recommend for children who are 2 years or older, although children of this age group who are at high risk for invasive pneumococcal disease should be vaccinated with the nonconjugated 23-valent PPV.

The most common adverse reactions following conjugated Streptococcus pneumoniae immunization are fever and local reactions at the injection site. Allergic reactions occur infrequently. Occasionally, fever may be high and local reactions severe, especially with subsequent doses of vaccine. Febrile seizures may complicate vaccine induced fevers.

Measles (Me) vaccine is an attenuated live virus vaccine that causes subclinical infection following administration, provoking a host immune response that protects against subsequent infection following exposure to wild-type virus. The first measles vaccine developed was a killed virus vaccine, which was associated with the potential development of an infection called "atypical measles" when vaccinated individuals were subsequently infected with wild-type virus. The current monovalent attenuated live virus vaccine (Attenuvax) contains the Moraten ("more attenuated") strain of measles virus, which effectively confers immunity while reducing the incidence of adverse events following vaccination (9).

Measles vaccine is most commonly administered in combination with mumps vaccine and rubella vaccine (MMR, mumps and rubella vaccines are also live attenuated virus vaccines), given as a subcutaneous injection to children between the ages of 12 months and 15 months of age. Approximately 95% of vaccine recipients respond to a single dose of vaccine; however, due to an increase in wild-type measles observed in vaccine recipients during the 1980s, current recommendations require a second dose of vaccine, generally administered between the ages of 4 years and 6 years prior to school entry (9).

The most common adverse reactions to MMR immunization are fever and local reactions at the injection site. Occasionally, transient rashes and transient thrombocytopenia may occur. Allergic reactions occur infrequently. Encephalitis has been suggested as an extremely rare complication of measles immunization, but definitive proof is lacking. No valid scientific evidence supports measles vaccine as causal causation for autism despite sensational claims to the contrary. Orchitis and parotitis have been rarely reported from mumps vaccine. Occasionally, transient arthralgia/arthritis and peripheral neuritis may occur from rubella vaccine (9).

Varicella (V) vaccine is an attenuated live virus vaccine that causes subclinical infection following administration, provoking a host immune response that protects against subsequent infection following exposure to wild-type virus. Oka strain varicella virus was initially developed in Japan. This strain was subsequently modified and is currently used in the United States. Varicella vaccine exists as monovalent vaccine (Varivax), which is administered as a single subcutaneous injection for children 12 months through 12 years of age, and as a two dose regimen separated by an interval of at least 4 weeks for children 13 years old and older. A single dose of varicella vaccine is associated with a 97% seroconversion rate in children <13 years old and a 94% seroconversion rate in older persons. A second dose of vaccine in associated with 99% seroconversion in adolescents and adults. Young children should routinely receive varicella vaccine as a component of universal childhood immunization, and older children and adolescent who have not had chickenpox should be identified and immunized (10,11).

The most common adverse reactions to varicella immunization are fever and local reactions at the injection site. Occasionally, recipients may have a localized (at the injection site) or more generalized varicella-like rash due to vaccine strain virus. A minority of vaccine recipients may have a mild case of chickenpox ("breakthrough chickenpox") due to wild-type virus following exposure to naturally occurring disease. Allergic reactions occur infrequently.

Hepatitis A virus (HAV) vaccine is a killed virus vaccine (12) containing formalin-inactivated hepatitis A virus that exists as monovalent vaccine and as bivalent vaccine in combination with hepatitis B vaccine (Twinrix). The first dose of vaccine produces protective antibody response within two weeks following administration. A second dose is administered to provide long term, durable protection against disease. The pediatric formulation of hepatitis A vaccine is indicated for use in the age group 2 years through 18 years. The initial dose is administered by intramuscular injection, followed by a second dose administered between 6 months and 12 months following the first.

Routine childhood immunization with hepatitis A vaccine is recommended for those regions and states where the incidence of hepatitis A infection is at least twice the national average, occurring at a frequency of at least 20 cases per 100,000 population annually. Eleven states surpass this threshold: Alaska, Arizona, California, Idaho, Nevada, New Mexico, Oklahoma, Oregon, South Dakota, Utah, and Washington. Childhood immunization with hepatitis A vaccine should be considered for those regions and states where the incidence of hepatitis A infection exceeds the national average and occurs at a frequency of between 10 and 20 cases per 100,000 population annually. Six states meet this criterion: Arkansas, Colorado, Missouri, Montana, Texas, and Wyoming. Hepatitis A immunization is also recommended for community control of recent outbreaks of infection, for travelers to hepatitis A endemic areas, for persons who have chronic liver disease, for homosexual and bisexual men, for injectors of illicit drugs, and for individuals with clotting factor disorders. The most common adverse reaction to hepatitis A immunization is a local reaction at the injection site. No serious adverse reaction is associated with hepatitis A vaccine.

Influenza vaccine is a vaccine that exists as an inactivated whole virus vaccine (not currently available in the United States) or as a split virus vaccine (subvirion vaccine; purified surface antigen vaccine) that contain the hemagglutinins of the predominately circulating strains of influenza virus. The vaccine traditionally contains antigens from two influenza A virus strains and one influenza B virus strain, determined by those most frequently isolated at the end of the current year's respiratory virus season and predicted to predominate in the next respiratory virus season. The vaccine is formulated and administered annually to compensate for antigenic shifts that occur in virus isolates in order to enhance strain-specific immunity during the current respiratory virus season. Those who should receive annual immunization include health care workers and others who may be significant vectors for contagion, healthy persons 50 years old or older, persons with underlying diseases (pulmonary, cardiac, metabolic, renal, and hemoglobinopathies), individuals receiving immunosuppression or chronic aspirin therapy, and pregnant women (beyond the first gestational trimester). Children between the ages of 6 months and 23 months should be immunized annually due to increased morbidity of influenza infection in this age group (13). Children younger than 9 years old receiving influenza vaccine for the first time should receive two doses of split virus vaccine administered in the age appropriate volume separated by at least a one month interval in order to enhance immunologic response and protection against infection.

In 2003, a live attenuated, cold-adapted trivalent viral influenza vaccine (FluMist) prepared by viral reassortment was approved for use in the United States. The vaccine exists as a spray for intranasal instillation, and contains the same three strains of influenza virus that are present in the current parenteral vaccine formulation. Use is limited to healthy individuals 5 to 49 years of age. Children 5 to 8 years old not previously immunized receive two doses of intranasal vaccine administered 60 days apart. Children 5 to 8 years old previously immunized with the intranasal vaccine, and all persons 9 to 49 years of age receive a single vaccine dose annually.

The most common adverse reactions to influenza immunization are fever and local reactions at the injection site. Allergic reactions occur infrequently. Guillain-Barre syndrome is a rare complication of influenza vaccination, apparently limited to adults.

Table 1: Recommended Childhood (Prior to School Entry) Immunization Schedule 2002 (1)
Vaccine (Route of Administration): Ages of Administration
HBV (IM): 0-1m, 1-4m, 6-18m
DTaP (IM): 2m, 4m, 6m, 15-18m, 4-6y
IPV (IM or SQ): 2m, 4m, 6-18m, 4-6y
Hib (IM): 2m, 4m, (6m), 12-15m
PCV (IM): 2m, 4m, 6m, 12-15m
MMR (SQ): 12-15m, 4-6y
Varicella (SQ): 12-15m
HAV (IM): 2-3y, 3-4y
Influenza (IM): 6-23m (annually)

Table 2: Recommended Childhood (Catch-Up) Immunization Schedule (12m-7y) 2002 (14)
Interval: Vaccines
0 (First visit): HBV, DTaP, MMR, Hib (12-60m)
1m: HBV, DTaP, IPV, Varicella
2m: DTaP, IPV, Hib (if first dose at 12-15m)
8m: HBV, DTaP, IPV
At age 4-6y: DTaP, IPV, MMR

Table 3: Recommended Childhood (Catch-Up) Immunization Schedule (7y-12y) 2002 (14)
Interval: Vaccines
0 (First visit): HBV, dT, MMR, IPV
2m: HBV, dT, MMR, IPV, Varicella (if susceptible)
8m: HBV, dT, IPV

Active immunization (as opposed to passive immunization) with vaccines provokes a host response that potentially confers durable immunity and protects against subsequent infection and disease following exposure to naturally occurring infection.

In the special circumstance of a susceptible person requiring immediate protection against disease, either prior to or following exposure to infection, transient immunity may be conferred by passive immunization, where preformed protective antibodies are administered. The advantages of passive immunization is the potential to provide immediate protection to the host. The major disadvantage of passive immunity is the subsequent decay of passively acquired antibody by metabolism and elimination, ultimately rendering the host potentially susceptible to infection once passively acquired antibody titers fall to subprotective concentrations.

Active immunization utilizes a live or killed antigen to stimulate the immune system to form an active immune response, while passive immunization is merely the injecting or infusing human or animal-derived antibodies into the body. Passive immunization preparations currently available include serum immunoglobulin, existing in formulations for intramuscular (IM-IG) and intravenous administration (IVIG), which can provide global protection against infections that are prevalent in the populations from whom these products are derived. In fact, this is why the administration of attenuated live virus vaccines (measles, mumps, rubella, varicella) is deferred for persons who have recently received blood products (including immunoglobulin preparations), since passively acquired antibody may prevent the vaccine-induced subclinical infection and the active immune response from developing. Killed virus, toxoid, conjugated polysaccharide, recombinant subunit, and bacterial antigen vaccines are not as adversely affected by the presence of passively acquired antibodies, and thus may be administered without consideration of blood products (including immunoglobulin preparations) recently received by the potential vaccine recipient.

Passive immunization products may also be specific for selected infections. These agents are labeled "hyperimmune" because effective concentrations of neutralizing antibody have been specifically ascertained. Those diseases for which passive immunity may be provided include respiratory syncytial virus (RSV-IG), palivizumab ("humanized" murine monoclonal anti-RSV antibody), hepatitis B (hepatitis B immune globulin, called HBIG), varicella (varicella zoster immune globulin; called VZIG), cytomegalovirus (cytomegalovirus immune globulin), and rabies (rabies immune globulin). Passive immunization products that protect against virulent toxins associated with infection are often called "antitoxin", and are administered to mitigate the significant systemic toxicity associated with infection. Tetanus immune globulin is derived from human serum. Botulism antitoxin (trivalent against botulism toxins A, B, and E) and diphtheria antitoxin are derived from horse serum (15).

Attenuated live virus vaccines (measles, mumps, rubella, varicella) should not be administered to persons who have impairment in immunity (congenital or acquired immunodeficiency, receiving immunosuppressive therapy, have malignancy or have undergone bone marrow or organ transplant) or are pregnant, due to the potential risk for the expected subclinical infection following immunization to become clinical, and potentially severe, posing risk to the vulnerable host or unborn child. Moreover, attenuated live virus vaccines should be administered simultaneously (during the same office visit), or individually separated by an interval of at least 4 weeks to prevent immunological interference with the second vaccine. Note specifically that attenuated live virus vaccines can be given simultaneously or at least 4 weeks apart, but at no time between these two time points. Additional doses of attenuated live virus vaccines in excess of those recommended for childhood immunization may be administered without increased risk of adverse reactions (16).

Noninfectious vaccines (killed virus, recombinant subunit, toxoid, conjugated polysaccharide, bacterial antigen) may be administered to persons who have impairment in immunity without increased risk, since these vaccines are incapable of causing infection. Immunologically impaired hosts may have suboptimal response to these vaccines, and may not be protected against subsequent development of disease following exposure. Noninfectious vaccines may be administered simultaneously or separated at any interval without appreciable risk of impaired immunologic response (16). Additional doses of these vaccines in excess of those recommended for childhood immunization are generally well tolerated, although the risk for enhanced systemic and local reactions may increase. Whole cell pertussis vaccine, diphtheria vaccine, and pneumococcal polysaccharide vaccine may be particularly prone to provoke exaggerated reactions with excessive doses of vaccine.

Vaccines are the single most cost-effective interventions performed to improve and maintain the health of citizens of the United States, and have been cited as one of the most significant advancements in medical practice occurring during the 20th century (17). Vaccines are not without risks, but the anxiety expressed by some parents is almost always the result of misperceptions fueled by misinformation. When considered against the risk of infection with concomitant associated morbidity and mortality, the benefits of universal childhood immunization far outweigh all risks for each of the vaccine-preventable diseases. In those circumstances where rare but potentially serious adverse reactions to immunization are demonstrated, such as the risk for intussusception following administration of the oral tetravalent rotavirus vaccine (18), the national Vaccine Adverse Event Reporting System (VAERS) provides identification of these rare complications and promotes the appropriate corrective actions. Health care providers should strongly endorse routine childhood immunization, and be capable and willing to adequately address any parental concerns.

Questions

1. Which of the following vaccines would be contraindicated in a 4 year old boy receiving immunosuppressive therapy for autoimmune hepatitis?
    a. Hepatitis A vaccine
    b. Hepatitis B vaccine
    c. Acellular pertussis vaccine
    d. Inactivated polio vaccine
    e. Varicella vaccine

2. Which vaccine should not be given to an 8 year old girl who has not been immunized previously?
    a. Hepatitis B vaccine
    b. Tetanus vaccine
    c. Acellular pertussis vaccine
    d. Inactivated polio vaccine
    e. Measles vaccine

3. Which parenteral vaccine should not be characterized as an attenuated live virus vaccine?
    a. Influenza vaccine
    b. Measles vaccine
    c. Mumps vaccine
    d. Rubella vaccine
    e. Varicella vaccine

4. Which passive or active immunization is specifically recommended for women in the second or third trimester of pregnancy?
    a. Respiratory syncytial virus immune globulin
    b. Cytomegalovirus immune globulin
    c. Rubella vaccine
    d. Influenza vaccine
    e. Varicella vaccine

5. Increased risk for intussusception was observed as a rare complication following immunization with which vaccine?
    a. Inactivated polio vaccine
    b. Oral polio vaccine
    c. Rotavirus vaccine
    d. Hepatitis A vaccine
    e. Hepatitis B vaccine

6. Indicate whether the follow are examples of active or passive immunity:
    a. palivizumab
    b. Diphtheria-Tetanus toxoid
    c. Diphtheria immune globulin
    d. MMR
    e. Influenza vaccine
    f. Botulism antitoxin

Chapter I.5. Hearing Screening
Teresa Han Seo

A 2 year old female presents to your office with her mother who is concerned that unlike her other children, her youngest daughter is not talking. Her child has a very limited vocabulary consisting of only word fragments such as "ma." She interacts with her parents and older siblings by grunting and pointing to objects. She cries when she does not get her way. Her mother has recently noticed that her daughter seems to ignore her unless she looks straight at her while speaking. Her mother feels that her child is otherwise normal since she likes to watch cartoons and play with dolls. Her child's past medical history is significant for numerous middle ear infections. Her immunizations are all up to date. Her birth history is normal.

Exam: VS T 37, HR 120, RR 24, BP 90/60. Height 89 cm (35 in) (75%ile), weight 13.2 kg (29 lbs) (75%ile). She appears well, in no acute distress. Her eyes are normal. Her tympanic membranes in both ears show some scarring and thickening. Oral mucosa is moist. Neck is supple without adenopathy. Heart regular. Lungs are clear. Abdomen is soft and non-tender. She is shy, so her speech is difficult to assess. A neurologic examination finds no abnormalities. She has age appropriate gross motor and fine motor skills.

Based on the history reported by her mother, you recommend that she undergo comprehensive audiology testing which reveals a bilateral moderate conductive hearing deficit attributed to repeated episodes of otitis media. Possible considerations at this point include: 1) Surgical tympanostomy tubes if she continues to have frequent episodes of otitis media. 2) Hearing aids with speech and audiology therapy sessions followed by special education preschool if language milestones are not age appropriate by the time she is 3 years of age.

The most critical period for the development of hearing and speech occurs in the first 6 months of life. Moderate to severe hearing impairments, as well as mild or unilateral hearing deficits, during the first year of life are known to affect speech, language, cognitive and behavioral development in children. In infants younger than 6 months of age, early intervention is thought to improve the development of speech, language, and cognition, which in turn, decreases the need for special education (1). Deafness is more prevalent than any other disabling condition for which mandated neonatal screening programs exist (2).

Each year, approximately 5000 infants are born in the United States with moderate to profound, bilateral permanent hearing loss (3). The prevalence of moderate to profound hearing impairment in newborns, including sensorineural (SNHL) and conductive hearing loss (CHL), is approximately 1 to 3 per 1,000. There is an approximate 2-fold increase in this number when infants with mild SNHL are included (1).

The prevalence of hearing impairment increases considerably in newborns that have any of the following risk factors as described by the Joint Committee on Infant Hearing, Year 2000 Position Statement (1,4):

- An illness or condition requiring admission of 48h to a neonatal ICU.
- Stigmata or other findings associated with a syndrome known to include a sensorineural or conductive hearing loss.
- Family history of permanent childhood sensorineural hearing loss.
- Craniofacial abnormalities, including those that have morphologic abnormalities of the pinna and ear canal.
- In utero infection, such as cytomegalovirus (CMV), herpes, toxoplasmosis, or rubella.

The Joint Committee on Infant Hearing, Year 2000 Position Statement also illustrates specific risk indicators associated with progressive or delayed-onset hearing loss (1,4):

- Parental or caregiver concern regarding hearing, speech, language, or developmental delay.
- Family history of permanent childhood hearing loss.
- Stigmata or other findings associated with a syndrome known to include a sensorineural or conductive hearing loss or Eustachian tube dysfunction.
- Postnatal infections associated with a sensorineural hearing loss, including bacterial meningitis.
- In utero infection, such as CMV, herpes, toxoplasmosis, rubella, or syphilis.
- Neonatal indicators, specifically hyperbilirubinemia at a serum level requiring exchange transfusion, persistent pulmonary hypertension of the newborn associated with mechanical ventilation, and conditions requiring the use of extracorporeal membrane oxygenation.
- Syndromes associated with progressive hearing loss (i.e., neurofibromatosis, osteopetrosis, Usher syndrome)
- Neurodegenerative disorders (i.e., Hunter syndrome) or sensory motor neuropathies (i.e., Friedreich's ataxia, Charcot-Marie-Tooth syndrome)
- Head trauma.
- Recurrent or persistent otitis media with effusion for at least 3 months.

Neonatal Hearing Screening

Sensitive techniques are available for performing neonatal hearing screening, and early intervention has been shown to positively affect language development in hearing impaired children (2). Prior to the mandate of universal newborn hearing screening (UNHS) programs in at least 32 states in the United States, the average age that children were diagnosed with hearing impairments was approximately 30 months. Children who had mild or moderate hearing losses often were not identified until entering school. Studies have shown that even targeted screening of high-risk groups can identify only up to 50% of children who have significant hearing impairments prior to the development of speech (1).

Initial screening for hearing deficits is conducted within the hospital following the birth of a newborn and depending on the results, additional screening may be implemented prior to or following discharge. Currently utilized screening methods include automated auditory brainstem response (AABR), transient evoked otoacoustic emissions (TEOAE), and distortion product otoacoustic emissions (DPOAE). These methods incorporate a device that objectively and automatically detects one's response to sound presented as an evoked potential or an otoacoustic emission. These screening techniques reveal whether specific stimulus levels elicit a response. These screening tests are unable to provide a quantitative estimate of the severity of the hearing deficit and cannot distinguish SNHL from CHL (1). The auditory brainstem response (ABR) test (also known as brainstem auditory evoked response-BAER), which is an electrical waveform or an evoked potential (similar to electroencephalography) produced by auditory nerve and brainstem activity following a click or other brief sound. ABR testing is independent of behavior and is influenced by the intensity and rate of stimulation. The presence of an ABR indicates that sound is perceived by the test subject. Abnormal ABR patterns have been shown to correlate with hearing deficits and

enables the differentiation between CHL and SNHL. Like any test, the validity, efficiency and test result interpretation is a function of the test administrator's skill and experience (1).

The transient evoked otoacoustic emissions (TEOAE) and distortion product otoacoustic emissions (DPOAE) both work on the principle in which a sound stimulus (such as a click) causes the cochlea to form an emission. This emission can be detected by placing a microphone in the ear canal connected to a computer specially designed to analyze this emission.

The current American Academy of Pediatrics guidelines recommend that hearing deficits are identified by 3 months of age and intervention initiated by 6 months of age (1). A review by Clemens and Davis (5) reports that the false-positive rates of previously reported UNHS (universal newborn hearing screening) programs range between 2.5 and 8%. Higher false-positive rates may lead to a variety of unnecessary negative effects, including emotional trauma, disease labeling, iatrogenic adverse events from unnecessary testing, and increased expense in terms of time and money. Clemens and Davis have shown that simply rescreening all infants who failed their initial UNHS before hospital discharge reduced the false-positive rate to 0.8% (5). Sokol and Hyde report that a maximum false-positive rate of 3% is generally acceptable for hearing screening programs (1). It is important to recognize that screening tests in high- and low-risk groups will yield different results due to variation in the presentation and distribution of hearing disorders within these groups and the fact that it is easier to achieve ideal testing conditions and results in babies who are sleeping, less distressed, and in low-risk groups (1).

There are some disadvantages with the UNHS programs. Sokol and Hyde's review (1) indicates that it is important that UNHS programs include follow-up of those infants who fail in-hospital screening or are not successfully screened before discharge due to shorter hospital stays and/or poor compliance with following-up on those who fail the first screen. One should also note that passing a UNHS program does not automatically indicate that an infant has normal hearing. Furthermore, acquired hearing disorders due to congenital (i.e., CMV) or acquired infections (i.e., meningitis), acquired conductive hearing impairment (due to recurrent otitis media infections), or auditory neuropathy will not be detected by UNHS programs (1).

UNHS programs have enabled earlier identification, diagnosis, and intervention of hearing deficits in infants. Sokol and Hyde's report (1) suggest that early intervention improves speech, language, cognition, and social skills through the use of interventions such as hearing aids and cochlear implants (1).

Post-Neonatal (older ages) Hearing Screening

Approximately 5-10% of newborns will display one of the risk factors for progressive or late-onset hearing loss described by the Joint Committee on Infant Hearing (1,4). Sokol and Hyde (1) suggest that infants who are at risk for developing hearing loss that manifests after neonatal screening (i.e., perinatal CMV infection) should be rescreened every 3 to 6 months for at least 3 years. (1,4).

Other conditions that may affect hearing including bacterial meningitis or head injury, should also be evaluated appropriately using screening methods such as DPOAE (distortion product otoacoustic emissions), TEOAE (transient evoked otoacoustic emissions), or the more accurate AABR (automated ABR screening) test. Postnatal screening failures should be followed up by full comprehensive audiologic and otologic examination.

Some of the best tests for evaluating hearing deficits in infants older than 6 months of age includes behavioral tests such as visual reinforcement audiometry (VRA) which evaluates one's response to specific tones projected within a soundproof room from various locations. VRA can accurately evaluate children 6 months of age and older who have normal neurological development. The reliability and accuracy of behavioral tests are limited in infants who are younger than 6 months of age or have developmental delays or certain physical disabilities (1).

The behavior of the child and environmental noise levels may affect the results of hearing screening in infants. OAE and AABR testing are most accurate when the child is preferably sleeping or resting quietly, which can be difficult in children greater than 6 months of age. If this is not possible, mild sedation or light general anesthesia may provide a better testing environment in these children (1). For children older than 6 months of age without cognitive impairments, behavioral screening by VRA or conditioned play audiometry (CPA) is acceptable. CPA is where the child is conditioned to make a response using common play materials (e.g., being taught to drop a block into a bucket) when hearing a sound stimulus. Informal behavioral screening using noisemakers and observing a child's response is inaccurate. Evaluating children with substantial cognitive disorders is more complex and challenging and requires long-term evaluation (1).

Screening preschool-aged children under a Early Hearing Detection and Intervention program may identify preschoolers who have developed hearing deficits that have presented following birth, are progressive, or associated with diseases (i.e., meningitis) or head trauma. This impairment may hinder further development of hearing, speech and language (1). Middle ear conditions are common in 3 to 5 year old children, and it is important for health care professionals to screen for both hearing loss and middle ear problems. The objectivity of OAE screening makes it ideal for cooperative children. CPA, which has the capacity of evaluating the full perceptual system of a child, can also be used for screening cooperative, responsive 3- to 5- year olds with an experienced tester. Children who cannot perform sufficiently on CPA can be tested successfully with VRA. Screening errors can be prevented by conducting both objective and behavioral testing, where practical. Screening failures in this group should also be followed by full audiologic assessment (1).

Failing an objective screen in a child should alert health care professionals to determine whether the failure is caused by middle ear disease. Tympanometry is used to detect middle ear conditions by utilizing varied air pressures to assess the compliance of the tympanic membrane. For example, an acute otitis media will result in low compliance indicating a stiff tympanic membrane because the space behind the tympanic membrane is filled with fluid. A normal tympanogram increases suspicion for SNHL and should be followed up by a comprehensive diagnostic audiologic assessment. An abnormal tympanogram suggests that the screening failure is probably a result of a middle ear disorder. One should remember that abnormal tympanograms do not necessarily rule out a sensorineural component of hearing loss (1).

Detailed guidelines for hearing screening protocols for children are available in the Joint Committee on Infant Hearing 2000 position statement (4).

Questions

1. True/False: In infants younger than 6 months of age, early intervention for hearing impaired infants is believed to improve the development of speech, language, and cognition, which in turn, decreases the need for special education.
2. Name some in utero infections which are known to cause hearing abnormalities.
3. True/False: Current screening methods including automated auditory brainstem response (AABR), transient evoked otoacoustic emissions (TEOAE), and distortion product otoacoustic emissions (DPOAE), are able to distinguish whether a child has sensorineural or conductive hearing loss.
4. What is the best test for assessing hearing deficits in infants older than 6 months of age?

5. After failing an objective hearing screen, tympanometry testing is conducted and the results are abnormal. What does this suggest?
6. True/False: OAE and AABR methods are most accurate when the child is resting quietly or sleeping.

Answers to questions

1. True
2. TORCH: toxoplasmosis, rubella, CMV, herpes
3. False
4. Best test for this age group: Behavioral tests that rely on operant conditioning, such as visual reinforcement audiometry (VRA) involves testing one's response to specific tones projected within a soundproof room from different locations.
5. Screening failure is attributable to middle ear disease. Yet, this does not completely rule out a sensorineural defect.
6. True

Chapter I.6. Anticipatory Guidance

Corinne C. Chan-Nishina, MD

A 2 year old male presents at a pediatrician's office for his annual physical. His mother has concerns about his appetite. He is described as a finicky eater and will not sit still at the dinner table for very long. He will occasionally eat meat. He eats vegetables, and loves rice. He also eats fruit and whole grain cereals. He drinks about two to three glasses of milk a day and maybe one glass of fruit juice per day. He has no problems with his bowel movements. She is also concerned about his temper tantrums, especially when he doesn't get his way. Spanking has not worked too well. He has difficulty sharing with his siblings. This often escalates from sibling conflicts to severe temper tantrums. She is also concerned that he is not making progress with his toilet training. He has used the toilet for both bowel movements and urination, but he will not consistently tell his mother when he has to go. His mother would also like to know when he should stop using his car seat. She has no concerns about his development. He actually seems advanced compared to his older sibling who is doing well at school. His birth and past medical history is unremarkable. His parents are happily married and there have been no remarkable changes in the household.

Exam: VS are normal. Height 90cm (75%ile), Weight 13.5kg (75%ile), Head circumference 50cm (50-75%ile). He is awake, alert and active. His head is normal. Red reflexes are present in both eyes. His pupils are equal, round and reactive to light. Extraocular movements are intact. The cover test is negative. The tympanic membranes are without erythema. There is a good light reflex bilaterally. The nares are clear and without discharge. Oropharynx is moist and pink without erythema, exudates or other lesions. There are multiple dental caries present. There are about twenty teeth. They are cream colored and have plaque present. His neck is supple without lymphadenopathy. His heart and lungs are normal. His abdomen is soft and nondistended without organomegaly or masses. There are normal Tanner I male genitalia with testes descended bilaterally. Extremities are normal. There are no signs of scoliosis. There is no rash. However, there is a Mongolian spot to the buttocks. His neurological exam demonstrates good strength and muscle tone. DTR's are 2+ in the lower extremities. He has good coordination and a normal gait. There is also normal sensation to light touch.

There are many challenges that parents and children face today. One of four children in the U.S. currently lives in poverty. These children and families face poor nutrition, poor access to health care, violence and neglect. Many of the nation's children grow up in single parent households (1). There are many children who live with foster families because of neglect, abuse, parental substance abuse or domestic violence. These families are at particularly high risk for their children having poor physical and emotional health.

However ALL parents and caregivers with support from medical professionals have the potential for greater impact on the health and well being of their children. Pediatricians and other child health providers emphasize prevention, early detection, and management of various behavioral, developmental, and social functioning problems (2). A major aspect of preventing and managing such problems includes concise and effective discussions with parents and other caregivers; what is commonly called anticipatory guidance.

The United States Preventive Services Task Force has compiled a list of evidence based preventive health recommendations. These include risk reduction with vehicle safety seats, smoke detector use, hot water heater temperature reduction, smoking cessation, use of bicycle helmets, and child proofing the home for medications and poisons. For a number of important health related behaviors (e.g. smoking) there is good evidence from high quality studies that physicians can change patient behavior through simple counseling in the primary care setting. For many other behaviors, the effectiveness of counseling has been demonstrated only over the short term or has not been examined in appropriately designed studies (3).

The child in the case above does not have any serious physical exam findings except for dental caries. He is growing well. A pediatrician or trained medical professional can address all his mother's other concerns.

Each age group has anticipatory, behavioral and developmental issues that relate particularly to children of that age. The following are some of the important topics used in anticipatory guidance for caregivers of two year old children. The gender throughout this discussion is for a boy (as in our case above) but this discussion is completely relevant for girls also.

Nutrition: The two year old toddler is in the process of becoming more independent and separating from his primary caregiver who has nurtured and protected him. He begins to make his own choices and has the desire to do things by himself. He is more interested in play and exploring the world, and discovering how it all works. Children at this age have a difficult time sitting down for extended periods of time, and want to choose their own foods, and feed themselves.

There are ways to continue to make mealtimes pleasant and enjoyable for everyone. It is important for the toddler (and children of all ages) to have meals with his family to support the promotion of constructive family relationships and to provide role models at mealtime. Parents should encourage conversation at mealtimes, and make meals pleasant and comfortable. The TV should be turned off and reading materials should be put somewhere else. Children at this age may receive two to three nutritious snacks per day. Nutritious snacks should be rich in complex carbohydrates. Sweets and high fat snacks should be limited or avoided, since this may cause children to lose their appetite for a nutritious lunch or dinner. Juice should be limited to 4-6 ounces per day. Children can be offered a variety of nutritious foods and be allowed to choose what to eat and how much. It is perfectly normal for children at this age to eat a lot for one meal, and not much the next. Reasonable mealtime behavior should be enforced, but eating should never be forced. Eating should not become a power struggle. Children at this age like to experiment with their food (1). Good nutrition can make a big difference in how children grow, develop and learn.

Pediatric Oral Health: Dental decay (caries) is the most common chronic infectious disease of childhood. If severe enough, they may lead to malnourishment, absence from school, and low self-esteem. Pediatricians need to take a more active role in promoting good oral health and counseling parents on the importance of preventing dental disease in children. High risk children need to be identified. A brief dental screening includes oral inspection, noting the number of erupted teeth, and their color, spacing and enamel status, as well as inspection for dental caries. Those with dental caries should be referred to the dentist immediately.

Caregivers should be taught the role of diet in promoting good oral health, and those factors that can lead to dental caries. Bottles and "Sippy" cups should not be used as pacifiers. Bottles or breastfeeding at bedtime should be discouraged after the eruption of teeth. Infants should be weaned from the bottle before 15 months (10). Parents should be informed of the effects of prolonged use of high sugar liquids and foods (such as juices, sodas, and candy). High sugar medicines may also lead to dental caries. For infants, parents should be instructed to clean their mouth and teeth regularly after feedings. The pediatrician should demonstrate this whenever possible. Toddlers and preschoolers will need the help of a parent, but they can be encouraged to brush their own teeth first, before receiving help as necessary from the parent.

Physicians should prescribe and counsel parents on the use of fluoride supplements in communities without fluoridated water supplies, and on the use of fluoride toothpaste (use only a pea-sized amount or less to prevent excessive fluoride ingestion). Both of these should be kept out of the reach of children to prevent ingestion of excessive amounts of fluoride. Most importantly, pediatricians can ensure that every child has an established "dental home". It is recommended that the first visit with a dentist occur six months after the eruption of the first tooth (which is at approximately twelve months of age) (4).

Discipline: This is a topic that often comes up at the well child visit. Parents often ask pediatricians for their advice regarding appropriate and effective discipline. The word discipline comes from the root word disciplinare, which means "to teach or instruct". This refers to the system of teaching and nurturing that prepares children to achieve competence, self-control, self-direction, and caring for others (5). There are three key elements to effective discipline: 1) a learning environment characterized by positive, supportive parent-child relationships; 2) a strategy for systematic teaching and strengthening of desired behaviors; and 3) a strategy for decreasing or eliminating undesired behaviors. All of these must be present to achieve improved child behavior (3).

The developmental age of the child must be considered when choosing a form of discipline. One would not expect an infant or toddler to respond to reasoning. A two year old might respond well to the caregiver providing attention to him to increase positive behaviors. A caregiver withholding attention can decrease undesirable behaviors. Being consistent is very important. Removing or eliminating undesirable behaviors requires that the parent and child are both clear on what the problem behavior is. Once this is established, then there should be an immediate consequence when the targeted behavior occurs. An appropriate consequence should consistently be provided each time the targeted behavior occurs at this age. At older ages more sophisticated techniques may be used that delay the positive or negative reinforcers. Time-out is a form of extinction that may be used at this age. For a two year old this would consist of removing parental attention or being placed in a chair for a specified time (one minute per year of age of the child is suggested) without any adult interaction. Initially this may result in an increase in negative behavior. If the parent accepts this as a normal reaction and chooses to ignore the behavior, this will eventually result in a decrease in outbursts, as well as a decrease in the targeted behavior (6).

Caregivers should try to remain calm. Parents are more likely to use aversive techniques and punishment when they are angry, irritable, fatigued and stressed. It can be difficult to discuss discipline with parents since many will use methods with their children that were once used on them. They may be hesitant to discuss methods of corporal punishment. One good way to start the discussion is to talk about a behavior that was observed during the visit, and discuss its occurrence at home. It is important to remain non-judgmental or the conversation may become emotionally charged.

Toilet training: This topic concerns many caregivers during the toddler stage. Parents should be counseled to start toilet training when the toddler shows interest and is willing to participate. It should not become a control issue. Signs that signify readiness are: staying dry for periods of about two hours; knowing the difference between wet and dry; being able to pull their pants up and down; wanting to learn; and being able to signal when they are about to have a bowel movement. Once these signs are present, parents may want to seat their child on their potty. Caregivers should give lots of positive reinforcement for sitting and also praise when the child is successful using the potty. Making the experience a pleasant and positive one will ensure success in toileting.

Injury prevention: There is a fair amount of evidence to suggest that injury prevention counseling to parents of young children is effective (3). Every child deserves to grow up in a safe environment, and most authorities believe that counseling families in injury prevention is both effective and cost efficient. This aspect of anticipatory guidance is an essential part of the comprehensive care of infants, children and adolescents. Severe injuries are most commonly caused by motor vehicle crashes, followed by drowning, burns, choking, and falls (7). Initially the focus should be on the parents, but as the child matures, the focus should switch more to the child as they become more responsible for their own actions. Counseling on the prevention of automobile injuries should be a priority, since there is good evidence to suggest that the use of car safety seats is effective. Motor vehicle injuries are a leading cause of death and morbidity. Child safety seats can reduce serious injury by as much as 67%, and mortality by as much as 71% (8). The focus of this counseling should be on the use of approved child safety seats, and following the instruction manual on the proper installation and use.

There is also good evidence to suggest that poisoning in young children is associated with parents' lack of awareness of the treatment of poisonings (7). Parents should be given the number for the poison control center. They should be advised to not administer anything for the poisoning before calling the poison control center. Most importantly, they should be counseled on the proper storage of

medications, cleaning agents, household chemicals and toxins. Bottles for chemicals and household cleaners, or other potential toxins should not be reused for other things.

An association exists between drowning and leaving a child less than 3 years old unattended in the bathtub. Evidence that a health provider can influence parental supervision of young children during bath time is limited (9). Still, parents should be cautioned of the dangers of leaving young children unattended around water, such as the bathtub, a bucket full of water or the swimming pool. Specifically, counseling should include example points such as attending to their infant in a bathtub is more important than answering the phone or the doorbell. Parents of older children may develop a false sense of security if their children have had swimming lessons and should be cautioned that their children still need to be supervised around water, since they are still at risk for drowning.

In conclusion, there are multiple potential opportunities in the office and clinic setting for preventing injury and disease with caregiver guidance and teaching. This is true for children with and without serious medical or social issues. A complete discussion of all the elements of anticipatory guidance at each age group is beyond the scope of this chapter. The American Academy of Pediatrics provides pediatricians with recommendations on anticipatory guidance counseling at each age group (1,10).

Questions

1. True/False: For most problems caused by parental child rearing knowledge deficits, there is good evidence from high quality studies that physicians can change parental behavior through simple counseling in the primary care setting

2. True/False: The anticipatory guidance issues for two year olds are very different for boys as compared to girls.

3. In "disciplining" a two year old child, one should
   a. Punish
   b. Explain verbally at length the reason for the "disciplining".
   c. Teach or instruct.
   d. Always use positive reinforcement.
   e. Do to the child what the child does to others so they learn why not to do certain things.

4. True/False: Children can develop fluorosis by using fluoride toothpaste and fluoride supplements.

5. What is the most common cause of serious injury and death for children and teens?
   a. Falls
   b. Water-related injuries (submersions, drownings)
   c. Burns
   d. Choking
   e. Motor vehicle crashes

6. True/False: Parents do not need to supervise their two year olds who have already completed swimming lessons.

7. Which is INCORRECT about a toddler around feeding issues?
   a. Parents should encourage conversation at mealtimes.
   b. Children at this age may receive two to three nutritious snacks per day.
   c. Juice should be limited to 4-6 ounces per day.
   d. Children can be offered a variety of nutritious foods and be allowed to choose what to eat and how much.
   e. It is abnormal for children at this age to eat a lot for one meal, and not much the next.

1.False, 2.False, 3.c, 4.True, 5.e, 6.False, 7.e

Chapter I.7. Common Behavioral Problems in Toddlers and Young Children

Sharon M. Tisza, MD

A 5 year old girl named Sue is brought to the pediatrician's office with a chief complaint of temper tantrums. Her mother is frustrated and explains that Sue kicks and screams anytime she doesn't get her way. She sometimes swears and destroys things in her fits of rage. Two days ago she flailed her arms around while out of control and sustained a scratch on her forearm that bled. Her mother has tried yelling at Sue, spanking her on the buttocks, and embarrassing her in public. None of these techniques seem to work. In fact, her mother says that the harder she tries to control Sue, the worse she gets. This problem is causing difficulty especially between Sue's parents, as they don't agree on how to handle these tantrums. Sue's mother feels that they should take action immediately by confronting Sue and telling her that what she is doing is not acceptable. Sue's father would prefer to spank her several times on the buttocks and give her a lecture after sending her to her room for an hour or so. They openly disagree on how to discipline Sue, and Sue seems well aware of the difference in their parenting styles.

Exam: VS are normal. Height, weight and head circumference are at the 50th percentile. Sue is a well developed, well nourished attractive little girl in no acute distress. She comes in quietly with her mother and father and sits on the chair near her mother, looking up shyly at the examiner. No abnormalities can be identified on examination of HEENT, neck, heart, lungs, abdomen, and back. There is a healing 5 cm healing linear abrasion to her right forearm. There are multiple bruises to both anterior tibial surfaces at different stages of healing, with normal range of motion, no deformities and strength 5/5. Her neurological exam is intact.

Following this initial evaluation for temper tantrums, her mother and father return to the pediatrician weekly for the next eight weeks. They receive twenty minutes of instruction each time on behavioral problems, effective methods of discipline and child management. Her parents also keep a journal of specific instances when Sue becomes out of control and how they handle it. The tantrums become less and less frequent as time goes by and her parents become more relaxed and start to enjoy Sue again. By the end of the eight weeks, the tantrums have decreased from several times per day to once or twice per week. The tantrums are also less severe than they used to be and the recovery time is much shorter. Sue's mother and father are pleased with the results and are encouraged to return in the future if they need to discuss Sue's behavior again.

Some children seem to get through childhood without many problems at all and others seem to have an unusual amount of difficulty. Parents are often puzzled as to why their children do not behave or listen while their friend's children seem to be perfect angels. Some of the most common behavioral problems in children include temper tantrums, not following directions, whining, fighting with siblings or other children, breaking rules and talking back. Fortunately there is hope in dealing with everyday discipline problems using methods that are effective and easy to learn.

Parents have the ability to shape their children's behavior towards both good and bad results. All behaviors are shaped by rewards that are given to them. A common mistake that parents make is to accidentally reward their children's bad behavior. Four year old Jack gets to eat ice cream before dinner. He has been whining and begging for the ice cream long enough that his mother gives it to him so she can finish preparing dinner. Unfortunately, by rewarding bad behavior it is often strengthened. On the other hand behavior that is not rewarded, but instead punished, will often weaken and therefore decrease (1).

Developmentally, it is expected that young children will have a difficult time controlling their emotions, particularly if tired, hungry or stressed. Toddlers and preschoolers often lack the self-control necessary to express anger and other unpleasant emotions peacefully. When this happens it is important for the child's caregiver to be able to provide him or her with the support to deal with these difficult and uncomfortable feelings. Children learn a lot through their parents' modeling of behaviors and this is the main reason for parents needing to be most in control when their children are feeling out of control. If a father or mother joins the child in an uncontrollable emotional state, the situation will likely worsen because the child will feel less safe and more out of control (2).

Luckily for their parents, most children want to please their parents. Parents can therefore use this to their advantage when deciding how to discipline children. When a parent shows joy for a behavior that is good, the child will be positively reinforced for doing this behavior. On the other hand if a parent shows disapproval for a behavior, the child is less likely to repeat this behavior given the basic principle that children want to please their parents (3).

Discipline is the system in which parents guide and teach their children. This word is often confused with the term punishment. The purpose of discipline is to teach children the difference between right and wrong, to tolerate delayed gratification and to incorporate a sense of limits and appropriate behavior. Teaching discipline is a challenging task for parents and caregivers and not one that is taught overnight. It takes many years for most children to be able to achieve self-control. Also, as children grow and develop, so do the types of things that they must be taught. The method of discipline must grow and change with the child. Caregivers need to be flexible because of changes in children and their environment as children mature and grow (4).

Do's and Don'ts: Three Good Child-Rearing Rules to Keep in Mind

1) Reward good behavior and do it quickly and often. A child's good behavior will be positively reinforced and therefore strengthened when they receive a reward from a caregiver. Social rewards are the most effective rewards and include smiles, hugs, kisses, words or praise, eye contact and attention. Other rewards include activity rewards such as going to the park or helping to bake cookies and material rewards like ice cream, money or a compact disc. Social reward are the most powerful, easiest to give and least expensive. The other types of rewards should be used less often. It is important for parents to remember that they are the most important reward for their children. It is very important to keep in mind that especially in younger children rewards need to immediately follow the behavior.

2) Avoid accidentally rewarding bad behavior. This will strengthen the bad behavior and is a very easy trap for parents to fall into. One example is when a child whines to get their parents attention. If a parent gives the child attention while they are whining, even if this attention is to yell at their child, it will act to reward the bad behavior of whining. Parents are very prone to making this mistake, especially if preoccupied with another activity like making dinner, talking on the phone or having a long day.

3) Punish some bad behavior by using mild punishment. Examples of mild punishment include time-out, scolding, natural consequences and logical consequences.

Time-out is a very effective form of mild punishment. Time-out literally means time-out from all the things the child enjoys, for example - rewards, parent's attention, reinforcement, toys, music and all other interesting activities. Time-out has two major goals. The immediate goal is the stop the problem behavior as quickly as possible and the long-term goal is to help the child learn self-discipline. The good thing about time-out is that it does not emotionally harm the child and it models calm and good behavior on the parent's part. Time-

out works best with children age two to twelve. This method should be considered with certain types of behaviors including impulsive, aggressive, hostile and emotional behaviors. Time-out does not work to get a child to begin doing a behavior, but it is very effective in stopping bad behaviors.

Time-out can be used initially with one or two target behaviors and once the parent and child get used to the technique it can be expanded to more problem behaviors. Getting started with time-out should occur after caregivers agree on this as a form of mild punishment. It should then be explained to the child before it is initially used so the child can understand what to expect the first time it is used. The child should immediately be placed in a very boring and safe predetermined location using up to ten words in less than ten seconds from the time the target behavior occurred. The child should be placed in time-out for one minute for every year of life (for example a five year old would sit in time out for five minutes) up to a maximum of about 10 minutes. A small portable timer should always be used to remind the child when the time-out is over. Once the timer rings the child will be asked why they went to time-out. Once they produce the answer the parent drops the issue and goes about their daily activities as usual. Time-out is not designed to make a child feel bad or humiliated.

Scolding is a common form of mild punishment used by parents. When scolding a child for bad behavior it is important to move close to the child, maintaining good eye contact, being stern, and expressing your feelings while naming the undesirable behavior. It is important to be brief and calm, showing disapproval for the behavior not the child. Another type of mild punishment is natural consequences. This is an event that would naturally occur after a child does a bad behavior. Some examples include not wearing an appropriate outfit to school and getting sent to the principal's office or being careless in not packing a lunch and being hungry at lunchtime. Logical consequences occur for behaviors that do not have natural consequences. Some examples include not eating all of your dinner and then not having any dessert; or riding the bicycle in the street and having the bike taken away for three days (1).

There are several ways in which parents can accidentally increase bad behaviors or decrease good behaviors. Once parents become aware of these common mistakes, avoiding them will be easier and promote a healthier parenting style. These errors include failing to reward good behavior, accidentally punishing good behavior, accidentally rewarding bad behavior and failing to punish bad behavior. A parent can fail to reward good behavior by not praising or recognizing that their child cleaned their room or brought home a great report card. Parents accidentally punish good behaviors by not being satisfied with a job well done and commenting that they could have done more or better. Some parents accidentally reward bad behavior by giving in to child who is whining and making unreasonable demands. Finally, parents can fail to punish bad behavior by ignoring it and saying something like "Oh well, boys will be boys" (1).

Common behavioral problems are challenges that all parents and caregivers face. Some caregivers have more difficulty than others in managing their children. Parents will often come to the pediatrician with questions about behavioral problems. It is important to listen to these parents, take them seriously and offer suggestions as to how some of these problems can be remedied. It is essential to praise the parents for the things that they are doing correctly and gently try to shape some of the less helpful things that they are doing in a positive way. Most children will show great improvements if the strategies in this chapter are followed. For those children with more serious behavioral problems, these strategies may not be enough and this is when the pediatrician may consider referral to a psychiatrist, psychologist or other behaviorally astute professional.

Questions

1. Which statement about solving child behavioral problems is FALSE:
    a. Toddlers and preschoolers often lack the self-control necessary to express anger and other unpleasant emotions peacefully.
    b. Children learn a lot through their parents' modeling of behaviors.
    c. Most children want to please their parents.
    d. Discipline is analogous to punishment.
    e. It takes many years for most children to be able to achieve self-control.

2. What is a TRUE statement about time outs?
    a. A good time out is when the parent praises the child outside of the child's playgroup.
    b. A terrific place to have a time out is the child's room.
    c. This method should be considered with certain types of behaviors including impulsive, aggressive, hostile and emotional behaviors.
    d. Time-out works to get a child to begin doing a behavior.
    e. A good rule of thumb is to use five minutes of time out per year of age (for example 25 minutes for a five year old).

3. Which of the following has as an example, not eating all of your dinner and then not having any dessert?
    a. Time-out.
    b. Triggering.
    c. Scolding.
    d. Natural consequences.
    e. Logical consequences.

4. Which of the following is an error in parent behavior when disciplining a child?
    a. Failing to reward good behavior.
    b. Accidentally punishing good behavior.
    c. Accidentally rewarding bad behavior.
    d. Failing to punish bad behavior.
    e. All are errors to avoid.

5. How could Sue's parent (case example) have better handled each error that they made?

6. Name three important child-rearing rules.

7. How does a parent successfully use time out? Name all the important steps?

8. What is the role of the pediatrician in helping parents with common behavioral problems?

9. When should a pediatrician refer a patient for more specialized evaluation of behavioral problems?

Answers to questions

1.d, 2.c, 3.e, 4.e

5. Sue's parents could have used time-out to manage her bad behaviors. Since Sue is five she would have been placed in time-out for five minutes (one minute for each year of life). Spanking is chosen as a method of punishment by some parents and if this is the case it should only be one time on the buttocks and not intended to cause excess pain or injury. Parents should discuss their discipline styles behind closed doors and provide a united front with their children.

6. Reward good behavior and do it quickly and often. Avoid accidentally rewarding bad behavior. Punish some bad behavior by using mild punishment.

7. Time-out can be used initially with one or two targeted behaviors and once the parent and child get used to the technique, it can be expanded to more problem behaviors. Getting started with time-out should occur after caregivers agree on this as a form of mild punishment. It should then be explained to the child before it is initially used so the child can understand what to expect the first time it is used. The child should immediately be placed in a very boring and safe predetermined location using up to ten words in less than ten seconds from the time the target behavior occurred. The child should be placed in time-out for one minute for every year of life (for example a five year old would sit in time out for five minutes) up to a maximum of about 10 minutes. A small portable timer should always be used to remind the child when the time-out is over. Once the timer rings the child will be asked why they went to time-out. Once they produce the answer, the parent drops the issue and goes about their daily activities as usual. Time-out is not designed to make a child feel bad or humiliated.

8. Pediatricians should be available to offer counseling on routine visits with their patients. When the pediatrician observes bad behaviors in the office they should observe how the parent handles them and offer advice in a nonjudgmental way if they note errors. Pediatricians may also provide tips on effective parenting when the child is very young and be particularly sensitive to the needs of first time parents who may not know the correct way to discipline. One good way to find out how a parent is likely to discipline, is to ask them how they were disciplined as a child and the pediatrician can adjust their advice accordingly. It is very important to remain nonjudgmental and calm as you describe these techniques, as you don't want to add additional stress to a parent who is already taking on a very difficult task of raising a child. Be compassionate, listen and gently advise.

9. A pediatrician would likely want to advise a parent to see a specialist like a child psychiatrist or child psychologist if the problem seems to be more then they can handle. Some of these behaviors include extreme aggression and violence or if the child is engaging in dangerous behaviors. If the child is threatening or tying to hurt or kill themselves or others, this needs to be taken very seriously. The pediatrician will need to clinically assess the situation and decide if an emergency room visit is warranted. Threats of self-harm or harm to others should always be considered as a potential emergency.

Chapter I.8. Disabilities and Physician Interactions with Schools
Jeffrey K. Okamoto MD

Case 1. A six year old girl named Zoe with a history of prematurity and spastic diplegia comes to the outpatient clinic for an annual review. She has no new acute medical symptoms. Zoe also sees an orthopedic surgeon and a physical therapist because of the spastic diplegia. She ambulates with ankle-foot orthoses (braces) and does not require a wheelchair. She requires help when using stairs.

Her mother relates that Zoe is happy in school but does not participate in art class. This art class is on the second floor of one of the school buildings which does not have an elevator. There are no school personnel to help Zoe get to the second floor classroom. Therefore Zoe has an extra reading period instead of art since she needs continued help with reading (where she is in special education). Zoe is in regular education placement for all of her classes except for a resource classroom placement for reading. She is therefore in the resource classroom two periods everyday. Her mother wishes that Zoe could participate in art as do all of Zoe's classmates.

On exam Zoe is a happy child without outstanding findings except for hyperreflexia of her knee deep tendon reflexes, and the ankle foot orthoses that she wears bilaterally. Her ankles can be positioned past neutral passively. She enjoys drawing pictures of her family in the clinic.

Case 2. Larry, a four year old child is diagnosed with Prader Willi Syndrome confirmed on genetic testing after presenting with hyperphagia, developmental delays and pneumonia. Larry was previously evaluated for hypotonia as an infant, without any etiology being found. Larry is referred for special education services but his family finds that the school wants to wait until Kindergarten next year to place him into regular education to determine if he can do well in that setting.

Medical and school personnel have similar interests and goals. Physicians and other health personnel are focused on child health. Teachers and other school personnel are focused on child education. Therefore, both fields are child focused with interaction with families. Both want to optimize the child's potential and try to minimize problems by addressing minor problems early, before they worsen.

Both physicians and educators also deal with many mildly to severely affected children. Some children have both medical and educational issues such as Zoe illustrated above. She has cerebral palsy, but also a learning disability in reading. Some problems overlap the medical and the educational worlds. A good example is Attention Deficit Hyperactivity Disorder. Children with this condition have major impact on their school behavior and performance. They also require medical attention because of diagnostic and treatment needs. Others examples with medical/educational overlap include mental retardation, autism, blindness, and deafness. A child such as Larry with Prader Willi Syndrome has overlapping medical and educational issues.

Advances in medical care mean that more children are surviving with disabilities and medical issues. Most of these children do not need to be isolated in the hospital or in a home environment. Rather, they can do well in school environments with the proper supports. Even children with complex technological needs, such as children with gastrostomy tubes, tracheostomy tubes or ventilators, can be in school with appropriate staff and education of those in the school.

However, schools do not always understand the medical needs and supports for children with disabilities. Physicians and other medical personnel do not always acknowledge the school's perspective and difficulties in adapting to children with special needs. Physicians and schools need to collaborate as a team around these children.

There are multiple possible roles for the physician in working with schools around children with disabilities. An important role is identifying children with disabilities so that appropriate medical care, and then appropriate educational programming, can take place. A child with mental retardation or autism that goes unrecognized often loses years of specialized teaching and support that could occur in early intervention and school systems. Screening and surveillance are important activities in order to identify children early (1). Further evaluation by medical subspecialists may also be necessary to delineate the child's condition fully.

Another important role is proper referral to early intervention programs (for children up to three years of age) or to school system resources (for children older than three) for suspected or confirmed disabilities or chronic health conditions. Several federal legislative safeguards are important for children with special health care needs in the United States. Knowledge of these help physicians and other health professionals in providing oversight over children in their care in ensuring that early intervention and school programs support children with special health needs optimally.

The Individuals with Disabilities Education Act (IDEA) supports special education and related services for children and teens with disabilities. The initial federal law was Public Law 94-142 enacted in 1975 but the most recent amendments to IDEA law was in 1997 as Public Law 105-17 (2). This most recent update restructured IDEA into four parts:

Part A - General Provisions (purposes of the laws and definitions).

Part B - Assistance for Education of All Children with Disabilities.

Part C - Infants and Toddlers with Disabilities (used to be Part H).

Part D - National Activities to Improve the Education of Children with Disabilities.

Physicians can be particularly helpful in interacting with the team at the early intervention program (Part C) or school (Part B) in providing medical and other information. This can be invaluable in helping the team determine issues and services needed. Transfer of information and records from the primary care provider and subspecialists to educators is essential in many situations. Early intervention programs produce Individualized Family Service Plans (IFSPs) and schools produce Individualized Education Plans (IEPs). These are legal documents that determine the level of special education to be provided, specific goals and objectives, and ongoing monitoring and planning. Guidance for an IEP includes that it is a FAPE (Free Appropriate Public Education) in the LRE (Least Restrictive Environment). Also, a meeting to develop an IEP must be "conducted within 30 days of a determination that the child needs special education and related services" (3).

Three other laws provide protections against discrimination of children with disabilities. Section 504 of the Rehabilitation Act of 1973, a civil rights law, is helpful for children that may or may not qualify for IDEA services but require accommodations in their school program because of health concerns. For example, a child with multiple hospitalizations for asthma or other chronic illness may have accommodations such as modified homework or class assignments, altered test dates or environmental controls. The Americans with Disabilities Act (ADA) is a wide ranging law that also affects programs for children with disabilities. The Head Start Act includes provisions for children with disabilities that are enrolled in Early Head Start or Head Start programs (4).

Physicians and other health care professionals should be the "medical home" for children with disabilities or chronic health problems. The medical home provides care that is "accessible, continuous, comprehensive, family-centered, coordinated and compassionate" (1). This is interpreted by many that the medical home should participate in IEP/IFSP development, collaborate with community resources such as schools and early intervention programs, and help support and advocate for programs that support children in early intervention and school programs (5).

Therefore in Case 1 above, medical personnel and schools should discuss options to help Zoe have art activities. There should be no discrimination against the child just because of her physical disability. Accommodations could include providing training to personnel that would help her up the stairs to the art classroom, moving the art class down to the ground level, or building an elevator in the building. When a medical home representative helps problem solve with the school, creative effective inexpensive solutions often result.

In Case 2, a medical representative on the IEP planning team can help assure that critical medical reports are shared with the school (with consent from the family). Increased knowledge by the school (which may have very few or only one child with a particular syndrome over several decades) can help initiate important special education and behavioral services. Mental retardation and excessive caloric intake leading to morbid obesity are found in children with Prader Willi (6). Special education programs and control of caloric intake at school are therefore critical considerations for the IEP. Complications of the severe obesity such as early death and decline of I.Q. that results from uncontrolled caloric consumption may be decreased with proper planning with school personnel and the family.

Questions

1. The school plan that includes educational programming that can take into account medical problems such as autism or mental retardation in an 8 year old child is called a/an:
   a. Individualized Family Support Plan (IFSP)
   b. Individualized Education Plan (IEP)
   c. Individualized Health Plan (IHP)
   d. Individualized Disability Plan (IDP)
   e. Free Appropriate Public Education (FAPE)

2. A 2 year old child with developmental delays in gross and fine motor activities can get a free program called a/an:
   a. Individualized Family Support Plan (IFSP)
   b. Individualized Education Plan (IEP)
   c. Individualized Health Plan (IHP)
   d. Individualized Disability Plan (IDP)
   e. Free Appropriate Public Education (FAPE)

3. Medical professionals have roles in helping children with disabilities EXCEPT:
   a. Diagnosing children with disabilities as early as possible.
   b. Participating in school planning for the child's educational program.
   c. Collaborating as the medical home with other related services such as rehabilitative therapists.
   d. Producing the Individualized Education Plan (IEP) for children with disabilities.
   e. Advocating for families of children with disabilities so that federally mandated timelines are met in planning an Individualized Education Plan (IEP).

4. A child with a tracheostomy:
   a. Should not go to school because school personnel are not trained to care for the tracheostomy.
   b. Should not go to school because school personnel cannot handle any emergencies as a result of the tracheostomy.
   c. Should go to school as the parents can supervise the care of the child while in school.
   d. Should go to school with accommodations from a Section 504 plan.
   e. Should go to school if not requiring a nurse during school hours.

5. True/False: Schools have medical consultants paid through the Individuals with Disabilities Education Act (IDEA).

Chapter I.9. Autism and Language Disorders

Mai Anh K. Nguyen, MD

A 3 year old male presents with a chief complaint of delayed speech. Previous physicians did not find any developmental problems. He started to babble at about 9 months of age and then learned a few words such as "Dada" and "boo" at 2 years of age. His parents have tried to stimulate his language development by reading to him, interacting with him during television watching, and teaching him to mimic others' speech. His parents became more concerned as he grew older, noting his speech was less than the other children in his play group. They try to engage him in interactive activities, but he does not seem interested. They note that he is very independent and that he is very serious. He likes to play by himself rather than talking with or singing with other children. They worry that he has no playmates or friends because of his speech delay. He has been generally healthy and has had a few ear infections.

His prenatal and past medical history are otherwise unremarkable and he has not had any serious infections or need for hospitalization.

Exam: Vital signs are normal. Height, weight, and head circumference are between the 25th and 50th percentiles. His HEENT, heart, lung, abdominal, skin and neuromuscular portions of the physical exam show no abnormalities. While you are talking with his parents, you notice that he separates from them easily and he wanders about the room. He does not seem to notice that everyone is talking about him. He finds some blocks in the corner and sits down to play with them. You call out to him, but he does not respond. He starts to sort the blocks by color into groups and lines them up. He seems content playing while you finish getting the history. After you are done, you go over to him in the corner. You sit down by him and notice that he does not seem to notice that you are there. He continues to line up the blocks (very neatly) and your attempts to interrupt him are unsuccessful. Although he seems content, you notice that he does not laugh or even smile much. You also notice that he does not look at you or check back to his parents. During the session, you notice that he does not say any words.

On developmental screening, his motor development is normal. He is delayed in his language, social, and self-help skills. Subsequent follow-ups include an audiology evaluation which shows his hearing to be normal and conducive to speech development.

It can sometimes be difficult to tell a child with autism from a child with a language disorder. This chapter is an orientation to autism and related disorders, and then language disorders.

Autism is the most well known of the Autism Spectrum Disorders (also known as Pervasive Developmental Disorders). This group includes the following conditions: Autistic Disorder (Autism), Rett's Disorder, Childhood Disintegrative Disorder, Asperger's Disorder, and Pervasive Developmental Disorder Not Otherwise Specified (PDD NOS). As a group, these disorders are characterized by disturbances in three main areas of functioning: social skills, communication, and restricted or repetitive interests/activities (1).

Autism was originally described by Leo Kanner in 1943 (2). The prevalence of autism is 2-10 cases per 10,000 people. The incidence of pervasive developmental disorder (not otherwise specified) may be as high as 1 per several hundred. The incidence of Asperger's Disorder is 9 to 90 cases per 10,000. It is more common than Autistic disorder, but children with Asperger's Disorder often aren't recognized or referred for specialty care since their verbal ability is much better. Rett's Disorder & Childhood Disintegrative Disorder are both much less common than autism (1).

Autism is associated with mental retardation with studies showing up to three-fourths scoring in the mentally retarded range. These children tend to have deficits in abstract thinking, sequencing/processing information, symbolic and verbal skills. They tend to do better with motor and perceptual-motor skills.

The ratio of males to females in autism is 4 or 5 to 1 in autism (1). Interestingly, almost all cases of Rett's Disorder occur in girls. The signs of autism and the other autism spectrum disorders include:

1) Social Disturbance: Notable for lack of eye contact, poor or absent attachments, and general lack of social interest (2).

2) Communicative Disturbance: Half of those with these disorders never gain useful communicative speech. They fail to point and fail to imitate. Those who do speak may have echolalia, perseveration, pronoun reversal, extreme literalness, monotony of tones, failure to use correct cadence and intonation, failure to develop semantics (word use), failure to develop reciprocity in dialogue, and failure to use language for social interaction. Humor is usually not understood by many of these children.

3) Behavioral Features: This is notable for particular attachments to objects. They often have stereotyped (purposeless & repetitive) movements such as hand flapping or toe walking. They enjoy spinning objects or themselves. A lack of imaginative play is typical. (1)

The characteristics of each disorder can be summarized:

Autistic Disorder (Autism): To meet DSM-IV criteria, this condition is characterized by at least two specified features of social interaction, one specified feature of communication, and one specified feature of restricted or repetitive interests/activities (required to have a total of six or more items from all three areas). Delay in at least one area of social interaction, language as social communication, or symbolic or imaginative play, must be present prior to three years of age.

Rett's Disorder: Initially there is normal development and normal head circumferences. Then, there is deceleration of head growth between 5 and 48 months, loss of purposeful hand skills and development of stereotyped behaviors between 5 and 30 months, loss of social engagement, delays in language development, and poor motor development.

Childhood Disintegrative Disorder: Similar to Rett's Disorder, there is initial normal development; in this case, for the first two years of life. Then, there occurs loss of acquired skills in at least 2 areas of the following: expressive or receptive language, social skills or adaptive behavior, bowel or bladder control, play, or motor skills. Also, impairment must be present in at least two of the three areas of social interactions, communication, or stereotyped behaviors.

Asperger's Disorder: This is characterized by impaired social interaction and stereotyped behaviors. Unlike autism, there is no clinically significant delay in language or cognitive development. Many become very interested and talented in one area. For example, they may know all the dinosaurs by name, or may be fascinated about anything relating to cars.

Pervasive Developmental Disorder, not otherwise specified (PDD NOS): This disorder has some of the characteristics of the entire group of disorders, but fails to meet full criteria for any of the other four diagnoses.

The differential diagnoses for this group of disorders include language disorders, sensory impairments, mental retardation, reactive attachment disorders, childhood schizophrenia, complex motor tics, and obsessive compulsive disorders (4).

About one third are able to achieve some level of personal and occupational independence. One to two percent are able to live independently. Important predictors of outcome are intellectual level and communicative competence. Childhood Disintegrative Disorder and Rett's Disorder have the worst prognosis. Asperger's Disorder and PDD NOS have the best prognosis as they have less severe language problems and many strengths (1).

Treatment and Management of Autism Spectrum Disorders include educational interventions to foster acquisition of basic social, communicative, and cognitive skills. Examples include Floor Time, Discrete Trial Training, and Picture Exchange Communication System. Behavioral interventions are used to increase appropriate behaviors (gestures) and decrease inappropriate ones (flapping). The use of psychopharmacology (refer to the table below) is purely symptomatic; however, many do not need medications. There is no standard medication for autistic spectrum disorders.

Education and support of the family is very important. Many families hear this diagnosis as a "life sentence" without hope. Medical and educational personnel need to educate and encourage the family to use early intervention. Also physicians need to address old ideas about these conditions being caused by parental neglect (the idea of the "refrigerator mother"). There are many support groups available to help.

Advocating for the child in working with educational systems is helpful since these children need special accommodations and class structure. Physicians need to work with schools, teachers, and help families work with the educational system as well.

Unfortunately, because these are chronic disorders currently without a cure, there are quite a few alternative therapies available for families to purchase. Many of these have not been studied systematically and families need to be made aware of the monetary cost, risks, and poor results that may result from their use.

Medication considerations for autistic spectrum disorders:

Neuroleptics - may enhance learning and improve behavioral adaptation.

Tranquilizers - may decrease activity levels, increase relatedness, and increase task involvement.

SSRI - may help with inappropriate behaviors and mood difficulties.

Stimulants - may decrease hyperactivity, but may exacerbate hyperactivity in some.

Vitamins - purported to help, as children with autism are sometimes thought to have improvement of socialization and language. However, the evidence so far is very weak. (1)

Language Disorders

Language disorders are usually first noticed in early childhood. The prevalence is about 15% of children in kindergarten. Generally, children can usually produce (on average) 2 word phrases by 24 months, 3 word phrases by 30 months, and 4 word phrases by 36 months. Almost all children should be able to articulate all vowel sounds by 3 years of age. Girls generally develop speech sounds earlier than boys (2).

The characteristics of different language disorders can be summarized as:

Stuttering: This is an impairment in speech fluency characterized by frequent repetitions or prolongation of sounds or syllables (3). Difficulty is mostly at the beginning of sentences and especially with words longer than five letters. Singing is usually spared. Stuttering usually starts between two to seven years of age (2). Recovery is usually by adolescence. About 1% of children stutter. The male:female ratio is about 3:1 (3). Left handers have a higher prevalence of stuttering. Stress and anxiety can exacerbate this (2). There generally is a familial component, a biological component (laryngeal movement), and an environmental component involved (3).

Phonological Disorder: This is an impairment in the production of developmentally expected speech sounds. Evaluation of this disorder needs to rule out problems with intelligence, hearing, or the speech apparatus. The disorder is characterized by distortions of sounds, omissions of sounds, incorrect substitutions of one sound for another, avoidance of certain sounds, or reversals or misorderings of sounds. It is usually recognized at about 4 years of age. This is the most prevalent communication problem affecting 2% of school age children and 3% of preschool children (3).

Developmental Language Disorder (Specific Language Impairment): This is diagnosed when verbal intelligence develops slower than intelligence in other cognitive domains. A thorough evaluation excludes co-morbid conditions that could cause it. Two to three percent of 3 year olds have deficits in expressive, receptive, or both areas of language. This disability may affect spoken language, writing, lip reading, manual alphabet, sign language, Braille, and verbal memory (2). There are two main categories of Developmental (Specific) Language Disorders: 1) Specific expressive language disorder, and 2) Mixed Receptive-Expressive Language Disorders. In Specific Expressive Language Disorder, children are late in talking and slow to add words to their vocabulary. They generally have trouble with syntax (sentence structure) and grammatical rules. Phonological problems frequently coexist. They may also have trouble with word retrieval and tend to use word substitutions. They show an "inflexibility" of language due to their limited repertoire of language available. This may hamper their social interactions because they are 'unable' to verbally express themselves well. Children with this disorder are generally recognized by 3 years of age. Children with Mixed Receptive-Expressive Language Disorders have impaired expressive language ability combined with impaired understanding of language. Unfortunately, they often are thought to have expressive problems only. But in actuality, they also have trouble with understanding single or multi-word utterances, concepts (time, space, relationships), and multiple meanings of words. They may also have difficulties with grammatical concepts such as tenses (past versus present) or numbers (single versus plural), syntax, or slang usages.

Selective Mutism: This is a "failure to speak in one or more environments". This disorder is more common in females and seen in <1% of the population referred to mental health settings. This usually involves not speaking at school or to adults outside of the home. It is generally more of a refusal to talk rather than an inability to talk. IQ is usually average or above average. Onset is usually between 3 and 8 years of age, generally with the start of school. Some associated characteristics are excessive shyness, social isolation, school refusal, immaturity, compulsive traits, anxiety, aggression, and depression. Generally, improvement is within months or years of treatment onset. The prognosis is worse if this occurs in children over 12 years of age. A biological component, possibly maturational, suggests that children with selective mutism may be predisposed for other difficulties such as other speech or language disorders, encopresis, or enuresis (3).

Acquired Aphasia: This is development of aphasia after language development has begun. This usually occurs after 2 years of age. Encephalopathy from bacterial infections, traumatic lesions, and stroke in the dominant hemisphere are the most common reasons. This almost always results in nonfluent speech and may also progress to loss of spontaneous speech or mutism. Unless cortical damage is

bilateral, recovery in children is more likely than in adults. However, they may retain residual language deficits that may hamper their school performance. Concurrent comprehension difficulties can happen, but occur less commonly.

Landau-Kleffner syndrome: This is a rare syndrome involving nonconvulsive status epilepticus. There are severe comprehension and recognition deficits. Oral expression is worse than written expression, but both are deficient. Nonverbal intelligence is normal. 70% have hyperactivity, impulsivity, oppositional, or other behavioral problems. Prognosis is poor even with anticonvulsant medications.

The differential diagnoses for these language disorders include: deafness or hearing loss, mental retardation, autism spectrum disorders, other psychiatric disorders, organically caused communication disorder (cleft palate, apraxia, cerebral palsy, or childhood acquired aphasia).

To make the diagnosis of a particular language disorder, a variety of language assessment tools can be used. Intelligence and cognitive testing (generally nonverbal based tests) such as the WISC (Wechsler Intelligence Scale for Children) performance subscale, Ravens Colored Progressive Matrices for Children, and the Leiter International Performance Scale, can help differentiate between mental retardation and more specific disorders. Audiology tests are essential to rule out hearing deficits (2). An important part of the evaluation is determining whether or not there is a specific speech/language disorder or it is a deficit that is part of a bigger picture (genetic syndrome, psychiatric disorder, etc.) (3).

Treatment may include individual or small group therapy with a speech/language pathologist. A child psychiatrist or child psychologist may be helpful for children with Selective Mutism. Learning of Alternative Communication Methods (AAC), such as sign language or communication boards, may be crucial for certain disorders. Educational tutoring, social skills training, and behavioral interventions such as operant conditioning, contingency management (positive and negative reinforcements), and shaping of behavior are important for many children with problems occurring secondary to the language disorder. Family education and support and close collaboration with educational systems are important roles for the physician.

Questions

1. What are the three main areas affected in children with Autistic Spectrum Disorder? (Select all that apply)
   a. Splinter skills
   b. Socialization
   c. Language
   d. Motor abilities
   e. Repetitive and restricted interests and activities

2. What differentiates Language Disorders from Autistic Spectrum Disorders? (Select all that apply)
   a. Social skills are secondarily affected.
   b. Interests are not usually restricted.
   c. There is usually no repetitive behavior.
   d. Autism doesn't affect language.
   e. Most children with language disorders are not usually mentally retarded, while the majority of children with autism are.

3. Which medical disciplines generally see children with autism? (Select all that apply)
   a. Pediatricians
   b. Child Psychologists
   c. Child Psychiatrists
   d. Neurologists
   e. Family Practitioners

4. True/False: Medications can directly treat autism.

5. Which evaluations would be important in diagnosing children thought to possibly have autism or language disorders? (Select all that apply)
   a. Audiology
   b. Intelligence/Cognitive Testing
   c. Allergy testing
   d. Behavioral assessment
   e. Physical examination

Answers to questions

1. b, c, e
2. a, b, c, e
3. all are correct
4. False, medications are used symptomatically for particular behaviors or related affective disorder.
5. a, b, d, e

Chapter I.10. Attention Deficit/Hyperactivity Disorder
Jeffrey K. Okamoto, MD

An 8 year old named Harry is accompanied by his mother to the primary care pediatric clinic. His mother relates that Harry's school wants him on a medication because he cannot sit still. He is always bothering other children in his classroom. There are 30 other children in his class. There is another boy Joel who has similar problems and is on methylphenidate (Ritalin), and is doing much better in not bothering others. Joel is now able to concentrate on his work. Harry's mother believes that Harry is quite bright but he is not learning well in his classroom. He is about to flunk math, reading and science - although he particularly likes science. His teacher says that he is well versed in identifying animals, which is part of the curriculum for his class, and he is much better than most of his classmates in doing so. However, he cannot work in a group, which is part of the science activities, without upsetting other members. He has impulsivity in working with materials and disrupts others who are trying to stay on task. Harry relates that he feels that everyone is out to get him, and that he gets teased about the teacher's frequent admonishments over his behavior. He often has to sit in a chair separated from other children. Harry's mother relates that his behavior was like this in earlier grade levels.

He is quite impulsive at home, often breaking things such as the computer and his toys. He also has broken his right tibia after riding his bicycle off the roof. He cannot sit still at meals. His mother relates that Harry's father has similar traits of being reckless, and inattentive. She relates that Harry's father is against medication for Harry. By his mother's report, Harry's father feels that he is quite successful, even after his own behavioral troubles in school during his childhood. His parents are happily married and his mother cannot think of any major social stressors other than Harry's behavior at this time.

His past medical history is unremarkable. His developmental milestones were all on time prior to age five.

Exam: VS T 37.2, P 105, R 16, BP 90/43. Height and weight are at the 20%ile. Head circumference is near the mean for age. He is happy and active, exploring the office, touching all medical instruments. He speaks coherently and in context, seems sad and then mad when talking about school. He draws a picture of three figures when asked to draw a picture of his family doing something. They are all swimming in the ocean. By Goodenough-Harris scoring, his figures in the drawing are at a 9 year old level. He has no dysmorphic features. His head, eyes, ears, mouth, dentition and neck are normal. His heart, lungs and abdomen are normal. No facial asymmetry or tics are observed. He moves all extremities well. He walks and runs well. He has good muscle tone and strength, without contractures or tremors. His DTRs are 2+/4 for knees, ankles and biceps. He has no rash and no neurocutaneous lesions. His hearing and vision screens were found to be normal.

Harry is evaluated using a variety of methods looking into several domains of his life. Behavioral rating scales (the 1997 revision of the Conners Rating Scale) shows Harry to be above two standard deviations in Attention-Deficit/Hyperactivity Disorder (ADHD) symptoms for both the Teacher and the Parent scales. A school psychoeducational assessment shows Harry to be above average in both performance and verbal IQs, although the examiner did relate that it was difficult to keep him focused on the tasks presented. He is at the 2nd grade level for his reading and writing, but the 3rd grade level for his math and listening comprehension achievement tests.

A behavioral management program is started at his school. He is given preferential seating and he has a rewards/consequences system for keeping on task or if bothering others. He is tried on psychostimulant medication with some loss of appetite. With titrating of the dose, he is found to be much less distracted in school, and he pays much better attention to class activities. A counselor helps Harry learn how to maintain group activities without the other children becoming mad, and gives Harry insight into following rules on the playing field. He is eventually placed in a "gifted and talented" program at his school because of the excellence of his schoolwork and achievements. Medication holidays help maintain his growth.

Attention-Deficit/Hyperactivity Disorder (ADHD) and its treatment have been controversial areas in the US. Because of the number of children thought to have this condition and the number of prescriptions written for this diagnosis, alarmed families and civic groups have wondered if this condition is overdiagnosed. They also worry that medications are overly used and that medications for this condition will be abused or lead to future drug abuse.

However, without diagnosis and treatment, these children face school failure, poor self esteem, drug abuse (ironically), and multiple other problems. The astute clinician understands family and societal concerns, the natural history of the condition, diagnostic tools, and important treatment modalities in order to prevent or ameliorate major problems.

It has been estimated that 3% to 7% of school age children have ADHD (1). Currently, ADHD is the most common neurodevelopmental disorder of childhood (2). With such numbers of children affected, pediatricians and other primary care providers have an important role in assessing and managing many of these children. There are not enough neurologists, psychiatrists, psychologists or similar subspecialists for all children thought to be affected. Boys are diagnosed at least three times as often as girls (3).

Diagnostic criteria can be found in the DSM-IV-TR version of the Diagnostic and Statistical Manual of Mental Disorders (1). Unfortunately, labels and criteria have changed over the years, causing some confusion among practitioners and research groups (4). Previous diagnostic labels have included Minimal Brain Dysfunction (MBD) and Attention Deficit Disorder (ADD). Physicians in Europe and other countries use the term Hyperkinetic Disorder (HKD).

However, it is clear that whatever term is used, this is a clinical diagnosis based on a history of symptoms in multiple environmental contexts observed over time. The core areas that need to be delineated are inattention, hyperactivity and impulsivity. DSM-IV-TR relate three subtypes: 1) a predominantly inattentive type, 2) a predominantly hyperactive-impulsive type, and 3) a combined type. DSM-IV-TR criteria also include the stipulation that some symptoms that caused impairment were present before 7 years of age. Impairment has to be in two or more settings (for instance home AND school), and there must be clear evidence of significant impairment in functioning in interrelationships, schoolwork or in job performance (1). Interestingly, if impairment in school performance and behavioral functioning are not used as part of the criteria, the ADHD prevalence is much higher - 16.1% without impairment criteria versus 6.8% with this criteria (5).

There is also a category in DSM-IV-TR for ADHD, NOS (not otherwise specified) that can be used for children and adults that do not meet criteria for the above mentioned subtypes but have significant impairment from such symptoms. Primary care providers still need to help families and schools with children who do not meet full DSM-IV-TR criteria but have characteristics that cause impairment.

Usually the diagnosis is made in the school age years. High activity levels in toddlers do not invariably lead to ADHD in childhood. Many "hyperactive and inattentive" toddlers end up focusing and engaging in activities without impulsiveness and hyperactivity after maturing through their preschool and early school years. However, one study showed about 1/2 of children thought to have ADHD in their preschool years had a clear diagnosis by age 9 years. These children had more severe symptoms in their preschool years overall compared

to peers (6). Therefore, a clinician needs to take great care to understand the ramifications of the child's age but still consider ADHD at these younger ages.

Much discussion has ensued on whether children with ADHD are just part of the normal continuum of children with varied levels of attention, activity and impulsivity. There is no firm evidence that shows a bimodal distribution where children with ADHD are clearly separate in a different part of the continuum. A recent National Institutes of Health report likens ADHD to essential hypertension or hyperlipidemia which are continuous throughout (and not bimodal) in a population, and where the importance of diagnosis and treatment has been shown (7).

The cause of ADHD is still being elucidated. Brain imaging studies (including MRI, PET and SPECT) show differences compared to healthy controls (8). There is a significant genetic inheritance component. Studies have started to implicate genes for dopamine in ADHD. This correlates with the fact that medications clinically helpful for ADHD involve dopamine transmission. Also, imaging studies have shown the frontostriatal regions of the brain to be important, which are rich in dopamine related neurons. Lastly, mice with impaired dopamine transport mechanisms, are hyperactive and resistant to medications (9).

Once diagnosed, ADHD appears to continue into the teen years for about 3/4 of the diagnosed pre-teen school aged children. Untreated, they often have more severe problems with their peers and family. Problems are worsened because of the multiple previous experiences of failing in endeavors, and also the bad relationship patterns that have been built up with family members (10). One half will have oppositional defiant disorder (ODD), conduct disorder (CD), or another psychiatric diagnosis in their teen years. Also, 1/4 will have comorbid learning disabilities (LD), which can be seen in a discrepancy between their scores in tests of learning ability as compared with achievement.

Interviewing the child and family is of utmost importance. Detailed history gathering will reveal the child's characteristics. Also the history should reveal whether the child's problem is in single vs. multiple settings, and how long symptoms have been noted over time. One needs to be careful not to use the child's appearance in the clinic visit as a measure of the child's problems. Children with (and without) ADHD often look different in structured, supervised, and/or novel settings such as a doctor's exam room. Although some children will show inattentiveness and hyperactivity in the clinic office, some children with severe ADHD may look fine in this setting (8).

Tools that can help in the diagnosis of ADHD include parent-child structured interviews which psychologists and psychiatrists are often familiar with, and ADHD behavioral rating scales which most child professionals have some familiarity with. Barkley, in his well known handbook for assessment and treatment of ADHD has detailed chapters regarding these (11). He finds that ADHD specific behavioral rating scales can be useful for a diagnostic assessment of a child or adolescent. Other reasons for using behavioral rating scales include evaluation of response to medication or child response to parent training in behavioral management. An analysis has shown the use of more global behavioral rating scales to not as effectively detect ADHD compared to ADHD specific scales (2).

After this careful information gathering, a clinician needs to decide if a particular child meets criteria for ADHD and whether an alternative diagnosis is primary. Other disorders that can affect attention include anxiety disorders, mood disorders, substance abuse, and schizophrenia. Head injury, seizure disorders, and brain infections can lead to symptoms of ADHD (8). Although hypothyroidism, fragile X syndrome, glucose-6-phosphate dehydrogenase deficiency and phenylketonuria have all been associated with ADHD, testing for these conditions have very low yields and are not suggested unless the history or physical suggests these in other ways (8). Also electroencephalograms (EEGs) and computerized Continuous Performance Tests (CPTs) have not shown sufficient consistent discrimination between children with and without ADHD (2). Children with lead toxicity as toddlers or preschoolers show normal lead levels by the time they are tested in the school age years. Therefore lead screening is also not recommended on a routine basis (2).

The conditions that are most commonly confused with ADHD are mood disorders and anxiety disorders (8). Both of these disorders are often episodic (and not continuous and unremitting like ADHD), with a later age onset compared to ADHD. Some clinicians like to treat the mood or anxiety disorder first, if one of these are suspected, and see if the symptoms of ADHD resolve.

Comorbid conditions that are often found in combination with ADHD include ODD, CD, LD, Tourette's disorder and speech/language disabilities. All of these may also be disorders that may mimic ADHD in some ways (for example a child who appears inattentive because of language processing disorders) but have substantial differences in criteria from ADHD.

Treatment of ADHD requires understanding of four aspects delineated in a recent American Academy of Pediatrics guideline (12):

1) ADHD is a chronic condition. Physicians should be working with families and schools over the long term to help support these children into adulthood. Follow-up over years is required. Initially the clinician needs to inform the family about ADHD. Then this provider will need to work with the family in coordinating other professionals as necessary, involve the family in treating the child and debriefing the situation, and connect the family to support groups as they desire.

2) Target symptoms need to be addressed. Physicians need to negotiate with the child's family and school over which target symptoms will be addressed at any particular time. These target symptoms should have the potential of being improved upon with appropriate support. These also need to be explicit and measurable. An example of a poor target would be to request the child to be a "good" child. More appropriate targets would include: a) Improvement of the relationships with people the child interacts with; b) Abating behaviors that interfere with the activities of others; c) Working on schoolwork being completed with improved accuracy and decreasing the time necessary for completion; d) Being able to work without supervision in schoolwork, homework and activities of daily living; e) Having better self esteem; and f) Improving safety skills.

3) Medication and behavior strategies are important. Many parents want to use only behavioral strategies rather than medication. Interestingly, the American Academy of Pediatrics' review that examined different treatments of ADHD rated medication as "good" and behavioral strategies as "fair" in strength of evidence. This was particularly affected by the Multimodal Treatment of children with ADHD (MTA) study (13). This study randomized 579 children with ADHD from ages 7 to almost 10 years of age to different groups: medication management alone, medication and behavior management, behavior management alone, and a standard community care group. Both groups that involved medication showed a substantial decrease in important ADHD symptoms over a 14 month period. The combined treatment group showed improved academic measures, measures of conduct, and some specific ADHD symptoms (although not on global ADHD symptom scales) compared to the single treatment groups. In reviewing most of the studies comparing behavior therapy with stimulants alone, there seems to be a much stronger effect from stimulants than with behavior therapy (9).

Medications used in ADHD include stimulants such as methylphenidate and dextroamphetamine; antidepressants such as imipramine and desipramine; and alpha-adrenergics such as clonidine. One of the stimulants, pemoline, was more widely used in the past but this has been advised against because of toxic hepatitis and acute hepatic failure (about 4 to 17 times the expected rate). Monitoring liver function tests usually does not alert the practitioner quickly enough to prevent the rapid progression of liver failure. The other more widely used stimulants have no such liver toxicity. Methylphenidate and dextroamphetamine have side effects such as appetite suppression (about 80%) and insomnia. Overall either of these two medications may cause short term slowing of weight gain and growth

but long term effects are minimal. Tics may be precipitated in those predisposed to them, with improvement often seen while on drug holidays (9). A new non-stimulant medication, atomoxetine (Strattera) is now an available treatment option.

Stimulant medications show quick and often dramatic results in the ADHD characteristics of children. Unfortunately children without ADHD have similar behavioral responses so the response from medication should not be used as a diagnostic trial. Interestingly, good behavioral effects have been repeatedly shown but long term academic effects have not been shown in any long term trial yet. Antidepressants have also shown good initial efficacy but not sustained effects compared to stimulants. These medications are usually reserved for those with coexisting disorders (such as depression and tics) since they have a higher risk of sudden death which cannot be predicted with plasma drug levels or electrocardiography. Clonidine has also led to sudden death when used in combination with methylphenidate. This medication has a patch form that some families prefer. Serotonin-reuptake inhibitors have no evidence based effects that have been shown (9). Newer delivery systems for more sustained release of stimulant medication (such as Concerta, a time released form of methylphenidate) show great promise. They enable a dose prior to school that lasts 12 to 14 hours, rather than requiring the child to go to the school nurse to obtain another dose after the 4 to 5 hour duration of a short acting stimulant (14).

Behavioral Strategies for children with ADHD include: a) Positive reinforcement (providing desired reinforcers contingent on the child's behavior and activity); b) Time-out (using ignoring and isolation away from desired activity); c) Response cost (taking away rewards or privileges if undesired activity takes place); and d) Token economy (a form of positive reinforcement where the child obtains "tokens" such as stars that can be collected towards a even more strongly desired reward) (12).

4) Close follow-up of target symptoms and medication use. Reevaluation of whether the child has ADHD, a comorbid diagnosis, or another diagnosis altogether is important. Target symptoms should be measured by multiple methods if possible and treatment modified as necessary. These reevaluations and monitoring should be done periodically and consistently. The frequency of follow-up would depend of the severity of ADHD, other important comorbid conditions or factors, and the effects and complications of treatment.

In the past it was thought that most children with ADHD would have most of these symptoms abate when they become adults (after a rocky adolescence as mentioned above). It is known that many still have the characteristics for the criteria of ADHD in adulthood, and many have significant problems in work, school or other environments (3). Because of the genetic predisposition, many of the parents of the children seen for ADHD will also have ADHD. This complicates management since parents are essential for the child with ADHD to administer medication, and to ensure behavioral follow-through and academic planning.

Questions

1. True/False: A child psychiatrist is necessary to diagnose and manage children with ADHD

2. The different subtypes of ADHD in DSM-IV-TR relate to criteria around (select all that apply:)
    a. Inattention
    b. Particular learning disability
    c. Impulsivity
    d. Hyperactivity
    e. Gender

3. Evidence is accumulating that shows ADHD to be connected to (select one):
    a. Serotonin
    b. Mast cells
    c. Cortical sleep centers
    d. Dopamine
    e. Mental retardation

4. Which is the LEAST important concern in managing children with ADHD? (select one):
    a. Parents of children with ADHD may have ADHD themselves.
    b. Target symptoms need to be addressed.
    c. The teen years.
    d. Side effects from Pemoline use.
    e. Growth problems from psychostimulant use.

5. Which should be used routinely in the evaluation of school aged children with ADHD? (select one):
    a. Lead screening.
    b. Electroencephalograms (EEGs).
    c. ADHD specific behavioral rating scales.
    d. Fragile X chromosomal testing.
    e. Parent depression inventory.

6. Which is a common comorbid condition with ADHD?
    a. Learning Disability
    b. Autism
    c. Obsessive Compulsive Disorder
    d. Diarrhea
    e. Seizure disorder

Chapter I.11. Medical Insurance Basics
Richard Y. Mitsunaga, MD

You have just completed an examination on a two-year-old child. The child seems normal in nearly every respect, but has only ten words in her vocabulary. You refer her for a speech and hearing evaluation. A developmental expressive speech delay is diagnosed. Speech therapy is recommended. The insurer declines to pay for this service because treatment of developmental language disorders is not a covered service in the patient's health plan.

Our professional survival depends on providing quality services for the patient at a fair cost and receiving just compensation for these services. Accordingly, a basic understanding of how things are paid or not paid is essential. This is particularly true when advocating for patients and for fair reimbursement.

Numerous terms and acronyms confront the newcomer to the field. The terminology must be learned, just as the anatomical, chemical and physiological terms, which were so foreign to you a few years ago, had to be learned. Salaried physicians who do not have formal fiscal duties must still understand the insurance systems used by their patients or risk making them spend more than they should under terms of their coverage. This can cause patient dissatisfaction despite excellent health care and results. It can cause medical-legal problems if the patient's outcome is less than optimal.

A glossary of the more common terms used herein is located at the end of this chapter to assist you with this new terminology. A more complete glossary is contained in other works (1). Some of the definitions used in this chapter are taken from that reference. Every contract you sign with an insurer contains definitions of the terms used in that contract. You are advised to read these carefully so you understand what you are agreeing to do.

A third party payer is an insurer; an entity contracted to arrange payments for services rendered to a patient. The payer may be an insurance company, mutual benefit society, a self-insured large employer, or a state or federal agency.

It is important to understand that an insurer pays with the patient's money, not its own funds. Money from premiums is redistributed as payments. This helps to protect patients from unexpectedly high expenses because the risks are spread among many subscribers. At the same time, it imposes an obligation on all parties to use the money wisely, just as if the payment was coming directly from your patient's pocket.

Sixty years ago, there were few insurers dealing with health. Physician's and hospital fees were paid from the patient's personal funds. Many did not seek medical care because they couldn't afford it. Physicians wondered with every decision whether or not the patient could afford the cost of their recommendations. By the 1960s, there were more health insurance plans. Most dealt with inpatient care, but outpatient plans were rapidly developing. Hawaii pioneered mandatory employer coverage by enacting the nation's first prepaid health care act in 1974. Hawaii's law requires covering only the employee, but charges for a family plan were then low enough that many employers incorporated them into their company plans. Medical costs were inexpensive by current standards. Hospital charges for a five-day mother-baby stay (average at the time for a normal vaginal delivery) in the mid-1960s were about $350, which included the delivery room.

There are four basic components to the American health care system. First are the patients who need care. Second, there are the professionals who provide care, including physicians. Third are the various institutional providers, including hospitals, that also provide care. Finally, there are those that pay for the services rendered by the providers. This may be the individual with or without a third party that assists in payment. These include private as well as government insurers such as Medicare and Medicaid. All parts are essential. In this era of high cost treatment and technology, the system collapses if one piece is missing. The focal point must be the patient. There is no reason for the existence of the others if no one needed their services.

HOW DO PHYSICIANS GET PAID? The person who owes the funds for professional services is the patient. Today, very few patients (or their families) are wealthy enough to pay for all their medical needs. As in the past, patients who have no outside financial assistance must compromise on the visits they make and the treatments they receive. This is far from ideal.

Usually, physicians are paid via some intermediary, which can take many and varied forms. All share a basic cash-flow pattern in which a service is rendered and a charge is made. A payment is then received. A physician must pay business expenses ("overhead"), including working space, personnel including professional (e.g., office nurse), clerical and maintenance, supplies, taxes, malpractice insurance, etc. Only afterward does the physician get paid. In an average pediatric office, overhead runs between 45 and 60 per cent of the gross revenues. If the physician does not attend to the business aspects of the practice, someone must be paid to do this. This administrator adds to the overhead expenses of the practice.

Physicians may be in solo or group practice. Groups may be as few as two physicians or there may be hundreds. Groups may consist of a single specialty or be a multispecialty group.

Payments to the physicians can take varied forms as well. In its simplest form, a practitioner keeps what is left after expenses and taxes are paid. More commonly, a fixed amount is taken and the remainder saved as a reserve. Physicians in groups may organize in an office-sharing arrangement, partnership, professional corporation or partnerships of individuals and corporations. Individuals may incorporate as well, by creating a legal entity known as Dr. XYZ, Incorporated. Payments may occur by taking a fixed amount from partnership revenues (called a "draw") each month, by salary, or by various formulas used to measure productivity and other contributions to the group such as administrative duties. There are also physicians who are employed by large entities such as a university, hospital, health care groups (e.g., Straub, Kaiser Permanente), federal or state agency or department, including the Military Services and the Public Health Service.

HOW DO INSURERS GET PAID? Insurance plans are basically capitated, which means that they receive a fixed amount per patient with which care must be provided for the contractual period, e.g., one year. This is true of private payers as well as government sponsored plans. Military services have congressional appropriations. How they distribute the funds to individual providers, hospitals, pharmacies, etc., is determined by each plan. This accounts for the multitude of payment billing and reimbursement methods encountered by physicians.

The funds received by an insurer represent the amount a purchaser (individual, employer, government agency, etc.) is willing to pay for the total services. The insurer must negotiate for a payment rate within which it can function and remain solvent. The insurer cannot create more money, so it is responsible to distribute the monies it receives fairly but wisely. Bankruptcy of a health plan is catastrophic, as its patients are left without health insurance and money owed to providers cannot be paid. Sufficient reserves must be maintained to provide for unforeseen variations in usage as well as emergencies so that patients and providers are protected.

Repeated withdrawals from reserves can rapidly deplete them, so insurers must operate within their budgets. This is limited to the amounts employers or individuals who buy the policies are willing to pay for premiums minus the operating expenses of the insuring company.

In the days when health insurance was scant or non-existent, physicians sent their patients a bill "for services rendered" and expected to be paid. It is more complicated now, but the fundamentals are the same. Currently, most patients have a large part of their medical expenses paid by a third party payer, who expects a more detailed statement of what services were rendered. How do patients and insurers know what services were delivered and what must be paid for? Most insurers use a standard claim form, called the HCFA 1500 form, to receive reports from providers on the services rendered, diagnoses and the fee requested. Knowledge of what goes on this form is essential even for salaried physicians, since large employers of doctors frequently use these forms as a measure of a physician's productivity and the complexity of the patients who are seen.

Most providers use a computerized billing program. This saves time with the collection of standardized information on a HCFA 1500 such as the patient's name, insurance number, etc. Additionally, computer billing permits better record keeping than is conveniently possible with a manual system, particularly when data retrieval or summaries must be prepared.

From your medical notes, ICD codes (see glossary) convey the diagnoses the patient has and CPT codes tell what level of service(s) was done, along with your charge for those services. Basically, these systems are intended to provide a quick way of informing the insurer about what was done.

Unfortunately, there is opportunity for exaggeration or gamesmanship by provider or insurer. Providers may exaggerate the level of the services provided or they might "unbundle" charges, which refers to charging separately for services that are normally provided as a package. Insurers may be arbitrary in "downcoding" claims, which refers to adjusting a provider's claim to a lower paying level or by refusing to recognize "modifiers" which are codes reflecting unusual complexity of the services rendered.

Both sides may retain coding experts, whose job is to extract the most benefit for their side, often using whatever technicalities they can muster. The codes are supposed to be a method of communication, but this often gets lost in the exchange. Codes were neither intended to give providers an opportunity to game insurers nor to provide insurers with a method to cheat providers. Until mutual trust and meaningful communication is established, part of the monies that could be spent for paying claims will be diverted to review activities. State law and provider contracts with insurers provide for appeals and one should be filed if it is felt that a patient's claim or your bill was unfairly denied. Appeals without merit, however, also cost the insurer money to review and process, and this is money that might be better spent paying claims.

It is critical to know that insurers including the government require adequate documentation of a service. For review purposes, a service not documented is considered to have never been performed (and will not be paid for). In short, documentation of the services rendered and a thorough knowledge of coding rules and procedures are essential to receiving the best compensation for your services. Coding is best done by the physician. It is a mistake to assign this duty to less experienced helpers.

Provider contracts with third party payers include provisions for fee schedules to be established. You may charge whatever you wish for a given service, but the insurer will pay no more than the "maximum allowable charge" (the amount for a service listed on the fee schedule) for the service. The difference between your charge and the lesser amount allowed is called a "provider adjustment," which is a discount off your fee that you have contractually agreed to with the insurer. Patients receive a report of this "provider adjustment" and all

insurers stipulate you cannot "balance bill" (i.e., charge the patient for the difference between your charge and the maximum allowable charge). If your fee is less than the maximum allowable charge, you will be paid only what you charged.

For a given claim, an insurance company pays a contractually agreed percentage of the allowable charge. For example, it may pay 80% of an office visit (the actual percentage varies with different plans). The patient must pay the "co-payment" which is the balance owed between the allowable charge and the amount paid by the insurance company. In this case, the patient will owe 20% of the bill plus applicable state tax. You bill the patient for this "co-pay". This is the typical fee for service (FFS) arrangement. One could consider "capitation" to be the opposite of FFS. Physicians who are capitated will receive a monthly payment for each patient registered to them by that insurer regardless of the number of visits that month.

Variations in the system are common. A large group or an IPA (Independent Practice Association) may receive a capitated payment for the patients under their care. This intermediary may choose capitation or a fee for service method of paying the physicians who render the care. Be sure you have a good explanation of the payment mechanisms that apply to you.

Obligations to patients by providers and by third party payers overlap, but not completely. Both providers and insurers are expected to provide those medically necessary services authorized by the terms of the physician's contract and the patient's coverage.

It is important to know that an insurance policy rarely covers all possibilities, but rather only those services that are "covered services" and are "medically necessary" (a term that is defined in state law) will be paid for. If a service is not covered in the patient's plan, it won't be paid for even if it is "medically necessary". An analogy exists with auto insurance. You won't be paid to fix your wrecked car if you didn't buy collision insurance or if you wrecked the car doing something excluded by your policy such as driving without a license. The sample case at the beginning of the chapter is another example, such that developmental speech abnormalities were not a covered service in the patient's plan, even though the need for the service is appropriate. Other services must meet specific criteria and be "pre-authorized" by the insurance company (i.e., be approved for coverage in advance or risk not having it paid for at all).

Providers are obligated to provide individualized services to each patient. Some community obligations exist, such as not abusing antibiotics and causing the development of resistant organisms, but the basic obligation is to the individual patient. Third party payers must consider their total membership and the community as well as the individual member. Prices must be affordable for those paying the premium and insurers have an obligation to remain fiscally solvent through the terms of their contracts. Accordingly, covered tests and treatments must be of proven efficacy and cost-effectiveness. Adequate reserves must exist to protect against unforeseen events. The differences in these obligations can lead to occasional conflicts.

There are fewer conflicts than people on both sides think. The overwhelming majority of claims are paid promptly and automatically. Neither side pays much attention to them because they are not a problem. Providers and payers interface when a conflict occurs (e.g., a denial of a prior-authorization request or a payment). Attention is paid only to the conflicts and both sides often have a very limited view of the other's role and the fact that their obligations may differ. An insurance company's staff that works all day with denials may incorrectly feel every physician is trying to cheat. The provider, whose attention is called to denials and not to the majority of claims that are immediately paid, may feel that all the insurer does is try to cheat them. The perceived frequency of these conflicts is therefore magnified.

Reason must prevail and discussions must change from the "win-lose" mentality currently prevalent. Conflict resolution must occur with each side appreciating the other's role in the overall scheme of managing patient care. Above all, communication is essential. Even agreeing to disagree on a given point is better than not communicating at all.

Questions

1. True/False: The decision to deny speech therapy in the case at the beginning of the chapter should be appealed, since it is medically necessary.
2. True/False: A cosmetic procedure is denied because it is not a covered service. The patient elects to have the procedure anyway. The doctor is allowed to charge for the service.
3. True/False: A charge is adjusted downward because it exceeds the maximum allowed for that service. The doctor is allowed to charge the patient for the difference.
4. True/False: A mechanism to appeal managed care decisions is contained in Hawaii State Law.
5. True/False: Due to their large reserves, insurers have minimal budgetary constraints in spending.

References

1. American Academy of Pediatrics. A Pediatrician's Guide to Managed Care, 2nd edition. 2001, Elk Grove Village: American Academy of Pediatrics.

Answers to questions

1. False. The service is not covered in this patient's plan even if it is deemed medically necessary.
2. True. The patient must be informed beforehand that the service may not be covered and that he or she will be expected to pay if they wish to have the service done.
3. False. Contracts between third party payers and providers stipulate that balance billing is not allowed when fees exceed maximum allowable charge on a covered service.
4. True. See Hawaii Revised Statutes Chapter 432e.
5. False. An insurer must observe its operating budget, which is dependent on the premiums received. Insurers cannot generate new money; they can only redistribute what they collect after expending reasonable amounts for operations. Reserves are for unforeseen emergencies. Repeated withdrawals from reserves threaten the solvency of the third party payer.

Glossary (1)

Capitation: A method of payment in which reimbursement to a provider or group of providers occurs through the payment of a fixed, periodic payment (usually monthly) in exchange for delivering a defined set of services to a specific population of patients, placing most of the financial risk for utilization on the provider. This is paid whether a patient has no visits or makes multiple visits (1).

CMS (Centers for Medicare and Medicaid Services): Formerly HCFA (pronounced hik-fa for short) or Health Care Financing Administration. This is the federal agency responsible for administering the Medicare, Medicaid, SCHIP (State Children's Health Insurance), HIPPA (Health Insurance Portability and Accountability Act), CLIA (Clinical Laboratory Improvement Amendments), and

several other health-related programs. Additional information regarding CMS and its programs is available at http://cms.hhs.gov/about/default.asp.

Cost Effective Care: Defined in Hawaii Law (Hawaii Revised Statutes Chapter 432e) as "a health intervention where the benefits and harms relative to the costs represent an economically efficient use of resources for patients with the medical condition being treated through the health intervention; provided that the characteristics of the individual patient shall be determinative when applying this criterion to an individual case." "Cost effective does not necessarily mean the lowest price."

Covered Services: Those services contractually or legally required of a third party payer. In Hawaii, the latter includes childhood preventive health services and immunizations through age five years.

CPT: Current Procedural Terminology. Developed by the American Medical Association, CPT is revised annually and is a listing of descriptive terms and identifying codes for reporting medical services and procedures performed by physicians.

Downcoding: The practice of designating a lower level or intensity of medical service provided for purposes of paying less to health care providers (physicians, hospitals, etc.). Downcoding is correct if the documentation does not reflect the service claimed. Insurer's can abuse downcoding if it is done arbitrarily or solely to pay the provider less.

EPSDT: Early Periodic Screening Detection and Treatment. A program on which the QUEST (Hawaii Medicaid Managed Care Program) Plans are rooted. All patients under age 21 years are considered to be in EPSDT, which makes them eligible for some benefits that are not available to adults.

FFS (Fee for Service): A mode of payment for health care services in which a physician charges a fee for each specific service or group of services. The patient and their insurer pay, usually in a ratio of 20% from the patient and 80% from the insurer. Plans covering FFS arrangements are typically the most expensive.

Formulary: A list of approved prescription drugs determined by a managed care plan for use by its patients and physicians (1).

HMO (Health Maintenance Organization): An entity that agrees to provide or arrange for the provision of a specified set of comprehensive health services to a defined population of patients for a prepaid, fixed sum (1).

ICD-9-CM (International Classification of Diseases, 9th Revision, Clinical Modification). A system of disease classification based on work by the World Health Organization and issued in the United States by the U.S. Department of Health and Human Services. The CM version refers to the standard method physicians use to report their diagnoses on an individual patient to insurers on their claims for payment.

IPA (Independent Practice Association): An association of physicians organized to provide various services for their members, including securing contracts with insurers, particularly for managed care contracts. IPAs may also do MSO functions (see MSO).

Managed Care: A means of providing health care services within a defined network of health care providers that is given the responsibility of managing utilization of health care services and providing quality, cost-effective health care (1).

Medicaid: A jointly funded, Federal-State health insurance program for certain low-income and needy people. It covers approximately 36 million individuals including children, the aged, blind, and/or disabled, and people who are eligible to receive federally assisted income maintenance payments (see QUEST).

Medicare: Health insurance program administered by the Centers for Medicare and Medicaid Services (CMS) for persons 65 years of age or older, some persons with disabilities, and patients with End-Stage Renal Disease. Medicare has two parts: Medicare Part A (hospital insurance) helps pay for care in hospitals, skilled nursing facilities, hospice care and some home health care. Medicare Part B is optional for beneficiaries and a premium must be paid. Part B helps pay for doctor's services, outpatient hospital care and some other medical services that Part A does not cover.

Medical necessity: To a physician, this has classically meant whatever a physician deems necessary in the care and treatment of an individual patient. Patients, of course, define the term as referring to services they feel they need. Third party payers changed this to refer to care that their payment teams deemed necessary for the management of a given patient. The term has become increasingly complex and specific criteria must be met for a service to qualify as "medically necessary". Hawaii has a definition of Medical Necessity defined in State Law.

MSO (Management Services Organization): An entity that provides management services to physicians, physician groups, hospitals or insurers. Services may include quality and utilization management and claims payment. An MSO can be owned by any of the entities for which it provides services, various combinations of the owning entities, or be completely independent (1).

PPO (Preferred Provider Organization): Groups of physicians usually assembled by an insurer or other large entity to provide services for its membership. Physicians in such a group are usually contractually required to participate with the plan, which generally includes items such as accepting payments that are reduced from the full payment usually given by that insurer. In return, the insurer guides its subscribers to utilize the preferred providers. Other contractual requirements may include mandatory participation in aspects of the plan to monitor quality or to save money, such as following a formulary.

QUEST: Medicaid Managed Care Program administered by the Hawaii State Department of Human Services.

Upcoding: The practice of designating a higher level or intensity of medical service provided for purposes of obtaining greater reimbursement from an insurer or other payer (1). Upcoding is appropriate if a higher level of service was actually rendered; inappropriate if it was not.

Chapter I.12. Pediatric Dental Basics
Cindy W. Yang

A 2 year old boy is brought to the office by his mother, who is concerned that her child has not been eating normally and has many dark spots on his teeth. He might be having dental pain, but she is not sure. Acetaminophen has been given, and this might be helping to some degree. His mother reports trying to wean him off the bottle. She typically feeds him at night, and he refuses to go to sleep without a bottle of milk or apple juice. She doesn't brush his teeth because he doesn't like it. She has never taken him to a dentist due to financial reasons. His past medical history and family history are unremarkable.

Exam: VS T 37.5, P 85, R 25, BP 95/55. Height and weight are at the 75th percentile. He appears alert and active in no apparent distress. His physical exam is normal, except for findings in the oral cavity. Intraorally, there are opaque brown and grey specks on the enamel surface of several upper primary teeth. The upper central and lateral incisors show extensive decay and are slightly loose. The gingival tissues above the upper right central incisor are slightly swollen. Moderate lesions are visible in the upper canines, upper first molars, and lower first molars. The upper and lower second molars are just emerging through the gingiva. The lower canines and incisors are all intact, with no signs of dental decay.

A diagnosis of early childhood caries (ECC) is made, and he is referred to a dentist. His mother is told to wean him off the bottle and to brush his teeth at least twice a day.

Pediatricians and primary care family physicians play a vital role in promoting good oral hygiene as a life long habit that begins during infancy. They are the first and most frequent health care providers seen by infants and young children, during the formative years of oral health care. Beginning from the newborn period, they are also the first to provide information and guidance to infants and their parents. The key to oral health promotion and disease prevention lies in anticipatory guidance and education of parents, early detection, and timely referral for appropriate intervention.

A general knowledge of basic dental anatomy and tooth eruption patterns enables the primary care physician to evaluate a child's general oral health. The primary structures of the tooth are the: 1) enamel (outermost protective layer), 2) dentin (calcified tissue layer deep to the enamel), 3) gingival margin (region of the gum surrounding the tooth), 4) pulp (soft tissue at the core of the tooth which contains blood vessels, nerves and lymphatics), 5) cementum (layer of bony tissue covering the tooth root surface), 6) periodontal ligament (membrane around tooth attaching it to alveolar bone), 7) alveolar bone (bone that surrounds the root and forms the socket for the tooth), 8) neurovascular bundle (nerves, arteries, and veins in the dental pulp that exits at the root of the tooth).

Teeth can be named by their anatomic shape or by a letter/number convention used by dentists to describe the upper/lower and left/right teeth. Letters refer to primary teeth and numbers refer to permanent teeth. There are 20 primary teeth (described by positions A through E) and 32 permanent teeth (described by positions 1 through 8). From the center proceeding posteriorly: central incisor (#A, #1), lateral incisor (#B, #2), canine (#C, #3), first premolar (#4), second premolar (#5), first molar (#D, #6), second molar (#E, #7), third molar (#8).

The formation of human dentition begins as early as the 6th week in utero, during which, tooth buds of the primary (deciduous) teeth develop at 10 specific sites in the developing maxilla and mandible (1,2). Primary teeth begin to calcify at about 3 to 4 months in utero, and the enamel of all crowns is completed by 10 months after birth. From the midline of the oral cavity, anteriorly to posteriorly, the primary central incisors are the first to erupt at about age 6 to 7 months, followed by the lateral incisors at 7 to 9 months, the first molars at 12 to 14 months, the canines at 16 to 18 months, and the second molars at 20 to 24 months. By the time the child is 2 years old, all 20 primary teeth should be evident in the oral cavity (1,2,3).

Beneath the primary teeth, 20 permanent (succedaneous) teeth develop. As root development takes place in the permanent teeth underneath, this causes exfoliation of the primary teeth. Osteoclast formation is stimulated, which results in the resorption of the roots of the primary teeth and their subsequent loss. In addition, 12 permanent molars develop distally in sequential order: 3 upper and 3 lower on each side of the oral cavity (2).

With the exfoliation of primary teeth and replacement by permanent teeth, the child enters a mixed-dentition stage. Permanent teeth erupt in the following sequence: lower central incisor and first molars at about age 6 to 7, followed by the upper central incisor and lateral incisors, the canines and premolars, second molars, and finally third molars (wisdom teeth) during late teens up to the early twenties (1,2).

Disorders of tooth eruption and positioning are common pediatric dental problems that present clinically as malocclusion or abnormal alignment of the dentition. Delayed eruption of all teeth is indicative of developmental delay, hormonal abnormalities, and nutritional or systemic disturbances (e.g., hypothyroidism, trisomy 21, rickets, type I osteogenesis imperfecta, cleidocranial dysostosis, Albright osteodystrophy, progeria, or incontinentia pigmenti). Failure of eruption of single or small groups of teeth suggests local causes such as malpositioning of teeth, supernumerary (extra) teeth, retained primary teeth, or cysts (2,3). In contrast, premature eruption of all teeth is associated with precocious puberty or hyperthyroidism. Early emergence of single or small groups of teeth can arise from early loss of a primary tooth from trauma or extraction caused by caries and infection. An example of premature eruption is the presence of natal or neonatal teeth (at or within the first month of life) which are often rudimentary in form and appear as mere scales of enamel or shells of tooth crowns. They represent supernumerary teeth in approximately 15% of cases, and are frequently associated with other conditions (e.g., cleft palate, chondroectodermal dysplasia, pachyonychia congenita, Hallermann-Streiff syndrome) (2,3).

Other common pediatric dental issues related to developmental disorders of the dentition are abnormalities of tooth number, size, shape, structure, and color. Anomalies in tooth number are due to hereditary patterns producing extra or missing teeth, physical disruption of the dental lamina, and overactive dental lamina or failure of dental lamina induction, leading to an excess or failure of tooth initiation, respectively (3,4). For example, if the dental lamina produces an increased number of buds or if there are physical disruptions in the embryonic dental lamina, supernumerary teeth occur and the condition is termed hyperdontia. The extra teeth erupt most often in the maxillary midline between the central incisors. In contrast, when no tooth buds form (e.g., in congenital tooth absence) or when a normal site of initiation is disturbed (e.g., in cleft palate), the resultant reduction in number of teeth is termed hypodontia. The teeth that are most commonly absent are the third molars, the maxillary lateral incisors, and the mandibular second premolars (2,3,4).

Abnormalities in tooth size and shape occur as a result of disturbances during the morphodifferentiation stage of tooth development. Common examples are macrodontia, microdontia, and twinning. Macrodontia describes teeth that are larger than normal. Regional macrodontia is associated with hemifacial hyperplasia while diffuse macrodontia, a rarer condition, is associated with pituitary gigantism (2,5). Microdontia refers to a reduction in teeth size that is of hereditary genetic etiology. Localized microdontia is common, most frequently affecting the maxillary lateral incisors which may become slender and tapered (peg-shaped). Diffuse microdontia, which occurs

rarely, is associated with pituitary dwarfism (2,3,5). Twinning is the phenomenon in which two teeth are joined together, and may result from fusion (the union of two separate tooth buds due to pressure, trauma, or crowding, creating a tooth of increased size or a reduction in number), germination (the incomplete division of a single tooth bud resulting in malformed teeth), or concrescence (joining of the roots of adjacent malpositioned teeth) (2,3,4).

Abnormalities in tooth structure, namely defects in the enamel or dentin layers, result from disruption during the histodifferentiation, apposition, and mineralization stages of tooth development. Common pathologies that affect the teeth surfaces and alter their appearances clinically are amelogenesis imperfecta (AI) and dentinogenesis imperfecta (DI). AI is a hereditary enamel defect that manifests as hypoplasia or hypocalcification, in which either insufficient quantities of enamel are formed during the histodifferentiation state of tooth development or the calcification stage of enamel formation is defective (4). Because there is faulty production of organic matrix, the teeth are covered by only a thin surface of malformed enamel which is susceptible to fracture and abrasion. The clinical appearance could range from the teeth being small and discolored as the yellow underlying dentin layer is seen, to the surfaces being pitted, rough, and worn down by attrition (3,6). Some nutritional and systemic disorders that can adversely affect enamel formation are vitamin A, C, and D deficiencies, exanthematous diseases, congenital syphilis, birth injury, prematurity, Rh hemolytic disease, local infection or trauma, and ingestion of chemicals (e.g., fluoride and tetracycline) (2). The treatment of AI varies depending on the extent of enamel involvement. The main concern is the loss of tooth structure due to attrition, thus full prosthodontic coverage with crowns is usually recommended for the preservation of the teeth in function. For patients without sufficient tooth structure remaining, over-dentures are recommended to prevent further erosion of the teeth. A physician who recognizes AI in a patient should make the proper referral to a dentist.

DI is an analogous condition in which the hereditary defect is in the dentin layer and dentinal organic matrix. It may be seen alone or occur with osteogenesis imperfecta, an inherited defect in collagen formation resulting in osteopenic bones, bowing of the limbs, bitemporal bossing, and blue sclera (4,6). During the histodifferentiation stage of tooth development, odontoblasts fail to differentiate normally, leading to poorly calcified dentin. The defect in dentin structure alters the junction between enamel and dentin. The enamel layer tends to flake away easily from the underlying dentin, exposing it, leading to rapid attrition. The typical clinical finding of DI is a bluish, brown translucent discoloration. Unless the crowns of these teeth are covered early and completely, the abrasion of chewing often reduces them to the level and contour of the supporting alveolar bone (3,6). Additional causes of dentin abnormalities are systemic disorders that impair normal absorption and circulating levels of calcium and phosphorous, such as Vitamin D-resistant rickets and hypoparathyroidism. Regional vascular abnormalities may also arrest calcification of both dentin and enamel and hinder tooth development (4). Depending on the morphology of each tooth, the size and shape of the crowns and root canals, full coverage prosthesis or full dentures are recommended. In the long run, these patients may be candidates for dental implants as well (6).

Tooth color abnormality is another commonly encountered dental problem that can result from intrinsic or extrinsic staining. Intrinsic staining is due to the incorporation of foreign substances into the developing enamel, while extrinsic staining is superficial and due to adherence of plaque or other discoloring substances to the teeth. Causes of extrinsic stains include a variety of foods and beverages (e.g., coffee), chromogenic bacteria, and iron found in infant formulas and vitamin supplements. In contrast, intrinsic stains are caused by blood borne pigments (e.g, congenital porphyria, cholestatic disorders, anemias, hemolysis) which produces red-brown discoloration, neonatal hyperbilirubinemia which produces blue-black discoloration of primary teeth, drug administration during enamel formation (e.g. tetracyclines) which causes brown-yellow discoloration, and hypocalcified-hypoplastic disease states which manifest as opaque white patches on the tooth or pitted areas devoid of enamel (2,3,4). At concentrations higher than 2.0 parts per million (ppm), fluoride content in drinking water can also cause a variety of discoloration, ranging from small white patches to severe brownish mottled enamel when concentrations exceed 5.0 ppm (3,4). The discoloration of intrinsic stain requires bleaching to remove, whereas extrinsic stains, which are developmental in nature, can be removed with abrasive agents used in dental cleanings.

Dental emergencies are a common occurrence, with the majority of cases due to trauma or pain (e.g., from dental decay and infection). As many as 10% of children may suffer significant tooth trauma requiring emergency management. Dental trauma tends to occur in toddlers (ages 1-3) from falls or child abuse, in school-aged children (ages 7-10) from bicycle, scooter and playground accidents, and in adolescents (ages 16-18) from fights, athletic injuries, and vehicle accidents (3). Facial trauma may loosen, avulse, or fracture teeth. If the family has a regular dentist, this dentist can be called for advice and many will provide after hours emergency care in their office. Without a family dentist, the patient will probably seek care in an emergency room, most of which are not optimally equipped for dental care. A frequently encountered dental emergency is tooth avulsion. If it is a permanent tooth, it should be rinsed and immediately inserted back into the gum socket (unless the patient is too young to be cooperative); alternatively, it can also be stored in saliva, saline, or milk. The tooth should not be scrubbed. Immediate dental consultation should be obtained.

Dental decay (caries) is the most common chronic disease of childhood, particularly in children of low socioeconomic backgrounds, minority groups, and developing countries who have limited access to dental care. The prevalence of dental decay is 30% to 50% among poor and minority children, and as high as 70% in some Native American groups (3). Beginning at an early age, cavities affect nearly 20% of 2 to 4 year olds, more than 50% of 8 year olds, and greater than 75% of 17 year olds according to CDC surveys.

The decay process of dental caries is characterized by demineralization and breakdown of tooth organic matrix. The development of caries is a complex, multifactorial process dependent on the presence of dental plaque, specific acidogenic bacteria (primarily Streptococcus mutans), fermentable carbohydrates, and a susceptible host. Host factors that increase the risk of caries include decreased salivary flow rate and pH, as well as areas of defective tooth maturation (e.g., enamel developmental dysplasia) where incremental layers have been disturbed and become susceptible to decay (2,7).

Caries formation is precipitated by specific oral bacteria that utilize dietary carbohydrates, primarily sucrose, as a substrate for acid production via fermentation. The acidic metabolic products in turn demineralize the tooth by reducing the pH of the surrounding dental plaque. The acidogenic bacteria most commonly associated with dental caries is Streptococcus mutans. S. mutans is a gram-positive bacteria with the ability to adhere to dental enamel, survive at low pH, and produce abundant acid. Carious lesions first appear as opaque white to brown specks, but gradually progress to cavitations of the enamel surface, invasion by other acidogenic bacteria (e.g., Lactobacilli) that worsen the decay, and eventual loss of the tooth if the damaging course is not halted (2,3).

A key determinant of dental decay is the frequency of carbohydrate consumption, and not necessarily the quantity consumed. In other words, retaining sweets orally for prolonged periods or drinking sweetened beverages constantly is more cariogenic than consuming the same amount of sugar in a single meal (3). Hence, the terms baby bottle syndrome and nursing bottle caries have been used to describe the phenomenon of early childhood caries (ECC), which is rampant decay that arises from the poor habit of bed time bottle feeding in infants and toddlers (< age 3) combined with concurrent S. mutans infection. ECC usually damages the upper primary teeth, due to the

child's prolonged sucking on a bottle containing sweet juice or milk during sleep hours. The mandibular (lower) anterior dentition are usually spared because of their proximity to major salivary glands which help to neutralize the bacterial acid by-products (2,8).

Children with ECC are at increased risk for developing further caries with age. Furthermore, long standing untreated caries may lead to dental abscesses, resultant soft tissue swelling intraorally and/or facial swelling. Therefore, early diagnosis and prevention can help eliminate significant dental complications in toddlers and reduce the risk of decay in later childhood. Bottle feeding should be discontinued at 12 months. This may be unrealistic for some families, but it should certainly cease by 15 months of age. A physician who notices signs of baby bottle caries during a routine examination should refer the child to a dentist.

All parents should receive anticipatory guidance regarding dental development, oral hygiene, fluoride use, diet and feeding habits. Experienced primary care physicians can also perform a basic dental exam to screen for problems such as baby bottle caries, other caries, abnormal eruption sequence, and malocclusion. The American Academy of Pediatric Dentistry recommends an oral examination for all infants within 6 months of the eruption of the first tooth and no later than 12 months of age (9). Children at high risk for dental disease (e.g., low socioeconomic background, poor feeding habits) should receive checkups as often as every 3 months. While low risk children can be seen yearly, most children are recommended to receive periodic dental exams at 6 month intervals.

The use of fluoride represents the most promising approach to caries control. Fluoride plays a key role in altering the composition of the calcifying tooth structure, which changes the tooth's susceptibility to caries. The only mineral component in tooth is hydroxyapatite, a form of calcium phosphate easily substituted by other chemicals. When a high fluoride content is incorporated into the tooth structure, it becomes less soluble to the acid by-products of cariogenic bacteria. The American Dental Association recommends supplemental fluoride based on the concentration of fluoride ion (ppm) in drinking water (10). No supplemental fluoride is needed in newborns until age 6 months. For children between ages 6 months to 3 years, if the water fluoride concentration is less than 0.3 ppm, the supplement dose should be 0.25 mg/ day. No supplement is needed if the water fluoride concentration is greater than 0.3 ppm. In children between ages 3 to 6 years, if the water fluoride concentration is less than 0.3 ppm, the supplement dose should be 0.5 mg/day. If the water fluoride concentration is between 0.3 to 0.6 ppm, the supplement dose should be 0.25 mg/day. No supplement is needed if the fluoride concentration is greater than 0.6 ppm. In children between ages 6 to 16 years, if the water fluoride concentration is less than 0.3 ppm, the supplement dose should be 1.0 mg/ day. If the water fluoride concentration is between 0.3 to 0.6 ppm, the supplement dose should be 0.50 mg/ day. No supplement is needed if the fluoride concentration is greater than 0.6 ppm.

Community water fluoridation provides the most effective means for fluoride supplementation during the formative years of a child's growth. The water supplies for most communities in Hawaii are not fluoridated which is a major reason why children in Hawaii have one of the highest per capita rates of dental caries in the U.S. If community water fluoridation is not available, two other delivery systems of fluoride are available. Systemic fluoride can be prescribed for the child, usually in the form of sodium fluoride drops or tablets. Systemic fluoride incorporates itself into the developing teeth long before eruption. Topical fluorides are also available by prescription. Neutral sodium fluoride gel 1.1% or stannous fluoride 0.4% can be brushed on teeth or placed in a fluoride tray and applied to teeth for 3 to 5 minutes once a day. Excessive fluoride, however, can result in fluorosis which most commonly presents as dental discoloration (white and brown spots). Fluorosis may occur from excess fluoride intake due to swallowed fluoridated toothpaste or overaggressive fluoride administration.

Since good eating habits can be established in early childhood, parents should be educated and informed of the importance of limiting a child's consumption of foods with high sugar content, such as candies, honey, cookies, jam, chewing gum, jellies, sugary drinks and other adhesive carbohydrates. The child's frequency of eating is also an important contributing factor to the formation of carious lesions, especially the habit of eating in between meals and at bedtime. In addition to a sensible restriction of the child's sugar intake, the role of plaque in the caries process should also be discussed with the parents. Dental plaque is composed of densely packed microbial structures, insoluble salivary glycoproteins, microbial extracellular products, and epithelial and dietary debris which adhere firmly to teeth. It houses various bacterial populations. Dental plaque resists displacement by the forces of aqueous rinsing, but are readily removable by the mechanical actions of brushing, flossing and dental prophylaxis.

Brushing should begin as soon as teeth erupt, and reinforced by parents until children develop enough coordination required for adequate oral hygiene (usually until age 8). Unfortunately, it is common for parents to stop brushing their child's teeth when faced with a non-compliant youngster who throws a temper tantrum to avoid toothbrushing. Such parents must be taught that yielding is reinforcing the wrong behavior, as children soon realize that they can get away with brushing simply by crying. Instead, the opposite message should be conveyed. Children must understand that no matter how hard they resist, they will still need to get their teeth brushed. As long as parents are firm in enforcing toothbrushing routines, children will usually learn to accept it.

Prevention is optimized by regular dental examinations. Periodic dental visits familiarize the child with the dental office and offer the chance to develop a healthy rapport with the dentist, minimizing fear during future dental visits. More importantly, regular checkups enable early caries detection, application of topical fluorides, and reinforcement of home dental care instructions. Together, these preventive strategies help ensure the maintenance of good oral hygiene.

Questions

1. True/False: Normally, there are 20 deciduous teeth and 32 succedaneous teeth.
2. Name some developmental disorders of the dentition.
3. True/False: Amelogenesis imperfecta (AI) is a hereditary dental disease that can occur with osteogenesis imperfecta.
4. Which microorganism initiates the development of dental caries?
5. What are some preventive measures against dental caries?
6. At the 2 year old well child check, a child is noted to have severe decay of his anterior upper teeth. His mother claims that he stopped drinking from the bottle at age 12 months. His other teeth appear be normally formed. What is your comment to his mother?
7. A 10 year old boy falls off his bicycle and is struck in the mouth as he falls. His mother calls you for advice. He lost his front tooth and she has put it in a cup of milk. He did not loose consciousness. He is awake and alert and he does not appear to have other facial injuries. You advise her to call their family dentist to see if he can reimplant the tooth. In the meantime, what should his mother do with the avulsed tooth?

Answers to Questions

1. True

2. Disorders of tooth eruption and positioning (premature, delayed, or failure of eruption, malocclusion or abnormal alignment), abnormalities of tooth number (supernumerary tooth), size and shape (macrodontia, microdontia, or twinning), structure (AI or DI), and color (intrinsic or extrinsic staining).

3. False. Dentinogenesis imperfecta is the condition that may occur with osteogenesis imperfecta.

4. Streptococcus mutans

5. Fluoride supplementation, good oral hygiene that includes brushing and flossing, limiting the amount but more importantly the frequency of intake of sweets (especially the habit of bedtime bottle feeding, eating in between meals and at bedtime), regular dental visits.

6. It is very likely that this history is not correct. These appear to be baby bottle caries, which is the most likely cause. It may be that mother feels guilty that she is not following your advice so she is denying that the child continues to go to bed with a bottle. Another possibility is that she is giving the child juice in a bottle at night and does not consider this to be "bottle feeding". Grandparents living in the same household will often interfere with childhood rearing practices, since they may insist on letting the child have a bottle to prevent the child from crying.

7. The best thing to do with the tooth is to push it back into its original location after a gentle rinse, if the child is cooperative. Otherwise, the tooth can be placed in saline gauze or milk. The tooth should not be scrubbed.

Chapter II.1. Nutrition Overview
Caron M. Hong

This is a 4 month old boy who is not growing well. His birth weight was 3.5 kg and his current weight is 4.0 kg (less than the 5th percentile). Mother states that he drinks 6 ounces of infant formula every 4 hours (six feeding per day). She also feeds him a small amount of rice cereal, but he is having difficulty holding this in his mouth. There is no history of vomiting or diarrhea. He has about 6 wet diapers per day and stools once or twice daily. His review of systems is negative.

Exam: VS T 37.4 (rectal), P 110, R 30, BP 75/55, oxygen saturation 100% in room air. Weight 4.0 kg (less than the 5th percentile), height 57 cm (10th percentile), head circumference 41 cm (40th percentile). He is thin appearing, but not acutely ill. Head is normocephalic. Anterior fontanelle is flat and soft. HEENT is otherwise normal. Heart regular, without murmurs. His lungs are clear. His abdominal exam is normal. His genitalia are normal. His extremities are thin. His visible perfusion is good. Muscle tone and reflexes are normal.

Based on history, his fluid intake is calculated at 270 cc/kg and his caloric intake is calculated at 180 calories/kg, plus additional calories from rice cereal. His maintenance caloric intake should only be 100 cal/kg. Thus, it is estimated that his caloric intake is well in excess of maintenance nutritional requirements and he should be growing better than this. He is hospitalized for evaluation. Admission laboratories including a complete blood count and comprehensive chemistry panel are normal. He gains 100 grams daily for the first three days of hospitalization on formula alone, which is calculated at 280 cc/kg and 187 calories/kg. Since this is not much different from what he was getting at home (by history), the medical staff suspect that something in the history is not correct. Upon further questioning, mother was not feeding him 6 ounces of formula per feeding as she had initially stated. Instead, she was offering him some juice and she added extra water to the formula to make it go farther.

Nutritional requirements of infants and young children differ from that of adults in a number of aspects due to energy expenditure (i.e., basal metabolism, metabolic response to food, and physical activity), rate of growth, new growth, body composition, and physiological changes (e.g., puberty). Due to the high nutritional needs of infants and young children, there is an increased risk for nutritional disruptions (i.e., undernutrition and overnutrition). This risk may be compounded by lack of knowledge or awareness of signs and symptoms on the part of the caregiver. Regular well child care visits aid in the prevention and screening of such disruptions and can alleviate associated detrimental effects.

A good nutritional assessment includes a family history, developmental assessment, medical history (including growth history), and physical examination, especially growth parameters (Table 1). Anthropometrics is the measurement of the physical dimensions of the human body at different ages (1). Reference curves derived from the normal population are used to plot each child to monitor and follow development and growth. Anthropometric parameters include weight, length, head circumference and body mass index (BMI).

Table 1. Aspects of Nutritional Assessment
Dietary evaluation
Growth (weight, height, head circumference)
Upper arm and skinfold measurements (optional)
BMI (body mass index)
Additional corrections for:
- -gestational age (premature infants)
- -delayed/precocious growth (radiographic bone age)
- -sexual maturity (Tanner stage)

Clinical evaluation (medical history, physical examination and anthropometry)
Laboratory data (e.g., hemoglobin, iron, serum proteins) (optional)

The guidelines for nutritional requirements incorporate dietary reference intake values including recommended daily allowances (RDA) and adequate intake (AI) values. These values should be used as a guideline and should be modified as needed (e.g., rapid changes in requirements that occur during infancy). General nutritional requirements are based on age, body size, growth rate, physiological losses and caloric intake. Therefore, a child's rate and stage of growth usually parallels nutritional needs (including physical activity, body size, basal energy expenditure and state of illness). In infants, 9-15% of calories should be from protein, 45-55% from carbohydrate and 35-45% from fat. In older children, 10-15% of calories should be from protein, 55-60% from carbohydrate and 30% from fat. On average, carbohydrate and protein contains 4 calories per gram, while fat contains 10 calories per gram. Nutritional calories are actually chemistry kilocalories. Vitamin deficiency states are covered in a separate chapter.

Breastfeeding is recommended for newborns. Breast milk is the natural food for full-term and premature infants during the first months of life (1,2). There are nutritional, practical, psychological, immunological and physiological benefits to breastfeeding (refer to the chapter on breast feeding). Contraindications to breastfeeding include: mother receiving chemotherapy or radioactive compounds, maternal HIV/AIDS, active untreated maternal TB, maternal primary Herpes or Herpes in the breast region, certain medications (anti-thyroid drugs, chloramphenicol), use of alcohol and drug abuse.

It is strongly recommended by WHO (World Health Organization) that infants receive human milk exclusively through the first 6 months of life and that complementary foods are added thereafter through at least the 1st year of life (1). The alternative for human milk is infant formula based on cow's milk or soy protein (refer to the chapter on infant formulas). Human and cow's milk differ in composition with regard to protein, fat type and quantity of minerals and vitamins. Although technological advances have improved formula composition, formula still lacks the immunological advantages of breast milk.

Fluid maintenance can be calculated at 100 cc/kg/day for the first 10 kg, then 50 cc/kg/day for the next 10 kg, then 20 cc/kg/day thereafter. Maintenance caloric requirements can be estimated by the same numbers. Thus a 14 kg child has a maintenance fluid volume of 1200 cc/day and a maintenance caloric requirement of 1200 calories per day. The caloric density of infant formula is 20 calories per ounce (or 2/3 of a calorie per cc). Human breast milk has a variable caloric density, but it is usually less than 20 calories per ounce. Since the maintenance fluid and calorie calculations are the same, and formula is less than one calorie per cc, infants must take in more than maintenance volume in order to consume maintenance calories (i.e., for an infant to get 1200 calories per day, he/she would have to take in 1800 cc of formula). Growing and thriving infants must consume more than maintenance calories to cover maintenance needs plus the

requirements for growth. Thus, they will often consume 200 to 300 cc/kg/day of formula. The addition of solid foods after infancy which have a higher caloric density (calories per cc) permit them to consume more solids and less fluid in order to grow and thrive.

Maintenance caloric calculations are estimates. Clinical conditions associated with increased metabolic needs (e.g., congestive heart failure) or increased catabolism (e.g., burns), will have higher maintenance caloric needs. Conversely, clinical conditions which lower metabolism (e.g., paralysis), have lower caloric requirements.

By 6 months of age, babies' swallowing mechanisms have developed sufficiently enough for them to be started on solid foods. Toward the end of the 1st year (12 months), weaning from breast or bottle to cup use is advised. However, it is very common for children to continue to drink from bottles beyond this age. Children who continue to drink from bottles for prolonged periods (past 15 months of age) have a high incidence of dental caries and this practice possibly adds to the risk for otitis media. Dietary recommendations during growth and development are summarized below:

0-12 months: Vegetarian diet NOT recommended for the first 2 years of life. 2% or skim milk is NOT used since fat is needed for neural development (whole milk contains 4% fat, 2% milk contains 2% fat, skim milk contains no fat). Whole cow's milk is not recommended before 9 months of age (high renal solute load, poor protein ratio composition, poor Fe absorption and inappropriate energy distribution). Breast milk and/or formula can be used exclusively (no other foods are necessary) until 6 months of age. Some vitamin supplementation may be necessary (e.g., vitamin K given at birth, vitamin D to prevent rickets). Adequate iron intake must be assured (some formulas called "low iron", do not have enough iron). Daily fluoride supplements should be started at 6 months of age and continued until 12-16 years of age, to reduce the incidence of dental caries, in areas that lack fluoridation of the water supply (e.g., Hawaii).

6-9 months: This is the age at which solid foods are introduced. Iron enriched cereals (e.g., rice cereal) should be started first because they are less allergenic. New foods can be added gradually (only one to two new foods per week to determine hypersensitivity and/or food intolerance). Pureed yellow/orange vegetables (e.g., carrots, squash) should be added next. Pureed green vegetables should be introduced after yellow/orange vegetables because they have more bulk. Vegetables with high nitrite contents (e.g., beets, spinach, turnips) should be avoided. Vegetables are generally offered before fruits because the sweet taste of fruits may cause infants to reject other foods. Pureed fruits and juices, pureed meats, fish, poultry, and egg yolk can be introduced after the infant demonstrates tolerance to pureed vegetables. Avoid egg whites until 12 months because of the risk of allergy. Avoid desserts, since these have no significant nutritional value and their sweet taste may cause infants to reject other foods.

9-12 months: Finger foods, peeled fruits, cheese and soft cooked vegetables may be. Avoid peanuts and raw, hard vegetables until 3-4 years old, because of the risk of aspiration. Avoid added sugar, salt, fat or seasonings.

1-2 years: Eating habits formed from 1-2 years of life affect subsequent years. A vegetarian diet is not recommended for the first 2 years of life. Very soft table foods can be offered. High protein foods contribute to their growth potential. Carbohydrates and fats contribute to meeting their energy requirements.

2 years: Snacks may be included (e.g., juice and crackers), but this should be encouraged. This age (also known as the terrible two's) is typically associated with a decreased appetite (due to social interactions/refusal of food) and poor weight gain. Parents often unintentionally reward the wrong behavior. For example, if a child does not eat much at lunch or dinner, parents feel sorry for them and want them to grow, so the child is given a snack (e.g., cookies, chips, ice cream) between meals. Because these snacks are never as nutritious as what is served at dinner, and the snacks often taste better, the child learns that if he/she refuses lunch or dinner, they will get a better tasting snack later. Poor growth typically results. Parents unintentionally reward the child to eat poorly at mealtime (i.e., if you eat poorly at dinner time, I'll reward you by giving you ice cream and cookies later). Proper counseling advises parents to avoid all snacks. Even if the child refuses lunch or dinner, he/she must learn that there will be no food until the next meal. When this is practiced consistently and reinforced, they will eat well at meal time, which is when the most nutritious food is served.

2-5 years (toddler years): Restrict fat to less than 30% of calories (saturated fats <10%). This can be accomplished by switching to low-fat milk (2% or skim), low use of butter/margarine and removing visible fat from foods. Dietary choices expand to the adult range of foods (i.e., most table foods). Emphasize the importance of adequate protein in the diet. Vegetarians should be cautioned that the absence of all animal proteins may lead to a deficiency of vitamin B12. In addition, the quantity of protein in plant substances (e.g., soy) is small compared to that in meat, chicken, fish and eggs. Since the body is largely comprised of protein, strict vegetarians are less likely to gain height as fast as their non-vegetarian peers.

Childhood obesity is a growing and serious problem. The prevalence of type 2 diabetes among school aged children is increasing. There are no easy solutions, but dietary counseling to reduce fat and total calorie consumption at an early age when obesity is first detected is appropriate. Caloric consumption increases markedly in the pubertal period and adolescent years. Adolescent activity ranges from very active to very sedentary (TV, video games and computers have contributed to this). Sedentary individuals may actually consume more calories and are at high risk for obesity. In females, attention should be given to iron and calcium intake. Calcium intake during the time of accelerated growth and skeleton formation is an important factor in reducing the risk of osteoporosis decades later. During adolescence, it is important to recognize the potential for eating disorders such as anorexia and bulimia nervosa (see chapter on eating disorders). With the exception of eating disorders, adolescents are at higher risk of over eating rather than under eating. Dietary counseling during adolescence is likely to contribute to healthier eating habits as an adult.

Questions

1. True/False: Technological advances in formula have eliminated the immunological difference between human milk and commercial infant formula (cow's milk and soy protein).

2. True/False: Vegetarian diets are acceptable in a 1 year old child.

3. True/False: During the second year of life, there is a decrease in appetite and low weight gain as children follow normal growth curves.

4. Should fluoride be supplemented? If so, when and under what circumstances.

5. Which of the following is NOT true about breast feeding?
   a. Recommended food for infants both term and preterm
   b. 50% of energy from proteins
   c. Contains immunological benefits (i.e. IgA, active lymphocytes)
   d. Promotes growth of lactobacillus in GI
   e. Decreases incidence of allergic disorders

6. Is a 9 kg child who is consuming 8 ounces of formula 5 times a day, likely to grow? Calculate cc/kg/day, calories/kg/day. 1 ounce = 30cc. Formula contains 20 calories per ounce.

7. Calculate the total number of calories for a serving of chicken noodle soup: Serving size=4 ounces, total fat per serving=2 grams, total carbohydrate per serving 8 grams, total protein per serving 3 grams, total sodium per serving 890 mg. Calculate the total calories from carbohydrate, protein and fat separately.

8. A premature infant in the neonatal ICU weighing 850 grams is receiving total parenteral nutrition (TPN). He is getting intralipids 10% (10 grams per 100cc) at 1 cc/hr and a separate infusion at 5.5 cc/hr of crystalloid which contains D12.5% (12.5 grams of dextrose per 100cc) and 2 grams of amino acids per 100cc. How many calories from carbohydrate, protein and fat is the patient receiving per day? How many calories per kg is the patient getting per day? Is this enough to gain weight?

Answers to questions

1. False. Formula still lacks the immunological advantages of breast milk.
2. False. Vegetarian diets are NOT recommended for the first two years of life.
3. True.
4. Yes, at 6 months in children in a community with a non-fluorinated water supply.
5. b. 50% of energy from FAT.
6. No, this child will lose weight (failure to thrive). This child is consuming 40 ounces per day which is only 800 calories per day. This child needs 900 calories (100 cal/kg/day) just for maintenance alone. Growth requires a caloric intake in excess of maintenance.
7. Roughly 64 calories. Protein=4 calories/gram, carbohydrate=4 calories/gram, fat=10 calories/gram. 12 calories from protein, 32 calories from carbohydrates, 20 calories from fat, no calories from sodium total calories=64 calories (roughly).
8. This child is receiving 10% (10 gram/100cc) intralipids at 1cc/hr, or 24 cc/day, which is 2.4 grams per day, which is 24 calories from fat per day. He is getting D12.5% (12.5 gm/100c) at 5.5cc/hr, or 132 cc/day, which is 16.5 grams of dextrose per day, which is 66 calories from carbohydrates per day. He is getting 2 grams of amino acids per 100cc, which means that he gets 2.64 grams of amino acids per day, which is 10.5 calories from protein per day. He is getting a total of 100.5 calories per day, which is 118 calories per kg/day. Since his maintenance caloric requirement is 100 calories/kg/day, he is getting more than maintenance which should give him the potential to grow.

Chapter II.2. Breastfeeding

Meta T. Lee, MD, MSEd

You are seeing a 7 day old infant for a routine post-nursery follow-up visit. The 18 year old first time mother is concerned that the baby is not eating enough. The infant is a normal full term male with no significant perinatal history. The baby drinks Enfamil 1-2 oz every 2-3 hours in addition to breastfeeding. She offers the baby the breast before each feed, but he either refuses to latch on or falls asleep after 5 minutes. When offered the bottle, he drinks about 1-2 ounces at a time. The mother complains that her breasts are full and tender, and that it hurts when the baby breastfeeds.

On review of systems, the baby is voiding 6-8 times a day, and stooling 4-6 times a day. There is no emesis, diarrhea, or excessive fussiness. FH is positive for allergies. The mother denies medical problems, denies prior surgeries, and is on no medications. SH is positive for a teen mother who lives with her parents. The father is not involved.

On exam, the infant is healthy appearing and has already surpassed his birth weight of 3700 grams. The exam is normal except for some mild jaundice to the face. The mother's breasts are hard, engorged, non-erythematous, and tender. Her nipples are cracked and bleeding.

You commend this mother on choosing breast milk as the preferred source of food for her infant. You reassure her that during the first six months of life, no additional liquids, foods, or vitamins are necessary for breastfed babies. You observe the baby and mother during a breastfeeding session in your office and explain that the pain experienced during breastfeeding is due to improper latch on. Improper latch on has also caused her nipples to crack and bleed, and resulted in inadequate excretion of milk. You explain to her that in order to maintain a good milk supply, milk needs to be removed from the breasts at least 8 to 12 times in every 24-hour period. You or your nurse teach her proper positioning and technique for proper latch on and refer her to the hospital lactation consultant for a next day appointment. You see her back in your office in 2-3 days and she reports that the baby is nursing much better and that her nipples and breasts are no longer painful.

Human milk is recommended as the optimal form of nutrition for infants (1). Breast milk contains the essential nutrition, immunomodulators, and anti-microbial agents for optimal growth and development. The AAP recommends exclusive breastfeeding to all infants in the first four to six months of life, and continued breastfeeding to at least the first year of life. However, national surveys report that 60% of women breastfeed postpartum, 30% exclusively breastfeed to six months of age, and an estimated 5% are still breastfeeding at 1 year of age (2). Although breastfeeding is the optimal nutritional source for growing infants, breastfeeding practices in this country are sub-optimal. Physicians can be influential in promoting and educating mothers about breastfeeding. This chapter presents a broad overview of basic concepts essential to understanding and promoting successful breastfeeding.

The breasts are paired mammary glands in which milk can be produced based on hormonal, psychological, and environmental influences. The smallest functioning unit of mature glandular tissue is the alveolus. Alveoli are composed of secretory acinar units, which are surrounded by myoepithelial cells. Myoepithelial cells form the contractile unit responsible for ejecting milk into ductal system. The ductal system is a branched pathway in which small ductules merge into larger ducts, which widen and drain into lactiferous sinuses. These collecting sinuses are located behind the nipple and the areola of the breast. Milk is transferred out of the lactiferous sinuses through multiple small openings on the nipple surface.

Lactogenesis begins during pregnancy. During pregnancy, breast size increases, as epithelial cells of the alveoli differentiate into secretory cells for milk production. Progesterone is responsible for the proliferation of glandular tissue and ductile development in breast tissue. Estrogen, placental lactogen, human chorionic gonadotropin, and human chorionic somatomammotropin also contribute to mammary gland growth during pregnancy. Prolactin is the primary hormone responsible for stimulating alveolar cells to produce milk. During pregnancy, high levels of progesterone inhibit prolactin from milk synthesis.

Hormonal changes occurring immediately after birth initiate the process of copious milk production. Following the delivery of the placenta, systemic levels of progesterone and estrogen drop steadily, while prolactin levels remain high. In addition, oxytocin, a hormone produced in the posterior pituitary, enables the milk-ejection or milk let-down reflex to occur. Tactile stimulus from the nursing infant releases oxytocin, which acts upon mammary myoepithelial cells to contract and force milk from the alveoli into the ducts toward the lactiferous sinuses where it becomes readily available for consumption.

The maintenance of milk production in lactation is dependent on systemic hormone regulation as well as autocrine regulation of the mammary gland. A peptide inhibitor in the mammary gland slows milk production unless it is removed by frequent nursing. Hence, lack of adequate milk removal results in stasis, and limited breast milk synthesis. Conversely, when frequent feeding occurs, the inhibitor is removed and milk production is increased. Hence, removal of milk from the breast facilitates continued milk production. This "supply-demand phenomenon" results in a feedback control mechanism that regulates the production of milk to match the intake of the infant. Human milk contains protein, non-protein nitrogen compounds, lipids, oligosaccharides, vitamins, minerals, hormones, enzymes, growth factors and other protective agents. The composition of human milk is considered the "gold standard" to which all formulas attempt to recreate.

The major carbohydrate constituent of human milk is lactose. Small quantities of oligosaccharides, galactose and fructose are also present. Lactose concentration in human milk is relatively constant at 7gm/dl. This value varies with maternal diet. Lactose enhances calcium absorption and metabolizes readily to galactose and glucose, which supply energy to rapidly growing organs such as the brain.

Casein and whey are the major protein constituents. Human milk is composed of approximately 30% casein protein and 70% whey protein. Whey protein consists of five major components: alpha-lactalbumin, serum albumin, lactoferrin, immunoglobulins, and lysozyme. The latter three elements contribute to immunological defense. Oligosaccharides, nucleotides, growth factors, and cellular components of human milk also enhance the infant's immune system. Immunoglobulin A is also excreted into breast milk, which provides specific passive immunity against foreign antigens to which the mother is exposed.

The fat content in human milk is variable, and fluctuates with gestational age, maternal diet, and lactation patterns. Fat accounts for about one-half of the caloric value of human milk. Triglycerides are the main fat constituent, and are broken down into free fatty acids and glycerol by the enzyme lipase. The lipid portion of human milk contains essential fatty acids, which are important for brain growth and development.

The vitamin and mineral contents in human milk vary with maternal diet and genetic influences. Fat soluble vitamins A, E, D and K are present in human milk. Human milk is a good source of Vitamin A, which is required for vision and the maintenance of epithelial structures. Colostrum is rich in Vitamin E, an antioxidant that protects cell membranes in the retina and lungs against oxidant-induced

injury. Vitamin D is present in low quantities in breast milk. Daily supplementation with Vitamin D is recommended to exclusively breastfed infants at risk for rickets. Infants at risk include children who are not adequately exposed to the sun and whose mothers who do not consume adequate nutrients. Vitamin K, required for the synthesis of blood clotting factors, is present in small amounts. Vitamin K supplementation in a single intramuscular injection at birth is recommended for all newborn infants even though it is normally produced in sufficient quantities by intestinal flora within a few days of birth.

Water soluble vitamins in human milk are very dependent upon maternal diet. Ascorbic acid, nicotinic acid, thiamine, B12, riboflavin, and pyridoxine (B6) levels increase with maternal ingestion of food containing these nutrients. Vitamin B12 is essential for early central nervous system development. Vitamin B12 supplementation should be considered for exclusive breastfed infants of strict vegetarian mothers.

The mineral content in breast milk is relatively constant. Sodium, iron, zinc, calcium, and other trace elements are present in human milk. Iron and calcium are present in small quantities in human milk, yet infants are able to absorb a greater proportion of these minerals than in cow's milk.

Advantages of breastfeeding

Human milk, through breastfeeding, provides nutritional, immunological, and developmental, benefits to infants. Studies have shown that human milk feeding decreases the incidence and severity of diarrhea, lower respiratory infections, otitis media, bacteremia, bacterial meningitis, botulism, urinary tract infections, and necrotizing enterocolitis (1). Limited studies also suggest a protective effect of human milk feeding against sudden infant death syndrome, insulin-dependent diabetes mellitus, Crohn's disease, ulcerative colitis, lymphoma, allergic diseases, and other chronic digestive diseases (1). There is also limited data that supports the potential for improved developmental outcome in certain breastfed infants at risk for developmental delay (3).

Mothers also benefit from breastfeeding. Increased levels of oxytocin result in more rapid uterine involution and less postpartum bleeding. Some recent studies also support that lactating women have an earlier return to pre-pregnancy weight, delayed resumption of ovulation with increased child spacing, improved bone remineralization postpartum, reduction of hip fractures in the postmenopausal period, reduced risk of ovarian cancer, and reduced risk of premenopausal breast cancer (1).

Breastfeeding also results in social, economical, and psychological benefits. Breast milk requires no preparation, hence increases time available to spend with the newborn. Lower incidences of infections in breastfed infants result in fewer days of work missed by parents. Families who breastfeed are relieved from a substantial financial burden incurred from the purchase of infant formulas throughout the first year of life. Last but not least, increased maternal-infant bonding is one of the major advantages of breastfeeding.

Clinical Approach

Preparation for breastfeeding should begin during pregnancy. An ideal time to discuss breastfeeding with the family is at the prenatal visit. A complete breastfeeding history includes a thorough discussion of the parents' intended method of feeding and the mother's previous breastfeeding history. A review of systems should include the incidence of previous postpartum hemorrhage and anomalies of the breast or nipple. Past medical history should include history of chronic medical illnesses, including seizure disorders, thyroid disorders, psychiatric disorders, or any other disorders requiring medications that may be contraindicated in breastfeeding. Past surgical history should include previous breast surgery, cardiac surgery, chest wall surgery, or breast trauma. A thorough medication history should be obtained. Family history should include incidence of breast cancer. Social history should include an assessment of the social support structure, as well as past or current history of illicit drug use and tobacco. Finally, questions the mother may have regarding breast changes during pregnancy or breastfeeding should be answered.

Breastfeeding is recommended as soon as possible after birth, preferably within the first hour of life. Immediate and sustained contact between mother and infant strongly correlates with longer durations of breastfeeding (4). During the first 48 hours of life, it is strongly recommended that a pediatrician, nurse, or lactation consultant observe and assist with at least one feeding in the hospital to document good breastfeeding technique prior to discharge. A follow-up visit is strongly recommended 48 to 72 hours after nursery discharge to ensure sustained adequate breastfeeding.

Anticipatory guidance should be directed at maintaining good breastfeeding technique, understanding signs of adequate intake, and forewarning new parents of the demanding and relentless feeding patterns of newborn infants.

Good breastfeeding technique requires proper positioning of the infant's body with proper "latch on", or attachment at the breast. An infant is in optimal positioning when the head and face are squarely in front of the breast, with the body in proper alignment with the head. Several positions of body alignment have been well described. In the "Madonna" position the infant lies across the mother's chest, with the infant's abdomen squarely facing the mother's chest. In the "football" position, the infant is "clutched" across the mother's side with the feet and body encompassing the side of the mother's body. In either position, the infant's head and body must be in proper alignment such that the infant is lying comfortably, with the mother's hand or arm firmly supporting the head.

An infant demonstrates good latch on when after properly positioned against the mother's body and triggered with an active rooting reflex, there is a wide opening of the jaw with relaxed lips that encompass contact beyond the nipple into the areolar space. Ensuring good latch on can prevent most common breastfeeding problems, such as sore nipples, engorgement, low milk supply, hyperbilirubinemia, and an unsatisfied baby.

Signs of good breastfeeding include the following: audible rhythmic swallowing during nursing, breasts feeling less full after each feeding session, at least 1-2 wet diapers per day for the first 2 days of life, 4-6 wet diapers every 24 hours after the 3rd day of life, and at least 3-4 bowel movements every 24 hours. Lack of persistent pain during breastfeeding sessions and absence of sore nipples are also signs of appropriate breastfeeding.

Anticipatory guidance on expected frequent feedings and nighttime awakenings can be helpful to new parents. Breastfed infants will often awake every few hours from hunger, and need to be fed at night to maintain growth. In addition, breastfeeding needs to occur at night in order to maintain adequate milk production. Hence, mothers should be prepared to expect to breastfeed newborns at least 8 to 12 times in a 24-hour period. Parents should also understand that newborns feed better when following their own sleep/wake cycles rather than when awakened around the clock. However, parents must understand that newborns in the first few weeks of life should be awakened if more than 4 hours pass between feedings.

Contraindications and Precautions

There are special conditions in which breastfeeding should not be recommended. Infants with galactosemia lack the essential enzymatic function to adequately digest the lactose component of human milk. Mothers with untreated active tuberculosis, human

immunodeficiency virus, human T-lymphocytic virus, or active herpes simplex virus on the breast can impose infectious health risks to breastfeeding infants. Breastfeeding should not be recommended in these instances.

Drugs given to mothers by various routes can also potentially affect a breastfed infant. The amount of drug that passes from the maternal bloodstream into human milk is variable and dependent on molecular size, pH of milk, pKa of the drug, fat solubility, and transport mechanisms. The amount of drug that reaches the infant's bloodstream is usually a very small percentage of the mother's dosage. Absolute drug related contraindications to breastfeeding include radioactive isotypes, antimetabolites, and cancer chemotherapy agents. There are a small number of other drugs, which have been shown to have potentially harmful effects on breastfeeding infants. All maternal drugs should be evaluated for breastfeeding safety through reference textbooks or local resources.

Previous breast or chest wall surgery is not a contraindication to breastfeeding (4). However, women who have had previous breast or chest wall surgery or trauma may have impaired lactation performance due to significant cutting of ducts or nerves important in the lactation process. Breastfeeding care should be individualized, and infants should be followed frequently for appropriate weight gain.

The American Academy of Pediatrics recommends that pediatricians promote and support breastfeeding enthusiastically. At the individual level, pediatricians are encouraged to take a strong position in favor of breastfeeding, as well as become knowledgeable and skilled in the physiology and clinical management of breastfeeding. At the local level, pediatricians are encouraged to work collaboratively with the obstetric and nursing community, promote hospital policies and procedures to facilitate breastfeeding, and become familiar with local breastfeeding resources. At the community and national level, pediatricians can also work to reform insurance coverage of necessary breastfeeding services and supplies, promote breastfeeding education as a routine component of medical school and residency education, and encourage the media to portray breastfeeding as positive and the norm.

Questions

1. What is the prevalence of breastfeeding in the United States?
2. What are the Healthy People 2010 goals for breastfeeding?
3. What is the American Academy of Pediatrics' position on breastfeeding?
4. What are the advantages and disadvantages of breastfeeding?
5. What anatomic and physiologic changes occur in the process of lactogenesis?
6. What is the difference between human milk and infant formula?
7. What are the barriers that prevent women from successfully breastfeeding?
8. What are some clinical indications that suggest inadequate or sub optimal breastfeeding?
9. What can health care providers do to improve breastfeeding practices for their patients?

Answers to questions

1. Approximately 60% of women breastfeed immediately post-partum, 20% are still breastfeeding at 6 months, and less than 5% are still breastfeeding at 1 year.
2. The Healthy People initiative set a target to increase the proportion of mothers who exclusively breastfeed to 75% at post-partum, 50% at 6 months, and 25% at 1 year.
3. The AAP recommends exclusive breastfeeding for the first 4-6 months of life, with continued breastfeeding to at least 12 months of age, and thereafter for as long as mutually desired.
4. Advantages of breastfeeding include health, nutritional, immunologic, developmental, psychological, social, economic, and environmental benefits. The major disadvantages to breastfeeding include time and energy required of the mother, decreased paternal (father) participation, and lack of universal social acceptance of breastfeeding practices by the public.
5. Anatomic and physiologic changes that occur in the breast include: a) differentiation of epithelial alveolar cells into secretory cells for milk production. b) proliferation of glandular tissue and ductile development by progesterone. c) copious milk production following placental expulsion due to prolactin unopposed by progesterone. d) milk ejection or milk let-down reflex by oxytocin.
6. Carbohydrate, protein, and fat composition differ. Human milk contains lactose as the main carbohydrate source, high whey to casein protein ratio, and variable fat stores which are dependent on maternal diet. Formulas have variable carbohydrate source which include lactose, starch or other complex carbohydrates. Protein sources can also vary by formula type: casein, whey, soy or protein hydrolysate. Fat sources in infant formula can vary as well: triglycerides with long or medium chains, etc. Breastmilk has more absorbable iron, calcium and zinc than formula.
7. Barriers to successful breastfeeding include: physician misinformation and apathy, insufficient prenatal breastfeeding education, inappropriate interruption of breastfeeding, early hospital discharge, and late hospital follow-up care.
8. Indicators for inadequate breastfeeding include: less than 6 urinations per day and 3-4 stools per day by day 5-7 of life, decreased activity level, difficulty arousing, weight loss of greater than 15% of birth weight within the first week of life.
9. Provide good breastfeeding education at the prenatal visit, be well educated on anatomy and physiology of breastfeeding, advocate for breastfeeding policies.

Chapter II.3. Infant Formulas
Nadine Tenn Salle, MD

A 24 year old first time mother brings her two week old son to your office for a well child examination. She is a single mother with strong family support. She will be returning to work in one week and has elected not to breastfeed. Today she is seeking your advice concerning her infant's nutrition.

In a 1986 policy statement, the American Academy of Pediatrics (AAP) reaffirmed its position on four issues pertinent to infant nutrition (1):

1. The AAP will continue to promote breastfeeding as the first form of infant nutrition.
2. The AAP will continue to work to maintain and improve the high quality of infant formulas in the United States because in some cases, breastfeeding is not practical or desired.
3. The AAP will continue to recommend against direct to consumer advertising of infant formula.
4. The AAP will continue to encourage the special supplement nutrition program for women, infants and children (WIC) and hospital nurseries, and programs to make available a diversity of formulas.

The AAP adheres to the belief that pediatricians have a responsibility for infant nutrition, have an obligation to be knowledgeable about the nutritional needs of both healthy normally developing infants as well as infants with unique nutritional needs such as those with metabolic, gastrointestinal, infectious and oncologic disease conditions (1).

Breast milk is considered to be the optimal nutrient for the term or near term infant as an exclusive source of nutrition during the first six months of life. Breast milk combined with the introduction of solids is recommended for the second six months of an infant's life (2).

There are indications for the use of infant formula:

1. As a supplement or substitute for breast milk when a mother cannot or chooses not to breast-feed.
2. Infants whose mothers are infected with organisms known to be transmittable by human milk (e.g., HIV)
3. Infants whose mothers are undergoing chemotherapy.
4. Infants whose mothers are receiving medication or drugs that are excreted into human milk.
5. Infants who are unable to tolerate human milk because of metabolic disorders (e.g., galactosemia).

In the event breast feeding is neither practical nor desired, there are a number of commercially available infant formulas that have been formulated to simulate human breast milk and provide an infant's nutritional requirements. On average, a neonate will drink about 165 cc of formula/kg/day (2.5 ounces/pound/day) and about 30-90 cc (1-3 ounces) per feeding. The caloric content of most infant formulas closely approximates that of human milk at 2/3 kcal/cc (20 kcal/oz). Infants are often their own best regulators, thus variation with each feeding should be expected. During the first 6 months of life, infants require 95-115 kcal/kg/day; 8-12% of these calories should be derived from protein, 30-50% from fat and 40-60% from carbohydrates. If these nutritional requirements are met, an infant will typically gain 25-40 grams per day (30 grams = 1 ounce) in the first 3 months and 15-20 grams in the second 3 months. Infant formulas are designed to mimic the nutritional composition of human milk, but in reality they contain a number of differences in the protein, fat and carbohydrate content.

Human milk contains approximately 1.1 g/dL of protein as compared to 1.5g/dL in most standard formulas. This represents 6-8% of an infant's total caloric intake. Milk protein can be divided into two classes based on relative solubility in acid: whey (acid soluble) and casein (acid insoluble). The whey:casein ratio of human milk is 70:30 as compared to a ratio of 18:82 for cow milk. The clinical significance of the difference in whey:casein ratio between human and bovine milk is illustrated when unmodified casein-predominant cow milk enters the acidic environment of the human stomach and forms a relatively hard curd of casein and minerals. This curd can be difficult for an infant to digest. Thus, the AAP recommends that cow's milk not be used until after the first birthday. Special toddler's milk is now being marketed as a transitional formula to whole cow's milk; however there are no proven special benefits compared to a toddler eating a balanced diet that includes milk and juice.

Lipid constitutes approximately 50% of the calories in human milk (5.7g/100 kcal) and standard infant formula (4.4-6.0g/100 kcal). The predominant portion of lipid in human and cow milk is triacyl glycerol. Triacyl glycerol is composed of a glycerol backbone with 3-hydroxyl group esterified to fatty acids.

Essential fatty acids lineoleic and alpha lineolinic acid play a crucial role in neurodevelopment. Approximately 5-7% of total calories in human milk and 1% of total calories in cow milk is lineoleic acid. The amount of lineoleic acid considered adequate is controversial but it in generally agreed it should not be more than 20%. For this reason all cow milk based formulas add vegetables oil (containing relatively large amounts of lineoleic and lineolinic) to their preparations. Most commercial infant formulas contain at least 10% of total fatty acids as lineoleic acid.

The primary carbohydrate source found in both human milk and formulas is lactose (except in lactose free formula). Lactose is a disaccharide that is converted to simple sugars, galactose and glucose by a lactase enzyme. Disaccharides require conversion to simple sugars to enable absorption through the gut via a monosaccharide transport system. The carbohydrate source in soy based formula is glucose polymers (also referred to as corn syrup solids) and/or sucrose. Sucrose is converted to simple sugars, fructose and galactose for absorption (3).

The iron content of human milk is much less than that of iron fortified cow milk based formula, but the bioavailability of human milk iron is much higher. Guidelines from the committee on nutrition of the AAP recommends 2-3 mg/kg/day of elemental iron. In a term infant, iron deficiency is uncommon before 4-6 months of age because of the abundance of iron stores at birth. Iron deficiency is most common among children 6 months to 3 years of age. To compensate for the depletion of iron stores by growth, dietary iron must be provided. Exclusively breastfed infants may require diet supplementation with iron (1 mg/kg/day) and vitamin D (400 IU/day) at 4-6 months of age. Standard formulas (about 32 ounces per day) will meet 100% of RDA for vitamins and minerals for term infants. Low iron formulas defined by the FDA as containing less than 6.7 mg/L of iron, once contained less than 1.5mg/L of iron, resulting in an unacceptably high rate of iron deficiency and anemia. Over the past five years, formula manufacturers have increased the amount of iron in low iron formulas to 4-5mg/L. A public perception that iron causes constipation and other feeding problems has allowed for the

continued market of low iron containing formulas. There is no data to support this belief and the AAP recommends iron-fortified formulas.

Symptoms of cow milk protein allergy typically begin between week 4 to 6, but the sensitivity may occur as early as 48 hours or may present in adulthood. The presence of gastrointestinal symptoms such as bloody stools, diarrhea and vomiting can indicate pathophysiological intolerance related to a specific component of cow milk formula. Symptoms such as flatus, fussiness and colic are less likely and difficult to directly relate to components of cow milk. True cow milk protein allergenicity as documented by a double-blinded study is present in less than 6% of the population (5,6). Some surveys show as high 30% of formula fed infants are switched to hypoallergenic formulas because of a perceived or suspected protein allergy (7). Hypoallergenic formulas are created by extensively hydrolyzing the cow milk protein (usually casein), thereby reducing its molecular weight to less than 1250 kDa. Proteins less than 1250 kDa are far less likely to produce a IgE-mediated allergic response (6). Hypoallergenic hydrolyzed casein formulas are effective in preventing protein allergy. It is however prudent to truly diagnose cow milk allergic infant before starting these formulas whose most significant disadvantage is a greater cost when compared to regular formula. Breastfeeding is even more strongly advocated in infants with milk hypersensitivity.

Primary lactose intolerance such as lactase deficiency and galactosemia, occurs approximately in 1:1000 infants. Secondary lactose intolerance by contrast is far more common and often presents with protracted diarrhea. The lactase enzyme is located at the villous tip of the intestine and appears to be more vulnerable than sucrase that is found deeper in the crypt. An infectious diarrhea may cause denuding and the lactase enzyme may take up to a week to fully recover. A low lactose or lactose free formula may reduce carbohydrate malabsorption (and subsequent exacerbation of diarrhea by an osmotic mechanism) during the illness. The lactose free cow-milk based formulas are designed to treat primarily secondary lactase deficiency. The contrast to lactose containing formulas is the substitution of its carbohydrate source. Instead of lactose, a corn syrup solid and/or sucrose is used.

Soy formulas support the growth of normal term infants through the first year of life. Soy formulas may be used in lieu of cow milk formula and in formula fed infants whose parents want their children to adhere to a vegetarian diet. Phytate in soy formula in addition to the absence of lactose diminish the absorption of divalent cations such as iron, calcium and zinc in the intestinal lumen. Supplementation of soy formula with iron, calcium and zinc has largely overcome these issues (8,9). Phytogens in soy formulas have the potential for hormonal action at critical points in development. The AAP has noted that limited human data does not support these concerns (10).

Summary of formulas:

Cow's milk based formulas:

Indications: Term or near term infant.
Protein: whey-predominant; carnitine and taurine usually added.
Carbohydrate: lactose.
Fat: vegetable oils.
Brands: Enfamil with iron, Similac with iron, Good Start (100% whey protein, thus may be used for constipation), Lacto-free (uses corn syrup and/or sucrose), Similac PM 60/40 (60:40 ratio of whey to casein, less Ca, P, K for cardiac and renal patients).

Soymilk based formulas:

Indications: Lactose deficiency or galactosemia, strict vegetarians, IgE mediated reaction to cow milk protein.
Protein: 2.2g/dl of protein from a plant source, cysteine and taurine as well as an additional methionine added.
Carbohydrate: corn syrup (glucose polymer), sucrose.
Fat: vegetable oils.
Brands: Isomil, ProSobee.

Casein Hydrosylate formulas:

Indications: Milk or soy protein intolerance, colic.
Protein: casein hydrolysate (hypoallergenic).
Carbohydrate: glucose oligosaccharides modified cornstarch.
Fat: MCT, corn oil.
Brands: Pregestimil, Nutramigen, Alimentum (increased MCT fat concentration; for cystic fibrosis patients).

Questions

1. The American Academy of Pediatrics recommends what form of nutrition for infants?
2. What is an appropriate quantity of formula for an infant?
3. When is iron supplementation required for an infant?
4. When comparing breast milk vs. cow's milk based formulas, which has a higher: a) kcal/cc? b) Concentration of casein protein? c) Carbohydrate content? d) Fat content?
5. What is the clinical significance of the whey:casein ratio in cow milk?
6. What is the main form of carbohydrate in breast milk? Cow's milk based formula? Soy based formula?

Answers to questions

1. Breastfeeding is regarded first and foremost except when it is not practical, desired or medically contraindicated.

2. From a practical standpoint, whether it is breast milk or infant formula, a healthy term infant is the best regulator of the frequency and quantity of their nutritional intake. However, since we are scientists at heart; during the first 6 months of life approximately 95-115 kcal/kg/day is recommended.

3. In a term infant, iron deficiency is uncommon before 4-6 months of age because of the abundance of iron stores at birth. To compensate for the depletion of iron stores by growth, dietary iron must be provided to exclusively breastfed infants. Iron fortified formulas can prevent iron deficiency in formula fed infants. Guidelines from the Committee on Nutrition of the AAP recommend 2-3 mg/kg/day of elemental iron.

4a. They are about the same. Human milk contains approximately 2/3 kcal/cc (20 kcal/oz). The standard infant formula usually remains close to this range.

4b. Whey:Casein of human milk is 70:30 as compared to a ratio of 18: 82 for cow milk. Please refer to the text to review the clinical significance of this profile difference.

4c. The carbohydrate content is about the same.

4d. Lipids constitute approximately 50% of the calories in human milk (5.7 g/100kcal) and standard infant formula (4.4-6.0 g/100kcal).

5. The clinical significance of the difference in whey:casein ratio between human and bovine milk is illustrated when unmodified casein-predominant cow milk enters the acidic environment of the human stomach and forms a relatively hard curd of casein and minerals. This curd can be difficult for an infant to digest. Thus, the AAP recommends that cow's milk not be used until after the first birthday.

6. Lactose is the main carbohydrate in mammalian milk. The lactose concentration of human milk is 7g/dL, cow milk contains 5 g/dL. Lactose is added to most standard infant formula to achieve the concentration of human milk. Soy formulas do not contain lactose; they contain sucrose, glucose polymers, or a mixture of the two.

Chapter II.4. Fluids and Electrolytes
Loren G. Yamamoto, MD, MPH, MBA

Case 1: A 4 year old male presents to the emergency department with a history of vomiting and diarrhea. He has had 10 episodes of vomiting (clear then yellow tinged) and 8 episodes of diarrhea with some mucusy material in the first few episodes. The diarrhea is now watery and the last few episodes have been red in color. The diarrhea odor is very foul. He has had a fever with a maximum temperature measured at 101 degrees at home. His parents gave him a sports drink (red color), and then they tried clear Pedialyte. Despite this, he continues to have vomiting and diarrhea. He feels weak and tired and he looks slightly pale at times. He has only urinated twice in the last 15 hours.

Exam: VS T 38.2 degrees (oral), P 110, R45, BP 90/65, oxygen saturation 100% in room air. Weight 18 kg. He is alert and cooperative, but not very active. He is not toxic or irritable. His eyes are not sunken. TMs are normal. His oral mucosa is moist but he just vomited. His neck is supple. Hear and lung exams are normal except for tachycardia. His abdomen is soft and non-tender. Bowel sounds are normoactive. He has no inguinal hernias and his testes are normal. His overall color is slightly pale, his capillary refill time is 2 seconds over his chest, and his skin turgor feels somewhat diminished.

He is clinically assessed to be 5% dehydrated by clinical criteria. Oral versus IV rehydration is discussed with his parents who indicate that they have tried oral hydration and are not happy with the results. They now have emesis on their furniture and carpet and he has splattered some diarrhea over the bathroom floor, so they would like the IV for him. An IV is started and a chemistry panel is drawn at the same time. A rectal swab for culture is also obtained. Normal saline is infused at 360 cc/hour for two hours (total of 720 cc). The resident on the case questions the high IV rate. It is pointed out that 360 cc is only 20 cc/kg which replaces only 2% of the body's weight (i.e., it corrects 2% dehydration), it doesn't include maintenance fluids, and 360 cc is the same volume as a soft drink can. He is also given ondansetron (Zofran) for nausea relief. His chemistry panel shows Na 135, K3.4, Cl 99, bicarb 15. During the first hour of the IV fluid infusion, he says that he feels much better. He more awake and his color improves. During the second hour of IV fluid infusion, he falls asleep. At the end of the two hours, he is awakened and since he feels better, he is discharged from the ER with instructions to rest and continue oral hydration efforts.

Three days later, his rectal swab is growing Salmonella. His parents are called. They indicate that he still has some diarrhea, but only about two episodes per day and his vomiting has stopped. He is on a regular diet and continues to improve. Because he has improved, no antibiotic treatment is started. However, vigorous hand washing and hygiene regarding dishes/utensils for all family members is recommended.

Case 2: An 18 month old female is directly admitted to the hospital from her primary care physician's office. She has had 15 episodes of diarrhea and 5 episodes of vomiting. She has a fever with a maximum temperature of 102.4 degree measured on a tympanic thermometer. She is weak, pale and her eyes are sunken. Her weight in the office is 11.0 kg which is decreased from her weight in the office of 11.6 kg just three days ago during a well child check. Urine output is difficult to assess because of the diarrhea.

Exam: VS T 37.8, P 110, RR 40, BP 100/60, oxygen saturation 100% in room air. Weight 11.0 kg. She is alert, but subdued and quite. She is not toxic and not irritable. Her eyes might be slightly sunken. Her oral mucosa is sticky (tacky). Her neck is supple. Heart regular, no murmurs. Lungs are clear. Abdomen is scaphoid, soft and non-tender with hyperactive bowel sounds. No inguinal hernias are present. Her skin turgor is diminished, but no tenting is present. Capillary refill time is 3 seconds over her thighs. Her extremities are cool in her feet, but warm elsewhere.

An IV is started and a chemistry panel is drawn. A stool rotavirus rapid assay is done which is positive. She is given 220 cc of normal saline IV over one hour and she feels much better. The appearance of her eyes have normalized and she is more active. Her chemistry panel shows Na 134, K 3.4, Cl 97, bicarb 12. The resident then writes the following IV orders: IV D5-1/3NS+20 mEq KCl per liter run at 88 cc/hour for 8 hours, then 66 cc/hour for 16 hours. She is also permitted to eat and drink small amounts, so a low fat diet without fruit juice is ordered for her. The medical student following the case asks how these IV orders are determined.

Since children are small, critical attention must be paid to fluid and electrolyte balance. An fluid administration could result in clinically significant overhydration, underhydration, or electrolyte imbalance. Normal humans will consume fluids and nutrients in response to their body's needs and regulation occurs automatically without any thought to this process. However, in pathologic conditions such as gastroenteritis, burns, neurologic dysfunction, etc., fluid losses may be excessive and the body's ability to respond to these deficits may not be intact. The purpose of this chapter is to familiarize the reader with normal fluid and electrolyte requirements. Much of this chapter consists of numbers, some of which should be memorized for personnel who provide medical care to children frequently. These will be called everyday basic numbers and are summarized in a table at the end of this chapter. Other numbers can be looked up in references when the need arises.

Body composition is 60% to 75% water. The 60% applies to adults and the 75% applies to newborns. Younger children have more water than adults. These numbers are estimates because body fat variations will modify these percentages as well (obese individuals have lower body water percentages). Out of this, about 60% is intracellular and 40% is extracellular. Of the extracellular fluid, 3/4 is interstitial and 1/4 is circulating as plasma (1). There is also a small percentage known as transcellular water (about 2%) which consists of synovial fluid, pericardial fluid, pleural fluid, bowel secretions, cerebral spinal fluid, etc. (1). This can be summarized below as:

Total body water: 60%-75% of body weight
- Intracellular: 30%-40% of body weight
- Extracellular: 20%-25% of body weight
  - Interstitial: 15% of body weight
  - Plasma: 5% of body weight

However, total blood volume is actually 8% to 9% of body weight for children and 7% of body weight for adults (2). This is because the red blood cell elements of blood are not considered to be "body water". Thus, if plasma consists of 5% of the body weight, a few more percentage points would account for the circulating blood volume (which is larger than the circulating plasma volume).

Fluid losses occur routinely through urine, stools, respiratory vapor and insensible skin losses. Perspiration can exaggerate skin losses. Illness and exercise can exaggerate respiratory fluid loss through vapor. Other conditions such as burns, vomiting, diarrhea, hemorrhage, diuretics, etc., can also exaggerate fluid losses.

Maintenance fluid volume for 24 hours can be calculated as follows: 100 cc/kg for the first 10 kg of body weight, 50 cc/kg for the next 10 kg of body, then 20 cc/kg thereafter. Thus, the maintenance fluid volume 40 kg patient would be calculated as: 10kg X 100 cc/kg + 10kg X 50 cc/kg + 20kg X 20 cc/kg = 1000cc + 500cc + 400cc = 1900cc per day. A shortcut for patients over 20 kg is to take 1500 cc and then add 20 cc/kg for additional weight above 20 kg. Maintenance electrolytes are calculated using maintenance fluid volumes as 3 mEq Na (sodium) and 2 mEq K (potassium) per 100cc of maintenance fluid. Thus, the 40 kg patient above would require 57 mEq Na (3 X 19) and 38 mEq K (2 X 19) per day.

This is translated into an IV rate in cc/hour by dividing the total volume of fluids by 24 hours. To deliver 1900 cc of fluid over 24 hours, the IV rate would have to be 80 cc/hr (roughly 1900 divided by 24).

The type of IV fluid is dependent on the electrolyte requirements. IV fluid basically comes as percentage of normal saline. Normal saline contains 0.9 grams of NaCl per 100 cc of fluid (0.9%). This is roughly 150 mEq of Na per liter. I remember this because I know that the body's normal osmolarity is 290 (or about 300). If "normal" saline has a "normal" osmolarity, then it's osmolarity must be about 290 mosm/liter. Therefore, half of its osmolar particles must be Na (sodium) and the other half must be Cl (chloride) to give a total osmolarity of about 300. Therefore, the concentration of Na (sodium) in normal saline (NS) is about 150 mEq/liter and the concentration of chloride in NS is about 15 mEq/liter. Half normal saline contains 75 mEq/liter. 1/3NS contains 50 mEq/liter and 1/4NS contains about 38 mEq/liter. It turns out that this is not exact. I could provide you with a table with the exact numbers, but no one can remember these. Fortunately, when selecting IV fluids, we just need to know approximate numbers. Therefore, following the rule of using "normal saline" permits one to know the approximate sodium concentrations of all IV fluids. Lactated Ringer's solution (LR) is similar to NS, but it also contains some potassium, lactate and calcium. Since LR also has a "normal" osmolarity, it will have less Na than NS in order to maintain its normal osmolarity. LR resembles the blood more physiologically. LR's electrolyte concentrations are Na 130 mEq/liter, K 4 mEq/liter, Cl 110 mEq/liter, lactate (similar to bicarbonate) 28 mEq/liter.

Since maintenance electrolytes are based 3 mEq Na and 2 mEq K per 100 cc of maintenance IV fluid, this will require a solution with 30 mEq Na per liter. The closest to this is 1/4 NS with about 38 mEq/liter. Potassium is always added as a separate electrolyte to the bag (with the exception of LR which already contains small amounts of potassium). The IV order that would be written for maintenance fluids on a 40 kg patient would be: IV D5-1/4NS + 20 mEq KCl per liter run at 80 cc/hr.

What exactly does maintenance mean? If the IV order above was accidentally written for 40cc/hr, would the patient become dehydrated? Alternatively, if the IV order was accidentally written for 200 cc/hr, would the patient develop pulmonary edema? If the IV order was instead written for D5NS (instead of D5-1/4NS), would the patient become hypernatremic? The answer to all of these questions is no (most of the time). By calculating the maintenance fluid volume for a 75 kg average adult, the maintenance volume would be 1500 cc + 55 kg X 20 cc/kg = 3000 cc. 30 cc is roughly one ounce. That's roughly 100 ounces, i.e., about 3 quarts or 8 soft drink cans per day. As an average busy adult, I normally do not drink this much, yet I do not become dehydrated. Also on some days, I consume a lot of salt (potato chips, etc.) and on some days I don't consume much salt. Yet my serum Na level stays in the normal range. If I drink an excess of fluid, my kidneys urinate more free water and if I don't drink much, my kidneys retain water and I don't put out much urine. Normal kidneys are able to compensate for wide ranges of fluid and electrolyte intake. Excess fluid and electrolyte intake is urinated out as excess, while inadequate intake results in renal retention of fluid and/or electrolytes to maintain normal fluid volumes and electrolyte balance. The

kidney has to do some work to remove excess substances or to retain substances which are in short supply. Renal consumption of ATP can be used as a marker of the amount of work performed by the kidney. Renal ATP consumption is high when excess fluid is consumed because it must work to excrete free water. Renal ATP consumption is high when insufficient fluid is consumed because it must work to retain water. In contrast, renal ATP consumption is low between these extremes because the kidneys do not have to work as hard. ATP consumption is lowest when the maintenance volume is consumed. Thus, maintenance volumes and electrolytes are beneficial because this results in minimizing the stress and workload on the kidneys. This is not very important in healthy individuals going about their everyday lives, but it becomes more important in very ill patients whose bodily functions are under great stress. Maintenance calculations using the formula provided are only valid under the assumption of the "average hospital patient". Some well people (e.g., while playing in a soccer game) will require more fluids than the maintenance calculation to minimize renal ATP consumption, while some well people (e.g., while reading a book) will require less fluids than the maintenance calculation to minimize renal ATP consumption. Special patients (e.g., severe burns) will require larger volumes of fluids to maintain fluid balance. Thus, the "maintenance" calculations provide a basic guide to determine the fluid and electrolyte intake that minimizes work stress on the kidneys of average hospital patients.

Although oral electrolyte solutions are commonly utilized for rehydration, they are actually maintenance electrolyte solutions. The most commonly recommended oral electrolyte solution known as Pedialyte contains 45 mEq Na per liter and 20 mEq K per liter. Sports drinks such as Gatorade have less sodium than this.

When a fluid deficit state is encountered, assessment of the severity is usually categorized as percent dehydration, which is really the volume of fluid loss as a percentage of body weight. Mild dehydration is 5% or less, moderate is about 10%, and severe dehydration is about 15% or greater. This classification is relative and not well standardized. Ideally, one could use their baseline body weight to determine the percentage of fluid loss, but this is almost never useful because growing children almost never have a known baseline body weight just prior to becoming ill. Additionally, factors such as anorexia and the duration of illness may lead to loss of lean body mass as well which adversely affects the weight calculation. Clinical and laboratory criteria have been developed to estimate dehydration percentage categories, but these are similarly flawed. Unfortunately, there is no certain way to accurately determine the degree of dehydration, therefore all clinical information (including weight loss if known) should be used to ESTIMATE the dehydration severity.

Criteria for 5% dehydration include: no tears when crying, oliguria, sticky (tacky) oral mucosa, less active than usual. Criteria for 10% dehydration include: sunken eyes, diminished skin turgor. Criteria for 15% dehydration include obvious shock (tachycardia, hypotension, cool extremities) and skin tenting. It should be noted that early signs of shock may appear as early as the 5% dehydration level. All of these clinical criteria have some flaws and they are not universally agreed upon. It is often not possible to estimate the urine output because of frequent diarrhea. The oral mucosa may appear to be moist if the patient has just vomited. Sunken eyes may be hard to determine if you don't know what the patient normally looks like. This is best assessed by asking the parent if the eyes look different. Parents will often use the word "hollow" to describe sunken eyes. A ketotic odor to the breath may signify ketosis due to poor oral intake which somewhat correlates with dehydration.

The serum bicarbonate is a measure of metabolic acidosis, but this can be misleading as well since sodium bicarbonate can be lost directly from diarrhea. However, an increased anion gap (calculated as Na minus Cl minus bicarb, which should be less than 12) is almost always present in clinically significant dehydration since lactic acid is produced in a dehydrated state (due to cellular hypoperfusion and a relative increase in anaerobic metabolism). This requires some thinking. For example, in vomiting patients, their bicarbonate initially increases (because of gastric acid loss resulting in a metabolic alkalosis); however, as fluid loss continues, they become dehydrated and a metabolic acidosis would indicate the presence of dehydration. In a patient with diarrhea, the bicarbonate value may be low from diarrheal losses of bicarbonate. So if the serum bicarbonate is relatively low and an increased anion gap is not present, this may not signify dehydration. However, the presence of an increased anion gap would indicate the presence of lactic acid production and dehydration. Similarly in diabetic ketoacidosis, the production of ketoacids and lactic acid results in an increased anion gap. Other clinical situations could affect the bicarbonate value and the anion gap in unusual ways, but this discussion is beyond the scope of this chapter. The above examples pertain to gastroenteritis only.

Replacing the fluid deficit (i.e., rehydration) can be done via oral rehydration or IV rehydration. Rehydration via a nasogastric tube is theoretically possible, but this option is not very popular since it possesses some of the negative characteristics of both oral and IV options. Oral hydration is generally preferable since this can be done at home, it is less invasive and it requires less costly resources. The AAP has published a practice guidelines on the management of acute gastroenteritis (3). Oral rehydration has been demonstrated to be successful in most (or perhaps nearly all) cases of gastroenteritis. The oral rehydration solution (ORS) developed by the World Health Organization takes advantage of the principle that glucose and sodium are co-transported in equimolar quantities across the GI mucosa. ORS contains this balance to optimize fluid absorption during gastroenteritis. Glucose in excess of sodium may remain in the bowel lumen as an unabsorbed osmotic particle which retains fluid in the bowel and inhibits fluid absorption.

ORS has been demonstrated to be efficacious even in children who are vomiting. The standard strategy is to give a small amount of fluid at a time. Giving 5 cc every 1 to 2 minutes reduces the volume remaining in the stomach at any given time. Since the stomach is similar to a bag, it is difficult for the stomach to vomit if only a small fluid volume is present. Giving 5 cc every minute results in a maximum fluid administration rate of 300 cc per hour, but this is very labor intensive for parents who must do this continuously for it to work. More commonly, 30 cc (1 ounce) is given every 15 minutes which results in a maximum fluid administration rate of only 120 cc per hour. This is more within the realm of what most parents are willing to do at home. If the child is not vomiting, then ORS can be given ad lib. It should be noted that a major difference between the clinical utilization of oral rehydration in the U.S. and other countries, is that American parents are very different from parents in much poorer countries. While parents in other countries may be willing to administer 5 cc every 1 to minutes, while the child continues to have a few emesis episodes, American parents are not likely to be this persistent. Often, if their child is not tolerating 30 cc every 15 minutes, American parents will frequently utilize the option of going to an emergency department for IV rehydration. Children in poorer countries do not have this option and despite sustaining greater degrees of dehydration, they are satisfactorily rehydrated via the oral route. It can be said that oral rehydration usually works for parents who are willing to persevere. In poor countries where an IV is rare, rehydration with ORS is life-saving to a very large number of children. In the U.S. severe dehydration is less common (better hygiene and nutrition), yet IV rehydration is used frequently for mild dehydration.

ORS is somewhat distasteful because it is rather salty and not very sweet. Even Pedialyte with much less sodium than ORS, is not very good tasting despite flavoring it. Significantly dehydrated children will usually drink ORS. Children who are not very dehydrated are not thirsty enough to be willing to drink ORS. However, some children who are significantly dehydrated do seem to refuse ORS or Pedialyte since they are either anorexic, too weak to drink, or are refusing because of behavioral reasons (i.e., "spoiled"). Children with mild dehydration can be placed on near normal diets (avoiding fat and excessive sugar), with good results in most instances.

Many textbooks will indicate that children with severe dehydration should be given immediate IV fluid boluses. While this is the standard practice in the U.S., it should be noted that in poor countries, many children with severe dehydration are successfully rehydrated using ORS. However, because severe dehydration is likely associated with a greater mortality risk than mild dehydration, it is reasonable to aggressively treat severe dehydration using IV fluids to reduce this risk. Even moderate dehydration could be treated using IV fluids since this reduces the risk of progression toward severe dehydration with its associated higher mortality risk. In the U.S. where IV fluid infusion resources are plentiful, there should be no hesitation to utilize IV fluids for severe dehydration.

For rapid IV rehydration, a fluid infusion utilizing normal saline (NS) or lactated Ringer's (LR) of 20 cc/kg is a common starting point. For severe dehydration, this should be given as a rapid bolus (over less than 10 minutes), but for mild dehydration this can be given over one hour. The term "isotonic" fluid is often used, but this is actually a misnomer. NS and LR are isotonic, but so is D5-1/4NS. All of these solutions have measured osmolarities of approximately 290. NS and LR behave very similarly since both have sodium concentrations similar to that of the serum. The major difference between NS/LR and D5-1/4NS is that NS/LR stays within the vasculature, while D5-1/4NS does not. Since fluid follows osmotic particles, the fluid volume will go, where the osmotic particles go. When NS/LR are used, the osmotic particles are largely sodium and chloride in concentrations very close to that of the circulating plasma. These ions stay within the circulating plasma and thus, the fluid volume expands the intravascular space preferentially. D5-1/4NS has a glucose concentration of 5000 mg/dL (D5W = 5% glucose = 5 grams/100cc). The serum concentration of glucose is only about 100 mg/dL. Thus, when D5-1/4NS is infused, the excess glucose is taken up by cells and converted to glycogen and the fluid volume leaves the intravascular space to enter the intracellular space. This might promote cellular edema under some circumstances, but at the very least, the fluid does not effectively expand the intravascular space. Thus, rather than use the term "isotonic IV fluids" to describe NS and LR, it would be more accurate to use the term "intravascular volume expanding IV fluids".

It should be noted that 20 cc/kg is actually a small volume. Take for example a 4 year child who weighs about 20 kg. 20 cc/kg results in a 400 cc fluid infusion. For mild dehydration this can be given over 1 hour so the IV rate would be 400 cc/hr for one hour. While this sounds like a very fast IV rate for a small child, this is actually a small volume. 20 cc/kg only replaces 2% of the body's weight, and thus it correctly for only 2% dehydration, which would be considered very mild and not generally in need of IV fluid rehydration. The 2% is determined by 400 cc divided by 20 kg (20,000 gms), or by 20 cc/kg (20 cc per 1000 cc = 2%). Another way to appreciate the truly small size of this fluid volume infusion is to equate this to soft drink cans, which are 12 ounce cans. Since 1 ounce equals 30 cc, a typical 12 ounce soft drink can contains 360 cc, which is similar to the 400 cc fluid infusion. One could say that we are giving a single can of IV fluid over an hour. Looking at it this way, most of us can see that this is not very much. Most 4 year olds can drink 3 or 4 soft drink cans on a hot day after a soccer game. Thus, 20 cc/kg fluid infusion volumes should almost always be repeated.

For severe dehydration in the range of 15%, the patient would actually need 150 cc/kg to fully replace the fluid deficit. For a patient with 5% dehydration, the patient would actually need 50 cc/kg to fully replace the fluid deficit. In addition to the deficit replacement, maintenance fluid needs must be added in.

Resuscitation of shock requires 20 cc/kg NS/LR as a rapid infusion and repeated until perfusion is restored. In most instances, fully rehydrating the patient very rapidly is not necessary and this may be harmful if excessive fluid shifts occur. Once satisfactory fluid resuscitation has stabilized the patient, continued rehydration and maintenance fluids can be administered more gradually.

Some patients with mild dehydration will prefer IV rehydration instead of oral rehydration. Although IV rehydration requires more resources and is more invasive, it has some definite advantages. Once the IV is in, fluid infusion is comfortable, rapid, and is not dependent on GI cooperation for absorption. Studies comparing IV and oral rehydration need to compare an "endpoint" to determine if the endpoint is better in one group or the other. Mortality is the most objective endpoint to measure. For mild dehydration, mortality risk is very low regardless of whether rehydration occurs orally or IV. IV rehydration results in rehydration certainty with minimal work by parents. Oral rehydration requires more work on the part of parents and some uncertainty exists as to whether it will be successful. Most parents bringing their child to an emergency department for IV hydration, have already attempted oral rehydration and they are not fully satisfied with the results. Even though IV rehydration may not be required, it is reasonable to offer it. Put yourself in the body of the child who is experiencing the vomiting and diarrhea. Imagine that you/he/she has vomited 8 times and has had 7 episodes of diarrhea beginning 8 hours ago. You have tried oral rehydration with ORS, but the vomiting and diarrhea have continued. Would you prefer to continue drinking ORS or would you prefer an IV fluid infusion, during which you would have to lie down and get some rest? At some point, many of us would prefer the IV route even though it is not required to avoid mortality. A rule of thumb is that an IV fluid infusion can be considered if V+D (vomiting and diarrhea episodes) is greater than or equal to 10. At this level, sufficient discomfort has been sustained by the patient and mild dehydration is likely. Most mildly dehydrated patients who are given 20 cc/kg per hour for 2 hours (total 40 cc/kg), feel much better with less nausea and fatigue. For such mild patients, they can usually be discharged from the emergency department to catch up on some rest. After a nap or overnight rest, oral rehydration attempts can resume, which are likely to be successful. Compare this to a similar oral rehydration patient, who is not permitted a nap and a period of bowel rest, and who must continue oral rehydration.

For inpatients who are hospitalized for IV rehydration, more time is available to gradually rehydrate the patient. Assuming that rapid IV fluid resuscitation has already taken place (or determined to be unnecessary), inpatient rehydration is a more complex calculation than emergency department rehydration. However, this knowledge is generally required for medical students and pediatric residents.

Fluid administration over a 24 hour period consists of deficit replacement plus maintenance administration. This is best described with the example presented in the case at the beginning of the chapter. A 12 month old male with vomiting and diarrhea is assessed to be 5% dehydrated by clinical criteria. His weight is 10 kg at presentation, but his pre-illness weight is not known. The patient's fluid deficit volume is 5% of 10 kg = 500 cc. The patient's maintenance fluid volume is 1000 cc. Fluid administration is generally broken up into 8 hour blocks for the next 24 hours. The maintenance fluid volume is administered evenly over the three 8 hour blocks. Half of the deficit volume is given in the first 8 hours, with one-fourth of the deficit volume given in the next two 8 hour blocks. This is diagrammed below:

	First 8 hours	Second 8 hours	Third 8 hours
Maintenance volume	1/3	1/3	1/3
Deficit volume	1/2	1/4	1/4

Fitting the clinical data for the patient's case results in the following volume calculations:

	24 hours	First 8 hours	Second 8 hours	Third 8 hours
Maintenance volume	1000 cc	333 cc	333 cc	333 cc
Deficit volume	500 cc	250 cc	125 cc	125 cc
Maintenance+Deficit	1500 cc	583 cc	458 cc	458 cc
IV rate		73 cc/hr	57 cc/hr	57 cc/hr

The IV rate is determined by the sum of the maintenance and deficit fluid volumes for the 8 hour block, divided by 8 hours as noted above. The next step is to determine the type of IV fluid to use (i.e., the optimal electrolyte content of the IV fluid). For maintenance IV fluids, Na is given as 3 mEq/100 cc of IV fluid, K is given as 2 mEq/100 cc of IV fluid. These electrolytes are replaced evenly over the three 8 hour blocks, as noted below (maintenance Na and K).

	24 hours	First 8 hours	Second 8 hours	Third 8 hours
Maintenance volume	1000 cc	333 cc	333 cc	333 cc
Maintenance Na	30 mEq	10 mEq	10 mEq	10 mEq
Maintenance K	20 mEq	7 mEq	7 mEq	7 mEq
Deficit volume	500 cc	250 cc	125 cc	125 cc
Deficit Na	??	??	??	??
Deficit K	??	??	??	??
Maintenance+Deficit	1500 cc	583 cc	458 cc	458 cc
IV rate		73 cc/hr	57 cc/hr	57 cc/hr

The deficit sodium and potassium are more difficult to determine. First of all it should be noted that if the onset of dehydration is rapid (e.g., over 12 hours), most of the fluid is lost from the extracellular space (intravascular and interstitial fluid). If the onset of dehydration is very gradual and prolonged (e.g., over 7 days), relatively more fluid is lost from the intracellular space as well, since the longer time interval permits fluids to shift from the ICF to the ECF space. The ECF (similar to plasma) has a high Na concentration (137 mEq/L) and a low K concentration (3.5 mEq/L). The ICF is the opposite of this to maintain a transmembrane gradient, such that the intracellular K concentration is about 140 mEq/L, while the intracellular Na concentration is close to zero. Deficit Na and K are calculated by the split of ECF and ICF. The ECF volume lost concomitantly loses 140 mEq/L of Na, while the ICF volume lost concomitantly loses 140 mEq/L of K. Short term dehydration results in mostly ECF loss (i.e., more Na and less K), while dehydration occurring over a prolonged period, results in more ICF loss (i.e., more K and less Na). The table below estimates the degree of ICF and ECF loss based on the duration of gastroenteritis symptoms.

Duration of symptoms (4):
- Less than 3 days: 80% ECF, 20% ICF
- 3 days or longer: 60% ECF, 40% ICF

Since our patient's dehydration occurred over one day, the ECF/ICF loss ratio is 80%/20%. Of the 500 cc fluid deficit, 400 cc is ECF loss, while 100 cc is ICF loss. ECF fluid loss contains 140 mEq Na per liter, while ICF fluid loss contains 140 mEq K per liter. Thus, the deficit Na lost is 140 X 0.4L = 56 mEq. The deficit K lost is 140 X 0.1L = 14. Deficit sodium is replaced in the same proportion as deficit fluid (i.e., 1/2, 1/4, 1/4) over the three 8 hour blocks. In contrast, only half of the deficit potassium is replaced and this is split evenly over the three 8 hour blocks (i.e., 1/6, 1/6, 1/6). This is a conservative approach since hyperkalemia due to a miscalculation could result in a life-threatening dysrhythmia. Another approach is to withhold all potassium until urine output is established and to begin potassium replacement at that time. The deficit and maintenance electrolytes can now be determined as in the table below:

	24 hours	First 8 hours	Second 8 hours	Third 8 hours
Maintenance volume	1000 cc	333 cc	333 cc	333 cc
Maintenance Na	30 mEq	10 mEq	10 mEq	10 mEq
Maintenance K	20 mEq	7 mEq	7 mEq	7 mEq
Deficit volume	500 cc	250 cc	125 cc	125 cc
Deficit Na (ECF 80%)	56 mEq	28 mEq	14 mEq	14 mEq
Deficit K (ICF 20%)	14 mEq	2.5 mEq	2.5 mEq	2.5 mEq
Maintenance+Deficit volume	1500 cc	583 cc	458 cc	458 cc
Maint+Def Na	86 mEq	38 mEq	24 mEq	24 mEq
Maint+Def K	34 mEq	9.5 mEq	9.5 mEq	9.5 mEq
IV rate		73 cc/hr	57 cc/hr	57 cc/hr
Na concentration		65 mEq/L	52 mEq/L	52 mEq/L
K concentration		16 mEq/L	21 mEq/L	21 mEq/L

For the first 8 hour period, the Na concentration must approximate 65 mEq/L, which somewhere between 1/2NS and 1/3NS. The IV order for the first 8 hour block could be "IV D5-1/2NS + 16 mEq KCl per liter run at 73 cc/hour for 8 hours." For the next 16 hours, the Na concentration must approximate 52 mEq/L which is approximately 1/3NS. The IV order for the next 16 hours should be "IV D5-1/3NS + 21 mEq KCl per liter run at 57 cc/hour for 16 hours".

Although this process is rather complex, a short cut exists. For 5% dehydration, which is the most common type of hospitalization, the fluid calculations can be approximated by D5-1/2NS + 20 mEq KCl per liter run at twice the maintenance rate for the first 8 hours, followed by D5-1/3NS + 20mEq KCl per liter run at 1.5 times the maintenance rate for the next 16 hours. For percentages other than 5%, this short cut will not work. For dehydration which occurs over more than 3 days, there is a greater loss of ICF (hence, more potassium loss) and relatively less ECF loss (hence, relatively less sodium loss), so the order can be modified to: D5-1/3+25 mEq KCl per liter run at 2 times maintenance for 8 hours, then 1.5 times maintenance for the next 16 hours.

Other factors can make these calculations even more complex. If the patient was given several rapid bolus infusions of NS in the preliminary resuscitation in the ED stabilizing the patient from 10% to 4% dehydration, a large amount of sodium was given initially. If the patient has hyponatremic or hypernatremic dehydration, then the sodium deficit will need to be recalculated. However in the acute resuscitation phase, it doesn't matter whether the patient is hyponatremic, normonatremic or hypernatremic, because the initial IV fluid indicated for resuscitation bolus infusions is NS or LR. The correction of hyponatremia, hypernatremia, hypokalemia and hyperkalemia is beyond the scope of this chapter. However, most cases of mild sodium and potassium imbalance, will eventually correct with most methods of calculating fluid replacement, as long as the kidneys remain functional to ultimately correct the imbalance. Correcting extreme deviations of sodium and potassium should be done with caution. Rapid electrolyte correction can result in cellular damage due to excessive fluid shifts. The use of 3% sodium chloride solution (more than 3 times the osmolarity of NS) should be used with extreme caution since this can cause severe hypernatremia in a short period of time. Administering potassium IV to correct hypokalemia is also dangerous, especially for infants since a small dose of IV potassium can easily make the patient critically hyperkalemic. A general recommendation is that, if the patient is stable, it is best to correct the electrolyte imbalance slowly.

Every day basic numbers to know (and memorize):
Maintenance fluid volume calculation: 100, 50, 20
Maintenance electrolytes: 3meq Na/100cc, 2meq K/100 cc
Volume expanding bolus (NS or LR): 20 cc/kg NS
Normal osmolarity 290 mosm/liter
30 cc = 1 ounce.

Questions:

1. Which of the following sets of signs and symptoms are most consistent with 5% dehydration?
    a. oliguria, tears with crying, less active than usual, normal skin turgor, moist oral mucosa.
    b. oliguria, no tears with crying, less active than usual, sticky oral mucosa, normal or slightly diminished skin turgor.
    c. oliguria, no tears with crying, sunken eyes, soft doughy skin (diminished skin turgor) without tenting.
    d. oliguria, sunken eyes, tenting, tachycardia, hypotension.

2. Which of the following sets of signs and symptoms are most consistent with 10% dehydration?
    a. oliguria, tears with crying, less active than usual, normal skin turgor, moist oral mucosa.
    b. oliguria, no tears with crying, less active than usual, sticky oral mucosa, normal or slightly diminished skin turgor.
    c. oliguria, no tears with crying, sunken eyes, soft doughy skin (diminished skin turgor) without tenting.
    d. oliguria, sunken eyes, tenting, tachycardia, hypotension.

3. Calculate the maintenance IV fluid and rate for a 4 kg infant and for a 25 kg 6 year old.

4. Estimate the concentration of sodium in NS, 1/2NS, 1/3NS and 1/4NS.

5. The resident writes an order for "isotonic" IV fluid to be bolused immediately for a patient with shock and severe dehydration. You look at all the IV fluid bags and notice that NS has an osmolarity of 310, LR has an osmolarity of 275, and D5-1/4NS has an osmolarity of 320. You grab a bag of D5-1/4NS. The resident tells you to get normal saline instead. Why is D5-1/4NS inappropriate even though it is "isotonic"?

6. You calculate the 24 hour maintenance volume for a 3 kg child with severe neurologic dysfunction. His maintenance volume is 300 cc/day. He is currently being fed infant formula via a nasogastric tube at 3 ounces every 3 hours. You do a calculation and notice that he is getting 720 cc/day which is more than twice his maintenance volume. Why isn't this child in congestive heart failure from fluid overload? Explain what maintenance means.

7. You are working as a volunteer physician in a refugee camp of a poor country. The clinic staff has a total of 5 IV sets and there are over 100 children presenting to your clinic with diarrhea and dehydration today. You are seeing a 10 month old infant who is thin and appears to be about 10% dehydrated. Should you use one of the IV sets, or should you implement oral rehydration? A company has donated 1000 liters of Pedialyte which are available for use. What is your rehydration plan for this patient?

8. Calculate an IV rehydration to be administered over 24 hours for a 16 kg child who is 7% dehydration from vomiting and diarrhea which has taken place over 4 days. Start by filling in the table below:

	24 hours	First 8 hours	Second 8 hours	Third 8 hours
Maintenance volume	_____cc	_____cc	_____cc	_____cc
Maintenance Na	_____mEq	_____mEq	_____mEq	_____mEq
Maintenance K	_____mEq	_____mEq	_____mEq	_____mEq
Deficit volume	_____cc	_____cc	_____cc	_____cc
Deficit Na	_____mEq	_____mEq	_____mEq	_____mEq
Deficit K	_____mEq	_____mEq	_____mEq	_____mEq
Maintenance+Deficit volume	_____cc	_____cc	_____cc	_____cc
Maint+Def Na	_____mEq	_____mEq	_____mEq	_____mEq
Maint+Def K	_____mEq	_____mEq	_____mEq	_____mEq
IV rate		_____cc/hr	_____cc/hr	_____cc/hr
Na concentration		____mEq/L	____mEq/L	____mEq/L
K concentration		____mEq/L	____mEq/L	____mEq/L
Type of IV fluid		_____	_____	_____

Answers to questions

1. b
2. c
3. 4kg: 4 X 100 = 400 cc over 24 hours. 3 mEq Na per 100 cc, 2 mEq K per 100 cc. D5-1/4NS + 20 mEq KCl per liter run at 17 cc/hour. 25 kg: 1500 + 5 X 20 = 1600 cc over 24 hours. Maintenance electrolytes are the same. D5-1/4NS + 20 mEq KCl per liter run at 67 cc/hour.
4. Since normal osmolarity is about 300, the Na concentration in NS must be about half that (since Na and Cl ions make up the total osmolarity), which is 150 mEq/L. 1/2NS is half that (75 mEq/L), 1/3NS is 50 mEq/L and 1/4NS is 38 mEq/L.
5. An intravascular volume expanding fluid is required to resuscitate severe dehydration and hypovolemic shock. D5-1/4NS is not an intravascular volume expanded (see text). NS and LR are intravascular volume expanders. The resident should not have used the term "isotonic" since what he/she really meant, was to administer an intravascular volume expanding IV solution.
6. The patient has normal kidneys, which will regulate his overall fluid status. Even normal infants drink about 250 cc/kg (about 2.5 times maintenance), which is why they use a lot of diapers. Since formula is only 2/3 of a calorie per cc, he needs more than maintenance to reach maintenance caloric intake. His excess fluid volume will be urinated out. Maintenance fluid volume is the volume which results in minimum work for the kidney. If less than maintenance fluid is taken in, the kidney must work (consume energy) to retain fluid. If more than maintenance fluid is taken in, the kidney must work to excrete excess fluid. Kidney energy consumption (work) is minimized at some point between these two extremes and this is the "maintenance volume". Patients receiving fluid volumes less than or greater than maintenance will not likely develop fluid balance problems as long as their kidneys are functioning normally. However, if they are very ill, it would be best to minimize renal stress by optimizing their fluid balance.
7. Oral rehydration with WHO ORS should be implemented immediately. Pedialyte is for maintenance fluid, is suboptimal for rehydration and is only useful for children with mild dehydration. This child is not ill enough to utilize one of the 5 IV sets available. According to studies, the mortality rate for oral rehydration and IV rehydration are the same for this type of dehydration.

8. 24 hour maintenance volume is 1300 cc. This is split up into three even 8 hour blocks. Maintenance electrolytes are 3 mEq Na and 2 mEq K per 100 cc. Deficit volume is 1120 cc (7% of 16 kg), half of which is given in the first 8 hour block with the other half distributed over the next two 8 hour blocks (1/4 for each 8 hour block). Since dehydration has occurred over a 4 day period, 60% of the deficit comes from the ECF (672 cc) and 40% comes from the ICF (448 cc). Thus, the sodium replacement for ECF fluid is 140 mEq per liter and the potassium replacement for ICF is 140 mEq per liter. The Na deficit is replaced as the deficit fluid is replaced over the next three 8 hour blocks (1/2 + 1/4 + 1/4). Half of the K deficit is replaced distributed evenly over the three 8 hours blocks (1/6 + 1/6 + 1/6). The results of these calculations are shown below:

Weight 16 kg 7% dehydration	24 hours	First 8 hours	Second 8 hours	Third 8 hours
Maintenance volume	1300 cc	433 cc	433 cc	433 cc
Maintenance Na	39 mEq	13 mEq	13 mEq	13 mEq
Maintenance K	26 mEq	9 mEq	9 mEq	9 mEq
Deficit volume	1120 cc	560 cc	280 cc	280 cc
Deficit Na (60%)	94 mEq	47 mEq	24 mEq	24 mEq
Deficit K (40%)	63 mEq	10 mEq	10 mEq	10 mEq
Maintenance+Deficit volume	2420 cc	993 cc	713 cc	713 cc
Maint+Def Na	133 mEq	60 mEq	37 mEq	37 mEq
Maint+Def K	89 mEq	19 mEq	19 mEq	19 mEq
IV rate		124 cc/hr	89 cc/hr	89 cc/hr
Na concentration		60 mEq/L	52 mEq/L	52 mEq/L
K concentration		19 mEq/L	27 mEq/L	27 mEq/L

D5-1/3NS+19 mEq KCl per liter run at 124 cc/hour for 8 hours, then D5-1/3NS+27 mEq KCl per liter run at 89 cc/hour for 16 hours. The KCl should actually be approximated to 20 mEq/L for the first 8 hours, then 25 mEq/L for the next 16 hours. This would make it easier for the nursing staff to carry out the order.

Chapter II.5. Failure to Thrive
Anthony P. S. Guerrero, MD

This is a 12 month old female who presents for a well child check. Within the past 4 months, her weight has fallen from the 25th percentile to significantly less than the 5th percentile. Her height has dropped from the 10th percentile to slightly less than the 5th percentile, while her head circumference has remained at about the 25th percentile. Her language, motor, cognitive, and social development are normal. She seems to eat appropriate foods for her age, but the her mother notes that she tends to be restless and fidgety while eating, and that she does not like the texture of certain foods, often leading to parental frustration at mealtimes. Her stools tend to be frequent, with particles of food seen. Urine is normal. There are no symptoms of respiratory or neurological disease, and her review of systems is otherwise negative.

Her past medical history is entirely unremarkable. She was born at term, weighing 3.0 kg (6 pounds, 10 ounces), without any perinatal complications. Her family history is negative for any endocrinopathies or chronic illnesses. Mother is 155 cm (5 feet, 1 inch) 61 inches tall, and father is 168 cm (5 feet, 6 inches). Mother experienced menarche at age 12.5 years and recalls that there were other children in the family who were deemed small as young children but who caught up later in childhood. Mother describes a history of increased sadness and worry since her child was born. Parents are married, and there is no history of abuse or violence in the household.

Exam: Vital signs, including blood pressure, are normal. Weight 7 kg (< 5th percentile), height 70 cm (5th percentile), head circumference 45.5 cm (50th percentile). She is alert and interactive, and appears to relate well with her mother. Her anterior fontanelle is still open, roughly 2 cm. Two teeth (one just emerging) are present. Thyroid, lymph nodes, heart, lungs, abdomen, genitalia, nervous system, and skin are all normal.

Laboratory studies: CBC, chemistry panel, lead level, TSH, urinalysis, PPD, and stool studies, including ova and parasites all normal. Bone age is consistent with skeletal maturity of an 8 month old infant.

Formulation: Failure to thrive, with components of genetic short stature with a family history of constitutional growth delay. Parental anxiety, active temperament, and oral/tactile sensitivity may lead to feeding difficulties.

Clinical course: The primary care physician sees the child and family every few months for support, ongoing education, and coordination of services. A dietitian assists in devising an enhanced calorie diet for the child. An occupational therapist offers suggestions for reducing sensitivity to certain food textures. A psychiatrist provides treatment for what is felt to be mild post-partum depression in the mother. Two years later, the child is at the 5th percentile for both height and weight and is otherwise doing well.

Failure to thrive (FTT) is a clinical sign (rather than a specific diagnosis) that describes inadequate growth and is defined as (1) a child younger than 2 years of age whose: 1) weight is below the 3rd or 5th percentile for age on more than one determination; 2) weight is less than 80% of ideal weight (i.e., 0.8 times ideal weight) for age; or 3) weight crosses two major percentile curves on a standardized growth grid (2). FTT is a relatively common problem that may be seen in 10% of children in a rural primary care setting during the first year of life and may account for 1% to 5% of all referrals to children's hospitals and tertiary care settings (3).

The etiologies of FTT are diverse. To arrive at a list of differential diagnoses (which essentially can include most pediatric illnesses), one can think critically about the disease conditions that may interfere with any of the steps in the mechanisms leading to normal growth.

Feeding etiologies include food unavailability, neglect, improper feeding technique, appetite loss, food refusal, and neurologic conditions with impaired swallowing. Other etiologies may include intestinal disease conditions or anatomic abnormalities, endocrinopathies, chronic or prolonged infection, malignancies, other chronic diseases, toxic substances and metabolic derangements.

The patterns of increase in weight, height, and head circumference over time are important to note. Weight reduction out of proportion to height and head circumference may result from malnutrition. Weight reduction in proportion to height reduction but with sparing of head circumference may result from structural dystrophies, genetic short stature, and other endocrinopathies. Global weight, height, and head circumference reduction may result from central nervous system defects or intrauterine growth retardation. The timing of the reduction in weight may also be important to note, as a fairly sudden reduction in velocity of weight gain may reflect either the development of a chronic illness or an adverse social circumstance. Other specific signs and symptoms associated with FTT will vary according to the specific etiology (4).

Because the differential diagnosis can be so broad, a thorough history, growth chart review, and physical examination are key in the evaluation of FTT. Mindful of the mechanisms underlying normal and abnormal growth, one should elicit: a thorough feeding history (beyond the usual "diet" history), a comprehensive review of systems (which often gets dismissed in favor of "as per HPI"), a developmental and psychosocial history, and a history of family members' growth, development, and medical illnesses. It is potentially useful to determine the mid-parental height. For boys: father's height + mother's height + 13 cm]/2. For girls: father's height - 13 cm + mother's height]/2. Plot this on the growth grid for 2 to 18 year olds, estimate the percentile of the child's predicted height, and compare this to the current growth percentiles (as was done in the case above). However, parental short stature does not automatically imply genetic short stature, as either of the parents could have been adversely affected by malnutrition and/or chronic illness. Physical exam should include all vital signs and organ systems and should note the child's level of physical development (e.g., fontanelle size, dentition, etc.).

In the child with a "normal" history and physical examination, there is no clear consensus on what should constitute a "screening" laboratory evaluation, and it is possible that certain laboratory tests may have more value for reassurance rather than substantial diagnostic yield. However, it may be reasonable to consider a complete blood count, basic chemistries, urinalysis, and tuberculin test (1). Laboratory tests that would be appropriate for routine well child care (e.g., lead level) are also reasonable. Further laboratory tests should be guided by specific findings on history and physical examination. In the case above, stool studies were obtained because of the possibly abnormal stools, and a TSH and bone age were obtained because of the possibly delayed skeletal growth.

Management of FTT is based upon a sound understanding of the underlying etiologies. Traditionally, FTT has been categorized into "organic" and "non-organic" etiologies, but recently, it has been recognized that nearly every case of FTT may have both "organic" components (e.g., cyanotic heart disease) and "non-organic" components (e.g., the stressful feeding interactions taking place around a fragile, fussy child), thereby challenging the clinician to approach management in a comprehensive manner. For the case described above, there are multiple interactions between the various factors: for example, the perception of an "abnormal" child (being small for age; albeit with a strong constitutional element) could increase parental anxiety (compounding the depressive symptoms) and could render the parent-child interactions (already challenged by the child's active temperament and sensitivity to food textures) even more difficult. Hence, ongoing support and education from the primary care physician and referrals to psychiatry and occupational therapy become important components of the treatment plan.

An important priority is the establishment and maintenance of adequate nutrition, and caloric intake should be determined based upon child's age, need for "catch up" growth, and (if applicable) increased needs in illness. Creative methods, including more frequent meals and snacks, high calorie foods (e.g., peanut butter, margarine), and nutritional supplementation (e.g., PediaSure) can be employed to augment the child's natural intake. If these methods are unsuccessful after a reasonable trial, supplementation via nasogastric feeds may be indicated.

In the past, hospitalization was felt to be important in differentiating between "organic" and "non-organic" etiologies, as it was believed that the former would not gain weight in the hospital, while the latter would. However, hospitalization may not necessarily distinguish the two, as children with "organic" FTT may, in fact, gain weight with around the clock feeding in the hospital, while certain children with "non-organic" FTT (e.g., with conditions involving an anxious temperament and/or difficulty adjusting to new environments) may become even less likely to feed in a hospital setting. On the other hand, hospitalization must be considered in cases where a child is at risk of serious medical morbidity as a result of either malnutrition or the condition underlying the FTT or at risk of neglect or abuse.

Children with FTT have been found to be at higher risk for adverse cognitive and other developmental/behavioral outcomes, although it is not clear the extent to which these are related to the medical conditions underlying the FTT, subtle neurological dysfunctions which manifested themselves pre-morbidly as feeding and interactional difficulties (hence FTT), or ongoing psychosocial adversity. Nevertheless, because of the known importance of good nutrition for brain development during the first few years of life, it is highly important to identify any potential growth disturbances and suboptimal feeding practices during routine well child care and to expeditiously manage FTT.

Questions (true or false):

1. "Organic" and "non-organic" FTT are clearly defined conditions which enable pediatricians to focus treatment on "organic" cases.
2. Hospitalization is indicated when a child is at risk of serious medical morbidity or abuse/neglect.
3. In addition, all children with FTT should be hospitalized to distinguish between "organic" and "non-organic" etiologies.
4. Blood pressure is useful in evaluating young children with FTT.
5. If both parents are of short stature, then the child must have genetic short stature.
6. History, growth chart review, and physical are key in the evaluation of FTT.
7. In evaluating a child with FTT, it may be important to elicit any history of excessive thirst, increased urination, and family members with renal disease.

Chapter II.6. Malnutrition and Vitamin Deficiencies
Adeline Winkes, MD

An 18 month old boy is brought to the emergency room by police for evaluation. He and his siblings were all removed from their home earlier in the day, after a neighbor's complaint. There are no parents or guardians present to give a history, although the police officer comments that the mother is thought to be an injection drug user. The 12 year old sister, who seems to be the primary caregiver, is worried that the toddler is sick, stating that "he's gotten really skinny" and he "keeps a cold," with constant rhinorrhea and cough. She is unsure if he has seen a doctor, but thinks that he "got all his baby shots".

Diet history is revealing: meals are generally prepared by the 12 year old and 10 year old siblings, and consist of packaged macaroni and cheese, canned spaghetti or noodles, peanut butter and jelly sandwiches, and occasionally fast food drive-ins. The older kids usually drink juice and sodas, though the toddler also drinks some milk.

On exam, the toddler is anxious, clinging to his older sister. He appears thin, with a large head and subcutaneous wasting. Vital signs are appropriate for age. Weight is 9 kg (<3rd percentile); height is 72 cm (<3rd percentile); head circumference is 47 cm (10th percentile). Exam is significant for subcutaneous wasting, sparse hair, dry skin, and a scaling rash in the diaper area. There are no overt signs of trauma, and no focal neurologic deficits.

Laboratory evaluation is significant for a microcytic anemia and a decrease in serum albumin. The toddler is admitted to the hospital for protection, and monitoring during the refeeding process, which proceeds without incident. With concern for infectious risk factors, an HIV test is ordered - which is positive. CD4 count is 1500. Antiretroviral therapy is instituted, with good immunologic response. With the provision of sufficient calories and protein in the diet, weight gain begins to improve.

Protein-energy malnutrition unfortunately remains a significant problem, both in developing countries, and in poverty-stricken areas of the industrialized world. Children with chronic or acute illness are at particular risk, particularly those with acute illnesses including: burns, sepsis, head injury, trauma, malabsorptive disorders, chronic liver, renal, or cardiac diseases, cancers, and HIV. Protein-energy malnutrition may present as the classic syndromes of marasmus and kwashiorkor, or more commonly, with overlap between the two.

Marasmus (1,2) is a classic description of a deficiency in the somatic protein compartment, resulting from primarily a caloric or energy deficiency, and leading to generalized muscular wasting and the loss of subcutaneous fat. The skin appears dry, loose, and wrinkled. Hair may become thin, sparse, and brittle. Hypothermia, bradycardia, hypotension, and hypoglycemia may occur. The visceral protein compartment (discussed below) is relatively spared. As a result, serum albumin measurements are generally normal, though anemia and evidence of vitamin deficiencies are common. There may be a coexisting T cell-mediated immune deficiency.

Kwashiorkor (1,2), in contrast, is a deficiency of the visceral protein compartment, resulting from a protein deficiency (in excess of the caloric deficiency), and leading to edema, dermatoses (including hyperkeratosis, dyspigmentation), dry, brittle, and sometimes red or yellowish hair (if alternating periods of protein deprivation, they may have alternating bands of hair texture = flag sign), hepatomegaly (fatty infiltration), protruding abdomen, and impairment in T cell-mediated immune deficiency. Risk of secondary infections is therefore increased. Laboratory abnormalities may include a low serum albumin, mineral deficiencies (iron, zinc, copper), and elevations of blood glucose, white blood cell count, urine nitrogen, and serum ferritin (as an acute phase reactant even if they are iron deficient). Other acute phase reactants may also be increased (3). Kwashiorkor has been known to occur in toddlers weaned to a protein deficient diet (white rice, yams, cassava-a Latin American staple root otherwise known as manioc or yucca), or in chronically ill or hospitalized patients, in the industrialized world. If kwashiorkor develops in patients with acute illness, such as burns, sepsis, or trauma, it will not resolve entirely until the underlying illness resolves.

Marasmus and kwashiorkor are at two ends of a spectrum of protein-energy malnutrition. In the industrialized world, a mixed picture is most common, often in the setting of chronic disease (perhaps impairing protein absorption), or acute illness (leading to an increase in the basal metabolic rate). Those who live in poverty are at increased risk, as are infants, adolescents, pregnant women, alcoholics, and patients with eating disorders. Assessment should include a careful diet history, comprehensive medical history and physical exam, with the goal of eliciting underlying medical problems. Particular attention should be paid to identifying possible co-morbid conditions, and likely concurrent vitamin deficiencies. Growth measurements should include weight, height and head circumference with adjustments for age, weight for height comparisons, and a body mass index (kg/m2) calculation for children older than 2 years of age. Children whose weights are less than 80% of expected (ideal body weight estimated by tracking growth over time, as well as weight-for-height for infants or body mass index measurements for older children) are considered malnourished. Children with marasmus generally fall as low as 60% of expected. Children with kwashiorkor (and concurrent edema) tend to fall between 60-80% of expected (2). A body mass index measurement of less than 18.5 is considered underweight (3). Treatment consists of the provision of adequate calories and protein to meet individual needs, and treatment of any underlying disease states. In severe malnutrition, close monitoring may be necessary to prevent complications such as refeeding syndrome (severe hypophosphatemia and consequences thereof, as complication of nutritional rehabilitation in severely malnourished patients) (1).

Vitamin deficiencies can be divided into deficiencies of fat-soluble vitamins (ADEK) and deficiencies of water-soluble vitamins, including vitamins B, C, folate, and niacin.

Vitamin A (2) (retinol, retinol ester, retinal, retinoic acid) is found in both plant and animal sources. Animal sources include liver, fish, eggs, milk, and butter. Plant sources include green leafy vegetables and some of the yellow vegetables, such as carrots and squash, as well. These also provide provitamins such as betacarotene, which may be further metabolized to vitamin A. Vitamin A functions as an essential component of visual pigments, and has a role in the maintenance of mucus-secreting epithelia, which may contribute to its role in resisting infection. Deficiency syndromes are therefore notable for: impaired vision, particularly at night, xerophthalmia (in which normal epithelium is replaced by keratinized epithelium), squamous metaplasia of the airways leading to secondary pulmonary infections, renal or urinary bladder stones, and immunodeficiencies. Vitamin A has also been studied as a supplement for use during acute infections, in the developing world. The mechanism is unclear, but it appears to be useful in particular disease states, with or without underlying vitamin A deficiency. This has led to a Red Book recommendation for vitamin A supplementation in some patients with measles (4,5).

Vitamin D (2) is found in two precursor forms: 7-dehydrocholesterol (provitamin D3) in the skin, and ergosterol in plants. It is synthesized endogenously from its precursor in the skin, and found in dietary sources such as: deep-sea fish, plants, and grains. It serves in the maintenance of appropriate serum calcium and phosphorus levels, through the regulation of intestinal absorption of calcium/phosphorus, the PTH-mediated mobilization of calcium from bone, and the PTH-mediated stimulation of calcium reabsorption in the distal renal tubules. Deficiency states are referred to as rickets in children, or osteomalacia in adults. Populations at risk for deficiency states are usually marked by limited sun exposure, and therefore inadequate endogenous synthesis, as well as a diet limited in vitamin D. The classic syndrome of rickets is marked by: craniotabes, rachitic rosary, wrist thickening, pigeon breast deformity, Harrison groove, flaring epiphyses, and bowing of the legs. This might be seen in breast-fed infants or toddlers, whose mothers are not supplementing with vitamin D. These children would likely also have sun exposure that was limited in some way, such as during the winter in northern latitudes.

Vitamin E (2) consists of the group of tocopherols and tocotrienols, of which alpha-tocopherol is the most common. Sources include: vegetables, grains, nuts, dairy, fish, and meats. It serves as an antioxidant, and is especially important in the nervous system and mature red blood cells. Deficiency syndromes of vitamin E are extremely uncommon, and are usually seen only in patients with fat malabsorption or other complicating chronic medical conditions. Deficiency syndromes are marked by posterior column/dorsal root ganglion-related signs, including: absent tendon reflexes, ataxia, loss of position and vibration sense, loss of pain sensations. Ophthalmoplegia may occur. Anemia has been reported in premature babies.

Vitamin K deficiency (2) may produce hemorrhagic disease of the newborn, which is fortunately rare, as vitamin K prophylaxis at birth has become routine. Vitamin K is derived from vegetables and by synthesis by intestinal bacteria in the lower ileum and colon. Absorption of vitamin K in the small intestine is dependent on bile salts. After absorption, transport occurs to the liver. It is converted in the liver to the hydroquinone form, which acts as a cofactor in carboxylase reactions, including the carboxylation of glutamic acid residues, in the formation of factors II, VII, IX, X, protein C and protein S (6). It is readily recycled in a healthy liver, and is widely available in the diet. Deficiency usually occurs, therefore, only in high risk populations. All infants are at some risk for vitamin K deficiency, as: 1) liver reserves are limited in the neonatal period, 2) the bacterial flora which produce vitamin K have not yet been established, and 3) the level of vitamin K in breast milk is low. A 3% prevalence of vitamin K dependent bleeds in neonates (who have not received prophylaxis) has been estimated (2). By 1-2 weeks of age, the developing bacterial flora provide sufficient vitamin K for normal term infants' needs. Premature infants, for several reasons, may have persistent need for increased supplementation. In older children and adults, vitamin K deficiency may occur in those with fat malabsorption syndromes (biliary tract disease, short gut syndrome) and advanced liver disease, as hepatocyte dysfunction interferes with synthesis of vitamin-K-dependent coagulation factors, even in the presence of vitamin K levels considered sufficient in other settings (2,7). Vitamin K supplementation (in addition to other fat-soluble vitamins) is therefore recommended for patients with fat malabsorption, cholestasis, and advanced liver disease (7).

Vitamin B1 (2) (active coenzyme thiamine pyrophosphate) is found in a wide variety of dietary sources, with the notable exception of refined foods, such as polished rice, white flour, and white sugar. It participates in the regulation of ATP, as a cofactor in the pentose phosphate pathway. It also has a role in maintaining membranes and conduction pathways of the peripheral nerves. Populations that are particularly at risk for vitamin B1 deficiency include those whose diets are high in refined foods, such as polished rice, and those with alcoholism. Several clinical deficiency states have been described, including: dry beriberi (polyneuropathy with toedrop/footdrop/wristdrop), wet beriberi (cardiovascular manifestations including peripheral vasodilation and high output cardiac failure), and Wernicke-Korsakoff syndrome (encephalopathy, with ataxia and psychosis, including retrograde amnesia, confabulation).

Vitamin B2 (2), or riboflavin, is derived from meat, diary, and vegetable sources. It is involved in oxidation-reduction reactions, and is incorporated into mitochondrial enzymes. The clinical deficiency syndrome consists of: cheilosis (fissures in the lips), glossitis, keratitis/corneal ulceration, and a greasy scaling dermatitis over the nasolabial folds, progressing to a butterfly distribution.

Niacin (2), or nicotinic acid and its derivatives, is endogenously synthesized from tryptophan, and exogenously derived from grains (in some grains, such as corn, it exists only in the bound form and is therefore not absorbable), legumes, seed oils, and meats. It is a component of NAD and NADP, and acts as a coenzyme for dehydrogenation reactions, especially those in the hexose monophosphate shunt, in glucose metabolism. Populations at particular risk for niacin deficiency include: those with chronic diarrhea, those with protein-deficient diets, and those taking isoniazid and 6-mercaptopurine. The clinical deficiency syndrome of pellagra consists of dermatitis, diarrhea, and dementia.

Vitamin B6 (2), or pyridoxine and the phosphorylated forms thereof, is found in almost all foods, though they may be lost after processing (such as dried milk preparations). It acts as a cofactor for a large number of enzymes, including the transaminases, carboxylases, deaminases, in lipid metabolism, amino acid metabolism, and immune responses. An overt deficiency of B6 is rare, but the subclinical deficiency state is common, particularly in those being treated with pyridoxine antagonists, such as isoniazid, estrogens, penicillamines, and acetaldehyde (ETOH met). There is an increased demand for vitamin B6 during pregnancy. The clinical deficiency syndrome is similar to that seen in riboflavin or niacin deficiency: seborrheic dermatitis, cheilosis, glossitis, peripheral neuropathy, and sometimes seizures. Pyridoxine is used as a therapeutic reversal agent in pyridoxine-dependent seizures and in the acute management of INH overdose.

Vitamin B12 (2) is derived from animal sources (meats, milk, eggs), and is absorbed in the distal ileum, only after forming a complex with intrinsic factor (produced by gastric parietal cells). It is then transported by transcobalamin. Adequate B12 is required for normal folate metabolism, and also for DNA synthesis and the maintenance of myelinization of spinal cord tracts. Populations at particular risk for deficiency include: neonates (if the maternal diet is deficient), those with insufficient production of intrinsic factor (juvenile pernicious anemia), and those in whom the distal ileum has been surgically removed. The clinical deficiency state may include:

megaloblastic anemia, leukopenia, thrombocytopenia, mild jaundice, and neurologic signs, such as posterior/lateral column demyelination, paresthesias, sensory deficits, loss of deep tendon reflexes, confusion, and memory deficits.

Folate (2) is derived from a variety of sources (whole wheat flour, beans, nuts, liver, green leafy vegetables), but is quite heat labile, and easily destroyed by cooking or processing raw foods. It acts as an essential cofactor in nucleic acid synthesis. Populations at particular risk include: 1.) fetuses with rapidly dividing cells (in whom an association with neural tube defects has been noted. Hence the recommendation for early supplementation, for all women of childbearing age); 2.) those on oral contraceptives, antiepileptics, ETOH, or with heavy cigarette use (decreases absorption); or 3.) those with intestinal malabsorption or metastatic disease. It is notable that adequate B12 is required for folate metabolism, leading commonly to concurrent deficiencies. Deficiency in folate alone will produce a megaloblastic anemia. In a deficiency of B12, supplementation of folate will reverse the megaloblastic anemia, but it will not reverse the neuropathic consequences of B12 deficiency.

Vitamin C (2), or ascorbic acid, is found in milk, liver, fish, fruits, and vegetables. It is involved in the activation of prolyl and lysyl hydroxylases from inactive precursors, therefore facilitating the hydroxylation of procollagen. Populations at particular risk for vitamin C include those with marginal or erratic diets (the classic example is of malnourished sailors without fresh vegetables), dialysis patients, or infants on processed milk only. The clinical spectrum of vitamin C deficiency encompasses bone disease (in growing children), hemorrhagic disease (skin, mucosal, and subperiosteal bleeds, bleeds into joint spaces), impaired wound healing, and anemia.

Questions

1. Name the classic syndrome:
   A. Toddler with edema, hepatomegaly, protruding abdomen, alternating bands of light and dark hair, dry skin, and lethargy.
   B. Cachectic infant with subcutaneous fat wasting, loose dry skin, brittle hair.

2. True/False: Serum albumin is usually decreased in kwashiorkor, or severe malnutrition affecting the visceral protein compartment.

3. True/False: Hemorrhagic disease of the newborn can be prevented with vitamin K prophylaxis (1 mg IM x 1) at birth.

4. Vitamin K is an important cofactor in the activation of which of the following coagulation factors:
   a. factor VIII
   b. factor X
   c. protein S
   d. von Willebrand's protein
   e. factor IX

5. True/False: Vitamin D, in response to serum hypocalcemia, regulates the mobilization of serum calcium through three mechanisms: increased intestinal absorption of Ca and Phos, mobilization of Ca from bone, and increased reabsorption of Ca from the distal renal tubules.

6. The three D's of pellagra are:
   a. diarrhea
   b. dementia
   c. deafness
   d. dermatitis
   e. dissociation

7. Cheilosis and glossitis are features of:
   a. vitamin A deficiency
   b. riboflavin (B2) deficiency
   c. vitamin C deficiency
   d. pyridoxine (B6) deficiency
   e. vitamin E deficiency

8. True/False: Both folate and B12 deficiency produce a megaloblastic anemia. In addition, patients with B12 deficiency may exhibit posterior column defects, such as: paresthesias, sensory deficits, loss deep tendon reflexes, as well as confusion and memory deficits.

9. The features of scurvy, or vitamin C deficiency, include:
   a. bone disease in growing children
   b. hemorrhagic disease, including mucosal involvement, subperiosteal bleeds, and bleeding into joint spaces
   c. cheilosis, glossitis
   d. impaired wound healing
   e. anemia

5. True
6. a, b, d
7. b, d
8. True
9. a, b, d, e

Chapter III.1. Routine Newborn Care
Joan Ceccarelli Meister, MD

This is a 3640 gram newborn male infant born at 39 weeks gestation via normal spontaneous vaginal delivery (NSVD) to a 17 year old G3P0 mother who is O+, VDRL NR, Hepatitis B surface antigen (HBsAg) positive, rubella immune, group B streptococcus (GBS) negative, and HIV negative . Artificial rupture of membranes (AROM) occurred 18 hours prior to delivery with clear fluid. Apgar scores were 8 and 9 at 1 and 5 minutes respectively.

Maternal history is remarkable for 1 prenatal visit 1 month ago. An ultrasound performed at that time was consistent with 34 weeks gestation. Toxicology screening at that visit and on admission were negative. Mother is reportedly healthy, with no chronic medical problems and no significant family history. She reports no difficulty during the pregnancy. She denies alcohol, cigarette, medication or drug use. Social history reveals that the mother's support system includes the father of the baby (FOB) and both maternal and paternal grandparents.

Exam: VS T 37.0 rectal, P 145, R48, BP 49/35. Weight 3640 grams (8 pounds) (75th%), 51 cm (20 inches) (75th%), head circumference 34 cm (13.5 inches) (50th%). This infant is term in appearance, pink and active. Anterior fontanelle is soft and flat. Caput succedaneum is present. Corneas are clear. Ears are normally placed. Nares are patent. Oral mucosa is pink and the palate is intact. Neck is supple without masses. Clavicles are intact. His chest is symmetric and mature breast buds are present. Lungs are clear with equal aeration. Heart is regular with no murmurs heard. Abdomen is flat and soft with no masses. Three vessels are visible within the umbilical cord. Femoral and brachial pulses are symmetric and 2+. Hips demonstrate full range of motion, no tightness, no clicks. Ortolani and Barlow signs are negative. Perineal creases are symmetric. Anus is patent. Male genitalia are normal, with both testes descended. His skin is pink with a few facial petechiae. He moves all extremities well. His Moro reflex is intact. His grasp response is symmetrical. His suck reflex is strong.

By 7 hours of age, he has passed meconium once, has had no urine output, and has nippled 15 cc of infant formula from a bottle. His mother does not want to breastfeed because she says she has no milk and will be returning to school soon. Besides, she read that formula makes your baby grow just as well as breast milk. During a discussion between one of the pediatric residents and the mother following the initial newborn exam, she begins to cry and says that she has no idea how to care for a baby. She doesn't know how often to feed him or how to position him for sleep. She has received paperwork describing tests and procedures to be performed before they are discharged (i.e., circumcision, hepatitis immunization, hearing screening), but doesn't understand why they are all necessary. She also wonders why there was medicine put in his eyes and why he received a shot shortly after birth. Additionally, she is quite shocked to discover that she needs a pediatrician as she thought her obstetrician would take care of the baby.

Routine newborn care encompasses not only the evaluation and health maintenance of the infant, but also the counseling and education of parents or other caregivers.

The maternal history provides pertinent information such as the presence of certain risk factors, which could affect the newborn. A comprehensive may not be readily available, especially if the mother has had limited or no prenatal care. Reviewing the maternal chart may identify maternal risk factors that could impact the health of the newborn, as well as complications of labor and delivery that could impact fetal/newborn well being and transition.

The initial physical examination should be performed within 24 hours of birth. It may demonstrate subtle differences related to the age of the infant. An infant who is 30 minutes old has not yet completed the normal transition (from intrauterine to extrauterine life) and thus, variability may exist in vital signs and examination of the respiratory, neurological, gastrointestinal, skin, and cardiovascular systems. It is therefore ideal that a comprehensive examination be performed after the infant has completed transition. In a quiet infant, the examination should proceed from the least invasive and noxious elements of the exam (auscultation of heart and lungs) to those most likely to irritate the infant (examination of the hips and eliciting the Moro reflex).

An enormous amount of information regarding the well being of an infant can be obtained by a general visual assessment. Initial observation gives an impression of healthy (stable) versus ill and term versus preterm. Gestational age is determined by assessing various physical signs and neurological characteristics that vary according to fetal age and maturity. The new Ballard scoring system provides an objective estimate of gestational age (accuracy plus or minus 2 weeks). Gestational age assessment is pertinent as it allows the clinician to plot growth parameters, and to anticipate potential problems related to prematurity/postmaturity and also to growth abnormalities such as SGA/LGA (small and large for gestational age). After assuring that the infant is stable and thus able to tolerate a full and in depth examination, the examiner should proceed in a step-wise manner, taking into account the state and tolerance of the infant.

The specific components of the typical newborn exam are listed as follows:

General: overall behavioral state, color, respiratory status; any congenital anomalies, gender

Head: occipitofrontal circumference and shape, molding (deformation of the skull caused by labor), caput succedaneum (normal scalp edema at the apex of the head secondary to the compression sustained during labor and delivery) versus cephalohematoma (subperiosteal bleeding), sutures, fontanels, scalp trauma, defects, craniotabes (soft portions of the skull which are benign).

Eyes: presence, retinal red reflex, symmetry and completeness of iris, pupil reactivity.

Ears: shape and position, skin tags.

Nose: patency of nares.

Mouth: mucosa color, palpation of palate, presence of teeth.

Neck: range of motion, length, cysts, sinuses or masses.

Chest: symmetry, pectus deformity, clavicles, breast tissue.

Respiratory: color, respiratory rate and effort, presence, quality and equality of breath sounds, and work of breathing.

Heart: rate and rhythm, presence of murmurs; situs and precordial activity.

Pulses: strength and equality in four extremities.

Abdomen: placement of the umbilicus, 3 vessels within the umbilical cord (2 arteries, 1 vein), palpation of the liver edge (not always palpable), palpation of the spleen and kidneys (not easily palpable), any masses, bowel sounds, contour (scaphoid, flat, distended).

Male genitalia: foreskin and position of urethra, palpable descended testes, scrotum with rugae, no other masses in scrotum/groin.

Female genitalia: labia majora and minora, position of urethra, discharge.

Anus: patency and position.

Extremities: number of digits, hip exam for dysplasia/dislocation (Ortolani/Barlow), perineal creases, range of motion at all joints (especially the hips).

Spine: presence of dimples, cysts, tracts, cutaneous defects, swellings or tufts of hair.

Skin: color, rashes, ecchymoses/petechiae, perfusion, nevi, pigmentation.

Neurological system: symmetry of movement, muscle tone, posture, strength, grasp reflex, suck reflex, Moro reflex, response to being handled.

In addition to a comprehensive physical examination, several preventive measures are undertaken to ensure good newborn health. Within 1 hour of birth, infants should receive erythromycin ophthalmic ointment to both eyes to prevent ophthalmia neonatorum (from gonococcal infection). Eye prophylaxis does not prevent chlamydia conjunctivitis. Intramuscular vitamin K should also be given within 1 hour to prevent hemorrhagic disease of the newborn. Finally, bathing of skin and hair should be completed once thermal and cardiorespiratory stability have been achieved in order to reduce skin bacterial colonization.

Screening for hearing, metabolic, endocrine, and hematologic disease should also be done prior to discharge. The State of Hawaii has recently expanded the newborn screening program to test for over 30 disorders. The previous newborn screen tested for 7 disorders: hypothyroidism, phenylketonuria (PKU), congenital adrenal hyperplasia (CAH), galactosemia, sickle cell anemia, biotinidase deficiency, and maple syrup urine disease (MSUD).

Hepatitis B immunization is offered to all infants prior to discharge. If a mother is hepatitis B surface antigen (HBsAg) positive, the immunization should be administered along with hepatitis B immune globulin.

Anticipatory guidance is a major part of providing care to the healthy newborn. Educating parents about the care of their baby, especially new mothers, is of utmost importance. Nutrition is a primary educational objective. All babies must have an appropriate feeding routine established prior to discharge. Breast-feeding and breastmilk are the most beneficial for the infant as well as the mother. The mother should be counseled on the nutritional and immunological benefits of breastmilk (e.g., provides protection against illnesses such as gastroenteritis and otitis media). In cases where breastfeeding is not feasible (medically contraindicated or lack of maternal interest), then it is imperative that the infant successfully establishes bottle feeding prior to discharge. A newborn feeds every 1 to 4 hours, with longer intervals expected in formula fed infants as breastmilk tends to empty from the stomach faster than formula. A typical feeding session should last approximately 20-30 minutes.

Prior to discharge the infant should have voided and passed meconium. The first void may not occur until 16 hours of life, but in general 90% of babies will have voided by this time. In addition, 98% of infants have had their first stool by 24 hours of age. The mother should be counseled on the change in appearance of stool from meconium (dark green sticky sludge) to transitional to normal milk feeding stools and the variability between formula fed stools (tends to be brown) and breast fed stools (tends to be yellow, loose and seedy). The mother should also be aware of the appropriate number of wet diapers per day. By the end of the first week, the infant should be voiding 5 to 7 times per day.

It is essential to discuss sleep position, since prone sleeping is a known risk factor for sudden infant death syndrome. Parents should be instructed to put their infant to sleep in a supine position. Pillows, blankets and thick comforters may pose a suffocation risk and should not be present in a crib or bassinet.

General safety issues should also be addressed. The law requires rear facing car seats for infants less than 1 year of age and less than 20 pounds. Parents should be warned to never leave an infant unattended on a raised surface, in a bathtub or near water (beach, pool, bucket, etc.). Parents should also be instructed about thermal regulation. Because infants lose much of their heat from their heads, caps should be used in the hospital and in cold environments. Otherwise, newborns should be dressed as is appropriate for their immediate environment.

Caregivers should know their physician's name, office number and location, and an after hours contact number. Additionally, they should be aware that in a true emergency, 911 should be called.

Parents should anticipate that their baby may lose up to 10% of their birthweight within the first 3 to 5 days of life. The baby should regain or exceed their birthweight by 2 weeks of age.

Peeling skin is normal and does not, in general, benefit from lotions. Sponge baths should be done until the umbilical cord falls off. The drying of the cord can be aided by wiping the base with rubbing alcohol when the diaper is changed.

Circumcision is the elective surgical removal of the penile foreskin. There are no true medical indications for circumcision in the newborn. All newborns have some degree of phimosis (inability to fully retract the foreskin). It has been demonstrated that there is a decreased incidence of urinary tract infections in the first year of life in circumcised male infants. Contraindications to circumcision include hypospadias, bleeding disorders, and small penile size. Local anesthesia should be used.

Pseudomenses occurs in many female neonates. Small amounts of blood tinged mucus or frank blood may be passed vaginally within the first two weeks of life. This is due to withdrawal from the high hormone levels that the infant was exposed to in utero. Anticipatory counseling prevents unnecessary anxiety when this occurs.

Physiologic jaundice is common in the first few days of life. Risk factors for pathologic jaundice include O+ maternal blood type, bruising/cephalohematoma, prematurity, infants of diabetic mothers, polycythemia, and ethnic groups (males) at risk for G6PD deficiency.

A baby's first follow up appointment may be scheduled 2 weeks after discharge for infants who remain in the hospital for more than 48 hours after delivery. However, many physicians choose to see the baby 1 to 2 days after discharge. This is especially the case for infants discharged from the hospital at less than 48 hours of age, in accordance with American Academy of Pediatrics recommendations.

Questions

1. List three disease prevention measures routinely administered to all newborns.
2. List three early disease detection measures routinely administered to all newborns.
3. True/False: Abnormal vital signs within the first 30-60 minutes of life are always pathologic and indicate an unhealthy newborn.
4. True/False: Breast milk is associated with a decrease in the incidence of several common infections.
5. True/False: Circumcision should be routinely recommended based on medical advantages.
6. True/False: Normal stools from breast fed infants appear to be loose, yellow and seedy.

Answers to questions

1. Vitamin K prophylaxis, antibiotic eye prophylaxis, bathing, and hepatitis B immunization. Breast feeding should also be considered to be an infection prevention/modifying measure.
2. Newborn blood and metabolic disease screening, hearing screening, physical examination.
3. False
4. True
5. False
6. True

Chapter III.2. Neonatal Hyperbilirubinemia

Carol Hirai, MD

Case 1

This is a jaundiced, 4 day old, 3.1 kg, appropriate for gestational age (AGA) Asian female infant born at term to a 25 year old A+ primiparous woman with gestational diabetes. The pregnancy was otherwise uneventful. Labor was augmented with Pitocin. The baby was discharged home on day of life 2 at which time her weight was down 4% from birth weight and she had mild facial jaundice. In the hospital, she was breast fed every 3 hours and had 2 wet diapers and one meconium stool over a 24 hour period. On day 3, her parents gave her water on two occasions as she appeared hungry despite regular and frequent breast feeding attempts. In addition, they noted an increase in the degree of jaundice, but failed to address it after being reassured by family members that jaundice is common. They also had an appointment to see their pediatrician the following day. In the office, on day 4, mother reports that she is breastfeeding the baby every three hours and that there have been 2 wet diapers per day. The urine is described as dark yellow in color and the stools appear dark green.

Exam: VS T 37.8, P 162, RR 55, BP 63/45. Weight 2.7 kg (25%ile), length 50 cm (75%ile), head circumference 34 cm (75%ile). The infant is jaundiced and irritable. The anterior fontanel is slightly sunken, the oral mucosa is tacky, and there is jaundice to the lower extremities. No cephalohematoma or bruising is present. The sclera of both eyes are icteric. Muscle tone and activity are normal. The remainder of the physical exam is normal.

The total bilirubin is 20 mg% with a direct fraction of 0.7 mg%. She is admitted to the hospital for phototherapy, supplementary formula feedings, and lactation consultation. By the following day, the bilirubin has decreased to 12 mg% and she is discharged home on breast milk feedings. The baby is scheduled for follow-up with both the pediatrician and the lactation consultant.

Case 2

A 4 day old, 36 week gestation male presents to his primary care physician with worsening jaundice. The maternal blood type is 0+. He was discharged home on day 2 of life after successfully breastfeeding for a 24 hour period. At the time of discharge, his physical exam was remarkable for mild jaundice and a cephalohematoma. At today's visit there is an 8% weight loss from birth and a history of "fair" urine output and yellow stools. He is markedly jaundiced and has a resolving cephalohematoma. Other physical exam findings are remarkable for a normal cry, flat anterior fontanelle, moist oral mucosa and a normal neurologic examination. The total bilirubin is 27 mg% with a direct fraction of 1 mg%. He is admitted to the hospital where phototherapy is initiated. His blood type is A+ with a positive direct Coombs. The hematocrit is 42% with a reticulocyte count of 12% and the pathologist identifies spherocytes on the blood smear. The G6PD is pending. After one hour of phototherapy, a repeat bilirubin is 25 mg%. The G6PD is normal. The decision is made to perform a double volume exchange transfusion. The infant remains on phototherapy for an additional 2 days and is discharged home after being off phototherapy for 1 day. The serum bilirubin on the day of discharge is 12 mg% and he passes an auditory brainstem response test.

More than 50% of term neonates become jaundiced (1). In this community (Hawaii), hyperbilirubinemia is one of the major reasons for re-hospitalization within the first two weeks of life. The primary reason for the level of concern over jaundice and hyperbilirubinemia in the newborn is the association of hyperbilirubinemia with kernicterus, which is a rare, but devastating neurologic complication of hyperbilirubinemia. Kernicterus can occur without signs and symptoms (2), but acute kernicterus in term babies is usually characterized by changes in muscle tone, drowsiness, poor feeding, a high pitched cry, apnea, possible seizures, fever, and death (3). Neurologic sequelae include dystonia and athetosis, upward gaze abnormalities, sensorineural hearing loss, intellectual deficits and tooth enamel dysplasia (3). In term patients, the MRI has increased signal intensity in the globus pallidus on T2 images (2). Although kernicterus is rare, it is potentially preventable and it is being seen with increasing frequency. This has prompted a recent Joint Commission on Accreditation of Healthcare Organizations Sentinel Event Alert (4).

The assessment and management of hyperbilirubinemia can be confusing. For instance, a bilirubin of 11 mg% has a different significance under different circumstances. It would be considered physiologic (not pathologic) in a 4 day old term breast fed baby, while the same level would be pathologic on day 1. A serum bilirubin of 11 mg% would also be concerning in a sick, two day old, 27 week gestation premature infant. Clinical decision-making is based on serum bilirubin values which are not directly reflective of risk for neurotoxicity (3). In an attempt to assist physicians with this common problem, the AAP released a practice parameter in 1994 on the Management of Hyperbilirubinemia in the Healthy Term Newborn (5). According to the commentary from the AAP Subcommittee on Neonatal Hyperbilirubinemia in 2001, this practice parameter is currently being revised (6).

Hyperbilirubinemia is more common in neonates due to the shortened life span of their red blood cells, declining hematocrit, immature liver uptake and conjugation of bilirubin, and increased intestinal reabsorption of bilirubin. Hemoglobin breakdown releases iron, carbon monoxide, and biliverdin. The latter is reduced to bilirubin, which enters the liver. Uridine diphosphate glucuronyltransferase (UDPGT) conjugates bilirubin into an excretable form. Intestinal bacteria can deconjugate bilirubin allowing for reabsorption of bilirubin into the circulation. This increased enterohepatic circulation occurs particularly in preterm neonates with diminished stool passage. In Asians, a variant in the UDPGT has been associated with hyperbilirubinemia.

Infants with red blood cell membrane G6PD (glucose-6-phosphate dehydrogenase) deficiency have a tendency for hemolysis and hyperbilirubinemia. In G6PD deficiency, hyperbilirubinemia can occur despite minimal evidence for hemolysis. Also, decreased conjugation of bilirubin has been described in G6PD deficiency.

Most unconjugated bilirubin is bound to albumin, but free unconjugated bilirubin (a form unbound to albumin) can enter the brain (i.e., it can cross the blood brain barrier). Sulfonamides are contraindicated in the neonatal period because they displace bilirubin from albumin. Conditions that disrupt the integrity of the blood brain barrier, such as infection (e.g., sepsis, meningitis, congenital viral infections), acidosis, prematurity, and hyperosmolarity, place the infant at increased risk for kernicterus. Hemolytic causes of hyperbilirubinemia (e.g., Rh incompatibility and G6PD deficiency) have higher risks of kernicterus compared to other causes of jaundice at comparable bilirubin levels.

Bilirubin may be the toxic substance responsible for kernicterus, but this is not a certainty. Very high bilirubin levels (in the 30 mg% range) most often do not result in kernicterus if no hemolytic disease is present. However, bilirubins in the 20 mg% range due to Rh incompatibility or G6PD deficiency, often result in kernicterus. The paradox that a very high bilirubin due to non-hemolytic causes has a lower kernicterus risk while a moderately high bilirubin due to Rh incompatibility or G6PD deficiency has a higher kernicterus risk, suggests that bilirubin itself may not be the direct cause of kernicterus. Bilirubin may only be a marker of the true toxic substance that causes kernicterus. This phenomenon may explain why the risk of kernicterus is not determined by bilirubin levels alone.

Jaundice can be detected clinically with tactile blanching of the skin revealing an underlying yellow color. The examination should be done in a well-lit, neutral light. Jaundice usually begins on the face and progresses caudally. The presence of scleral icterus should be assessed. Generally, the farther the jaundice progresses down the body, the higher the total serum bilirubin (3). The more intense the color (which can approach a yellow-orange) also suggests a higher total serum bilirubin. Jaundice may be clinically detected with a total serum bilirubin of 5 mg%. The presence of jaundice in particularly dark skinned newborns can be difficult to assess. Any time there is uncertainty, the recommendation is to check a total serum or transcutaneous bilirubin. Universal screening has been recently recommended, perhaps simultaneously with the newborn screen. If a patient is under phototherapy, jaundice is difficult to visually assess because phototherapy preferentially reduces bilirubin concentrations near the skin. If assessing a patient under phototherapy, jaundice severity is best determined by examining unexposed sites (e.g., under the eye shield) and phototherapy should be interrupted during the exam. If the skin is green or bronze colored, this suggests an elevated direct (conjugated) bilirubin fraction, so a fractionated bilirubin should be obtained. The patient should also be assessed for pallor, plethora and hepatosplenomegaly.

It is essential to distinguish whether the jaundice is physiologic or pathologic. Jaundice noted within the first 24 hours is pathologic and a total serum bilirubin should be drawn. Early jaundice is usually related to hemolysis, infection, drug effect, neonatal hepatitis or liver enzyme defects (e.g., Crigler-Najjar-deficiency of UDPGT) (7). A total bilirubin greater than 17 mg% in a full term neonate is pathologic (2). Jaundice that persists beyond 2 weeks should be evaluated beginning with a fractionated bilirubin (5). Direct hyperbilirubinemia is also considered pathologic, (i.e., direct bilirubin >1.5-2 mg% or > 20% of the total bilirubin) (8).

Direct (conjugated) hyperbilirubinemia cases are relatively uncommon. The differential diagnosis includes neonatal hepatitis, biliary atresia, sepsis, metabolic disorders (e.g., galactosemia), and hepatotoxicity from hyperalimentation. A detailed discussion of direct hyperbilirubinemia is beyond the scope of this chapter. One of the principal diagnoses to exclude is biliary atresia which is associated with dark urine or light colored stool. Early surgical intervention done prior to 2 months of age reduces mortality and the probability of future liver transplantation (refer to the chapter on biliary atresia).

Indirect (unconjugated) hyperbilirubinemia, is more common and presents a risk for kernicterus. The most common causes of indirect hyperbilirubinemia are physiologic, breast milk, breast feeding with a large postnatal weight loss (3), ABO incompatibility, cephalohematoma, bruising, G6PD deficiency, and East Asian ethnicity. Of these, G6PD deficiency poses a higher risk of kernicterus, but ABO incompatibility is a more common reason for exchange transfusion. Rh incompatibility is less common, but represents a high risk of kernicterus. Breastfeeding jaundice is related to inadequate intake by the newborn (i.e., components of poor feeding and dehydration are contributory). Breast milk jaundice (i.e., due to breast milk itself) has its onset later than breastfeeding jaundice. It is related to increased enterohepatic circulation and is relatively uncommon. Uncommon causes of indirect hyperbilirubinemia include other RBC membrane defects (e.g., hereditary spherocytosis) and hemoglobinopathies. In the pilot kernicterus registry, 31% of the cases were idiopathic (no identified cause), approximately equal to the incidence associated with G6PD deficiency (3).

A rise in bilirubin of greater than 0.5 mg% per hour and failure to control hyperbilirubinemia despite phototherapy are suggestive of hemolytic disease. ABO incompatibility occurs in approximately 20% to 25% of pregnancies of which significant hemolysis occurs in 10%. G6PD deficiency (X-linked recessive) occurs in African, Mediterranean, and Southeast Asian ethnic groups. In our community, some pediatricians routinely screen for G6PD in males delivered to mothers of high risk ethnic groups (e.g., Filipino).

Prenatal testing includes maternal blood typing and screening for antibodies to major RBC antigens (1). Rh incompatibility occurs with an Rh negative mother (usually not a primigravida) and an Rh positive baby. The routine use of RhoGAM at 28 weeks gestation and following delivery or pregnancy termination is generally effective in preventing maternal Rh sensitization (i.e., the production of anti-Rh antibodies by the mother). An adequate amount of RhoGAM must be given to neutralize the amount of Rh Ag or the volume of blood from a feto-maternal transfusion. Thus, the incidence of Rh isoimmunization and Rh incompatibility is uncommon. The Rh antigen is markedly more antigenic than the A or B antigen. In situations where the maternal blood type and antibody screening results are unknown, an Rh and Coombs test should be performed on the baby's blood (1).

In ABO incompatibility, the mother's blood type is O. More commonly, the babies blood type is A rather than B. Hemolysis in ABO isoimmunization usually has a positive direct antiglobulin testing (DAT), also known as a direct Coombs test. Clinically significant hemolysis is associated with a decreasing hemoglobin, hematocrit and an elevated reticulocyte count. Due to phagocytic removal of antibody and portions of the RBC membrane, the smear in ABO incompatibility may have spherocytes, mimicking spherocytosis. Therefore, a CBC with differential, reticulocyte count and a smear should be requested with suspected hemolysis. Nucleated RBCs may also be present with more severe causes of hemolysis, but is classically associated with Rh incompatibility.

If the baby is at risk for G6PD deficiency or other hemolytic diseases, appropriate testing should be done. When a G6PD level is obtained, it is important to realize that false negatives may occur in the face of active hemolysis because G6PD is increased in nucleated red blood cells.

An evaluation should be done for newborns with feeding intolerance, behavioral changes, hepatosplenomegaly, excessive weight loss, and instability of vital signs regardless of clinical detection of jaundice. Urine that is positive for reducing substances, but negative for glucose is suggestive of galactosemia. Galactosemia, a cause of direct hyperbilirubinemia, is one of the over 30 metabolic disorders included in the expanded newborn screen.

Educating parents about proper infant feeding practices (both breast and bottle), detecting their infant's hydration status, observing changes in behavior, and how to detect and report worsening jaundice, are extremely important anticipatory guidance measures. Parents should also be counseled that jaundice is common, but in rare instances, it can lead to severe morbidity and mortality which is largely preventable. At follow-up, the primary care physician should document the presence/absence of jaundice and/or the serum bilirubin level. The pediatrician's goal is to discharge a functional maternal-infant dyad with early follow up (in 1-2 days) if the infant is discharged from the hospital at less than 48 hours of age. If certain risk factors exist such as blood group incompatibility or prematurity, or if early follow-up cannot be scheduled, discharge should be delayed until after the infant has been monitored for an appropriate period of time. Some of the patients with kernicterus had a bilirubin of less than 25 mg% and did not have predictable risk factors (9). Potential separation of the parent and newborn needs to be minimized and weighed against the risks of hyperbilirubinemia complications. In this community, most mothers are discharged within 48 hours of a vaginal delivery and 3-4 days post C-section. Discharging the mother prior to the newborn can affect bonding and breastfeeding. This needs to be weighed against the risk for significant hyperbilirubinemia and compliance with follow up.

The clinician should be responsive to parents who are concerned about their child's degree of jaundice, feeding frequency or volume, drowsiness, and/or irritability (3). Caution should be used when sending patients home while awaiting lab results. Never presume that a lab value is falsely elevated. Parents should also be counseled to seek medical attention for jaundice that persists beyond 2 weeks of age.

Bhutani developed an hour specific bilirubin nomogram in healthy term and near term newborns with a negative direct Coombs (12). The patient population consisted of term and near-term appropriate for gestational age (AGA) newborns. Total serum bilirubins (TSB) of greater than or equal to 8 mg% at 24 hours, greater than or equal to 14 mg% at 48 hours, and greater than or equal to 16 mg% at 72 hours were above the 95th percentile. A TSB of greater than or equal to 17 mg% during the first week of life was above the 95th percentile. This group is at higher risk for bilirubin-induced neurologic dysfunction (BIND), including kernicterus. Bhutani advocates universal bilirubin screening with early follow up to also catch neonates who may move up from the lower percentiles.

The 1994 AAP Practice parameter (5) is an appropriate guideline for managing jaundice in the healthy term newborn without hemolysis. The guideline has age-based recommendations for therapy. At 25 to 48 hours, phototherapy is recommended at a bilirubin of greater than or equal to 15 mg%. At 49 to 72 hours, the threshold increases to 18 mg%. From greater than 72 hours, the threshold is 20 mg%. If G6PD deficiency or other kernicterus risk factors are present, it is advisable to have a lower threshold to begin phototherapy. The AAP Practice parameter also contains recommendations for exchange transfusion. Table 1 below describes hyperbilirubinemia treatment guidelines for preterm infants. Table 2 below describes hyperbilirubinemia treatment guidelines for term infants.

Table 1 - Suggested Maximum Indirect Serum Bilirubin Concentrations (mg%) in Preterm Infants (10)

Birthweight (g)	Uncomplicated	Complicated*
<1,000	12-13	10-12
1,000-1,250	12-14	10-12
1,251-1,499	14-16	12-14
1,500-1,999	16-20	15-17
2,000-2,500	20-22	18-20

For table 1 above, phototherapy is usually started at 50% to 70% of the maximum indirect levels. If values greatly exceed this level, if phototherapy is unsuccessful in reducing the maximum bilirubin level, or if there are signs of kernicterus, exchange transfusion is indicated. *Complicated cases include those associated with perinatal asphyxia, acidosis, hypoxia, hypothermia, hypoalbuminemia, meningitis, intraventricular hemorrhage, hemolysis, hypoglycemia, or signs of kernicterus (10).

Table 2 - Treatment Strategies for Indirect Hyperbilirubinemia in Healthy Term Infants Without Hemolysis (10)

Age (hrs)	Phototherapy	Intensive phototherapy and preparation for exchange transfusion if phototherapy fails	Exchange transfusion
24-48	15-18	25	20
49-72	18-20	30	25
>72	20	30	25

If the initial bilirubin on presentation is high, intense phototherapy should be initiated and preparation made for exchange transfusion. If the phototherapy fails to reduce the bilirubin level to the levels noted on the column to the right (table 2), an exchange transfusion should be initiated. Intensive phototherapy usually reduces serum bilirubin levels 1 to 2 mg% in 4 to 6 hours. This is often done with IV fluid administration at 1 to 1.5 times maintenance and oral alimentation should continue (10).

Hyperbilirubinemia of the degree noted in the 24-48 hours line of table 2, is unusual and should suggest hemolysis, concealed hemorrhage, or causes of conjugated (direct) hyperbilirubinemia (10).

Jaundice suddenly appearing in the second week of life or continuing beyond the second week of life with significant hyperbilirubinemia levels to warrant therapy should be investigated in detail, as it most probably is due to a serious underlying cause such as biliary atresia, galactosemia, hypothyroidism, or neonatal hepatitis (10).

Supplementing feeds with water or dextrose has been associated with higher bilirubin levels. Use of metalloporphyrins which inhibit bilirubin production has been limited to study trials in newborns. The mainstay of treatment is phototherapy with a wavelength of 450 nm. It induces photoisomerization of bilirubin, forming lumirubin which is water soluble and excreted in the urine. Phototherapy is generally delivered by fluorescent lights, spot lights, or fiberoptics, the latter generating less heat. Unless there is a high risk for an exchange transfusion, phototherapy can usually be discontinued for an hour to allow for neonatal care. Discontinuation of phototherapy in a term baby without hemolysis generally is not associated with rebound hyperbilirubinemia, i.e., a significant increase in bilirubin.

Although phototherapy may be commonly thought of to prevent kernicterus, this is less than accurate, since if the patient is at significant risk of kernicterus, an exchange transfusion should be done. Phototherapy's major role is to avoid an exchange transfusion. By implementing phototherapy, the belief is that this will reduce the likelihood that bilirubin levels will reach these exchange transfusion levels, thus avoiding an exchange transfusion.

In term neonates with hemolytic disease, if the bilirubin approaches 20 mg% despite medical management, informed consent should be obtained for an exchange transfusion. In preterm neonates less than 37 weeks gestation, most neonatologists will await serum bilirubin levels of 15-20 mg% before considering an exchange (11). Exchange transfusion removes bilirubin and antibodies causing hemolysis. Twice the patient's blood volume is exchanged (i.e., double volume exchange) while monitoring cardiovascular stability. Risk factors include those related to catheters, electrolyte imbalance and blood products superimposed onto preexisting medical problems. Thrombocytopenia is common. Necrotizing enterocolitis, graft versus host disease, and death have also been reported as complications of exchange transfusion.

Does phototherapy reduce the need for an exchange transfusion? In ABO incompatibility, prophylactic phototherapy was not shown to be superior to no therapy at all in this regard (13). However, phototherapy intensities have increased since the time of that study and anecdotally, it appears that fewer exchange transfusions are being done, possibly due to more routine use of phototherapy. Additionally, phototherapy appears to be harmless, so its utilization is reasonable to treat moderately high bilirubin levels.

Although extreme bilirubin levels are associated with kernicterus, the adverse effects of moderate hyperbilirubinemia may be more difficult to identify. For example, subclinical adverse effects, learning disabilities or behavioral disorders would be more difficult to causally link to moderate hyperbilirubinemia, since this would only be manifested in later childhood.

Most cases of hyperbilirubinemia resolve without sequelae. However, there may be impairment of auditory nerve conduction (2). After significant hyperbilirubinemia, the patient should undergo auditory brainstem response testing (6).

Questions

1. Which of the following factors leads to neonatal hyperbilirubinemia?
    a. Shortened neonatal red cell life span.
    b. Impaired excretion of unconjugated bilirubin.
    c. Limited conjugation of bilirubin in the liver.
    d. Increased enterohepatic circulation.
    e. All of the above.

2. True/False: Hemoglobin degradation results in the formation of biliverdin and carbon monoxide.

3. A total serum bilirubin >17 mg% in a term neonate is:
    a. physiologic
    b. pathologic

4. In G6PD deficiency, there is hyperbilirubinemia on the basis of:
    a. hemolysis
    b. decreased conjugation
    c. both
    d. neither

5. True/False: In Asians, a variant in UDPGT is associated with neonatal hyperbilirubinemia.

6. True/False: Systemic sulfonamide medications are avoided in the newborn because they displace bilirubin from albumin and increase free bilirubin.

7. True/False: Breast milk jaundice is more common than breast feeding jaundice.

8. True/False: Supplementation of breast feeding with water or dextrose lowers the serum bilirubin.

9. True/False: Discontinuation of phototherapy in a healthy, term neonate is usually associated with rebound hyperbilirubinemia.

10. Which of the following factors should be strongly considered in determining whether an exchange transfusion is indicated in a term neonate with an indirect bilirubin of 21 mg%.
    a. Age of the neonate (time since birth).
    b. Whether the cause is hemolytic or non-hemolytic.
    c. The presence of other clinical factors such as intraventricular hemorrhage or meningitis.
    d. All of the above.
    e. None of the above.

Chapter III.3. Newborn Resuscitation
Sheree Kuo, MD

You are asked to attend an emergent cesarean section delivery of a 40 weeks' gestation infant with non-reassuring heart tones. Mother is a 30 year old gravida 1 married woman who was admitted in active labor four hours ago. She had good prenatal care starting at 6 weeks gestation and her pregnancy has been uncomplicated. Prenatal labs are as follows: blood type A+, antibody negative, rubella immune, VDRL non-reactive, Gonococcus negative, Chlamydia negative, HIV negative, Hepatitis B surface antigen negative, and Group B Strep negative. Prior to delivery, mother received general anesthesia, fentanyl and IV fluids, but no other medications. Membranes are ruptured at the time of delivery revealing bloody amniotic fluid, but no meconium. The obstetrician suspects placental abruption.

At delivery, you receive a floppy, apneic, and blue term male infant. You bring him to the warming table where he is quickly positioned, dried, stimulated and given free-flow oxygen. At 30 seconds of life, he remains apneic and cyanotic. His heart rate is 30 beats per minute. You administer positive pressure ventilation with 100% FiO2 and note good chest wall rise with each positive pressure breath. The infant continues to be apneic and bradycardic with a heart rate of 40 bpm. Chest compressions are begun and positive pressure ventilation is continued. Following 30 seconds of coordinated ventilation and chest compressions, his heart rate is still 40 bpm. You intubate the infant while the nurse draws up 0.1 cc/kg of 1:10,000 concentration of epinephrine to be given via the endotracheal tube. There is no improvement in his heart rate following administration of epinephrine. You then catheterize the umbilical vein and give the second dose of epinephrine intravenously. The infant remains bradycardic. Positive pressure ventilation and chest compressions are continued as you reassess the infant. Good breath sounds are heard bilaterally, but his skin remains pale and mottled and pulses are difficult to palpate. Suspecting hypovolemia, you then administer 10cc/kg of normal saline through the umbilical vein catheter over 5 minutes. The infant's heart rate rises to 150 and his color gradually improves. You check the security of the endotracheal tube and umbilical catheter and prepare for transport to the newborn intensive care unit.

The transition from intrauterine to extrauterine life occurs without incident in approximately 90% of all births. However, 10% of newborns will require some assistance with breathing at birth, while 1% will need extensive resuscitative measures in order to survive. Worldwide, the outcome of more than 1 million newborns per year may be improved with the use of neonatal resuscitative measures.

In utero, the lungs do not perform gas exchange and accordingly, pulmonary blood vessels are markedly constricted. Oxygenated blood flows from the placenta through the umbilical vein to the right heart where the majority of the blood is shunted to the aorta through the foramen ovale and patent ductus arteriosus. Seconds after birth, three major changes occur in the newborn in order to transition to extrauterine life. First, fluid in the alveoli is absorbed into lung tissue and is replaced by air. Next, the umbilical cord is clamped, disconnecting the infant from the low resistance placental circulation and increasing systemic blood pressure. Lastly, the pulmonary vasculature relaxes in response to increased oxygen levels in the lungs causing a dramatic increase in pulmonary blood flow. The right to left shunt through the patent ductus arteriosus decreases, becoming bi-directional and the foramen ovale functionally closes in association with the increase in blood return to the left atrium. Infants who fail to complete the transition to extrauterine life may exhibit cyanosis, bradycardia, hypotension, depressed respiratory drive and/or poor muscle tone (1).

Although it is impossible to consistently predict the need for active newborn resuscitation, many antepartum and intrapartum maternal and obstetrical conditions are associated with increased risk to the newborn. Antepartum risk factors include: maternal diabetes, hypertension (pregnancy induced or chronic), chronic maternal illness, anemia or isoimmunization, previous fetal or neonatal death, bleeding in the second or third trimester, maternal infection, polyhydramnios, oligohydramnios, premature rupture of membranes, post-term gestation, multiple gestation, size-dates discrepancy, maternal drug therapy, maternal substance abuse, fetal malformation, diminished fetal activity, no prenatal care and maternal age <16 or >35 years. Intrapartum risk factors include: emergency cesarean section, forceps or vacuum-assisted delivery, breech or other abnormal presentation, premature labor, precipitous labor, chorioamnionitis, prolonged rupture of membranes, prolonged labor, prolonged second stage of labor, fetal bradycardia, non-reassuring fetal heart rate patterns, use of

general anesthesia, uterine tetany, narcotics administered to mother within 4 hours of delivery, meconium-stained amniotic fluid, prolapsed cord, abruptio placentae, and placenta previa.

A team approach should be applied to all potential newborn resuscitations. Appropriate preparation for an anticipated high-risk delivery requires detailed communication between the mother's caregivers and the newborn resuscitation team. At least one person capable of initiating resuscitation should attend every delivery and be responsible for the care of the infant. Resuscitations involving assisted ventilation and chest compressions require at least two experienced persons. Three or more trained persons would ideally be available for an extensive resuscitation requiring medication administration.

The need for resuscitation should be determined immediately after birth. Most term newborn infants who transition normally to the extrauterine environment (with crying, pink color and good tone) can remain with the mother to receive routine care. Indications for further assessment under a radiant warmer include meconium in the amniotic fluid or on the skin, absent or weak responses, persistent cyanosis and preterm birth. Following this initial assessment, all subsequent assessments are based on the triad of breathing, heart rate and color. Regular respirations are adequate if they can maintain a heart rate of >100 bpm and good (pink) color. Gasping, apnea and central cyanosis generally indicate the need for additional interventions. A newborn's heart rate can be assessed by either auscultating the precordium or counting pulsations through palpation of the base of the umbilical cord. Heart rate should be >100 bpm in the uncompromised newborn. A newborn's color is best determined by examining the face, trunk, and mucous membranes. An uncompromised infant will maintain pink mucous membranes without supplemental oxygen. Cyanosis of the distal extremities or acrocyanosis, is a normal finding at birth and should not be used to determine the need for supplemental oxygen.

For the infant who is not vigorous at delivery, the basic steps in newborn resuscitation include providing warmth, positioning and clearing the airway, drying and stimulating the infant and providing supplemental oxygen as needed. Warming the infant immediately after birth will decrease cold stress and oxygen consumption. This can be done by simply placing the infant under a radiant warmer, quickly drying the skin, removing wet linens and wrapping the infant in pre-warmed blankets. The airway is cleared first by positioning the infant supine or lying on its side with the head in a slightly extended position. If airway secretions are concerning, the infant can be suctioned, mouth first, then nose, with a bulb syringe or suction catheter. Additional stimulation may be provided by gently rubbing the back or flicking the soles of the feet if an infant fails to initiate effective respirations following drying and suctioning. 100% free-flow oxygen should be administered by mask or oxygen tubing to the breathing newly born infant with cyanosis, bradycardia or other signs of distress. These initial steps should be performed during the first 30 seconds of life and the infant should then be reevaluated for breathing, heart rate and color (1,2).

If the infant continues to be apneic, is gasping, has a heart rate of less than 100 bpm and/or has persistent central cyanosis despite 100% free flow oxygen, then positive pressure ventilation with a bag and mask should be administered. Adequate ventilation is the most important and most effective step in cardiopulmonary resuscitation of the compromised newborn infant. Before assisting ventilation with a bag and mask, the proper size mask must be selected, the airway must be clear, and the baby's head should be positioned. The mask should cover both nose and mouth to achieve a tight seal with the face. Noticeable chest wall rise, bilateral breath sounds and improved color and heart rate are indications that ventilation is adequate. Breaths should be delivered at a rate of 40 to 60 per minute. After 30 seconds of proper ventilation, breathing, heart rate and color should be reevaluated. If the baby is breathing spontaneously and the heart rate is greater than 100 bpm, positive pressure ventilation can be stopped. However, if the infant's heart rate is greater than 60, but less than 100 bpm, then positive pressure ventilation must be continued.

If the infant's heart rate remains less than 60 bpm following the initial 30 seconds of positive pressure ventilation, it is likely that blood oxygen levels are low and myocardial contractility (and cardiac output) is poor. Chest compressions must be started and assisted ventilation continued until the myocardium recovers adequate function. Two people are required to administer chest compressions: one to administer compressions and one to continue ventilation. To perform chest compressions, enough pressure is applied to the lower third of the sternum to depress the sternum to a depth of approximately one third of the anterior-posterior diameter of the chest then released to allow the heart to refill. Poor technique may result in liver laceration and/or rib fracture. Three compressions should be administered for every one assisted ventilation so that 90 compressions plus 30 breaths are given each minute. Reevaluation of respiration, heart rate and color should be done after 30 seconds of coordinated ventilation and chest compressions. If the heart rate is above 60 bpm, then chest compressions can be stopped, but assisted ventilation should continue until the heart rate is greater than 100 bpm and there is spontaneous breathing. However, if the infant is not improving, that is, the heart rate remains below 60 bpm despite 30 seconds of well coordinated ventilation and chest compressions, then epinephrine should be given.

Epinephrine is a cardiac stimulant that increases contractility (inotropy) and heart rate (chronotropy) while causing peripheral vasoconstriction (alpha adrenergic effect). The recommended dose is 0.1 to 0.3 ml/kg of a 1:10,000 solution (equal to 0.01 to 0.03 mg/kg). It can be administered through an endotracheal tube for absorption by the lungs into the pulmonary veins, which drain directly into the heart. Alternatively, epinephrine can be given into a catheter placed in the umbilical vein. This route will likely deliver more effective blood levels of the drug, but additional time is required to insert the catheter. Thirty seconds following administration, an increase in heart rate to more than 60 bpm should be observed. If the heart rate remains depressed (<60 bpm) repeat doses of epinephrine may be given every 3 to 5 minutes. In the meantime, good chest movement, equal bilateral breath sounds, and well coordinated chest compressions to an appropriate depth must all be ensured. If the infant displays pallor, poor perfusion and/or there is evidence of blood loss, hypovolemic shock should be considered in the infant who has not responded to resuscitative efforts.

The recommended solution for acutely treating hypovolemia in the newly born infant is normal saline. Alternative acceptable solutions include Ringer's lactate and O-negative blood. Volume expanders must be given intravenously, usually through an umbilical vein catheter, although the intraosseous route can also be used. The initial dose is 10ml/kg given over 5 to 10 minutes. Repeat doses may be needed if large volume blood loss has occurred. If the heart rate is detectable but remains below 60 bpm after administering adequate ventilation, chest compressions, epinephrine, and volume expanders, the possibility of metabolic acidosis should be considered. Moreover, mechanical causes of poor response including airway malformation, pneumothorax, and diaphragmatic hernia or congenital heart disease should also be considered.

If the heart rate remains absent after 15 minutes of resuscitative efforts (establishing an airway, delivering positive pressure ventilation, administering chest compressions, administering epinephrine, addressing the possibilities of hypovolemia, acidosis, congenital airway malformation or congenital heart disease) discontinuation of resuscitation may be appropriate (2).

Apgar scores are commonly recorded as part of the delivery record. Apgar scores of 8 and 9 at 1 and 5 minutes, respectively, are normal. Scores are given as noted in the table below. A one minute Apgar score of 8 is usually due to a zero score for color since truncal cyanosis is still present at one minute. A 5 minute Apgar score of 9 is normal because acrocyanosis of the feet persists for some time past five minutes. Low Apgar scores at five and ten minutes may reflect birth depression and/or need for resuscitation.

Apgar Scoring

Score	0	1	2
Heart rate	Absent	<100	>100
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion	Active motion
Reflex irritability	No response	Grimace	Cough or sneeze
Color	Blue	Extremities blue	Completely pink

Questions

1. What antepartum and intrapartum risk factors are seen in the case presented?
2. Name three major physiologic changes that must occur in the newborn shortly after birth in order to transition to extrauterine life.
3. What three elements of the newborn physical examination are reassessed every 30 seconds during resuscitation until the infant is stable?
4. Ideally, how many caregivers should be available for the resuscitation presented in the case vignette?
5. What is the most important step in cardiopulmonary resuscitation of the compromised newborn infant?
6. What are the indications for beginning assisted ventilation with a bag and mask? At what rate?
7. How can you assess whether or not assisted ventilation is adequate?
8. When should chest compressions be administered? At what rate?
9. What injuries are associated with chest compressions?
10. What is the recommended dose of epinephrine for neonates? By which routes can it be given?

Answers to questions

1. Antepartum risk factors: None. Intrapartum risk factors: emergency cesarean section, non-reassuring fetal heart tones, use of general anesthesia, narcotics administered to mother within 4 hours of delivery, and abruptio placentae.
2. Fluid in alveoli is absorbed and air fills the air sacs, umbilical cord is clamped disconnecting the infant from the placental circulation and pulmonary vasculature must relax allowing increased pulmonary blood flow and decreased right-to-left shunting.
3. Breathing, heart rate and color.
4. Three or more trained persons would ideally be available for an extensive resuscitation requiring medication administration.
5. Ventilation of the lungs is the most important and most effective step in cardiopulmonary resuscitation of the compromised newborn infant.
6. If the infant continues to be apneic, is gasping, has a heart rate of less than 100 bpm and/or has persistent central cyanosis despite 100% free flow oxygen, then positive pressure ventilation with a bag and mask should be administered. Breaths should be delivered at a rate of 40 to 60 per minute.
7. Noticeable chest wall rise, bilateral breath sounds and improved color and heart rate are indications that ventilation is adequate.
8. If the infant's heart rate remains less than 60 bpm following the initial 30 seconds of positive pressure ventilation, chest compressions must be started and assisted ventilation continued. Three compressions should be administered for every one assisted ventilation so that 90 compressions plus 30 breaths are given each minute.
9. Liver laceration and rib fracture.
10. The recommended dose is 0.1 to 0.3 ml/kg of a 1:10,000 solution (equal to 0.01 to 0.03 mg/kg). It can be administered through an endotracheal tube or through an umbilical vein catheter.

Chapter III.4. High Risk Pregnancy
Mary Elaine Patrinos, MD

A 26 year old G1P0, O+, VDRL NR, rubella immune, HBsAg negative female at 27 weeks gestation presents to labor and delivery with a 2 day history of headache and facial swelling. Maternal history is remarkable for a single prenatal visit in the first trimester.

Exam: VS T 37, P 75, RR 14, BP 170/100. Her exam is remarkable for facial and pretibial edema and hyperreflexia.

Labs: Urine dipstick positive for 3+ protein. Ultrasound demonstrates decreased amniotic fluid. The fetus is in the breech position and no fetal abnormalities are noted. Estimated fetal weight is 650 grams.

A decision is made to deliver the infant by cesarean section following maternal treatment with betamethasone.

The risk factors identified in the above scenario include poor prenatal care, severe preeclampsia, prematurity, oligohydramnios, and intrauterine growth restriction. For the pediatrician, detailed knowledge of the maternal and pregnancy history is critical to providing timely and comprehensive care to the infant. Therapeutic interventions are planned based on the neonate's anticipated problems. Appropriate steps in preparing for the delivery of the above infant include: 1) mobilization of the high risk delivery team comprised of a physician (typically a neonatologist), neonatal nurse, and respiratory therapist, 2) notification of neonatal intensive care nursery staff, 3) preparation of exogenous surfactant for treatment of anticipated surfactant deficiency or respiratory distress syndrome (RDS), 4) planning for immediate vascular access to meet the infant's fluid and metabolic needs.

A high risk pregnancy can be defined as any pregnancy where maternal and/or fetal conditions may lead to an adverse perinatal outcome. Preterm labor (PTL) and delivery, premature rupture of membranes, multiple gestation, preeclampsia, diabetes, maternal substance abuse, and vaginal bleeding, are common high risk conditions. A pregnancy may be identified as high risk during the antepartum or intrapartum period. Indeed, lack of, limited, or late prenatal care, in and of itself, is a common high risk condition seen in urban perinatal centers. Screening tests for certain high risk problems such as diabetes, genetic conditions, and congenital anomalies are either routinely or selectively performed during the antepartum period for early recognition and intervention. This chapter will focus on a few of the more common pregnancy complications with an emphasis on neonatal outcome.

Preterm labor is defined as the onset of labor prior to 37 weeks gestation. The World Health Organization defines preterm delivery as a delivery that occurs between 20 and 37 weeks gestational age. Preterm labor is responsible for 40-50% of all preterm births. The remainder of preterm births occur from preterm premature rupture of membranes (PPROM) and maternal medical or obstetrical (maternal and/or fetal) complications (1). Most of the major risk factors for preterm delivery are: African-American ethnicity, socioeconomic status, smoking, substance abuse, poor nutrition, absent or inadequate prenatal care, history of preterm labor/delivery, uterine/cervical anomalies, uterine abnormalities (myomata, DES exposure), hypertension/preeclampsia, diabetes, multiple gestation, oligo- or polyhydramnios, vaginal bleeding, and infection.

After reviewing the list above, it is readily apparent that preterm delivery is the common denominator for many high risk conditions of pregnancy. Timely detection of preterm labor and delivery allows for prompt referral of the mother to a facility where more intensive surveillance, monitoring, and care for both mother and newborn can be accomplished (2).

The pathogenesis of spontaneous, isolated PTL is multifactorial; however, many cases appear to result from occult upper genital tract infections with activation of the decidua. Inflammatory cytokines such as interleukin-1 (IL-1), interleukin 6 (IL-6), and tumor necrosis factor-a (TNFa) have been detected in amniotic fluid in association with intrauterine infection and preterm labor. These cytokines stimulate the production of PGE2 and PGF2a which increase dramatically during labor. Although eliminating or markedly reducing the incidence of PTL seems an impossible goal when considering its multiple causes, ongoing efforts to actively treat PTL remain critical, especially for the patient population less than 32 weeks gestation. Studies assessing prevention methods such as education and surveillance programs and home uterine activity monitoring have demonstrated no benefit in reducing the frequency of preterm birth. Other strategies involved in the treatment of preterm labor are: cervical cerclage, tocolytics (beta sympathomimetics such as terbutaline and ritodrine, magnesium sulfate, prostaglandin synthetase inhibitors such as indomethacin), and antibiotics. Of these, the most frequently used methods at Kapiolani Medical Center for Women and Children are cerclage, terbutaline, magnesium sulfate, and antibiotics. Although it has been difficult to demonstrate the efficacy of tocolytics and antibiotics in clinical trials for preterm labor, these agents may provide a 48 hour latency period during which antenatal corticosteroids can be administered. Maternal and fetal side effects must be considered with the use of any intervention for PTL. Cerclage is generally limited to patients with a history of incompetent cervix. It involves placing a suture circumferentially around the internal cervical os between 12-14 weeks gestation. Maternal risks associated with cerclage placement include the risk of anesthesia, bleeding, infection, rupture of membranes, maternal soft tissue injury, and spontaneous suture displacement. The major risks to the fetus are infection and preterm birth. Terbutaline, the most commonly used beta sympathomimetic, stimulates the beta-2 receptors found in the uterus. Potential fetal side effects of beta-2 agonists include elevation in baseline heart rate, rhythm disturbances, septal hypertrophy, and hypoglycemia. Magnesium sulfate affects uterine activity by decreasing the release of acetylcholine and altering the amount of calcium pumped out of myometrial cells. Respiratory and motor depression can occur in the neonate with high maternal magnesium levels. In general, side effects to the fetus and neonate are minimal when compared to beta sympathomimetics. Given the role of prostaglandins in labor, indomethacin would seem a logical choice for a tocolytic agent. Reported fetal side effects include oligohydramnios secondary to decreased fetal urine output, ductal constriction with the potential for subsequent persistent pulmonary hypertension in the neonate, and necrotizing enterocolitis. The use of indomethacin is restricted to pregnancies at <30-32 weeks gestation and for a treatment period of less than 48 hours. The benefits of antibiotic therapy are best appreciated in relation to PPROM. Ampicillin and erythromycin have been shown to increase the latency period from the time of rupture of membranes to delivery with significant neonatal benefits (1).

The incidence of neonatal mortality and morbidity increases with decreasing gestational age. Although it is outside the scope of this chapter to address the multiple medical, psychosocial, neurodevelopmental and financial problems associated with prematurity, it should be emphasized that the "borderline viable" population of infants (<25 weeks gestational age) remain the greatest challenge. Due to their statistically poor outcomes, the question of whether or not to provide life supportive measures in the delivery room is, ideally, discussed with the prospective parents prior to delivery. The management of these most fragile newborns remains an ongoing area of controversy and debate in neonatal medicine.

Preeclampsia is defined as new onset gestational hypertension with proteinuria, with or without edema. It complicates approximately 8% of pregnancies and is a major cause of maternal and perinatal morbidity and mortality. Uteroplacental ischemia mediated by the renin-angiotensin system is one of the most fundamental abnormalities of this disorder, however, the etiology of

preeclampsia is still unknown. Predisposing factors include primiparity, younger and older age extremes, familial/genetic factors, twin gestation, diabetes, and non-immune hydrops fetalis. The oldest and most effective treatment is delivery. Additional and alternative treatment strategies such as antihypertensives and magnesium sulfate for prevention of seizures are commonly employed especially when the degree of fetal immaturity (balanced with maternal status) precludes immediate delivery. The increase in perinatal morbidity and mortality associated with preeclampsia is largely due to prematurity. Uteroplacental insufficiency and abruptio placenta contribute to poor outcomes (3). Fetal intrauterine growth restriction is a frequent and expected by product of uteroplacental ischemia. Interestingly, despite the increase in fetal growth restriction and prematurity, preeclampsia is associated with a decreased risk of cerebral palsy (4).

Diabetes mellitus is classified as type 1 (lack of insulin production or pre-gestational), type 2 (adult onset, insulin resistance). An elaborate and more detailed classification system for diabetes in pregnancy was developed by Priscilla White and later modified where type A1 is described as gestational diabetes treated with diet, and type A2 requires insulin therapy. Gestational diabetes is defined as carbohydrate intolerance first recognized during pregnancy. It accounts for the majority (80-90%) of the 3-5% of pregnancies complicated by diabetes and is caused by a 60% decrease in peripheral insulin sensitivity (a normal phenomenon in pregnancy), for which some women cannot compensate (i.e., there is a concomitant inability of the pancreas to produce adequate insulin in response to a glucose load). Because this condition is often asymptomatic, screening is indicated between 24 and 28 weeks gestation. Glucose management is strict with the recommendation to maintain levels between 60 and 120 mg/dl. It is well established that tight metabolic control is associated with a marked reduction in the fetal and neonatal complications associated with diabetes in pregnancy listed in the table below:

Fetal and Neonatal Complications of Diabetes in Pregnancy:

A. Congenital Anomalies (Type 1 DM only)
    - Caudal dysplasia (sacral agenesis)
    - Neural tube defects
    - Cardiac anomalies (transposition, VSD, hypertrophic cardiomyopathy)
B. Macrosomia (DM Types 1 and 2)
    - Hypoglycemia
    - Birth trauma
    - Perinatal asphyxia
C. Polyhydramnios (DM Types 1 and 2)
D. Hypoxia (DM Types 1 and 2)
    - Polycythemia
E. Delayed lung maturation (DM Types 1 and 2)

Congenital anomalies in infants of mothers with type 1 diabetes occurs in up to 25% of pregnancies (compared to 2-5% for non-diabetic pregnancies) depending upon the status of glucose control during embryogenesis (the first 8 weeks of pregnancy) (5). Macrosomia occurs in 25%-45% of pregnancies complicated by diabetes which is a direct result of fetal hyperglycemia and hyperinsulinemia. Neonatal management of all infants of diabetic mothers includes a thorough evaluation for birth trauma and congenital defects, screening for and management of hypoglycemia, and close scrutiny of the infant for signs of respiratory distress.

Maternal substance abuse occurs in 5-6% of all pregnancies. This condition presents the greatest clinical challenge to the pediatrician because prevention and treatment strategies are either nonexistent or unsatisfactory. Coexisting problems include sexually transmitted diseases (syphilis, HIV), tuberculosis, hepatitis, preterm labor, and both acute and long term consequences to the newborn. Agent specific neonatal outcomes are frequently confounded by polysubstance abuse, poor nutrition, poor health care and unsatisfactory home environments. In Hawaii, the most commonly abused drugs are alcohol, marijuana, amphetamines, and methamphetamines. Additional substances of abuse include cocaine, heroin, and miscellaneous other agents. As a general rule, the severity and frequency of fetal/neonatal side effects associated with maternal substance abuse is related to timing, dose, and duration of use. Heroin has been one of the best studied and well characterized due to its prolonged existence as an illicit drug. Complications of heroin addiction in pregnancy include an increased incidence of stillbirth, preterm birth, and the delivery of infants who are small for gestational age. Neonatal abstinence syndrome (symptoms of withdrawal) occur in 50%-75% of infants and usually begin within 48 hours after birth and consists of a combination of irritability, jitteriness, coarse tremors, high pitched cry, sneezing, yawning, tachypnea, poor feeding, vomiting, diarrhea, sweating, temperature instability, hyperreflexia, and, occasionally, seizures. A scoring system has been devised using the above symptoms to assist with the management of these infants. Pharmacotherapy for severe withdrawal symptoms include tincture of opium, phenobarbital, and methadone. The use of naloxone is strictly contraindicated as it can lead to acute, severe withdrawal and seizures. Methadone withdrawal seen in infants of mothers under treatment for heroin addiction has many similar characteristics to heroin abstinence syndrome. Methadone is associated with both delayed onset and increased severity of withdrawal symptoms, including seizures.

Fetal alcohol syndrome (FAS) has also been extensively addressed in the literature. Alcohol is a physical and behavioral teratogen (6). Exposure during pregnancy may result in a spectrum of symptoms secondary to varying degrees of insult to the central nervous system. Microcephaly, mild to moderate mental retardation, subtle cognitive and behavioral deficits have all been well described. Additional features of FAS include growth deficiency, short palpebral fissures, hypoplastic philtrum, thin upper lip, micrognathia, cardiac defects and a variety of other anomalies. Acute neonatal withdrawal from alcohol is rare.

No consistent or specific complications have been associated with the use of marijuana in pregnancy. Adverse pregnancy outcomes associated with cocaine abuse include higher incidence of stillbirth, asphyxia, prematurity, and babies with low birth weight and smaller heads. Symptoms of withdrawal are subtle and not well characterized. Breastfeeding is contraindicated as cocaine intoxication has been demonstrated in breast fed infants. Abuse of either amphetamine or methamphetamine during pregnancy is associated with a higher incidence of perinatal mortality, prematurity, and growth deficits. Abnormal central nervous system findings including cystic encephalomalacia and hemorrhage have also been described (6). Selective drug screening of mothers and newborns takes place routinely at most perinatal centers. Decisions regarding who to screen is often related to other perinatal risk factors such as inadequate prenatal care, previous history of substance abuse, high risk clinical signs in the mother (inappropriate or unusual behavior), history of prostitution, history of preterm labor, and presence of sexually transmitted disease(s). Documentation of fetal drug exposure by newborn urine or meconium toxicology screening typically results in referral to child protective services. All too often, these infants are placed in foster care pending rehabilitation of the mother or correction of the potentially harmful home situation.

In summary, there are many high risk conditions of pregnancy that can result in adverse neonatal outcomes, especially prematurity. It is important for the pediatrician to be fully aware of maternal risk factors so that he/she may be fully prepared to receive the newborn in the delivery room and provide ongoing care. Timely recognition of certain high-risk conditions during pregnancy often results in the transfer of the mother and fetus to a facility equipped to provide subspecialty care.

Questions

1. True/False: Preterm labor is defined as the onset of labor prior to 34 weeks gestation.

2. An effective and safe measure for treating preterm labor and delaying preterm delivery is:
    a. Antibiotics
    b. Cerclage
    c. Detection of uterine contractions through the use of home uterine activity monitoring
    d. Magnesium sulfate therapy

3. The most widely accepted explanation for the onset of preterm labor is
    a. Adrenal cortical suppression
    b. Decidual activation and inflammatory cytokines
    c. Increased levels of serum oxytocin
    d. Premature, idiopathic activation of the normal labor process

4. True/False: Preeclampsia is a complication of pregnancy associated with hypertension and proteinuria.

5. Which of the following is not a predisposing factor for preeclampsia
    a. Age
    b. Cigarette smoking
    c. Diabetes
    d. Twins

6. True/False: Naloxone is the treatment of choice for drug withdrawal in methadone addicted newborns.

Chapter III.5. Common Problems of the Premature Infant
Venkataraman Balaraman, MBBS

This is a 1300 gram male born via normal spontaneous vaginal delivery at 30 weeks gestation to a 25 year old. G3P2 mother with a history of incompetent cervix. The mother was hospitalized at 27 weeks gestation due to cervical changes and received 2 doses of betamethasone two weeks prior to delivery. At delivery, the infant was noted to have a lusty cry. Apgar scores were 6 and 6 at one and five minutes, respectively due to poor respiratory effort, decreased tone and decreased response to stimulation. He is transported to the neonatal intensive care unit on blow-by oxygen and on admission, he is placed on nasal continuous positive airway pressure (CPAP) of 10 with an FiO2 of 0.3 (30%).

Exam: VS T36, HR 140, RR 50, BP 45/30 (mean of 38), oxygen saturation 96%. Weight 1300 gm (50th percentile), length 40 cm (50th percentile), HC 28 cm (50th percentile). His head is normocephalic with minimal molding and overlapping sutures. There are no craniofacial or oropharyngeal anomalies noted. There is fair aeration over both lung fields with clear breath sounds. He has a normal precordium and a grade 2/6 holosystolic murmur at the upper left sternal border. His pulses are equal, 2+ in strength with no radiofemoral delay. His capillary refill is 2 seconds. He has decreased tone but he responds well to stimulation and he has normal age appropriate reflexes

A chest x-ray demonstrates a normal heart size, lungs expanded to 9 ribs, and clear lung fields. On DOL (day of life) 2, the infant is taken off CPAP and placed in room air. A percutaneous central venous line is placed to provide parenteral nutrition. He is also started on small feedings of mothers' breast milk/colostrums. Thermal support is provided by an isolette. The following day he is noted to have several episodes of apnea and bradycardia. These resolve with nasal CPAP. Caffeine citrate is also started to stimulate his respiratory effort. Because of a persistent heart murmur, an echocardiogram is performed which reveals a moderate to large patent ductus arteriosus with normal cardiac anatomy and function. He is not treated for this initially since he is not exhibiting signs of congestive heart failure. Phototherapy is also started for a serum bilirubin of 12 mg/dl. A head ultrasound, done at one week of age, reveals bilateral grade I-II intraventricular hemorrhages. He continues on parenteral nutrition but his feedings had to be discontinued due to abdominal distention and the presence of excessive residual breast milk noted in a gastric aspirate obtained just prior to his next feeding. By DOL 28, the infant, now 34 weeks adjusted age, is receiving full enteral feedings of breast milk and is occasionally breast fed by his mother. A routine eye exam is performed to screen for retinopathy of prematurity. He is found to have incomplete retinal vascularization to Zone 3 in both eyes. The ophthalmologist recommends follow-up in 2-3 weeks. His hemoglobin level is 10 g/dL and he is started on supplemental iron.

Prematurity is defined as birth prior to 37 completed weeks of gestation. Although, the rate of premature birth appears to vary by geographic region, the reported incidence varies between 6 and 10%. Despite significant improvements in perinatal care, there has not been a concomitant reduction in the rate of premature births in developed countries.

Prematurity and its associated problems are major contributors to the morbidity and mortality in the first year of life (which is reflected in the infant mortality rate).

Neonatal transition is the process involved in physiologic adaptation of the fetus to extrauterine life. Premature babies are at higher risk for slower transition to neonatal life due to immaturity of organ systems and lack of body mass. Premature (also called preterm) infants generally do not tolerate labor as well as term infants. This leads to a higher incidence of low Apgar scores and need for resuscitation in the delivery room.

Preterm infants have significant problems related to thermoregulation. Significant thermal stress may occur as they transition at birth from the in-utero fluid-filled environment supported by mother to the relatively cool air-filled environment of the delivery room. This can be avoided by providing exogenous heat with a radiant warmer during transition and minimizing heat loss by drying them quickly (evaporation of amniotic fluid on the skin is a potential cause of significant heat loss).

These infants are at risk for hypoglycemia because of limited glycogen stores and relatively immature glucose homeostatic mechanisms. It is important, therefore, to provide them with either a constant infusion of glucose solution intravenously, or early adequate enteral nutrition or both, depending on the baby's gestational age and degree of illness.

Respiratory problems are among the most common and important conditions related to prematurity. The immaturity of surfactant systems leads to respiratory distress syndrome (RDS).

Another common factor leading to respiratory difficulties is the relative compliance of the total respiratory system (chest wall, lung parenchyma and airways). Since the bony thorax that assists in the process of respiration is not fully developed (abnormally increased compliance) and the lung is often surfactant deficient (abnormally decreased compliance), the premature infant has increased work of breathing to maintain adequate functional residual capacity and tidal volume. This may lead to fatigue and respiratory failure in the smallest of infants. This problem often necessitates either endotracheal intubation and mechanical ventilation, or continuous positive pressure support to the airways and chest wall in the form of nasal CPAP via nasal prongs.

An additional factor is the incomplete development of the lungs (respiratory immaturity or immature lung disease). Alveolar development is not complete until several years of life. Immature lungs are at increased risk for long term injury. Some of the risk factors contributing to this injury include positive pressure/ventilator support (barotrauma), oxygen (oxygen toxicity), infections, and aspiration.

The gastrointestinal tract, especially with respect to the digestive enzymes and absorptive surfaces, is relatively well developed in premature infants. This is in contrast to the external muscular layer and neural control which is relatively less developed. Considering these factors, the inability of the GI tract to fully support the nutritional needs of the premature infant is related to volume (the total volume capacity of the system is low) and peristalsis (incomplete development of the neuromuscular components of the GI tract). The caloric intake required for the preterm infant to approach intrauterine growth rates is in the range of 120 to 150 Kcal/kg/d. These values are typically met by the 7th to 10th DOL Typically, a combination of enteral feeding and parenteral nutrition is necessary to achieve nutritional goals. Enteral feedings are often started at volumes of 10-20 cc/kg/d and advanced daily at increments of the same value. Thus, the majority of premature infants are at total enteral feedings within the first three weeks of life. Enteral feeds may consist of either with breast milk (ideally) or commercially available premature infant formula when breast milk is not available or contraindicated. Parenteral nutrition is comprised of a mixture of dextrose (carbohydrates), amino acids (proteins) and intralipids (fat) along with electrolyte additives and multi-vitamin supplements. Electrolyte and other mineral requirements (calcium, phosphorus, iron, zinc etc.) are higher for preterm infants because the body stores for these are significantly lower (the fetus builds up body stores primarily in the third trimester of pregnancy). Specially prepared formulas for preterm infants also contain additional amounts of calcium, phosphorus, and vitamins.

Necrotizing enterocolitis is a unique GI disorder related to prematurity and characterized by inflammation and necrosis of the intestinal tract. The ileum, cecum, or colon may be involved. The etiology is multifactorial. Risk factors include systemic infection, rapid advance of enteral nutrition, decreased intestinal blood flow (relative ischemia), the presence of catheters in umbilical vessels, and poor gut motility. The pathology consists of pneumatosis intestinalis (air dissecting within the bowel wall) and areas of bowel wall necrosis, occasionally leading to frank perforation. Perforation presents clinically with pneumoperitoneum, peritonitis, abdominal wall discoloration, and/or portal venous air. Management of this condition is primarily directed towards providing gut rest (NPO status), medical supportive measures (respiratory support, parenteral nutrition, intravascular volume, antibiotics), and surgical management in the case of perforation. Infants with NEC are at increased risk for intestinal strictures later in life.

Premature infants are not able to regulate their body temperatures as well as term infants. Factors that contribute to this problem are immaturity of the hypothalamic regulatory center, lack of subcutaneous fat (insulation shield), lack of brown fat (allows for thermogenesis in adverse climatic environmental conditions) and a relatively large body surface area to body mass ratio.

Typically, temperature control is maintained by providing an external heat source (radiant warmers or incubators/isolettes). These sources are set to provide heat to maintain a neutral thermal environment. In this environment, the infant has minimal energy expenditure to maintain core body temperature.

The majority of premature infants are able to regulate their body temperatures by a post conceptional age of 34 weeks. However, they remain at continued risk for poor thermal regulation at the extremes of environmental temperature. Parents should be appropriately counseled and encouraged to avoid subjecting their infant to temperature extremes.

The occurrence of physiologic jaundice in otherwise healthy term newborn infants is well recognized. Similar factors are associated with jaundice in the premature infant. These factors include a larger red cell mass at birth, shorter red cell half life, immaturity of liver enzyme systems, and poor gut motility promoting increased enterohepatic circulation. In contrast to term infants, physiologic jaundice in the premature infant tends to be visible earlier (1-2 days of age), peaks later (5-7 days of age) and may take up to two weeks to completely resolve. Whether premature infants are at greater risk for bilirubin neurotoxicity is unclear. It is well known that the potential for bilirubin neurotoxicity is increased in the presence of other associated medical conditions such as hemolysis, acidosis, respiratory failure, infections, and intraventricular hemorrhage. In the absence of such complications, there appears to be no evidence to suggest that bilirubin is more neurotoxic to the premature brain.

The most common cardiovascular problem in premature infants is the persistence of the ductus arteriosus. This vital in-utero communication pathway is programmed to close shortly after birth in term infants. This normal transition occurs less efficiently in the premature infant and the rate of spontaneous closure in inversely proportional to the degree of prematurity.

As the body systems go through other post-natal adaptations, the persistence of the ductus leads to significant problems including poor lung function related to increased pulmonary blood flow, ductal steal phenomenon leading to decreased systemic blood flow, and high output cardiac failure. Clinically, infants may present with a varied constellation of signs and symptoms that, in addition to a systolic murmur heard best at the left upper sternal border, include tachycardia, active precordium, bounding pulses, and cardiomegaly with pulmonary congestion on chest x-ray. Patent ductus arteriosus can be managed medically by using fluid restriction and indomethacin (prostaglandin inhibitor) therapy or surgically, by ductal ligation.

The germinal matrix is a unique vascular bed that is present in the region of the choroid plexus during development. Generally, this vascular system regresses completely by 32 weeks gestation. In infants born prior to 32 weeks gestation, this area is prone to vascular accidents that can lead to intraventricular hemorrhage. As is the general rule, the risk for more severe bleeding is inversely proportional to gestational age. One of the most important factors predisposing to hemorrhage in this area is hypoxic-ischemic injury. This type of intracranial hemorrhage tends to occur within the first week of life. Intraventricular hemorrhages are graded between 1 and 4 based on the extent of the hemorrhage, associated ventricular dilatation and associated parenchymal injury/infarction. Generally, Grade 1 and 2 lesions are compatible with near normal neurological outcomes while the long term neurological prognosis associated with Grade 3 and 4 lesions are more guarded.

Periventricular leukomalacia (PVL) is another manifestation of hypoxic-ischemic brain injury. It appears later than germinal matrix hemorrhages (GMH) described above. The lesions of periventricular leukomalacia are visualized as discrete cystic lesions in the periventricular white matter on cranial ultrasound. They appear primarily in the frontal and motor areas of the cerebral cortex.

All infants with the diagnosis of GMH or PVL need close neurodevelopmental follow up. They may need an early intervention program as deficits are identified. With timely developmental intervention, there is evidence that neurodevelopmental outcomes can be improved.

Apnea of prematurity is another physiologic entity that can complicate the clinical course of premature infants, especially those <34 weeks gestation. It is, in large part, related to the immaturity of the central respiratory center. By definition, apnea is the cessation of air flow/exchange. Apnea is often associated with bradycardia and hypoxemia. The majority of apnea events in premature infants are typically mixed (central and obstructive) in origin. The airway obstruction is usually the result of upper airway collapse or laryngeal closure. The response of the respiratory system to chemical stimuli (the primary process by which the respiratory center controls respirations) can be modulated by methylxanthines. The most commonly used drug to treat apnea of prematurity (AOP) is caffeine. This drug has been shown to reduce the severity and frequency of central apnea and periodic breathing in premature infants. In addition, caffeine toxicity is rare.

Retinal vascularization is incomplete until the completion of 32 weeks gestation. Thus, for infants born prior to this gestation, there is a risk of abnormal vascularization of the retina leading to retinopathy of prematurity (ROP). This is a disorder of angiogenesis that could potentially lead to blindness secondary to retinal detachment. The classification of ROP is based both, on the severity of the vascular disease, and the zone of the retina that is affected. The American Academy of Pediatrics and the American Academy of Ophthalmologists have jointly recommended a schedule for screening high risk premature infants for this disorder. Later on in life, prematurely born infants are at higher risk for refractive errors and, therefore, need to be closely monitored. It is recommended that they have a comprehensive ophthalmologic examination at 6 months to one year of age.

Premature infants are at the same risk for developing anemia of infancy as are term infants. This physiologic process occurs generally between the ages of 6 to 12 weeks. In addition, premature infants are at higher risk for protracted anemia, because they are born with lower body iron stores. This situation is further compounded by significant phlebotomy losses in the neonatal period related to hospitalization after birth. Anemia of prematurity may at least partially be overcome by the use of erythropoietin, which is used to stimulate erythropoiesis. Nevertheless, it is important to replenish the body's iron stores and the provision of supplemental iron is critical until the hemoglobin levels reach normal values for age. In this respect, the iron supplementation during therapy should be at the levels used in the treatment of anemia at any other age (up to 6 mg/kg/d of elemental iron).

Premature infants are at higher risk for infections. This risk is multifactorial. The primary source of immunity for the neonate is passively derived antibodies from the mother and this tends to occur primarily in the third trimester. Thus, the relative amount of antibody transferred is affected by the duration of gestation. Additionally, a significant proportion of premature infants who are hospitalized in intensive care units, require interventions such as IV therapy, and placement of central vascular catheters for providing nutrition, and invasive monitoring. All of these factors contribute to the increased risk of infections in this population. Premature infants present with nonspecific signs and symptoms of infection. This mandates close monitoring for infectious complications, both during hospitalization, in the immediate neonatal period, and in subsequent months during the first year of life.

Given their propensity for infections, the American Academy of Pediatrics recommends that all childhood immunizations be administered to premature infants at the appropriate chronological age. The only exception to this rule is the hepatitis B immunization, which should be initiated only after the infant's weight exceeds 2 kg. Despite lower titers of antibody response in these infants, there is no recommendation for additional doses of specific immunizations.

Passive prophylaxis for respiratory syncytial virus (RSV) infection is currently recommended during the cooler winter months for certain premature infants at highest risk for serious complications from RSV. These guidelines are evolving. The most current recommendation is published in the Red Book 2003 of the American Academy of Pediatrics. These infants will also benefit from receiving influenza immunization at 6 months chronological age during the cooler winter months (3).

The premature infant is ready for discharge when he/she is able to fulfill the following criteria: 1) ability to appropriately regulate their temperature without the need for technological support, 2) ability to ingest adequate calories to achieve consistent growth, and 3) to have demonstrated other parameters of global physiologic stability (the absence of clinically significant apnea, bradycardia, or hypoxemia). In addition, and most importantly, it is critical that the parents/caregivers feel comfortable with the care of the infant in the home environment. One of the issues that may alleviate some of the parental anxiety is training in infant CPR. Thus, the process of discharge of the infant is a continuum that begins several days to weeks prior to the actual discharge of the infant. Many of these infants will have additional needs and it is important that all of these needs and appropriate community resources are identified prior to discharge. At the time of discharge, the routine mandated screening for hearing and metabolic diseases should be completed with the results forwarded to the primary care physician.

The long term outcome of premature infants is inversely related to gestational age (better outcomes in older infants), and directly related to the clinical course in the neonatal period, and the associated morbidities and diagnoses during their hospitalization. In general, these infants need close neurodevelopmental monitoring and early interventions for identified problems. They are at increased risk for repeated hospitalization for various residual problems of prematurity such as bronchopulmonary dysplasia, failure to thrive, and feeding problems. Developmental outcome is also related to the home environment and the ability of the family to properly nurture the infant. Unfortunately, the stress associated with parenting a high-risk infant often leads to dysfunctional family dynamics. In addition, these infants are frequently born into families who are already high-risk. On a positive note, if an optimal nurturing environment is provided, there is evidence to suggest that it can result in a significant improvement in overall long term outcome.

Questions

1. True/False: Morbidity associated with prematurity is a significant contributor to the infant mortality rate.

2. Strategies to reduce thermal stress at birth should include (mark all correct answers):
    a. Keeping the delivery room warm and performing the stabilization under a preheated radiant warmer.
    b. Drying the infant and then wrapping them up with the same blanket.
    c. In a stable premature infant allowing skin to skin bonding with the mother.

3. Premature infants are at higher risk for hypoglycemia because (choose one):
    a. They are born with adequate glycogen stores but have immature homeostatic mechanisms to mobilize glucose.
    b. They are born with inadequate glycogen stores but have mature homeostatic mechanisms to mobilize glucose.
    c. They are born with inadequate glycogen stores and have immature homeostatic mechanisms to mobilize glucose.

4. Respiratory Problems in premature infants may be secondary to (choose one):
    a. Surfactant deficiency
    b. Increased chest wall compliance
    c. Incomplete alveolar development
    d. All of the above.

5. Feeding difficulties in premature infants are usually secondary to (choose one):
    a. Immature development of the intestinal enzyme systems.
    b. Immature neuromuscular development of the intestinal tract.

6. In contrast to term infants, the following statements are true regarding physiologic jaundice in the premature infant in the neonatal period (choose one):
    a. Has its onset later, reaches its peak later and has slower resolution.
    b. Has its onset earlier, peaks earlier and has earlier resolution.
    c. Has its onset earlier, peaks later and has slower resolution.

7. The following statements regarding the persistence of ductus arteriosus are true in the premature infant (choose one):
    a. Is one of the most common cardiovascular dysfunction.
    b. May be asymptomatic and spontaneously resolve in many.
    c. Can be treated with medications.
    d. All of the above.

8. Hypoxic-Ischemic brain injury can lead to (choose one):
    a. Germinal matrix hemorrhage/intraventricular hemorrhage
    b. Periventricular leukomalacia
    c. Both
    d. None

9. Apnea events in premature infants are usually (choose one):
    a. Central because of immaturity of the brain respiratory center.
    b. Obstructive secondary to collapse of the upper airway structures and closure of the glottis.
    c. Neither a or b.
    d. Both a and b.

10. In premature infants, routine immunizations should be (choose one):
    a. Administered at a post-conceptual age of two months.
    b. Administered at a post-natal age of two months.

11. True/False: The weight of the premature infant is an absolute criterion for discharge from the hospital.

Chapter III.6. Respiratory Distress in the Newborn

Daniel T. Murai, MD

A 2 hour old, 38 week gestation, 3 kg male infant was born to a 25 year old G1P1 A+, VDRL negative, Hepatitis B negative, GBS unscreened, Rubella immune, woman who had an uncomplicated pregnancy, labor and delivery. Apgar scores were 9/9. He was sent to the newborn nursery. He breast fed 1 hour ago without concerns. He now presents with respiratory distress.

Exam: VS T 37, HR 160, RR 80, BP 60/35 (mean 45), oxygen saturation 95% in 2 L/min oxygen via mask. Wt 3kg (50%), Lt 48cm (50%), HC 33.5 cm (50%). He is a term male with obvious respiratory distress and tachypnea. Skin is pale and pink without petechiae, ecchymoses, or lesions. His head is normocephalic with molding. His anterior fontanel is flat. His face is symmetrical with normal palpebral fissures, normal red reflexes, patent nares, normal ears, no clefts, and no neck masses. His chest is symmetric with equal and clear breath sounds. Mild to moderate chest retractions are present. Heart is regular with a normal S1, split S2, and no murmurs. His pulses are normal. His abdomen is soft and round with normal bowel sounds, no masses and no organomegaly. He has normal male genitalia with descended testes. His hips and anus are normal. He has mild hypotonia.

Laboratory results: CBC: WBC 15,000, 8% bands, 50% segs, 40% lymphs, 2% monos, Hct 55%, Plt 250,000. No toxic granulations or vacuoles of the neutrophils are noted. ABG: pH 7.35, PCO2 55 torr, PO2 70 torr, BE -7 in a 30% oxygen hood. CXR: 10 ribs of inflation, streaky linear perihilar densities, and small scattered patchy densities bilaterally.

Over the next several hours, the infant develops progressively more distress and a greater oxygen requirement. He is sent to the newborn special care nursery with worsening tachypnea (RR 90), more retractions and grunting. He is now in 50% O2 by hood.

What is your differential diagnoses? How would you manage this infant?

This chapter will cover the common problems which cause respiratory distress in the newborn within the first week of life. Based on the clinical presentation, onset and gestational age, the most likely diagnosis can be determined.

Respiratory distress is one of the most common presenting problems of newborns. The constellation of signs and symptoms can be the result of pulmonary, cardiac, metabolic, infectious, renal, gastroenterological and neurologic pathologic processes. Newborns with disorders involving any one of these organ systems may present with varying degrees of tachypnea, retractions, grunting, cyanosis, lethargy and tachycardia. Given the similar presentations, the circumstances of the newborn's birth provide important clues to the diagnosis.

Transient tachypnea of the newborn (TTN) is the most common respiratory disorder of the newborn. These infants are usually full term or slightly preterm. They are not at risk for other illnesses. Some infants are delivered by cesarean section; some without labor. The most significant discriminatory findings are the onset of the illness and the degree of distress exhibited by the infant. Typically, the infant becomes tachypneic immediately after birth and has mild respiratory distress. They are neurologically normal. If followed closely, infants remain stable for several hours and/or begin to improve. The chest radiographs reveal hyperinflation with clear lung parenchyma except

for perihilar linear densities and fluid in the fissures. There should be no areas of consolidation . The pathophysiological mechanism is the delayed resorption of fetal lung fluid which eventually clears over the next several hours to days. A worsening clinical picture should suggest another diagnosis. Treatment is generally close observation and symptomatic care. Low flow supplemental oxygen may be necessary for several hours.

Meconium in the amniotic fluid occurs in approximately 20% of pregnancies. As a consequence, meconium aspiration is considered to be a relatively common event. Other substances such as blood or amniotic fluid can also be aspirated. Infants with this disorder typically have symptoms similar to infants with TTN, but the presentation may suggest a more severe condition. In addition, while many infants have the onset of symptoms at birth, some infants have an asymptomatic period of several hours before respiratory distress becomes apparent. Infants with aspiration syndromes may require more oxygen, and have greater degrees of tachypnea, retractions and lethargy. The arterial blood gases may reveal more acidosis, hypercapnia and hypoxemia than in infants with TTN. The chest radiographs vary between that of TTN with hyperinflation and perihilar infiltrates to significant heterogeneous lung disease with hyperinflated and hypoinflated areas, patchy and linear infiltrates and atelectasis.

The pathophysiologic mechanism is the obstruction of large and small airways with the aspirated material (meconium, blood, amniotic fluid contents). Pulmonary hypertension may be develop when meconium aspiration occurs in conjunction with varying degrees of in utero asphyxia. Pulmonary hypertension, which often results from hypertrophic pulmonary vascular muscular tissue, is a severe condition characterized by cyanosis from right to left shunting across the atrial septum and patent ductus arteriosus. As the disease process progresses, the symptoms and severity of hypoxemia increase over the subsequent hours. While TTN is in the differential diagnoses initially, this progression should alert the clinician to another diagnosis such as an aspiration syndrome, pulmonary hypertension or infection. Treatment may include supplemental oxygen, mechanical ventilation and specific treatment for pulmonary hypertension, which includes high supplemental oxygen, high frequency mechanical ventilation, inhaled nitric oxide therapy and in the most severe cases, extracorporeal membrane oxygenation therapy (ECMO).

The duration of distress with mild to moderate aspiration syndromes is from several hours to days. Aspiration can occur in utero or during the intrapartum period as well as during the early postpartum period. Since meconium aspiration is the most common problem, much effort has been made over the last 30 years to prevent this disease by reducing intrapartum and postpartum aspiration. Thorough suctioning of the oropharynx with a large bore catheter upon the delivery of the head is typically performed by the obstetrician. The pediatrician, needs to assess the quality of the meconium (thin, moderate or thick) and the state of the newborn before determining what is needed after birth. A large randomized trial has confirmed that aggressive intubation is not necessary for most infants with meconium in the amniotic fluid. The recommendations provided by the NRP (Neonatal Resuscitation Program) are to suction the oropharynx of all infants after the delivery of the head and to intubate and suction the trachea of any infant with meconium in the amniotic fluid, if the infant is depressed (weak. respiratory effort, hypotonia and/or bradycardia).

The sudden onset of significant respiratory distress should raise the possibility of an air leak syndrome. The most common air leak syndromes are pneumomediastinum, pneumothorax and pneumopericardium. In addition to respiratory distress, a severe air leak condition may cause hypotension (due to decreases in cardiac output), muffled heart tones, abdominal distention, asymmetric chest shape and deviation of the cardiac sounds. Chest radiographs are diagnostic with free air in the hemithorax and a visible edge of the collapsed lung. If under tension (i.e., a tension pneumothorax), clinical deterioration will be rapid, the mediastinum will be deviated to the opposite (contralateral) side and the ipsilateral diaphragm will be depressed. The elevation of the thymus with a sail or bat wing sign suggests a pneumomediastinum. The heart is outlined with a halo of air in a pneumopericardium. Hypotension and bradycardia occur rapidly in a tension pneumothorax or pneumopericardium (cardiac dysfunction is due to reduced venous return due to compression of the heart and mediastinal vascular structures). The air leak syndrome known as pulmonary interstitial emphysema (PIE) is usually observed as a consequence of mechanical ventilation in an infant with severe respiratory distress syndrome.

Treatment of significant air leak syndromes requires immediate air evacuation (thoracentesis or pericardiocentesis) with a needle or small catheter, followed by chest or pericardial tube insertion. Pneumomediastinum does not require drainage. In cases other than a bronchopleural fistula, the air leak will usually seal within a few days.

Respiratory distress syndrome (RDS) is the most common disorder of the premature infant. Most infants are less than 34 weeks gestation and the incidence and severity increase with decreasing gestation age. These premature infants have progressively more severe respiratory distress after birth. The classic findings of cyanosis, grunting, nasal flaring, intercostal and subcostal retractions and tachypnea are present. The chest radiograph reveals decreased lung inflation with diffuse symmetrical reticulogranular (ground glass appearance) lung fields and air bronchograms. Oxygen requirements progressively increase over the first few hours after birth. The presence of apnea suggests severe disease accompanied by refractory hypoxemia and acidosis.

While the lung's structural immaturity contributes to the pulmonary dysfunction, the major reason for this disorder is surfactant deficiency. Without surfactant, the surface tension of the alveolar sacs is high, leading to an increased tendency of the alveoli to collapse. Laplace's law describes the behavior of the alveoli without surfactant. This relationship states that as the radius of the air filled alveolus decreases, the pressure within the alveolus increases. This increased pressure requires an equivalent external opposing pressure to keep the alveolus inflated. Without the opposing pressure, the gas under this pressure is forced out of the alveolus. If the alveolus is connected to an adjacent alveolus with a larger radius, air will preferentially inflate the larger alveolus and ultimately collapse the smaller alveolus. This leads to the network of air-filled alveoli juxtaposed to atelectatic alveoli and creates the reticulogranular pattern (ground glass appearance) of the lung. The air bronchograms are created by atelectatic alveoli outlining the adjacent rigidly distended airways. Air filled right and left mainstem bronchi are not visible if they are superimposed over air filled lungs, but when they are superimposed over partially collapsed, fluid filled lungs (as in RDS), the air filled bronchi are visible as air bronchograms. Grunting is the infant's attempt to maintain the pressures and gas volume within the lung by causing expiratory braking using the vocal cords (the glottis is partially closed during exhalation to maintain alveolar distending pressure during exhalation). Surfactant reverses this process. The phospholipids and surfactant related proteins, contained in surfactant, spread along the air liquid interface to decrease alveolar surface tension. Therefore the pressure required to keep the alveoli inflated is lower. Furthermore, the surfactant molecules contribute to the larger alveoli developing a higher surface tension during inspiration and a lower surface tension (as the alveoli deflate) during expiration when the surfactant molecules become more compact along the air liquid interface.

The treatment of RDS generally includes positive pressure ventilation and artificial surfactant replacement. The first purely synthetic surfactant is no longer available. Today, several types of animal based surfactants have been approved for clinical use. After endotracheal intubation, surfactant suspension is administered through the endotracheal (ET) tube and the infant is supported, until extubation is possible, with positive pressure ventilation and continuous positive airway pressure (CPAP) therapy as needed. High frequency ventilation has been shown to improve the short term management of these infants.

Moderately premature infants (29 to 34 weeks gestation) are usually extubated within several days after treatment. However, extremely premature infants (23 to 28 weeks gestation) may continue to require positive pressure respiratory support for several weeks. They are at high risk for bronchopulmonary dysplasia or chronic respiratory insufficiency of the premature. Bronchopulmonary dysplasia is the chronic lung disease consequence of early acute lung disease and/or lung immaturity of the premature infant. Chronic respiratory insufficiency of the premature develops despite early improvement after surfactant therapy and mechanical ventilation.

Infectious pneumonia in newborns is relatively rare. However, premature infants have at least a 10 fold increased incidence of infections when compared to term infants. Mothers with intrapartum fever and prolonged rupture of membranes (>18-24 hours) have a greater risk of transmitting infections to their infants. This risk can be reduced by administering intrapartum antibiotics for mothers with high risk pregnancies or women who are group B Streptococcus (GBS) carriers. However, the use of ampicillin for the GBS infections has increased the incidence of ampicillin resistant coliform infections. The most common bacterial organisms which infect neonates are the GBS, coliforms (E. coli being the most common member of this group), and Listeria monocytogenes. Infected infants present either immediately after birth with respiratory distress or they may present after several hours of an asymptomatic period. The degree of respiratory distress initially may mimic any respiratory disorder. Infants may have fevers or become hypothermic. The symptoms progressively increase in severity and if not treated may lead to shock, DIC and death. Due to the serious consequences associated with delays in treatment for infections, many infants with non-infectious conditions are evaluated and empirically treated with antibiotics for this possibility. The chest radiographs may resemble RDS (with reticulogranular infiltrates and air bronchograms), TTN or aspiration syndromes (with linear or patchy densities). It is unusual to have lobar consolidation from infection in the newborn. A term infant with RDS should be considered to have pneumonia until proven otherwise. The CBC may reveal either a leukocytosis or leukopenia. A left shift with greater than 20% band forms of the total neutrophils is suggestive of infection as are neutrophilic vacuoles and toxic granulation. Platelet counts may be normal or decreased. In severe cases, a coagulopathy with elevated PT and PTT and depressed fibrinogen levels may be present. The gold standard still remains the blood culture or culture of lung and tracheal secretions. Treatment with an aminoglycoside and penicillin is standard to treat for the common organisms. Supportive care may include mechanical ventilation, supplemental oxygen, inotropic agents for hypotension and nitric oxide for infection associated pulmonary hypertension. The mortality from infections has decreased from 50% to 20% with more aggressive intensive care.

Some congenital malformations of the cardiopulmonary system will be addressed here. The first is the infant with cyanotic heart disease. Most infants with transposition of the great arteries, tetralogy of Fallot and hypoplastic right and left heart syndromes, will present in the newborn period. Most infants with cyanotic heart disease typically have a paucity of respiratory distress symptoms except for cyanosis or duskiness. A murmur is usually present, but may be absent. Typically the chest radiograph reveals a normal sized heart or cardiomegaly with clear lung fields and decreased vascular markings (due to diminished pulmonary blood flow). When the infant develops respiratory symptoms, it is usually from severe hypoxemia or acidosis. The infant who is cyanotic with respiratory distress and does not respond to supplemental oxygen (i.e., their oxygen saturation does not improve significantly when given supplemental oxygen). Infants with both cyanosis and respiratory distress may have chest radiographs typical of pulmonary disease. The hyperoxy test (measuring the arterial pO2 while the infant is breathing 100% oxygen) is helpful in distinguishing cyanotic heart disease from severe respiratory disease. The echocardiogram is also diagnostic and will distinguish between cyanotic heart disease and persistent pulmonary hypertension.

Therapy for cyanotic heart disease consists of medical support until definitive surgical repair can take place. In many instances, patency of the ductus arteriosus is necessary to maintain mixing of pulmonary and systemic circulations. This is accomplished with an intravenous infusion of prostaglandin E1 infusions. Later, an artificial shunt is created from the aorta to the pulmonary arteries. Moderate oxygen supplementation to keep oxygen saturations approximately 80% or higher and mild acidosis to maintain a fetal type circulation is attempted to preserve pulmonary function. Multistaged open heart surgery may be necessary for most complex cyanotic heart diseases.

Structural abnormalities of the pulmonary system may also cause respiratory distress. Infants with congenital diaphragmatic hernia frequently present in the immediate newborn period with respiratory distress and refractory cyanosis. The abdomen is scaphoid since the intestines are in the thorax. Bowel sounds are heard over the chest if air enters the intestines from spontaneous breathing or mask valve ventilation. The chest radiograph reveals a bowel gas pattern typically in the left hemithorax with a mediastinal shift to the right. The heart compresses the right lung which may also be hypoinflated or hypoplastic. Surgery to remove the bowel from the thorax and close the diaphragmatic defect is necessary after the infant has been stabilized. High frequency ventilation and nitric oxide therapy are used to treat the bilateral hypoplastic lungs. The hypoplastic lungs develop excessive and abnormal musculature of the pulmonary vessels which lead to pulmonary hypertension. In the most severe cases, extracorporeal membrane oxygenation (ECMO) therapy is used to support the cardiopulmonary failure. However, despite aggressive treatment, approximately 50% of the infants with this condition do not survive. Lung volumes may reach normal values, but there is a persistence of decreased number of alveoli (emphysema). Please refer to the focused chapter on congenital diaphragmatic hernia.

In summary, the term infant with respiratory distress usually has transient tachypnea of the newborn. However, based on the time of onset and the progression and severity of the symptoms, other causes of respiratory distress must be entertained. Premature infants usually have RDS, but must be considered to be at risk for infection. In the case presentation at the beginning of this chapter, the later onset of respiratory distress which increases in severity with time, suggests either aspiration or an infectious process. The unremarkable CBC makes a pneumonia less likely and possibly supports an aspiration syndrome; however the CBC may change with time. Empiric antibiotic therapy is indicated. Management is supportive and supplemental oxygen should be continued. A repeat arterial blood gas is indicated and if the pCO2 is elevate, then consider mechanical ventilation. If the chest radiographs suggest significant atelectasis or a further increase in FiO2 is required, either nasal CPAP (continuous positive airway pressure) or mechanical ventilation with positive pressures may enhance oxygenation.

Simplified summary of some of the major newborn respiratory conditions:

RDS:
Clinical factors: Prematurity
CXR: Ground glass appearance

TTN:
Clinical factors: Short labor, C-section delivery
CXR: Fluid in the fissures, central/perihilar congestion

Meconium aspiration:
Clinical factors: Meconium in amniotic fluid
CXR: Infiltrates

Pneumonia:
Clinical factors: Prolonged rupture of membranes, maternal GBS, prematurity.
CXR: Infiltrates or hazy lungs (may be identical to RDS).

Pneumothorax:
Clinical factors: Sudden deterioration, often while on positive pressure ventilation.
CXR: Collapsed lung, free air in the hemithorax.

Cyanotic congenital heart disease:
Clinical factors: Heart murmur, persistent hypoxia despite supplemental oxygen.
CXR: Hypoperfused lungs (lungs appear darker). CXR is often normal.

Questions
1. What is the most common cause of respiratory distress in newborns?
2. When is the onset of symptoms for transient tachypnea of the newborn and how might this help distinguish TTN from other disorders?
3. Aspiration syndromes can be caused by what types of materials?
4. The sudden onset of significant respiratory distress and hypotension should suggest what respiratory disorder?
5. Respiratory distress syndrome of the premature infant is caused by what deficiency? What is the radiographic manifestation of this deficiency?
6. What organisms commonly cause newborn pneumonia?
7. What disorder would you consider in a cyanotic infant without respiratory distress?

Answers to questions
1. TTN
2. TTN symptoms occur soon after birth. Later onset of symptoms should suggest other disorders.
3. Meconium, blood, amniotic fluid.
4. Air leaks such as a tension pneumothorax.

5. Surfactant deficiency, which causes some alveoli to collapse next to alveoli which are emphysematous. Some atelectatic alveoli are adjacent to rigid bronchi. These conditions lead to a reticulogranular infiltrate (ground glass) and air bronchogram pattern on the chest radiograph.
6. Group B Streptococcus, gram negative rod organisms (usually E. coli) and Listeria monocytogenes.
7. Cyanotic congenital heart disease.

Chapter III.7. Cyanosis in Newborns
Kenneth Ash, MD

A 5 hour old male newborn infant was born at 39 weeks gestation via normal vaginal delivery to a 23 year old G2 P2 O+ mother with unremarkable prenatal serology studies. Apgar scores were 8 and 9 at 1 and 5 minutes. His initial physical exam was normal. He stayed in mother's room and breastfed shortly after delivery. At 5 hours of age, with the second feeding, the baby appears tachypneic and cyanotic, and he is therefore taken to the nursery for further evaluation.

Exam: VS T 37.0, HR 145, RR 78, BP 67/38, oxygen saturation 82% in room air. Length 53 cm (50%ile), weight 3.7 kg (50%ile), HC 34 cm (50%ile). He is an alert active, nondysmorphic and mildly cyanotic term male. Tachypnea and mild nasal flaring are present. His heart is regular with a grade 2/6 systolic ejection murmur at the lower left sternal border. The precordium is quiet. Lungs are clear bilaterally. No hepatosplenomegaly is noted.

He is placed in an oxygen hood with a fraction of inspired oxygen (FiO2) of 0.5 (50%) with no appreciable rise in his oxygen saturation.

A chest radiograph is normal. A radial arterial blood gas shows pH 7.44, pCO2 35, paO2 34, bicarb 22 in FiO2 0.7 (70%) by hood. Echocardiography reveals D-transposition of the great vessels with a 5mm ventricular septal defect and patent ductus arteriosus. A prostaglandin E1 infusion is started. The infant is mechanically ventilated and subsequently transported to a pediatric cardiac surgical specialty center. An arterial switch procedure is performed successfully. He is discharged home 3 weeks later.

The newborn infant with cyanosis challenges the clinician to identify the cause and institute appropriate treatment. Although cardiorespiratory disorders dominate the differential diagnosis, hematologic and metabolic derangements and neuromuscular disorders should also be considered.

As with all neonatal conditions, diagnosis is aided by obtaining a thorough maternal and birth history. Clues to infant problems may be found in pregnancy screening tests such as maternal serum alpha-fetoprotein, a marker for fetal aneuploidy, or knowledge of pre-existing maternal medical conditions such as diabetes. Maternal medications should also be noted. Both diabetes and chromosomal abnormalities increase the likelihood of congenital heart malformations. Although fetal ultrasound may reveal congenital heart, lung, or CNS anomalies, major anomalies frequently escape prenatal detection (1). Maternal serologies and cultures identify newborns at risk for perinatal group B streptococcal pneumonia or intrauterine toxoplasmosis infection.

The progress of labor and delivery, as reflected in Apgar scoring and delivery room resuscitation, also provides valuable information. An intrapartum complication leading to the need for aggressive neonatal resuscitation suggests an acquired perinatal etiology for neonatal cyanosis as opposed to a congenital cardiac malformation. Fetal heart rate pattern abnormalities, meconium staining of the amniotic fluid, maternal fever or bleeding may suggest neonatal pneumonia, hypoxic-ischemic injury, meconium aspiration syndrome or persistent pulmonary hypertension.

Cyanosis is recognized by evaluation of the mucus membranes and tongue. Peripheral cyanosis (acrocyanosis) is a normal finding in newborns and does not indicate systemic desaturation. The nail beds are not the place to look in newborns. Pigmentation of the vermilion border and facial bruising may also masquerade as cyanosis. It is necessary to look in an infant's mouth to get a true assessment of oxygenation.

The prerequisite for recognition of cyanosis is thought to be 5 g/dL or more of desaturated hemoglobin. Infants who are both hypoxic and severely anemic may escape recognition because the amount of desaturated hemoglobin is below the level of detection. Likewise, the polycythemic infant with a normal oxygen saturation may appear cyanotic from peripheral sludging of desaturated red cells despite normal oxygen saturation.

Minor levels of desaturation may also escape visual detection. Infants with oxygen saturation in the mid 80's often appear pink, especially under the bright lights above radiant warmers, and are judged to have normal Apgar scores and transition assessments. Only later is the hypoxia detected with the investigation of ancillary signs such as tachypnea, tachycardia or other signs of distress.

In general, cyanosis associated with respiratory problems is accompanied by dyspnea, retractions and grunting, possibly leading to apnea. The quality and symmetry of breath sounds may suggest focal disorders such as pneumothorax and diaphragmatic hernia or more generalized ones such as respiratory distress syndrome. Cyanotic cardiac disease may produce only tachypnea or a more dramatic picture of respiratory distress if pulmonary circulatory overload is present.

Heart murmurs are common in neonates during perinatal transition. The systolic murmurs of a patent ductus arteriosus and tricuspid regurgitation are heard in normal neonates. More infrequently heard holosystolic or diastolic murmurs require definitive evaluation. Conversely, many serious cyanotic congenital heart malformations are not accompanied by murmurs. The quality of peripheral pulses should be noted. Generally weak pulses denote systemic hypoperfusion as in low volume states and decreased cardiac output. Decreased femoral pulses alone suggest coarctation of the aorta. Bounding pulses suggest a widened pulse pressure.

The association of cyanosis with dysmorphic features may provide diagnostic information. For example, Down syndrome (trisomy 21) as well as trisomy 18, trisomy 13 and Turner (XO) syndrome are associated with specific cardiac malformations. Colobomata (eye defects), choanal atresia, genital and ear anomalies appear with cardiac defects such as tetralogy of Fallot in the CHARGE association (Coloboma, Heart defects, Atresia choanae, Retardation of growth and development, Genitourinary problems, Ear abnormalities). Facial and limb deformation associated with oligohydramnios is associated with hypoplastic lungs and pulmonary hypertension leading to cyanosis (5).

The most common congenital heart lesions presenting with cyanosis in the newborn period are those of the hypoplastic right heart syndrome complex (pulmonary and tricuspid atresia) and transposition of the great vessels. The basic pathophysiologic mechanisms leading to hypoxemia are inadequate perfusion of the lungs or marked right-to-left shunting and admixture of desaturated venous blood in the systemic arterial circulation. The most common cardiac conditions seen in Hawaii are listed in the table below.

Table. Cyanotic Congenital Heart Disease in Hawaii 1986-1998 (2). N=264,833 births

Diagnosis	Number
Pulmonary Artery Atresia/Stenosis	407
Persistent Pulmonary Hypertension	187
Tetralogy of Fallot	105
Transposition of the Great Vessels	104
Pulmonary Valve Atresia/Stenosis	43
Tricuspid valve atresia/stenosis	38
Hypoplastic Left Heart	44
Truncus arteriosus	26
Total Anomalous Pulmonary Venous Return	22
Single Ventricle	17
Partial Anomalous Pulmonary Venous Return	12
Ebstein's Anomaly	9

Persistent pulmonary hypertension (PPHN) of the newborn mimics many signs and symptoms of structural heart disease, and the effort to distinguish the two is a common clinical challenge. PPHN (formerly called persistent fetal circulation) may be a primary problem with little antecedent history or more commonly an associated problem of primary pulmonary diseases such as meconium aspiration syndrome, congenital diaphragmatic hernia, respiratory distress syndrome and congenital heart disease.

The entire gamut of neonatal respiratory disorders may present with cyanosis. The chest x-ray and history in combination often suggest the diagnosis. Some of the more common conditions include respiratory distress syndrome, meconium aspiration syndrome, neonatal pneumonia, and pneumothorax. Less common conditions include congenital anomalies of the lungs such as congenital diaphragmatic hernia, tracheoesophageal fistula and pulmonary hypoplasia. Transient tachypnea of the newborn, a common neonatal respiratory disorder, generally is not accompanied by marked cyanosis.

Central nervous system dysfunction caused by hypoxic ischemic injury, seizures, intracranial hemorrhage, infection, or metabolic derangement such as hypoglycemia may lead to cyanosis. Severe neuromuscular diseases such as phrenic nerve palsy, Werdnig-Hoffmann disease, or neonatal botulism may affect respiratory function and lead to cyanosis (6).

Methemoglobinemia may produce a slate gray hue to the skin generally accompanied by low oxygen saturation and hypoxemia, although an arterial pO2 on a blood gas will be paradoxically normal (similar to carbon monoxide poisoning since methemoglobin similarly does not carry oxygen). Methemoglobinemia is associated with ingestion of toxic agents such as nitrites and congenital absence of methemoglobin reductase. An usual pattern of methemoglobinemia has also been described in infants with diarrheal disease of various etiologies including milk protein intolerance and infectious gastroenteritis accompanied by severe systemic acidosis (3,4).

Echocardiography with color-flow Doppler is the definitive test for cyanotic structural heart disease and PPHN. However, prior to obtaining a cardiology consultation and echocardiogram, the clinician may perform a number of other valuable tests to define the cause or mechanism of cyanosis.

An anteroposterior chest x-ray will identify pneumonia, pneumothorax or the intrathoracic bowel gas patterns characteristic of diaphragmatic hernia. The shape and size of the cardiac silhouette and prominence of the central pulmonary vessel may provide clues to cardiac pathology. The classic cardiac silhouettes of transposition of the great vessels ("egg on side"), total anomalous pulmonary venous return ("snowman" heart) and tetralogy of Fallot (boot-shape) are uncommon in the newborn period. The chest x-ray appearance of PPHN is variable: oligemic (hypoperfused) lung fields in the idiopathic variety, prominent infiltrates (if accompanied by meconium aspiration syndrome), or normal in some cases.

The hyperoxy test is a rapid bedside screen for cyanotic diseases that do not respond to supplemental oxygen. The patient is placed in a high concentration oxygen hood (FiO2 at or near 100%) and the paO2 or oxygen saturation by pulse oximetry is compared to the value in room air. A significant increase in oxygen saturation or paO2 suggests pulmonary pathology, whereas an insignificant change in oxygenation suggests the fixed right-to-left shunting of structural cyanotic congenital heart disease, PPHN or very severe pulmonary disease.

Two pulse oximeter probes placed simultaneously on an upper and lower extremity will give clues to right-to-left shunting across a patent ductus arteriosus. A higher oxygen saturation reading in the hand than the foot is classically seen in PPHN and interrupted aortic arch. Likewise, a marked differential in paO2 between blood drawn from an upper extremity artery and umbilical artery catheter or posterior tibial artery carries the same implication.

Laboratory studies such as arterial blood gases can also supply information on ventilation and acid base status. A methemoglobin level can be ordered if methemoglobinemia is suspected. A rapid bedside screen for methemoglobinemia is arterial blood which has a "chocolate" color which does not turn red after several minutes of exposure to room air or oxygen.

The CBC provides an index of hemoglobin level. Polycythemia may exaggerate or falsely mimic cyanosis, while anemia may mask it. The white count, differential, and platelet count provide clues to disorders associated with inflammation and coagulopathy such as sepsis. Blood glucose should be monitored, as hypoglycemia may be an accompanying factor or the inciting cause of cyanosis. Infants ill enough to be cyanotic may require blood transfusion either for stabilization or surgery.

Echocardiography provides the definitive answer in the majority of common congenital heart lesions and PPHN. Rarely is cardiac catheterization required, except in confusing cases of complex anatomy or instances of uncertainty. The diagnosis of PPHN rests primarily on the finding of normal cardiac anatomy and direct evidence of right-to-left or bidirectional shunting of blood on color-flow Doppler through the foramen ovale or ductus arteriosus. Elevated right ventricular systolic pressures estimated by regurgitant flow through the tricuspid valve, ventricular septal flattening or paradoxical wall motion suggest but do not define PPHN in the absence of demonstrable shunting (7).

Targeted treatment is dependent on accurate diagnosis and understanding of pathophysiology. Respiratory support with oxygen or mechanical ventilation is often required in cyanotic newborns. In most cases, oxygen supplementation is helpful if not vital. An

exception to this rule is in functionally univentricular hearts (as in hypoplastic left heart syndrome), in which cardiac output to the systemic versus pulmonary circulation is dependent on a balance of the relative resistance of each vascular bed. Oxygen, a potent pulmonary vasodilator, may increase pulmonary blood flow at the expense of systemic perfusion. In anomalous pulmonary venous return with obstruction, oxygen therapy may be particularly hazardous contributing to increasing pulmonary venous hypertension and clinical deterioration. However, in most pulmonary problems and PPHN, oxygen and ventilation are important aspects of supportive care. When a prostaglandin E1 infusion is used to maintain patency of the ductus arteriosus in ductal dependent lesions, apnea is a common side effect. Anticipation of this common complication and stabilization of the patient's airway and ready availability of ventilatory support can avoid deterioration especially in the transport setting. In transposition of the great vessels, timing and severity of presentation relates to the degree of right/left mixing. If there is a coexisting ventricular septal defect with adequate mixing, recognition may be delayed up to several weeks. However if a VSD is absent or mixing is inadequate, an emergency balloon atrial septostomy (Rashkind procedure) may be necessary prior to definitive repair (8).

Therapeutic use of nitric oxide, an endogenous regulator of vascular tone, has revolutionized the treatment of PPHN. Mortality from this condition, which at one time approached 50%, has improved in recent decades. Strategies for treatment have included aggressive oxygen use and hyperventilation to lower pulmonary vascular tone. When these approaches failed, extracorporeal membrane oxygenation (ECMO) was used as a successful rescue treatment. Multiple ECMO centers were established around the country in the 1980s. However with clinical trials of inhaled nitric oxide (iNO) in the 1990s and FDA approval of iNO in 1999, there has been a steady decrease in the use of ECMO in the United States (9).

Adequate support of cardiac function with inotropic agents such as dopamine, dobutamine, epinephrine, and milrinone infusions is extremely important in both PPHN and other cardiovascular diseases resulting in cyanosis. Red blood cell transfusion is commonly employed to support oxygen carrying and delivery capacity. Metabolic needs are addressed with provision of adequate glucose and nutritional support. Attention to fluid and electrolyte balance includes calcium maintenance for optimal cardiac performance. Acid-base derangement is addressed with attention to treatment of underlying disorders and the judicious use of sodium bicarbonate.

In the unusual event of cyanosis due to methemoglobinemia, methylene blue, an exogenous electron donor for NADPH-methemoglobin reductase, can be used in severe symptomatic cases. Methylene blue will be ineffective in babies with G6PD deficiency, because reduction of methylene blue requires an intact pentose phosphate pathway (10). Although methemoglobin is produced during iNO therapy for PPHN, concentrations are generally clinically insignificant.

Cardiac surgery techniques have improved to the point where palliative procedures such as systemic to pulmonary shunts have been largely replaced when possible by primary definitive repair in the newborn period. Examples are the arterial switch (Jatene) procedure for transposition of the great vessels and primary repair of anomalous pulmonary venous drainage and tetralogy of Fallot. Staged procedures are used for more complex lesions with unfavorable anatomy. Immediate outcome for the arterial switch procedure is 90-95% survival in the newborn period. The best outcomes for neonatal cardiac surgery are seen in pediatric cardiac centers with high volumes and skilled teams (8,11).

Questions

1. What are the 2 most common congenital heart diseases leading to cyanosis in the newborn period?

2. What therapies are used as a bridge to definitive therapy in cyanotic congenital heart disease?
   a. Prostaglandin E1 infusion
   b. Mechanical ventilation
   c. Inotropic agents
   d. All of the above

3. True/False: The definitive treatment for pulmonary hypertension of the newborn is surgical?

4. A 12 day old infant, exclusively fed cow's milk formula, presents to the ER appearing greyish/cyanotic. With 5L/minute oxygen by mask, his radial artery paO2 is 236 torr. His most likely diagnosis is:
   a. Tetralogy of Fallot
   b. Persistent Pulmonary Hypertension
   c. Methemoglobinemia
   d. Transposition of the Great Vessels

5. A 2 day old term infant previously thought to be well and about to be discharged from the nursery becomes acutely pale, slightly cyanotic, with weak femoral and brachial pulses. The congenital heart disease most likely to present in this manner is:
   a. Tetralogy of Fallot
   b. Hypoplastic Left Heart Syndrome
   c. Tricuspid Atresia
   d. Total Anomalous Pulmonary Venous Return

6. Name the four components of Tetralogy of Fallot. Of these four, which one most determines the severity of the cyanosis?

7. True/False: Because cardiac murmurs are uncommon in the newborn period, echocardiography should be performed on all newborns when a murmur is detected.

8. True/False: Cyanosis of the hands and feet of a newborn may be normal if the mucus membranes are pink.

Answers to questions

1. Hypoplastic right heart syndrome/Pulmonary atresia (these two are part of a spectrum) and transposition of the great vessels.
2. d. All of the choices are correct.
3. False
4. c
5. b
6. Ventricular septal defect (VSD), overriding aorta, pulmonic stenosis, right ventricular hypertrophy. The severity of the pulmonic stenosis is the most important factor in determining the degree of cyanosis.
7. False.
8. True.

Chapter III.8. Neonatal Hypoglycemia
Joel Ruff, MD

This is a newborn infant male delivered to a 25 year old G5P3, A+ mother at 37 weeks gestation by C section (for non-reassuring fetal heart tones). The pregnancy is notable for an antenatal ultrasound diagnosis of cleft lip and palate. Maternal serologies are unremarkable and her prenatal glucose tolerance test is normal. At delivery, blow-by oxygen is given for about 2 minutes for poor color and respiratory effort. Apgar scores are 6 (-2 color, -1 tone, -1 respiratory effort) and 9 (-1 color) at one and five minutes, respectively.

Exam: Vital signs are normal. Oxygen saturation is 99% in room air. Weight is 3950 gms, height is 54 cm and head circumference is 37.5 cm (all >95th percentile for gestational age). The infant is active and jittery with an obvious left sided cleft lip and palate. Heart is regular without murmurs. Lungs are clear. Abdomen is soft, without masses or hepatosplenomegaly. The remainder of the initial exam is normal.

The infant is transferred to the term nursery for transitioning. A bedside glucose is obtained and the blood sugar is read as close to 0 mg/dl. A serum sample is then sent STAT to the lab. An IV is started and 8 ml (2 mg/kg) of 10% dextrose in water (D10W) is given IV. The infant is transferred to the intermediate nursery where a repeat blood sugar 30 minutes after the bolus is still <20 mg/dl. A second IV bolus of D10W is given. The earlier serum glucose sent to the lab, comes back at <2 mg/dl. IV D10 is infusing at 80 ml/kg/day, which is a glucose infusion rate of 5.6 mg/kg/min. A blood sugar obtained 30 minutes after a second bolus is 31 mg/dl. The fluid is changed to 12.5% dextrose (D12.5W), the maximum concentration that can run in a peripheral IV. A third glucose is still below 40 mg/dl and a third bolus is given. The D12.5W infusion is increased to 100 ml/kg/day, which is a glucose infusion rate of almost 9 mg/kg/minute, and the baby is offered some formula. The next blood glucose is 48 mg/dl. The infant requires 100 ml/kg/day of dextrose 12.5% for about 24 hours, and then is able to be slowly weaned off the IV fluids.

Neonatal hypoglycemia is a very common condition. The stated incidence is estimated at 1 to 5 per 1000 births, but it is significantly higher in certain subgroups, 8% in LGA (large for gestational age) infants and about 15% in SGA (small for gestational age) infants (i.e., those with intrauterine growth retardation) (1). Neonatal hypoglycemia can be easily treated in most cases if it is recognized, but untreated hypoglycemia can have serious consequences for the infant as glucose is the major substrate for energy in all organs and almost exclusively used for cerebral metabolism (1).

In the fetus, serum glucose levels are about 70% of those in the mother (i.e., baby's glucose is about 70, when mother's glucose is 100) and almost all of this comes from facilitated diffusion across the placenta. Stores of glycogen in the liver accumulate slowly through gestation with a marked increase during the last trimester.

After delivery, the maternal supply of glucose is interrupted. Fetal glycogen storage is temporarily inactivated and glycogen phosphorylase breaks down hepatic glycogen stores to supply glucose. A term infant is estimated to have only enough hepatic glycogen to support metabolic demands for about 10 hours without an exogenous energy source. At the same time, synthesis of enzymes involved in gluconeogenesis increases and catecholamine levels are high (stimulating the release of substrates in the form of free fatty acids and free amino acids). Blood glucose levels in all infants take a physiologic dip in the first 30 to 60 minutes of life and then increase to a stable level at about 1.5 to 3 hours after birth.

Since Van Creveld recognized that premature infants had lower levels of blood sugar than term infants in 1929 (2) and Hartmann and Jaudon defined groups of "mild," "moderate" and "extreme" hypoglycemia in 1937 (3), the concept of what level of hypoglycemia is physiologically significant has been evolving. Animal studies suggest that hypoglycemia causes brain injury via multiple mechanisms which include excess glutamate, an excitatory amino acid neurotransmitter, free fatty acid release and increased mitochondrial free radicals. Glutamate action on its main receptor, the N-methyl-D-aspartate (NMDA)-type glutamate receptor may transport excess sodium and calcium into neuronal cells and cause selective neuronal necrosis via multiple mechanisms. Although there is an understandable lack of controlled studies in human infant subjects, it is known that the neonatal brain is more tolerant of low blood sugars than the adult brain. Long term effects on cognition and development are difficult to define from a case report literature base. There is a lack of correlation between the glucose level alone and permanent neurodegeneration (4, 5).

Studies in humans, limited to follow up evaluations of infants with hypoglycemia, are complicated by confounding problems such as hypoxia or prematurity, non-uniform definitions of hypoglycemia and lack of control groups. Some studies show adverse neurodevelopmental outcomes and some do not. The article by Cornblath and Ichord (6) is an excellent review of the current state of the literature on this topic. Recently, new imaging modalities including positron emission tomography (PET) and magnetic resonance imaging (MRI) are being used to evaluate function and structure of infant brains affected by hypoglycemia. One study stated that the "prognostic value of these techniques remains still obscure" but the possibilities are exciting (7).

Practically, however, an operational threshold of hypoglycemia for evaluation and treatment needs to be available for the practitioner. It is important to realize that the definition of hypoglycemia may vary from patient to patient. A healthy term infant in no distress may tolerate 30 mg/dl well but a stressed, premature infant may be symptomatic at 50 mg/dl. Symptomatic and very low blood sugars (<20 mg/dl) deserve quick assessment and treatment.

Some infants deserve special attention because of their high risk of hypoglycemia (8,9,10). These include: 1) Infants of diabetic mothers many of whom are LGA, 2) All macrosomic (LGA) infants (mothers may have occult diabetes), 3) SGA, (i.e., intrauterine stressed) infants, 4) Stressed infants (i.e., difficult delivery, low Apgar <7 at five minutes), 5) Infants of mothers on tocolytics (terbutaline, ritodrine), oral hypoglycemics or propranolol within 72 hrs before delivery, 6) Premature infants (<37 weeks gestational age), 7) Postmature infants (>42 weeks gestational age).

Hypoglycemic newborn infants may present with a variety of symptoms or be entirely asymptomatic. Symptoms may include: apnea, jitteriness, exaggerated Moro, irritability, poor sucking or feeding, cyanosis, hypotonia, lethargy or coma, temperature instability, seizure, tachypnea (rare), heart rate abnormalities (slow or fast), abnormal cry or vomiting. Because these signs and symptoms are fairly nonspecific, the differential should include other entities such as sepsis, hypocalcemia or intracranial hemorrhage, as appropriate for the clinical setting (1,8).

The differential diagnosis of hypoglycemia is wide, but a few diagnoses make up the bulk of cases. A convenient way to consider the differential is to divide it into transient hypoglycemia or persistent/recurrent hypoglycemia. The latter is defined as requiring either parenteral glucose for more than 7 days or high IV glucose infusion rates (>12-16 mg/kg/min) (6,8).

Transient hypoglycemia can be due to maternal or neonatal conditions. Refer to the table below.

1. Maternal conditions causing transient hypoglycemia:
    a. Intrapartum glucose given at too high a rate to the mother.
    b. Drug treatment (terbutaline, ritodrine, propranolol, oral hypoglycemics).
    c. Intrauterine growth retardation (IUGR): placental insufficiency resulting in SGA infant.
    d. Diabetes in pregnancy (hyperinsulinism).

2. Neonatal conditions causing transient hypoglycemia:
    a. Failure to adapt to extrauterine life: "Transient developmental immaturity of critical metabolic pathways" (6).
    b. Birth asphyxia: Hypermetabolism following acute brain injury and/or energy metabolism shifting from aerobic to anaerobic pathways (exact mechanism unknown) (6,10).
    c. Infection: Hypoglycemia due to overwhelming sepsis. Intracranial infection may also be associated with hypoglycemia (6,10).
    d. Hyperviscosity: There is an inverse correlation with hematocrit and blood glucose levels (10) .
    e. Congenital heart disease: May be related to metabolic demands of congestive failure (10).
    f. Erythroblastosis fetalis: Previously reported to be associated with erythroblastosis fetalis from Rh incompatibility, which is uncommon today (10).
    g. Hypothermia: Increased calories expended to thermoregulate (6).
    h. Inadequate provision of calories.
    i. Other iatrogenic causes: Associated with exchange transfusion and/or low lying umbilical artery catheter which selectively perfuses the pancreas (T11-L1) with a high glucose solution resulting in hyperinsulinism (8, 10).
    j. Decreased glycogen stores: Associated with pre and postmature infants (8).

An endocrinology consult is indicated for persistent and/or recurrent hypoglycemia. Causes include hyperinsulinism, endocrine deficiency, inborn errors of metabolism and neurohypoglycemia (a rare condition in which the subject lacks a transport protein (GLUT1) that facilitates glucose transport across brain microvesicles) (10).

1. Hyperinsulinism conditions which cause persistent/recurrent hypoglycemia:
    a. Nesidioblastosis: A very rare condition in which the pancreas has beta cell hypertrophy. This condition is on a continuum with islet cell adenoma and usually requires subtotal or total pancreatectomy to treat (8,10).
    b. Beckwith-Wiedemann syndrome: Visceromegaly, macroglossia, hypoglycemia.

2. Endocrine deficiency conditions which cause persistent/recurrent hypoglycemia:
   a. Pituitary insufficiency: Associated with syndromes such as septo-optic dysplasia, craniofacial defects and anencephaly (the case patient had a cleft lip and palate which has been associated with patients who have pituitary insufficiency) (10). Deficiency of pituitary hormones such as growth hormone and ACTH, results in hypoglycemia.
   b. Cortisol deficiency/adrenal failure.
   c. Congenital glucagon deficiency.
   d. Epinephrine deficiency: Extremely rare (10).

3. Inborn errors of metabolism conditions which cause persistent/recurrent hypoglycemia (6):
   a. Carbohydrate metabolism: Galactosemia, glycogen storage disease, fructose intolerance.
   b. Amino acid metabolism: Maple syrup urine disease, propionicacidemia, methylmalonic aciduria, tyrosinemia, glutaric acidemia.
   c. Fatty acid metabolism: Carnitine metabolism defect, Acyl-CoA dehydrogenase defect.

Your first evaluation of such an infant should be of airway, breathing and circulation (ABCs). Sepsis may present with hypoglycemia. Most nurseries use a glucose oxidase/peroxidase chromogen test to do bedside determination of blood glucose (Chemstrip or others). This method is quick and fairly easy, but variability in the amount of blood on the strip or residual isopropyl alcohol on the baby's skin may affect readings. Values are given in a range (i.e., 20-40 mg/dl or 40-80 mg/dl). Estimates of sensitivity of this method are 85% but the false positive rate may be as high as 25% (1). The strips are less accurate in the lower ranges (40 mg/dl or less). Because these lower values are of greater clinical concern and because of the variability of reading these strips, these visual methods of estimating blood glucose have been replaced by more precise electronic bedside glucose measurement devices. A stat serum level should be sent to the lab to verify low glucose values. A complete blood count may be a helpful screen for infection and to evaluate the possibility of polycythemia (8). In the lab, plasma or serum is separated from the blood sample and the glucose concentration is measured on the plasma or serum. Thus, a "blood" glucose is really a serum or plasma glucose. The terms blood, serum and plasma glucose can be used interchangeably since they are numerically identical.

The goal of treatment is to establish normoglycemia, usually defined as a stable glucose value above 40 or 50 mg/dl. Definitions vary depending on the clinical situation. All symptomatic infants should be treated with intravenous glucose. Asymptomatic infants in the 20-40 mg/dl range may have a trial of oral feeding, but if the glucose fails to normalize, an IV glucose infusion should be started. Although dextrose 5% (D5W) oral solution is occasionally used for treatment, formula has the advantage of containing fats and proteins which are metabolized slowly and provide a more sustained level of substrates for glucose production (1). Blood glucose should be rechecked in 30-60 minutes after feeding.

For symptomatic infants or asymptomatic infants with severe hypoglycemia (<20 mg/dl), a small IV bolus of dextrose has been shown to raise blood sugar levels safely and more quickly to adequate levels than intravenous infusion alone. The usual bolus is 2 ml/kg of a dextrose 10% (D10W) solution given intravenously followed by a glucose infusion rate of 6 to 8 mg/kg/min. The first part of the infusion, i.e., the bolus is given as a dose of ml/kg, but the second part of the infusion is given in mg/kg/min. This makes it a more difficult conversion because the user must convert grams of glucose to ml, then they must convert ml per minute to ml/hour, since ml/hr is the unit used on IV pumps. A simplified formula for glucose infusion rate (in mg/kg/min) is:

Glucose infusion rate (GIR) = (dextrose%concentration X ml/kg/d) / 144

So if dextrose 10% is used at 80 ml/kg/day that gives us:

GIR = (10 x 80) / 144 = 800 / 144 = 5.6 mg/kg/min

A faster way to figure this out is to use one of the following formulas to achieve a glucose infusion rate of 7 mg/kg/minute.

D5W: IV rate (in ml/hr) = 8.4 X Body Wt (in kg)
D10W: IV rate (in ml/hr) = 4.2 X Body Wt (in kg)

For a 3 kg newborn infant, using D5W would result in an IV rate of 25 ml/hr, which results in 600 ml/day, or 200 cc/kg/day, which is too much. This is why D10W must be used instead. The D10W infusion rate using the above formula would still give 100 cc/kg/day.

The glucose utilization of healthy infants is 5 to 8 mg/kg/min so the above mimics the endogenous requirements. A healthy term infant typically requires only about 60 ml/kg/day of fluids (on the first day of life). In this case, the increased fluids are being used as a vehicle for adequate glucose administration. Giving 15 ml (1/2 ounce) of a standard 20 calorie per ounce formula provides roughly 1.1 gm of carbohydrate (plus protein and fat, which provides additional calories). A 15 ml IV bolus of D5W provides 0.75 grams of glucose, while 15 ml of D10W, provides 1.5 grams of glucose. Formula provides more glucose equivalent than D5W and about as much glucose equivalent as D10W.

What if the follow up glucose (which should be obtained 30-60 minutes after the infusion) is still low, as it was in the patient described above? The options include either increasing the IV rate or increasing the dextrose concentration (i.e., increasing the GIR). The next higher dextrose concentration that is readily available is D12.5W. Because of hypertonicity, peripheral veins cannot tolerate more than 12.5% dextrose. This means that an infant requiring a higher glucose concentration needs a central line. Some infants may require glucose infusion rates as high as 16-20 mg/kg/min, but any infant in this range needs further evaluation and an endocrinology consult.

If the plasma glucose cannot be raised by glucose infusion alone, other options include a trial of corticosteroids (hydrocortisone 5-15 mg/kg/day IV in 2-3 divided doses or prednisone 2 mg/kg/day by mouth). If this fails, other drugs that may be used to raise the plasma glucose include human growth hormone, diazoxide, glucagon or long acting synthetic somatostatin (octreotide) (8).

The first step in evaluating persistent/recurrent hypoglycemia is to obtain serum glucose, insulin, and ketone levels. If the ratio of insulin to glucose (I/G ratio) is >0.3, then the cause is hyperinsulinism. Ketones should be low or absent in hyperinsulinism (4). Ketones are normally generated in hypoglycemic states because the body breaks down fat to acetyl CoA and other ketone bodies, in an effort to generate more substrate for the Krebs cycle. However, in a hyperinsulin state, insulin stimulates lipid synthesis (the opposite of fat breakdown) and thus, ketone levels will be low or absent. Other labs that can be helpful in the diagnosis include growth hormone levels, serum cortisol, free fatty acids, free T4, TSH, uric acid, glucagon, lactate, alanine, amino acids, and somatomedins. Imaging of the pancreas, heart or brain may also be indicated (8).

If the patient is stable, the blood sugar is steady at 50 mg/dl or above, and a more serious condition is not suspected, the frequency of blood glucose measurements can be reduced to every 4 to 6 hours. The intravenous glucose infusion may be weaned after the glucose has been stable and in the normal range for 12-24 hours (1). Some clinicians prefer 2 to 3 days of stable blood sugars before weaning (10). The infusion should be weaned 10-20% every several hours. Enteral feedings may be started concurrently if the infant is otherwise stable and fluid overload is not a concern. Failure to wean should prompt the above evaluation.

Questions

1. True/False: The level of hypoglycemia resulting in serious sequelae is well defined by scientific studies.

2. The advantage of using formula over 5% dextrose water (oral) to feed a moderately hypoglycemic term infant is:
   a. More sustained rise in blood sugar.
   b. A much faster rise in blood sugar than with dextrose 5% oral.
   c. Infants less than 3 hours old cannot take formula yet.
   d. One ounce of standard formula is equivalent gm per gm to a 2 ml/kg intravenous bolus of 5% dextrose.

3. When evaluating a hypoglycemic infant, the first thing to assess is:
   a. Ballard exam.
   b. Presence or absence of symptoms.
   c. Airway, breathing, circulation.
   d. Presence or absence of a suck reflex.

4. What is the formula to calculate the glucose infusion rate and at what level should you start?

5. Which of the following infants are at risk for hypoglycemia and should have a screening blood sugar performed in the term nursery? (more than one answer)
   a. Infant of diabetic mother.
   b. A jittery infant.
   c. Small for gestational age infant status post difficult delivery.
   d. 37 week infant born to a GBS positive mother.

Answers to questions

1. False
2. a
3. c
4. GIR = (dextrose % x ml/kg/d) / 144. Start at 6-8 mg/kg/min and titrate.
5. a, b and c are all correct.

Chapter III.9. Neonatal Seizures
Lynn M. Iwamoto, MD

This is a term female infant born to a 28 year old mother who is A+, serologies unremarkable, and group B strep (GBS) negative with no preexisting medical problems. Labor and delivery was notable for a tight nuchal cord. The infant was delivered vaginally. Brief oxygen blow by and tactile stimulation were required. Apgar scores were 7 (-1 tone, -2 color) and 9 (-1 color) at 1 and 5 minutes, respectively. Initial glucose screen was 40mg%. The infant had no respiratory distress and fed adequately overnight. Early in the morning on the second day of life, she has a 1 minute generalized tonic-clonic seizure. She is taken to the nursery and oxygen is administered. The rapid glucose is 60mg%. An IV is started and a loading dose of phenobarbital is given. She is then transferred to the NICU. She then has a second seizure, initially noted to start in the right arm which then becomes generalized. In retrospect, slight decreased fetal movements were noted, in utero.

Exam: VS T36.8, P140, R60, BP 90/50, birth weight 3300g. Length and head circumference are at the 50th percentile. She is in no respiratory distress, but she is sleepy. Head shows mild molding, no caput or cephalohematoma. No dysmorphic features are evident. Lungs are clear to auscultation. Heart regular without murmurs. Abdomen with normal umbilicus, no masses, no hepatosplenomegaly and normoactive BS. Normal female genitalia. Extremities are well perfused with good pulses. There is mildly decreased generalized tone. DTRs are 2+ and symmetric.

The infant requires a second dose of phenobarbital. Maintenance dosing is started. No further seizures are noted. Electrolytes and glucose are normal except for a bicarbonate level of 19. BUN, Cr, Ca, P, and Mg are normal. CBC is remarkable for a hemoglobin of 12 g/dl, hematocrit 36% (anemic for a newborn), normal WBC and differential, normal platelet count. A lumbar puncture is performed which shows normal CSF findings. An MRI scan shows an increased signal in the left hippocampus, suggesting ischemic injury. EEG shows moderate burst suppression.

Most neonatal seizures occur within the first few days of life, with an incidence between 1.8 and 3.5 per 1000 live births (1). The clinical manifestations of seizures in newborns differ significantly from that seen in older children and adults as the human neonatal brain is still in the process of organization and development. Premature infants have a higher frequency of seizures and their seizures are less organized (2).

Seizures in newborns can be classified as subtle, clonic, tonic, or myoclonic (3). Subtle seizures are often difficult to recognize, they occur more frequently in premature infants, and they are not always correlated with electroencephalographic seizure activity. Examples of subtle seizures include bicycling movements, autonomic dysfunction, horizontal eye deviation, and repetitive facial movements. Clonic seizures are slow, rhythmic movements. They can be focal or multifocal. Tonic seizures can be focal or, more commonly, generalized. They consist of sustained extension and/or flexion posturing. Lastly, myoclonic seizures are composed of rapid, flexion twitching or jerking movements. These seizures can be focal, multifocal, or generalized.

A clinical seizure results from excessive depolarization of neurons in the central nervous system. The pathophysiology of this excessive depolarization is unclear, but is thought to be related to energy production failure, membrane alteration, excess excitatory neurotransmitters, or deficit of inhibitory neurotransmitters (2). Hypoxemia, ischemia and hypoglycemia can result in significantly decreased energy production and increased release of glutamate, the principal excitatory neurotransmitter in the cerebral cortex. Hypocalcemia and hypomagnesemia cause increased depolarization by increasing sodium influx across the neuronal cell membrane. In addition, the inhibitory pathways are not well developed early in life.

Neonatal primary seizure disorders, epileptic syndromes, do occur, but at a very low frequency. The major etiologies of neonatal seizures include hypoxic-ischemic encephalopathy, intracranial hemorrhage, metabolic disturbances, intracranial infection, developmental defects, and drug withdrawal.

The most common cause of neonatal seizures is hypoxic-ischemic encephalopathy (HIE) brain injury. Asphyxial injury may occur in utero as a result of decreased uteroplacental perfusion, for example in abruptio placenta, cord compression, preeclampsia, or chorioamnionitis. Postnatally, conditions such as persistent pulmonary hypertension of the newborn, cyanotic congenital heart disease, sepsis, and meningitis can also result in hypoxic-ischemic brain injury. In those infants with HIE who have seizures, onset of seizures is generally within the first 24 hours after birth. However, the timing of onset is not a reliable indicator of the timing of the neurologic injury (4).

Seizures due to intracranial hemorrhage may also be associated with hypoxic-ischemic or traumatic injury since these events are frequently associated with each other. Onset of seizures due to subarachnoid hemorrhage or subdural hemorrhage is usually the second or third day of life, while those due to germinal matrix-intraventricular hemorrhage present after the third day (2).

CNS infections can also be associated with neonatal seizures. Congenital infections with viruses (cytomegalovirus, rubella, herpes, and others) or toxoplasmosis can cause severe encephalopathic disease. Seizures also often occur in neonates with acute intracranial bacterial infections, most commonly Escherichia coli and group B streptococcal meningitis.

Metabolic disturbances such as hypoglycemia, hypocalcemia, and hypomagnesemia are associated with neonatal seizures. Newborn infants who are premature and infants of diabetic mothers (large for gestational age, or small for gestational age) are most at risk for hypoglycemia. Those infants who are of low birth weight, born to diabetic mothers, or who have suffered hypoxic-ischemic injury are also at risk for hypocalcemia. Hypomagnesemia often accompanies hypocalcemia. Other metabolic abnormalities associated with seizures include local anesthetic intoxication, hyponatremia, and inborn errors of metabolism (2,5).

Diagnostic evaluation includes glucose, electrolytes, calcium, magnesium, and phosphorus in order to identify an immediately correctable metabolic condition. Spinal fluid analysis is performed to identify a potential bacterial infection. CT and magnetic resonance imaging (MRI) can delineate the brain anatomy with high sensitivity and resolution (MRI better than CT). Lesions of hypoxic-ischemic injury can be identified within the first 2-3 days after the asphyxial event (6). The electroencephalogram (EEG) is used to confirm the presence of seizure activity and to define the background electrical activity which is valuable in estimating prognosis.

Treatment of neonatal seizures should focus on the primary etiology as well as direct seizure control. Neonates are less likely to incur seizure related injury. Phenobarbital is often used as the first line anticonvulsant, followed by phenytoin and lorazepam. Oral phenytoin is poorly absorbed from the infant GI tract.

Prognosis varies as a function of primary etiology and gestational age of the infant. The background EEG activity is also correlated with outcome in both term and preterm infants. Infants with a normal background activity are less likely to have neurological sequelae as

opposed to those with moderate to severe abnormalities such as burst-suppression pattern, voltage suppression, and electrocerebral silence (2).

Questions

1. True/False: Neonatal seizures are always the tonic-clonic type.

2. Which of the following conditions is LEAST likely to be associated with neonatal seizures?
   a. E. coli meningitis
   b. syndrome of inappropriate diuretic hormone
   c. transient tachypnea of the newborn
   d. umbilical cord prolapse

3. True/False: Oral phenytoin is often used as a first line anticonvulsant. Why or why not?

4. Facial twitches are an example of what kind of seizures?
   a. tonic-clonic
   b. myoclonic
   c. clonic
   d. subtle

5. True/False: Neonates have an immature inhibitory neurotransmitter system.

6. Which of the following would be LEAST helpful in the immediate diagnostic evaluation of an infant with a neonatal seizure?
   a. brain ultrasound
   b. serum glucose level
   c. cerebral spinal fluid gram stain
   d. serum calcium level

Answers to questions

1. false
2. c
3. false, since it is poorly absorbed from the infant GI tract.
4. d
5. true
6. a

Chapter III.10. Neonatal Sepsis
Sherry W.H. Loo, MD

This is a 3200 g term newborn female delivered via normal spontaneous vaginal delivery to a 25 year old G1P0 syphilis non-reactive, group B strep (GBS) negative, rubella immune, hepatitis B surface antigen negative mother with early preeclampsia and thrombocytopenia (platelet count 80,000). Rupture of membranes occurred 11 hours prior to delivery with clear fluid. Intrapartum medications included 3 doses of butorphanol (narcotic opioid analgesic). The last dose was administered within 1 hr of delivery. There was no maternal fever. Apgars were 8 and 9.

In the newborn nursery, vital signs are: HR 140, T 37, BP 47/39, RR 54. Oxygen saturation is 98-100% in room air. The infant appears slightly pale and mottled. She is centrally pink with persistent grunting, shallow respirations, and lethargy. Her fontanelle is soft and flat. Heart exam is normal. Lungs show good aeration. Abdomen is soft and without masses. Pulses are 1+ throughout with 3-4 sec capillary refill. Neuro exam shows decreased tone and a weak, intermittent cry.

Labs: CBC with WBC 3,200, 6% segs, 14% bands, 76% lymphocytes, Hgb 15, Hct 43, platelets 168,000. Blood glucose 52. The chest x-ray is rotated with fluid in the right fissure, diffuse streakiness on the left, and a normal cardiac silhouette. CBG (capillary blood gas) pH 7.31, pCO2 43, pO2 44, BE-4. CSF: 2430 RBCs, 20 WBCs, 1% PMN, 17% lymphs, 82% monos, glucose 39, protein 133, gram stain shows no organisms.

You are asked to consult on this case. What other tests would you obtain? What would your assessment be for this infant? What would your recommendations be (if any) for further evaluation or treatment? If you were to treat this infant, how long would you treat her?

The evaluation and management of the neonate at risk for sepsis is potentially a source of frustration for students and practitioners. The convention in the past has often been to evaluate and empirically treat all neonates felt to be at significant risk, especially as relates to maternal factors and the receipt of maternal antibiotics in labor. Due to evolutions in health care and the advent of intrapartum prophylaxis for group B streptococcal sepsis (mothers are routinely screened for group B strep and if found to be positive, they are given ampicillin prior to delivery), more attention has come to focus (very appropriately) on the clinical evaluation of the infant as a major part of the decision to evaluate and treat with antibiotics. This factor; however, remains fraught with a degree of uncertainty related to the nonspecific manifestations of infection in the newborn, the sometimes rapid progression of sepsis in the newborn, and the lack of laboratory tools which have high positive predictive accuracy.

The approach in this section of neonatal sepsis will be to: 1) incorporate the evolutionary changes in management which are based on more recent evidence; 2) to emphasize the lack of a gold standard underlying the variations in practice (i.e., clinical sepsis with a negative blood culture is still more often diagnosed than blood culture proven sepsis); and 3) to suggest (based on interpretation of older and recent evidence) newer concepts which place more reliance on tests with high negative predictive accuracy and the efficacy of intrapartum antibiotics (1-7).

The information upon which former standard practice is based is also provided throughout the chapter. These are necessary and basic to understanding the problem of neonatal sepsis and perinatal infections. However, the evaluation and management will de-emphasize empiric treatment for risk alone, and variation in practice will be seen as a necessary consequence of our lack of knowledge and the inherent variation in individual practitioner's tolerance of degree of risk and uncertainty.

Table 1. Common bacterial and viral infectious agents causing sepsis (or something similar to sepsis):
- E. Coli
- Group B streptococcus (GBS)
- Listeria monocytogenes
- Herpes simplex
- Cytomegalovirus
- Any virus infecting the mother in the week prior to delivery any bacteria cultured from the mother on admission for labor

Table 2. High risk factors for neonatal sepsis:
- Late maternal prenatal care
- Maternal UTI, STD, or abnormal serologies
- Prolonged rupture of membranes (>24 hrs)
- Maternal fever prior to delivery
- Maternal chorioamnionitis
- Prematurity
- GBS positive screen without intrapartum prophylaxis

Table 3. Signs and symptoms of neonatal infection (most are NONSPECIFIC):
- Apnea and dusky episodes for no clear reason.
- Lethargy, poor color, hypoactivity, poor capillary refill.
- Feeding intolerance (more than usual spit-up), abdominal distention.
- Clinical appearance; doesn't look "good".
- Tachypnea, temperature instability, look of distress.

Table 4. The most important risk factors for neonatal sepsis:
- Prematurity
- Untreated maternal chorioamnionitis.
- Untreated maternal prolonged rupture of membranes.
- Maternal fever, untreated.
- Untreated positive maternal GBS screen.

Table 5. Equivocal risk factors (i.e., they overlap or may result in similar manifestations):

Fetal distress.
Depression at birth (needs resuscitation, low 5 minute Apgar).
Meconium staining.
Hypoglycemia.
Any unusual finding which may be due to infection.

Although we have gained more knowledge about risk factors and have more antibiotics at our disposal, there is still NO GOLD STANDARD for the diagnosis of neonatal infection. There are still many unknowns in neonatal sepsis which continue to elude us, and compel the diagnosis of neonatal infection to be made clinically more often than not.

Table 6. The Unknowns in Neonatal Sepsis:

1. How effective is GBS prophylaxis as prescribed? >95%
2. How sensitive are blood cultures (i.e., how often are they positive) ?
3. Can an elevated I/T ratio (immature to total granulocyte ratio) indicate acute OR resolving inflammatory response?
4. Will ampicillin resistant organisms be seen with more use of intrapartum ampicillin prophylaxis?
5. What is the minimum duration of antibiotic treatment to effectively treat sepsis?
6. Is neonatal infection with a positive blood culture the same as neonatal sepsis?
7. When does neonatal sepsis become SIRS (systemic inflammatory response syndrome), i.e., overwhelming sepsis?
8. What is the immunologic competence level of a given infant at risk (i.e., will the infant be able to respond positively with appropriate antibiotics)?
9. Does intrapartum treatment of the mother for chorioamnionitis also treat the fetus effectively?

Because we have many unknowns and the worst case scenario for neonatal infection is sepsis and perhaps overwhelming sepsis or death from SIRS, pediatricians have tended to err on being conservative in the evaluation for sepsis. This intention paradoxically results in a more "aggressive" approach to the patient in terms of tests and/or treatment. This paradox is underscored by the lack of a gold standard for diagnosing sepsis in the newborn, and complicated by the recent increase of intrapartum antibiotics prescribed to women in labor.

Table 7. The full sepsis work-up.

1. CBC differential, platelet count.
2. Blood, urine, and CSF cultures.
3. CXR. Add a tracheal aspirate for gram stain and culture if the patient is intubated.
4. Equivocal: gastric aspirate for gram stain and culture.
5. Start broad spectrum antibiotics while awaiting culture results.

For a partial sepsis work-up, one could pick any one or more of the above items. For a totally asymptomatic infant with high risk factors, none of the steps might be elected (practice variation). This is based on the premise that the clinical appearance and serial monitoring of the infant is just as accurate as any laboratory test for indicating the presence of infection, given any set of risk factors in an infant with a relatively normal exam.

This wide variation of practice suggests that the unknowns in neonatal sepsis (see above) are quite important to practical management. This may lead one to be more or less restrictive in practice, and requires one to have thorough knowledge of the predictive accuracy of the objective tools available in the assessment of neonatal sepsis. From an outcomes point of view, one would expect that if certain practices were inappropriate, there would be a higher rate of readmission within two weeks of discharge from the normal nursery for those regimens which were "least restrictive." Such evidence has not emerged from this institution, based on a review of early discharge from the nursery in the mid-1990's, when the most common cause for readmission was jaundice (infection and sepsis were not found).

The highest degree of controversy surrounds the group of infants who are asymptomatic with some risk factors for sepsis, especially those whose mothers received intrapartum antibiotics. In these infants, there is the fear of partially treated sepsis, prompting evaluation and treatment of these infants based on their risk factors and discounting the maternal antibiotics. However, the asymptomatic state could also be interpreted as adequate prophylactic treatment for neonatal bacteremia. In 1990, Wiswell et al., reported on a survey of academic infectious disease departments with respect to management of this scenario. They concluded that there is no consensus regarding management of pretreated, healthy appearing, term gestation neonates (8). In contrast, Teji et al (1994) surveyed neonatologists in Midwestern states of the U.S. with regard to the management of PROM (prolonged rupture of membranes) without chorioamnionitis, chorioamnionitis without treatment prior to delivery, and chorioamnionitis with treatment prior to delivery. One hundred thirty seven responses were received and prematurity and severity of maternal illness significantly influenced the decision to treat empirically, irrespective of screening test results (9). More recently, Eichenwald (1997) has suggested a very reasonable scheme for evaluation of the asymptomatic term infant, based on a protocol developed by the Joint Program in Neonatology in Boston (Table 8) (10). However, the question persists and evolves regarding the benefits and risks of routine therapy of high risk neonates vs. clinical observation and selective therapy of only those infants who manifest symptoms. This evolution is highlighted by the recent reports of ampicillin-resistant organisms in neonatal sepsis (11-13) and the dramatically increased incidence of Candida species sepsis in very premature infants in NICU settings over the last decade, of which one very important contributor is the prior use of antibiotics.

Table 8. Management of asymptomatic term infants with risk factors for infection for term, well appearing infants with maternal antibiotics given in labor.

Tests: CBC, differential, platelet count, blood culture (volume of blood is important; 1cc recommended).
Antibiotics until 48 hour blood culture results are available if:

1. I/T>0.2 (immature neutrophils to total neutrophil ratio) or
2. WBC <5000 or
3. Mother received antibiotics for suspected or diagnosed chorioamnionitis.
4. GBS positive mother, adequately treated, but with a history of a previously affected infant with invasive GBS infection

In this scenario, the availability of rapidly available tests with high negative predictive accuracy would seem particularly useful. Several fitting this category are:

1. The total WBC and l/T ratio (14)
2. Serial CBC's using total WBC and l/T ratio (15)
3. A hematologic scoring system (16)
4. A combination of CRP and IL-6 (17)

Singhal and La Gamma (1996) in a study of 6620 pregnancies, found that 82% of at-risk patients are asymptomatic and have negative body fluid cultures. They concluded that their data support restricting a full course of antibiotic treatment to only those patients with clinical or laboratory signs of sepsis (18%) (5). Escobar et al (2000) reported on a large population of newborns in the Kaiser system of whom 15% were evaluated for sepsis (4). Only 2.2% met criteria for proven, probable, or possible bacterial infection, and of those meeting criteria, 0.8% had positive cultures while 1.4% had clinical evidence of bacterial infection. 1568 out of 2785 infants evaluated were not treated, and the initial asymptomatic status was associated with a decreased risk of infection (adjusted odds ratio; AOR=0.26). Factors associated with increased AOR for infection were chorioamnionitis, low absolute neutrophil count, and meconium stained amniotic fluid. They concluded that evidence based observation and treatment protocols could be defined, based on a limited set of predictors: maternal fever, chorioamnionitis, initial neonatal examination, and absolute neutrophil count (4). Ultimately, each practitioner must determine the degree of risk or uncertainty that he or she can accept on the basis of clinical and institutional experience.

Table 9. A revised and composite screen and evaluation for sepsis in the neonate.

Risk factors: Prematurity, chorioamnionitis, prolonged rupture of membranes, maternal fever, fetal tachycardia and depression at birth.

Screening tests: CBC and differential and platelet count; total WBC and I/T ratio (initial and serial); blood culture; urine culture or GBS antigen; others as may be available to increase negative predictive accuracy such as CRP, IL-6; clinical exam of the infant.

Completing the evaluation: Lumbar puncture for CSF studies and culture; CXR and/or endotracheal aspirate for gram stain and culture.

Treatment: Institute broad spectrum antibiotic coverage for neonatal sepsis. If meningitis is suspected, add cefotaxime to the regimen.

For premature infants in whom the physical exam may be more equivocal and whose prematurity constitutes an additional risk factor, the threshold for a full sepsis evaluation and antibiotic treatment is much lower.

Table 10. Rates of infection in neonates and mortality rates.

Proven sepsis: 2.5 per 1000 live births, mortality 8.7% (18).
Clinical sepsis: 3.6 per 1000 live births, mortality 4.3% (18).
VLBW (very low birth weight) proven sepsis: 26.5 per 1000 live births (18).
VLBW clinical sepsis: 32.4 per 1000 live births (18).
EOGBS (early onset GBS) 0.5 per 1000 live births, mortality 10% (19).
Other early onset infection 0.5 per 1000 live births (19).

Questions

1. For the case presented at the beginning of this chapter, you are asked to consult on this case. What other tests would you obtain'?
2. What would your clinical assessment of this infant be?
3. What would your recommendations for further evaluation and/or treatment be?
4. If you were to treat this infant, how long would you treat?
5. What tests have the highest positive predictive accuracy in neonatal sepsis?
6. What tests have the highest negative predictive accuracy in neonatal sepsis?
7. Is the volume of blood obtained for the blood culture important to the culture being positive or negative?
8. Is there good evidence that treatment of maternal chorioamnionitis prior to delivery significantly reduces the risk of neonatal infection?
9. Does prophylaxis for group B strep infection alter the time course of early onset group B streptococcal sepsis if prophylaxis is ineffective?
10. What is the incidence of neonatal sepsis and what is the mortality from neonatal sepsis?

Answers to questions

1. Blood and urine cultures, if not already done.

2. Clinical sepsis with poor perfusion and neutropenia; possible septic shock with narrow pulse pressure.

3. a) Repeat CBC to monitor the neutropenia and thrombocytopenia. b) Volume bolus to improve perfusion. c) Follow-up exam of abnormal tone and cry after instituting supportive therapy. d) Start broad spectrum antibiotics parenterally. e) Transfer from the normal nursery to a higher level nursery or intensive are unit for continuous monitoring of vital signs.

4. Seven to ten days empirically, given the clinical presentation and depending on culture results. Serial CRPs may also be used to assist with duration of treatment.

5. Any 2 from the battery reviewed by Sinclair (14) gave 62% for sepsis proved or probable.

6. Again any 2 from the above reference (14) gives 98% negative predictive accuracy for sepsis proved or probable. However, the CBC and differential alone will give you two out of this battery.

7. Yes. At least one ml should be obtained for blood cultures.

8. Yes

9. No. This has implications for the current AAP protocol for monitoring infants whose mothers did not receive prophylaxis.

10. 2.5 per 1000 live births, with mortality rate of 8.7% (18). Clinical sepsis is cited as 3.6 per 1000 live births with mortality of 4.3%. Figures are much higher for VLBW infants.

Chapter III.11. Congenital and Perinatal Infections
Sheree Kuo, MD

Case 1

You are asked to attend the precipitous vaginal delivery of an estimated 33 week gestation infant whose estimated fetal weight is 1800 grams. Mother is a 26 year old gravida 5, para 4 woman who was admitted in active labor 45 minutes ago. She did not seek prenatal care with this pregnancy, but reports no medical problems during the pregnancy. She denies tobacco, alcohol and illicit drug use. Mother's blood type is O+, antibody negative. All other prenatal labs are pending. Prior to delivery, mother received one dose of ampicillin only. Membranes are ruptured at the time of delivery revealing clear amniotic fluid.

At delivery, you receive a small, but vigorous male infant and bring him to the warming table. He is quickly positioned, dried, and stimulated. He is pink with good respiratory effort and his heart rate is 150 beats per minute. You note his skin is mildly jaundiced with raised red/purple lesions. You allow the mother to bond briefly with the infant and inform her that because you suspect the infant has a congenitally acquired infection, you are transferring him to the special care nursery for a more detailed examination and further management.

Exam: VS T 37.5, P120, RR 40, BP 60/36, oxygen saturation 100% in room air. Ballard exam: 38-40 weeks gestation. Growth parameters: weight 1.845 kg (<5%ile for 38 weeks, 50%ile for 33 weeks), length 44cm (<5%ile for 38 weeks, 50%ile for 33 weeks) and head circumference 31.5 cm (5%ile for 38 weeks, 50%ile for 34 weeks). He is a small, thin male infant with little subcutaneous fat, who is in no acute distress. His skin is mildly jaundiced with the "blueberry muffin" appearance of diffuse raised red/purple lesions and petechiae. His anterior fontanelle is soft, but full. His sclerae are mildly icteric. The abdomen appears distended and protuberant, but it is soft and non-tender. A firm liver edge is felt 4 cm below the right costal margin and the spleen is felt 3 cm below the left costal margin. The remainder of the examination is unremarkable.

On admission, you order a CBC with differential, liver function tests, fractionated bilirubin levels and a urine culture for CMV. The CBC is remarkable for moderate anemia (Hct = 30%), thrombocytopenia (50,000) and atypical lymphocytosis (10%). Both SGOT (210 mU/mL) and direct serum bilirubin (8 mg/100mL) are elevated. Three hours after birth, the infant develops generalized tonic-clonic seizures that stop after administration of 20mg/kg of phenobarbital. Cranial ultrasound done the next morning reveals periventricular calcifications and generalized brain atrophy. These findings are most consistent with congenital cytomegalovirus infection. To complete the workup you consult ophthalmology to evaluate the patient for chorioretinitis.

Case 2

A former 31-week premature male infant is now four weeks old and nearly ready for discharge from the intermediate nursery. At birth, he was delivered at an outlying hospital via emergent caesarean section for placental abruption to a 25 year-old G1 female with negative serologies and an otherwise unremarkable prenatal course. At the time of delivery, he required resuscitation and was transfused with O negative blood in the delivery room for a hematocrit of 15%. After stabilization, he was transferred to your facility where he has done well for the past month. Today, he has had a sudden deterioration in his respiratory status accompanied by hypotension.

Exam: VS T 36.0 rectal, P 178, RR 90, BP 40/23, oxygen saturation 84% on RA. Growth parameters are all at the 50% for 35 weeks' gestation. He is a pale, mottled premature male infant in moderate to severe respiratory distress. His skin is mildly jaundiced. His mucous membranes are pale. He has nasal flaring with intercostal and subcostal retractions. He is tachypneic with coarse breath sounds. His heart has an increased rate, but regular rhythm. His pulses are barely palpable in his extremities and his capillary refill is 4-5 seconds. His abdomen is soft, but no bowel sounds are present. The remainder of the examination is unremarkable.

Suspecting nosocomial bacterial infection, you perform a CBC, blood culture, urinalysis, and spinal tap. Antibiotics for nosocomial infection are started. Initial urine and CSF studies are normal. CBC is remarkable for an elevated white count with lymphocytosis. The baby has moderate anemia (Hct = 32%) and thrombocytopenia (platelets = 30,000). Chest x-ray shows new diffuse symmetric infiltrates bilaterally. Tracheal aspirate shows moderate WBCs but no organisms on gram stain. After 48 hours on antibiotics, there has been no improvement in his clinical condition. The infant remains intubated on high ventilator settings and dopamine for persistent hypotension. His blood, urine, tracheal aspirate and CSF cultures are all negative for growth. You wonder about CMV infection in light of his pneumonia, shock and history of blood transfusion at the time of delivery and send his urine for CMV culture. Two days later, his urine culture is found to be positive.

Case 3

A young mother rushes into the emergency department with a baby swaddled in her arms. She reports that earlier today, her one week old son developed a low grade fever that she attributed to overbundling. However, throughout the course of the day, his interest in feedings has diminished and he is now difficult to arouse. There is no history of vomiting, breathing difficulties, URI symptoms, diarrhea, or change in bowel and bladder pattern. She denies excessive weight loss as the infant was seen by his primary care physician yesterday.

His birth history is noncontributory: he was born at 39+ weeks gestation via normal spontaneous vaginal delivery to a 23 year-old G1 female who had good prenatal care. Prenatal labs are unremarkable. Mother denies any history of sexually transmitted diseases or abnormal Pap smears. There was no history of prolonged rupture of membranes or maternal fever. Apgar scores were 9 and 9 at 1 and 5 minutes. Birthweight was 3750 gms (75%ile). The infant had an unremarkable hospital course and was discharged home on day 2 with mother.

Today's exam: VS T 39.0, HR 160, RR 40, BP 75/52, oxygen saturation 95% in room air. Growth parameters: weight 3.695 kg (75%ile), length 50 cm (50%ile) and head circumference 35.5 cm (>50%ile). He is a well developed, well nourished term male infant who appears sleepy and lethargic. When he does awake, he is difficult to console and displays a weak, high pitched cry. He is pale, but in no acute distress. He has mild facial jaundice, but no other skin lesions. His anterior fontanelle is soft, but full. Mucous membranes are moist. The abdomen is soft and non-tender. The liver edge is felt 2 cm below the right costal margin and the spleen tip is palpated just below the left costal margin. Neurologically, the infant has decreased tone throughout his extremities and he is difficult to arouse.

You order a complete sepsis workup consisting of a CBC with differential, blood culture, urinalysis, urine culture, and cerebral spinal fluid for glucose, protein, cell count with differential, gram stain, and culture. You obtain an extra tube of CSF to be held in the lab. IV access is obtained and the infant is immediately given ampicillin and gentamicin. IV fluids are also started in light of his decreased level of consciousness and poor appetite. Prior to transfer to the pediatric wards, the patient develops rhythmic right-sided tonic-clonic movements. After administering IV phenobarbital, the seizures stop. You then order IV acyclovir and call the lab to run PCR for herpes

simplex virus and enterovirus on the extra tube of CSF. This clinical presentation is consistent with a perinatal infection, possibly due to herpes simplex virus.

Infections in the newborn infant can be classified as congenital or perinatal. It is important to make this distinction as the clinical presentations, causative organisms, diagnostic approaches, treatments and long-term considerations differ for these two groups. A congenital infection is an infection seen in the newborn infant that was acquired transplacentally during the first, second, or early third trimester. In contrast, a perinatal infection is acquired either around the time of delivery or during the first week of extrauterine life.

The incidence of congenital infection in the fetus and newborn infant is relatively high at 0.5-2.5%. The most common causative agents are rubella virus, cytomegalovirus (CMV), Toxoplasma gondii, Treponema pallidum, human immunodeficiency virus (HIV), human parvovirus B19 and Epstein-Barr virus (EBV). Despite the diversity of these organisms, many produce similar syndromes in the newborn infant. Common manifestations of congenital infections include growth retardation, hepatomegaly, splenomegaly, jaundice (secondary to direct hyperbilirubinemia), hemolytic anemia, petechiae and ecchymoses, microcephaly, hydrocephaly, and pneumonitis. However, the majority of affected infants are entirely asymptomatic.

The incidence of congenital rubella syndrome is 0.5 per 1000 live births. Infants are usually born small for gestational age. Common clinical findings include: purpura, thrombocytopenia, hepatosplenomegaly, cardiac defects, eye defects (glaucoma and cataracts), pneumonia and meningoencephalitis. Diffuse purpuric lesions on the skin resembling a "blueberry muffin", represent cutaneous extramedullary hematopoietic tissue that may be seen in this and other congenital infections. Congenital rubella infection can be diagnosed with an elevated anti-rubella IgM titer in the perinatal period or high anti-rubella IgG titers throughout the first year of life. Virus can also be isolated from a throat swab, CSF or urine. Common long term problems seen in infants with congenital rubella include communication disorders, hearing defects, mental and/or motor retardation, microcephaly, learning deficits, balance and gait disturbances, and behavioral problems. Although live attenuated rubella virus vaccine is available to prevent the disease, there is no specific therapy for congenital rubella.

Annually, approximately 40,000 infants are born with congenital CMV infection in this country. Twelve percent of these infants will die and more than 90% of survivors will suffer late complications, most commonly sensorineural hearing loss. Congenital CMV infection may be the result of a newly acquired maternal infection or a reactivated old maternal infection. Although less common, newly acquired maternal infection poses a much higher risk of severe disease and a worse prognosis. Ninety percent of infected newborns are surprisingly asymptomatic at birth. However, those that are symptomatic are small for gestational age and often present with petechiae, ecchymoses, thrombocytopenia, jaundice, direct hyperbilirubinemia, anemia, hepatosplenomegaly, elevated SGOT, microcephaly, seizures and chorioretinitis. The diagnosis of congenital CMV infection is best made by isolating the virus in urine culture. Periventricular calcifications can be seen on cranial ultrasound. Of the affected infants that survive the neonatal period, 1/3 will have hearing loss, one third will have neuromuscular disorders (seizures or spasticity) and a few will have vision problems secondary to chorioretinitis. Although there is no specific therapy for congenital CMV infection, trials examining the effectiveness of ganciclovir, alpha interferon and CMV immune globulin are underway (1).

The incidence of congenital toxoplasmosis infection varies with geographic location and local dietary habits. Maternal toxoplasma infection is usually due to ingestion of tissue cysts found in raw or undercooked meats or consumption of water or other foods containing oocysts from infected cats. Congenital infection with Toxoplasmosis gondii occurs during maternal parasitemia. In the neonate, the primary focus of toxoplasma infection is in the central nervous system, leaving necrotic, calcified cystic lesions dispersed within the brain. Less commonly, similar lesions can be found in liver, lungs, myocardium, skeletal muscle, spleen and other tissue. Approximately 85% of infants with congenital infection have normal examinations and are asymptomatic. Those infants that exhibit illness at birth frequently present with fever, hepatosplenomegaly, jaundice, rash and pneumonitis. The classic triad of toxoplasmosis, chorioretinitis, hydrocephalus and intracranial calcification occurs in only a small proportion of symptomatic patients. Abnormal laboratory findings include anemia, thrombocytopenia, eosinophilia, and abnormal CSF studies. Seizures, mental retardation, spasticity, and relapsing chorioretinitis are common long-term complications of congenital toxoplasmosis, even if not present at birth. Prenatal diagnosis is made between 20 and 26 weeks by detection of IgM anti-Toxoplasma antibodies and on isolation of the parasite from fetal blood or amniotic fluid. Antenatal ultrasound can suggest the diagnosis of congenital toxoplasma infection when bilateral, symmetric ventricular dilatation, intracranial calcifications, increased placental thickness, hepatomegaly and ascites are noted. Postnatal diagnosis is also made by detection of anti-Toxoplasma IgM antibodies in the infant's serum. Treatment, antenatally and postnatally, consists of pyrimethamine and sulfadiazine. Spiramycin may also be used, if available. Historically, prognosis in untreated infants is poor. However, with recent advances in antenatal diagnostic capabilities and available medical therapies, the frequency of major neurologic sequelae has decreased (2).

Syphilis is caused by the spirochete Treponema pallidum. Transplacental transmission usually occurs during the second half of pregnancy. Most infants born to mothers with primary or secondary syphilis have congenital infection; though only half of those who are infected are symptomatic. Because congenital syphilis is associated with significant neurodevelopmental morbidity, it is imperative that both maternal status and infant risk for syphilis be checked in all pregnancies. Early features of congenital syphilis include hepatosplenomegaly, skin rash, anemia, jaundice, metaphyseal dystrophy, periostitis and CSF abnormalities including elevated protein and mononuclear pleocytosis. However, in some cases, the infant is asymptomatic and may not develop any signs or symptoms of congenital infection for weeks or months. "Snuffles" is obstruction of the nose with initial clear discharge progressing to purulent or sanguineous discharge. It is seen in infants with congenital syphilis usually after the newborn period. Detection of IgM-FTA-ABS (fluorescent treponemal antibody absorption) in the newborn's blood is the most reliable method of diagnosing congenital syphilis. However, this test is not always positive early on in life, thus repeat testing at 3 to 4 week intervals is frequently indicated. Treatment for both the pregnant mother and baby is penicillin G. Despite antibiotic therapy, it is recommended that infants undergo repeat blood and CSF testing during the first 12-15 months of life until negative or stable low titer levels are achieved. Vision, hearing and developmental evaluations are also indicated before three years of age in infants with congenital syphilis (3).

One to two-thirds of adults in the United States are seropositive for human parvovirus B19. However, the overall risk of fetal infection from human parvovirus B19 is low. Fetal infection with the virus can result in neonatal nonimmune hydrops fetalis and fetal aplastic crisis (i.e., severe anemia resulting in high output congestive heart failure and hydrops), but has not been shown to cause congenital anomalies. B19 is known to have an affinity for progenitor erythroid cells in the bone marrow. This affinity most likely produces bone marrow aplasia that may lead to congestive heart failure and nonimmune hydrops fetalis. The diagnosis of B19 infection can be made either serologically (anti-human parvovirus B19 IgG and IgM levels) or by viral culture. Antenatal treatment of infected infants with hydrops includes fetal transfusion and maternal digitalization. No specific antiviral treatment is currently available.

Perinatally acquired infections are those that are acquired either around the time of delivery or during the first week of extrauterine life. Common pathogens include bacteria, such as group B streptococci, E. Coli, and Listeria (covered elsewhere in this text), herpes simplex virus, hepatitis viruses and human immunodeficiency virus. Infants with perinatally acquired viral infections are often normal at birth, developing illness later in life (1).

A few pathogens like cytomegalovirus (CMV) can cause both congenital and perinatally acquired infection in the newborn with striking contrasts in presentation. The infant in Case 1 presents with growth restriction, anemia, thrombocytopenia, extramedullary hematopoiesis, and intracranial calcifications, all indicative of a chronic process; namely, congenital CMV infection that was transmitted transplacentally during the first or second trimester of pregnancy. In contrast, the infant in Case 2 acquired CMV infection after birth resulting in illness several weeks later. Perinatally, CMV can be transmitted through breast milk or vaginal secretions. Premature infants however, are particularly susceptible to transmission through transfusion of blood products. The resulting syndrome is characterized by shock, pneumonitis and lymphocytosis as described above (4). The role of ganciclovir in perinatally acquired CMV infection is unclear.

The majority of neonatal herpes simplex virus (HSV) infection is acquired from the maternal genital tract with an incidence of approximately 1 case per 3500 live births. However, infection may also be acquired after birth from mother or other persons with non-genital tract lesions (e.g., oral herpes, herpetic whitlow) following close contact with the infant or handling. Primary maternal infection is associated with a 50% risk of perinatal/neonatal infection, while a risk of <5% is seen with recurrent maternal infection. Of note, active HSV lesions are present at the time of delivery in only 1/3 of mothers of affected infants. Several defects in cellular immune function contribute to neonatal susceptibility to HSV. Perinatally acquired HSV infection results in massive coagulation necrosis of the liver, lungs, adrenal glands and brain. Most infants are asymptomatic at birth, developing illness during first 1 to 2 weeks of life. Clinical illness can be characterized as being localized or disseminated. Disseminated illness can be further described as those with and those without central nervous system involvement. Systemic symptoms of disseminated HSV infection usually present towards that end of the first week of life, including poor feeding, lethargy, fever, irritability, and seizures with rapid progression to hypotension, disseminated intravascular coagulation, apnea and shock. Skin vesicles are present in less than half of patients. With antiviral therapy, 15-20% of patients die and 40-55% of survivors suffer long-term neurologic impairment. Localized disease may involve the central nervous system alone, the central nervous system and skin, eyes, and oral mucosa or only the skin, eyes and oral mucosa. Except in cases of isolated viral encephalitis, HSV is readily recovered in culture from scrapings of skin vesicles, blood, cerebrospinal fluid, conjunctivae, respiratory secretions, and urine. Once neonatal HSV infection is suspected, antiviral therapy should be started immediately (1). Parenteral acyclovir is the treatment of choice for herpes neonatorum. Treatment duration varies depending on whether the infection involves the CNS and/or is disseminated (5). Despite antiviral therapy, overall outcome for survivors is poor. More than half of infants who survive disseminated disease will develop microcephaly, spasticity, paralysis, seizures, deafness, or blindness. Those with skin involvement may be subject to recurrent vesicular outbreaks for several years. Of note, HSV can also be transmitted in utero during the first or second trimesters of pregnancy. Those fetuses that are not stillborn or spontaneously aborted demonstrate a syndrome similar to other congenital viral infections like CMV. Treatment is supportive as acyclovir has no proven benefit for these infants (1).

The most important of the hepatitis viruses for the general pediatrician is Hepatitis B. The virus is found primarily in the liver parenchyma, but can be found in circulating blood from a few days to many years. Regardless of maternal acute or chronic infection, the virus rarely crosses the placenta, thus perinatal/neonatal infection is most likely acquired from infected maternal blood encountered during the delivery process. Overall, there is 60-70% chance of transmission during delivery if mother has an acute infection at that time. Mothers may also be carriers which still has a risk of transmission to the newborn. In the U.S., hepatitis B surface antigen (HBsAg) carriage rate is relatively low, about 0.1%. However, rates may be as high as 15% in Taiwan and parts of Africa. At birth, infected infants are asymptomatic. By 2 to 6 months of age, liver enzymes are often elevated and infants are antigen seropositive. Occasionally, infection may present with jaundice, fever, hepatomegaly and anorexia, followed by complete recovery or chronic active disease (1). Approximately 95% of perinatally acquired HBV infection can be prevented by early active and passive immunoprophylaxis of infants born to HBsAg positive mothers. Infants born to HBsAg positive mothers should receive the initial dose of hepatitis B vaccine and hepatitis B immune globulin (HBIG) within 12 hours of birth (given at separate injection sites). Infants born to unscreened mothers should receive their first hepatitis B vaccine within 12 hours of birth while awaiting maternal blood test results. If the mother should be found to be HBsAg positive, HBIG should be given within the first week of life. All infants should complete the hepatitis B immunization series by 6 months of age. Infants born to HBsAg positive mothers should be tested for anti-HBsAg antibodies and HBsAg 1 to 3 months after the third dose of vaccine is given to determine those who may be chronically infected and those who may require additional doses of the vaccine. Breastfeeding by an HBsAg positive mother has not been shown to cause hepatitis B infection in infants (6).

Once seen exclusively in children who had received blood products, pediatric human immunodeficiency virus (HIV) infection is now overwhelmingly the result of perinatal transmission (7). There are three distinct modes of transmission of human immunodeficiency virus (HIV) from mother to fetus. Congenital HIV infection results from the transplacental transmission of virus during early pregnancy. Intrapartum transmission may occur following exposure of the infant to mother's blood or as a result of maternal-fetal transfusion during the delivery. Perinatal infection with HIV can occur either during the birthing process or shortly after birth through breastfeeding (8). Risk factors associated with perinatal HIV transmission include maternal viral load (plasma and genital tract), primary infection of late stage HIV, low CD4 count, STDs/other co-infections, pre-term delivery, increasing duration of rupture of membranes, placental disruption, invasive fetal monitoring (eg. scalp probes), vaginal delivery and lack of AZT prophylaxis (9). The transmission rate from mother to infant is approximately 20-30%. However, recent studies have shown that for select HIV-infected women, zidovudine (AZT) may decrease transmission to 8% of their infants (10). Maternal treatment with AZT in combination with elective cesarean section delivery prior to rupture of membranes and the onset of labor has shown further reduction of the transmission rate to 2% (9). Infants with congenital infection present in a similar fashion to other congenital infections and may also exhibit craniofacial abnormalities. Infants with perinatally acquired infection are usually asymptomatic at birth (8). To maximize the opportunity to prevent perinatal transmission of HIV infection, maternal HIV status should be determined during the first trimester of pregnancy. Anti-retroviral therapy should be started in those found to be HIV positive. During labor and delivery, AZT, 2mg/kg should be administered IV during the first hour, then 1mg/kg per hour until delivery. The infant should then be started on AZT syrup, 8-12 hours after birth, 2mg/kg QID until 6 weeks of age when the infant's HIV status can be determined (9,10). Detection of HIV antibody by ELISA or Western blot in the newborn is complicated by transplacental passage of maternal IgG and should not be performed before 18 months of age. Detection of HIV DNA by PCR is the preferred test for diagnosis of HIV infection in infants. Testing should be performed at birth, then at 1-2 months of age, and a third time between 3 and 6 months of age. Any time an infant tests positive, a second repeat specimen should be obtained immediately to confirm the diagnosis of HIV infection. Viral culture for HIV can also be done; however, issues of cost, regional availability and delay in reporting results make it less useful than HIV DNA by PCR. Umbilical cord blood should not be used for testing. If neither PCR or viral culture are

available, detection of the p24 antigen may be used to assess HIV infection status in infants older than one month, though sensitivity is lower than the other two tests (8,10). The diagnosis of HIV infection in an infant is made with positive results on 2 separate specimens using HIV nucleic acid detection, HIV p24 antigen test, or HIV isolation by culture. An infant with at least 2 negative HIV virology tests from separate specimens, 1 of which was performed at 1 month of age and 1 of which was performed after 4 months of age can be considered "not infected with HIV". Finally, because transmission of HIV through breastmilk has been reported, counseling to discourage breastfeeding should be provided to all mothers who are HIV positive (10).

Questions

1. What physical findings in Case 1 suggest this infant has a congenital infection?
2. How does a congenital infection differ from an infection that is acquired perinatally?
3. What are the most common causes for congenital infection?
4. True/False: A term infant with a normal physical exam and no risk factors for infection may have congenital infection.
5. Periventricular calcifications in the brain are seen with which congenital infection? Diffuse calcifications?
6. True/False: An infant born to a woman with recurrent herpes infection is at higher risk for developing herpes neonatorum than one born to a woman with primary herpes infection at the time of delivery?
7. Administration of what agents can prevent 95% of perinatally acquired hepatitis B infections?
8. True/False: Breastfeeding should be encouraged in all mothers who are HIV positive, but do not have AIDS.

Answers to questions

1. Small for gestational age, microcephaly, jaundice, pale skin, petechiae, blueberry muffin spots, hepatomegaly, and splenomegaly
2. A congenital infection is an infection seen in the newborn infant that was acquired transplacentally during the first, second, or early third trimester. A perinatal infection is acquired either around the time of delivery or during the 1st week of extrauterine life.
3. Rubella virus, cytomegalovirus (CMV) Toxoplasma gondii, Treponema pallidum, human immunodeficiency virus (HIV), human parvovirus B19 and Epstein-Barr virus (EBV)
4. True
5. Periventricular calcifications are seen in congenital CMV while diffuse calcifications in the brain are seen in congenital toxoplasmosis.
6. False
7. Hepatitis B vaccine and hepatitis B immune globulin.
8. False

Chapter III.12. Necrotizing Enterocolitis
Kelly S. Yamasato

This is a 14 day old infant female born to a 24 year old G1P1 mother at 30 weeks gestation via spontaneous vaginal delivery. Birthweight was 1340 g. Apgar scores were 6 and 7 at 1 and 5 minutes. Her early hospital course was remarkable for respiratory distress syndrome and patent ductus arteriosus. Recent problems include apnea and bradycardia of prematurity and feeding intolerance. Her nutritional needs have been met by advancing enteral feedings of preterm formula supplemented with parenteral hyperalimentation. On the day prior to the onset of symptoms, she was no longer receiving hyperalimentation and she was feeding 30 cc every 3 hours. Today she presents with abdominal distention and bilious vomiting. Her stool color has darkened and her urine output is reduced. She is also having more apnea and bradycardia events.

Exam: VS T 36, HR 180, RR 60, BP 63/40, weight 1425 grams. She is lethargic, slightly toxic, and poorly perfused. Cardiac exam demonstrates tachycardia and no murmurs. Lungs are clear. Her abdomen is tympanitic, distended, and questionably tender, with hypoactive bowel sounds. Stool is guaiac positive.

Abdominal radiographs demonstrate pneumatosis intestinalis. She is made NPO and a nasogastric tube is placed to suction. Following an intravenous bolus of normal saline, her tachycardia resolves and she is placed on maintenance intravenous fluids at 150 cc/kg/day. Empiric antibiotic therapy of ampicillin and gentamicin is started. Serial abdominal radiographs and examinations are regularly performed to monitor her status. She begins to show improvement shortly after the initiation of therapy, and enteral feeding is reintroduced 10 days later. Her feedings are slowly advanced. She is discharged from the hospital at 6 weeks of age. She is evaluated for intestinal stricture later in infancy and none is found.

Necrotizing enterocolitis (NEC) is a fulminant syndrome causing bowel wall necrosis, which can lead to air in the intestinal wall, portal venous system, or peritoneal cavity (1). It occurs in 1-5% of neonatal intensive care unit admissions and is the most common GI emergency in neonates (2,3). NEC may affect the gastrointestinal (GI) tract from the stomach to the rectum, although the distal ileum and proximal colon are the segments most commonly involved (2). The incidence of this disease is 1 to 3 per 1000 live births, with 75-95% of cases occurring in premature infants (4,5). Onset is most common between 3 to 10 days of age, with the age of onset inversely related to gestational age at birth (6). The overall mortality rate in NEC may be as high as 30% (7). NEC in full-term infants is associated with a lower mortality rate than that of premature infants (5).

Prematurity and low birthweight (<1500 grams) are important risk factors for NEC. Although findings vary widely, an estimated 10% of infants with birth weights less than 1500 grams develop NEC (7). Enteral feeding is also a suspected risk factor, as more than 90% of infants who develop NEC have been enterally fed (6). Aggressive enteral feeding rates (greater than 20 cc's/kg per day) and the use of formula rather than breast milk are particularly associated with increased NEC incidence (8). Other suggested risk factors include conditions that increase the risk of infection or hypoxia, such as maternal infections during delivery, exchange transfusion via the umbilical vein, polycythemia, congenital heart disease, perinatal asphyxia, and respiratory distress (1,5).

NEC is a multifactorial disease with an unclear pathophysiology. The pathogenesis of NEC is believed to involve triggers such as bacterial colonization, intestinal ischemia, and formula feeding, that activate proinflammatory mediators (7). These mediators lead to intestinal epithelial cell necrosis and ischemic injury (secondary to vasoconstriction) (8), producing the epithelial disruption and bowel necrosis characteristic of NEC. Some of the mediators suspected to play a role include platelet activating factor, nitric oxide, and interleukin-8 (7). Infants with NEC also show increased cyclooxygenase-2 expression, suggesting involvement of this pathway (3). Rapid enteral feeding (2) and increased intraluminal pressure (1) may also contribute to intestinal damage. Immature GI tracts are especially susceptible to the proinflammatory mediator damage that appears to contribute to NEC. Intestinal defenses against inflammatory injury are not completely developed (7,8). For example, premature infants may have deficiencies in protective compounds such as erythropoietin, epidermal growth factor, and intestinal trefoil factor (7). In addition, premature infants display under-developed immunologic and digestive functions, increasing their risk of intestinal infection. Decreased small intestine motility in premature infants may also contribute to NEC by facilitating bacterial overgrowth and bowel distention (8). Although bacteria such as Pseudomonas, Klebsiella, some E. coli strains, Salmonella, and Clostridium butyricum are suspected to have a role in NEC (1), no pathogen is identified in most cases (2). The role of intestinal hypoxia in NEC has not been established (8), however, congenital heart disease or a patent ductus arteriosus may contribute to the development of NEC by reducing gut perfusion (ischemia) (9).

Early signs and symptoms of NEC involve abdominal distention with gastric retention, episodes of apnea, and vomiting (1,6). Visible blood in the stool occurs in about 25% of patients (2), while occult blood occurs more frequently. NEC often progresses rapidly and may quickly lead to intestinal perforation, shock, and septicemia (1). Pneumatosis intestinalis (gas in the bowel wall) is nearly diagnostic of NEC and is estimated to occur in about 75% of cases. Portal venous gas (PVG), another virtually pathognomonic sign, is seen about 10-30% of the time. The radiographic appearance of PVG is characterized by gas lucencies visible over the liver on x-ray or air bubbles imaged on ultrasound. PVG usually indicates more severe disease (10).

NEC is most commonly staged using the following system proposed by Bell, et al (6,8,11):

Stage 1: Suspected NEC involving a wide range of nonspecific symptoms such as mild abdominal distention, apnea, guaiac-positive stools, lethargy, and bradycardia.

Stage 2: NEC is proven, primarily by the detection of intestinal dilatation and pneumatosis intestinalis through abdominal radiography. Stage 2 NEC mortality rates approximate 15%.

Stage 3: Advanced NEC possibly involving septic shock, respiratory and metabolic acidosis, disseminated intravascular coagulation, neutropenia, and ascites. Pneumoperitoneum may be present. The mortality rate for stage 3 NEC is approximately 60%.

One of the primary diagnostic tools in NEC is the abdominal radiograph. The abdominal radiograph may be used to detect nonspecific early signs of NEC, such as diffuse intestinal gaseous distention or asymmetric bowel gas patterns. However, its major use is to confirm or monitor for the development of NEC by detecting pneumatosis intestinalis. Suspected NEC usually warrants a series of abdominal films every 12 to 24 hours for a minimum of 2 to 3 days to monitor for pneumatosis intestinalis. Contrast enemas are not commonly used in the diagnosis of NEC, but may prove useful when abdominal radiographs are unclear. A contrast enema in an infant with NEC may display mucosal irregularity and edema (10).

The differential diagnosis of NEC includes systemic and intestinal infections, congenital intestinal obstruction (e.g., volvulus, pyloric stenosis, ileal atresia, Hirschsprung's disease), neonatal appendicitis, spontaneous bowel perforation, and pseudomembranous colitis or ecchymotic colitis (1,5,9).

Aggressive treatment is indicated in all suspected cases of NEC. Such measures include oral feeding cessation, nasogastric decompression, and intravenous fluid therapy. Systemic antibiotics, usually ampicillin or an anti-pseudomonas penicillin with an aminoglycoside, are administered following blood culture collection. Umbilical catheters should also be removed. Respiratory status, coagulation profile, and acid-base electrolyte balance should be carefully monitored. Abdominal radiographs may be taken every six hours and the patient's general condition assessed every 4-6 hours (6).

Early consultation with a surgeon is advised in all cases of NEC. Conservative treatment is insufficient in 20-40% of cases (9). Surgical procedures may include exploratory laparotomy, necrotic bowel resection, and external stoma diversion. Intraperitoneal drainage is another option that is often used on patients who may not be able to tolerate a laparotomy and resection (9). Indications for surgical intervention include failure of medical management, pneumoperitoneum (an indication of perforation), abdominal wall cellulitis, and signs of gangrenous intestine (e.g., fixed intestinal loop, ascites) (6). Mortality rates in NEC cases involving surgery range from 20-50% (9).

The elusiveness of the etiology of NEC has made it difficult to establish effective preventive measures. The use of total parenteral nutrition with slow progression to enteral feeding rather than a rapid enteral feeding protocol may be one such measure. Studies also suggest that dopamine and dobutamine may reduce the risk of NEC by improving mesenteric blood flow and cardiovascular function (9). The use of human breast milk, rather than formula, may reduce the incidence of NEC by providing phagocytic cells, lymphocytes, neutrophils, and IgA (6,8).

NEC outbreaks have been reported, and epidemic precautions and infection-control measures are indicated in a suspected outbreak. Prophylactic antibiotics have been employed in the past; however the possibility of developing resistant organisms has discouraged their routine use (8).

NEC has a recurrence rate of about 4% in infants (6). About 10% of patients will develop strictures due to scarring and fibrosis of the bowel (6). Even mild cases of NEC can result in strictures (10). Intestinal resection may lead to short bowel syndrome and the many complications associated with the prolonged use of parenteral alimentation such as central venous catheter related sepsis and thrombosis, and cholestatic jaundice (2). NEC may also lead to enterocolonic fistulas, possibly through the adherence of inflamed bowel to adjacent bowel segments or through a previously closed perforation (9).

Questions

1. True/False: The majority of patients with NEC have visible blood in the stool.

2. Which of the following has not been suspected as a risk factor for NEC?
   a. aggressive enteral feeding
   b. maternal infections during delivery
   c. dopamine administration
   d. umbilical vein catheters
   e. all of the above have been considered as risk factors

3. True/False: Prophylactic antibiotics are a commonly used measure to prevent NEC.

4. How is the reduced intestinal motility of premature infants thought to contribute to the development of NEC?

5. A premature infant is suspected to have NEC. Name three initial treatment measures that should be employed.

Answers to questions

1. False, an estimated 25% show visible bloody stool.
2. c. Dopamine may actually reduce the risk of NEC by increasing mesenteric blood flow.
3. False, the development of resistant organisms presently discourages routine prophylactic antibiotic use.
4. Reduced intestinal motility increases the chances of bacterial overgrowth.
5. Acceptable answers include: 1) oral feeding cessation, 2) nasogastric decompression, 3) intravenous fluid therapy, 4) systemic antibiotics, 5) umbilical catheter removal, 6) acid-base electrolyte balance monitoring, 7) early consultation with a surgeon.

Chapter IV.1. Prenatal Genetic Screening and Testing

Greigh I. Hirata, MD

Mrs. H is a 37 year old G1P0 with irregular menstrual periods. She presents to you early in her pregnancy for prenatal counseling. Her significant family history includes a brother with unexplained mental retardation and a niece with beta-thalassemia major. She is of mixed Asian/Caucasian ethnicity. Her husband and the father of the baby is a 49 year old African-American with no significant family history. She seeks advice with regards to prenatal screening for birth defects and/or prenatal testing.

This case brings up important issues regarding prenatal screening and testing. It must be remembered that screening tests are designed to identify a high risk population from the general population. Screening tests are generally inexpensive and noninvasive. Prenatal testing is designed to answer a specific question in a population at high risk. Definitive diagnostic testing is typically expensive and invasive.

A complete prenatal evaluation begins with a careful medical and family history. When used in conjunction with a thorough physical examination (ultrasound evaluation) and laboratory testing, the practitioner is better able to individualize the patient's risks and recommend the appropriate diagnostic tests.

In this section, we will discuss the appropriate steps in risk assessment beginning with the family history. One typically begins the assessment by asking questions regarding other family members. A pedigree is constructed which includes three generations; grandparents, uncles, aunts, cousins, parents and siblings of the proband (the index case), in this case the fetus. Significant information includes histories of birth defects, genetic diseases, unexplained stillbirths, and unexplained mental retardation. It is important to recognize combinations of abnormalities and illness and patterns of inheritance that may require referral to a geneticist for diagnosis and further evaluation.

Also significant is the ethnic background of both parents. Specific genetic diseases are much more common in certain ethnic groups. For example, southeast Asians and Mediterraneans are at risk for thalassemia and glucose-6-phosphate dehydrogenase deficiency, African-Americans are at risk for beta thalassemia and sickle cell disease, Ashkenazi Jews are at risk for Tay-Sachs disease and have a genetic predisposition to certain types of cancers, and northern Europeans are at risk for cystic fibrosis. Screening tests for the carrier status are readily available for each of these disorders and should be performed prior to any prenatal diagnostic test if the couple is at risk.

The most obvious screening test for fetal aneuploidy is maternal age. This association has been well characterized and has lead to the recommendation that invasive genetic testing be offered to any women 35 years or older at the expected date of delivery. Although every pregnant women is at risk for aneuploidy, this age cutoff offers the most efficient and effective method for determining candidates for prenatal testing. Advanced maternal age is also a risk factor for increased maternal morbidity and mortality primarily related to increase rates of pregnancy complications such as preeclampsia and gestational diabetes. Pregnancy wastage, unexplained stillbirths and other adverse perinatal outcomes are also increased. As women increasingly delay childbearing to later years, clinicians should become aware of these risks to better counsel their patients.

Advanced paternal age (45 years or greater) places the fetus at risk for new autosomal dominant mutations. Examples of these genetic disorders include achondroplasia, Marfan syndrome and certain types of osteogenesis imperfecta. Unfortunately the exact occurrence risk is unknown and invasive prenatal testing are not available for many of these genetic disorders.

One of the greatest breakthroughs in prenatal diagnosis has been the emergence of maternal serum screening in the identification of pregnancies at risk for chromosomal aneuploidy and birth defects. Originally designed as a test for spina bifida and ventral abdominal wall defects, these tests are performed at 15-20 weeks gestation.

Abnormal levels of the maternal serum markers human chorionic gonadotropin (hCG), alpha-fetoprotein (aFP), and unconjugated estriol (uE3) are associated with trisomy 21 and 18. Moreover, these markers are predictive of aneuploidy independent of maternal age related risks. This has lead to the development of calculated individualized risk for these specific aneuploidies (utilizing maternal age and maternal serum biochemical markers). This test, also known as the triple screen, is rapidly replacing maternal age alone as an indicator for invasive genetic testing. It has enabled clinicians to identify women at risk for aneuploid fetuses who are less than advanced maternal age (< 35 years old). Conversely, many women greater than 35 years old have been reassured by risk reduction and thus have avoided placing the pregnancy at risk with invasive genetic testing. The maternal serum screening is also useful in identifying those pregnancies at risk for specific birth defects such as neural tube defects and ventral abdominal wall defects. In this case, the maternal serum marker aFP is elevated. Typically hCG and uE3 are unaffected.

Other etiologies for abnormal test results include fetal demise, multiple gestations, and incorrect gestational age determination. By identifying these problem pregnancies and evaluation by ultrasound, clinicians are better able to intervene or anticipate pregnancy complications. In the absence of recognizable explanations for an elevated maternal serum aFP level, there has been a noted increased risk for adverse perinatal outcomes such as preterm birth, intrauterine growth retardation, oligohydramnios and stillbirth. Unfortunately treatment protocols have been unsuccessful in significantly improving the outcomes of these high risk pregnancies.

The future of maternal screening involves earlier identification of pregnancies at risk either by serum screening or ultrasound as well as noninvasive methods for prenatal diagnosis. We will now explore tests which will become clinically available in the not too distant future. Researchers are busy investigating promising new maternal serum markers applicable earlier in pregnancy. Like hCG, aFP, and uE3, these markers are independent predictors of aneuploidy, primarily trisomy 21. The utilization of these markers is estimated to increase sensitivity rates by approximately 5%. In the near future, maternal age in conjunction with serum markers such as inhibin, pregnancy associated plasma protein-A (PAPP-A), and urinary human chorionic gonadotropin-core may be used alone or in combination as screening tools in pregnancy. Nuchal translucency (significant swelling of the nuchal area seen on ultrasound) occurs in approximately 70 % of aneuploid fetuses at 10-14 weeks gestation independent of maternal age risks. Evaluation of early gestations by sonography may identify these fetuses at risk. The promising future direction of early pregnancy screening will probably involve a combination of nuchal translucency, maternal age, and serum screening utilizing beta-hCG and PAPP-A in identifying these abnormal gestations.

Fetal cells normally appear in the maternal circulation. Because of breakthroughs in isolating these cells from the maternal circulation and genetic technology enabling testing minute samples of tissue, noninvasive prenatal diagnosis is a real future possibility. Prenatal diagnosis would therefore be possible without placing the fetus at risk (i.e., an amniocentesis may not be necessary in most instances). Clinical trials are currently underway investigating the feasibility of this new technology.

Ultrasonography has revolutionized the field of prenatal diagnosis since its introduction into clinical medicine in the 70's. The previously visually inaccessible uterus has been revealed by this noninvasive technology. It is important to realize that sonography can be

used not only as a screening tool but also a diagnostic tool. The value of ultrasound as a screening tool is controversial most likely because it is highly dependent on the skill of the examiner.

Prenatal testing involves invasively obtaining samples from the fetus or fetal tissues. The cells can then be analyzed for a variety of tests including karyotype analysis, molecular DNA analysis, and chemistries and cultures. We will now explore the different prenatal testing procedures that are currently available.

Amniocentesis is generally performed at 15-20 weeks gestational age. This test involves sonographic localization of the placenta, fetus and amniotic fluid. Under ultrasound guidance, a spinal needle is inserted percutaneously into the amniotic sac withdrawing approximately 20 cc's of amniotic fluid. Within this fluid, fetal cells from the fetal skin, urinary system and amniotic membranes are spun down and collected. The cells are then grown in culture for approximately 5-6 days and arrested in the metaphase of the cell replication cycle. After fixation and staining, the chromosomes are identified and counted to assess the number and gross structure. Typically, humans have 22 pairs or autosomes and two sex chromosomes for a total of 46 chromosomes. As with any invasive tests, there is a risk for miscarriage of approximately 1:200-300 procedures performed.

Chorionic villus sampling can be accomplished in the first trimester by sampling the placenta either transcervically or transabdominally. Since the placenta is fetal in origin, karyotype analysis of the placental cells will most often accurately reflect the fetal chromosomes. This test is typically performed at 10 ½ to 13 weeks gestation. The major advantage to this procedure is the earlier gestational age at the time of diagnosis. The draw back is a slightly increased risk for miscarriage of approximately 1:75-100 procedures performed.

Percutaneous umbilical blood sampling (PUBS) of fetal blood is sometimes required to evaluate fetal anemia, fetal infection, and rapid fetal karyotype. This procedure allows direct evaluation of fetal blood and serum. The procedure is performed much like that of an amniocentesis under ultrasound guidance. The needle is directed to the umbilical cord and blood removed directly from the fetal blood vessels. Because the target is much smaller, skill at imaging the vessel and directing the needle is an absolute requirement. Blood withdrawn can be analyzed much like any other blood sample. In addition, since the white blood cells in the fetal circulation are actively dividing, karyotype analysis is accomplished much quicker, often without requiring many days of cell growth. This procedure can be performed as early as 16 weeks gestational age. The miscarriage risk for this procedure is approximately 1%.

Questions

1. Pertinent family history includes all of the following except:
    a. Ethnic background
    b. Family members with mental retardation
    c. Family members with birth defects
    d. Step parents

2. True/False: The risk of aneuploidy such as trisomy 21 only exists in women over 35 years old.

3. Increased paternal age is associated with which of the following:
    a. Aneuploidy
    b. Increased perinatal mortality and morbidity in otherwise normal fetuses
    c. New dominant genetic mutations
    d. Pregnancy medical complications

4. Midtrimester maternal serum screening utilized levels of these analytes (biochemical markers) except:
    a. human chorionic gonadotropin
    b. alpha-fetoprotein
    c. fetal cortisol
    d. unconjugated estriol

5. Potential confounding factors in the analysis of maternal serum screening include all of the following except:
    a. Fetal demise
    b. Wrong dates
    c. Multiple gestation
    d. Male fetus

6. Unexplained elevated maternal serum alpha-fetoprotein levels portends higher risk for the following perinatal outcomes except:
    a. Oligohydramnios
    b. Stillbirth
    c. Gestational diabetes
    d. Preterm delivery

7. In addition to the detection of aneuploid fetuses, maternal serum screening aids in all of the following except:
    a. Detection of multiple gestations
    b. Determining paternity
    c. Detection of wrong estimation of gestational age
    d. Identifying patients at risk for adverse perinatal outcome

8. Future maternal screening may involve the following analytes except:
    a. Progesterone
    b. Inhibin
    c. Pregnancy Associated Placental Protein A
    d. Urinary human chorionic gonadotropin core

9. True/False: The nuchal translucency measurement in the 10-13 week gestation as a predictor of aneuploidy is independent of maternal age:

10. Prenatal testing procedures currently include all of the following except:
    a. Amniocentesis.
    b. Fetal cells in the maternal circulation.
    c. Chorionic Villus Sampling.
    d. Percutaneous Umbilical Blood Sampling.

Chapter IV.2. Congenital Anomalies and Teratogenesis
Greigh I. Hirata, MD

Ms. T is a 17 year old G3P0Tab2 who presents in her 18th week of pregnancy seeking prenatal counseling. She states she has been a type II diabetic under poor control for 4 years and does not regularly take her oral hypoglycemic agent. She is also taking lithium for a manic disorder and has been drinking alcohol regularly for the past 6 months. She is undecided on her commitment to this pregnancy.

This example demonstrates that there are multiple opportunities to effect fetal development. Medical illnesses, prescription medication and environmental exposures play important roles in the pathogenesis of birth defects. In this section we will review the broad topic of teratogens and congenital anomalies.

Physiologic Basis of Birth Defects

The development of birth defects is greatly dependent on the gestational age, nature of the teratogens and the intensity and duration of exposure. The reader is strongly encouraged to review human development, particularly embryology as it relates to organogenesis, to better understand how and when environmental factors may influence fetal development. Organ systems differ in the timing and duration of formation, which results in marked differences in susceptibility. For example, the cardiovascular system undergoes a lengthy and complex developmental phase which probably explains why this organ system has the highest incidence for birth defects. Also as general rule, significant early insults (less than 8 gestational weeks) result in spontaneous miscarriages, whereas exposure later in the gestation (typically after organogenesis or approximately 14-16 weeks gestation) has less of an effect. There are, however, many exceptions to these basic rules.

It is essential to understand the pathophysiologic mechanisms for fetal mal-development, which may be divided into malformation, deformation, disruption or dysplasia. A malformation is commonly defined as a single localized poor formation of tissue that initiates a chain of subsequent defects (1). Anencephaly, for example, is a result of a failure of closure of the anterior neural tube prior to 26 days of fetal life which ultimately results in the degeneration of the forebrain. The recurrence risk for malformations generally range from 1 to 5 per cent. In comparison, a deformation is a result of extrinsic mechanical forces on otherwise normal tissue. This is illustrated in the characteristic pattern of abnormalities including the abnormal facies, pulmonary hypoplasia, and limb contractures that result from prolonged oligohydramnios, either secondary to renal agenesis (Potter syndrome) or premature rupture of membranes (Potter sequence). A disruption results from an extrinsic insult, which destroys normal tissue altering the formation of a structure. The patterns of findings that result from amniotic bands and limb strangulation (a condition in which torn amniotic tissue strands surround a portion of the of body, often digits or extremities, resulting in deep grooves or amputations) are good examples of a disruption type birth defect. Finally, if the primary defect is a lack of normal organization of cells into tissue, a dysplasia will result. This is best illustrated by the pattern of bony abnormalities found in achondroplasia where a defect in the gene encoding fibroblast growth factor receptor 3 results in abnormal cartilage formation.

It is also important to recognize the differences between a "syndrome" and an "association". Syndromes are typically a result of a single genetic abnormality whereas associations are nonrandom collections of birth defects, which may have resulted from a number of genetic factors. This is illustrated when one compares Down syndrome (a result of an extra copy of chromosome 21) with VATER Association (a nonrandom association of vertebral anomalies, imperforate anus, and esophageal atresia with tracheoesophageal fistula). The understanding of these pathophysiologic mechanisms and nomenclature is important in the study of birth defects.

Medical Conditions Affecting Fetal Development

Medical illnesses are seldom thought of as fetal teratogens. This is not the case in the following examples demonstrating how important pre-conceptual counseling is in prevention of birth defects.

Diabetes mellitus: It is well known that pre-gestational and early gestational glucose control greatly influence the rate of miscarriage and fetal anomalies. In a study performed by Hanson et al (2), hemoglobin A1c levels for those women seeking prenatal care were linearly correlated with the rate of miscarriage and anomalies. Moreover, in a summary of 11 studies by Gabbe (3), the incidence of birth defects were 2.5% in those women seeking glucose control pre-conceptually versus 7.8% in those women presenting after conception. The hemoglobin A1c level at 14 weeks, reflecting glycemic control 3-4 weeks prior, is predictive of the rate of fetal anomalies. A hemoglobin A1c level >8.5% confers a risk of birth defects of approximately 22% versus 3.4% in women with A1c levels <8.5% (4).

The pattern of anomalies secondary to diabetes are characteristic. Infants of diabetic mothers are particularly prone to defects in the cardiovascular system, central nervous system and skeletal system. The relative risk for cardiac anomalies is 4.3 times higher compared

with normal glycemic controls (5). The relative risk for central nervous system anomalies such as anencephaly (3.3 RR) and spina bifida (1.4 RR) are also increased (5). The rare disorder, caudal regression syndrome is almost pathognomonic (RR 175) for maternal diabetes mellitus (5).

The goals of pre-conceptual treatment are euglycemia and avoidance of glycemic fluctuations. Pre-prandial capillary glucose should be <110 mg/dl with the one-hour post-prandial levels <140 mg/dl. Because of these strict goals and concerns regarding transplacental exposure, oral hypoglycemic agents are deemed inadequate. The optimal treatment would involve preconceptual counseling and glycemic control at least 3 months prior to conception.

Seizure Disorders: Maternal seizure disorders are another example of an illness associated with birth defects. There is some evidence suggesting that epilepsy in and of itself may be teratogenic. However, the pattern of abnormalities encountered with this disease is not well defined. Of major concern is the potential for teratogenesis because of exposure to anti-seizure medications. Most anticonvulsants have significant risk for birth defect formation. However, the ultimate goals of any treatment are first and foremost, control of seizure activity. Moreover, if at all possible, monotherapy is preferred over polytherapy.

The fetal effects of valproic acid include increased risks for specific craniofacial abnormalities, cardiovascular defects and neural tube defects. It is estimated that the risk for neural tube defects is 1-2%. Since valproic acid interferes with folic acid metabolism, patients on this medication may benefit from preconceptual folic acid administration.

Phenobarbital may lead to fetal withdrawal in the neonatal period. The possibility of a fetal barbiturate syndrome is currently controversial. Babies exposed to this medication in utero have be found to be relatively vitamin K deficient leading to the recommendation of maternal vitamin K administration at least one month prior to parturition.

The hydantoin (phenytoin) syndrome consisting of the constellation of growth and performance delays, cranio-facial abnormalities, and hypoplasia of the nails and distal phalanges has been well recognized. Like phenobarbital, vitamin K deficiency has been observed in these neonates and therefore maternal vitamin K administration is recommended one month prior to birth is recommended.

Carbamazepine is generally well tolerated and safe in pregnancy. There is an estimated 1% risk for neural tube defect which may be amenable to reduction by preconceptual administration of folic acid. There has also been a suggestion of a pattern of malformations similar to that seen with phenytoin exposure.

Teratogens

In this section we will review a compilation of some of the common teratogens. Remember that the risk for the fetus is greatly dependent on the timing of exposure, duration and intensity of the agent, and genetic susceptibility. For a complete list of teratogens and potential fetal effects, the reader is referred to resources listed in the reference section of this chapter.

Coumarin (coumadin, warfarin) is a vitamin K antagonist used for anticoagulation which has been linked to a well described pattern of malformations including nasal hypoplasia, intrauterine growth retardation, developmental delay and a characteristic stippling of the bone epiphyses. The incidence of this pattern is estimated to be 10% if exposure occurs within the first trimester of pregnancy.

Lithium is commonly used in the treatment of bipolar or manic disorders. Exposure to this medication in the first and early second trimester of pregnancy is associated with a 1-5% risk of congenital heart defects, particularly Ebstein anomaly.

Angiotensin-converting enzyme (ACE) inhibitors, a class of antihypertensive agents, is associated with renal tubular dysplasia/anuria, oligohydramnios, intrauterine growth retardation, and defects of ossification when the fetus is exposed in the late second and third trimester of pregnancy.

Fetal exposure to retinoic acid, such as isotretinoin (Accutane) is associated with characteristic craniofacial abnormalities, central nervous system defects, cardiovascular abnormalities and mental retardation. The estimated risk is 35% if taken beyond the 15th day following conception. Similar types of birth defects are also seen in women who ingest large amounts of other forms of vitamin A.

Maternal pyrexia is not commonly thought of as a fetal teratogen but there are a number of experimental and observational studies suggesting otherwise. In laboratory guinea pigs, Edwards et al has shown that heat exposure to fetal pup at a critical stage in development has induced a number of neurologic developmental abnormalities and vascular disruption defects such as bowel atresias (6). In humans, maternal exposure to hot tubs significantly increased the incidence of neural tube defects (relative risk 2.9, confidence interval 1.4-6.3) over nonexposed controls (7).

Perhaps the most common avoidable human teratogen is alcohol. It is estimated that the risk for fetal alcohol syndrome is 10% if exposed to 1-2 drinks per day. The incidence increases to 40% if the exposure increases to 6 drinks per day. The syndrome consists of small for gestational age/intrauterine growth retardation, characteristic craniofacial abnormalities, congenital heart defects, and developmental delays. A greater number of infants are born with fetal alcohol effect, a clinically milder but similar form of fetal alcohol syndrome. This uncertainty has prompted the recommendation that there is no safe amount of alcohol consumption during pregnancy.

Exposure to illicit recreational drugs such as amphetamines and cocaine is theorized to cause defects in prosencephalic development or neuronal migration resulting in abnormalities such as agenesis of the corpus callosum and brain clefts. It is also hypothesized that the incidence of fetal vascular accidents is increased resulting in cerebral infarcts, intracerebral hemorrhage, and intestinal atresias and limb reduction defects. Late exposure has been associated with intrauterine growth retardation, preterm delivery and placental abruption.

Genetic basis of fetal teratogen susceptibility

It has long been observed that exposure to many teratogens results in a wide range of effects. It has been speculated that certain individuals carry a genetic susceptibility. These are two examples of how genetic predisposition may interact with the environment and result in the formation of a birth defect.

In epoxide hydrolase deficiency, (this enzyme is critical in the metabolism of anticonvulsant medications such as phenytoin), it has been speculated that a deficiency in this enzyme may result in an accumulation of oxidative metabolites. Bueher, et al has found that in 19 women on phenytoin, four fetuses with low levels of enzyme activity were found to have clinical features of the phenytoin embryopathy whereas 15 fetuses similarly exposed with enzyme activity above 30% of controls (i.e., more normal enzyme levels) were normal (8).

Methylenetetrahydrofolate reductase (MTHFR): A common abnormal variant of this enzyme leads to elevation of homocysteine levels through inhibition of the folate-mediated remethylation of that compound. It is very common, with an estimated 30-40% of the general population heterozygous and 10% homozygous for this mutation. There is evidence that elevated homocysteine levels may be teratogenic in laboratory animals and humans. It is speculated that fetuses homozygous for the MTHFR mutation born to folate deficient mothers are at increased risk for defective neural tube formation.

Questions

1. Achondroplasia is an example of a:
    a. Malformation
    b. Deformation
    c. Disruption
    d. Dysplasia

2. Amniotic Band Syndrome is an example of a:
    a. Malformation
    b. Deformation
    c. Disruption
    d. Dysplasia

3. An "association" is a:
    a. result of a single genetic abnormality.
    b. nonrandom collection of birth defects.

4. Anencephaly is an example of a:
    a. Malformation
    b. Deformation
    c. Disruption
    d. Dysplasia

5. A significant fetal insult in the first trimester of pregnancy most commonly results in a:
    a. severe birth defect
    b. minor birth defect
    c. no birth defect
    d. miscarriage

6. The most common organ systems involved with diabetic embryopathy include:
    a. the cardiovascular system
    b. the central nervous system
    c. the spinal system
    d. all of the above
    e. none of the above

7. The safe level of alcohol consumption in pregnancy is:
    a. less than 2 drinks per day
    b. less than 6 drinks per day
    c. there is no safe level

Chapter IV.3. Common Chromosomal Disorders
Julie Won Ireland, MD

A two day old male infant is referred from a community hospital for bilious vomiting and a heart murmur. The baby was born at 37 weeks gestation to a G4P3 39 year old woman who had no prenatal care.

Exam: VS T37.1 (ax), P150, R45, BP 75/50, oxygen saturation 99% in room air. Height, weight and head circumference are at the 50th percentile. He appears jaundiced, and has a flat facial profile; short, upslanting palpebral fissures; a flat nasal bridge with epicanthal folds; a small mouth with protruding tongue; and single palmar creases. His lungs are clear to auscultation. His heart is tachycardic with a loud holosystolic murmur. His abdomen is non-distended. Generalized hypotonia is present.

An abdominal radiograph shows a "double-bubble sign". Duodenal atresia is suspected. A nasogastric tube is placed and IV fluids are administered. He later undergoes a duodenoduodenostomy. An echocardiogram demonstrates a ventricular septal defect, which is medically managed. A chromosomal abnormality is suspected and a karyotype is done. Trisomy 21 is diagnosed.

This chapter deals with some of the more common chromosomal abnormalities encountered in clinical practice. While the infant described above has trisomy 21, or Down syndrome, other disorders of chromosomes include trisomy 18 (Edwards syndrome), trisomy 13 (Patau syndrome), XXY (Klinefelter syndrome), 45X (Turner syndrome), Noonan syndrome, XYY syndrome and Fragile X syndrome.

Trisomy 21 (Down syndrome)

Dr. John Langdon H. Down first described a cluster of mentally retarded patients in an England asylum in an essay, "Observations on an Ethnic Classification of Idiots," in 1866. It was not until the 1950s that an extra 21st chromosome was found to be responsible for what was to become known as Down syndrome. The incidence is 1 in 600-800 births. The sporadic form has a higher frequency with advanced maternal age. In mothers less than 25 years of age, the risk is 1 in 2000 births and climbs to 1 in 20 births for mothers over age 40. All patients with Down syndrome have three copies of chromosome 21. In 95% of patients, there are 47 chromosomes with trisomy of chromosome 21. In about 5%, there are 46 chromosomes, with an abnormally translocated 21st chromosome. Robertsonian translocations involve the transfer of chromosomal material from 21 to usually chromosome number 13, 14, or 15. The Down phenotype occurs when even a small, but critical piece of the long arm of chromosome 21 is trisomic. Carriers of a Robertsonian translocation are usually phenotypically normal, but are at increased risk for miscarriages and chromosomally abnormal children. Another cause is a 21q/21q translocation. This is rare, but significant because a carrier parent only has one 21st chromosome (the translocated chromosome with double the genetic material). When this chromosome is passed on, all of the offspring will have trisomy 21. An example of this is a mother who had this translocation and had four children with Down syndrome. Milder phenotypes may be seen when patients are mosaic for trisomy 21. This happens when nondisjunction occurs early in embryonic development as a mitotic error.

Affected patients have a characteristic facies including epicanthal folds, a flat nasal bridge, small mouth, protruding tongue with microcephaly and a flat occiput. Other features may include a high arched palate, a single palmar crease (Simian crease). The pupils may have light smudgy opaque Brushfield spots. At birth, patients are often hypotonic and have a higher incidence of other types of malformations. Cardiac anomalies are present in 33-50% and include endocardial cushion defects and ventricular septal defects. Gastrointestinal anomalies can include duodenal atresia and Hirschsprung's disease. Later in life, hypothyroidism and leukemia can occur, and there is an increased susceptibility to infections. Atlanto-occipital instability may be present in a few and is a concern when intubating these patients. A pneumonic for remembering the major complications found in Down syndrome patients is using the word VALIDATE as follows: VSD, Atlanto-occipital instability, Leukemia, Immunodeficiency, Duodenal atresia, Alzheimer's disease, Thyroid dysfunction, and Endocardial cushion defects.

There is no treatment for the trisomy itself, so therapy is directed towards other complications present, such as cardiac and gastrointestinal anomalies, thyroid dysfunction, and infections. Their IQ is usually about 50-75, at best they function at a sixth grade level, and few are severely retarded. These children are placed in infant stimulation programs, enrolled in special education classes, and later given occupational training to help them become more independent and a functioning part of society. It is very important to counsel parents who have one child with Down syndrome about the risk of having a second affected child. The risk of recurrence is 1% in otherwise low risk moms and if the parent is not a translocation carrier. Obstetric screening tests can identify some pregnancies at risk, so that fetal chromosome testing can be offered. Involvement in compassionate support groups should be encouraged to the parents.

Trisomy 18 (Edwards Syndrome or Trisomy E)

Infants with trisomy 18 are severely affected and usually die in the first week of life. Less than 10% of patients survive beyond twelve months and are profoundly mentally retarded. The cause of this syndrome is usually full trisomy for chromosome 18. The incidence is 1 in 4000-8000 births, with a 3:1 predominance of affected females to males. The risk increases with maternal age. The recurrence risk is very low based on the observation that most affected children die in utero. Patients with trisomy 18 mosaicism have a less severe clinical expression and longer survival depending on the degree of mosaicism. Partial trisomy 18 varies in its clinical picture from mild mental deficiency and improved survival to being indistinguishable from full trisomy 18. This depends on the extent and which part of the chromosome is affected.

Numerous malformations have been reported in trisomy 18. These infants have a characteristic head shape and facial features, such as a prominent occiput, low-set ears, and micrognathia. The hands are often clenched with the index finger overlapping the third finger. Dysmorphic joints produce this typical finger position. Deformities of the lower extremities include hypoplastic nails of the feet, malaligned toes and "rocker-bottom feet", where the calcaneus is prominent. Heart defects, such as ventricular septal defect, patent ductus arteriosus or atrial septal defect, are found in at least 50% of these patients. They also have a short sternum with small nipples.

Supportive care is the treatment for this syndrome. Genetic counseling is indicated. Chromosomal studies should be done to determine translocation cases. The recurrence risk for full 18 trisomy cases is less than 1% because most die in embryonic or fetal life. Some children with trisomy 18 have reached adulthood. Heart failure or pneumonia are some of the complications that often cause death.

Trisomy 13 (Patau Syndrome or Trisomy D)

The constellation of findings in this condition have been described as far back as the 1600's. Klaus Patau and his colleagues were the first to attribute the syndrome of trisomy for chromosome 13 by cytogenetic analysis in 1960. The cause of this syndrome is usually trisomy for chromosome 13. Its overall incidence is 1 in 12,000 births, but the risk increases with maternal age. The recurrence rate is

very low, except for the parent who has a balanced translocation. Patients with trisomy 13 mosaicism have been described and usually have a milder phenotype depending on the degree of mosaicism.

Patients are severely affected and often die in infancy. The median survival has been reported as two and a half days. Surviving infants have severe mental retardation and may have midline CNS defects, incomplete development of the forebrain, apneic episodes and EEG abnormalities. Bilateral cleft lip and palate are common. Microcephaly, microphthalmia, and deafness may also be found. Lethal cardiac anomalies are found in 80% of patients, with VSD being the most common. PDA, ASD, dextroposition, and valvular abnormalities can also occur. Disorders of the extremities may include a single palmar crease (Simian crease). Polydactyly, particularly of all extremities, strongly suggests trisomy 13. Overlap of the middle and ring fingers are seen.

Treatment is supportive. Prevention by genetic counseling is indicated. Critical decisions in regards to extensive therapy and resuscitation measures in a severely affected infant must be decided at birth. Those affected usually die in infancy; very few live to become adults. Children who survive are severely retarded and are rarely able to suck. They fail to thrive and have seizures.

Klinefelter Syndrome (47 XXY)

Harry Fitch Klinefelter worked with Dr. Fuller Albright in clinical endocrinology when he saw his first patient, who was a young man with small testes and gynecomastia. During his fellowship, he encountered 8 other patients with similar findings and described Klinefelter syndrome in 1942. Klinefelter syndrome affects 1 in 1000 newborn boys and is caused by an extra X chromosome from meitotic nondisjunction. The incidence is 1% among the mentally retarded and 3% among males seen at infertility clinics. In 54% of the patients, the extra X chromosome comes from the mother and in the other 46%, the extra X chromosome comes from the father. Maternal age, but not paternal age is often advanced. The most common chromosomal pattern is 47,XXY. Others have mosaic patterns: 46,XY/47,XXY; 46,XY/48,XXYY; or 46,XX/47,XXY. These patients tend to have milder phenotypes. Children with mosaicism have a better prognosis for fertility and virilization. In chromosome variants with multiple X chromosomes (XXXY and XXXXY), the clinical manifestations are much more severe. In general, the mental and physical abnormalities associated with Klinefelter syndrome worsen as the number of X chromosomes increase.

The characteristic findings of Klinefelter syndrome usually do not become apparent until after puberty. They have a eunuchoid habitus; usually tall, slim and underweight, with long legs. One third have gynecomastia and they have less facial hair. Their gonads are small and soft, and the phallus tends to be smaller than average. The seminiferous tubules are atrophied because of excess gonadotropin. There is hyperplasia of the Leydig cells, producing azoospermia and infertility. Cryptorchidism may occur in some patients. Hypogonadism becomes recognized after puberty when the testicles fail to grow and develop normally. This is usually the time when the diagnosis is suspected. Pubertal development may be delayed. These patients tend to have learning and psychosocial problems. They have normal to borderline IQ, with a mean IQ of 90. In boys with mental retardation, learning disabilities or adjustment problems at school, Klinefelter syndrome should be a consideration. Later in life, these individuals are at higher risk to develop diabetes mellitus. There is also an increased incidence of cancer of the breast, varicose veins, and pulmonary disease.

Chromosomal analysis should be done to confirm the diagnosis of Klinefelter syndrome. In males younger than 10 years of age, they have normal levels of FSH and LH and respond appropriately to GnRH and hCG. In late adolescence, testosterone levels decrease, and gonadotropins increase. In adults, urinary excretion of gonadotropins is high, with levels comparable to those seen in post menopausal women. Gynecomastia is a result of an elevated estradiol to testosterone ratio. In the management of Klinefelter syndrome, testosterone replacement therapy should start at 11 to 12 years of age, if testosterone levels are deficient and gonadotropin levels become elevated. With early recognition and diagnosis, treatment can be initiated to allow a more normal maturation for the affected male, but infertility cannot be reversed.

Turner Syndrome (45X)

In 1938, a series of young women with failure of sexual maturation, short stature, and neck webbing were reported by Henry Turner. He believed this was due to a defect in the anterior pituitary gland. It was not until 1959, when the absence of the X chromosome was first described by Charles Ford. The incidence is 1 in 2500 live female births, 95% of 45X fetuses die in utero. About 50% of patients apparently have the full monosomy 45,X, the others all have detectable mosaicism. About 2/3 retain the maternal X and 1/3 have the paternal X. Advanced maternal age is not a factor in this syndrome. Only one X is normal and functioning; the other X is not present or is missing a part of its chromosome by structural abnormality, deletion or translocation. Mosaicism 45,X/46,XX or 45,X/46,XX/47,XXX may also be present. 10% of Turner mosaics have a Y chromosome, 45,X/46,XY is seen. The presence of the Y chromosome increases the risk of gonadoblastoma. Milder phenotypes are usually seen in those without the full monosomic karyotype.

The characteristic features include a triangular face, small mandible, prominent ears, webbed neck, low posterior hair line, shield chest with wide set nipples, cubitus valgus (increased carrying angle of the elbow), and short stature. Sometimes short stature may be the only clinical finding present in a young girl. Their average adult height is about 143 cm (4 ft., 8 in.). In most of these girls, secondary sexual characteristics are absent. They have amenorrhea and are infertile due to ovarian dysgenesis. Intelligence is usually normal, but they may have a learning disability. These patients may have cardiac defects; 30-50% have bicuspid aortic valve, and 10-20% have coarctation of the aorta. Other cardiac complications include aortic stenosis, aortic dissection and idiopathic hypertension. Urinary tract malformations are found with a higher frequency in these patients. Most common presentations include a horseshoe kidney, kidney located in the pelvis, double collecting system, or absence of a kidney.

Growth hormone alone or in combination with anabolic steroids has been successful in managing these patients. This is still very controversial. Opponents claim that growth hormone accelerates growth, but does not increase adult height. Therapy should begin when the height of the patient drops below the 5th percentile on the growth curve. For those who are deficient in estrogen and progestin, long term replacement therapy is required for development of secondary sexual characteristics and initiation of the menstrual cycle. As for all post-menopausal women, these women especially need hormonal therapy, in combination with calcium supplementation and exercise, to help prevent osteoporosis. Rarely, spontaneous puberty and menses can occur and pregnancy is possible. There is an increased risk of giving birth to a child with chromosomal or congenital anomalies. Genetic counseling and a medical work up are required. Support groups can be of much benefit. These women can become independent and lead productive lives. Most die in utero, but for those who survive, the average age of death is 69. Increased mortality can primarily be attributed to cardiovascular disease.

Noonan Syndrome

This syndrome resembles Turner syndrome and occurs in males and females. The occurrence is often sporadic, but an autosomal dominant inheritance has been reported. A gene for this disorder has been mapped to chromosome 12q; although not in every family, suggesting that other loci may be involved.

The clinical manifestations are short stature, short or webbed neck, shield chest and pectus excavatum or carinatum. They have a characteristic facies; epicanthal folds, ptosis, hypertelorism, downslanting palpebral fissures, and low or abnormal ears. Interestingly, their facies can normalize with age. The most common cardiac abnormality is pulmonary valve stenosis, but they can also have atrial septal defects, left ventricular hypertrophy, or patent ductus arteriosus. Males may have cryptorchidism, small penis, and hypogonadism. However, in males without cryptorchidism, fertility is normal. Fertility is also normal in females. About 25% of affected patients have some degree of mental deficiency.

There is no specific treatment. Genetic counseling should be offered to parents regarding the recurrence risk.

XYY Syndrome

In random newborn males, the incidence of the 47,XYY karyotype is 1 in 1000. In some prison populations, the incidence is 1-2 %. In institutionalized men or juvenile delinquents taller than 6 feet, 10% have XYY syndrome. Most 47, XYY males are phenotypically normal, however variable, non-specific characteristics may be seen. Stature tends to be tall, and patients may have large teeth and severe nodulocystic acne. They are not well coordinated or strong relative to their large size. Some males have anti-social behavior. They may be impulsive, hyperactive, have poor social skills, and low self esteem. They were once stereotyped as being violent and aggressive. However, longitudinal studies suggest that aggressive behavior is usually not a problem, and they learn to control their anger by the time they become young adults. These males have a normal to low IQ, and 50 % have a learning disability. The majority of patients are fertile. Their sperm may have 23,X, 23,Y, 24,XY or 24,YY, so the syndrome can recur. However, they usually have children with normal chromosomes.

XYY syndrome is diagnosed by karyotype. There are no consistent clinical findings. There is no treatment for this syndrome. In general, affected children are normal. However, behavioral modification is necessary in dealing with the hyperactivity and aggressiveness that may be seen during childhood. The majority are well-adapted citizens.

Fragile X Syndrome

The syndrome was first described by Martin and Bell in 1943, though the fragile site on the X chromosome was reported in 1969 by Lubs. It occurs in 1 in 1000 males. This disorder is caused by an expanded trinucleotide repeat (CGG) in the FMR-1 gene on the X chromosome with X-linked inheritance. When cells, from patients with this disorder, are cultured in a certain medium deficient in folate or thymidine, the fragile site can be visualized. The normal allele repeat range is 6-40. The intermediate allele repeat range is 41-60 repeats (most are stably inherited), and the premutation allele repeat range is 61-200 repeats. Carriers of the premutation are usually phenotypically normal and not at increased risk for retardation. Females who carry this premutation may pass down an expanded version resulting in full expression of the phenotype in males and variable phenotypic expression in females. The severity correlates with the increase in size of the repeat sequence. The full mutation (disease causing) repeat range is greater than 200 repeats. Other disorders that are caused by expanded trinucleotide repeats include Huntington disease, myotonic dystrophy and Friedreich ataxia.

Physical abnormalities in males with fragile X syndrome include large ears, a large jaw and large, soft testicles. Connective tissue dysfunction, mitral valve prolapse and dental crowding can also be found. Cluttered speech, autism, hyperactivity and mild to severe mental retardation are common. Females with fragile X syndrome (usually heterozygous) tend to have a less severe clinical expression and only 1/3 have mental retardation.

Treatment and management includes supportive care. Genetic counseling is important in prenatal and postnatal diagnosis of fragile X syndrome. Clinical expression is different depending on which parent transmits the gene. DNA analysis helps to identify full mutations as well as premutation carriers. The life expectancy is normal.

Questions

1. What chromosomal disorder(s) can present with bilateral cleft palate, cleft lip and a ventricular septal defect?
2. This syndrome presents with a prominent occiput, clenched fists and "rocker bottom feet". What are 2 complications that can cause death in these children?
3. Name 4 disorders associated with a trinucleotide repeat?
4. Name 8 complications of Down syndrome.
5. What is the etiology of infertility in women with Turner syndrome?
6. What causes gynecomastia in males with Klinefelter syndrome?
7. Which terminology below (one or more) for trisomy 21 is (are) incorrect?
    a. Down syndrome
    b. Downs syndrome
    c. Down's syndrome
    d. Mongolism
    e. Trisomy 21

Chapter IV.4. Inborn Errors of Metabolism
Catherine Y.H. Wagoner, MD

This is a 2 day old male infant who is referred from an outside hospital for persistent hypotonia and mild respiratory distress since birth. He also has feeding intolerance characterized by emesis following each feeding. He is the product of a full term pregnancy to a 26 year old G1P1Ab0, O+, hepatitis B negative, rubella immune, STS negative mother via NSVD with Apgar scores of 7 and 8 at 1 minute and 5 minutes, respectively. Birth was complicated by a nuchal cord x 1 and a maternal fever to 102 degrees just prior to delivery for which one dose of ampicillin was given. After delivery, the infant required some blow-by oxygen and was transferred to the newborn nursery. In the newborn nursery, the infant continued to require oxygen until 2 hours of life when he was noted to have adequate oxygen saturations in room air. A CBC was done which was reported as unremarkable. The baby nursed overnight without any difficulty, and was able to pass his first meconium at less than 24 hours old. However, his first breastfeeding was followed by emesis. A second feeding of water also resulted in emesis. Due to the persistent hypotonia, feeding intolerance, and continued mild respiratory distress despite adequate oxygenation, the infant was transferred to a tertiary care neonatal intensive care unit (NICU).

Exam: VS T 36.5, P 136, RR 44, BP 58/41, oxygen saturation 100% in room air. Wt: 3.95 kg (80%ile). He is a term-appearing male infant who is noted to be slightly tachypneic and intermittently grunting. His head, ears, eyes, nose and oropharyngeal structures are without obvious abnormalities, except for his tongue which is remarkable for lateral fasciculations. His neck is supple. His lungs are clear, but he has notable intermittent grunting. His heart is regular with no murmurs. His abdomen is flat and soft, but his liver is palpable 2 cm below RCM. His extremities are normal, with 1+ pulses. His DTRs are absent. Genitalia are normal. He is hypotonic with poor head control.

A full sepsis workup is done and he is started on empiric antibiotics. An ABG demonstrates a severe metabolic acidosis with pH 7.22 and Bicarbonate 10. Anion gap is 23. Lactic acid and ammonia levels are elevated.

A bicarbonate infusion is initiated to treat the acidosis, dropping the base deficit from -13 to -5, and then to +6. After consultation with genetics, it is felt that the infant likely has a defect in energy metabolism based on the persistent hypotonia and severe acidosis. A metabolic defect workup is done, including urine for organic acids, plasma for amino acids, and muscle biopsy for fibroblast culture and electron microscopy analysis. He is started empirically on a vitamin cocktail consisting of thiamine, niacin, riboflavin, B12, biotin, and L-carnitine for the possibility of a fatty acid oxidation or mitochondrial defect. An MRI on day 3 of life reveals severe cerebral atrophy and developmental brain anomalies including agenesis of the corpus callosum. He later decompensates requiring life support. The severe metabolic acidosis recurs and additional sodium bicarbonate infusions are required. Despite this level of support, he does not improve. A decision is made by his parents and the medical team to withdraw support, since the infant's condition is felt to be terminal.

Inborn errors of metabolism (IEM) are a diverse group of disorders. They are genetically based defects of the normal biochemical processes of the body that are required to maintain homeostasis (1). The potential for a problem is great since there are a great number of biochemical reactions that must be enzymatically carried out for normal metabolism. An enzyme defect in any pathway (e.g., Krebs cycle, urea cycle, oxidative phosphorylation, etc.) will potentially result in a condition that is incompatible with life, unless a therapeutic way to circumvent the metabolic defect can be accomplished. Unfortunately, many and probably most of the diseases in this group can lead to a debilitating and even tragic ending, as illustrated in the case above. Due to the sheer number of disorders classified as inborn errors of metabolism, literally hundreds with more being discovered each year, it would be impossible to give a comprehensive review of the subject in a single book chapter. However, there are several overriding principles and practices that are fundamental to the diagnosis and management of the patient with a suspected inborn error of metabolism.

The objectives of this chapter will be to: 1) Understand the basic genetic mechanisms which underlie inborn errors of metabolism. 2) Know some of the more commonly affected biochemical pathways that manifest as metabolic disease. 3) Learn to recognize the subtle signs and some of the constellations of symptoms that may point toward a specific metabolic disease. 4) To learn about the Hawaii State Newborn Screening Program, its goals, and the systems in place to ensure the identification of babies who may have a correctable or treatable disorder.

Some of the great discoveries of science in the 20th century were the identification of biochemical pathways in the body that facilitate the existence of life in all organisms. These biochemical processes, such as the Krebs cycle that converts glucose to energy in the form of ATP and the urea cycle that converts ingested nitrogens into a form that can be excreted, form the basis for the routine production of energy from food, excretion of waste products, and the regulation of the internal environment of the body.

There are literally hundreds of individual steps in the body's processes. Roche Pharmaceuticals Group has an interactive diagram of most of the known biochemical processes on their website (2). It is these biochemical steps that are the sites of defects that result in metabolic disease. Since each step is dependent on the product of the previous step to provide the substrate for a reaction, a "mistake" in either the substrate produced or the enzyme required for the reaction will result in a seriously magnified effect on all the products of the

reactions downstream from the defective step. Ultimately, this may result in the inability to produce a necessary end product or to carry out a detoxification process.

The extent to which a metabolic defect may affect the function of the body is highly dependent on the final product of a biochemical cascade. For example, in ornithine transcarbamylase deficiency (OTC), a part of the urea cycle, carbamyl phosphate and ornithine are converted to citrulline. Citrulline is able to move outside the mitochondria, thereby transporting waste products of respiration to the cytoplasm where they can be processed further and ultimately excreted from the body. In OTC deficiency, there is accumulation of the upstream products of the reaction that leads to hyperammonemia. Over time, the high levels of ammonia will affect the brain, due to the toxicity of the waste product on the neurons. This will lead to the ataxia, seizures, cerebral atrophy, and encephalopathy observed in this disease (1-12).

It is of primary importance to understand the variable genetic mechanisms that can cause abnormal biochemical functioning. DNA is transcribed into ribonucleic acid (RNA) that is then processed into messenger RNA, which is then transcribed to a protein that may undergo further processing to become a functional enzyme, carbohydrate, signaling protein, hormone or structural element. Within this whole process of DNA to protein, there are multiple regulatory processes and feedback loops that will alter the rate of the transcription of DNA, processing of RNA, and the production of the final product. Thus, any defect in the DNA will lead to a change in the whole cascade and ultimately may affect multiple systems and biochemical processes.

One might postulate that a metabolic defect would render an individual unable to survive without modern medical interventions (e.g., transplantation, life support machines, exclusionary diets with special supplemental formulas). In fact, that is very likely true. Many infants who died in early childhood prior to the advent of sensitive diagnostic testing may have succumbed to a potentially treatable metabolic disease. It is easy to see that there is a natural selection against individuals with metabolic diseases, especially those who have a decrease in survival or basic life functioning.

It is, therefore, not surprising that many of the metabolic diseases are inherited in an autosomal recessive, X-linked recessive (males only), or sporadic (new mutation) pattern (1). Conditions that are lethal prior to reproductive age would not survive in the gene pool unless the condition was recessive (the heterozygous state could survive in the gene pool). Thus ALL lethal conditions are recessive or spontaneous new lethal mutations. In urea cycle defects, every known deficiency is autosomal recessive except OTC deficiency which is X-linked recessive (1). This also holds true for the lipidoses (disorders in lipid metabolism leading to the accumulation of lipoid material within cells). Niemann-Pick, Gaucher, Krabbe, and metachromatic leukodystrophy are all autosomal recessive, if a case is not sporadic (3). The other causes of neonatal degenerative encephalopathies, such as peroxisomal disorders and mitochondrial disorders are also autosomal recessive or X-linked recessive (4).

How might one go about determining whether an infant has a metabolic disease? The answer will always be clinical suspicion. There are a few "classic" presentations that should trigger consideration of an inborn error of metabolism as a reasonable possibility. These include metabolic acidosis, hyperammonemia, hypoglycemia and unusual odors. The respective clinical manifestations of these abnormalities are described below.

In urea cycle defects, the common toxin is ammonia (NH3), since the urea cycle is designed to excrete excess nitrogen. Therefore, the presentation of this group of defects is quite similar. Hyperammonemia causes an encephalopathic picture. Presenting signs and symptoms include vomiting, lethargy, poor activity, poor feeding, decreased mental status, and even coma. They may eventually develop spasticity, mental retardation, seizures, and ataxia. These disorders usually present in the first few days to weeks of life as the ammonia waste product accumulates quickly, leading to serum ammonia levels which are described as "sky-high" (>1000 umol/L). The afflicted newborn very rapidly decompensates (1,4). The initial clinical presenting signs and symptoms (other than hyperammonemia) more commonly signal a serious infection of the newborn. It is very difficult to differentiate the two disease processes. However, the existence of these symptoms along with low risk for a neonatal infection may raise the index of suspicion that would lead the clinician to conduct a thorough laboratory evaluation for a metabolic condition along with the sepsis workup.

A group of metabolic disorders related to the urea cycle defects is the organic acidemias. These are caused by defective processing of the amino acids resulting in accumulation of organic acid byproducts or lack of production of a necessary end product. The symptoms are very similar to the urea cycle defects; however, there are subtle laboratory differences. While urea cycle disorders result in hyperammonemia without acidosis and only occasionally hypoglycemia, the organic acidemias (as the name suggests) result in metabolic acidosis and hyperammonemia that is more on the order of 200-900 umol/L. One of the best understood diseases from this class of metabolic diseases is Maple Syrup Urine Disease (MSUD).

MSUD occurs in the immediate neonatal period, presenting with acute decompensation within the first 2 weeks of life. Symptoms include lethargy, poor feeding, vomiting, and seizures, which eventually lead to coma and cerebral edema. Laboratory evaluation yields hypoglycemia, hyperammonemia (to a lesser degree than in urea cycle defects), acidosis, and ketosis. The urine from these patients has a striking odor of maple syrup.

Phenylketonuria (PKU), one of the best understood genetic disorders and the first to be screened for in Hawaii (1966) (5), results from phenylalanine hydroxylase (PAH) deficiency. The enzyme deficiency leads to build-up of phenylalanine that is toxic in high levels to brain growth and nerve myelination. This causes mental retardation, abnormal behaviors and skin rashes. In addition, the PAH enzyme is necessary to convert phenylalanine to tyrosine which is required for melanin synthesis. With a defective enzyme, the individual is unable to produce proper levels of tyrosine which results in poor pigmentation of skin and hair (1,5).

Galactosemia is one of the commonly occurring disorders of carbohydrate metabolism. This disease occurs from a deficiency of galactose-1-phosphate uridyltransferase with the deficiency most noticeable in those organs which utilize the most energy (liver, brain, kidney and adrenal gland). Over time, there is an accumulation of galactose-1-phosphate, which manifests as vomiting, lethargy, diarrhea, cataracts, developmental delay and mental retardation, liver and kidney disease. In galactosemia, there is an increased likelihood of sepsis from gram negative organisms that may cause death in the neonatal period (1,4,5).

In an infant who has signs and symptoms consistent with a metabolic disorder, there are certain diagnostic steps that can help delineate what type of metabolic disorder could exist. Of course, the most important evaluation is always the history and physical. With metabolic disorders, one must always ask if there is a family history of early infant death or disability, developmental delay, mental retardation, or seizures. There should also be an assessment of the likelihood that the presenting illness is sepsis, which is much more common than metabolic disorders (4). Thus, some investigation for neonatal infection risk factors should be conducted (e.g., maternal fever, prolonged rupture of membranes, maternal colonization with group B strep, intrapartum maternal antibiotic treatment, fever or temperature instability in the infant, the presence of respiratory distress, etc.).

When a reasonable suspicion of a metabolic disease is established, then an appropriate workup can be undertaken. Laboratory evaluation should include a full sepsis workup (CBC, blood culture, urine culture, chest x-ray, cerebrospinal fluid studies and culture),

since sepsis may not be easily distinguished from an inborn error of metabolism. In addition to the sepsis workup, metabolic screening laboratories should include a glucose level, electrolytes, an arterial blood gas, ammonia level, lactic acid level, urinary ketones, and liver function tests. Definitive diagnosis will depend on what type of metabolic disorder is suspected.

Once the screening laboratories are available, one can systematically eliminate possible diagnoses until there are only a few possibilities left. Then, a few specific diagnostic tests can be performed to hopefully, identify the type of metabolic disorder that is present.

The first useful marker is the ammonia level. Urea cycle defects have extremely elevated ammonia levels, sometimes in excess of 2000 ug/dL. Organic acidemias and benign transient hyperammonemia of the newborn (THAN) have ammonia elevations that can overlap, but are not usually as high as those found in urea cycle defects.

The next useful laboratory marker is the presence or absence of hypoglycemia. Infants with elevated ammonia levels in the presence of hypoglycemia have a reasonable likelihood of having an organic acidemia. Infants with hyperammonemia without hypoglycemia tend to have urea cycle defects. Hypoglycemia without hyperammonemia can signal a carbohydrate metabolism defect (e.g., galactosemia, defect in gluconeogenesis, or a glycogen storage disease) or a fatty acid oxidation deficiency in the older infant.

Metabolic acidosis is a key tool in the differentiation of urea cycle defects versus organic acidemias, but it is also quite useful in the evaluation of respiratory or energy transport chain defects. Persistent, severe, metabolic acidosis with absence of urine organic acids will signal primary lactic acidosis. The presence of primary lactic acidosis usually means a defect in pyruvate metabolism (leading to inability to convert lactic acid back to pyruvate to enter the Krebs cycle), gluconeogenesis disorder (leading the body to scavenge pyruvate which is converted to lactic acid with ATP production), respiratory chain defect (causing inability to produce ATP during the Krebs cycle), or a mitochondrial disorder (e.g., error in oxidative phosphorylation). If the metabolic acidosis is due to a primary lactic acidosis, a lactate/pyruvate ratio may be helpful to further narrow the differential diagnosis (4).

Although it may be possible to determine the general class of metabolic defect, it is often not possible to determine the exact enzyme which is defective or lacking. For example, since there are so many enzymes involved in oxidative phosphorylation, a defect of any one of these will result in a lethal condition.

Current diagnostic studies for inborn errors of metabolism have limitations. The primary drawback is the 3-4 day turnaround time from receipt of the sample to the results being available. A critically ill infant may not be able to survive that time period without appropriate treatment. Thus, in the first few days it is crucial to initiate empiric therapy. This should be done with the available clinical and laboratory evaluation in conjunction with a metabolic specialist guiding treatment.

The presence of a possible organic acid or urea cycle defect requires that the patient undergo protein restriction to prevent accumulation of toxic metabolites or hyperammonemia. However, this requires prevention of catabolism of body protein for conversion to energy (i.e., gluconeogenesis) to prevent additional nitrogen waste production. Thus, an infusion of proper carbohydrate calories should be initiated as soon as possible. In infants, this is usually 10% dextrose (a simple hexose) water intravenously at 80-100 ml/kg/day (1,4).

Many of the organic acidemias and urea cycle defects can be mitigated with the use of vitamins and cofactors that can bypass the defect by shunting the toxic metabolites to an alternate pathway or they can serve as transport molecules to shuttle byproducts in and out of the mitochondria. For example, in citrullinemia and argininosuccinic aciduria, infusions of arginine can result in significant drops in the ammonia level. Biotin can be used in carboxylase deficiencies while vitamin B12 can be useful in some forms of methylmalonic acidemias (1).

After 2-3 days, the body's natural processes will require amino acid input for normal functioning. Otherwise, catabolism and metabolic decompensation can occur. If a definitive diagnosis has not been established, there are commercially available protein-free formulas (e.g., Prophree by Ross) that can be used until a tailored diet can be established after the diagnosis is made (4).

Fatty acid oxidation disorders can present with hypoglycemia with lack of ketones present in the urine. Obviously, the hypoglycemia can easily be treated with a glucose infusion. The inability to process fatty acids means that these individuals will need their dietary fat restricted since they would not be able to metabolize fat. In addition, L-carnitine, a transport molecule in the liver, should be given as a supplement.

Galactosemia, which is suspected by the presence of reducing substances in the urine, is treated by elimination of galactose and lactose (glucose + galactose) from the diet. In infants, this can be accomplished by the exclusive use of soy formulas (no cow's milk or breast milk) (1,4).

Other therapy is strictly supportive: ventilatory support for those infant who are in imminent respiratory failure, bicarbonate infusions for infants with severe, unremitting acidosis, volume expansion for signs of hypoperfusion. Exchange transfusions or hemodialysis may be used in patients with high levels of ammonia. However, if empiric therapy and protein restriction are implemented early with the suspicion of a metabolic disorder, many infants may never have to undergo dialysis or exchange transfusion. Definitive therapy will depend on the metabolic defect that is identified.

The State of Hawaii has a newborn metabolic screening program which began in 1966 with PKU, but has since progressed to the inclusion of metabolic, endocrine, and hemoglobin disorders. The newest panel of disorders for which all newborns are screened includes congenital hypothyroidism, phenylketonuria, hemoglobinopathies, biotinidase deficiency, galactosemia, maple syrup urine disease, and congenital adrenal hyperplasia (5).

The Newborn Screening Program (NSP) in Hawaii has been enormously successful in capturing nearly all infants born in the State of Hawaii. Newborn Screening Programs exist in all 50 of the United States. Each state has jurisdiction over what panel of screening tests exists and the timing of the blood collection (http://www.aap.org/policy/01565t1.htm). For example, in Hawaii, the blood collection is conducted during the newborn period, prior to discharge from the hospital. Even in the Neonatal Intensive Care setting, the blood collection is done in the newborn period, but may be done earlier if the neonate is going to receive a blood transfusion.

Almost all results are reported out to the primary care provider within 2 weeks of the testing. The abnormal results are flagged for the physician and instructions for diagnostic testing, either at the Regional Laboratory (Oregon for all tests from Hawaii) or at a laboratory of the physician's choice, are included. Most abnormal results are also mailed with an instructional pamphlet for the family and physician of the affected child describing the disorder and possible diagnostic, therapeutic, and reproductive considerations.

The NSP was designed as a key preventive public health tool to identify disorders that have a treatment that when started early, can lead to reductions in mental retardation, physical disability or death.

Questions

1. True/False: Infants with an inborn metabolic defect are always symptomatic within the first two weeks of life.

2. Many of the metabolic defects can present clinically like which of the following:
   a. sepsis.
   b. formula intolerance or gastroesophageal reflux.
   c. necrotizing enterocolitis.
   d. neonatal hepatitis with liver failure.
   e. all of the above.

3. Newborn screening is designed with which of the following principles in mind:
   a. To identify all infants with the metabolic diseases that are included in the screening panel.
   b. To generate more paperwork for the physician.
   c. To screen for diseases that have no cure, but that can be alleviated through early intervention.
   d. To ensure early screening of future offspring for the family of affected infants.
   e. To screen for all possible metabolic diseases.
   f. To disseminate information regarding genetic/metabolic disease to the public and the physicians.

4. True/False: None of the metabolic diseases have a cure.

5. An infant with hyperammonemia, metabolic acidosis, and hypoglycemia most likely has what class of defect:
   a. fatty acid oxidation disorder.
   b. galactosemia.
   c. organic acidemia.
   d. urea cycle defect.
   e. lipid storage disease.

Answers to questions

1. False: Many infants with metabolic defects classified as storage disorders (lipid storage disorders) and fatty acid oxidation defects will present at many months of age.

2. e. And, there are many other disorders that can be on the list of possibilities, including child abuse (shaken baby).

3. c, d, f. The other answers are incorrect because: a. Newborn screening is not a diagnostic tool; it merely indicates need for further definitive testing. b. Obviously, physicians do not need more paperwork. e. Ideally, newborn screening could identify all metabolic disease, however, since cost and technology are prohibitive, the current principles are to screen for diseases which have a "significant" prevalence in a population and have some potential for treatment.

4. True: Unfortunately, there are no permanent cures, only lifelong supportive measures to mitigate the effects of the metabolic disease.

5. c

Chapter IV.5. Inherited Connective Tissue Disorders
Steven C. Crook, MD

A 3 year old male presents to the ER with a gross deformity of his left upper arm. His mother reports that her son "slipped while taking a bath" and struck his arm on the side of the tub. He has a history of a previous right femur fracture that resulted from a fall down the stairs one year ago. In addition to the gross deformity to the left humerus, his physical exam is notable for bluish sclera and no other signs of trauma (no bruising or scars). A skeletal survey is ordered by the ER physician, who thought that the injury did not fit the history provided by the parent. The plain films reveal a comminuted fracture in the middle of the left humerus, and signs of multiple healed rib fractures in addition to the healed right femur fracture. The ER physician notifies child protective services (CPS) as required by law. He is later referred to a geneticist who makes the diagnosis of osteogenesis imperfecta.

The true connective tissue disorders are not the acquired immunologic disorders of lupus, rheumatoid arthritis, or vasculitis, but are instead inherited disorders of the molecules which comprise the various connective tissues. While these diseases were originally defined by their most severe presentations, their modern definitions have been broadened to recognize a spectrum of disease from the most severe cases to near-normalcy. The clinician should focus on recognizing the potentially life threatening presentations of diseases and differentiating subtle presentations from more common diagnoses.

Osteogenesis imperfecta (OI) presents in a varied range of phenotypes which share a common molecular basis: a defect in type I collagen production. Type I collagen, the principal structural component of all bones, is composed of 3 procollagen proteins: 2 copies of the gene product of COL1A1, and 1 copy of the gene product of COL1A2. Eighty to ninety percent of individuals diagnosed with OI have mutations in one of these two genes, but the number of different mutations in each of these genes is so great that DNA testing is not feasible. Molecular confirmation of an OI diagnosis is achieved through culturing dermal fibroblasts, isolating and amplifying the genes and gene products of COL1A1 and COL1A2, and assessing the quantity and quality of these procollagen proteins. The classic clinical description of OI is a combination of fragile bones, blue sclera, and deafness. Sillence described four distinct types of OI. More recently however, we have learned that the clinical variability of OI is so great as to render these distinctions solely of academic importance.

In its most severe form, OI is incompatible with life. Affected infants are either stillborn or die in the early neonatal period as a result of extreme skeletal fragility. These patients produce a normal quantity of structurally defective collagen. In its mildest form, OI causes bones to be more brittle than normal, resulting in a propensity for fractures to occur or it may go undiagnosed entirely. These patients do not produce malformed collagen; instead they produce less than normal quantities of normal collagen. Life span may be affected in the extreme, or not at all. Hearing loss may be present at birth, develop in childhood, or may never occur. The color of the sclera ranges from a striking dark blue to normal white. Predicting prognosis in early life is very difficult and is best achieved by sorting the patient into one of the four Sillense groups upon which most research is based. Rough prognosis for future ability to walk is based on the ability to sit independently by 10 months of age. OI does not affect cognitive ability.

Treatment always includes physical therapy and often includes orthopedic intervention. The critical goal is achieving greater than 3/5 muscle strength in the proximal muscle groups of the extremities. Fine motor skills are usually unaffected by OI. Bowing of long bones is very common and if the curvature is greater than 40 degrees, prophylactic intramedullary rodding is often performed. A careful fracture history is important to target weak bones in an individual and specifically strengthen the muscles around those bones. Growth failure is quite common but incompletely understood. While no medical therapy is currently available, there are several theoretical gene therapy interventions. As the most severe form of OI is caused by incorrectly formed type I collagen, the use of antisense RNA or ribosomal RNA to prevent the translation of mutant collagen would convert a severe form of OI into a less severe one. Other researchers are working on bone marrow transplant of cells that produce normal collagen in order to increase the amount of type I collagen available for bone construction.

As the case illustrates, the recognition of OI is crucial to differentiating abuse from accidental or pathological trauma. The prevalence of OI recognizable at birth is 1 in 20,000. The actual prevalence of all OI including the mildest and least often diagnosed forms is unknown, but the disorders certainly remain quite rare. For comparison, there are an estimated 30,000-50,000 children with fractures caused by abuse each year, and approximately 200 children born each year with OI. In general, the radiographic findings of abused children include epiphyseal and metaphyseal fractures of the long bones. In contrast, OI fractures usually occur in the shaft of long bones with relative sparing of the metaphysis. Rib fractures occur in both; however, it is the consensus of radiologists and clinicians that in the vast majority of cases these two causes of fracture can be differentiated. If doubt persists, a geneticist should be consulted to determine if biochemical analysis of dermal fibroblasts would be useful.

In general, the severe forms of OI which result in infant death, are inherited in a recessive manner since this is the only way that such a mutation would be able to remain in the gene pool. The more occult forms of OI are usually inherited in an autosomal dominant pattern, which means that the family history should be positive. A family history which is positive for family members who have frequent fractures (especially those which occurred with minor trauma), scoliosis or other orthopedic conditions, should strongly raise the suspicion of OI. Family history is not totally reliable since there is variability in the expression of the condition and there are many spontaneous mutations.

Marfan syndrome is a spectrum of abnormalities involving the skeleton, great vessels, and eyes resulting from defects in a single gene responsible for a component of elastin. Fibrillin 1 is the protein produced from the gene FBN1 which is found mutated in nearly all cases of Marfan syndrome. The protein is used to create microfibrils which form elastin and are also used to anchor some tissues (e.g., suspensory ligament of the lens). Marfan syndrome is autosomal dominant and hundreds of defects have been found in the FBN1 gene; all of which create defective fibrillin proteins in normal quantities. The diagnosis is based on a clinical constellation. Four of the following major criteria must be present: pectus carinatum (pigeon breast), pectus excavatum (concave sternum) sufficiently severe to require surgery, reduced upper to lower segment ratio (measurements of pubis to top of head and pubis to soles, respectively), positive wrist and thumb signs (thumb protrudes beyond 5th finger when a closed fist is made), scoliosis greater than 20 degrees of curvature, reduced extension of elbows, medial displacement of medial malleolus causing pes planus (flat foot or collapsed longitudinal arch), or protrusio acetabuli (inward bulging of the acetabulum into the pelvis). If a family member has been diagnosed with Marfan syndrome, then the presence of a single major criteria along with several of the following minor criteria is sufficient: pectus excavatum (not requiring surgery), joint hypermobility, high arched palate, or typical facial appearance. There is no mental retardation or negative impact on cognitive development.

Life expectancy is reduced in Marfan syndrome. This is commonly due to progressive dilation of the aortic root and an increased risk of aortic dissection with advancing age. Death often occurs in the third decade in the absence of palliative surgery to prevent aortic valvular regurgitation and aortic rupture. Considerable debate remains among the surgical community as to the proper timing of prophylactic aortic arch repair. Currently, an aortic diameter of 50 mm along with cardiac symptoms is a conservative guideline, as death is common with root enlargement beyond 50 mm.

As with all of the heritable disorders of connective tissue, Marfan syndrome presents along a spectrum of severity. It is crucial to consider this diagnosis in patients with long thin limbs, joint laxity, or vision problems because the potentially lethal cardiac complications of the disease can be prevented. However, it is important to note that many patients with Marfan syndrome do not have the typical Marfanoid appearance. Likewise, it is important to keep in mind that patients in their twenties and younger can present with aortic root dilation causing aortic regurgitation, aortic dissection and aneurysm. When the diagnosis is suspected, an echocardiogram (to measure aortic root size) and a slit lamp examination (looking for ectopia lentis, an upward dislocation of the lens, is present in 50-80% of cases) should be performed.

Ehlers-Danlos is a group of inherited defects involved in the production of collagen fibers. The result is a wide clinical spectrum of diseases which share hyperextensible doughy skin (often described as having a velvety soft texture), atrophic scars, joint hypermobility, connective tissue fragility, and bruising. The defect can occur at any step in the production of collagen fibers. The procollagen fiber itself can be defective, as can enzymes which perform the post-translational hydroxylation of lysine or any of the enzymes which chaperone (i.e., molecular regulation) the assembly of procollagen fibers into normal collagen. Several different genes have been identified but many cases remain without molecular description. The disease occurs in up to 1/5000 live births, making this the most common of the connective tissue disorders. Clinical presentation usually occurs after birth. Many distinct phenotypes have been described, but as with the other connective tissue disorders, the majority of affected individuals do not fit into these groupings.

Skin fragility is caused by a thin dermis depleted of collagen fibrils. Splits or tears over bony prominences are common. Minor trauma cause widely gaping wounds which heal slowly. Surgery is complicated by frequent wound dehiscence. Patients will often present to ERs with a history of multiple lacerations requiring suture closure despite relatively minor trauma. Vascular fragility may be due to defects in collagen type 3, resulting in vessels with low tensile strength. In these individuals, aneurysms, arteriovenous malformations, and dissections are common. Ecchymoses are present with hemosiderin deposits over bony prominences. Hyperextensibility and joint hypermobility are caused by ligamentous laxity (which predisposes to dislocated hips in infants). Clubfoot, joint effusions, and spondylolisthesis (vertebral displacement) may also be present. The gastrointestinal tract can be similarly affected; decrease in tensile strength of the bowel walls predisposes to spontaneous rupture. Bony involvement usually manifests as kyphosis. Individuals diagnosed with E-D usually display one or a combination of these different symptoms. Life expectancy is highly variable in Ehlers-Danlos. The most severe complications of disease result from bowel and vasculature weakness. Hypermobility syndromes represent the mild end of the spectrum described by the Ehlers-Danlos disorders. No curative therapy is available. Vitamin C helps some individuals who are deficient in lysyl hydroxylase (which uses vitamin C as a cofactor in strengthening collagen fibers).

Other Connective Tissue disorders: Homocystinuria is an inborn error of methionine metabolism which results in a Marfan-like syndrome. The two disorders are differentiated by the presence of mental retardation in homocystinuria. Stickler syndrome is a constellation of progressive myopia, sensorineural hearing loss and hypomobility associated with distinct facial features. The diagnosis is suspected in neonates with swollen wrists, ankles or knees, and in children with hearing loss and marfanoid characteristics.

Questions

1. How is osteogenesis imperfecta differentiated from child abuse?
2. How are future fractures prevented in children with OI?
3. Name 3 major criteria for Marfan syndrome
4. What is the most common cause of early death in children with Marfan syndrome?
5. What are 3 of the cardinal features of Ehlers-Danlos?
6. How is homocystinuria differentiated from Marfan syndrome clinically?

Answers to questions

1. Presence of associated physical findings. Family history. Location of fracture (femur and radius vs tibia and radius), type of fracture (comminuted mid shaft vs epiphyseal and greenstick). Radiographic appearance of the fractures (i.e., presence of osteopenia).
2. Careful fracture history, identifying weak bones, and targeting physical therapy to strengthen those bones.

3. Any of the following: pectus carinatum (or excavatum sufficiently severe to require surgery), reduced upper to lower segment ratio, positive wrist and thumb signs, scoliosis greater than 20 degrees of curvature, reduced extension of elbows, medial displacement of medial malleolus causing pes planus, protrusio acetabuli.

4. Aortic root dilation causing aneurysm and dissection.

5. Any three of the following: hyperextensible doughy skin, atrophic scars, joint hypermobility, connective tissue fragility, and bruising.

6. Marfan syndrome, unlike homocystinuria, is not associated with mental retardation.

Chapter IV.6. Genetic Testing and Gene Therapy
Steven C. Crook, MD

Your nurse knocks on the door interrupting your examination of a child. On the phone is a lab technician from another state who reports that a newborn screen reveals a positive test for galactosemia in one of your patients. The patient, you recall, is the first child of a young professional couple. Reviewing her chart you are reminded that there were no perinatal complications. The child was discharged home from the hospital at just under 48 hours of age, he appeared well with only a 3% weight loss and mild facial jaundice upon follow-up at day 4 of life. His parents reported no breast feeding difficulties and, despite their concern for the number of hours their new baby slept, the new family appeared to be thriving.

Genetic testing has received much attention in the press, with interest focusing on the ethics and repercussions of genetic information. Despite this attention, most people do not realize that for the past twenty years, almost all newborns in the United States have been screened for a number of genetic diseases. Almost all newborn screen tests are quantitative tests for the presence or absence of metabolic or endocrine molecules. When the concentration of the tested molecule is greater or less than a level determined by the reference lab, the test is reported as positive. In order to provide 100% sensitivity for disease, the level of positive detection must be adjusted to a point at which specificity may be quite poor. Classical galactosemia affects roughly 1:59,000 infants born in the US. In 1994, 10,210 infants tested positive on newborn screening for galactosemia. Of these, 54 infants were confirmed to have the disease (positive predictive value 0.53%). Improvements in mass spectroscopy are greatly increasing the number of inborn errors of metabolism that can be efficiently screened in all newborn infants.

Metabolic screening represents one type of genetic testing. For diseases such as sickle cell disease and cystic fibrosis, in which the disease gene and disease alleles are known, very specific tests based on DNA are used. Unlike the quantitative screens for inborn errors, DNA-based tests have virtually 100% specificity. These tests provide binary answers (yes/no) to the hypothesis "does this particular unique region of DNA exist in this patient?" With this knowledge, we can understand the current limitations of DNA-based genetic testing.

1. A single gene must be discovered and sequenced, which when altered, produces a recognizable disease state.
2. The various disease-sequence alterations must be catalogued.
3. For every detectable alteration, a single unique test must be created and performed.

Since sickle cell disease is caused by a single diseased allele in all patients affected, a single PCR (polymerase chain reaction) test can diagnose it with near perfect sensitivity and specificity. On the other hand, some diseases such as Duchenne muscular dystrophy or osteogenesis imperfecta, may result from one of hundreds of different possible alleles. In these cases, DNA-based testing is not practical. Cystic fibrosis represents a middle ground, in which hundreds of disease alleles exist, but only a handful produce the vast majority of illness in select populations. In European descendants, the delta F508 allele represents 70% of disease alleles in that gene pool and four additional alleles represent another 10-20%. For this population, a handful of PCR based tests can be performed on a patient's blood which that cover the vast majority of possible alleles.

As more disease alleles are discovered, more tests can be run to determine if each allele is present in a given patient. Currently, most tests are PCR-based and involve duplicating small parts of a patient's genome in sufficient quantities to be detected on a gel by fluoroscopy or radioactivity. In the late 1990s, DNA chip technology was invented with the power to perform hundreds of thousands of DNA-based experiments simultaneously on a single patient. A DNA chip is a grid of hundreds to hundreds of thousands of individual matching tests mass produced on silicon wafers the size of a dime. Each matching test involves a small unique section of single stranded nucleic acid which is glued to the wafer in a specific grid position. A patient's DNA or RNA is extracted from blood, broken up into short strands, made single stranded (in the case of DNA) and then used to bathe the DNA chip. Sections of patient DNA or RNA which closely match specific test sequences on the chip bind and are detected. This technology has the potential to increase the sensitivity of DNA-based genetic testing as disease alleles continue to be discovered.

There are several other methods to detect genetic based illnesses, including the visual inspection of chromosomes, the augmented inspection of chromosomes using fluorescent antibodies, and multiple methods of detecting the presence, absence and relative quantity of proteins.

A person's DNA essentially remains unaltered from the moment his/her mother's ovum and father's sperm join, until the day that the last nucleus in his/her body is destroyed. In theory, the information to predict susceptibility to all genetically based disease is available in zygotes and ancient human remains. As science progresses and discovers how genetic information predicts disease states, the ethical debates over how best to use the information must also progress. Currently, the AAP recommends:

1) The introduction of new newborn screening tests only if identification provides clear benefit to the child, the diagnosis can be confirmed after a positive screening test result, and treatment and follow-up are available for each infant tested.

2) Informed parental consent.

3) No screening of healthy children for the detection of disease-carriers (children with potential to pass on an inherited disease to their children) except in the case of certain prenatal screening tests in well informed teens.

4) No testing for adult onset illness until the child is an adult and is able to make informed decisions for him/herself.

Since the discovery that genetic information can predict disease states, people have been afraid that this information might be used in a discriminatory manner. One such fear is the possibility that insurance companies might use genetic test results to increase rates or even deny coverage to individuals with genetic susceptibility to expensive illnesses. So far, these fears are only speculative. A panel of lawyers, genetic counselors, and geneticists reported (at the 1999 meeting of the American Society of Human Genetics) that they had been unable to identify any cases of discrimination by health insurers (6).

Simply stated, gene therapy is medicine practiced with a nucleic acid based pharmacy. The patient is given nucleic acids in order to modify a pathologic pattern of protein expression. One form of gene therapy, bone marrow transplant, is currently in widespread use. The treatment for refractory leukemia involves massive chemotherapy to destroy all cancerous cells that are then replaced by a population of cells with "normal" cell cycle regulation. The more classical definition of gene therapy requires the modification of protein expression in existing cells. Only a handful of individuals have undergone this experimental form of therapy. These therapies are based on the idea of utilizing a virus as a vector to implant new genetic information into a patient's cells. Thousands of viruses have evolved to efficiently insert their DNA or RNA into specific human cell lines for the purpose of turning the cells into viral copy machines. In creating vectors, scientists remodel viruses, retaining the machinery to identify and infect specific cells (adenoviruses which preferentially affect respiratory epithelium, lentiviruses which preferentially attach to T-cells, and herpes viruses which recognize neurons) but change the genetic material which the virus inserts into the cells.

The inserted nucleic acid can take any of the following forms: 1) RNA can be used to immediately translate functional proteins. 2) RNA or DNA can be engineered to be the non-coding ("anti-sense") sequence of a specific pathologic mRNA so as to produce functionless double stranded mRNA. 3) Ribozymes (RNA with the enzymatic ability to degrade specific mRNAs) can be introduced to degrade pathologic mRNA. 4) DNA can be inserted in the middle of a disease gene to turn off pathologic production. 5) Sections of DNA can be inserted permanently into the target cell to restore the production of proteins, or alter the degree to which proteins are expressed by the cell. Despite the elegance of these theories, no disease state has been "cured" using gene therapy in a human patient as of this writing. The failure of gene therapy to date, is attributable to both vector and nucleic acid design, which are limited by our rudimentary knowledge of basic cell and molecular biology.

The dream of the Human Genome Project, that one day patients will provide a drop of blood, a scraping of cheek cells, or a hair follicle and be provided with a set of probabilities of acquiring all disease states and a range of treatment options based on targeted gene therapy, is far from being realized. However, in the early 1990s the Human Genome Project's basic goal of sequencing the entire genome also appeared a pipe dream which was projected to run over time and budget. In 2000, five years ahead of projections, the first working draft sequence of a human genome was completed. Noninvasive, perfect tests will never become available for all diseases and silver bullets filled with DNA will not rid the world of illness, but it is certain that the power of nucleic acids to diagnose, treat, and prevent illness will become significantly greater in the coming decades.

Questions

1. True/False: Current newborn screening can diagnose a handful of inborn errors of metabolism like Galactosemia?
2. What are the limitations of DNA based genetic testing?
3. Why is it not currently ethical to test a 7 year old girl for the BRCA1 (breast cancer 1 gene) mutations even if early breast cancer runs in her family?
4. Currently, what is the most widely used form of gene therapy?
5. What is the function of a gene therapy vector?
6. Describe the various methods of introducing nucleic acids into a cell to alter disease states.

Answers to questions

1. False. Newborn screening is not diagnostic. Rather, it is a screen for illness with VERY poor specificity, which, if positive, must be followed with a more specific diagnostic test.
2. Sequence knowledge of the disease locus and mutant alleles and the 1:1 correlation of test to disease allele. For disease conditions with multiple mutant alleles, all possibilities must be specifically tested.
3. The disease does not affect the patient until adulthood when she can make her own decisions. There is no effective prophylactic treatment for a child that will prevent the illness before she reaches adulthood. Testing may be appropriate for a 17 year old who desires pregnancy, has the consent of her parents, and who plans to make the decision to become pregnant based on the information of the test.
4. Bone marrow transplant.
5. Vectors transport engineered nucleic acids (DNA or RNA) into existing human cells.
6. 1) DNA based: Insertion of intact functional gene. Insertion of intact functional promotor or exons to correct production. Insertion of DNA for the purposes of disrupting expression of a gene. Insertion of single stranded DNA for the purposes of binding to mRNA and preventing translation. 2) RNA based: Insertion of RNA to be reverse transcribed and incorporated into DNA. Insertion of RNA to be translated immediately. Insertion of RNA ribozyme to destroy mRNA. Insertion of anti-sense RNA to prevent translation of mRNA.

Chapter IV.7. Basic Genetic Principles
Bryan O. King, MS

Dr. G, the pediatric chief resident, rushes to the delivery room to assist with a resuscitation being attended by a first year resident and a medical student. The newborn has low Apgar scores and is not breathing well. Endotracheal intubation and ventilation results in improvement. The newborn is transferred to the NICU. A chest X-ray demonstrates severe demineralization of all the bones and multiple rib fractures. A skeletal survey demonstrates severe osteopenia and multiple fractures with crumpling of the long bones. Osteogenesis imperfecta (OI) is diagnosed. This infant dies at about one month of age due to respiratory failure. There is no family history of previous neonatal deaths or bone problems.

On the pediatric floor, there is a teenager with "osteogenesis imperfecta" who has sustained a tibia fracture. The father, aunt and two uncles of this patient also have OI. The house staff and medical students ask Dr. G to explain why one case of OI can be so severe, while another case can be relatively mild. Also, why does one case have a negative family history, while the other case has a positive family history? A second year resident mentions that this is similar to muscular dystrophy in which some cases are very severe (with no family history) and other cases are milder with a teen or adult onset (and sometimes with a positive family history).

A significant proportion of human illnesses have a genetic basis. The topic of genetic diseases is therefore broad and encompasses both inherited diseases as well as somatic diseases caused by spontaneous mutations. This chapter covers the mechanisms of gene and chromosome mutation and their relevance to both inherited and somatic diseases. Mendelian genetics and chromosome disorders associated with a variety of clinical conditions will also be reviewed.

Genetic mutations occur anytime there is a permanent change in the primary nucleotide DNA sequence. Mutations can be lethal, deleterious, or confer an evolutionary advantage. Genes and chromosomes can mutate in either somatic or germinal tissue. Somatic mutations can occur during embryogenesis or in dividing somatic tissue. A single somatic cell that mutates will be the progenitor for a clonal population of cells known as the mutant sector. This "patch" of developing mutant cells tends to stay close together and is phenotypically distinct from the surrounding population of normal somatic cells. If the mutation is compatible with cell survival, phenotypic variations can be visualized such as the pigmented lesions seen in McCune-Albright Syndrome. Somatic mutations are often associated with cancer because they can offer growth advantages. Cancer mutations occur in a special category of genes called proto-oncogenes, many of which regulate cell division. When mutated, such cells enter a state of uncontrolled division, forming a cluster of cells known as a tumor.

A germinal mutation occurs in germ cells which are specialized tissue that is set aside during development to form sex cells. If a mutant sex cell participates in fertilization, then the mutation will be passed on to the next generation. It is possible for mosaic germline mutations to occur in which case the mutation can be transmitted to some progeny but not others. This causes confusion when attempting to determine patterns of inheritance.

Mutations may be classified into three categories: genome, chromosome, and gene. Genome mutations involve the loss or gain of whole chromosomes, giving rise to monosomy or trisomy. These mutations are infrequently transmitted to the next generation because they are often incompatible with survival or at least result in reduced fertility. Thus, most monosomies and trisomies are the result of spontaneous events (new mutations). Chromosome mutations result from rearrangement of genetic material and result in structural changes to the chromosome (e.g., translocations, which will be discussed later). The most common type of mutations associated with hereditary diseases are gene mutations, the mechanisms of which will be briefly reviewed here.

Point mutations (single base substitutions) within coding sequences may alter the DNA in such a way that the new mutated sequence encodes a different amino acid. Because these mutations alter the meaning of the genetic code, they are called missense mutations. Sickle cell anemia is a classic example of a coding sequence point mutation which affects the beta-globin chain of hemoglobin. The nucleotide triplet CTC, which codes for glutamic acid, is changed to CAC, which codes for valine. This single amino acid substitution causes the formation of structurally abnormal hemoglobin resulting in a clinically significant hemoglobinopathy.

Point mutations can also change amino acid coding sequences into chain terminating stop sequences. Because these new stop sequences do not code for amino acids, they are known as nonsense mutations. An example of this occurrence again involves the beta-globin gene in a severe form of anemia known as beta-thalassemia. In this condition a point mutation affecting the codon for glutamine (CAG) creates a stop codon (UAG) leading to premature termination of beta-globin chain translation.

Mutations within noncoding sequences can also interfere with protein synthesis at various levels. Point mutations or deletions affecting promoter and enhancer sequences may suppress gene transcription. Such is the case in certain forms of hereditary hemolytic anemias. Lastly, deletions and insertions can cause frame-shift mutations unless the number of base pairs involved is three or a multiple of three.

All Mendelian disorders are the result of expressed mutations in single genes with a noticeable phenotypic effect. The number of these disorders is great with some estimates listing more than 5000 disorders. As the name implies, most of these conditions follow classic Mendelian patterns of inheritance. Although gene expression is usually described as dominant or recessive, in some cases, both of the alleles of a gene pair may be fully expressed in the heterozygote, a phenomenon known as codominance. Histocompatibility and blood group antigens are good examples of condominant inheritance.

In autosomal dominant (AD) disorders, if an affected heterozygous person marries an unaffected person, every child they have, carries a 50% chance of having the disease. AD disorders are generally compatible with survival until reproductive age since this is the only way that the mutation would be able to remain in the gene pool (i.e., if the condition were not compatible with reproduction, then the mutation would not be passed on). AD disorders are manifested in the heterozygous state so that at least one parent of an index case is usually affected (along with aunts/uncles on the affected parent's side of the family). However, every AD disorder has cases where neither parent is affected. In these cases, the disease is caused by new mutations of the egg or sperm. Also, the clinical features of a particular AD disorders can vary. For instance, some individuals inherit the mutant gene but are phenotypically normal. This is referred to as reduced penetrance, a termed that is expressed mathematically as the percentage of patients that phenotypically express their genotypic mutations. On the other hand, variable expressivity occurs when a trait is seen in all individuals carrying a mutant gene, but is expressed differently.

Autosomal dominant disorders usually do not involve diseases where there is a loss of function of an enzyme (i.e., enzyme deficiency states are almost never autosomal dominant). Because a 50% reduction of most enzymes can be compensated by the 50% that remain viable (i.e., the person is phenotypically normal), heterozygous enzyme mutations usually do not present with an autosomal

dominant pattern of inheritance. Instead, autosomal dominant disorders usually affect non-enzyme proteins that can be divided into two categories.

The first involves proteins that are involved in the regulation of complex metabolic pathways that are subject to feedback inhibition (e.g., regulator genes). For example, patients with familial hypercholesterolemia carry a loss of function mutation in the gene encoding the LDL receptor. As a result, there is a loss of feedback control of plasma cholesterol levels due to the fact that the liver is less capable of clearing circulating plasma LDL. Additionally, a reduction of LDL receptors on the liver reduces LDL entry into the liver which disrupts the negative feedback regulation of hepatic cholesterol synthesis. As a consequence of these receptor abnormalities, cholesterol levels are elevated and induce premature atherosclerosis resulting in increased risk of heart disease.

The second type of non-enzyme proteins that are affected by autosomal dominant disorders are certain structural proteins. The detrimental effects of reducing levels of a structural protein by 50% become clearer when considering that the abnormal products from a mutant allele can interfere with the assembly of a functionally normal multimeric complex. For example, the collagen molecule is a trimer in which the three collagen chains are arranged in a helical configuration. Each of the three collagen chains in the helix must be normal in order to produce a stable collagen molecule. Even a single mutant collagen chain disrupts the integrity of the trimeric complex. The effects of these autosomal dominant structural protein disorders are seen in conditions such as osteogenesis imperfecta (occult types), Marfan syndrome, and Ehlers-Danlos syndrome. A simplistic way of looking at this is to consider structural protein mutations like a wall of bricks composed of 50% normal bricks and 50% defective bricks (from the abnormal allele). Such a wall is likely to be very weak and eventually collapse.

Disease states with an autosomal recessive inheritance pattern comprise the largest category of Mendelian disorders. Most of these disorders are enzyme or protein factor deficiency states (e.g., hexose amidase deficiency, factor 10 deficiency). Because autosomal recessive disorders require that both parents have the mutant allele, such disorders are characterized by the following features: 1) the trait does not usually affect the parents, but siblings may show the disease, and 2) siblings have one chance in four of being affected with a recurrence risk of 25% for each subsequent birth.

In contrast to autosomal dominant disorders, the following features generally apply to autosomal recessive disorders: 1) The expression of the defect tends to be more uniform than in autosomal dominant disorders. 2) Complete penetrance is common. 3) Onset is frequently early in life. 4) Many autosomal recessive conditions result in defective non-functional enzymes (i.e., loss of enzyme function). 5) Autosomal recessive disorders include almost all inborn errors of metabolism. 6) Many of these disorders are incompatible with life.

All sex-linked disorders are X-linked, and most are X-linked recessive. There are no Y-linked diseases because the only functional gene on the Y chromosome is the determinant for testes. If this gene is mutated, then the person is infertile and hence, no inheritance is possible. In terms of X-linked recessive inheritance, the heterozygous female usually does not express the full phenotypic change because of the normal paired allele on the other X chromosome. However, because of random inactivation of one of the X chromosomes in females (a phenomenon known as Lyonization), there is a remote possibility for the normal allele to be inactivated in most cells, thereby permitting full phenotypic expression. (e.g., G6PD deficiency). An enzyme deficiency such as RBC G6PD deficiency is compatible with a relatively normal life span. Therefore, an affected male may pass on the abnormal X allele to his daughter, who may also receive an abnormal X allele from her unaffected heterozygous mother. Thus, this is another mechanism that a female could be affected by an X-linked recessive disorder. This is not possible if the affected condition is incompatible with survival to reproductive age.

There are only a few X-linked dominant conditions. They are caused by dominant disease alleles on the X chromosome. These disorders are transmitted by an affected heterozygous female to half her sons and half her daughters and by an affected male parent to all his daughters but none of his sons. Vitamin D-resistant rickets is an example of this type of inheritance.

The aberrations underlying chromosome disorders may take the form of an abnormal number of chromosomes or alterations in the structure of one or more chromosomes. In humans, the normal complement of chromosomes in a haploid cell is 23. A cell with any multiple of the haploid number is called euploid. Aneuploidy refers to conditions where errors occur during meiosis or mitosis that result in the formation of cells with a set of chromosomes that are not a haploid multiple. The most common causes of aneuploidy are nondisjunction and anaphase lag.

Nondisjunction occurs when homologous chromosomes fail to separate during meiosis I or when sister chromatids fail to separate during meiosis II. During gametogenesis, the consequence of nondisjunction during either meiosis I or II is that gametes formed have either an extra chromosome (n+1) or one less chromosome (n-1). Subsequently, fertilization of such gametes by normal gametes yields a trisomic zygote (2n+1) or a monosomic zygote (2n-1) respectively. In anaphase lag, one homologous chromosome in meiosis or one chromatid in mitosis lags behind, is left out of the cell nucleus and eventually undergoes degeneration. Anaphase lag is similar to nondisjunction except that the chromosome or chromatid gets lost, so that one daughter cell has the right number of chromosomes and one daughter cell has one less than normal. This can occur in either of the gametes before fertilization or in the zygote. In the former case, fertilization with a normal gamete will form a zygote with one less chromosome yielding a true monosomic zygote. In the latter case, if anaphase lag occurs after the zygote has already formed, a mosaic, composed of normal cells and monosomic cells, is produced.

Monosomy or trisomy involving sex chromosomes (XXY syndrome, Turner syndrome, Klinefelter syndrome, Multi-X females) are compatible with life and are usually associated with a range of severity of phenotypic abnormalities. Autosomal monosomy generally involves the loss of too much genetic information to permit live birth or even embryogenesis. Conversely, a number of autosomal trisomies do permit survival such as Down syndrome (trisomy 21). With the exception of trisomy 21, all other trisomies yield severely handicapped infants that usually die at an early age.

Mosaicism is a condition characterized by the formation of aneuploid cells that arises when mitotic errors in early development give rise to two or more distinct populations of cells in the same individual. These errors usually occur during the cleavage of the fertilized ovum or in somatic cells. Mosaicism affecting the sex chromosomes is relatively common. For example, in a dividing fertilized ovum, a mitotic error may lead to one of the daughter cells receiving three sex chromosome while another receives only one and can be represented as a 45,X/47,XXX mosaic. All descendent cells from these two precursor cells will accordingly have either a 47,XXX or a 45,X makeup. Depending on the percentage of 45,X cells, this person can potentially further develop to become a mosaic variant of Turner syndrome. Autosomal mosaicism, on the other hand, appears much less commonly than sex chromosome mosaicism. An error during early mitosis that affects the autosomes usually forms a nonviable mosaic with autosomal monosomy. Trisomy 21 is an exception to this rule. Approximately 1% of Down syndrome patients are mosaics, usually having a mixture of cells with 46 and 47 chromosomes. This mosaicism results from mitotic nondisjunction of chromosome 21 during early embryogenesis. Symptoms in such cases are usually milder, depending on the proportion of abnormal trisomic cells.

A separate category of chromosomal aberrations is associated with changes in the structure of chromosomes. Such alterations occur spontaneously at a low rate that is increased by exposure to environmental mutagens. In addition, several rare autosomal recessive genetic

disorders (Fanconi anemia, Bloom syndrome, ataxia-telangiectasia) are highly associated with chromosomal instability and are therefore known collectively as chromosome-breakage syndromes. Also, there is a significantly increased risk of cancers in all these conditions.

Common forms of alterations in chromosome structure include deletions, ring chromosomes, inversions, isochromosomes, and translocations. Deletions refer to loss of a portion of chromosome that may involve either the terminal or interstitial regions. A ring chromosome is produced when a deletion occurs at both ends of a chromosome with fusion of the damaged ends. This might be expressed as 46,XY,r(14). Inversion is a rearrangement that involves two breaks within a single chromosome with inverted reincorporation of the segment. An inversion of only one arm is known as pericentric while breaks on opposite side of the centromere are known a paracentric. Isochromosome formation results when one arm of a chromosome is lost and the remaining arm is duplicated, resulting in a chromosome consisting of only two short arms or of two long arms. In translocations, a segment of one chromosome is transferred to another. In one form, called balanced reciprocal translocation, there are single breaks in each of the two chromosomes, with exchange of material. For example, a balance reciprocal translocation between the long arm of chromosome 2 and the short arm of chromosome 5 would be written 46,XX,t(2;5)(q31;p14). Because there is no loss of genetic material, the individual is phenotypically normal. However, a balance translocation carrier is at increased risk for producing abnormal gametes. Subsequently, fertilization between a carrier and a normal person could lead to the formation of an unbalanced zygote, resulting in spontaneous abortion or birth of a malformed child.

Robertsonian translocations result when the two long arms of acrocentric chromosomes (those with the centromere very near to one end) fuse at the centromere, losing the two short arms, forming a single chromosome (with twice the genetic material), thus having a karyotype with only 45 chromosomes. Common Robertsonian translocations are confined to the acrocentric chromosomes 13, 14, 15, 21, and 22, because the short arms of these chromosomes contain no essential genetic material. Individuals with these translocations are phenotypically normal and carry 45 chromosomes in each of their cells. Their offspring, however, may either be normal and carry the fusion chromosome or they may inherit a missing or extra long arm of an acrocentric chromosome. About 4% of Down syndrome patients have 46 chromosomes, one of which is a Robertsonian translocation between 21q and the long arm of an acrocentric chromosome (usually chromosomes 14 or 22). The translocation chromosome replaces one of the normal acrocentrics but gains an additional chromosome 21 which yields a total of 46 chromosomes with trisomy 21. The karyotype of a Down syndrome patient with a Robertsonian translocation between chromosomes 14 and 21 is 46,XX or XY,rob(14,21),+21. Unlike trisomy 21 caused by nondisjunction, there is no relation between maternal age and the incidence of rob(14,21). However, there is a relatively high recurrence risk in families when the parent, especially the mother is a carrier of the translocation.

Lyonization (X chromosome inactivation): Females have two X chromosomes while males have only one. Thus, one might expect that females should have twice the level of X chromosome proteins and enzymes than males. Empirically, however, this does not happen. The levels are equal in men and women. The reason for this is that in the cells of a human female, one and only one X chromosome is active. The other X coils and condenses into a small ellipsoid structure that is called a Barr body and is functionally deactivated and the genes on that chromosome are not transcribed. The geneticist Mary Lyon hypothesized this almost 40 years ago, so the phenomenon is often called Lyonization. During the very early embryonic development of a female, both her maternal and paternal X chromosomes are active. After 12 days of development, when the embryo has about 5,000 cells, one of these chromosomes is randomly deactivated in all the cells. Once a chromosome is inactive in a given cell, all its daughter cells will have the same chromosome deactivated. That is, if "cell number 23" has the paternal X deactivated, then all descendants of cell 23 will also have the paternal X deactivated. The particular X chromosome deactivated in the original cell is random. Consequently, half of a female's cells will express her paternal X chromosome while the other half will express her maternal X. Thus, females are genetic mosaics.

The gene responsible for X chromosome inactivation, the XIST locus, has recently been localized to the long arm of the X, but the precise mechanism for achieving inactivation is not totally understood. Certain data suggest that the major reason for Lyonization is "dosage compensation"-making certain that the same levels of proteins and enzymes are expressed in males and females. Females with Turner syndrome (only one X chromosome) do not have Barr bodies, females with three X chromosomes have two Barr bodies in each cell, and males with Klinefelter syndrome (two X chromosomes and one Y chromosome) have one Barr body. It appears that the process evolved to guarantee that one and only one X chromosome is active in any given cell. However, inactivation is not totally complete. A few loci of the chromosome comprising a Barr body remain active, most notably those loci homologous to the pseudoautosomal region of the Y chromosome. The fact that inactivation is incomplete is used to explain the phenotypic irregularities for Turner, XXX, and Klinefelter syndrome.

In summary, understanding some common genetic principles permits a better understanding of most genetic disorders. To summarize the case that was initially described, osteogenesis imperfecta (see chapter on connective tissue disorders) is the name given to a group of several different disorders. The severe infantile type is autosomal recessive (an enzyme deficiency) and incompatible with life. The milder adult type is autosomal dominant (a heterozygous structural protein mutation) and compatible with life beyond reproductive age. The autosomal dominant form will probably have a positive family history in one of the parents, and aunts/uncles on the affected parent's side of the family, while the autosomal recessive form will only have a positive family history in siblings. Similarly, Duchenne muscular dystrophy, which is severe, has an early onset, and is often incompatible with reaching reproductive age, is X-linked recessive due to deficiency of the dystrophin protein. Fascioscapulohumeral dystrophy, which is milder, has a later onset, and is compatible with life beyond reproductive age, is autosomal dominant. A positive family history in a parent, aunts, and uncles is likely to be present.

Questions

1. A genetic condition which is lethal in infancy is most likely to be:
    a. An X-linked structural protein.
    b. An autosomal recessive enzyme deficiency.
    c. An autosomal dominant enzyme deficiency.
    d. An autosomal dominant structural protein abnormality.

2. An enzyme deficiency condition can only be inherited in one of two ways:
    a. Autosomal dominant.
    b. Autosomal recessive.
    c. X-linked dominant.
    d. X-linked recessive.
    e. Spontaneous new mutation.

3. The cytologic mechanism(s) by which trisomy 21 (Down Syndrome) can occur include:
    a. Nondisjunction
    b. Robertsonian translocation
    c. Mosaicism
    d. Two of the above
    e. All of the above

4. If there is a family history of genetic disorders, knowing the gender of an unborn child can be important because:
    a. Male children are more likely to have autosomal defects show up in their phenotypes.
    b. Female children are more likely to have autosomal defects show up in their phenotypes
    c. Male children are more likely to have X-linked traits show up in their phenotype
    d. a and c

5. An exchange of fragments of chromatids between non-homologous chromosomes may occur during the first meiotic division. This chromosomal structural abnormality is called:
    a. Deletion
    b. Inversion
    c. Nondisjunction
    d. Segregation
    e. Translocation

Answers to questions

1. b. An autosomal dominant condition which is lethal in infancy is not going to survive in the gene pool. Such conditions must be autosomal recessive to survive in the gene pool. Most autosomal recessive conditions are enzyme deficiencies. An X-linked enzyme deficiency is also a possible answer, but this is less likely and it is not one of the choices given.

2. b,d. Enzyme deficiencies must be homozygous for the condition to manifest, because a 50% reduction of the enzyme level is generally sufficient to carry out the biochemical reaction involved, such that no clinical disease results. The observed inheritance pattern is autosomal recessive. Enzymes on the X-chromosome such a RBC G6PD are not present on the Y-chromosome, so enzymes can also be inherited in an X-linked recessive fashion. An enzyme deficiency is not likely to manifest from a spontaneous new mutation, because it would have to coincidentally occur in both alleles for this to occur.

3. e. Trisomy 21 results from meiotic nondisjunction in about 95% of patients. About 4% have a Robertsonian translocation. A small percentage of patients are mosaic. An even rarer cause of trisomy 21 is the 21q21q translocation, a chromosome comprised of two chromosome 21 long arms. It is thought to originate as an isochromosome.

4. c. There is a far greater probability of males expressing recessive alleles in their phenotypes if they are carried on X chromosomes. For females to have such traits, they would have to inherit the recessive allele for them on both of their X chromosomes.

5. e. An exchange of fragments of chromatids between non-homologous chromosomes during the first meiotic division is termed a translocation.

Chapter V.1. Common Allergies and Management
Akaluck Thatayatikom, MD

A 12 year old girl presents with a chief complaint of year-round nasal stuffiness and itching eyes for the last 2 years. Her complaints include eyes which are red, watery and itchy; nasal drip (runny nose), congestion, itching, and a poor sense of smell; and sneezing. Her nasal stuffiness bothers her most. Her symptoms disrupt her daily activities and her sleep. Most of these symptoms improve slightly when she takes diphenhydramine and when she is away from home. However, her nasal stuffiness does not change with taking the medication. She has a cat which sleeps in her bed room.

Past history: As an infant she developed egg allergy and an eczematous rash on her face, trunk and extremities. She has no history of asthma. Family history: Both her mother and brother have asthma and hay fever.

Exam: VS are normal. Her height and weight are at the 50th percentile. She has bilateral conjunctival inflammation (redness) with mild chemosis (edema), dusky discoloration of the skin under the eyelids, marked pale swelling of the nasal mucosa which almost completely occludes the nasal airways without evidence of nasal polyps or masses. Both eyes and her nose have whitish clear exudates. Otoscopic examination shows fluid behind both tympanic membranes. She has generalized dry skin with a scatter of hyperkeratotic plaque on both extremities and pityriasis alba of her face.

She is diagnosed with severe persistent allergic rhinoconjunctivitis and otitis media with effusion (OME) with a history of atopic dermatitis and egg allergy. She is treated with a non-sedating antihistamine without significant improvement. Intranasal corticosteroids are added next with minimal improvement. She is then referred to an allergist for evaluation and further treatment. Her skin allergy test is positive to dust mite and cat dander. Her family follows the allergist's recommendations which include: encasing the mattress and pillows in a plastic bag wrap, removing the cat from the house, using an antihistamine with mast cell stabilizing activity (olopatadine) eye drops and allergen immunotherapy. All of her symptoms have gradually decreased with these recommendations. She has currently discontinued all of her medications; except when she exposes herself to cats or house dust (she may require antihistamines as needed).

Symptoms due to allergy commonly occur in children. Atopy refers to a tendency of exaggerated IgE antibody production and is defined by the presence of specific IgE in vivo (skin prick test) or in vitro (RAST test). Atopy represents a predisposition to atopic or allergic diseases including allergic rhinitis, asthma, eczema and food allergy. Scientific evidence of the systemic link between all of the atopic diseases has been increasing recently.

The atopy march starts early in life and most believe that the fetal environment may already be important for both the development of subsequent sensitization and disease manifestation. Early events under the influence of a variety of environmental factors, such as exposure to environmental endotoxin, allergens, infections, and variations in nutrient intake, affect the expression of the atopy genotype. Age of onset of each atopic disease is unique and may be influenced by the mentioned factors. Typically, both atopic dermatitis and food allergy are commonly seen in young infants; while asthma usually starts after 3 years of age, and allergic rhinitis develops in later childhood.

Allergic Rhinoconjunctivitis

By definition allergic rhinoconjunctivitis is a symptomatic disorder of the nose (allergic rhinitis) and eyes (allergic conjunctivitis) resulting from an IgE-mediated immunological reaction following exposure to allergens. Rhinoconjunctivitis is a combined term of rhinitis and conjunctivitis because conjunctivitis is usually accompanied with rhinitis in allergic conditions.

Allergic rhinitis (AR) is extremely common in the general population. The prevalence of AR in the US is about 10-20%. An international study shows that the prevalence of allergic rhinitis varies in different parts of the world from 1%-15% in the 6-7 year-olds and 1%-40% in the 13-14 year-olds. Allergic conjunctivitis (AC), the most common form of ocular allergies, is a self-limited, bilateral inflammation of the eyes.

The nose is a specialized structure with 5 important functions: smelling, resonating for phonation, filtration, heating, and humidification of inhaled air. As a filter for inhaled particles, the nose receives an allergen burden, which per square centimeter is considerably higher than in the lower airways. Its function seems to be the price to be paid for the higher prevalence of AR than other atopic diseases. When airborne allergens come in contact with surface fluid on the nasal mucosa, allergenic molecules are removed within seconds by mucociliary transport and only a small fraction of the allergen molecules will penetrate the epithelial lining since proteins of this size are not easily absorbed from the nasal mucosa. The allergens initiate an allergic reaction when they bind with cell-attached IgE molecules. Mast cells, basophils and Langerhans cells are responsible for the interaction and releasing inflammatory mediators.

Human conjunctiva consist of a nonkeratinized, stratified squamous cell epithelium. The conjunctiva includes goblet cells within the epithelium and overlies the substantia propria, which is composed of connective tissue with cellular elements including mast cells, lymphocytes, macrophages and fibroblasts. One of the highest concentrations of mast cells is at the limbus (the junction of the conjunctiva/sclera and the cornea). The mast cells in the human conjunctiva tend to be centered just beneath the basal epithelial cell layer and around blood vessels. AC is caused by direct exposure of the ocular mucosal surfaces to environmental allergens. The allergic inflammation starts the same as in the nose when allergens bind to the cell-attached IgE molecules and then mediators are released from the cells. Histamine is the principal mediator involved in ocular allergy and inflammation. Most of the allergic reactions are mediated through the effects of histamine on H1 receptors which are found the conjunctiva, cornea, and ophthalmic arteries.

There are two phases of the allergic response in allergic rhinoconjunctivitis: the early phase (minutes to hours) and late phase (6 hours to days). The early phase is induced by mediators such as histamine, prostaglandin, neuropeptides and leukotrienes released by the mast cells. Histamine directly stimulates sensory neurons, inducing pruritus and sneezing, and in concert with the leukotrienes, stimulates the vascular endothelium, inducing vasodilation and increased vascular permeability. Histamine also induces cholinergically mediated reflex glandular secretions, which can be inhibited by atropine or ipratropium. The early phase results in itchy eyes and nose, sneezing, watery eyes, rhinorrhea, edematous conjunctiva and nasal mucosa. After several hours of allergen exposure, other inflammatory cells including eosinophils, neutrophils and activated lymphocytes are demonstrable in the last phase response. The late phase or cellular phase leads to a recrudescence of nasal or eye symptoms associated with a second rise in histamine occurring in some affected persons. Basophils are felt to be responsible for the late-phase histamine peak. Eosinophil activation and accumulation with the release of eosinophilic proteins and mediators are the cause of increasing nasal blockage and hypersensitivity. It results in increasing sensitivity when repeatedly exposed to the same allergens (called the priming phenomenon).

The major symptoms of AR are sneezing, rhinorrhea, nasal pruritus and nasal congestion. There are two common presentations, seasonal and perennial allergic rhinitis. Seasonal allergic rhinitis is characterized mainly by periodic symptoms of the nose, ears, and throat with watery rhinorrhea, nasal congestion, sneezing, and pruritus occurring during the pollination season of the plants (typically, trees in spring, grass in summer and weeds in fall) to which the patient is sensitive. The sneezing, pruritus and rhinorrhea are a main complaint in the seasonal type. Perennial allergic rhinitis is characterized by intermittent or continuous nasal symptoms resulting from indoor allergen exposure (house dust mites, animal fur) without seasonal variation. Nasal obstruction may be the major or sole complaint of the perennial type, particularly in children, in whom the nasal passage is relatively small. Lacrimation, sneezing, clear rhinorrhea and itching of the nose, ears and throat may also occur. The symptoms are less severe than seasonal allergic rhinitis. The decreased severity of the symptoms seen in these patients may lead them to interpret their symptoms as resulting form "sinus trouble" or "frequent colds". In reality, the differentiation of seasonal and perennial types may not be clearly defined. Physical findings of AR often reveal changes in the eyes, nose, ears and throat. A horizontal nasal crease, caused by upward rubbing of the nose due to itching (allergic salute), is usually seen in children. The pale or bluish nasal mucosa with variable degrees of swelling and nasal blockage, and clear watery or yellow nasal secretions may be seen. The appearance of dark circles under the eyes (allergic shiners) is due to venous engorgement secondary to nasal congestion. Periorbital eczema, erythematous conjunctiva with papillary hypertrophy, and gelatinous secretions may appear. Posterior pharyngeal lymphoid hyperplasia secondary to postnasal drip is also noted. Middle ear fluid (otitis media with effusion or serous otitis media) is commonly noted. In some patients, however, the above findings are absent. All of the symptoms may be associated with recurrent sinusitis, asthma or eczema.

The symptoms of AC are watery, itchy, red, sore, swollen, stinging and burning eyes. Corneal symptoms, including photophobia and blurring of vision, are reported in rare cases. The ocular symptoms are frequently associated with nasal and/or pharyngeal symptoms. AC is seldom followed by permanent visual impairment. The presentation can be varied from mild to very severe and can be categorized into seasonal and perennial type. Seasonal allergic conjunctivitis (SAC) is more common and more severe. The onset of symptoms is seasonally related to specific circulating aeroallergens. Grass pollens are more commonly thought to be associated with more ocular symptoms than other aeroallergens. Ragweed is the most common cause of AC accompanying AR. Perennial allergic conjunctivitis (PAC) has symptoms throughout the year. PAC patients may have seasonal exacerbations. Dust mites, animal dander, and feathers are the most common airborne allergens implicated in PAC, which is more likely than SAC to be associated with perennial rhinitis. Both PAC and SAC patients are similar in distribution of age, sex, and associated symptoms of AR, asthma or eczema. Clinical findings of AC include: milky or pale pink conjunctiva with vascular congestion that may progress to conjunctiva swelling (chemosis), a white exudate during the acute state that becomes stringy in the chronic form. The conjunctiva surfaces are mildly injected with various degrees of chemosis. Lid edema sometimes occurs, as well as papillary hypertrophy along the tarsal conjunctival surface (the palpebral surface may appear bumpy). The clinical signs and symptoms are usually bilateral, although the degree of involvement may not be symmetrical.

The diagnosis of allergic rhinoconjunctivitis is based on a detailed history and physical findings as mentioned. Many allergic patients do not report the ocular or nasal symptoms unless they are asked directly about them during a medical examination. When evaluating patients who present with significant nasal symptoms, the following questions should be asked:

1. Is the nasal congestion or sneezing/itching/runny nose a main concern? Are there eye symptoms?
2. Does an activity or allergen exposure or a specific environment contribute to the symptoms? Seasonal or year-round symptoms? What are the clinically relevant allergens?
3. Are there other atopic diseases in the patient or the family?
4. Were any medications including topical OTC preparations (nasal and eye drops) used in the past?
5. Do the symptoms cause a major impact on lifestyle such as school activity or sleeping?

Typically, patients with classic symptoms do not require any tests. Slightly elevated serum IgE, mild peripheral blood eosinophils and eosinophilia of the nasal secretions are common findings; but these results are not diagnostic. Allergy testing including skin testing or radioallergosorbent test (RAST) may be required for the diagnosis and guidance of environmental avoidance in some patients with uncontrollable disease or atypical presentations. The allergy tests in young children are limited because positive specific IgE or skin prick tests to inhaled allergens usually develop after the second year of life.

Skin testing is the most common test for the diagnosis of allergy because of its simplicity, high sensitivity, low cost and rapidity of the result. Prick testing is widely used by allergists since the test is quick, not painful, inexpensive, highly specific with a low risk of systemic reaction. Prick testing requires: 1) devices such as metal needles or lancets or commercial test devices, 2) allergen extracts, 3) positive controls (histamine) and negative controls (glycerin or saline). A physician and equipment for treating anaphylaxis reaction should be readily available while performing the test. Patients should be instructed to discontinue some medications inhibiting skin response for a period of time including tricyclic antidepressants (5 days), hydroxyzine (3 days), astemizole (60 days), and other antihistamines (3 days). Contraindications for skin tests are generalized skin disease, inability to discontinue antihistamines, history of severe reactions or anaphylaxis to previous skin testing, pregnancy, dermatographism, unstable angina and beta-adrenergic receptor agent therapy (beta blockers, beta agonists or both). A response to an allergen with a wheal size greater than 3 mm in diameter indicates a positive result and having a specific IgE to the allergen. If the skin prick result is negative, an intradermal skin test may be considered in a highly suspected patient since the intradermal skin test is more sensitive.

RAST is an in vitro test for specific IgE antibodies based on the principle of immunoabsorption . This in vitro test for allergy is a convenient allergy test for non-allergist physicians or for patients who have contraindications for skin testing. RAST is not as sensitive as the skin test in most instances. Appropriate in vitro tests correlate up to 70-80% of the time with prick skin tests. CAP-RAST testing (a type of RAST test) is preferred over other RAST tests because of better standardization.

The differential diagnosis of allergic rhinoconjunctivitis includes infectious rhinoconjunctivitis, which includes the common cold, usually caused by rhinovirus, RSV, parainfluenza virus, influenza virus and adenovirus. Fever, sore throat, thick purulent rhinorrhea or eye discharge, erythematous nasal mucosa, and the presence of cervical lymphadenopathy are helpful differential findings in infectious rhinitis. Common diseases that may be confused with perennial allergic rhinitis are recurrent infectious rhinitis, chronic sinusitis, and vasomotor rhinitis. Structural and mechanical conditions that may mimic perennial allergic rhinitis include a deviated nasal septum, hypertrophic turbinates, adenoid hypertrophy, foreign bodies and tumors. Inflammatory and immunologic diseases such as Wegener's granulomatosis and sarcoidosis may present with rhinitis symptoms. Nasal polyposis, an uncommon condition causing nasal congestion in children, is usually associated with cystic fibrosis, asthma and aspirin intolerance and predisposes to sinusitis.

Nonallergic rhinitis with eosinophilia (NARES) may be misdiagnosed as allergic rhinitis. NARES is not IgE dependent and is not associated with high IgE levels or positive skin tests. Symptoms in NARES are more likely to be induced by exposure to irritants, strong

odors, cold air, and cigarette smoke. Drug-induced rhinitis is associated with use of various oral agents, especially certain classes of antihypertensive beta- blockers, oral contraceptives, chlorpromazine, aspirin and overuse of topical (nasal drops and sprays) sympathomimetics (rhinitis medicamentosa). Other less-common causes of rhinitis include occupational exposure, hormones, food and alcohol.

Several eye diseases need to be differentiated in patients with allergy and ocular symptoms. Irritative and chemical conjunctivitis is commonly confused with AC. The main symptom caused by environmental pollutants and smoke is conjunctival hyperemia. Atopic keratoconjunctivitis typically occurs in patients with atopic dermatitis. It is a bilateral, sight-threatening disease and symptoms are much more severe than SAC and PAC. The symptoms include significant itching, burning and redness, eventual fibrosis, decreased keratinization of conjunctival surfaces, cataract formation and lid malposition. Vernal keratoconjunctivitis is a chronic form of allergic conjunctivitis characterized by large "cobblestone" papillae on the underside of the eyelid. The symptoms are intensely pruritic and sight-threatening. Giant papillary conjunctivitis, a non-allergic condition, may be confused with ocular allergy. Giant papillae on underside of eyelid and non itching are distinguishing symptoms.

The management of allergic rhinoconjunctivitis in children includes allergen avoidance and education, medications and allergen immunotherapy as in adults. Allergen avoidance and environmental control are the main stay of treatment in all age groups.

Allergen avoidance and environmental control:

A wide range of allergens have been associated with allergic rhinoconjunctivitis, of which house dust mites are clearly the most important. The single most effective strategy for reduction of dust mite exposure involves bed-covering systems, which separate the mite allergens from the allergic individual by encasing mattress, pillows and blankets with mite allergen impermeable covers. Other recommendations for dust mite control are: 1) Washing the blankets, bed linen or other washable material such as curtains and toys in hot water over 55 degrees C regularly once a week. 2) Removing children's soft toys or washing/freezing the toys once a week. 3) Removing and replacing carpet in the house with vinyl or polished wooden floor boards. If it is impossible to remove the carpet, the carpet can be completely covered by polyethylene sheeting. 4) Mite control (acaricide) sprays have demonstrated some effects in reducing mite numbers and allergen levels. However, the clinical efficacy demonstrates only reducing symptom scores but not medication use. 5) High efficiency particulate air (HEPA) vacuum cleaners can reduce allergen load but no trial has demonstrated that this will improve symptoms.

Cat and dog fur is one of major allergens implicated in causing the perennial type. The allergens are not the dander itself but are contained in the saliva and in sebaceous secretions, which can flake off in small particles and remain airborne for considerable periods of time. This results in a ubiquitous allergen that can be found in many public places, even in a cat-free or dog-free buildings and schools. It makes avoidance much more difficult. The only effective measure for avoiding the allergens in the home is to remove the pets, carefully vacuum and clean all carpets, mattresses and upholstered furniture. Frequent washing of cats may reduce allergen exposure. However, clinical studies have not shown a clear benefit from this procedure when carried out once a week. A placebo-controlled trial of a HEPA air cleaner in the treatment of cat allergy did not find a significant effect on rhinitis.

Indoor molds can be removed with a bleach solution and can be followed by measures to reduce local moisture or humidity such as using a dehumidifier. Outdoor allergens, such as pollens, grass and fungal spores, are difficult to avoid. Outdoor exercising in the morning for sufferers with pollen allergy is recommended. These sufferers should be reminded to keep their bedroom window closed during the daytime and open windows only at night when the pollen count is low.

Medical treatment for allergic rhinitis:

It should be noted that there are only a few medications that have been tested in children under the age of two years. In young children under the age of four, use of nasal saline drops or spray can simply comfort them and help to clear their nose before eating or sleeping. Several concerns of medical treatment in children have been raised. The most important aspects are the antihistamine side effects on the cognitive functions of pre-school and school children. The use of systemic corticosteroids such as oral or depot-preparations should be deferred due to their systemic adverse effects. Children with allergic rhinitis who are athletes should be advised about the medications used since some of these medications are prohibited by various sports organization. Alpha-adrenergic agonists and systemic decongestants (both often combined with H1-antihistamines) are often prohibited in organized youth sports since they have a central stimulant effect. For intranasal corticosteroid use, a medical certificate documenting medical necessity should be issued. However, the regulations vary between countries, so physicians treating the athletes should be aware of these regulations.

All H1 antihistamines are competitive antagonists of histamine and are rapidly absorbed from the gastrointestinal tract. Antihistamines are most effective for sneezing, pruritus and rhinorrhea. They exert little effect on nasal congestion. Therefore, as a rule, they are more effective in acute, seasonal allergic rhinitis than in the perennial form in which congestion or stuffiness is usually more prominent. The use of H1-antihistamines is important for the treatment of rhinitis in children. The response to different antihistamines may differ from patient to patient, but it has been demonstrated that children not responding to one antihistamine may respond to another.

Antihistamines have been classified into first and second generation families. Some of the commonly used first generation antihistamines are triprolidine, diphenhydramine, chlorpheniramine, azatadine and hydroxyzine. All of them except hydroxyzine are over-the-counter medications (OTC). The first-generation antihistamines cause drowsiness, reducing one's ability to concentrate, blunting cognitive functions to some extent, and have varying anti-muscarinic effects such as dry mouth, constipation, blurring of vision, urinary retention. Their adverse effects limit their utility. Their use should be restricted to two relatively uncommon situations: 1) Children with urticaria or atopic dermatitis whose pruritus is so severe that the sedation produced by an old H1-antagonist, such as diphenhydramine or hydroxyzine, is a benefit rather than a risk. 2) Children with anaphylaxis who require intravenous diphenhydramine as adjunctive treatment to epinephrine and other medications.

Second-generation antihistamines are recommended for seasonal AR. Currently available forms include:

azelastine (Astelin): nasal spray, BID.
cetirizine (Zyrtec): low sedating, PO, once daily.
loratadine (Claritin): non-sedating, PO, once daily.
fexofenadine (Allegra): non-sedating, PO, BID.
desloratadine (Clarinex): non-sedating, once daily.

Only cetirizine and desloratadine are approved by FDA for perennial allergic rhinitis. Loratadine and fexofenadine are less sedating (minimal or no drowsiness). The above oral antihistamines are available as a combination medication with pseudoephedrine (Zyrtec-D,

Claritin-D, Allegra-D) since antihistamines have little effect on congestion. However, the use of an antihistamine with decongestant is limited to children older than 12 years. Desloratadine (Clarinex) is a non-racemic form of loratadine.

Intranasal corticosteroids ("steroids" for short) have proved to be the most effective class of drugs in reducing the symptoms of allergic rhinitis. This clinical response reflects the broad anti-inflammatory activity and multiple pharmacologic actions of corticosteroids. They have demonstrated specific effects on decreasing the activity of inflammatory cells such as mast cells, basophils, eosinophils, Langerhans' cells and decreasing the levels of chemical mediators including histamine, Th2 cytokines, chemokine and adhesion molecules. A single dose of intranasal steroid administration blocks the late-phase response; whereas repeated dosing blocks both early and late response, as well as the priming phenomenon. Intranasal steroids reduce the specific IgE production in seasonal allergic rhinitis and decrease nasal hyperresponsiveness or the priming phenomenon.

Intranasal steroids have been considered as second line agents after antihistamines by many physicians; however, first-line use of intranasal steroids is becoming increasingly common, especially for patients with moderate to severe symptoms. Intranasal steroids are more efficacious in chronic symptom relief than oral antihistamines, decongestants and cromolyn except for eye symptoms. Regular use of intranasal steroids is more effective than intermittent p.r.n. use, but p.r.n. use does have some efficacy in many patients. Although no well controlled study of a combination use of steroids and other medications is published, in clinical practice, intranasal steroids can be used in combination with other therapies to achieve optimal improvement in overall symptoms.

Several intranasal steroids are available including beclomethasone (Beconase, Vancenase), flunisolide (Nasarel), triamcinolone (Nasacort), budesonide (Rhinocort), fluticasone (Flonase) and mometasone (Nasonex). After using the recommended dosage for 2 weeks, the patient should be reevaluated, and the dosage can be adjusted based on the clinical response. The goal of therapy should be to use the lowest dosage that provides effective relief of symptoms. With proper use of intranasal steroids, 60-90% of patients may have nearly complete relief of rhinitis symptoms.

The most frequently observed adverse effect with intranasal steroids is local irritation. Approximately 10% of patients have some form of nasal irritation, nasal burning or sneezing after administration. Bloody nasal discharge occurs in approximately 2% and a few cases of septal perforation were reported due to improper techniques of administration. Long-term use of intranasal steroids does not appear to cause a significant risk of adverse morphologic effects on the nasal mucosa. Systemic side effects of intranasal steroid are rare, such as growth suppression due to low systemic absorption. Generally, the systemic absorption can occur through direct intranasal absorption or through gastrointestinal absorption of the swallowed fraction of the administered dose. It is likely that approximately 80% of the administered intranasal dose is swallowed resulting in systemic absorption. Mild growth suppression may result from chronic use of beclomethasone since it is metabolized to another active steroid compound.

Cromolyn sodium (Nasalcrom) has been one of the common drugs used for AR in children. It inhibits mast cell mediator release, and may inhibit C-type sensory nerve fiber transmission which modulates vascular and glandular responses. The drug is effective only when applied topically to the mucosal surface of the allergic end organ. It cannot be used orally for allergic disease. Cromolyn has been shown in numerous studies to be effective for both types of AR. It has a greater benefit in seasonal type symptoms and in highly allergic persons.

The major advantage of cromolyn is its safety, since there are no significant side effects of this drug. Its major drawback is the Q.I.D dose. In addition, it must be used on a regular basis to be effective, and ideally should be started before the onset of the symptoms. In patients with the seasonal type, cromolyn is best initiated just before the season starts at a dose of one spray in each nostril four times daily, and is continued throughout the season. In patients with perennial type, it can be started at any time, but it may take a few to several days to be effective. The recommended dose is one to two sprays in each nostril four times daily. After a patient's symptoms have stabilized, the dose may be decreased to three times daily, with increases to four times daily if symptoms worsen. Patients who are allergic to known triggers, such as animals, can use two sprays of cromolyn in each nostril 30 minutes before allergen exposure to prevent an allergic reaction.

Montelukast (Singulair), a leukotriene receptor antagonist given orally, has a new indication to be used for seasonal allergic rhinitis. Its efficacy might be equal to oral antihistamines (more data are needed), but it is less effective than intranasal corticosteroids and more expensive than both.

Nasal ipratropium (Atrovent), a topical anticholinergic nasal spray, is useful in patients with both allergic and non allergic rhinitis who experience rhinorrhea from various other triggers (e.g., cold air, eating spicy foods, and other irritants), by controlling rhinorrhea induced by nonspecific activation of cholinergic receptors. Its effectiveness is limited in patients with moderate to severe allergic rhinitis because ipratropium has little effect on other symptoms, such as sneezing, pruritus, or congestion. It is commonly used as an adjunct therapy if the rhinorrhea symptoms still persist with the antihistamine or intranasal steroid treatment. It is recommended for use in children older than 6 years. Common adverse effects are drying of the nasal mucosa and mild epistaxis.

Adrenergic nasal decongestants are available in both topical forms (e.g., oxymetazoline, phenylephrine and propylhexedrine) and oral forms (e.g., pseudoephedrine, phenylpropanolamine). The decongestants increase nasal patency by inducing vasoconstriction and reducing tissue swelling and obstruction. Although the decongestants have been used in children for years, there are very few studies in these young patients. The decongestants can be useful initially, often coupled with an antihistamine to control active allergic rhinitis symptoms. Once control is achieved, further symptoms usually can be prevented by the judicious use of antihistamines alone or with a nasal corticosteroid.

Decongestants should be deferred in small children and in patients who currently take MAO inhibitors. The side effects of oral decongestants are nervousness, dizziness, tachycardia, shakiness, urinary retention, insomnia. Its long-term round-the-clock use may increase the risk for hypertension. There is an association of hemorrhagic stoke and phenylpropanolamine (PPA) use in adults. Therefore, PPA was removed from the market by the FDA in November 2000. The major concern of nasal decongestants is the prolonged use which may induce rhinitis medicamentosa (especially with topical decongestants), which is rebound mucosal swelling from withdrawal of the medication. This discomfort may prompt the patient to use the medication frequently to avoid a sense of smothering. Ultimately, this cycle can induce serious irreversible mucosal damage. Therefore, topical preparations should be used for not more than 3 to 5 consecutive days to prevent rhinitis medicamentosa.

A guideline of treatment for allergic rhinitis: Recently, an expert panel in association with the World Health Organization (WHO) has recommended a guideline for the medical treatment of AR based on clinical severity ("mild" or "moderate-severe"). The severity is further subdivided into "intermittent" or "persistent" according to the duration of symptoms. It is necessary to define the severity of the allergic individual, then the choices of medications are based on the severity:

"Mild" means that none of the following items are present: sleep disturbance, impairment of daily activities (leisure and/or sport), impairment of school or work, troublesome symptoms. "Moderate-severe" means that one or more of the above items is present and a disturbance or impairment exists which not found in "mild". "Intermittent" means that the symptoms are present for less than 4 days a

week or for less than 4 weeks. "Persistent" means that the symptoms are present more than 4 days a week or for more than 4 weeks. Treatment recommendations are as follows:

For mild intermittent disease: oral or intranasal H1 antihistamines or intranasal decongestants (for less than 10 days and not to be repeated more than twice a month) or decongestants (not recommended in children less than 12 years old).

For moderate-severe intermittent disease: oral or intranasal H1 antihistamines or oral H1-antithistamines or decongestants or intranasal steroids or cromolyn sodium .

For mild persistent disease: Same medications as for moderate-severe intermittent above. The patient should be reassessed after 2 to 4 weeks. A stepwise approach is advised. If the patient has persistent mild symptoms and is on an H1-antihistamine or cromolyn treatment, changing the medication to an intranasal steroid is suggested. The dosage of intranasal steroids may be reduced by half if the patient responds well to the treatment. In seasonal allergy, a shorter course of treatment is required depending on the pollen season. However, long-term treatment may be needed especially in perennial allergy.

For moderate-severe persistent disease: Intranasal steroids are the first line treatment. The patient should be reassessed after 2 to 4 weeks of the treatment. A stepwise approach is advised. If the patient does not improve, consider other reasons for failure to respond to the treatment including heavy persistent allergen exposure (e.g., cat on the bed), inadequate medication compliance, nasal obstruction preventing drug delivery, other additional nasal pathology such as nasal polyps, sinusitis or nasal septal deviation, and a wrong diagnosis. If the major symptom is blockage, doubling the dose of the intranasal steroid is suggested. Add an H1-antihistamine if the symptoms of sneezing, itching or rhinorrhea still exist. Add ipratropium if rhinorrhea is not improved. If the patient's symptoms are less, a step down approach should be used. However, the treatment should last for at least three months or for the duration of the pollen season. In the step down treatment, a low dose of intranasal steroid may be required as a maintenance treatment to control symptoms. Referral to a specialist may be considered if the treatment is not fully effective, or if the duration of the treatment is over 3 months and the medications are not helpful.

Medical treatment of allergic conjunctivitis:

The primary goal of medical treatment is to alleviate the ocular symptoms and signs which disrupt the patient's quality of life. Initial management with allergen avoidance, cold compresses, and lubrication (artificial tears) should be tried before ocular agents are tried. Cold compresses provide considerable symptomatic relief, especially from ocular pruritus and swelling. In fact, all ocular medications provide additional subjective relief when applied immediately after refrigeration. Tear substitutes consisting of saline solution combined with a wetting and viscosity agent, such as methylcellulose or polyvinyl alcohol, can be applied topically 2 to 4 times a day and as needed. It is a soothing, effective, convenient and inexpensive option which directly removes and dilutes allergens that may come in contact with the conjunctiva.

Oral antihistamines used for the treatment of systemic or nasal allergy can reduce but do not eliminate the eye symptoms. However, treatment with oral antihistamines, especially the first generation, may cause eye dryness which interferes with the ocular defense mechanism and increases the potential for ocular irritation and sensitivity. The use of a "topical" agent on the affected eyes is the easiest and most direct therapeutic method. An important consideration for effective topical treatment is compliance. Treatments causing ocular irritation are likely to diminish compliance and may lead to a chronic duration of the condition, decreased patient satisfaction, and increased ocular sensitivity. Efficacy of these agents varies from patient to patient, and the choice of agent used will depend on the underlying health of the eye and other variables, such as drug cost, contact lens wear, and compliance. Several topical agents are available for the treatment and the prophylaxis of ocular allergies. These include vasoconstrictors, antihistamines, mast cell stabilizers, and anti-inflammatory agents.

OTC topical antihistamines are widely used in combination with topical vasoconstrictors. The combination is more effective than either agent alone or a systemic antihistamine. Adverse effects of topical vasoconstrictors include burning and stinging on instillation, mydriasis, rebound hyperemia or conjunctivitis medicamentosa with chronic use and drug interaction with MAO inhibitors. Topical vasoconstrictors are contraindicated in patients with narrow angle glaucoma.

Topical prescription antihistamines, including levocabastine, emedastine and azelastine, are a good option for symptomatic relief of an ocular allergy. Since these agents do not provide mast cell stabilization, they do not prevent or treat a significant cause of the allergy. All of the topical antihistamines require dosing as frequently as every 4-6 hours, except azelastine which requires only BID dosing, which may improve compliance.

Topical mast cell stabilizers include cromolyn, nedocromil, lodoxamide and pemirolast. It should be noted that the medications require several days (3-5 days) to start providing symptomatic relief of ocular allergy. The relief reported within 15 minutes probably represents a "washout" effect immediately after contact with the eyes. Long term use of these agents is necessary since they are preventive only. These agents require Q.I.D. administration with the exception of nedocromil which is B.I.D.

Topical dual action antihistamine and mast cell stabilizers include ketotifen and olopatadine. Therefore, they have rapid onset and prolonged duration of action. Both of them are approved for twice a day dosing for treating AC in children 3 years and older. Topical ketorolac (a nonsteroidal anti-inflammatory agent) is approved for use in children 12 years and older with acute SAC. It inhibits allergen induced prostaglandin production which diminishes the ocular itching and conjunctival hyperemia. Local administration of topical corticosteroids is associated with localized ocular complications such as viral infection, elevated intraocular pressure and cataract formation. Therefore, routine use is not recommended and their use should be under the close supervision of an ophthalmologist.

Allergen immunotherapy (AIT) is a safe and effective treatment for long-term control of allergic rhinoconjunctivitis. AIT is considered when environmental control is limited, when medications are ineffective or not well tolerated, or when the symptoms are a significant trigger for other chronic problems such as asthma or sinusitis. AIT results in successful treatment of AR in 85%-90% of cases. It is also recommended as a treatment for venom or insect hypersensitivity and selected cases of asthmatics. Patients with chronic urticaria, atopic dermatitis, or food allergy do not benefit from AIT. AIT induces immune tolerance to the specific allergens. In many cases, AIT can prevent clinical progression of allergic disease and may minimize the development of sensitization to multiple allergens in patients who are sensitized to a single allergen. The terms, "allergen vaccination" and "allergen immunotherapy", can be used interchangeably.

Prior to considering AIT, the patient must have evidence of specific IgE sensitivity such as a positive skin test or RAST test. Small doses of allergen extracts to which the patient is sensitized, are administered subcutaneously. The injected dose can be gradually increased as in a conventional AIT or rapidly increased as in a rush AIT until the maintenance dose is reached. The goal is to blunt the immune response with an optimal dose.

The efficacy of AIT for common allergens including house dust mite, cat, cockroach, birch, grass, and ragweed pollens have been well-documented. The efficacy of AIT depends on the quality of the allergen extract, the duration, the frequency of administration, the relevant allergens and the allergen doses. The dose of specific protein delivered in an allergen extract is crucial for induction of immune tolerance. If the extract is highly diluted or there are too many allergens which result in reduction of the relevant allergen dose, it will compromise the efficacy. In low doses, AIT is not effective in most patients. Therefore, a high dose of allergen extract per injection must be achieved as a maintenance dose to provide significant clinical benefit.

Allergic rhinoconjunctivitis causes substantial morbidity although the disease is not associated with mortality. Many physicians do not pay attention to the disease because they underestimate the impact of allergic rhinoconjunctivitis on other diseases, quality of life and performance. AR is a common cause of asthma exacerbation or uncontrolled persistent asthma. It is estimated that up to 90% of children with asthma have respiratory allergies, especially to indoor allergens such as house dust mite, Alternaria species, cockroach, or cat. All asthmatics should be evaluated for allergic rhinitis. Untreated or undertreated allergic rhinitis is associated with the development of otitis media with effusion (OME) and sinusitis. The OME may result in hearing impairment, which worsens progressively as the symptoms continue. There is strong evidence that AR and atopic dermatitis are more common in children with OME compared with normal subjects. Therefore, children with OME should be assessed for allergic rhinoconjunctivitis and children with allergic rhinoconjunctivitis should be assessed for OME. Adverse effects of allergic rhinoconjunctivitis in children are school absences, poor performance, poor concentration, headaches, malaise, and lethargy as a consequence of sleep disturbance and therefore reduced ability to learn. Furthermore, many of the antihistamines employed have some sedating effects, thereby aggravating the problem.

Although genetic factors contribute to the risk of allergic disease development, it is likely that environmental factors are partially responsible for the increase in the prevalence of atopic diseases. Therefore, changing the surrounding environment or other factors may decrease or prevent the atopic diseases. The following measures are recommended:

1. Raising children in a smoke-free environment, starting in utero.
2. Breast feeding for 4-6 months, delaying the introduction of solid food until 6 months of age, and withholding highly allergenic foods such as egg and peanut for 2 to 3 years, especially in a highly allergic family.
3. Reducing exposure to environmental allergens, especially in patients who have already developed respiratory allergies.

A hygiene hypothesis is supported by some studies. This hypothesis implies that overcrowding and unhygienic contacts early in life may protect from atopic diseases. The changes of human microbial flora, declining exposure to food-borne and orofecal infections, to helminths and to environmental sources of endotoxin are putative contributors to the rise of allergy cases among populations living with a western lifestyle. Lifestyle or clinical recommendations based on this hygiene hypothesis still remain to be proven.

Questions

1. The most prevalent of allergic disease in school-age children is:
    a. Atopic dermatitis
    b. Food allergy
    c. Asthma
    d. Allergic rhinitis
    e. Drug allergy

2. A 15 year-old has had persistent year-round nasal itching and stuffiness. What is the most likely allergen responsible for the symptoms?
    a. Dust mite
    b. Weed
    c. Tree
    d. Grass
    e. Mold

3. Which one is the most effective method for controlling dust mite exposure?
    a. Encasing mattresses, pillows and blankets
    b. Spraying an acaricide agent in the house
    c. Using HEPA air filter and vacuum
    d. Removing furniture and carpet in the house
    e. Washing washable materials in hot water

4. The most effective measure for allergen avoidance in furred animal allergy is:
    a. Washing the animal twice a week.
    b. Using HEPA air filter and vacuum in the house.
    c. Limit areas of the animal in the house.
    d. Removing furniture and carpet in the house.
    e. Removing the animal from the house.

5. Which one is the appropriate medical treatment of an 8 year old girl who develops nasal allergy in spring season?
    a. Diphenhydramine
    b. Cetirizine
    c. Fexofenadine with pseudoephedrine
    d. Nasal decongestant spray
    e. Beclomethasone nasal spray

6. The most effective and appropriate for a child with chronic allergic rhinitis and nasal stuffiness is:
    a. Intranasal antihistamine
    b. Intranasal corticosteroid
    c. Intranasal decongestant
    d. Oral antihistamine
    e. Oral antihistamine and decongestant

7. Which one is the most common adverse effect of intranasal steroids?
    a. Nasal irritation
    b. Septal perforation
    c. Nasal bleeding
    d. Short stature
    e. Adrenal suppression

8. Which one of the diseases benefits from allergen immunotherapy?
    a. Food allergy
    b. Atopic dermatitis
    c. Allergic rhinoconjunctivitis
    d. Latex allergy
    e. Chronic urticaria

9. Which one of the following eye drops has both antihistamine and mast cell stabilizer properties?
    a. Naphazoline
    b. Levocabastine
    c. Cromolyn
    d. Olopatadine
    e. Rimexolone

10. A mother of children with multiple allergic diseases asks you for allergy prevention advice for her next child. What would you recommend?
    a. Smoking free environment
    b. Breast feeding at least 4 months
    c. Diet control during pregnancy
    d. Using HEPA air filter and vacuum
    e. Both a and b

Chapter V.2. Anaphylaxis and Other Acute Allergic Reactions
Todd T. Kuwaye, MD, MS

A 12-year-old boy is brought to the emergency department after being stung by a bee. He had been well until he was stung on his right forearm, while playing in the yard. He initially complained of localized pain and swelling. Fifteen minutes later, he began to complain of shortness of breath. His parents observed him to be wheezing. He also said that he felt very weak and dizzy. His parents brought him immediately to the local emergency department.

Exam: VS T 37.1, P 120, R 39, BP 69/45. He is in mild respiratory distress. He is drowsy and pale, but awakens when you talk to him. He has generalized urticaria. He has no conjunctival edema. His lips and tongue are not swollen. His voice sounds normal. Heart tachycardic without murmurs. His lung examination shows mild wheezing and fair aeration with minimal retractions. His abdomen is soft and non-tender. His face is moderately pale. The bee sting site on his right forearm is unremarkable with no foreign body seen.

He appears to in early anaphylactic shock and he is immediately given subcutaneous epinephrine and an albuterol updraft with improvement of his symptoms. An IV is started, but since his condition is improving, he is not given IV epinephrine. He is given diphenhydramine IV, cimetidine IV, methylprednisolone IV, and an IV fluid bolus of normal saline. His urticaria resolves, his blood pressure normalizes and his lungs sound clear. After being observed in the ER for three hours, he feels as if he is back to normal. He is discharged from the ER on oral diphenhydramine and prednisone.

Anaphylaxis is a clinical syndrome involving the circulatory and respiratory systems. There are no specific criteria for anaphylaxis. Anaphylaxis is a word that is poorly defined. According to one dictionary, it means an exaggerated allergic reaction, while others have defined anaphylaxis as being more severe, involving the respiratory and/or cardiovascular systems. Allergists and immunologists define anaphylaxis as an immediate systemic reaction caused by IgE mediated release of potent mediators from tissue mast cells and peripheral blood basophils. This definition, however, does not allow the clinician to differentiate anaphylaxis from other less severe allergic conditions. This definition does differentiate anaphylaxis from anaphylactoid reactions, but to the physician this is arbitrary since both will be managed the same. Most clinicians will agree that anaphylaxis is a severe, potentially life-threatening allergic response to a repeat exposure to an allergen. Symptoms may include swelling, urticaria, angioedema, hypotension, bronchospasm, airway obstruction/edema, shock, loss of consciousness and ultimately death if help is not received.

Due to a lack of specific clinical criteria for anaphylaxis there is no accurate data on its occurrence. In the United States, it is estimated that more than 40 people per year die from insect sting anaphylaxis (1).

Clinical manifestations include rapid onset of symptoms, a feeling of impending doom, weakness, dizziness, confusion, loss of consciousness and seizures. Airway and pulmonary findings include congestion, sneezing, rhinorrhea, swelling of the lips and tongue, stridor, hoarseness, dyspnea and wheezing. Cardiovascular findings include light headedness, syncope, tachycardia, hypotension, pallor, arrhythmia and complete cardiovascular collapse. Cutaneous findings include erythema, flushing, pruritus, angioedema and urticaria. GI findings include: nausea, emesis, abdominal cramping and diarrhea. Patients with anaphylaxis may have any combination of the above.

After the onset of the initial symptoms, symptoms may recur despite initial treatment. This recurrence of symptoms has been called biphasic anaphylaxis. In adults, the rates of biphasic anaphylactic reactions are between 5-20% and in children 6% (2,3). The differential diagnosis for anaphylaxis includes asthmatic attacks, vasovagal reactions, Scombroid fish poisoning (a histamine reaction), hereditary angioedema, systemic mastocytosis, vocal cord dysplasia, shock, metastatic carcinoid, serum sickness, panic attacks as well as the less severe acute allergic reactions.

Etiologies of anaphylaxis include food, insect stings, antibiotics, vaccines, latex and idiopathic causes. Common foods that trigger anaphylaxis include tree nuts, peanuts, shellfish and dairy products. The pathogenesis of anaphylaxis involves prior exposure to an allergen (such as mentioned above). Upon first exposure of the offending allergen, a specific IgE antibody is produced against the allergen. These IgE antibodies attach themselves to the outer surface of mast cells. Upon re-exposure to the offending allergen, the allergen complexes with the IgE antibodies on mast cells. This interaction between the specific IgE antibody and the allergen sets into motion the degranulation of tissue mast cells and blood basophils. The mast cell releases potent inflammatory mediators such as histamine, proteases and chemotactic factors such as tumor necrosis factor. In addition to these primary mediators, there are secondary mediators such as prostaglandins and leukotrienes that are also produced. These potent mediators have the effect of producing the symptoms of anaphylaxis. The main inflammatory mediator is histamine, which causes initial erythema (vasodilatation), edema (vasopermeability) and secondary flare (axon reflex with arteriolar dilation) (4). Anaphylactoid reactions produce a similar inflammatory response, but the primary difference is that the reaction is not IgE mediated. Examples of anaphylactoid reactions are those caused by radiocontrast media, anesthetics, and exercise.

The diagnosis of anaphylaxis is made clinically. Thus, it is important to rule out disorders mentioned in the differential diagnosis. There is some evidence that measuring a serum tryptase within 2 hours of an anaphylactic episode is helpful to diagnose anaphylaxis. However, the test is not available and is limited to research labs. The difference between anaphylaxis and anaphylactoid reaction to the clinician is not important since both are treated the same.

The primary immediate treatment of anaphylaxis is epinephrine. If a patient has a history of a previous severe reaction, then it is recommended that the epinephrine may be given immediately after contact or ingestion, with no waiting periods to see if a severe reaction will occur (5). Pediatric dosage for epinephrine is 0.01mg/kg up to a max dose of 0.5mg per dose or 0.5ml of 1:1000 SQ/IM Q15minutes for two doses and then Q4 hours as needed. The adult dosage is 0.2-0.5ml of a 1:1000 epinephrine solution. IM administration is faster than subcutaneous (SQ) (6). IV epinephrine is given for severe reactions in which patients are in severe shock. When in severe shock, the skin and muscle may not be adequately perfused, so SQ or IM epinephrine will not be absorbed sufficiently in the circulation unless it is given IV. It is usually recommended to prepare a dilute infusion of epinephrine calculated as 0.1 to 1.0 mcg/kg/min. This is cumbersome, time consuming and impractical for the patient who needs IV epinephrine immediately. Another practice is to utilize the 1 mg 1:10,000 epinephrine injector (1 mg diluted in 10cc), and inject this very slowly into the IV line, allowing the clinician to titrate the dose. Epinephrine is a dangerous drug, which will cause severe palpitations and/or dysrhythmias if it is given too fast. You could calculate the SQ/IM dose and administer only this dose IV between 2 to 10 minutes depending on the severity of the patient.

Patients with a previous history of anaphylaxis are usually given epinephrine autoinjectors for home use (e.g., EpiPen 0.3 mg, EpiPen Junior 0.15 mg). All patients receiving epinephrine should immediately go to the emergency department or call 911 (5).

Adjunctive therapy for anaphylaxis includes antihistamines. H1 blockers appear to be effective. Diphenhydramine (H1 blocker) is the most commonly used drug given parenterally. A combination of H1 and H2 blockers (such as diphenhydramine and cimetidine) given

together may have more benefit than a single antihistamine in treating severe allergic reactions (7). However no study has shown the addition of H2 blockers to provide additional benefit in the treatment of anaphylaxis. Corticosteroids are not effective in the treatment of anaphylaxis in the acute period. There is some discussion that it may be effective in the biphasic phase of anaphylaxis. Although corticosteroids are commonly given in anaphylaxis and other severe allergic reactions, there are no studies that clearly demonstrate its effectiveness. In fact, in a study by Lee, 5 of 6 biphasic cases of anaphylaxis received corticosteroids initially at time of presentation (2). Bronchodilators are effective for patients developing wheezing and bronchospasm, although epinephrine alone may be sufficient.

Finally glucagon may be helpful in those patients on beta-blockers who develop anaphylaxis. There are no studies documenting effectiveness and only anecdotal accounts in the literature. The management of anaphylaxis also requires hospitalization or observation for 24 hours because of the possibility of biphasic anaphylaxis. All patients require at least observation since one cannot predict which patient will develop the biphasic response of anaphylaxis. However, if the parents are reliable observers and they are able to get to the hospital quickly, then the observation time in the emergency department can be shortened.

Physicians who identify a patient with a history of anaphylaxis should encourage their patient to obtain a Medic Alert bracelet or ID. The patient should be instructed on epinephrine use and dispensed an epinephrine syringe. Physicians should be responsible for demonstrating and training patients on the use of epinephrine syringes. However, considering the practical consideration that this epinephrine injector is not likely to be available (i.e., the patient won't have it) when their next reaction occurs, patients should also be taught the best means to obtain medical care depending on the severity of the reaction. Patients should also be prescribed an oral antihistamine, which should be taken immediately. Lastly, the management of anaphylaxis should be directed toward avoiding the offending agent and education of where the offending agent can be hidden (especially if it is a food item). For example, patients who are allergic to peanuts will probably react to foods cooked in peanut oil and patients with dairy product allergy may need to avoid butter and foods cooked with butter. This can be extremely challenging and almost impossible to avoid, especially at restaurants. An instruction to the waiter of "no peanut oil", will often translate to "use corn oil instead" to the cooks in the back. However, if the pan used had some peanut oil on it for the previous dish that was cooked, this may still be sufficient to cause a reaction in the patient. Allergy testing may be useful to determine the cause of the allergy and desensitization therapy may be useful for some types of allergies.

Urticaria, also commonly known as hives, are raised erythematous, circumscribed, pruritic lesions. Urticaria occurs from focal mast cell degranulation causing the release of histamine and other mediators. Individual lesions of urticaria generally do not remain in the same place for greater than 24 hours. Urticaria is divided into acute and chronic urticaria. Urticaria that lasts less than 6 weeks is acute and more than 6 weeks is chronic. Acute urticaria is more common in children and young adults, while the peak incidence of chronic urticaria is during the third and fourth decades (4).

Urticaria can occur from food allergies, collagen vascular disease, infections, environmental factors such as heat, cold or pressure, and medications. Despite an extensive workup, most cases of chronic urticaria is idiopathic. Urticaria is treated with antihistamines. In most instances, the urticaria should be largely resolved within several hours. H1 blockers, such as diphenhydramine or the newer non-drowsy antihistamines such as loratadine, are the standard therapy, but H2 blockers, such as ranitidine and cimetidine, have variable degrees of success so routine use is controversial (8). Avoidance of known triggers of urticaria is probably the most important aspect in chronic management.

Angioedema is a similar process that occurs in the deeper subcutaneous layers of the skin or mucus membranes, giving rise to nonpitting, stretched, colorless, well demarcated skin lesions. In contrast, urticaria lesions are typically raised, erythematous and pruritic. Characteristically, pruritus is absent in angioedema. There are fewer mast cells and sensory nerve endings in the deeper layers of skin involved. Most frequently, angioedema affects the scalp, lips, face, eyes, extremities and genitalia. Otherwise, angioedema is similar to urticaria with the main distinguishing feature of involvement into the dermis. Angioedema is treated similarly as urticaria.

Hereditary angioedema is an autosomal dominant disorder characterized by recurrent bouts of swelling typically affecting the face, extremities, respiratory and GI tract. This condition occurs because of the absence or abnormally functioning C1 esterase inhibitor. C1 esterase inhibitor prevents complement activation. If CI esterase is not functioning or absent, then the activation of the classical complement pathway could be unchecked. The disorder is usually self-limited, however, severe laryngeal edema or GI involvement may occur. Treatment involves the use of androgens, which causes the production of sufficient amount of C1 esterase inhibitor to prevent C1 activation.

Erythema multiforme may also resemble urticaria, especially in the early stages. However, erythema multiforme (EM) does not respond to antihistamines or corticosteroids. The lesions are varying in size and shape (multiformed) and some lesions have a target appearance with a rim of urticaria surrounding a central depression (target lesion). The most common presenting complaint is that of "hives" which has not responded to an antihistamine. Serum sickness may present a similar clinical picture. Joint swelling may accompany both conditions. These conditions generally resolve on their own within about 2 weeks. Withdrawing the allergic substance is a good idea, but it is usually not possible to determine what the inciting cause was. Group A beta hemolytic streptococci, herpes simplex and mycoplasma are known causes of EM, but there are numerous other causes as well. Stevens Johnson Syndrome is a severe form of EM (also known as EM major) which requires hospitalization. Treatment is supportive, but corticosteroids may be beneficial.

Questions

1. True/False: Anaphylaxis is well defined with its own clinical criteria.

2. What is the primary treatment of severe anaphylaxis and what is the appropriate dose?

3. What are some of the adjunctive therapies for anaphylaxis?

4. Two weeks following a viral illness, a teenage boy breaks out in an evolving rash that is remarkable for target lesions. What is the primary treatment?
   a. Epinephrine
   b. Glucagon
   c. Corticosteroids
   d. Antihistamines
   e. Symptomatic or supportive therapy depending on severity.

5. A girl is brought to her pediatrician by her mother because of recurrent bouts of non-pitting, non pruritic facial swelling that have occurred three times prior. Her father also has an history of recurrent facial swelling. What is the probably diagnosis?

a. Environmental allergen
b. Hereditary angioedema
c. Child abuse
d. Anaphylaxis
e. Urticaria

Answers to questions

1. false
2. Epinephrine. Pediatric dosage for epinephrine is 0.01mg/kg up to a max dose of 0.5mg per dose or 0.5ml of 1:1000 SQ/IM Q15minutes for two doses and then Q4 hours as needed. The adult dosage is 0.2-0.5ml of a 1:1000 epinephrine solution.
3. Adjunctive therapies includes antihistamines, bronchodilators, and perhaps glucagon and corticosteroids.
4. e. This is erythema multiforme.
5. b

Chapter V.3. Food Allergies

Akaluck Thatayatikom, MD

Case 1

A 9 month old infant with severe eczematous rash is seen by his pediatrician. His mother reports that he has had this rash since 6 months of life when bottle feeding started. The skin rash did not respond to 1% hydrocortisone treatment and it has worsened in the past few weeks. On exam, he is noted to have generalized dry skin with subacute eczematous lesions on both cheeks and the extensor surfaces of his extremities without other abnormal findings. A diagnosis of cow's milk allergy is suspected which is confirmed by a highly positive CAP-RAST test for milk specific IgE antibody. He is successfully treated with 1% hydrocortisone cream, daily cetirizine (antihistamine), avoidance of cow's milk and dairy products, and a trial of soy milk formula feeding. His skin rash is controlled well within 2 weeks and this totally disappears after 1 year of age. At 3 years of age, cow's milk is accidentally given to him, however, no skin rash or other reaction is noticed. A cow's milk challenge is given to him in the physician's office and no reaction is noted. His cow's milk allergy has spontaneously resolved and he has no further problems with milk or dairy products.

Case 2

A 3 year old girl is brought to a pediatrician's office immediately since she develops her second episode of hives on her face and torso with dry coughing after eating peanut butter. Exam findings reveal normal vital signs, generalized expiratory wheezing and generalized urticaria. The symptoms respond well to diphenhydramine, subcutaneous epinephrine and an albuterol nebulizer treatment. Subsequently, she is evaluated by an allergist for possible peanut allergy. Her skin test demonstrates a strongly positive skin test (2 cm) and a CAP-RAST test shows a high level of peanut-specific IgE. Peanut avoidance is recommended. Her parents are given instructions on antihistamine and EpiPen use. In pre-school, she develops difficulty breathing and urticaria after eating a cookie given to her by another child. An ambulance is called and she is treated in an emergency department. At age 10, while on a school field trip, she develops urticaria, wheezing and she passes out after eating chili for lunch. An ambulance is called and she is treated with IV epinephrine, diphenhydramine, cimetidine and methylprednisolone for anaphylactic shock.

Case 3

A 16 year old female with seasonal allergic rhinitis is referred to see an allergist for evaluation of recurrent itching and swelling of her lips and tongue after eating bananas. The symptoms develop immediately after eating bananas and spontaneously resolve in 45 minutes. There is no history of sore throat, breathing difficulty, wheezing, GI symptoms, or skin rash. Physical examination at the visit are essentially normal. A skin test with a commercial extract yields a negative result; however, a skin test with fresh banana gives a positive result which confirms a diagnosis of oral allergy syndrome.

Case 4

An 11 month old boy develops a rash around his mouth after eating eggs. He is treated with hydrocortisone cream. He is taken to his physician and his parents ask if he might be allergic to eggs. A RAST test for eggs is ordered and the result is 1+ (very low). His

parents are informed that he is not allergic to eggs. His parents feed him some scrambled eggs two days later and he immediately develops hives and wheezing. He is treated with diphenhydramine, subcutaneous epinephrine and albuterol in an emergency department, where his parents are informed that he is probably allergic to eggs.

The four case scenarios illustrate common presentations, diagnostic work up approaches and management of food allergies. Food allergies are an increasing problem in westernized countries. Although an unpleasant reaction to food is often thought to be a food allergic reaction, only 8% of children under 3 years of age and roughly 2% of the adult population are affected by food allergies, which are mediated by an allergic/immune mechanism (e.g., IgE mediated). An adverse food reaction is a general term for a clinically abnormal response to an ingested food or food additive. Adverse food reactions may be caused by food hypersensitivity (allergy) or food intolerance. Food intolerance is a descriptive term of an abnormal physiologic response to an ingested food or food additive. The response is not immunologic in nature and it may be caused by many factors such as a toxic contaminant (such as histamine in scombroid fish poisoning or toxins secreted by Salmonella or Shigella), pharmacologic properties of the food (such as caffeine in coffee or tyramine in aged cheese) and idiosyncratic responses or host factors (such as lactase deficiency).

Food allergy, with acute onset of symptoms after ingestion, is IgE-dependent and potentially involves 4 major target organs: skin, GI, respiratory tract and cardiovascular systems. Acute urticaria and angioedema are the most common food allergic reactions, but the reaction may be a severe, life threatening event, such as anaphylactic shock. In fact, food allergies account for a large proportion of anaphylaxis cases in the United States. Other forms of acute presentations include: oral allergy syndrome, immediate gastrointestinal reaction (nausea, emesis, and diarrhea), anaphylaxis, rhinitis, asthma, and exercise-induced anaphylaxis. Delayed onset of food allergy symptoms includes atopic dermatitis, eosinophilic gastroenteropathies, dietary protein enterocolitis, dietary protein proctitis, dietary protein enteropathy, celiac disease and dermatitis herpetiformis. This chapter will focus on the IgE mediated food allergies.

Atopic dermatitis is a mixed IgE and cell mediated disease. There is substantial evidence indicating that food allergies cause many cases of atopic dermatitis in children, although food allergy is rarely a trigger of atopic dermatitis in adults. In a study, food allergies were found in 35% of children with moderate-severe atopic dermatitis (4). The skin lesions are generally provoked by an oral food challenge and are resolved by avoidance of the causal foods.

The pattern of food allergy in children is somewhat different from that in adults. The most common foods that cause problems in children are eggs, milk, peanut, soy, wheat, and fish. Most children will outgrow food allergy for eggs, milk or soy by age 4. In contrast, food allergies for shellfish (shrimp, crayfish, lobster, and crab), fish, peanuts and tree nuts are usually life-long.

An association of food allergy and latex allergy has been reported and confirmed. Approximately 30-50% of individuals who are allergic to natural rubber latex show an associated hypersensitivity to some fruits and vegetables (known as latex-fruit syndrome) such as avocados, bananas, chestnuts, kiwi, peaches, tomatoes, potatoes and bell peppers. Individuals who are allergic to pollens may produce specific IgE antibodies directed to homologous allergens of both pollens and fresh fruits/vegetables such as: 1) birch pollen with apples, peaches, pears, almonds, hazelnuts, potatoes and carrots. 2) ragweed pollen with melons and bananas. 3) mug wort pollen with celery and carrots. 4) grass pollen with tomatoes. This cross reactivity accounts for oral allergy syndrome in individuals with seasonal allergic rhinitis. The classic presentation of oral allergy syndrome is an acute episode of swelling, itching, tingling sensation, angioedema of lips or palate and erythematous mucosa localized only in the oral cavity after eating certain fresh fruits and/or vegetables (such as bananas, apples, peaches, carrots, melons, tomatoes) but not cooked fruits or vegetables since the allergens for oral allergy syndrome are heat labile.

In general, individuals do not develop clinical symptoms after being exposed to food allergens in the GI tract since the mucosal immune system and local GI factors (including intestinal epithelial cells, dendritic cells, T cells, mediators and gut flora) induce a state of unresponsiveness known as oral intolerance. Food allergy develops in genetically predisposed persons when oral intolerance fails to develop properly. In infants, the developmental immaturity of various components of the gut barrier and immune system increases the risk of developing food allergies during the first few years of life. The maturation of the gut with reduced systemic absorption and maturation of immune responses are thought to be the mechanism explaining why children outgrow food allergies or develop tolerance. Acute IgE-mediated reactions develop when food specific IgE antibodies residing on mast cells and basophils, bind circulating food allergens and activate the cells to release a number of potent mediators and cytokines. The pathogenesis of cell-mediated food allergy or delayed onset types remains unclear.

The diagnostic approach begins with the medical history and physical examination, followed by appropriate diagnostic tests. The goal is to determine whether the patient is likely to have experienced an adverse reaction to food involving an immunologic (allergic) mechanism. One should obtain information on: 1) the suspected food, 2) the quantity of the ingested food, 3) the time between ingestion and development of the symptoms, 4) description of the symptoms, 5) whether similar symptoms developed on other occasions when the food was eaten, 6) whether other factors (such as exercise) are necessary to provoke the reaction, and 7) the time since the last reaction. If an allergic reaction is suspected, it is essential to categorize reactions mechanistically (i.e., IgE mediated or non-IgE mediated) because subsequent diagnostic tests depend on the suspected mechanism. Most of the histories are useful and reliable only when the reactions are acute in onset such as with acute urticaria or anaphylaxis. In the case of delayed onset of symptoms such as atopic dermatitis, the history is often unreliable in implicating the offending allergens.

There are three methods to more definitely confirm or rule out IgE mediated food allergies: 1) Skin testing, 2) RAST, and 3) Oral challenge. Skin prick testing is done by pricking the skin with commercially available allergen extract solutions. Skin testing is generally done by allergists (i.e., not primary care physicians). A positive test identifies food specific IgE antibodies (suspected IgE mediated food allergy). A positive result yields a wheal (not erythema) of at least 3 mm in diameter larger than the negative control. A skin test that provokes a serious allergic reaction should also be considered to be diagnostic of a food allergy. There are some exceptions for interpretation of the results: 1) When testing a patient suspected of oral allergy syndrome, false negatives often occur if commercial food extracts are used for the skin test because these extracts are heat treated (rendering the allergen non-immunogenic, typical of oral allergy syndrome). However, by using a fresh fruit or vegetable for skin prick testing, a positive result may be confirmed as noted in the example described in case 3. 2) Children under one year of age may have IgE mediated food allergy without a positive skin test, and children under 2 years of age may have smaller wheals, possibly the result of a lack of skin reactivity. Negative skin prick test responses have excellent negative predictive values for excluding the presence of IgE mediated food allergy.

RAST (radioallergosorbent test) is an in vitro measurement of serum food specific IgE. The test is more available and practical for primary care physicians to evaluate food specific IgE antibodies. It should be noted that RAST tests are heterogenous yielding potentially unreliable results. CAP-RAST (the Pharmacia CAP system FEIA) is a newer generation of RAST which provides more reliable quantitative measurements of specific IgE levels. Table 1 is a recommended interpretation of food allergen-specific IgE levels (kUA/L) by CAP-RAST in the diagnosis of food allergies (5). For example, if a child's egg-specific IgE level is 7 or greater by CAP-RAST, there is a

greater than 95% likelihood that the child is truly allergic to eggs. In contrast, if the egg-specific IgE is less than 0.35 and there is no compelling history of egg allergy, there is a 95% chance that the child is not allergic to eggs. However, there is a 5% chance (1 in 20), that the child's CAP-RAST is falsely negative and that the child is allergic to eggs (as in case 4). If there is a strongly suggestive history of a food allergy, it should be noted that a low CAP-RAST can be misleading.

Table 1: CAP-RAST results

	95% NPV	95% PPV
Egg	0.35	7
Milk	0.35	15
Peanut	0.35	14
Fish	0.35	20
Soy	0.35	65
Wheat	0.35	80

If a CAP-RAST value falls somewhere between the 95% positive and negative predictive values (between the two values in the columns), it is uncertain whether a food allergy for that food exists. The patient will have to be referred to an allergist for skin testing, or an oral food challenge will have to be performed.

An oral food challenge is performed by feeding gradually increasing amounts of the suspected food under observation by a physician over hours or days. The double-blind, placebo controlled food challenge (DBPCFC), by giving increasing quantities of the suspected food allergen or placebo, either in opaque capsules or camouflaged in a liquid or semisolid vehicle, is considered the gold standard test of both IgE and non-IgE mediated food allergy. Elimination of the suspected food from the patient's diet for at least 7-14 days; withdrawal of potentially interfering medications (e.g., antihistamines); control of symptoms of chronic allergic disease (such as atopic dermatitis or asthma); administration of the challenge in a fasting state; use of fresh or dehydrated foods; and use of challenge vehicles that do not contain fat which can interfere with protein absorption, have been suggested to optimize the outcome. The absence of an allergic reaction after ingesting up to an equivalent of 10 grams of the dehydrated food essentially rules out a food allergy in that such a result has a high negative-predictive value. However, an average false-positive rate of 0.7% and false-negative rate of 3.2% for the DBPCFC were reported (7). Since the patient with IgE mediated food allergy may develop severe reactions to the challenge, the test should be performed by a well-trained physician in a facility capable of close monitoring, which is well equipped with drugs, supplies and equipment for resuscitation. The contraindication for such a test is recent anaphylaxis. An alternative to the DBPCFC,is a supervised open (unblinded) food challenge to confirm the safety of eating the particular food. This is recommended for a patient with a low likelihood of food allergy based on a low CAP-RAST result or an individual with a negative DBPCFC result.

A differential diagnosis of food allergies first aims to distinguish food allergies from food intolerance or other illnesses. Food poisoning is a possibility when food is contaminated by microorganisms and their products (such as toxins). Lactase deficiency, resulting in lactose intolerance, in children and adults, is a common food intolerance that is often confused with food allergy. There are also natural substances, such as histamine in cheese, wines and certain kinds of fish, that can occur in foods and stimulate a reaction similar to an allergic reaction. If someone eats one of these foods with a high level of histamine, that person may have a reaction similar to an allergic reaction to food. This reaction is called histamine toxicity, and it is often responsive to antihistamines. Reactions to MSG (monosodium glutamate) are not due to allergy mechanisms since MSG contains sodium and glutamate, both of which are normally present in the body. Excess amounts of consumed MSG are metabolized to neurotransmitters which may cause a reaction to MSG (Chinese restaurant syndrome) which is not allergic in nature.

The primary treatment for a child with a food allergy is to remove the offending antigen from the diet. In exclusively breast fed infants, a strict elimination of the causal protein from the diet of the lactating mother should be tried. Over time, many children who have food allergy (such as egg or milk) will develop tolerance to the food, making cautious, periodic attempts to introduce the offending food possible. An elimination diet can often be successful in children who have a single food allergy. However, dietary modification and nutritional counseling may be necessary for children who have multiple food allergies to identify hidden ingredients in processed foods and cross-reacting foods (e.g., peanuts, legumes). Aggressive restriction of allergenic foods may compromise the nutritional adequacy of the diet and interfere with the normal growth of the child. Patients and their families should be educated to avoid accidentally ingesting food allergens (e.g., by reading food labels), to recognize early symptoms of an allergic reaction, and to initiate early management of an anaphylactic reaction.

Many foods are ubiquitous in the environment and are often hidden in foods. Some helpful information can be obtained from www.foodallergy.org or www.anaphylaxis.org.uk. For example, a person eating peanuts may aerosolize sufficient quantities of peanuts to cause a nearby peanut allergic patient to react. Young children may share foods. Adults (other than parents) who serve food or supervise children (e.g., teachers, pre-school aids) are often not familiar with hidden foods in labels or they are not familiar with simple precautions. For example, peanuts are found in chili and scooping ice cream at a party may contain microcontamination with nuts if nuts are used in the ice cream of other children.

Just as an example, patients who are allergic to peanuts must learn to avoid peanut oil (Asian cooking), almond chunks (may actually be peanuts), baked goods, sauces (Chinese hot sauce, barbecue sauce, etc.), gravy, egg rolls (glue for edges), enchilada sauce, chili and other substances as well. Patients who are allergic to tree nuts (i.e., other nuts) must learn to avoid salad dressings, dessert toppings, sauces, exotic nut oils, pie crusts (almonds, macadamia nuts), ice cream toppings, cookies, almond extract, etc. Patients who are allergic to eggs must learn to avoid albumin, lysozyme, ovalbumin, egg substitutes (low cholesterol only), pastry, sauces, salad dressings, some shampoos, pet foods, influenza vaccine, cosmetics, fresh pasta, etc. Patients who are allergic to milk are usually allergic to the whey or casein protein in milk so they must learn to avoid whey, casein, ghee, nougat, rennet, caramel color, "natural flavors", canned tuna, hot dogs, imitation butter flavor, non-dairy whipped cream, non-dairy coffee whitener, imitation cheese, calcium caseinate, etc. Patients who are allergic to wheat must learn to avoid cracker meal, semolina, spelt, couscous, cornstarch, bulgar, farina (Cream of Wheat), etc. Patients who are allergic to fish must learn to avoid imitation crab, Worcestershire sauce (anchovy), Caesar salad (anchovy), many Asian foods (fish sauce), etc.

The above list is already difficult. Many pet foods contain nuts, which could be aerosolized when scooping this out for the pet dog. Facial scrubs may contain pulverized walnut shells. "Bean bag" furniture may contain walnut shells. Egg substitutes still contain eggs (with a reduced cholesterol formulation). "Non-dairy" products may still contain whey and casein.

Restaurants present a serious risk for patients with food allergies. When a cook is told to avoid a certain food, any pans, pots, woks, griddle surfaces or cooking utensils must not be exposed to any of these substances. For example, if a cook is attempting to avoid eggs, dairy products and peanuts, then the cooking surfaces and utensils must have no eggs, no butter and no peanut oil. If eggs were cooked on the griddle 30 minutes ago and the griddle was cleaned several times since, there may still be microscopic amounts of egg remaining. Similarly, cooking with butter or peanut oil is likely to leave microscopic residues on utensils or cooking surfaces, which may be sufficient to cause an allergic reaction.

An antihistamine is sometimes the only medication needed to reduce the itching and rash. In an acute event of anaphylaxis, immediate resuscitation is required. Epinephrine (0.01 ml/kg of the 1:1000 dilution given IM or subcutaneously) is often required for more severe allergic reactions. The term "anaphylaxis" is vague, but it implies a severe allergic reaction. Anaphylactic shock with associated vasodilation and hypotension, generally requires an IV epinephrine infusion with fluid replacement, in addition to preliminary IM or subcutaneous epinephrine. Having medical alert bracelets, carrying epinephrine for self injection and antihistamines available at home and school are strongly recommended for patients who have experienced a severe food allergy reaction. Some food allergies are more serious than others. On average, peanut allergies are the most serious, thus early epinephrine treatment should be considered even if a severe allergic reaction has not yet been encountered. Skin care with topical corticosteroid therapy and food avoidance is advised in food allergy induced atopic dermatitis. Immunotherapy by injection or sublingual administration of offending antigens has not proven to be effective in the management of patients who have food allergy. A new anti-IgE therapy (TNX-901, a humanized IgG1 monoclonal antibody against IgE) may alleviate some severe allergic reactions of peanut allergy (8).

There is some potential for prevention. Breastfeeding should be encouraged for all infants for the first 4-6 months of life. Breastfeeding mothers should avoid potentially allergic foods. Breastfeeding and the late introduction of solid foods (beyond the 5th month of life) is associated with a reduced risk of food allergy and other atopic diseases in early childhood. In formula fed infants with a documented hereditary atopy risk (affected parent or sibling), the exclusive feeding of a formula with a confirmed reduced allergenicity (protein hydrolysate formulas such as Nutramigen, Pregestimil and Alimentum) is recommended because it can reduce the incidence of adverse reactions to food, especially to cow's milk protein. There is no conclusive evidence to support the use of formulas with reduced allergenicity for preventive purposes in healthy infants without a family history of allergic disease. Preventive dietary restrictions after the age of 4-6 months are not scientifically documented (9).

Questions

1. Which one is likely to be a food allergic reaction in a teenager?
    a. Recurrent dizziness after eating Chinese foods.
    b. Recurrent tingling sensation in the mouth after eating a piece of apple.
    c. Recurrent palpitations after drinking a cup of coffee.
    d. Recurrent diarrhea after drinking a glass of milk.
    e. Recurrent facial redness (flushing) after drinking a glass of wine.

2. Which one of the following is an IgE mediated food allergy?
    a. Oral allergy syndrome
    b. Eosinophilic gastroenteropathies
    c. Dietary protein enterocolitis
    d. Celiac disease
    e. Dermatitis herpetiformis

3. Which one is the common natural course of cow's milk allergy in children?
    a. spontaneously resolves by age 4.
    b. spontaneously resolves by age 10.
    c. persists without changing severity.
    d. increases severity through their lives.
    e. is an unpredictable pattern.

4. Which one is the least common food allergy in children?
    a. Egg
    b. Peanut
    c. Soy
    d. Wheat
    e. Shrimp

5. Which food/fruit potentially causes an allergic reaction in a latex allergy individual?
    a. Banana
    b. Kiwi
    c. Tomato
    d. Potato
    e. All of the above

6. Which of the following are considered safe for patients with peanut allergy?
    a. Chinese and Southeast Asian foods
    b. Ice cream
    c. Dry pet food
    d. Chili
    e. Pastry
    f. None of the above

7. Which of the following are considered safe for patients with milk protein allergy?
   a. Lactose
   b. Non-dairy creamer
   c. Canned tuna
   d. Soy infant formula
   e. Hot dogs
   f. Casein

Answers to questions

1.b. Tingling in the mouth after eating fruits suggests the possibility of an oral allergy syndrome. Dizziness after eating Chinese food is more likely due to an adverse non-allergic reaction to MSG. Facial redness after drinking a glass a wine may be due to tyramine.

2.a

3.a

4.e

5.e

6.f. Chinese and southeast Asian foods are frequently cooked with peanut oil. None of the above are safe. Ice cream is potentially contaminated by nuts since nuts are frequently served with ice cream or mixed with ice cream. Dry pet food and chili frequently contain peanuts. Pastry may contain peanuts even if they are called other types of nuts such as almonds.

7.a. Lactose is merely a disaccharide. Lactose by itself is not part of milk protein. However, if the source of lactose is a dairy product, then this dairy produce should be avoided. All of the other products including "non-dairy" creamers and canned tuna may contain milk or milk products.

Chapter V.4. Corticosteroids
M. Scott Hickman, MD

This is a 15 year old male with a PMH of steroid-dependent asthma who presents with a chief complaint of "always feeling tired and weak". Since the age of 7 he has taken inhaled bronchodilators, and for the last 4 years has used high doses of inhaled steroids. During the last 10 months, he required hospitalized twice for status asthmaticus, during which he was given IV and oral corticosteroid bursts. In addition, he has been taking daily oral steroids for the last 5 months. Review of symptoms is significant for a weight gain of 15 kg in the last 3 months, an increased incidence of recent "colds", and the observation by his mother that he seems not to be growing as quickly as his siblings did at this age. His mother also wants to know why, if her son is getting "steroids", he looks as he does rather than "all the athletes on TV who are using steroids".

Exam: VS T 37.3, P 88, RR 14, BP 145/98. Height is at the 10% percentile, and weight in the 50% percentile. He appears tired but in NAD. His visual fields are full. He has severe acne, truncal obesity and a "moon facies". His extremities show several small bruises, muscle wasting with 4/5 weakness, but no areas of hyperpigmentation were seen. There are two areas of poorly healing wounds on his left arm from a fall 3 weeks ago.

Labs: CBC of 14,000 with 1% eosinophils, 2% monocytes, 68% neutrophils, and 29% lymphocytes. Sodium 149, potassium 3.3, chloride 96, bicarbonate 28.5, glucose 110. Cortisol levels were slightly elevated with no diurnal variation.

Given the patient's history, the diagnosis of iatrogenic Cushing's syndrome is made. The patient is weaned off corticosteroid treatment over a period of 5 weeks. His Cushingoid features resolve and his height approaches the 40th percentile. An ophthalmology referral for a subsequent decrease in his vision identifies posterior subcapsular cataracts from his corticosteroid treatment, which are stable but do not resolve.

Corticosteroids are four-ringed steroid hormones produced by the adrenal cortex, with their common biochemical precursor being cholesterol. The corticosteroids are comprised of two major physiological groups: the glucocorticoids and the mineralocorticoids. However, the term "corticosteroids" is generally used to refer to glucocorticoids.

Mineralocorticoids, mainly aldosterone, influence electrolyte balance, and by consequence, intravascular volume and blood pressure. Glucocorticoids are named for their effect on carbohydrate metabolism, but they also have many other effects. One of their most important uses clinically is their complex effect on the immune system. Cortisol is the main physiologic glucocorticoid. Cortisol is called hydrocortisone when it is used pharmacologically. Androgens of the adrenal cortex affect the growth spurt seen in childhood and are responsible for secondary sexual characteristics. It is important to remember that these compounds are chemically similar, and there are clinically important areas of overlap seen in the effects of corticosteroids among these three groups; i.e., some glucocorticoids will have some mineralocorticoid effects, and vice versa.

The adrenal cortex has three layers (GFR): zona glomerulosa, zona fasciculata, zona reticularis, which are responsible for mineralocorticoids, cortisol, and androgenic steroids (salt, sugar, sex), respectively. Cortisol is also produced to some degree in the zona reticularis. Adrenal function is covered in the chapter on adrenal disorders. This chapter will focus on glucocorticoid corticosteroids.

Once corticosteroids are released from the adrenal cortex or absorbed in the body, 90% are bound to plasma proteins, the main two being corticosteroid-binding globulin (CBG) and albumin (1). Once the glucocorticoid is freed from its binding in the plasma by albumin or CBG, it crosses into the cytoplasm by simple diffusion to bind to the glucocorticoid receptor. In the cytoplasm, a glucocorticoid receptor is found in its inactive form bound to various heat-shock proteins. The heat-shock proteins dissociate, and the glucocorticoid-receptor dimer enters the cell nucleus. Short DNA sequences, called glucocorticoid response elements, interact with the glucocorticoid-receptor complex, and this regulates gene transcription by RNA polymerase II and associated transcription factors. The mRNA that is produced is ultimately exported to the cytoplasm for protein production and the final cellular response. Enzyme activity increased by cortisol results in an increase in providing carbon precursors (transaminases, etc.), conversion of pyruvate to glycogen (pyruvate carboxylase, glycogen synthetase, etc.), release of glucose (glucose-6-phosphatase) and disposal of ammonia liberated from urea cycle amino acids (arginine synthetase, argininosuccinase, etc.) (2). This whole process may take several hours for a response to be seen after corticosteroids are given.

In regards to the immune system, cortisol decreases the availability of arachidonic acid, a precursor to many of the inflammatory immune mediators, such as leukotrienes, prostaglandins, and thromboxanes. Cortisol has these effects by inducing the synthesis of a phosphoprotein called lipocortin that inhibits the activity of phospholipase A2. This decreases the synthesis of phosphatidyl choline to arachidonic acid. In addition, cortisol decreases the expression of the gene for cyclooxygenase 2 (which is involved in the production of leukotrienes and thromboxanes) and nitric oxide synthase (that decreases the production of nitric oxide that limits vasodilatation) (2). Corticosteroids are metabolized by the liver and made water soluble so that they may be excreted by the kidneys (1).

The fetal adrenal cortex has two zones, an outer definitive zone that is mainly responsible for glucocorticoid and mineralocorticoid synthesis, and a fetal zone which makes androgenic precursors used by the placenta. At one year of age, the fetal zone has involuted completely, and the definitive zone enlarges. The zona glomerulosa and zona fasciculata are not fully differentiated until age 3, and the zona reticularis may not be fully formed until age 15. At birth, the adrenal glands weigh 8-9 grams, which is twice the size of adult adrenal glands (3). High levels of cortisol may be seen in the first few hours of life, due to the high stress of birth and possibly due to increased levels crossing the placenta. Cortisol changes the fetal digestive pattern to the digestive enzyme capacity of an adult, allowing the newborn to use disaccharides present in milk (2). Cortisol prepares the fetal lung for breathing air by accelerating the rate of alveolar development and thinning of lung septa, and increasing pulmonary surfactant production by increasing the activity of phosphatidyl acid phosphatase and choline phosphotransferase. Betamethasone (a corticosteroid) is given clinically to mothers in premature labor to accelerate fetal lung maturation to reduce the severity of neonatal respiratory distress syndrome. Case reports of newborns with cleft palate, neonatal cataracts, growth retardation, and adrenal suppression have been reported in maternal corticosteroid use (4).

The use of inhaled corticosteroids at recommended doses in childhood does not have a substantial measurable effect on bone mineral density, ocular toxicity, or suppression of the HPA (hypothalamic pituitary adrenal) axis in childhood (5). Studies of inhaled corticosteroids on vertical growth have produced conflicting results. Its effects from childhood to adulthood are not known with certainty (4).

The various steroid compounds have differences in their glucocorticoid and mineralocorticoid activity which are related to their chemical structures, altering their affinities for the mineralocorticoids and glucocorticoids receptors. These structural changes also affect metabolism of the hormones by the liver, fat, or other tissues, its solubility and binding to plasma proteins, its ability to be absorbed, and

its excretion. Clinically, these affect the potency and duration of the corticosteroid. For example, if a double bond is placed in the 1,2 position of ring A, then a four-fold increase in glucocorticoid activity is seen with slower metabolism (longer duration) compared to hydrocortisone. This is the case with prednisolone and prednisone. Another example is fluorination at the 9-alpha position on ring B. This increases activity with the glucocorticoid receptor 10-fold, but also increases the mineralocorticoid activity by 125-fold, allowing these to be used as mineralocorticoids at small doses but with little to no glucocorticoid activity at the small doses used. If substitutions are made at C16 on ring D with the 9-alpha fluoro derivatives, then these compounds have marked glucocorticoid activity and virtually no mineralocorticoid activity (triamcinolone, dexamethasone, betamethasone) (1). Cortisone and prednisone are synthetic corticosteroids that require enzymatic reduction by the liver before becoming biologically active. In cases of severe hepatic failure, hydrocortisone and prednisolone should be used, since they do not require this enzymatic activation.

Hydrocortisone, and its synthetic analogs, are effective when given by mouth. Esters of hydrocortisone are more water-soluble and can be given intravenously for quicker and higher concentrations in the body. Glucocorticoids applied topically over the skin can be absorbed systemically with effects on the HPA axis if administration is prolonged or when high potency corticosteroids are used topically over large areas of skin.

Besides being classified by their mineralocorticoid and glucocorticoid relative potencies, corticosteroids can be classified by their duration of action. Short-acting glucocorticoids include cortisol (hydrocortisone) and cortisone. Intermediate-duration glucocorticoids include prednisone, prednisolone, triamcinolone, and methylprednisolone. Long-acting glucocorticoids include dexamethasone and betamethasone. The latter have very high glucocorticoid potencies and very little mineralocorticoid activity.

The table below summarizes glucocorticoid potency and duration. Substitutions and dose equivalencies can be made based on these values.

Glucocorticoid potency equivalence (7):

	Glucocorticoid equivalent dose (mg)	Glucocorticoid potency	Mineralocorticoid potency	Plasma half-life (minutes)
Short-acting, low potency				
Cortisol	20	1	2	90
Cortisone	25	0.8	2	80-118
Intermediate-potency				
Prednisone	5	4	1	60
Prednisolone	5	4	1	115-200
Triamcinolone	4	5	0	30
Methylprednisolone	4	5	0	180
Long-acting, high potency				
Dexamethasone	0.5	25-50	0	200
Betamethasone	0.6	25-50	0	300

When used pharmacologically (i.e., higher than physiologic levels), glucocorticoids have profound effects on inflammation and the immune response of lymphocytes. These two processes are linked because both involve leukocyte function. Glucocorticoids, as mentioned above, inhibit phospholipase and cyclooxygenase, limiting the release and production of prostaglandins, thromboxanes, and leukotrienes by mast cells, basophils, and eosinophils. By inhibiting leukotrienes, neutrophil phagocytosis and bacterial function are decreased. Glucocorticoids decrease extravasation of leukocytes and also diminish the secretion of lipolytic and proteolytic enzymes, so that fibrosis is reduced (1). In this way, glucocorticoids can be clinically used to modify (suppress) the inflammatory response. These therapeutic effects have a physiologic basis. Many immune mediators, such as IL-1, IL-6 and TNF-alpha, stimulate the HPA axis during times of stress, increasing glucocorticoids and thus causing a decrease in the immune response.

Glucocorticoids are used in physiologic doses to treat adrenal insufficiency and in pharmacological doses to treat inflammatory and autoimmune conditions. Given that cortisol levels can rise 10-fold in times of stress, high-dose corticosteroids may have a beneficial physiologic effect on the immune system. If the many immune mediators are unopposed by corticosteroids in times of stress, decreased vascular tone and cardiovascular collapse can occur. This important physiologic immune-modulating effect protects the body from an unchecked and full-blown inflammatory response that can have life-threatening consequences (1). Continued use of pharmacological doses can have other adverse effects, such as increasing susceptibility to various bacterial, viral, and fungal infections, permitting their dissemination. Corticosteroid use is contraindicated in patients with tuberculosis, and they must be used with extreme caution with ophthalmic herpes simplex infections. Hypertension, electrolyte and fluid abnormalities, osteoporosis, fat redistribution, acne, hirsutism, and myopathy (among others) can all develop with pharmacologic does of corticosteroids, especially when used over a long period.

Giving a patient glucocorticoids, also affects the amount of different immune cells found in the peripheral blood. The leukocyte count shows a polymorphonuclear leukocytosis (increased WBC count due to increased neutrophils which can be greater than 11,000) with lymphopenia (B and T cells), basopenia, a decreased monocyte count, and eosinopenia in four to six hours after a single dose of hydrocortisone. Neutrophils are increased due to demargination from vascular walls and increased release from the bone marrow. Lymphocytes, basophils, monocytes, and eosinophils are redistributed away from the periphery (1). Glucocorticoids can be used to treat various lymphoid malignancies, either due to being directly toxic to these cells or by inducing apoptosis (programmed cell death).

The acquired or adaptive immune system involves two main parts, cellular immunity and humoral immunity. Cellular immunity is manifested by cytotoxic T cells and natural killer cells involved in protection against intracellular bacteria, protozoa, fungi, and certain viruses. Humoral immunity provides protection against parasites, extracellular bacteria, soluble toxins and allergens, and certain viruses. It involves the production of antibody by B cells. These two systems are controlled by different types of helper T cells. Th1 cells, upon stimulation by IL-12, IFN-delta (among others) from antigen presenting cells (APC), causes a cellular immune response. Th2 cells, upon stimulation by IL4, cause a humoral response. These two systems are related, and an increase in IL-12, will inhibit IL-4 production, shifting the immune response to a mainly Th1, and thus a cellular immune response. Physiologic levels of glucocorticoids cause an

increase in humoral immunity, and a decrease in cellular immunity. This effect is mainly due to a glucocorticoid-induced inhibition of IL-12 secretion by APC and IL-12 responsiveness in Th1 cells. This inhibition of IL-12 frees IL-4 to have a more unopposed effect, triggering an enhanced humoral response (6).

Clinically, this decrease in cellular immunity has many important effects. Stress, and the subsequent physiologic increase in glucocorticoids and the Th2 shift, alters an individual's response to infection and autoimmune diseases. Cellular immunity is important in mycobacterial infections and HIV, correlating with the observation that these two diseases may be accelerated with stress and an increase in cortisol. Autoimmune diseases, although extremely complex in their pathophysiological mechanisms, can be thought of as involving mainly Th1 and Th2 mechanisms. Rheumatoid arthritis, multiple sclerosis, type I diabetes, and Crohn's disease are thought to be due to a hyperresponsive Th1 response, with excess IL-12 and TNF-alpha production. Women in their third trimester of pregnancy have increased levels of cortisol, which favors a Th2 response, and a expected remission of these diseases are seen during this time of pregnancy. In addition, decreased stress in the postpartum period or the stopping of glucocorticoid therapy can cause a worsening of these conditions. Th2 driven diseases, such as systemic lupus erythematous, can become worse during stress and pregnancy, when cortisol causes an increased Th2 response (6).

Glucocorticoids induce gluconeogenesis and they have catabolic effects on the periphery which supplies the liver with the amino acids and glycerol needed for gluconeogenesis. Glucocorticoids also decrease glucose uptake in adipose tissue, most likely by moving glucose transporters from the plasma membrane to an intracellular location. This can be thought of as protecting glucose-dependent tissues such as the brain and the heart from starvation during stress. Thus, under prolonged high levels of glucocorticoids, lymphoid tissue, muscle, fat, bone, and skin undergo wasting. This can lead to Cushing's syndrome, with a redistribution of fat from the periphery to the back of the neck (buffalo hump), face (moon facies), and supraclavicular area with less fat in the periphery. One hypothesis to this redistribution is that adipose cells in the neck, face, and supraclavicular area are sensitive to insulin, so the glucocorticoid induced hypoglycemia leads to increased fat deposition in these areas. The peripheral tissues are less sensitive to insulin and respond mainly to the glucocorticoid-induced lipolysis.

Corticosteroids are required for permissive contraction of skeletal muscle. Patients with Addison's disease frequently have fatigue and weakness as symptoms, which may be partly due to vascular insufficiency. Chronic use of corticosteroids can cause skeletal muscle wasting, called steroid myopathy.

Corticosteroids can have direct effects on a patient's mood and behavior. Patient's with Addison's disease can show psychosis, apathy, depression, and irritability. Glucocorticoid administration can have a stimulatory affect, with mood elation, euphoria, insomnia, restlessness, and increased motor activity. These effects are thought to be due to corticosteroid’s involvement in the regulation of neuronal activity (neurosteroids).

The most dangerous and life threatening complication of stopping corticosteroid therapy is acute adrenal insufficiency due to the HPA axis being suppressed by exogenous corticosteroids, disabling its ability to endogenously produce corticosteroids in sufficient quantities. By withdrawing corticosteroids, the so-called corticosteroid withdrawal syndrome can lead to cardiovascular collapse due to the loss of cardiovascular tone, with hypotension, shock, and death. Other symptoms of this syndrome include malaise, anorexia, headache, lethargy, nausea, and fever. Hypoglycemia and hyponatremia may be present. This should be considered in patients who have been given supraphysiologic (i.e., pharmacologic) doses of corticosteroids (e.g., a course of prednisone) in the previous year. Patients taking glucocorticoid therapy for 7-10 days can safely be discontinued abruptly. Those on longer therapy need to be tapered, with a 25% reduction in the previous weekly level usually recommended, although patients need to be followed clinically for signs of withdrawal (3). Once a physiological dose is achieved (8-10 mg per square meter body surface area per day) and the patient is stable, the dosage can be decreased to 4-5 mg per square meter per day for 4-6 weeks to allow the adrenal axis to recover. Most patients recover their HPA axis within several weeks, although there is wide variation and some may take a year or longer to recover fully, especially in the physiological response of the HPA to stress. Stress doses of glucocorticoids, usually 3-10 times the physiological replacement, are recommended if a physiologically stressful event (such as surgery) is encountered, for patients receiving chronic or long-term glucocorticoid therapy or for those who have been recently withdrawn from corticosteroids. A further problem of withdrawal can be a flare-up of the disease for which the corticosteroids were originally given.

Other complications or corticosteroids include Cushing's syndrome, growth retardation, the development of posterior subcapsular cataract formation, and advanced bone necrosis. Complications are unlikely if given for less than 2 weeks with moderate doses. Most side-effects of corticosteroids resolve with the exception of the formation of cataracts, which are permanent.

Questions

1. Which of the following is not a corticosteroid:
    a. cortisol
    b. aldosterone
    c. adrenal androgens
    d. norepinephrine

2. Glucocorticoids that are intermediate-potency include
    a. prednisone
    b. prednisolone
    c. triamcinolone
    d. dexamethasone
    e. a, b, and c

3. Immune system cells that are increased in the peripheral circulation after corticosteroid administration are
    a. neutrophils
    b. eosinophils
    c. lymphocytes
    d. monocytes

4. Safely tapering steroids in patient taking oral steroids for more than 10 days involves
   a. stopping steroid administration all at once
   b. changing a long-acting glucocorticoid to a short-acting glucocorticoid
   c. reducing previous weekly levels 10% with no clinical follow-up needed
   d. reducing previous weekly levels 25% with clinical follow-up

5. Glucocorticoids induce a Th2 shift by
   a. decreasing IL-12 production by antigen presenting cells, which allows an increase in IL-4 effects and thus more humoral immunity
   b. increasing IL-12 production by antigen presenting cells, which allows for a decrease in IL-4 and thus more humoral immunity
   c. glucocorticoids induce a Th1 shift
   d. none of the above

6. Glucocorticoids do NOT reduce inflammation by
   a. inhibiting phospholipase and production of arachidonic acid
   b. inhibiting cyclooxygenase and production of prostaglandins and thromboxanes from arachidonic acid
   c. decreasing the levels of neutrophils in the peripheral blood
   d. inhibiting leukotriene action and thus neutrophil function
   e. decreasing production of nitric oxide by inhibiting nitric oxide synthase

7. A physician orders 40 mg of IV methylprednisolone for a 20 kg patient (2 mg/kg) with status asthmaticus. The hospital pharmacy notifies the physician that IV methylprednisolone is not currently available and is on back order. Utilizing corticosteroid potencies, which of the following are approximate glucocorticoid equivalents?
   a. Dexamethasone 4 mg (0.2 mg/kg)
   b. Hydrocortisone 200 mg (10 mg/kg)
   c. Prednisone 40 mg (2 mg/kg)
   d. Dexamethasone 400 mg (20 mg/kg)

8. Explain how corticosteroids could be beneficial in croup and status asthmaticus due to a viral pneumonia. In both instances, a viral infection is causing the problem. Since corticosteroids are potentially immunosuppressive agents, is there a net beneficial or detrimental effect?

Answers to questions

1.d. Norepinephrine is a hormone of the adrenal medulla, not the adrenal cortex. Corticosteroids are by definition hormones of the adrenal cortex.

2.d. Dexamethasone is a high-potency, long-acting glucocorticoid. Prednisone, prednisolone, and triamcinolone are intermediate-potency glucocorticoids.

3.a. Eosinophils, lymphocytes, and monocytes are reduced in the peripheral circulation after corticosteroid administration. Although neutrophil numbers are increased, their bactericidal activity is decreased.

4.d. Safely tapering corticosteroids in a patient who has taken corticosteroids for more than 10 days, involves reducing the previous week's levels by 25%, and the patient should be monitored clinically for signs of corticosteroid withdrawal (malaise, anorexia, headache, lethargy, nausea, fever, loss of cardiovascular tone, with hypotension, shock, and death) and a worsening of the condition that the corticosteroids were originally given for.

5.a. Th1 cells are stimulated by IL-12 from APC to cause a cellular immune response. Th2 cells, upon stimulation by IL4, cause a humoral response. IL-12 will inhibit IL-4 production as well. Glucocorticoids cause a decrease in IL-12 secretion by APC and IL-12 responsiveness in Th1 cells. This inhibition of IL-12 frees IL-4 to have a more unopposed effect, triggering an enhanced humoral response.

6.c. Glucocorticoids inhibit production of arachidonic acid, prostaglandins, thromboxanes, leukotrienes, and nitric oxide, all of which are involved in the inflammatory response. Neutrophils are increased in the peripheral blood, not decreased.

7. a,b,c are correct. 0.2 mg/kg of dexamethasone would probably be the best answer, although its duration is longer than that of methylprednisolone. This should not be a problem for status asthmaticus. 10 mg/kg of hydrocortisone has equivalent glucocorticoid activity, but it has unnecessary mineralocorticoid activity. 2 mg/kg of prednisone is roughly the same as 2 mg/kg of methylprednisolone, but prednisone would have to be given orally since it cannot be given IV. 20 mg/kg of dexamethasone is clearly an overdose, which results from multiplying by 10 instead of dividing by 10. A good clue would be that dexamethasone comes in 10 mg vials. A 400 mg dose

would require 40 vials. This should clearly prompt questioning by pharmacy and nursing staff. Whenever a pediatric dose requires more than one vial, the dose should be questioned.

8. The symptoms of croup and status asthmaticus are largely due to the inflammatory response induced by the viral infection. The virus itself causes less of a problem compared to the body's inflammatory response. Corticosteroids suppress the inflammatory response resulting in less laryngeal and bronchial inflammation. It cannot be assumed that this is true for all viral infections. For example, in viral pharyngitis, the symptoms of a sore throat and nasal congestion may be suppressed with corticosteroids. However, it may cause more harm than good. In the case of croup and status asthmaticus, numerous studies have supported the net benefit of corticosteroids in these two conditions. In bacterial meningitis due to H. flu, a similar benefit has been demonstrated, but for bacterial meningitis due to other organisms and for viral meningitis, the benefit has not been clearly demonstrated.

Chapter V.5. Immune Deficiency
Akaluck Thatayatikom, MD

This is a 14 month old male infant who presents to the emergency department with a chief complaint of high fever and no response to antipyretic therapy. This illness started suddenly with the abrupt onset of fever early yesterday morning. He then developed a severe cough and increased work of breathing. No other symptoms are noted. The patient was born in a refugee camp and has lived in Florida and Texas before moving to Hawaii 3 months ago. The mother reports that he is frequently ill. No reports from Florida or Texas are available, but his mother reports he was also seen as an outpatient frequently and he was hospitalized at least once in Florida. He was hospitalized 2 months ago for pneumococcal pneumonia (right upper lobe consolidation and pneumococcal bacteremia).

Exam: VS T 40.3, P 145, R 55, BP 100/60, oxygen saturation 98%, weight 7 kg (<5th percentile). He is a listless, tired, and small for age. He is lying on the gurney, moving little and whimpering slightly to stimulation with tachypnea and chest retractions. His head is normocephalic, without signs of trauma. Both ear canals contain purulent drainage. Mouth exam is unremarkable. His heart is tachycardic with no murmurs heard. His chest shows mild retractions, tachypnea, dullness to percussion over the posterior upper chest, decreased breath sounds in the area of dullness with occasional fine crackles. His abdomen is scaphoid and soft, with active bowel sounds, no masses, and no hepatosplenomegaly. His extremities are slender and wasted with decreased muscle mass and strength. Neurological exam is normal.

Because of his poor general appearance, he is hospitalized for possible sepsis. He is treated with intravenous antibiotics and he improves slowly over one week. A blood culture is positive for pneumococcus. Because of his recurrent infections and the failure to meet normal growth expectations, an immunologic work up is done. He is found to have markedly elevated IgM, undetectable IgG and IgA with diminished total B lymphocytes (CD19). His clinical picture is consistent with hypogammaglobulinemia with high IgM or Hyper-IgM syndrome. A confirmed diagnosis shows a deficiency of CD40 ligands on T cells. He is placed on monthly IVIG replacement therapy with trimethoprim-sulfamethoxazole prophylaxis for Pneumocystis carinii pneumonia (PCP) and he begins to gain weight and he clears his ear infections.

Recurrent infections in children are one of the common problems encountered by physicians. The majority of these children have normal immune function. However, some patients have immune deficiencies and these patients are frequently not diagnosed. Therefore, physicians should be aware of recurrent infections caused by non-immunologic conditions (Table 1) and clinical clues suggestive of immunologic disorders (Table 2). Immune defects may be either primary (congenital) or secondary to certain diseases or agents (Table 3).

Table 1: Nonimmunologic Causes of Recurrent Infections

Abnormal mucous membranes and integuments: Burns, severe eczema, bullous diseases, ectodermal dysplasia, percutaneous catheters.

Obstruction of hollow viscus: Cystic fibrosis, inhaled foreign body, posterior urethral valves, ureteropelvic junction obstruction.

Foreign body: Ventriculoperitoneal shunt, prosthetic cardiac valves, orthopedic devices, catheters.

Vascular abnormalities: Large left to right intracardiac shunt, diabetes mellitus.

Congenital: Cysts and sinus tracts, tracheoesophageal fistula, abnormal ciliary function.

Neurologic: Incoordinate swallowing, recurrent aspiration, poor respiratory effort.

Metabolic disorders: Galactosemia, certain amino acid and organic acid disorders.

Secondary immunodeficiency: Malignancy, chemotherapy, chronic renal failure, protein losing enteropathy.

Table 2: Conditions suggestive of immune deficiency

>10 episodes acute otitis media per year (infants and children).

>2 episodes consolidated pneumonia per year.

>2 life-threatening infections per lifetime.

Two or more serious sinus infections within 1 year.

Unusual organisms.

Unusual response to organism.

Recurrent deep skin or organ abscesses.

Two or more deep-seated infections such as meningitis, osteomyelitis, cellulites or sepsis.

Persistent oral thrush or candida infection elsewhere on the skin, after age 1 year.

Recurrent autoimmune phenomena.

Dysmorphic features associated with recurrent infection.

Infections worsening chronic disorders (asthma or seizure).

Development of vaccine pathogen after vaccination (e.g., HiB infection despite previous HiB vaccine).

Family history of immunodeficiency or recurrent infection.

Table 3: Classification of Primary and Secondary Immunodeficiency Disorders

Primary Antibody Deficiency Diseases (50%):
- X-linked agammaglobulinemia.
- Hyper-IgM syndrome, autosomal recessive.
- Common variable immunodeficiency (CVID).
- IgA deficiency.
- Selective IgG subclass deficiencies.
- Specific antibody deficiency with normal immunoglobulins (SADNI).
- Transient hypogammaglobulinemia of infancy.

T-cell and Combined Immunodeficiency Diseases (30%):
- Severe combined immunodeficiency (SCID).
- X-linked Hyper-IgM syndrome.
- DiGeorge anomaly.
- Wiskott-Aldrich syndrome (WAS).
- Ataxia-telangiectasia (AT).
- Cartilage-hair hypoplasia.
- Chronic mucocutaneous candidiasis.
- X-linked Lymphoproliferative syndrome.

Phagocytic Disorders (18%) (described further in the chapter on neutrophil disorders):
- Chronic granulomatous disease (CGD).
- Leukocyte adhesion defect (LAD).
- Cyclic neutropenia.
- Chediak-Higashi syndrome.
- Myeloperoxidase deficiency.
- Shwachman syndrome.
- Kostmann's syndrome.

Complement Deficiency (2%):
- C1q, C1r, C2-C7, C8a, C8b, C9, C1 inhibitor.
- Factor I, H, D, Properdin.

Other well defined immunodeficiency:
- Hyper-IgE syndrome.
- Lymphoproliferative syndrome.

Immunodeficiency associated with other congenital conditions:
- Down syndrome
- Shwachman syndrome

Secondary Immunodeficiency:
- Malnutrition.
- Infection (congenital rubella, HIV infection, infectious mononucleosis and other such infections).
- Protein-losing enteropathy.
- Nephrosis.
- Sickle cell disease.
- Infiltrative diseases such as histiocytosis, leukemia.
- Metabolic problems such as diabetes mellitus, uremia, vitamin and mineral deficiency.
- Immunosuppressive medications.
- Splenectomy.
- Disruption of barrier protection (burns, severe eczema, catheters).

Over 70 primary immune deficiency diseases have been recognized. The antibody deficiencies constitute about 50% of all cases of primary immunodeficiencies. T cell deficiencies and combined immunodeficiencies are the second largest group, making up about 30%. Phagocytic defects and complement disorders make up about 18% and 2% of immunodeficiencies. Only the more common primary immune deficiency syndromes will be emphasized in this chapter. HIV infection is covered in a separate chapter.

1. Transient hypogammaglobulinemia in infancy (THI). THI is due to a normal variability of the developing immune system in infants with prolonged periods of physiologic hypogammaglobulinemia. All infants develops physiologic hypogammaglobulinemia at approximately 5-6 months of age. In these age groups, the serum Ig level reaches its lowest point (approximately 350mg/dl), and many normal infants begin to experience recurrent respiratory tract infections. The diagnosis of THI is based on low levels of IgG and normal levels of IgA with variable levels of IgM. The normal levels of IgA exclude other congenital hypogammaglobulinemia. Most children with THI are typically able to synthesize specific antibodies in response to immunizations. However, inadequate specific antibody responses do not exclude the diagnosis of THI, but should prompt further investigation for other forms of immunodeficiency. Most cases of THI will spontaneously resolve by 4 years of age.

2. X-linked agammaglobulinemia (XLA) is characterized by four findings: 1) Onset of recurrent bacterial infections in the first 5 years of life; 2) Serum IgG, IgM and IgA values that are at least 2SD below the normal for age; 3) Absent isohemagglutinins or poor response to vaccines; and 4) Less than 2% CD19+ B cells in the peripheral circulation. It should be noted that the variability of clinical and laboratory findings for XLA is exist. Some XLA cases have been undiagnosed and untreated for more than five decades. 10-20% of XLA have serum IgG values greater than 200mg/dl at the time of diagnosis. The most consistent findings in XLA are the marked reduction in the number of B cells in the peripheral circulation.

The primary defect in XLA is the failure of pre-B cells to differentiate into mature B lymphocytes due to a gene mutation of Bruton's tyrosine kinase (Btk) which plays a multifaceted role in signal transduction for normal B cell development. However, approximately 10% of boys with presumed XLA do not have the mutation in Btk and 10% of patients with the early onset of recurrent

infections, profound hypogammaglobulinemia and absent B cells, are girls. These observations suggest that there are autosomal recessive disorders clinically indistinguishable from XLA.

Intravenous immunoglobulin (IVIG) has been used as a mainstay therapy for XLA and other antibody deficiency disorders or combined immunodeficiency including autosomal recessive agammaglobulinemia, CVID, Hyper-IgM syndrome, SCID, WAS and AT. IVIG therapy may be beneficial for a selective antibody deficiency with IgG1 or IgG2 deficiency and significant recurrent infections. The usual dose of IVIG is 400 mg/kg every 4 weeks and then the dose should be adjusted based on the IgG level after 3-4 infusions (to keep IgG levels above 500mg/dl). Headache, fever, myalgia, chills, rigors, nausea and vomiting are common adverse reactions of IVIG infusion; however, aseptic meningitis has been reported.

3. Common variable immunodeficiency (CVID) is a heterogeneous syndrome, presenting with low IgG levels and no association with drugs or diseases known to cause secondary antibody deficiency. More than 95% of CVID clinically presents with recurrent sinopulmonary infections just like XLA or other hypogammaglobulinemia syndromes. The cause of CVID has not been identified yet. However the intrinsic defects of B cells, diminished T helper cells and dysregulation of cytokines have been described. Most of the patients usually do not become symptomatic until 15-35 years of age. CVID patients have an increased risk of developing autoimmune diseases, lymphatic and gastrointestinal malignancies, malabsorption and granulomatous inflammation.

The diagnosis of CVID is based on low IgG levels and poor specific antibody responses to immunizations without an identified cause of the hypogammaglobulinemia. IgM and IgA levels may present in significant amounts or absent. A patient with borderline immunoglobulin levels needs an evaluation of specific antibody responses with immunizations. T cell and B cell enumeration are usually normal; however, decreasing numbers of the cells have been occasionally seen. Some patients may have abnormal T cell function studies such as absent delayed hypersensitivity or depressed responses of mitogen stimulation. Treatment of CVID is identical to XLA. Frequent use of broad-spectrum antibiotics is required. The delayed diagnosis and treatment leads to chronic lung diseases such as bronchiectasis so periodic screening with chest x-rays, high resolution chest CT and pulmonary function tests are needed.

4. Hyper-IgM syndrome (HIM) is characterized by high levels of IgM with deficiency of IgG, IgA and poor specific antibody responses to immunizations. X-linked hyper-IgM syndrome is the commonest type which has a defect of the CD40 ligand (CD40L or CD154) gene of T cells. The interaction between CD40 on the B cells and CD40L on T cells is essential for the immunoglobulin class switching from IgM to IgG production, which explains why a deficiency in CD40L leads to hyper-IgM production with deficiency of IgG and IgA. HIM presents with recurrent sinopulmonary infections and Pneumocystis carinii pneumonia (PCP). There are associated abnormalities including neutropenia, hemolytic anemia and aplastic anemia. The unique susceptibility to opportunistic infections and neutropenia with high IgM levels distinguishes HIM from XLA or other hypogammaglobulinemias. Treatment of HIM is based on regular administration of IVIG and use of trimethoprim-sulfamethoxazole to prevent PCP. IVIG not only reduces the severity and frequency of infections, but also diminishes IgM levels and neutropenia. G-CSF (granulocyte colony stimulating factor) may be given for severe neutropenia. Recently stem cell transplantation has been performed successfully. The long term prognosis of HIM appears to be worse than in other forms of congenital hypogammaglobulinemia. Pneumocystis carinii infection has an important impact on morbidity and mortality during the first years of life, whereas liver disease mainly contributes to late mortality.

5. Selective IgA deficiency is the most common primary immunodeficiency disorder with the prevalence between 1 in 400 to 1 in 800. Although many patients are asymptomatic, IgA deficiency predisposes to respiratory, GI and urogenital tract infections, autoimmune diseases, sprue-like syndrome, malignancy, allergy and anaphylaxis reactions to blood products. Moreover, the progression of selective IgA deficiency to CVID or IgG2 subclass deficiency has been reported. The cause of the disease has not been known. Some infectious agents and drugs such as congenital rubella, EBV infection or phenytoin, may cause low IgA levels. The physiologic lag in serum IgA may delay the diagnosis until after the age of 2. The diagnosis can be made if a patient presents with IgA levels less than 7 mg/dL with no other evidence of any immune defects. Unlike XLA, HIM or CVID, selective IgA deficiency has a normal IgM and IgG response to pathogens and vaccines, therefore the routine schedule of immunization is suggested. IVIG replacement is not indicated. Aggressive treatment with broad spectrum antibiotics is recommended for recurrent sinopulmonary infections to avoid permanent pulmonary complications. Some selective IgA deficiency patients may develop antibody to IgA, in which case, there is a risk of anaphylaxis with blood product transfusions.

6. Selective IgG subclass deficiencies are generally defined as a serum IgG subclass concentration that is at least 2 standard deviations below the normal for age. There are four subclasses of human IgG, designated IgG1, IgG2, IgG3 and IgG4. Approximately 67% of serum IgG is IgG1, 20-25% is IgG2, 5-10% is IgG3 and 5% is IgG4. The concentrations of IgG subclasses are physiologically varied with age; IgG1 reaches adult levels by 1 to 4 years of age, whereas IgG2 level normally begins to rise later in childhood compared to other subclasses. The subclass deficiency has been reported in patients with recurrent infections, despite normal total IgG serum or with an associated deficiency of IgA and IgM deficiency.

The diagnosis and its implication have long been problematic since there are insufficient normative data for very young children and major technical problems of measurement of IgG subclass. Additionally, normal healthy children with low IgG2 subclass levels and normal responses to polysaccharide antigens as well as completely asymptomatic individuals with lacking IgG1, IgG2, IgG4 have been reported. A low value of IgG2 in a child may be a temporary finding which normalizes in adulthood. Approximately 10% of males and 1% of females have IgG4 deficiency without significant infections. IgG3 levels may be low with an active infection because it has the shortest half life and the greatest susceptibility to proteolytic degradation. Therefore, IgG subclass measurements are not routinely recommended and treatment with IVIG should be reserved for the patients who have been clearly demonstrated to have impaired responses to both protein and polysaccharide antigens to which they have been immunized.

7. Severe combined immune deficiency (SCID) is a life-threatening syndrome of recurrent infections, oral candidiasis, persistent diarrhea, dermatitis, graft versus host disease after blood transfusion and failure to thrive caused by a number of molecular defects that lead to severe compromise in T cell function with or without B cell dysfunctions. The defects in SCID block the differentiation and proliferation of T cells and in some types, of B cells and natural killer (NK) cells. Immunoglobulin and antibody production are severely impaired even when mature B cells are present. NK cells, a component of innate immunity, are variably affected. The majority of the patients present by age 3 months with unusually severe and frequent common infections such as bacterial otitis media and pneumonia or opportunistic infections including Pneumocystis carinii, and cryptosporidiosis. Viral infections such as herpes simplex, RSV, rotavirus, adenovirus, enterovirus, EBV, CMV are also commonly seen.

The most common defect of SCID is X-linked SCID (XL-SCID), accounting for 50-60% of cases. Adenosine deaminase (ADA) deficiency, accounting for 15% of SCID, is the second common defect. Other defects are purine nucleoside phosphorylase (PNP) deficiencies, IL-7 receptor alpha chain deficiency, recombination activation gene-1 and gene-2 (RAG1, RAG2) deficiency, CD45 deficiency, CD3 deficiency, MHC class I and II deficiency.

SCID is typically diagnosed by clinical features: absence of lymph nodes and tonsils, lymphopenia, absence of a thymic shadow on chest x-ray, abnormal T, B, NK cell enumeration with flow cytometric analysis, abnormal in vivo T cell function studies with skin tests of delayed skin hypersensitivity to tetanus, candida, diphtheria and in vitro lymphocyte function studies by measuring response to phytohemagglutinin (PHA), concanavalin A, pokeweed mitogen, phorbol myristate acetate (PMA) and ionomycin, tetanus and candida.

Skin testing for delayed hypersensitivity (which tests type IV cellular immunity function) is a basic way of testing T cell function. Antigens such as tetanus, candida, trichophyton, and mumps are frequently used because nearly everyone should be positive to all of these; however, occasionally normal young children may have a negative response. A positive response to these intradermal antigens indicates intact T cell function. If no response results from all these antigens, the patient may be "anergic". Thus, this panel of antigens is known as an "anergy panel".

Bone marrow or other stem cell reconstitution is a first-line, specific therapy for almost all forms of SCID. ADA deficiency has specific therapy as an alternative to the transplantation. Polyethylene glycol-treated (PEG) ADA replacement may be administered with improvement but not complete reconstitution of immune function. Currently gene therapy is successful for XL-SCID. Prophylactic antibiotics, IVIG replacement, meticulous skin and mucosal hygienic care, avoidance of exposure to infectious agents, and irradiation of all blood products prior to transfusion are recommended while awaiting stem cell reconstitution. Many patients with SCID are fully reconstituted without complications with bone marrow and other stem cell reconstitution techniques. Patients who are well nourished, uninfected and younger than 6 months prior to transplantation have the best outcomes. Without stem cell reconstitution, it is rare for a patient with SCID to survive.

8. Complement deficiency: Complement proteins are a key component of the innate immune system due to their function of direct lysis of their targets and being an opsonin. Most of the complement deficiency diseases are inherited in an autosomal recessive mode except C1 inhibitor deficiency (autosomal dominant) and properdin deficiency (X-linked). C2 deficiency is the most common defect; however, 50% of individuals with C2 deficiency are asymptomatic. Patients with C1, C4, C2 and C3 deficiencies have a higher incidence of autoimmune diseases such as SLE and encapsulated bacteria infections. Patients with absent factor H and factor I will have excessive consumption of C3; therefore, those patients will have similar infections as those with C3 deficiency states. The most commonly performed test for evaluation of functional complement activity is the CH50 test. APH50 is a useful screening test for the alternative pathway. There is no specific treatment for complement deficiency, except a purified C1 inhibitor preparation for hereditary angioedema due to C1 inhibitor deficiency.

9. WAS is an X-linked recessive disease, caused by a defective gene encoding Wiskott-Aldrich syndrome protein (WASP), which is expressed only in lymphocytes and megakaryocytes. This protein is involved in the reorganization of the actin cytoskeleton in the cells. WAS has a classic presentation with eczema, microcytic thrombocytopenia and recurrent encapsulated infection in a young boy. The initial manifestations often present at birth and consist of petechiae, bruises, bleeding from circumcision or bloody stools. The diagnosis can be made based on the manifestations and immunologic findings including low IgM, high IgA and IgE, poor antibody responses to polysaccharide antigens, moderately reduced number of T cells and variable depression of in vitro T cell function studies. Treatment includes IVIG infusion, irradiated fresh platelet transfusions and splenectomy for bleeding tendency, prophylactic antibiotics after splenectomy, and bone marrow transplantation.

10. Ataxia-Telangiectasia (AT) is an autosomal recessive disorder characterized by sinopulmonary infections, telangiectasia, progressive ataxia and hypersensitivity to ionizing radiation. Immunologic studies reveal combine immunodeficiency consisting of selective IgA and IgG2 deficiency, cutaneous anergy and depression of in vitro T cell function study. Supportive treatment is recommended. Other treatments which may be considered include IVIG and bone marrow transplantation.

11. Hyper-IgE syndrome is characterized by chronic pruritic dermatitis, recurrent staphylococcal infections (skin and respiratory tract), markedly elevated serum IgE, eosinophilia and coarse facial features. The diagnosis may be difficult since there is no clear definition of high IgE levels and IgE levels may fluctuate from time to time. In addition, a high IgE level with eosinophilia is commonly seen in severe atopic dermatitis. Therefore, recurrent staphylococcal infections involving the skin, lungs and joints with other features including a distinctive facial appearance, dental abnormalities and bone fractures are essential for the diagnosis. Treatment with good skin care and continuous antimicrobial therapy such as trimethoprim-sulfamethoxazole are necessary. No specific immunotherapeutic regimen has been successful. The role of IVIG therapy remains to be determined.

12. Chronic granulomatous disease (CGD) is a defect of phagocytic cells with dysfunction of the NADPH oxidase enzyme complex required for the production of reactive oxygen intermediates to destroy microbes. The defect leads to recurrent and uncontrolled catalase-positive organisms including S. aureus, E. coli, Serratia marcescens, Salmonella, Klebsiella spp, Clostridium difficile, Legionella bosmanii, Pseudomonas cepacia, Mycobacterium fortuitum, Chromobacterium, Aspergillus spp, Nocardia spp and Actinomyces spp. The most common infections are lymphadenitis, abscesses of the skin, and of the viscera such as liver. Granuloma formation occurs in CGD because the defect of the intracellular microcidal mechanism causes persistent antigen presentation and induces a sustained cell-mediated response by CD4 T cells, which recruit other inflammatory cells and set up a chronic local inflammation called a granuloma. The diagnosis of CGD can be ascertained by taking advantage of the metabolic defect in the phagocytic cells. A dye called nitro blue tetrazolium (NBT) is pale yellow and transparent. When it is reduced, it becomes insoluble and turns a deep purple color. In normal blood, the NBT is reduced to a dark purple or blue, easily seen in the phagocytic cells. In CGD blood, no dark purple or blue color is seen. Treatment includes short-term treatment of the infections, prophylactic trimethoprim-sulfa, recombinant human interferon-G (enhancing the production of reactive oxygen intermediates) and bone marrow transplantation. This condition is described in further detail in the chapter on neutrophil disorders.

13. Leukocyte adhesion molecule defect (LAD) syndromes are failures of innate host defenses against bacteria, fungi, and other microorganisms resulting from defective tethering, adhesion, and targeting of myeloid leukocytes (PMN, monocytes) to sites of microbial invasion. Killing of microbes is intact, but since the cells can not be mobilized to the point of inflammation and complement-mediated phagocytosis is impaired, the result is a lack of an inflammatory response. The hallmark of the disease is neutrophilia without PMNs in the infected tissue or pus. Histories of delayed separation of the umbilical cord, recurrent bacterial infections, necrotic skin lesions, severe gingivitis, periodontitis, and alveolar bone loss leading to early loss of deciduous and permanent teeth suggest the diagnosis. A definitive diagnosis with flow cytometric analysis reveals a decreased or absence of CD18 and its associated heterodimers: CD11a,CD11b and CD11c in LAD type I and absence of CD15s in LAD type II. Treatment includes continuous antimicrobial therapy, good oral hygiene, white blood cell transfusions and bone marrow transplantation.

Clinical Approach to Suspected Immunodeficiency

The history should include the onset and type of the infections, the frequency, chronicity, severity and the responses to the previous treatments. The associated conditions such as failure to thrive, autoimmune disease, congenital anomalies and family history of consanguinity, fetal wastage and early childhood deaths should be noted. Types of infections and presentations are helpful for differentiation of primary immune defects (Table IV).

Table IV: Typical Clinical Findings in Each Group of Primary Immunodeficiency

Antibody Deficiency Diseases:

Presentation after passively acquired maternal antibody wanes (6 months old).
Infection with encapsulated bacteria such as Haemophilus influenzae type B, pneumococcus, etc.
Recurrent sinopulmonary infection, otitis media.
Possible poor growth or failure to thrive.

T-Cell and Combined Immunodeficiency:

Presentation in early infancy.
Poor growth or failure to thrive.
Persistent oral thrush.
Opportunistic infection.

Phagocytic Defects:

Presentation in infancy or childhood.
Poor wound healing, delayed umbilical cord separation..
Gingivitis, abscesses, skin infection, including cellulitis and furunculosis.

Complement Defects:

Early complement deficiency: Sinopulmonary infection, autoimmune disease.
Late complement component deficiency: Recurrent infection caused by Neisseria species, including meningococcal and gonococcal infection

Most immunodeficiencies present during infancy or early childhood with the most notable exceptions being common variable hypogammaglobulinemia (CVID), selective IgA deficiency, cyclic neutropenia, and complement deficiencies and some of the secondary immunodeficiencies, which may present later in life. Patients with severe combined immunodeficiency (SCID) suffer major infections very early in life, usually during the first weeks or months of age. Congenital agammaglobulinemia typically presents during the second 6 months of life when maternally transferred antibodies wane. Other immunodeficiencies that present clinically before 5 years of age include Wiskott-Aldrich syndrome (WAS), leukocyte adhesion defects (LAD), chronic granulomatous disease (CGD), hyperimmunoglobulin (Ig)M syndrome, ataxia-telangiectasia (AT), and complement deficiencies.

Certain physical findings alert one to the possibility of primary immune deficiency. Failure to thrive secondary to recurrent infections is commonly seen in some antibody deficiencies and combined T and B cell deficiencies. Persistent sinopulmonary infections, especially ear drainage, pneumonia or bronchiectasis, are seen in antibody deficiencies, T and B cell deficiencies and complement deficiencies. Absence or scanty lymphoid tissue such as tonsils and lymph node suggests X-linked agammaglobulinemia (XLA), SCID or complete DiGeorge anomaly. Chronic eczematous rash are found in hyper-IgE syndrome and WAS. Recurrent skin infection with oral ulcers, periodontitis or gingivostomatitis are associated with phagocytic cell defects such as CGD and LAD. Failure or delayed umbilical cord separation is a clinical clue of LAD. Recurrent mucosal candidiasis suggests T cell deficiencies such as SCID and AIDS. Adenopathy and hepatosplenomegaly is frequently encountered in HIV infection.

Several congenital and hereditary conditions with musculoskeletal abnormalities are associated with immunodeficiency. These include Bloom syndrome, Fanconi anemia, trisomy 21, Turner syndrome, short-limbed skeletal dysplasia, cartilage-hair hypoplasia, Shwachman syndrome and ectodermal dysplasia. Classical findings of some specific syndromes should be carefully noted including DiGeorge syndrome (micrognathia, hypertelorism, low-set ears, shortened upper lip philtrum, mandibular hypoplasia, a bifid uvula, an antimongolian slant of the eyes, notched ear pinnae, high arched palate, fish-shaped mouth and congenital heart disease), AT (telangiectasis on bulbar conjunctiva, skin, the bridge of the nose, the ears and antecubital fossa), and Chediak-Higashi syndrome (partial albinism, photophobia).

The proper choice of laboratory tests is based on a careful history and physical examination which target specific suspected immunodeficiency possibilities. A complete blood count is an initial screening test. The number of neutrophils, lymphocytes, abnormalities of white blood cells or red blood cell morphology, numbers and morphology of platelets should be noted. Abnormal CBC findings may point out to a specific disease such as: 1) Lymphopenia (less than 2,000) in XLA, SCID, WAS, AT, DiGeorge, malnutrition and AIDS. 2) Neutropenia in hyper IgM syndrome, cyclic neutropenia, drug-induced neutropenia, Shwachman syndrome and autoimmune-mediated neutropenia. 3) Eosinophilia in WAS, and hyper-IgE syndrome. 4) PMN cells with large cytoplasmic granules in Chediak-Higashi syndrome. 5) Thrombocytopenia in WAS. 6) Howell-Jolly bodies in asplenia. 7) Leukocytosis with few neutrophils in the inflammatory lesions of LAD.

Certain culture results may point out a specific immune defect such as: 1) Encapsulated bacteria in antibody, T cell and complement deficiencies. 2) Opportunistic organisms in T cell deficiencies. 3) Recurrent staphylococcus infections in CGD, LAD and Hyper IgE syndrome. 4) Recurrent catalase-positive organism infections in CGD.

In blood chemistry, a decreased globulin fraction suggests hypogammaglobulinemia, malnutrition, or protein loss. An elevated globulin level is seen in HIV infection, certain autoimmune diseases, hepatitis, myeloma or chronic infections.

If the defect of B cells or humoral immunity defect is suspected, measurements of isohemagglutinins, immunoglobulin levels of IgG, IgA, IgM, specific antibody levels against of diphtheria, tetanus, H. influenzae and pneumococcus, and B cell enumeration (CD19) by a flow cytometer are needed. It should be noted that normal levels of IgG, IgM and IgA in children are lower than that in adults. A second test for specific antibody levels is required after having a booster dose of the vaccine if the first test result is low. Measurement of IgG subclass levels should not be used as a screening test and may not yield any more useful information than a total serum IgG level with

specific antibody titers. In a suspected immunodeficiency case with eczema, IgM and IgE measurement are appropriate to evaluate hyper-IgE syndrome, WAS and atopic dermatitis.

Cellular immunodeficiencies or T cell disorders can be screened in vivo with the use of the delayed hypersensitivity skin test (DHST) including Candida albicans (1:100), tetanus toxoid (1:100), trichophyton (1:30), tuberculin (5TU and 250TU) and mumps (i.e., the anergy panel). An induration of 10mm or more to one antigen or more than one antigen of indurations of 5mm or more indicates normal cell-mediated immunity. Approximately 90% of normal adults show a good response to at least one antigen when three to five antigens are applied. However, DHST may be difficult to evaluate in infants because such immunity has not yet been acquired or because of insufficient sensitization. Other tests for T cell disorders are T cell enumeration including CD3 (pan T), CD4 (helper T cell), CD8 (cytotoxic T cell) by a flow cytometer and in vitro assays for T cell functions such as lymphocyte proliferation to mitogens (phytohemagglutinin, concanavalin-A) and antigens (candida, tetanus, mumps, PPD, streptokinase or toxic shock syndrome toxin). Normally T cells constitute 55% to 80% of peripheral blood lymphocytes, with an absolute count of at least 1,000cells per cu-mm, and the number of CD4 cells is 1.5 to 2 times the CD8 cells. Higher absolute numbers of T-cell subsets and CD4 cells are commonly seen in normal infants and children.

Two screening tests for complement deficiencies are total hemolytic assay, CH50 for the classical pathway and AH50 for the alternative pathway. In a disseminated meningococcemia case or when terminal complement deficiency is suspected, AP50 and properdin levels are indicated if CH50 is normal. If CH50 is completely or partially absent, measurement of C3 and C4 levels is recommended. Normal C3 and C4 levels with low CH50 indicate deficiency of one of the other classic pathway components. If low levels of C3 and C4 are found, increased complement consumption is likely.

Determining the number and morphology of circulatory neutrophils, and assessing the oxidative metabolism by the nitroblue tetrazolium (NBT) test or chemiluminescence test, can screen phagocytic function in clinical practice. If a chemotaxis defect is suspected, a Boyden chamber test is recommended. Adhesion molecules such as CD11 a,b,c/ CD18 on granulocytes should be evaluated if LAD suspected.

Questions

1. The least likely recurrent infection caused by primary immune deficiency is:
    a. Recurrent otitis media
    b. Recurrent bacterial skin infection
    c. Recurrent bacterial pneumonia
    d. Recurrent osteomyelitis
    e. Recurrent urinary tract infection

2. Which one is considered as a characteristic of transient hypogammaglobulinemia of infancy (THI)?
    a. Normal IgG
    b. Normal IgM
    c. Normal IgA
    d. Normal IgD

3. Which one is the most likely diagnosis of an 18 year old female who presents with a history of recurrent sinopulmonary infection, low IgG and IgA and ITP?
    a. X-linked agammaglobulinemia
    b. Severe combined immunodeficiency
    c. Common variable immunodeficiency
    d. Ataxia-telangiectasia
    e. Cystic fibrosis

4. A 7 month old infant with a history of failure to thrive, recurrent oral candidiasis, and Pneumocystis carinii pneumonia is being evaluated. Which of the following is the least useful diagnostic test?
    a. Immunoglobulin levels and functional antibody
    b. Enumeration of T cells and lymphocyte proliferation assay
    c. Anti-HIV antibody
    d. Delayed type hypersensitivity skin test
    e. Nitroblue tetrazolium test and phagocytic tests

5. A mother brings her son, a 6 year old boy with severe eczema, recurrent bacteria skin infections and history of staphylococcal pneumonia for evaluation of immunodeficiency. Initial tests reveal normal CBC and platelets, 50,000 IU of IgE, normal IgG, IgM and IgA levels. Which one is the most likely diagnosis?
    a. Atopic dermatitis
    b. Wiskott-Aldrich Syndrome
    c. Hyper-IgE syndrome
    d. Chronic granulomatous disease
    e. Leukocyte adhesion defect

6. Which one is a true association of a primary immune deficiency and an abnormal hematologic finding?
    a. Leukocyte adhesion defect and thrombocytopenia.
    b. Hyper-IgM syndrome and neutropenia.
    c. Wiskott-Aldrich syndrome and gigantic platelets.
    d. Chronic granulomatous disease and large cytoplasmic granules in PMNs.
    e. Hyper-IgE syndrome and mastocytosis.

7. Which one is the characteristic infection in patients with terminal complement (C5-C9) deficiency?
    a. MRSA
    b. Pneumocystis carinii
    c. Meningococcus
    d. Catalase-positive organisms
    e. Herpes viruses

8. A contraindicated vaccine in an isolated IgA deficiency patient is:
    a. OPV
    b. Varicella
    c. Influenza
    d. MMR
    e. None of the above

9. IVIG replacement is indicated in all of the following, except:
    a. X-linked agammaglobulinemia (XLA)
    b. X-linked hyper-IgM syndrome
    c. Chronic granulomatous disease (CGD)
    d. Wiskott-Aldrich syndrome (WAS)
    e. Common variable immunodeficiency

10. PCP prophylaxis with trimethoprim-sulfamethoxazole is recommended in:
    a. X-linked agammaglobulinemia (XLA)
    b. X-linked hyper-IgM syndrome
    c. Chronic granulomatous disease (CGD)
    d. Wiskott-Aldrich syndrome (WAS)
    e. Hyper-IgE syndrome

Chapter V.6. Hematopoietic Stem Cell Transplantation and Graft Versus Host Disease
Jocelyn M. Sonson

This is a 7 year old female who presents to the office with a chief complaint of a rash on her head, arms and legs. She has a history of acute lymphoblastic leukemia. She had undergone chemotherapy, went into remission and subsequently received an allogeneic stem cell transplantation from her older brother 20 days ago. The rash started 3 days ago on her ears, palms of her hands and the soles of her feet, progressing further to her arms and legs. It has not progressed to involve her trunk or her extremities and there is no desquamation or bullae formation. She denies any GI discomfort, crampy abdominal pain or diarrhea.

Exam: VS T 38, P 100, R 20, BP 118/65. She is alert and active, in no apparent distress. HEENT negative except for the rash. The rash is an erythematous, maculopapular rash on her palms and soles bilaterally, and on the anterior aspects her arms and legs. The rash is also on the nape of her neck. Neck is supple. Chest is clear. Heart regular without murmurs. Abdomen is soft and non-tender. There might be some slight hepatosplenomegaly, but it is difficult to be certain.

She is diagnosed with early graft versus host disease. She is hospitalized and treated with cyclosporine and methylprednisolone for 10 days until the graft versus host disease (GVHD) is controlled. This was followed by a taper of her corticosteroids.

Hematopoietic stem cell transplantation, commonly called bone marrow transplantation (BMT), is indicated for various hematopoietic disorders (aplastic anemia, hemoglobinopathies), storage diseases, and severe immunodeficiencies. Pediatric malignancies that are candidates for stem cell transplantation include acute myelogenous leukemia, acute lymphoblastic leukemia (ALL), chronic myelomonocytic leukemia (CML), lymphomas, neuroblastomas, brain tumors and other solid tumors. Transplantation is recommended only in high-risk situations or when conventional treatment fails. In malignancies such as CML and juvenile myelomonocytic leukemia, hematopoietic stem cell transplantation is used as primary therapy because no other curative treatment exists.

Major sources of stem cells for transplantation include bone marrow, peripheral blood and cord blood. Since the mid-1990s, peripheral blood-derived stem cells have been used with increasing frequency over the traditional marrow cells. Peripheral blood stem cells (PBSC) contain higher numbers of progenitor cells, natural killer cells, and T cells as compared to bone marrow. Studies comparing bone marrow to PBSC transplantation have shown that PBSCs are associated with a shorter period of neutropenia and red blood cell and platelet transfusion dependence, with an equal probability of acute and chronic GVHD. Umbilical cord blood is a new and promising source of hematopoietic progenitor cells with remarkable proliferative potential, which may overcome the limitation of their relatively low absolute cell numbers. Because only a small number of cells are collected, successful transplants are typically limited to smaller sized recipients.

When the stem cells are from an identical twin, the transplant is termed syngeneic. When the stem cells are harvested from the recipient, the transplant is termed autologous. And lastly, when the stem cells are from someone other than the recipient, it is termed allogeneic. The best donors for allogeneic transplantation are siblings who inherit identical human leukocyte antigen (HLA) haplotypes.

Located in the major histocompatibility complex (MHC) on the short arm of chromosome 6, the HLA genes define histocompatibility and determine tolerance of the graft. Although there are over 35 HLA class I and II genes and over 684 alleles, HLA-A, HLA-B (class I), and HLA-DRB1 (class II) genes are used primarily in determining the histocompatibility of donors and recipients for stem cell transplantation. A 6-of-6 match refers to matching these three genes, each of which have two alleles. When none of the 6 alleles match, it is termed a mismatch and the various degrees of mismatch are termed one-antigen mismatch, two-antigen mismatch, etc. When only 3 of 6 alleles mismatch, the term is haploidentical. Graft rejection and graft-versus-host disease (GVHD) are the major immune-mediated complications associated with HLA disparity. The greater the HLA disparity, the higher these risks. Only 25-50% of patients have an HLA-identical sibling, therefore large donor registries have recently been successful in identifying phenotypically matched unrelated donors. In the United States, the National Marrow Donor Program has typed nearly 4 million volunteer donors and uses 118 donor centers and over 57 transplant centers to add 40,000 potential new donors each month.

The initial phase of stem cell transplantation entails the administration of the preparative regimen: chemotherapy and/or radiation therapy. The most common conditioning regimens include total body irradiation (TBI) and cyclophosphamide or busulfan and cyclophosphamide. Other combinations are also used during this conditioning period and include drugs such as etoposide, melphan, carmustine, cytosine arabinoside, thiotepa, ifosfamide, and carboplatin. The combinations are designed to eliminate malignancy, prevent rejection of new stem cells, and to create space for the new cells.

The stem cells infusion takes over an hour, although this time frame depends on the volume infused. Before infusion, the patient is premedicated with acetaminophen and diphenhydramine to reduce the risk of hypersensitivity reaction. The cells are then infused through a central venous catheter. Anaphylaxis, volume overload, and a transient GVHD are the major complications involved.

After stem cell infusion, the primary focus of care is managing the high-intensity preparative regimen. During this period, patients have little or no marrow function and are neutropenic, thus they must depend on transfusions for maintaining erythrocytes and platelets at acceptable levels. Patients are susceptible to life-threatening infections such as herpes simplex virus (HSV) or hospital-acquired nosocomial infections as well as other complications such as veno-occlusive disease, fluid retention, pulmonary edema, and acral erythroderma.

The rate of engraftment is a function of the preparative regimen, the nature and dose of stem cells, and the administration of medications that can suppress recovery. Engraftment, typically defined as a neutrophil count greater than 500 per cubic mm and a platelet count of 20,000 per cubic mm can occur as soon as 10 days to as long as several weeks after infusion. It is during this period that GVHD may occur.

Graft failure and graft rejection of transplanted stem cells, as well as transplanted organs, are influenced by several factors such as HLA disparity, the conditioning regimen, the transplanted cell dose, post-transplant/immunosuppression, donor T cells, drug toxicity and viral infection. Graft rejection may occur immediately, without an increase in cell counts, or may follow a brief period of engraftment. Rejection is usually mediated by residual host T cells, cytotoxic antibodies, or lymphokines and is manifested by a fall in donor cell counts with a persistence of host lymphocytes. Using stem cells from HLA-disparate donors significantly increases the risk for graft rejection/failure.

Transplants for nonmalignant disease generally have more favorable outcomes, with survival rates of 70-90% if the donor is a matched sibling and 36-65% if the donor is unrelated. Transplants for acute leukemias, ALL and AML, in remission at the time of transplant have survival rates of 55-68% if the donor is related and 26-50% if the donor is unrelated . Outcome statistics of autologous transplant for solid tumors are not as good for pediatric malignancies, except for lymphomas.

Graft-versus-host disease (GVHD) is a clinical syndrome that affects recipients of allogeneic stem cell transplants and results in donor T-cell activation against host MHC antigens. There are three requirements for this reaction to occur: 1) the graft must contain immunocompetent cells, 2) the host must be immunocompromised and unable to reject or mount a response to the graft, and 3) there must be histocompatibility differences between the graft and the host.

GVHD can be classified as acute, occurring within the first 100 days after stem cell transplant, or chronic, occurring after the first 100 days. The acute form of GVHD (aGVHD) is characterized by erythroderma, cholestatic hepatitis, and enteritis. aGVHD typically presents about day 19 (median), when patients begin to engraft. It usually starts as either erythroderma or a maculopapular rash that involves the hands and feet and may progress from the top of the scalp down toward the torso, potentially leading to exfoliation or bulla formation. Hepatic manifestations include cholestatic jaundice with elevated values on liver function testing. Intestinal symptoms include crampy abdominal pain and watery diarrhea, often with blood. aGVHD is graded in 5 steps from 0-IV based on involvement of the skin, liver, and GI tract. Grade 0 indicates no clinical evidence of disease. Grade I-IV are graded functionally. Grade I indicates rash on less than 50% of skin and no gut or liver involvement. Grade II indicates rash covering more than 50% of skin, bilirubin 2-3 ml/dL, diarrhea 10-15 ml/kg/d, or persistent nausea. Grade III or IV indicates generalized erythroderma with bulla formation, bilirubin greater than 3 mg/dl, or diarrhea more than 16 mL/kg/d. Survival rates vary from 90% in stage I, 60% in stage II or III, to almost 0% in stage IV.

The development of chronic GVHD (cGVHD), usually occurs after day 100 and resembles a multi-system autoimmune process manifesting as Sjogren's (sicca) syndrome, systemic lupus erythematosus, and scleroderma, lichen planus, and biliary cirrhosis. Recurrent infections from encapsulated bacterial, fungal, and viral organisms are common. The survival rate after onset of chronic GVHD is approximately 42%.

Management of GVHD and graft rejection focuses on both prevention and control of progressive disease. Finding the best HLA matched donor results in the lowest risk of severe disease and rejection. Younger age in either the donor or the recipient is associated with reduced risk. Same gender transplantation is also associated with reduced risk for GVHD. Prophylactic immunosuppression aims to inhibit the host T-lymphocyte activation that mediates rejection and inhibits the donor T-lymphocyte activation that mediates GVHD without altering immunity against infection or malignancy. Because donor T cells are responsible for GVHD, a form of prevention involves depletion of T cells in donor marrows or grafts using monoclonal antibodies or a physical separation technique. Elimination of T cells from the donor graft is an effective approach in some clinical settings, however depletion of T cells allows the persistence of host lymphocytes, which are capable of mediating graft rejection. In addition, loss of donor T cells decreases the benefit of producing a graft-versus-leukemia (GVL) effect and a lower relapse rate.

Treatment of aGVHD focuses on eliminating activated alloreactive T-cell clones. High-dose corticosteroids remain the most effective. Other studied approaches include anti-thymocyte antibodies, anti-TNF and IL-2 receptor antibodies, and immunosuppressive therapy such as cyclosporine, FK506, or mycophenolate mofetil. Treatment for cGVHD should begin with the earliest development of symptoms and requires continued therapy for a minimum of 6 to 9 months, even if symptoms resolve. Therapy for cGVHD includes corticosteroids usually in combination with another agent, often cyclosporine.

Late effects of transplantation can be classified into three basic categories: 1) toxicity from the preparative regimen, 2) toxicity from GVHD, and 3) toxicity from long-term immunosuppression. Clinical conditions include effects on growth and development, neuroendocrine dysfunction, fertility, second tumors, chronic GVHD, cataracts, leukoencephalopathy, and immune dysfunction. The effect of radiation on growth is relatively common and can be a result of a multitude of factors. Disruption of growth hormone production is the most common effect, however thyroid dysfunction, gonadal dysfunction, and bone growth effects also occur due to radiation. Other toxicities include cataracts, azoospermia, and gonadal failure.

Long-term cGVHD effects on the body include disruption of normal glandular function resulting in drying of the eyes, which can lead to corneal injury, and decreased salivary gland production, which can cause severe dental caries. Chronic inflammation of the intestine can lead to strictures and webs. The skin manifestations such as maculopapular rash or a sclerodermatous condition, can extend to all parts of the body and cause fibrosis of the underlying subcutaneous tissues and fascia resulting in contractures.

Continued use of chronic immunosuppressive drugs can cause toxicity that hamper quality of life. These toxicities include hypertension, glucose intolerance, weight gain, growth failure, avascular necrosis of the femoral head, and chronic osteopenia that leads to recurrent fractures. Long-term use of immunosuppressive drugs can lead to recurrent infections, such as bacterial, fungal, cytomegalovirus, adenovirus and varicella zoster.

Questions

1. Which of the following is a requirement for a graft-versus-host disease reaction to occur.
    a. The graft must contain immunocompetent cells.
    b. The host's T-lymphocytes must be able to mount an immune response against the graft.
    c. The host must be immunocompromised
    d. a and b
    e. a and c

2. True/False: The best predictors for developing GVHD are the age and sex of both the donor and recipient.

3. During the conditioning period prior to stem cell transplantation, which of the following purposes does chemotherapy and/or radiation try to accomplish?
    a. Prevent rejection of new stem cells
    b. Create space for new cells
    c. Eliminate malignancy
    d. All of the above
    e. None of the above

4. True/False: A limitation of cord blood as a source for stem cells is the small number of cells collected.

5. During which period does graft-versus-host disease typically occur?
    a. Conditioning
    b. Engraftment
    c. Postengraftment
    d. All of the above
    e. None of the above

Answers to questions

1. e
2. False. HLA matching is the best predictor.
3. d
4. True
5. b

Chapter VI.1. Virology
Loren G. Yamamoto, MD, MPH, MBA

A 5 year old boy is seen in the office with a history of fever, body aches and nausea. His temperature at home was 39 degrees (102.2 degrees F). He was treated with acetaminophen which resulted in normalization of his temperature and improvement in his body aches. He has been taking fluids without vomiting. He has a slight cough and nasal congestion, but no sore throat, headache, diarrhea, abdominal pain, or urinary complaints.

Exam: T37.2, P80, R25, BP 90/60, oxygen saturation 100% in room air. Height and weight are at the 50th percentile. He is alert, active and cooperative. He is not toxic and not irritable. His exam findings are unremarkable except for nasal congestion.

You tell his mother that he has a virus infection, which is something like a flu type of illness. She says, "That's what he had two weeks ago. How can he keep getting the same virus over and over again? What's the name of this virus anyway? How can he get rid of it?" You explain that this is not the same virus, that there are many different viruses, and that his immune system eventually clears the virus from his system. But he is still susceptible to many other viruses. You're not really sure of the name for his current virus, but we don't have any antiviral treatments for this virus anyway.

While most clinicians have a fairly good background of bacteriology, our knowledge of viruses is usually not as good. Optimal use of antibiotics improves with knowledge of bacteriology. Since we don't have many antiviral agents, it is generally unnecessary (from a therapeutic decision standpoint) to be able to distinguish most of these viruses. However, in the future, as more antiviral agents become available, we will need to improve our knowledge of virology to optimally utilize these future antiviral agents.

Similar to bacteria which can be basically classified using gram stain and morphology, viruses can be classified based on their envelope and nucleic acid type. Viruses are obligate intracellular organisms which utilize the host cell for varying degrees of viral replication. They can only be grown in cell culture media. They are too small to see with a light microscope, but the "cytopathic effect" on the cells in the cell culture media can be seen with a light microscope. Other clinical laboratory methods to identify the presence of viruses are: immunologic assays, antibody serology, polymerase chain reaction (PCR) to detect nucleic acid, detection of reverse transcriptase and electron microscopy.

Viruses are either naked or enveloped. All naked virus have an icosahedral head shape. All enveloped viruses utilize the host cell's membrane by budding off a section to create its envelope. In general, there are four types of disease patterns produced by viruses: 1) acute infection, 2) chronic infection, 3) latent infection, and 4) post-infectious or para-infectious phenomena. Acute infection is caused by naked viruses or enveloped viruses. They kill cells as more viral particles are released. Chronic infection, which is the chronic continued release of viral particles lasting 6 months or more, can only be caused by enveloped viruses such as hepatitis B and HIV. Naked viruses cannot cause chronic infection. Latent infections result when the viral nucleic acid sequence is incorporated into the cell, but the cell is not actively producing viral particles unless it is somehow reactivated in the future. Latent infections, such as with Herpes simplex, are characterized by recurrent episodes of clinical infection. Post and para-infectious phenomena are the result of the body's immune system damaging the host cells and tissues in an effort to get rid of the virus. This is most clinically evident in encephalitis and myocarditis.

The nucleic acid of viruses can be either DNA, +RNA, -RNA, retroviral RNA, or double stranded RNA. DNA viruses usually utilize double stranded DNA (dsDNA) which separates and replicates to form new dsDNA for the new viral particles. Some viruses utilize single stranded DNA (ssDNA). +RNA contains a single stranded RNA which is directly utilized as a messenger RNA (mRNA) to synthesize viral proteins using the host ribosomes. -RNA contains a single stranded RNA which is used as a template for a virion associated polymerase to transcribe an mRNA strand which then uses the host ribosomes to synthesize viral proteins. Retroviral RNA viruses contain a single strand of RNA and a virion associated reverse transcriptase which is used to synthesize dsDNA from the RNA strand. This dsDNA is often integrated into the host cell genome. There are a few exceptions to these general classes.

DNA viruses include parvovirus, papovavirus, adenovirus, hepadnavirus, herpesvirus and poxvirus. This can be remembered by "Poor pappy adds hep to her pox". The first three are naked DNA viruses. The latter three are enveloped DNA viruses.

Parvoviruses commonly cause veterinary disease. The major human parvovirus is called human parvovirus B19. This virus causes Fifth disease (erythema infectiosum), which is a viral exanthem of childhood. Clinical manifestations of Fifth disease are pink cheeks (slapped cheeks), fever and a slight rash on the body. Human parvovirus is a more serious problem for children and adults with hemoglobinopathies (thalassemia, sickle cell disease, etc.). Human parvovirus infection is responsible for aplastic crisis in sickle cell disease. Human parvovirus seems to cause mild anemia in healthy persons, but it causes severe erythrocyte suppression in patients with hemoglobinopathies. A fetus with thalassemia may be stillborn due to hydrops fetalis if the mother is infected by human parvovirus during pregnancy.

Papovaviruses include human papillomavirus and polyomavirus. Papillomaviruses cause various types of cervical cancer and warts such as: plantar warts and genital warts (condyloma acuminata). Polyomaviruses mostly affect birds, but they also include JC virus (which causes progressive multifocal leukoencephalopathy dementia in immunocompromised patients), and BK virus (which causes kidney disease in immunocompromised patients).

Adenoviruses commonly affect children. These illnesses are usually self limited. Many different adenoviruses classified by serotype numbers, cause various combinations of fever, conjunctivitis, pharyngitis, rhinitis, pharyngitis and pneumonia. Some adenoviruses cause gastroenteritis.

The most important hepadnavirus is hepatitis B virus. Since it is an enveloped virus, it is capable of chronic disease in some hosts. Chronic hepatitis B may cause chronic hepatitis, hepatic failure and hepatocellular carcinoma.

Herpesviruses are a large family which include herpes simplex virus (HSV), varicella-zoster virus (VZV), Epstein-Barr virus (EBV) and cytomegalovirus (CMV). HSV and VZV are similar in that they both start with acute infection with subsequent latent lifelong infection and periodic reactivation of symptomatic infection. HSV-1 causes oral herpes while HSV-2 causes genital herpes. Both cause initial acute infections with fever, viremia, mucosal lesions and/or central nervous system infection. The virus survives (latent) in nerve tissue and upon lifelong periodic reactivation, mucosal or vesicular lesions recur. Similarly varicella virus causes an acute systemic infection as varicella (chickenpox), with subsequent reactivation of latent infection manifested as zoster (or shingles). HSV-1 usually causes an initial acute infection characterized by gingivostomatitis (high fever, gum swelling and multiple mouth sores on the lips and anterior tongue). However, some children may present with encephalitis. Neonates are especially prone to encephalitis with HSV-1 and

HSV-2. Thus, all measures must be taken to prevent HSV exposure to neonates. Mothers with a history of genital herpes must undergo Cesarean section prior to the rupture of membranes to prevent neonatal exposure to occult genital herpes lesions.

EBV and CMV are similar in that they both cause syndromes of prolonged viral infection with fever, malaise, lymphadenopathy, and organomegaly. This EBV syndrome is known as infectious mononucleosis, which also includes tonsillitis. EBV is capable of latent infection and is associated with Burkitt's lymphoma (the cells of which contain EBV DNA).

CMV and HSV cause recognizable congenital viral syndromes, which occur when a pregnant mother acquires an initial acute infection with CMV or HSV during early pregnancy. The acute infection results in viremia which may infect the fetus and placenta. This results in a recognizable pattern of findings which include central nervous system calcification, microcephaly, thrombocytopenia, petechial rash, small for gestational age, etc. Recurrent maternal infection does not usually result in a systemic viremia, so congenital infection is not likely with anything other than an acute maternal infection. Congenital infection should be distinguished from perinatal infection in that congenital infection occurs during early gestation while perinatal infection occurs at the time of birth or just after. Thus, a mother with a history of genital herpes many years ago is at no risk for delivering an infant with congenital herpes, but this does pose a risk for perinatal herpes, which may present as an acute encephalitis or overwhelming acute viremia.

The poxviruses do not include VZV (chickenpox) which is in the herpesvirus family. The poxviruses include variola virus (smallpox), vaccinia (cowpox) and molluscum contagiosum virus. Smallpox no longer exists on the planet except in bio-warfare programs. This is a contagious virus with a fairly high mortality rate. Vaccinia virus is called cowpox because it was found in dairy cattle and milk maids would get a mild infection with vaccinia, manifested as pox lesions on their milking hands. Vaccinia virus infection elicits cross immunity against smallpox. The classic observation that milk maids never got smallpox was noticed by Edward Jenner who eventually demonstrated that inoculation with vaccinia virus, could prevent smallpox (variola virus infection), a process which he called vaccination (named after vaccinia virus).

The +RNA viruses (remembered by: "Pete can float toward the coast backward") include picornavirus, calicivirus, flavivirus, togavirus, coronavirus, and retroviruses (retro = backward in the mnemonic).

Picornaviruses include (PEECoRnA) polio, entero, echo, coxsackie, rhino and hepA virus genera. Polio is covered in a separate chapter. Enteroviruses cause viral meningitis, occasional encephalitis, gastroenteritis and myocarditis. Coxsackie virus usually causes fever and stomatitis, such as in hand-foot-mouth disease. Echovirus causes fever and rash. Rhinoviruses cause common cold symptoms.

Caliciviruses include Norwalk virus (which causes gastroenteritis) and hepatitis E virus. Flaviviruses include hepatitis C, yellow fever, dengue fever and St. Louis encephalitis. Togaviruses include the equine encephalitis viruses (such as western equine encephalitis and eastern equine encephalitis), and rubella virus (German measles). Coronaviruses include multiple serotypes which cause cold symptoms.

Retroviruses include human immunodeficiency virus (HIV) and human T-cell lymphotrophic virus.

The -RNA viruses (remembered by: "raspberry filled parfaits are often burned") include rhabdovirus, filovirus, paramyxovirus, arenavirus, orthomyxovirus and bunyavirus families. Rabies is the most important rhabdovirus. Ebola virus is the most important filovirus. Paramyxoviruses include rubeola (measles), mumps, respiratory syncytial virus (RSV), and parainfluenza virus (colds, laryngitis, croup). Arenaviruses include lymphocytic choriomeningitis virus and Lassa fever virus. Orthomyxoviruses include influenza A and B. Hanta virus is the most important bunyavirus.

The -RNA viruses include several deadly viral infections: rabies, Ebola and Hanta viruses. This group also includes many illnesses for which we are routinely immunized against: measles, mumps, and influenza. Premature and other high risk infants routinely receive passive immunity against RSV.

The double stranded RNA viruses include orbivirus, rotavirus and reovirus (ORR). Orbivirus includes Colorado tick fever. Rotavirus is a major cause of pediatric diarrhea. Reoviruses causes febrile illnesses without other specific findings.

Summary of virus classifications

I. DNA viruses (Poor pappy adds hep to her pox)
   - A. Naked
     1. Parvovirus (human parvovirus B19)
     2. Papovavirus (papillomavirus, polyomavirus)
     3. Adenovirus (many which cause febrile respiratory infections)
   - B. Enveloped
     1. Hepadnavirus (hepatitis B)
     2. Herpesvirus (HSV, VZV, EBV, CMV)
     3. Poxvirus (variola, vaccinia, molluscum contagiosum)

II. +RNA viruses (Pete can float toward the coast backward)
   - A. Naked
     1. Picornavirus (PEECoRnA = polio, entero, echo, coxsackie, rhino, hepA)
     2. Calicivirus (Norwalk, hepatitis E)
   - B. Enveloped
     1. Flavivirus (yellow fever, dengue, St. Louis encephalitis, hepatitis C)
     2. Togavirus (rubella, equine encephalitis)
     3. Coronavirus (colds)
     4. Retrovirus (HIV)

III. -RNA viruses (raspberry filled parfaits are often burned)
- A. Naked - none
- B. Enveloped
  1. Rhabdovirus (rabies)
  2. Filovirus (Ebola)
  3. Paramyxovirus (measles, mumps, RSV, parainfluenza)
  4. Arenavirus
  5. Orthomyxovirus (influenza)
  6. Bunyavirus (Hanta)

IV. dsRNA viruses (ORR)
- A. Orbivirus (Colorado tick fever)
- B. Rotavirus
- C. Reovirus

Questions
1. Name the 3 naked and 3 enveloped DNA virus families.
2. In terms of the potential duration of infection, how do naked viruses differ from enveloped viruses?
3. Name 6 viruses within the picornavirus family.
4. How are members of the herpesvirus family similar?
5. Name 4 viruses which cause cold symptoms?
6. Name the +RNA viral families.
7. Name two naked (non-enveloped) viruses which cause chronic infection.
8. Name the -RNA viral families.
9. Naked viruses are mostly of what morphologic shape on light microscopy?
10. Name 4 virus families which cause central nervous system infections.

Answers to questions
1. Poor pappy adds hep to her pox: Parvovirus, papovavirus, adenovirus, hepadnavirus, herpesvirus, poxvirus. The first three are naked, the latter three are enveloped.
2. Naked viruses cause acute infection only. Some enveloped viruses are capable of chronic infection.
3. PEECoRnA: polio, entero, echo, coxsackie, rhino, hepA.
4. VZV and HSV are similar in that they both cause acute vesicular infections with lifelong latency and recurrence. EBV and CMV are similar in that they both cause infectious mononucleosis type syndromes. CMV and HSV both cause congenital viral infection malformation syndromes.
5. Rhinovirus, RSV, parainfluenza virus, coronavirus, adenovirus. Influenza virus may be included also.
6. Pete can float toward the coast backward: picorna, calci, flavi, toga, corona, retro.
7. None. Only enveloped viruses can cause chronic infection.
8. Raspberry filled parfaits are often burned: rhabdo, filo, paramyxo, arena, orthomyxo, bunya.
9. Viruses are too small to be seen on light microscopy. On electron microscopy, nearly all naked viruses have an icosahedral shape.
10. Herpesvirus (HSV, VZV, CMV), picornavirus (poliovirus, enteroviruses), flavivirus (encephalitis), togavirus (encephalitis), rhabdovirus (rabies), bunyavirus (encephalitis).

Chapter VI.2. Basic Bacteriology
Loren G. Yamamoto, MD, MPH, MBA

You arrive at your clinic in the morning and a nurse tells you that the lab has called with three positive culture reports. The nurse hands you the lab reports and the patients' charts.

The first culture is a beta strep, not group A. This is a throat culture from a 10 year old boy seen in the clinic yesterday for a sore throat. He was treated with penicillin pending the outcome of the culture. You know that group A strep should be treated for 10 days, but you ask your associate what to do about non-group A beta hemolytic strep. He tells you that non-group A strep in the throat is non-pathogenic.

The second culture is a blood culture with gram positive rods. This is from a 14 month old male who was seen in the clinic 3 days ago with fever. A CBC was normal at the time. He was treated with fever medications and no antibiotics. You call his home and his mother says that he has not had any fever for the past two days. He is now well and he seems back to his usual self. He comes to the clinic for a follow-up exam and you determine that he is no longer ill. You conclude that this organism must be a non-pathogen (i.e., a contaminant of the blood culture bottle).

The third culture is a urine culture with 100,000 colony forming units (cfu) per ml of gram negative rods. This is an 18 month old female who presented with fever and vomiting. Her UA showed 25-50 wbc's per high powered field (hpf). She was treated with IM ceftriaxone and oral cephalexin. She is seen in follow-up later today and she is doing well. Her antibiotics are continued. Her urine culture the next day identifies the organism as E.coli which is sensitive to cephalosporins.

Basic microbiology knowledge can be very useful clinically if one focuses on the clinically important aspects of bacteriology. It can greatly help in the preliminary management of patients before definitive identification of the organisms and antibiotic sensitivities are determined.

Gram stain morphology results are the first step in identification. Gram positive cocci and gram positive rods greatly narrow the possibilities. Gram negative organisms are more difficult to narrow down.

Gram positive cocci are either staphylococci or streptococci. One could distinguish these morphologically since staph are usually arranged in clusters, while strep are usually arranged in pairs and/or chains. The catalase assay is more reliable since staph are catalase positive and strep are catalase negative. There are only two types of clinically important staph species, Staph epi and Staph aureus. These two are distinguished by the coagulase test. Staph epi is coag negative, while Staph aureus is coag positive. Aureus means "gold", because most Staph aureus colonies (growing on a Petri plate) have a gold color, while most Staph epi colonies have a white color. Staph aureus is methicillin and cephalosporin resistant about 25% of the time. MRSA (methicillin resistant Staph aureus) are similarly resistant to oxacillin, cloxacillin, nafcillin, dicloxacillin and cephalosporins. Staph epi is methicillin and cephalosporin resistant over 90% of the time. Vancomycin can be used for resistant Staph epi and Staph aureus.

Staph epi is usually not a clinical pathogen and it is frequently a contaminant in blood cultures. If Staph epi grows from a blood culture, it is more likely to be a contaminant if the patient is healthy and doing well by the time the culture comes back. Staph epi growing from a blood culture is more likely to be a true pathogen if the patient has any type of indwelling plastic or prosthetic materials, such as a ventriculoperitoneal shunt, a central venous catheter, etc., since Staph epi has a propensity to adhere to indwelling plastic devices forming slime layers of bacterial colonization onto the device which often requires removal of the device since antibiotic treatment alone is often insufficient to eradicate the colonization.

Staph aureus frequently causes skin and soft tissue infections, such as cellulitis, impetigo and abscesses. Staph aureus is a common cause of more serious infections such as septic arthritis, osteomyelitis, discitis, severe pneumonia, etc. Staph aureus can produce an exotoxin which can result in septic shock but additionally, these toxins can cause several clinical entities depending on the type of toxin produced. Toxic shock syndrome (TSS) is due to a staph aureus toxin which causes an erythroderma (commonly mistaken for scarlet fever), high fever and shock. Staphylococcal scalded skin syndrome (SSSS) toxin causes a generalized exfoliative desquamation and severe infection. Bullous impetigo causes localized blistering due to a less virulent exfoliative toxin. Staph aureus food poisoning is a heat stable toxin that results in vomiting and diarrhea very soon after the ingestion of contaminated food containing pre-formed toxin.

When a blood culture grows Staph aureus, it should always be considered to be a serious pathogen. Empiric coverage with IV vancomycin should be started for potentially serious Staph aureus infections until culture and sensitivities are known, since the resistance rate to methicillin and cephalosporins is too high (at least 25%). However, if the Staph aureus infection is deemed less serious, such as impetigo or a small abscess, treatment with a cephalosporin (75% sensitive) or clindamycin (95% sensitive) may be satisfactory.

Streptococci are first classified using their hemolytic pattern on sheep blood agar. Clear colonies are called beta hemolytic. Green colonies are called alpha hemolytic. Streptococcal colonies which do not result in any hemolysis are called non-hemolytic or gamma hemolytic. For the most part, non-hemolytic strep are not clinically important since they don't cause much clinical disease. Alpha hemolytic strep include Strep pneumoniae (pneumococcus), Strep viridans, and other miscellaneous non-pathogenic alpha strep (often found in mouth and nasal flora). Strep pneumoniae and Strep viridans can be distinguished by several lab sensitivity tests to bile and Optochin.

Pneumococci cause many human infections including pneumonia, meningitis, sinusitis, otitis media, occult bacteremia, primary peritonitis, sepsis, osteomyelitis and septic arthritis. Some pneumococci contain polysaccharide capsules which add virulence to the organism. Non-encapsulated pneumococci are less virulent and are often implicated in otitis media or other minor infections. Severe pneumococcal infections are usually due to encapsulated pneumococci. The immune system forms antibodies against the polysaccharide antigens. Pneumococcal vaccines are developed against these polysaccharide serotypes. Several multivalent pneumococcal vaccines are currently available. Pneumococcus is usually sensitive to penicillin, but resistance is emerging requiring treatment with higher penicillin doses, cephalosporins or for high level resistance, vancomycin is required. Strep viridans (not a species, but rather a group of organism species) is a less common human pathogen, sometimes causing bacterial endocarditis.

Beta hemolytic strep are further classified using the Lancefield classification, which utilizes letters. Group A strep (also known as Strep pyogenes) causes strep pharyngitis, tonsillitis, impetigo, scarlet fever and cellulitis. It occasionally causes pneumonia, endocarditis and necrotizing fasciitis (commonly called the flesh eating bacteria syndrome). Group A strep are still penicillin sensitive. Post-infectious complications include acute rheumatic fever and acute glomerulonephritis.

Group B strep (also known as Strep agalactiae) commonly colonizes the maternal gyn tract. Newborns are exposed to this, so group B strep is a common cause of neonatal pneumonia, meningitis and sepsis. Maternal infections with group B strep include chorioamnionitis

and endometritis. Since this organism is common and potentially highly virulent, mothers are currently screened for group B strep routinely and if found, they are given ampicillin prophylaxis to reduce the risk of neonatal sepsis. Group B strep are still penicillin sensitive. They are sensitive to cephalosporins, but less so, such that treatment with penicillin or ampicillin is still recommended even in neonates treated with cephalosporins.

Terminology such as "beta strep" or "group A strep" may be considered incomplete. Technically, beta strep is not the name of an organism since there are many different types of beta hemolytic strep (group A, B, C, D, etc.). However, "group A strep" is unambiguous, since by definition, only beta hemolytic strep can be group A. Thus, it is not necessary to say "group A beta hemolytic strep", since "group A strep" will suffice. It is only sufficient to say "beta hemolytic strep" or "beta strep" if your intention is to refer to all beta hemolytic strep, but this does NOT refer to a single specific organism.

Group C strep are less pathogenic. They are sometimes found in the pharynx. While group C strep may cause pharyngitis, such infections are almost always self limited without suppurative or post-infectious complications. Thus, antibiotic treatment with penicillin may be used to treat non-group A beta hemolytic strep pharyngitis (such as group C strep) if the patient is symptomatic with a sore throat or fever, but it is not absolutely necessary since such infections are generally self limited.

Group D strep is a confusing group, because this is the only group which does not name a single organism. There are two important group D strep organisms; Strep faecalis and Strep bovis. The term "enterococcus" is often used to refer to Strep faecalis; however "enterococcus" can be Enterococcus faecalis (new name for Strep faecalis), Enterococcus faecium or others. Additionally, group D strep are not always beta hemolytic. Thus, group D strep are identified on a separate plate (other than sheep blood agar) for identification. Group D strep are difficult to treat, often requiring two drug therapy such as ampicillin and an aminoglycoside. You may see the abbreviation "VRE" which stands for vancomycin resistant enterococci.

Gram positive rods are uncommon causes of human infection. Lactobacilli may be found in urine. Diphtheroids are frequent contaminators of blood cultures. Clostridium, corynebacteria, bacillus and listeria are all capable of causing severe disease, but these are all uncommon infections. They are generally penicillin sensitive (with the exception of Clostridium difficile). Clostridium and bacillus species are spore formers. These dormant spores are highly resistant to environmental stress such as dehydration and heat, making it difficult to eradicate the infectious particles from the environment.

Clostridium are anaerobes which produce disease through exotoxin production. C. tetani and C. botulinum produce potent neurotoxins. Children are routinely immunized with tetanus toxoid. Botulism is prevented by strict regulation of canned goods (heat and/or pressure cooking requirements), but infant botulism may still occur from exposure to spores (usually from soil or foods). C. difficile (penicillin resistant) produces a toxin which causes pseudomembranous colitis, which results from gastrointestinal C. difficile overgrowth with prolonged broad spectrum antibiotic treatment. C. perfringens causes cellulitis and tissue gas gangrene (tissue necrosis results from exotoxin production).

Corynebacterium diphtheria causes a severe throat infection, but its exotoxin is cardiotoxic and neurotoxic. Immunization with diphtheria toxoid prevents the toxin effects and severe infection. Listeria monocytogenes is an uncommon infection which may be transmitted in foods (commonly deli meats and cheese). It produces mild gastroenteritis in most individuals, but it may cause sepsis in pregnant women, neonatal sepsis, and severe infections in immunocompromised patients.

Bacillus species, are aerobic gram positive rods. The major pathogen is bacillus anthracis which is an uncommon organism except when used for biological warfare. It can cause cutaneous anthrax (localized necrotic infection) or anthrax pneumonia (high mortality).

Gram negative organism species are more numerous. They generally produce endotoxins, as opposed to the exotoxins produced by many gram positive organisms. Their laboratory identification methods are more complex and beyond the scope of this chapter.

The most common gram negative rods are those found in the GI tract, commonly called the Enterobacteriaceae. Human disease from these organisms most commonly originates from the GI tract. Urinary tract infection (UTI), neonatal sepsis and peritonitis most commonly result from exposure to stool organisms. The most common organism involved is Escherichia coli. E. coli is the most common cause of UTI and a common cause of neonatal sepsis (along with group B strep). Normal flora gram negative rods include E. coli, klebsiella, proteus, serratia, etc. These can sometimes causes disease, but usually because they have entered the wrong part of the body (such as UTI, neonatal sepsis and aspiration pneumonia). Most E. coli are normal flora, but some E. coli subtypes are pathogenic such as E. coli 0157 (causes dysentery and hemolytic uremic syndrome), enterotoxigenic E. coli (causes traveler's diarrhea) and enteropathogenic E. coli (causes pediatric diarrhea). Pathologic gram negative rods include salmonella, shigella, yersinia, pseudomonas, etc. Most gram negative rods are covered by aminoglycosides, cephalosporins, broad spectrum penicillins, sulfonamides and quinolones. Pseudomonas is particularly resistant so it commonly emerges in patients treated with prolonged courses of antibiotics.

Gram negative cocci are basically Neisseria and Moraxella species. Moraxella catarrhalis is part of the upper respiratory tract normal flora. It is commonly found in otitis media and sinusitis. It is usually treated with a broad spectrum penicillin such as amoxicillin, but some M. catarrhalis are resistant.

Neisseria meningitidis (also called meningococcus) is highly virulent causing meningitis and meningococcal sepsis (known as meningococcemia). Meningococcus contains a polysaccharide capsule adding to its virulence. A meningococcal vaccine directed against the polysaccharide capsule is available. Neisseria gonorrhoeae (also called gonococcus or GC) is sexually transmitted causing urethritis, epididymitis cervicitis, pelvic inflammatory disease and pharyngitis. Disseminated GC causes polyarticular and monoarticular septic arthritis. Infants exposed to GC may develop ophthalmia neonatorum. All newborns receive routine eye prophylaxis with ophthalmic silver nitrate or antibiotics. Meningococcus is still penicillin sensitive. GC used to be penicillin sensitive, but most GC today are penicillinase producing (known as penicillinase producing Neisseria gonorrhoeae, or PPNG for short). PPNG can still be treated with ceftriaxone, doxycycline or azithromycin.

Haemophilus species used to be a major pediatric pathogen. They are gram negative organisms commonly called coccobacilli, or pleomorphic (variable forms) rods. Haemophilus influenzae (H.flu) is either capsulated (only one major polysaccharide serotype called type B) or non-encapsulated. Haemophilus influenzae type B (known as HiB for short) was a major cause of sepsis, meningitis, septic arthritis, pneumonia, epiglottitis and cellulitis in young children. These serious and life threatening infections from HiB have largely been eliminated from our community through widespread HiB immunization (a major public health and pediatric accomplishment). This is a polysaccharide vaccine which does not provide immunity against non-encapsulated (also called non-typable H.flu). Since non-typable H.flu does not have a polysaccharide capsule, it is less virulent, so it is associated with only minor infections such as otitis media and sinusitis. H.flu (non-typable and type B) is 30% resistant to amoxicillin, due to beta-lactamase production. Anti-beta-lactamase drugs (clavulanic acid, sulbactam, etc.) overcome this resistance. Thus, amoxicillin-clavulanic acid and high generation cephalosporins cover 100% of H.flu.

Gram negative anaerobes typically cause polymicrobial infection. Most anaerobes are sensitive to penicillin with one major exception and that is Bacteroides fragilis (B.frag), which is commonly found in bowel (stool). Anaerobes cause a putrid (foul decay) odor (e.g., feces). Esophageal and mouth anaerobes typically do not contain B.frag., which is why most texts refer to anaerobe infections above the diaphragm (B.frag unlikely) versus anaerobe infections below the diaphragm (B.frag is likely). Thus, classically, the anaerobe component of aspiration pneumonia may be treated with penicillin as opposed to peritonitis due to a ruptured appendix which is likely to involve B.frag. Bacteroides fragilis is classically treated with clindamycin, metronidazole or chloramphenicol. Some cephalosporins such a cefoxitin and cefotetan have better coverage against B.frag, but they are not 100%. If an anaerobic infection is suspected, culture samples must be sent to the lab in special anaerobic culture/transport media (e.g., thioglycolate).

Other gram negative organisms that deserve mention include Legionella, Bordetella, Brucella, Francisella, Campylobacter, Helicobacter, Vibrio and Pasteurella. Spirochetes include Treponema (syphilis, yaws, etc.), Borrelia (Lyme disease) and Leptospira (leptospirosis).

Mycobacterium species do not stain well with the gram stain. They stain best with the acid-fast stain. Mycobacterium tuberculosis causes tuberculosis. M. leprae causes leprosy (Hansen's disease). M. avium-intracellulare causes pulmonary infections in immunocompromised patients. M. marinum is a marine organisms which causes "fish tank" granulomas in those who are frequently exposed to aquarium and marine environments.

Mycoplasma and Chlamydia are similar to viruses in that they are obligate intracellular organisms. They cannot be grown on Petri plates because they require cells to grow. Mycoplasma and Chlamydia must be grown in cell media (similar to viruses) in labs, thus, they are difficult to culture. Despite their obligate intracellular requirements, they utilize bacterial DNA ribosomes and are thus, susceptible to erythromycins, tetracyclines and some quinolones. The epidemiology of infections with Mycoplasma and Chlamydia is unclear since these organisms are difficult to identify definitively. It was once thought that Mycoplasma pneumonia only occurred in young adults, but it is now known to occur in all age groups, although its frequencies in each age group are unclear. It was once thought that Chlamydia infections were largely limited to an eye infection called trachoma. However, it is now known that Chlamydia causes respiratory infections and pelvic inflammatory disease. The true epidemiology of these organisms is still unclear. They may play a role in many other infections that we have yet to discover. Other obligate intracellular organisms include Rickettsia (Rocky Mountain Spotted Fever, typhus), Coxiella, Ehrlichia, and Bartonella (not intracellular).

Summary Table:

Gram Positive Cocci:
- Catalase (+) Staph:
  - Coagulase (+) Staph aureus
  - Coagulase (-) Staph epidermidis
- Catalase (-) Strep:
  - Alpha hemolysis on sheep blood agar (green colonies):
    - Bacitracin sensitive: Strep pneumoniae (pneumococcus)
    - Bacitracin resistant: Strep viridans
  - Beta hemolysis on sheep blood agar (clear colonies):
    - Group A (Strep pyogenes)
    - Group B (Strep agalactiae)
    - Group C (not very pathogenic)
    - Group D (not always beta hemolytic)
      - Strep faecalis (enterococcus)
      - Strep bovis

Gram positive rods:
- Clostridium (tetanus, botulism, perfringens, difficile)
- Corynebacterium (diphtheria)
- Listeria monocytogenes
- Bacillus (anthracis)
- Lactobacillus
- Diphtheroids (flora)

Gram negative cocci:
- Neisseria (gonorrhoeae, meningitidis)
- Moraxella

Gram negative rods:
- Enteric gram negative rods (E. coli, Proteus, Klebsiella, Serratia, etc.)
- Pathologic gram negative rods (Salmonella, Shigella, Yersinia, Pseudomonas, etc.)

Gram negative coccobacilli:
- Haemophilus influenzae

Gram negative anaerobes:
- Bacteroides fragilis (penicillin resistant)
- Most others (penicillin sensitive)

Spirochetes:
- Treponema, Borrelia, Leptospira

Acid-fast bacilli:
- Mycobacterium (TB, leprae, avium-intracellulare, marinum)

Non-viral obligate intracellular organisms:
- Mycoplasma
- Chlamydia
- Rickettsia
- Other: Coxiella, Ehrlichia, Bartonella (not intracellular)

Questions

1. A lab slip returns which says "coag negative staph". What does this mean and what is the likelihood that this organism is sensitive to methicillin and cephalosporins?
2. At laparotomy, a patient is found to have a ruptured appendix and peritonitis. A swab from the peritoneal fluid is expected to grow what types of organisms? Is there any special swab or sample that must be sent to properly culture this fluid?
3. Name two characteristics of anaerobic infections?
4. Name 5 disease conditions which result largely from toxin production?
5. Group A streptococcal pharyngitis is usually a self limited infection even without antibiotic treatment. What is the reason for treating "strep throat"?
6. A lab tech identifies beta hemolytic colonies on a sheep blood agar plate. What is the next step to identify the organism?
7. Two days after a blood culture is drawn, the lab reports gram positive cocci. This patient is a 10 month old with fever and no other identifiable clinical infection. The child is now afebrile and looks good. What organism possibilities could be growing in this blood culture?
8. A lumbar puncture is done on a very ill 8 month old infant. The fluid is cloudy and the gram stain shows many WBCs and gram positive cocci. What organism is likely causing the meningitis? What organism would be likely if the gram stain showed gram negative cocci instead?
9. A new resident on the pediatric service orders a gram stain on a stool sample. What is the result likely to be?
10. If staph epi grows from a blood culture, how can one determine whether this is a contaminant or a staph epi bacteremia?

2. Chapter 24: The Gram-Positive Pyogenic Cocci. In: Volk WA, Gebhardt BM, Harmmarskjold ML, Kadner RJ (eds). Essentials of Medical Microbiology, fifth edition. 1996, Philadelphia: Lippincott-Raven, pp. 329-347.

Answers to questions

1. This is Staph epi which is almost always resistant to methicillin and cephalosporins.
2. The peritoneal fluid is likely to grow multiple stool organisms. E. coli will predominate. A polymicrobial anaerobic infection is also likely. To properly culture anaerobes, an anaerobic culture swab sent in special anaerobic media (e.g., thioglycolate) must be sent.
3. They are usually polymicrobial and they have a foul odor.
4. Tetanus, botulism, diphtheria, toxic shock, staphylococcal scalded skin syndrome, scarlet fever, etc.
5. Early antibiotic treatment results in a slightly shorter course of symptoms, but the main reason to treat is to prevent suppurative complications and rheumatic fever.
6. Lancefield classification to determine if this organism is group A, group B, etc.
7. Pneumococcus or Staph epi (contaminant).
8. Most likely gram positive cocci is pneumococcal meningitis. Most likely gram negative cocci is meningococcal meningitis.
9. This is an inappropriate order. The stool will be full of enterobacteriacae, anaerobes, and enterococcus. The gram stain will show mostly gram negative rods and perhaps a few gram positive cocci.
10. It is not possible to determine this with certainty in most instances. However, healthy patients who are no longer ill by the time the culture comes back are unlikely to have had Staph epi bacteremia. Thus, in these patients, the Staph epi is most likely a contaminant. In patients with indwelling plastic (central catheters, ventriculoperitoneal shunts), it should be assumed that the Staph epi is a clinically important infection, probably colonizing the plastic tubing.

Chapter VI.3. Fever
Marian E. Melish, MD

A 15 month old boy is brought to the office by his very concerned mother who reports that he has a high fever which doesn't come down even with double doses of acetaminophen and a cold water bath. He has had fever for 24 hours. His temperature has been measured as high as 40.8 degrees (105.4 degrees F). His mother and grandmother have given acetaminophen as directed on the package. When his fever remained over 40 degrees (104 F), they gave a second dose one hour after the first during every 4 hour period over the past day. His last dose was 1 hour prior to your exam. He has also been placed in a cold water bath but he objected so forcefully that it lasted only 5 minutes. Despite the fever he has been playing with his toys but has refused solid foods. He has had some juice. He has urinated slightly less often than usual. He has not vomited, had one normal formed stool today, and does not appear to be in pain although he is more fussy than usual and he appears tired. His mother notes that he is getting a new molar.

His past medical history, family history and review of systems are unremarkable.

Exam: VS T 40.7 (105.3 degrees F), P 185, R 24, BP 95/56, oxygen saturation 99%. He is alert and active, sitting on the exam table playing with a toy car. His movements appear jerky. He cries immediately when touched with a stethoscope and vigorously resists examination. The physical exam is otherwise unremarkable except for the fever and tachycardia.

Your nurse urgently requests permission to give him a dose of ibuprofen and a cold water bath to lower his temperature. His mother is crying, saying, "Do something! The temperature keeps going up. He will go into convulsions or develop brain damage!" What should you do?

Fever is a fascinating phenomenon, highly conserved throughout the animal kingdom as a response to infection and inflammation. Fever in children is associated with many myths and fears which are widely shared by lay people and medical professionals alike. This chapter will review what is known about this "hot topic" and suggests an approach to the questions and concerns above.

Fever is a state of elevated core temperature caused by a complex and highly regulated host response involving cytokines and numerous other acute phase reactants with activation of physiologic, endocrine and immune systems. It is stimulated by the presence of an infectious or inflammatory trigger. The interactions of these triggered host factors result in a change in the normal temperature range which is usually tightly controlled. Fever as a response to an infectious or inflammatory stimulus must be distinguished from hyperthermia caused by exposure to extreme environmental conditions or pathologic responses to anesthetics or drugs.

The measurement of true core temperatures is too invasive for routine clinical use. Core temperatures are best measured in the pulmonary artery or by a deep colonic probe. Even these invasive measurements are not accurate for all parts of the body. For example, in shock or other poor peripheral perfusion states, the temperature of the peripheral sites may be much lower than the core. Conversely, during vigorous exercise the muscle temperature may be considerably higher than the core. There are accuracy problems with all of the proposed formulas for converting a measured temperature at any one site with the temperature at another site or with the theoretical core temperature. Therefore conversion is neither necessary nor appropriate.

The oral temperature as measured under the tongue is the most accurate and practical site for thermometry. Rectal temperature measurements are preferred in infants and children who are too young to cooperate with oral measurements. Rectal temperature measurements are a mean of 0.4 C (0.7 F) degrees higher than oral temperatures. As rectal temperature readings may be affected by the presence or absence of stool in the rectum and peculiarities of local blood flow, oral temperature readings are considered to be the best reflector of core temperature. Tympanic temperature measured with a probe against the tympanic membrane as commonly employed by anesthesiologists is very accurate compared with other core temperature measurements. Recently infrared ear thermometers have become popular because they give very rapid readings. However these commonly available infrared ear thermometers used in clinics, hospital wards, and homes are somewhat inaccurate and show significant variation between measurements. They may read falsely low if the seal in the ear canal is poor (1). I have also encountered falsely elevated readings in multiple patients especially when the instrument is older or malfunctioning. Therefore, an unexpected elevated reading from an infrared ear thermometer should be confirmed with an oral or rectal measurement before embarking on an investigation of fever. Once it is proven that the patient has a fever, infrared ear readings may be used to measure trends in temperature associated with therapy of the basic process as long as one remembers that ear readings are variable and less accurate. Axillary temperature measurements are less accurate. Axillary temperature accuracy can be improved by keeping the thermometer in place for 5 to 12 minutes and holding the arm flexed against the body for the entire period. Skin temperature as measured with temperature sensitive crystals implanted in a strip can approximate the body's temperature, but should not be relied upon to give an accurate temperature.

In two studies, elevated tactile temperatures as measured at home by mothers touching their child's forehead had moderate (46% to 73%) correlation with later documentation of fever in the ED or hospital (2,3). Therefore if tactile fever is reported, later confirmation of either elevated temperature or an abnormal clinical appearance is needed before embarking on an etiologic investigation (4).

The first comprehensive study of temperature variation was published in 1868 by Carl Wunderlich (5,6). It is still the most comprehensive study and involved nearly one million observations in 25,000 subjects. He demonstrated that normal individuals have a range of temperature readings and that there is a diurnal variation with the lowest daily reading falling between 2 and 8 a.m. and the highest readings recorded from 4 to 9 p.m. These studies established the definitions of 37 C (98.6 F) degrees as the normal mean value and 38 C (100.4 F) as the fever threshold. More recent studies using more modern instruments found normal oral temperature to vary between 35.6 C (96.0 F) to 38.2 C (100.8 F) in 700 observations of a sample of 148 normal well young adults. In these adults, the 99th percentile of readings was 37.7 C (99.9 F), the median was 36.8 C (98.2 F), the mode was 36.7 C (98.0 F), and only 8% of the readings were at Wunderlich's normal temperature point of 37 (98.6) (6). These studies confirmed Wunderlich's finding of diurnal variation. Temperature was lowest at 0600 hours and peaked in late afternoon between 1600-1800. The mean difference between lowest and highest daily temperatures in these adult subjects was 0.5 degree C (0.9 degree F). For each individual, there existed a characteristic narrow range or normal set-point of body temperature showing diurnal variation of 0.1 to 1.3 degree C. Body temperature is affected very little by environmental conditions but to a greater degree by vigorous exercise. For a population of normal adults, the range of oral body temperature measurements is wider than the individual variation of 0.5 C, spanning 35.6 to 37.8 C (96.0 to 99.9 F) (the 1st to 99th percentiles) (6). A systematic review of articles published from 1939-1990 showed the range for normal oral temperatures to be somewhat wider 33.2 to 38.2 C, (men: 35.7 to 37.7 C, women: 33.2 to 38.1 C) (7).

There has been less systematic study of normal temperatures in children. It has been suggested that preschool children have a more exaggerated diurnal difference in than adults with higher temperatures late in the afternoon or after physical activity (8). A study of rectal temperatures taken once throughout the day in 671 well infants < 3 months old demonstrated (9):

Age in days	Mean temperature C	Mean + 2 SD
Birth - 30 days	37.4	38.0
31-60 days	37.5	38.1
61-91 days	37.6	38.2

The eruption of new teeth was shown to be associated with a slight increase in temperature within the normal range in 2 studies (10,11). A third study found no evidence for temperature elevation with tooth eruption or the 5 days preceding (12). There is no evidence that teething causes an elevation into the febrile range. The idea that teething causes fever is a widespread folk belief shared by a majority of parents and pediatric dentists but by less than 10% of pediatricians (13).

It remains somewhat uncertain exactly where the febrile range begins but oral temperatures greater than 37.7 degrees C (99.9 F) are greater than the 99th percentile for normal adults. Many lay people and health care professionals regard oral temperature readings between 37 and 38 degrees C (98.6 to 100.4 F) as "low grade fever." This is inappropriate as these values fall within the normal adult range in multiple studies. Temperature readings above the range of 38 to 38.2 C (100.4 -100.8 F) by any route suggest the presence of fever. This definition of the fever threshold is convenient and generally accepted. Certain individuals may have temperature elevations greater than this while being entirely well especially in late afternoon or after vigorous exercise. The presence of sustained fever of any degree indicates a problem which may need evaluation. Recognizing the presence of fever is of significance, but concern about the height of the fever is of less importance since the height of fever by itself is of limited diagnostic value.

Physiology of Fever: Fever producing substances are divided into two categories: those produced outside the body (exogenous pyrogens) and those produced inside the body (endogenous pyrogens). Exogenous pyrogens are usually microorganisms, their components or their extracellular products. Endogenous pyrogens are host cell derived cytokines which are the principal central mediators of the febrile response. The secretion of endogenous pyrogens is induced by both exogenous pyrogens and many endogenous molecules such as antigen-antibody complexes, complement, steroid metabolites, certain bile acids, and many lymphocyte derived molecules. The most prominent currently recognized pyrogenic "pro-inflammatory" cytokines include interleukin-1, tumor necrosis factor alpha, and interferon gamma. Regulation of cytokine secretion is very complex with many interactions between individual molecules and classes of molecules. The initial cytokine mediated rise of core temperature is only one facet of the febrile response. Other physiologic changes which are together called the acute phase response are somnolence, anorexia, changes in plasma proteins, altered synthesis of the hormones ACTH, glucagon, insulin, cortisol, catecholamines, growth hormone, TSH, thyroxin, aldosterone and vasopressin. Hematologic alterations include changes in leukocytes, lymphocytes, platelets and decreased red blood cell formation. Many acute phase proteins are secreted during the febrile response, some of which play a role in modulating inflammation and tissue repair. Pyrogenic cytokines act upon the preoptic region of the anterior hypothalamus of the central nervous system and upon peripheral tissues through specific receptors and pathways which are not yet delineated to produce changes in body temperature and also to limit the height of the fever rise. Thermoregulatory neurons involved in the febrile response are known to be completely inhibited at 41 to 42 C (105.8 to 107.6 F), the ceiling of the natural febrile range. Pyrogenic cytokines are balanced or "braked" by anti-inflammatory cytokines, arginine vasopressin, hypothermic neurochemicals, hypothermic peptides and even some of their shed soluble receptors. Thus, there is a complex and changing interplay of factors influencing the thermoregulatory set-point which causes it to change frequently resulting in the frequent changes in body temperature characteristic of most fevers.

Patterns of Fever: In the febrile state, the temperature is not controlled as tightly as the 0.5 degree C (0.9 degree F) variation that normal adults show during the day. There are several patterns of fever, some of which are associated with particular disease processes. Intermittent fevers are characterized by temperature patterns which dip into the normal range one or more times per day. Remittent fevers demonstrate wide swings in temperature but always remain above 38 (100.4). Hectic or "septic" or "high spiking" fevers show wide swings between highs and lows and may be either intermittent or remittent depending upon whether the low is in the normal range. Sustained fevers have temperatures that are always in the febrile range but vary less than 0.5 C (1 F). Relapsing fevers are recurrent over days to weeks. The pattern of fever has some value in diagnosis although exceptions to the associations are very common. Intermittent fever is associated with the systemic form of juvenile rheumatoid arthritis (Still's disease), miliary tuberculosis, mixed malarial infections, and may be produced with antipyretic therapy. Remittent fevers are associated with many viral infections, acute rheumatic fever, endocarditis with lower grade pathogens and Kawasaki syndrome. Hectic fevers suggest bacterial septicemia, endocarditis with high grade pathogens, occult or deep tissue abscesses, peritonitis, toxic shock syndrome and Kawasaki syndrome. Sustained fevers are associated with typhoid fever, nosocomial infection of devices such as intravenous lines and cerebral spinal fluid shunts. Relapsing fevers are characteristic of malaria, dengue, brucellosis and rat-bite fever.

Knowledge of the patterns of fever is useful in documentation and in describing the patient to others. It is sometimes of value in diagnosis and prognosis. It is important not to describe a patient as "afebrile" unless the temperature is in the normal range for at least an entire 24 hour period. Afebrile literally describes a patient with the "absence of fever," not just a patient whose temperature has briefly fallen into the normal range before it rises again. It is also imprecise to describe a "spiking fever" or a fever "spike" unless the temperature rises several degrees in a short period of time such as 4 hours or less.

Height of Fever and Response to Antipyretics: There is a weak correlation between height of fever and the severity of infection or whether it is viral or bacterial. However, this correlation is so weak that it is not clinically useful, because there is too much overlap between the viral and bacterial infection groups. The overwhelming majority of high fevers are caused by viral agents. Some highly lethal infections such as gram-negative bacterial septicemia may have only modest fever or even, most ominously, hypothermia. Conversely, the very benign and universal Human Herpesvirus (HHV) 6 and 7 or roseola infantum infections are characterized by fevers near the febrile ceiling, 40.5 C (104.9 F) or greater. There is a slightly increased likelihood (from about 4% to 8%) of occult bacteremia in young (6-18 months) children with temperatures over 40.0 C (104 F). However the overwhelming majority of children with high fever have non focal and presumed viral infections. Whether viral or bacterial, serious or trivial, five prospective studies in children have shown that temperature elevations had the same degree of response to antipyretic therapy (14-18). Therefore response or lack of temperature response to antipyretics usually does not distinguish between viral or bacterial infection or between trivial or serious infection. The child's clinical appearance, especially his level of alertness and appropriate social behavior, does help in determining if serious illness is present. Children with severe bacteremic infection still appeared clinically ill after successful fever reduction while the clinical appearance of children with

non-severe infections improved (18). Thus the focus for parents and physicians should be on the child's appearance and behavior, not the height of the fever or presence or absence of response to antipyretics.

A temperature rise is accomplished by increasing heat generation primarily through shivering and decreasing heat dissipation by shunting blood away from the skin surface. Non-shivering thermogenesis is accomplished through many other metabolic processes especially those in brown fat. Patients with a rising temperature are hyperalert, feel jumpy or jittery, complain of cold sensations and have shivering, chills or violent rigors. Temperature lowering is associated with increased heat dissipation at the skin surface with dilatation of surface vessels and sweating which causes further evaporative cooling. Patients feel hot and have profound lassitude which inhibits muscle activity and prevents heat generation. These states alternate as the body temperature rises and falls. The rate at which the temperature changes determines the severity of these symptoms. Chills and shivering are increased and made much more uncomfortable if external cooling is applied.

Is fever harmful? To date there is no clear evidence that fever causes harm to the host. Temperatures of up to 41.5 C (106.7 F) are tolerated without any reported evidence of damage to the brain or other organs (19). Temperature elevations higher than this are not caused by response to an infecting agent but are usually associated with profound failure of thermoregulation such as exposure to extreme heat (heat stroke), severe brain injury with damage to the thermoregulatory center, and adverse reactions to anesthetics or neuroleptic drugs (malignant hyperthermia). There are no reports of brain damage caused by fever as a response to infection in a previously normal individual. Concerns have been expressed that fever may pose an increased stress in seriously ill individuals by increasing metabolic activity, heart rate, and respiratory rate. There is little evidence on this point. One large placebo controlled study of febrile adult ICU patients demonstrated that ibuprofen reduced fever and metabolic rate but had no beneficial effect on survival (20).

Is fever beneficial? There is limited evidence that fever is beneficial. Some animal infection studies have demonstrated a direct association between fever and survival (21-25). Other animal model infection studies demonstrated an increase in mortality if fever was suppressed with antipyretics (26-28). These types of studies have flaws which reduce their applicability to humans especially because some are done in cold blooded animals, some induce elevated temperature with external warming and some use uncommon pathogens. Some studies of patients with severe bacterial infections have shown a direct positive correlation between height of fever and survival (29-34). A controlled study in children with varicella demonstrated both a shorter duration of fever and more rapid healing of lesions in placebo recipients than those treated with acetaminophen. The magnitude of the effect was approximately equal to the effect of antiviral therapy on varicella (35). Two common cold studies showed more severe respiratory symptoms and longer duration of rhinovirus shedding when fever was suppressed with aspirin or acetaminophen (36,37).

Should Fever be treated with Antipyretics? Current clinical practice is that fever reducing drugs are employed routinely, often before any investigation as to the nature or cause of the fever is carried out. The rationale supporting this practice is that it is harmless and increases patient comfort. Indeed, antipyretics are often requested for and given to patients who are perfectly comfortable and have very modest temperature elevation. Patients often initiate antipyretic therapy on their own without medical consultation. It would be unreasonable to seek medical evaluation for all fevers so some degree of discretion needs to be permitted to patients. Some precautions need to be considered when recommending routine antipyretic treatment:

1. Aspirin therapy for fevers of varicella and influenza caused an epidemic of life-threatening Reye's Syndrome.
2. Acetaminophen is an extraordinarily safe drug within its dosing range. However, fatal liver damage from unintentional overdose of acetaminophen for fever has been reported.
3. Case control studies indicate that treatment of the fever of streptococcal toxic shock syndrome with ibuprofen is associated with increased mortality (38-39).
4. Ibuprofen causes platelet inhibition and upon occasion, significant gastrointestinal hemorrhage. Routine use of ibuprofen amplifies this risk.

If patients appear to be very uncomfortable from fever, it is reasonable to administer antipyretics. Antipyretic therapy may also be useful in a febrile child who appears slightly ill with a non-focal examination suggesting a benign illness. The administration of antipyretics with temperature normalization may result in improvement of the patient's behavior and appearance, thus avoiding unnecessary laboratory testing, antibiotics or hospitalization.

Another rationale for the routine use of antipyretic therapy in children under 5 years is that it will reduce the likelihood of febrile seizures. Many febrile seizures occur early in the course of illness with the seizure being the first sign that the child is febrile. In these cases, there is no opportunity for antipyretics to lower the temperature. A study of children with a history of febrile seizures found the recurrent seizure rate to be 5% in children treated with phenobarbital and antipyretics while 25% of those treated with placebo and antipyretics had a recurrent seizure (40). Two placebo controlled studies using standard and high dose acetaminophen during fever failed to show a benefit for the active drug in preventing seizure recurrence (41,42). We have no way of determining which normal child will be affected, but all children do not appear to be at equal risk for febrile seizures. Only 2% of children ever have a seizure while exposure to high body temperature is virtually universal by age 5 years. Although the literature fails to provide evidence that antipyretic therapy prevents recurrent febrile seizures, these seizures are very emotionally distressing to parents. Parents may feel more comfortable if antipyretic therapy is employed. When seizures occur despite appropriate use of antipyretics, parents should be counseled that they did all that was appropriate so that they will not employ excessive treatment with the next febrile illness or suffer unnecessary grief.

Approach to the febrile child: There are several clinical decision rules that are commonly employed in pediatric practice. Following these decision rules constitutes a conservative approach. Highly experienced clinicians may be able to identify low risk individuals who may fit the decision rule, but are unlikely to benefit from their recommendations.

Fever in infants under 8 weeks of age: This generally prompts a sepsis work-up consisting of a CBC, blood culture, catheterized urine culture, urinalysis, chest X-ray (if respiratory symptoms are present), and lumbar puncture. Empiric antibiotics and hospitalization are recommended routinely for this age group; however, children in the 4 to 8 week range have been treated as outpatient in some patient series if the following conditions are met: 1) the sepsis work-up is negative, 2) empiric antibiotics (e.g., ceftriaxone) are given, 3) the infant is feeding well, is not fussy and appears well clinically, 4) parents are assessed to be reliable observers, and 5) a source of reliable primary care is identified. A positive RSV ELISA may be considered to be the source of the fever which would make the infant less likely to benefit from the urine and cerebrospinal fluid studies, however, hospitalization may still be necessary.

Occult urinary tract infection: UTI may be difficult to diagnose in young children. Girls under 24 months of age and boys under 6 months of age with temperatures greater than 39 degrees C (102.2 F) are at modest risk for UTI. Most experts have recommended catheterized urine cultures for this group. Uncircumcised males are at a higher risk (although the magnitude of this additional risk is controversial). Some experts have recommended that uncircumcised boys be checked for UTI up until 24 months of age. Some children

in this age group present with predominant respiratory symptoms (e.g., bronchiolitis), which point to a respiratory source of the fever. One study demonstrated that such patients are at reduced risk for UTI, but it still occurs, therefore urine testing may still be valid even for those with respiratory symptoms (43).

Occult bacteremia: Children from 3 months to 36 months of age with a temperature greater than 39 degrees C (102.2 F) are at risk for occult bacteremia. The risk of this is less than 4% and most cases, result in spontaneous resolution, even without antibiotic therapy. The risk of occult bacteremia is further modified by H. influenzae vaccine, pneumococcal vaccine, age and other factors making this decision complex and the management options controversial.

Otitis media is often diagnosed in febrile children, but it is likely that most cases of otitis media cause only mild degrees of fever. Thus, assuming that a diagnosis of otitis media accounts for the fever, may result in missing a UTI. Although antibiotic treatment for otitis media will frequently treat the UTI as well, if a vesicourinary anomaly is responsible for the UTI, then the patient will be at risk for subsequent recurrent pyelonephritis in the future until the vesicourinary anomaly is identified.

The utility of routine CBCs to identify septic patients has been studied extensively. Because of the excessive overlap of WBC results, CBCs are only occasionally indicative of a serious condition and generally not helpful in identifying septic patients. Clinical appearance (does the child appear to be toxic, lethargic, excessively irritable, or very ill appearing) is the most reliable clinical predictor of sepsis after 2 to 3 months of age.

Fever is a complex and highly regulated host response to a microbial or inflammatory stimulus. Fever is most often related to infection but is also seen prominently in auto-immune and neoplastic disease. Controlling fever should not be a major objective in itself. Although fever is often uncomfortable, it is not medically harmful to the host and may be beneficial. With that in mind we can now answer our mother and the nurse's concerns outlined in the vignette which introduced this chapter. Her son will not become brain-damaged as a result of his fever which is a natural and possibly helpful response to an as yet undiagnosed infection. It is unlikely that her son will have a seizure or "go into convulsions" both because it is statistically unlikely and because he has been febrile for several hours without having had a seizure. His fever will not continue to rise much as he has already approached the natural ceiling for the febrile response. It is more important at this point to assess the cause of the fever with a physical examination and any diagnostic testing which may be indicated, rather than to administer antipyretics. Drastic external cooling measures such as a cooling blanket or a cold water bath are absolutely not indicated and will certainly make the child feel worse (44). He should not be given another dose of acetaminophen as he has already received double doses. His mother must be told that giving more acetaminophen than indicated in future illnesses could cause liver damage. Acetaminophen and ibuprofen appear to be equally effective and safe in fever reduction in children (45,46). There is no reported clinical trial of the safety and efficacy of combining these agents in the symptomatic treatment of fever in children. Since our patient does not appear to be uncomfortable, it is not necessary to give him ibuprofen at this time. Simply dressing him minimally and offering him extra fluids without expecting him to eat solid foods is all that is required for fever treatment. Since he has a normal physical examination and has been previously immunized with Haemophilus influenzae b and pneumococcal conjugate vaccines, he is at very low risk for serious bacterial infection. Once his underlying illness has been fully addressed, ibuprofen therapy may be offered if he appears uncomfortable. It should be stressed that antipyretic therapy is entirely optional and should be given only if he needs relief of noxious fever related symptoms. Given his normal physical exam and age appropriate behavior, he most likely has an HHV 6 or 7 roseola related illness. Considering all that is known about temperature regulation in the febrile response, the control of the typically high fever characteristic of this illness rests more with the patient's physiology than with the influence of his mother or the medical profession. In evaluating any patient with fever it is of paramount importance to remember that fever is a sign of disease and not the disease process itself.

Notes:
Acetaminophen is generically also called APAP (abbreviation) and paracetamol (other countries).
The formula to convert degrees F to degrees C is TempC = (TempF - 32)/1.8
The formula to convert degrees C to degrees F is TempF = (TempC X 1.8) + 32

Questions

1. True/False: Defining an elevated temperature is difficult and variable because the "normal" core temperature is not a fixed value, and the methods of measuring temperature have varying degrees of accuracy.

2. Which of the following is true?
   a. Treating fever with antipyretics is clearly harmful and should be always discouraged.
   b. Treating fever with antipyretics is clearly beneficial, without adverse effects and should always be recommended.
   c. Treating fever with antipyretics is optional.
   d. None of the above.

3. True/False: Temperatures above 40 degrees C (104 F) result in febrile seizures in most patients.

4. True/False: Ibuprofen has a superior antipyretic effect compared to acetaminophen.

5. Febrile children at risk for occult urinary tract infection include those with a temperature above 39 degrees C. What is the commonly used age ceiling for boys and for girls?

6. True/False: Teething is known to cause fever.

7. True/False: The diagnosis of acute otitis media is a reliable explanation for a high fever, thus eliminating the need to for other diagnostic considerations in a patient with an otherwise benign examination.

8. True/False: High fever may cause brain damage.

Answers to questions
1. True
2. c
3. False
4. False
5. 6 months for boys, 24 months for girls.
6. False. At the most, teething might causes a very slight temperature elevation.
7. False. Otitis media is not considered to be a reliable source of causing a high fever. Other conditions, such as UTI, need to be considered.
8. False.

Chapter VI.4. Inhibitory and Bactericidal Principles (MIC & MBC)

Loren G. Yamamoto, MD, MPH, MBA

A 7 year old male presents to his physician's office with thigh pain and fever since yesterday afternoon. He has a minimal limp and no history of trauma.

Exam VS T37.5, HR 90, RR 18, BP 110/70. He is alert and not toxic. His exam findings are only positive for tenderness in his mid femur region. His hip exam is normal. He has no skin sores, bruises or other areas of tenderness. His gait appears to be normal except for an occasional suggestion of a limp.

Plain radiographs of his femur and hip are normal. His CRP and ESR are high so a bone scan is obtained that afternoon which shows a hot spot in his mid femur. He is hospitalized for acute osteomyelitis. He is initially treated with IV vancomycin. An orthopedic procedure is performed to drain some pus and to obtain a culture and biopsy. On hospital day 3, his clinical condition is improved. Cultures of his blood and the bone aspirate grow Staph aureus which is sensitive to cephalosporins and methicillin. His antibiotics are changed to IV oxacillin. He continues to improve. Consultants recommend that he be treated for 6 weeks with IV antibiotics. His medical insurance company approves inpatient antibiotics for 7 days and requests that the remainder of his antibiotics be administered as an outpatient. Is there a rational method to provide him with inpatient levels of antibiotics as an outpatient?

Each bacteria has a level of antibiotic which will inhibit growth but not kill the organisms. This is called the minimum inhibitory concentration (MIC). Related to this, a higher antibiotic concentration will kill the organisms. This is called the minimum bactericidal concentration (MBC). By understanding the concepts in determining antibiotic concentrations compared to the MIC and MBC, we can make rational decisions in determining how successful antibiotic treatment is likely to be.

Pharmacologists have taught us that some antibiotics are "bactericidal" and some are "bacteriostatic". These terms are slight misnomers since all antibiotics are potentially bactericidal and bacteriostatic at different concentrations. The "bactericidal" and "bacteriostatic" terminology originates from whether the antibiotic's mechanism is based on inhibiting cell wall formation ("bactericidal") or inhibiting bacterial metabolism or ribosomal protein synthesis ("bacteriostatic"). The idea is that if cell wall formation is blocked, the organisms will lyse and perish, but if metabolism or protein synthesis is blocked, the organisms merely slow down. While this is true to some degree, bactericidal or bacteriostatic outcomes are dependent on the concentration of the antibiotic as well. A low dose of a "bactericidal" antibiotic may only inhibit bacterial growth, while a high dose of a "bacteriostatic" antibiotic will be bactericidal. Additionally, organisms which are not proliferating may not be significantly affected by anti-cell wall antibiotics, in which case anti-ribosomal antibiotics would be more effective.

An example of this is the effect of bug spray on a cockroach. A light spray will only slow the cockroach down (a cockroach-static level). By tomorrow, the cockroach will recover. However, if one drowns the cockroach in bug spray (a cockroach-cidal level), the cockroach will perish.

Modern laboratory methods can rapidly determine the MIC and MBC for cultured organisms for multiple antibiotics simultaneously. However, to understand this better, the following clinical example will be used to demonstrate these concepts. Refer to the table below:

Tube	Antibiotic Concentration	Day 2	Day 4
1	10.0	Clear	Clear
2	5.0	Clear	Clear
3	2.0	Clear	Turbid
4	1.0	Clear	Turbid
5	0.5	Turbid	------
6	0.2	Turbid	------

The table above is an example which describes the result of MIC/MBC determinations for an organism from our patient with a hypothetical antibiotic. There are six tubes with varying concentrations of antibiotic in a bacterial culture broth. Tube 1 contains the highest concentration of antibiotic and tube 6 contains the lowest concentration of antibiotic. The organism is inoculated into all 6 tubes. After a 2 day incubation, the first 4 tubes are clear (which indicates that the organisms did not grow in these tubes). Tubes 5 and 6 are turbid due to bacterial growth which means that an antibiotic concentration of 0.5 is neither inhibitory nor bactericidal.

For tubes 1, 2, 3 and 4, it is not known whether the organisms present in these tubes have died (bactericidal concentration) or their growth is merely inhibited (inhibitory concentration). These tubes contain either dead organisms or viable growth-inhibited organisms. The next step is to centrifuge tubes 1 through 4. All solid debris (dead or alive organisms) will be centrifuged to the bottom of the tube. After centrifugation, the supernatant containing the antibiotic is poured off. Fresh broth without antibiotic is now added to the tubes. After another two days of incubation (on day 4), tubes 1 and 2 are clear, while tubes 3 and 4 are turbid. This means that tubes 3 and 4 contained viable organisms which were inhibited by the antibiotic, but now that the antibiotic is gone, they are able to grow. Tubes 1 and 2 are still clear which means that all organisms in these tubes were killed. Thus tubes 3 and 4 contain inhibitory concentrations of antibiotic, while tubes 1 and 2 contain bactericidal concentrations of antibiotic. Thus, the minimum inhibitory concentration (MIC) of this organism for this antibiotic is 1.0 (tube 4), while the minimum bactericidal concentration (MBC) of this organism for this antibiotic is 5.0 (tube 2).

Now that we know the MIC and MBC for this organism and this antibiotic, we can put the patient on oral antibiotics and see what antibiotic levels can be achieved in the patient's bloodstream. We could measure an antibiotic level 1-2 hours after an antibiotic dose is given (peak level) and one hour before the next antibiotic dose is given (trough level). At a minimum, the tough level should be above the MIC and the peak level should be above the MBC. In practice, the peak level should be several times higher (e.g., 8 times higher) than the MBC, depending on the type of infection. If such levels cannot be obtained by oral antibiotics, then IV antibiotics must be maintained for the duration of therapy.

Most clinical laboratories are not able to measure levels of all antibiotics. For example, a clindamycin or a trimethoprim/sulfamethoxazole level may not be available. If preliminary sensitivity testing shows drug sensitivities to such antibiotics, a different method may be necessary to determine if satisfactory MICs and MBCs can be obtained with these antibiotics. This is called the Schlichter test, which is demonstrated in the example below:

Peak Tube	Peak serum Dilution	Day 2	Day 4
1	1:2	Clear	Clear
2	1:4	Clear	Clear
3	1:8	Clear	Clear
4	1:16	Clear	Turbid
5	1:32	Clear	Turbid
6	1:64	Turbid	------

Trough Tube	Peak serum Dilution	Day 2	Day 4
A	1:2	Clear	Clear
B	1:4	Clear	Clear
C	1:8	Clear	Turbid
D	1:16	Clear	Turbid
E	1:32	Turbid	------
F	1:64	Turbid	------

The tables above are an example which describes the result of MIC/MBC determinations for an organism from our patient with a hypothetical antibiotic for which, antibiotic levels are not routinely available in the clinical lab. There are six tubes with varying dilutions of the patient's serum mixed with culture broth. Tubes 1-6 are drawn just after the patient receives an antibiotic dose (peak level). Tubes A-F are drawn just before the patient receives an antibiotic dose (trough level). Tube 1 contains the highest concentration of antibiotic for the peak levels. Tube A contains the highest concentration of antibiotic for the trough levels.

The organism is inoculated into all 6 tubes for peak and tough. After two days of incubation, tube 6 is turbid for the peak tubes, and tubes E and F are turbid for the trough tubes. For these turbid tubes, we know that active bacterial growth has taken place so these dilutions are neither inhibitory nor bactericidal.

For tubes 1, 2, 3, 4, 5 for the peak tubes, and tubes A, B, C, D for the trough tubes, it is not known whether the organisms present in these tubes have died (bactericidal concentration) or their growth is merely inhibited (inhibitory concentration). These tubes contain either dead organisms or viable growth-inhibited organisms. The next step is to centrifuge tubes 1, 2, 3, 4, 5 for the peak tubes, and tubes A, B, C, D for the trough tubes. All solid debris (dead or alive organisms plus some blood cells) will be centrifuged to the bottom of the tube.

After centrifugation, the supernatant containing the antibiotic (from the patient's serum) is poured off. Fresh broth without antibiotic is now added to the tubes.

For the peak and trough tubes, after another two days of incubation (on day 4), tubes 1, 2, 3, A, B are clear, while tubes 4, 5, C, D are turbid. This means that turbid tubes 4, 5, C, D contained viable organisms which were inhibited by the antibiotic (in the patient's serum), but now that the antibiotic is gone, they are able to grow. Tubes 1, 2, 4, A and B are still clear which means that all organisms in these tubes were killed. Thus tubes 4, 5, C and D contain inhibitory concentrations of antibiotic, while tubes 1, 2, 3, A and B contain bactericidal concentrations of antibiotic. Thus, the minimum inhibitory concentration (MIC) of this organism for this antibiotic is occurs at a 1:32 dilution (tube 5) at peak antibiotic levels, and 1:16 dilution (tube D) at trough antibiotic levels, while the minimum bactericidal concentration (MBC) of this organism for this antibiotic is 1:8 dilution (tube 3) at peak antibiotic levels, and 1:4 dilution (B) at trough antibiotic levels.

What does this mean? This data tells us that the antibiotic blood levels exceed the MBC 4 to 8 times from trough to peak. This is excellent. However, for an infection such as osteomyelitis, bone levels are not necessarily the same as blood levels. Thus, blood levels well in excess of MBC and MIC are desirable. If such levels can be demonstrated with oral antibiotics using these tests, then the patient can be treated with oral antibiotics as an outpatient, and therapeutic success is more certain. Thus our patient does not need to remain in the hospital for 6 weeks of IV antibiotics. He can be discharged and take antibiotics at home. This is much less costly and it should be just as effective as long as the patient is compliant.

The utilization of MIC/MBC data and the Schlichter test is complex and controversial. The most common infections which require very long antibiotic courses (4 to 6 weeks) are bone and joint infections (osteomyelitis and septic arthritis) and bacterial endocarditis. While still controversial, peak drug levels 8 times the MBC are felt to be the minimum levels to predict therapeutic success for these infections. Peak levels below this may be insufficient. In general, higher levels are better, and some organisms typically require higher levels than other organisms.

Questions

1. How does a bacteriostatic antibiotic behave in a bactericidal fashion?
2. How does a bactericidal antibiotic behave in a bacteriostatic fashion?
3. Do all infections require MIC/MBC or Schlichter tests? Why or why not?
4. When should a Schlichter test be performed?
5. When is it NOT possible to perform MIC/MBC determination testing?
6. If the infection is in bone (osteomyelitis), in joint fluid (septic arthritis), in urine (UTI), or in any body space, how can we be sure that adequate antibiotic levels are obtained if we are only able to measure MIC/MBC in the blood?

Answers to questions

1. When the level of the antibiotic is so high that all organisms are killed.
2. When the level of the antibiotic is so low that organism growth is inhibited, but they are not killed.
3. No. MIC/MBC or Schlichter tests are only useful when a very long course of antibiotics are anticipated and the patient must be changed to oral antibiotics to complete the antibiotic course as an outpatient. These tests are necessary to determine if it is possible to attain sufficient blood levels with the oral antibiotics to predict therapeutic success. The most common clinical scenarios would be for osteomyelitis, septic arthritis and bacterial endocarditis.
4. A Schlichter test should be performed when the lab is unable to measure levels of the antibiotic that is to be used.
5. When we don't have an organism (cultures are negative).
6. We are never totally sure. We do know that compared to blood levels, most antibiotics have lower levels in bone and in joint fluid, but higher levels in urine.

Chapter VI.5. Antibiotics
Loren G. Yamamoto, MD, MPH, MBA

A 7 year old presents to the emergency department with fever and an expanding area of redness over his left calf. He has had fever for only 8 hours with a maximum temperature of 39 degrees C. He had a bug bite on his left calf three days ago. It now appears to be infected and painful. There is no pus, but overnight, there is a large area of redness noted with slight swelling. Because of these symptoms, he is brought to the emergency room.

Exam VS T 38.5, HR 90, RR 24, BP 100/65. He is alert and not toxic. His HEENT, heart, lung and abdominal exam findings are unremarkable. His left lower extremity is negative for any lymphangitis or lymphadenopathy. There is a 6 by 12 cm oval region of erythroderma with a sharply demarcated border over his mid lateral calf. There is a central skin sore which does not appear to excessively swollen. There is no fluctuance or drainage. There is mild tenderness within the red region. There is no bony tenderness and he is able to ambulate normal.

A culture of the central skin lesion is obtained. A blood culture is also obtained. He is given a dose of IV clindamycin and he is prescribed a course of oral clindamycin. His conditions improves the next day. His skin sore culture grows beta hemolytic group A streptococci. His blood culture is negative. His antibiotic treatment is changed to penicillin and he has a full recovery.

Antibiotics are one of the most important classes of medications prescribed by physicians. When you consider the major classes of pharmacologic agents which are used to treat children, you will find that there are only a few classes of drugs which are used frequently. These include antipyretic/analgesics, antibiotics, bronchodilators and a few others which are less common such as corticosteroids, anesthetics, cardiac medications, etc. Thus, out of the three large classes of drugs which are frequently used for children, antibiotics are a major group. Proper antibiotic prescribing is an important medical practice skill.

The most important item of information is to be able to use an antibiotic which satisfactorily cures the patient of an infection. While the mechanism of action of the different antibiotics are important, this is not as important in most instances. Antibiotic therapy is initiated in three basic ways: 1) empiric therapy, 2) specific therapy, 3) prophylaxis.

Empiric therapy is the selection of treatment based on clinical and laboratory information with the exception of culture and sensitivity information. Specific therapy is the selection of an antibiotic based on the culture and sensitivity testing of the organism causing the infection. Prophylaxis is the use of antibiotics to prevent an infection which is anticipated.

Empiric therapy is based on a three step process: 1) identifying a clinical entity, 2) knowing which organisms cause this entity, 3) selecting an antibiotic which covers these organisms. Some physicians use a two step process which is to identify the clinical entity, then select an antibiotic which is commonly used for this entity. I would prefer that students and physicians in training learn the three step process because it is a deeper level of understanding. The three step method is a universal approach which will always work as the future challenges us with changes in antimicrobial resistance patterns, newly developed antibiotics, insurance company drug coverage restrictions, side effect profiles, allergies, compliance issues, etc. The two step process is similar to following a cook book without understanding it.

Many students have learned simple rules to select antibiotics. Unfortunately, simple rules usually DO NOT work. A commonly taught rule is that penicillins and cephalosporins (which inhibit peptidoglycan synthesis) work for gram positive organisms, while aminoglycosides (which inhibit bacterial ribosome function) work for gram negative organisms. This is often true, but it is an oversimplification which has too many exceptions for this rule to be useful. This rule is based on the premise that gram positive organisms are more dependent on peptidoglycan cell wall synthesis (that's why they stain gram positive), while gram negative organisms are not as dependent on peptidoglycan cell wall synthesis. Staphylococcus aureus is a gram positive organism which is highly resistant to penicillin. Staph aureus is usually sensitive to penicillinase resistant penicillins and cephalosporins, but resistance to these is becoming more frequent (25% or more). Aminoglycosides such as gentamicin cover Staph aureus with a much higher frequency than cephalosporins. Neisseria gonorrhoeae is a gram negative organism for which the treatment of choice is ceftriaxone. Neisseria gonorrhoeae used to be treated with penicillin, but the emergence of PPNG (penicillinase producing Neisseria gonorrhoeae) has rendered penicillin ineffective. Staphylococcus epidermidis is a gram positive organism which is highly resistant to penicillins and cephalosporins. Staph epi must generally be treated with vancomycin.

Are there any simple rules which work? Unfortunately, no. However, it is a certainty that antibiotic resistance patterns will change and new antibiotics will be developed. The best way to learn the three step process is to do it frequently. If you do it again and again, it will become routine and relatively easy.

Empiric therapy is generally used first. Handbooks on antimicrobial therapy are commonly available. Such a handbook will provide useful information in learning the three step process. Most handbooks have three separate listings:

1. A list of clinical infections and most commonly used antibiotics for these infections.
2. A list of clinical infections and the common organisms which cause these infections.
3. A list of organisms and their usual sensitivity and resistance patterns (this is often a table). Similarly, most hospitals publish annual sensitivity and resistance percentages of the organisms which have been cultured in the clinical laboratory. These hospital results would be the most current and community specific sensitivity and resistance patterns for the organisms that are likely to be affecting your patients.

The first listing (#1 above) is the two step method of selecting antibiotics. Once a clinical entity is identified, then an antibiotic from this listing can be selected.

Items #2 and #3 above, are necessary for the three step method. Although this may seem a longer process at first, it will provide students and physicians in training with a better understanding of antibiotic use. After utilizing the three step method frequently, you will become very good at this, and most antibiotic decisions in the future will not require the assistance of a handbook, The three step process described below:

Step 1. Identification of a clinical entity. A history and examination provides clinical information. Sometimes laboratory and imaging information may also be necessary to add more certainty to a diagnosis. Such an entity may be cellulitis, otitis media, pneumonia, osteomyelitis, gastroenteritis, pelvic inflammatory disease, urinary tract infection, rule out sepsis, etc.

Step 2. What organisms cause this entity? For an entity such as cellulitis, we know that the most common organisms are group A streptococci and staphylococcus aureus.

Step 3. Select an antibiotic which covers the organisms which are potentially causing the infection. Group A strep is sensitive to all penicillins and cephalosporins. Staph aureus is usually sensitive to cephalosporins and penicillinase resistant penicillins such as oxacillin and cloxacillin. However, there is growing staph aureus resistance to these drugs (currently about 25% or more). Staph aureus is about 95% sensitive to clindamycin and this also covers group A strep. Thus, clindamycin appears to be the best choice to treat cellulitis in this instance. Another consideration is the severity of the infection. For a life threatening infection such as bacterial meningitis, there must be the certainty of 100% coverage. Thus, initial broad spectrum or multiple antibiotics may need to be used empirically. As opposed to a less serious infection such as otitis media or impetigo, in which case 80% coverage certainty may be sufficient.

It is possible to stratify this further. A more experienced physician examines the cellulitis and indicates that this cellulitis is caused by group A strep which more commonly causes large areas of erythroderma surrounding a single skin sore. Staph aureus cellulitis is usually associated with suppuration and a smaller area of redness and induration surrounding a central abscess. Thus, clinically, one could be more certain that this is a group A strep cellulitis which can be treated with penicillin. In the case, the patient was initially treated with IV clindamycin because high antibiotic levels are immediately achieved to be followed by a course of oral clindamycin. When the results of the culture returned identifying the organism and its sensitivity to penicillin, the patient could then be changed to specific therapy with penicillin.

Specific therapy utilizes culture and sensitivity information which is usually available 1 to 3 days later. The general principle is to select the antibiotic which is the most effective with the least side effects. Additionally, it may be preferable to select the antibiotic with the most narrow spectrum to reduce the likelihood of significantly altering the patient's normal flora. Sometimes, physicians may be limited by cost and compliance issues. For example, there may be two possible treatments; one which is B.I.D. costing $80 and another which is Q.I.D costing $10. One is less expensive, but it may be more difficult to ensure compliance. Such decisions are judgments which physicians must make in conjunction with patient preferences.

Prophylaxis is the utilization of antibiotics for an infection which is anticipated. An example would be a dog bite wound in which an infection is anticipated several days later. In addition to cleansing and irrigating the wound, antibiotics may be able to reduce the patient's risk of infection. Patients with vesicoureteral reflux are at greater risk for urinary tract infections. Thus, placing these patients on prophylactic antibiotics (usually once a day or twice a day) will reduce their likelihood of acquiring a UTI. Patients with rheumatic fever and subsequent rheumatic heart disease are at risk for worsening heart disease if another group A streptococcal infection is acquired. Thus, such patients are placed on daily oral penicillin or monthly long acting benzathine penicillin injections to prevent group A streptococcal infections.

New antibiotics will be developed in the future. As a preliminary discussion, antibiotics can be classified into 7 groups: penicillins, cephalosporins, aminoglycosides, sulfonamides, quinolones, macrolides and other.

Penicillins

Penicillins inhibit bacterial cell wall formation by inhibiting peptidoglycan synthesis. Penicillins can be further classified into three groups: penicillin, broad spectrum penicillins and anti-staph aureus penicillins. Penicillin typically covers group A and group B streptococci, most pneumococci, Neisseria meningitidis, Pasteurella multocida, Listeria and most anaerobes (with the exception of bacteroides fragilis). Broad spectrum penicillins include amoxicillin, ampicillin, carbenicillin, ticarcillin, piperacillin, azlocillin, mezlocillin, etc. This group covers more gram negative organisms such as E. coli, Proteus, Klebsiella, etc. With the exception of amoxicillin and ampicillin, the other broad spectrum penicillins cover pseudomonas as well. Broad spectrum penicillins can be combined with penicillinase inhibitors such as clavulanate and sulbactam. These combinations drug such as Augmentin (amoxicillin/clavulanate), Unasyn (ampicillin/sulbactam), Timentin (ticarcillin/clavulanate) and Zosyn (piperacillin/tazobactam) cover most staph aureus (but not MRSA) and other penicillinase producing organisms such as beta-lactamase producing Haemophilus influenzae B.

It should be noted that amoxicillin is metabolized to ampicillin in the bloodstream. Thus, these two antibiotics have identical coverage. Amoxicillin is better absorbed from the GI tract which is why amoxicillin should be favored via the PO route (except for GI infections) over ampicillin, and ampicillin should be favored via the IV route (amoxicillin is no longer available IV).

The anti-staph aureus penicillins are also called the penicillinase resistant penicillins which include methicillin, oxacillin, nafcillin, cloxacillin, dicloxacillin. These drugs are targeted against staph aureus which is why this group should more accurately called the anti-staph aureus penicillins. Methicillin resistant staph aureus (MRSA) is resistant to all the penicillins in this group. About 25% or more of staph aureus are currently MRSA. The term "penicillinase resistant penicillins" is a misnomer. It is true that staph aureus is penicillin resistant because of penicillinase production, but the term "penicillinase resistant penicillins" implies that they will cover all penicillinase producing organisms, but they do not cover penicillinase producing Neisseria gonorrhoeae, Haemophilus influenzae, Bacteroides fragilis, and many other penicillinase producing organisms. Thus, this group should be more appropriately called the anti-staph aureus penicillins, because the only penicillinase producing organism which they cover to a moderate degree is staph aureus.

Cephalosporins

Cephalosporins are structurally similar to penicillins with a similar mechanism of action. Cephalosporins are difficult to learn because there are many of them and new ones are frequently introduced. The "generation" of cephalosporins is only slightly helpful. In general, all cephalosporins cover all penicillin sensitive organisms with the exception of Listeria and Pasteurella. Coverage for group B streptococci is better with penicillin than with cephalosporins. Cephalosporins also cover many gram negative organisms such as E. coli, Klebsiella, Proteus, etc. Cephalosporins also cover staph aureus, but only to a similar degree as the anti-staph aureus penicillins (i.e., MRSA is cephalosporin resistant as well). Two generalizations that usually hold true are: 1) lower generations of cephalosporins cover staph and strep better than the higher generation cephalosporins (but staph and strep coverage with high generation cephalosporins is still generally adequate), and 2) higher generations of cephalosporins have extended coverage of gram negative organisms. Unfortunately, the "generation" of cephalosporins does not provide clinicians with specific properties which permit us to use any drug in the same generation. Within the higher generations, each cephalosporin has specific properties which make one more useful than others. In my view, using the generation of the cephalosporin is NOT the best way to learn how to use cephalosporins. The best way to select cephalosporins, is to learn the properties of a single first generation cephalosporin, then find other useful clinical properties of another cephalosporin which provides clinicians with a useful clinical advantage. If a cephalosporin has no clinically useful advantages which separate it from other cephalosporins, then we should purge it from our memory.

The prototype first generation cephalosporin is cefazolin (Kefzol and Ancef are trade names), which is for IV use. Cephalexin (Keflex trade name) is an oral first generation cephalosporin with an essentially identical spectrum. These drugs have the basic cephalosporin coverage described above.

What if we needed coverage for anaerobes? Then we would use IV cefotetan (Cefotan) or cefoxitin (Mefoxin), since these cephalosporins cover most anaerobes (but not 100%). Thus, these cephalosporins would be preferred for appendectomy prophylaxis.

What if we needed Haemophilus influenzae or Moraxella catarrhalis coverage? Then we would use IV cefuroxime (Zinacef), cefotaxime (Claforan) or ceftriaxone (Rocephin). We could also use oral cefuroxime (Ceftin) or cefaclor (Ceclor).

What if we needed to cover meningitis? We need the additional property of penetration through the blood brain barrier into the CNS and CSF. Although cefuroxime covers all the meningitis organisms, it does NOT penetrate the blood brain barrier as well as cefotaxime and ceftriaxone, therefore, one of these two latter drugs would be preferable.

What if we needed pseudomonas coverage? Then we would use ceftazidime (Fortaz) since this is one of the few cephalosporins with pseudomonas coverage.

What if we wanted to treat an infection as an outpatient, but we wanted to be certain that high antibiotic levels would be maintained for at least 24 hours (similar to an over night hospitalization for IV antibiotics)? Then we would use ceftriaxone (Rocephin) since it has a long half-life and its usual dosing interval is every 12 to 24 hours. Thus, giving a single dose of IM or IV ceftriaxone, results in antibiotic levels which would be similar to an overnight hospitalization with IV antibiotics, at a substantially lower cost since it can be done as an outpatient.

Thus, as a simplification, the only IV cephalosporins we need to know for pediatrics are cefazolin (first generation), cefotetan (better anaerobe coverage), ceftriaxone (extended coverage which includes Haemophilus influenzae and Moraxella, good blood brain barrier penetration, and a long duration of action), and ceftazidime (pseudomonas coverage). The only oral cephalosporins we need to know are cephalexin (first generation), cefuroxime (extended coverage) and perhaps cefixime (once a day dosing often recommended for UTI). Other cephalosporins are less important. We will still be exposed to them, because other physicians will prescribe them, and there are additional subtle factors which may slightly favor other cephalosporins. But for most clinical applications, the above will suffice.

Aminoglycosides

Aminoglycosides inhibit bacterial ribosomal function. Aminoglycosides are more toxic than penicillins and cephalosporins. Thus, they must be maintained within a certain therapeutic range. At high levels, aminoglycosides are nephrotoxic and ototoxic. These drugs are also weak neuromuscular blocking agents so they can cause respiratory depression or apnea if given in to a patient with neuromuscular compromise (e.g., early infant botulism, Guillain Barre syndrome, severe myopathies, etc.).

Aminoglycosides are generally directed at gram negative organisms (especially the Enterobacteriacae, also known as stool germs). However, aminoglycosides also cover gram positive organisms such as Staph aureus and many streptococci. In fact, while Staph aureus may be 25% resistant to the anti-staph aureus penicillins and cephalosporins, Staph aureus resistance to aminoglycosides is 10% or less.

Gentamicin is the most basic aminoglycoside. Other aminoglycosides with extended coverage include tobramycin and amikacin. Note the spelling of Gentamicin compared to tobramycin. The difference is the "micin" (no "y"). Gentamicin is commonly misspelled. Tobramycin and amikacin have extended gram negative coverage which includes most pseudomonas.

Sulfonamides

Most sulfonamides inhibit various steps in metabolic pathways such as those which inhibit folate metabolism. The popular combination drug trimethoprim-sulfamethoxazole inhibits folate metabolism at two points. Sulfonamides are inexpensive and they have a broad spectrum. Sulfonamides are usually used for gram negative infections such as urinary tract infections; however, they cover many gram positives, such as Staph aureus well. This is an ideal combination of effective broad coverage and low cost, except that sulfonamides have a slightly higher risk of severe drug reactions such as Stevens-Johnson syndrome. Additionally, sulfonamides result in acute hemolytic reactions in some patients with G6PD deficiency. Since we usually don't know who has G6PD deficiency and Stevens-Johnson syndrome can result in death or severe morbidity, these factors have tempered the popularity of sulfonamides. Law suits involving sulfonamides suggest that malpractice occurs when the clinicians fails to warn the patient of adverse reactions such as hemolytic reactions and Stevens-Johnson syndrome. Thus, if you intend to prescribe a sulfonamide to a patient, you must inform them of these risks (blood reaction if they have a hidden blood problem, or a severe allergic reaction which can result in death). In most instances after being informed of such risks, patients will prefer alternative antibiotics which have similar coverage and less side effects. In most instances, other antibiotics can provide the same coverage with less risk and similar cost. However, in patients with allergies to other antibiotics, sulfonamides may be useful. Additionally, if the patient's medical history indicates that they have used a sulfonamide in the past without problems, then their risk of an adverse reaction is substantially lower.

Quinolones

This class of antibiotics are related structurally to nalidixic acid. These drugs inhibit bacterial DNA synthesis by inhibiting B-subunit of DNA gyrase, an essential enzyme that allows DNA supercoils to be relaxed and reformed. Quinolones such as ciprofloxacin, norfloxacin and levofloxacin are very broad spectrum with coverage against Staph aureus (including MRSA), pneumococcus, Haemophilus influenzae, Mycoplasma, Chlamydia, gram negative enterics, Pseudomonas, etc.. Their main indication is in resistant urinary tract infections, but their broad spectrum makes them effective in other conditions. Their use is limited in pediatrics since they are currently contraindicated in children and pregnant women, because these drugs have impaired bone growth in laboratory animals.

Carbapenems

This new class of antibiotics target bacterial cell wall synthesis by inhibiting the transpeptidase enzymes required for peptidoglycan cross-linking. These drugs are very broad spectrum similar to high generation cephalosporins. Examples include imipenem and meropenem. These drugs have not been used commonly in pediatrics since they are most commonly used in highly resistant adult infections.

Macrolides and others.

The typical macrolide is erythromycin. These drugs inhibit bacterial ribosomal function. These drugs cover most streptococci and some Staph aureus. They also cover many atypical organisms such as Mycoplasma, Chlamydia, Legionella, Bordetella, Yersinia, Campylobacter, and Tularemia. Erythromycin ethylsuccinate (EES) and erythromycin estolate (also known as erythromycin propyl-laurel sulfate, or Ilosone) are commonly used. EES has less hepatic toxicity. Erythromycin estolate gets higher tissue levels and is commonly recommended for pertussis. Newer and more expensive erythromycins such as azithromycin and clarithromycin have broader coverage, less side effects and more convenient dosing. Azithromycin is dosed once a day for 5 days to give 10 days of clinical efficacy.

The tetracycline family (tetracycline, doxycycline, minocycline, etc.) shares some properties with erythromycins in that they inhibit bacterial ribosomal function and cover many of the same atypical organisms. Tetracyclines tend to be photosensitizers which limits their use in Hawaii. Tetracycline use is discouraged in children because it causes staining of teeth, hypoplasia of dental enamel, and abnormal bone growth in children.

Vancomycin is a glycopeptide which inhibits bacterial cell wall synthesis. It is available for IV since it is not absorbed from the GI tract. Vancomycin is broad spectrum and its major pediatric application is to cover resistant Staph aureus (MRSA) and resistant pneumococci. Vancomycin use is associated with a "red man syndrome" which is a histamine like reaction that can be inhibited by pretreatment with diphenhydramine and slowing the IV administration rate of the vancomycin. Vancomycin can also be given orally for pseudomembranous colitis caused by Clostridium difficile.

Clindamycin inhibits bacterial ribosomal function. It covers most streptococci and Staph aureus. Clindamycin covers most MRSA, but not 100%. If 100% coverage for Staph aureus is needed, then vancomycin is indicated. Clindamycin is a useful for the outpatient treatment of cellulitis and other infections commonly caused by group A strep and Staph aureus. Staph aureus resistance to clindamycin is present, but it is uncommon. Many clinicians treat cellulitis and other suspected outpatient Staph aureus conditions with clindamycin instead of cephalosporins since resistance to cephalosporins is too frequent. Clindamycin is also used for coverage of anaerobes including Bacteroides fragilis.

Chloramphenicol inhibits bacterial ribosomal function. Chloramphenicol is used infrequently because it has the potential to cause irreversible bone marrow suppression. It more commonly causes reversible bone marrow suppression which is not nearly as severe. Chloramphenicol covers all anaerobes similar to Clindamycin. Chloramphenicol crosses the blood brain barrier well and penetrates into the CSF, so it was frequently used to treat meningitis. Chloramphenicol has the unusual property of attaining high serum levels from oral administration. Most other drugs require IV administration to get high serum levels. When I was a resident in the early 80's, all children with bacterial meningitis would be treated initially with ampicillin and chloramphenicol. If the organism was resistant to ampicillin, then chloramphenicol would be used. These children could actually be switched over to oral chloramphenicol if starting an IV was difficult. CBCs would be checked daily or every other day to check for bone marrow suppression. Cephalosporins and vancomycin have largely replaced these older drugs to treat meningitis.

Metronidazole (Flagyl) is a anti-parasitic anti-amebic drug, but it also has nearly complete coverage of anaerobes. Thus, when 100% anaerobe coverage is required, the options include metronidazole, clindamycin or chloramphenicol. The broad spectrum penicillins in combination with clavulanate or sulbactam may also cover anaerobes sufficiently.

Questions

1. How many generations of cephalosporins are there?
2. Can the generation of the cephalosporin (in itself) be the sole selection criteria for a particular clinical situation?
3. List some organisms which cause the following entities: osteomyelitis, bacterial meningitis.
4. What empiric antibiotic(s) could be used to cover the organisms in the above question?
5. Select an empiric antibiotic for a 10 year old female who has a small pneumonia on chest x-ray. She is afebrile and has a frequent non-productive cough.
6. Select an empiric antibiotic for an 18 month old female with fever and pyuria on UA (i.e., suspected UTI)?
7. You decide to prescribe an erythromycin to a patient. You could prescribe erythromycin ethylsuccinate (EES) which is $10 for 40 tabs (1 tab q.i.d. for 10 days), or you could prescribe azithromycin (Zithromax) which is $70 for 6 tabs (two tabs today, then one tab daily for 4 more days). What considerations should be made in making such a decision?

Answers to questions

1 and 2. There are at least four, and probably five, and possibly six. No doubt in the future, there will be more. How do these cephalosporins differ from each other and what characteristic places them in a given generation? The answer to this question is not an easy one. If you enter "fourth generation cephalosporin" into Medline's search engine, you will find some articles on fourth generation cephalosporins. Similarly, searches for fifth and sixth generation cephalosporin yields some articles. If I was a slick marketer of drugs, I would simply call my new cephalosporin "Tenth Generation" and almost everyone would buy it. However, what specific characteristic of the cephalosporin makes it clinically useful over other cephalosporins? If the drug was a tenth generation cephalosporin, but it had no clinical advantage over an existing third generation cephalosporin, then there is no need for a such a tenth generation cephalosporin. The generation is not nearly as important as the specific property of the cephalosporin which makes it clinically useful over another cephalosporin.

3. Osteomyelitis: Most likely Staph aureus. Bacterial meningitis: Pneumococcus, meningococcus, Haemophilus influenzae type B (HiB).

4. For osteomyelitis, we could cover the Staph aureus with an anti-Staph aureus penicillin such as oxacillin, nafcillin or methicillin or a first generation cephalosporin such as cefazolin. However, resistance to these drugs is currently about 25% to 30%. Although there is a good chance the patient will respond, in 25% to 30% of cases, this treatment will fail and the patient will suffer the consequences of inadequate treatment which would include: death from sepsis, Staph pneumonia, spread of the osteomyelitis, chronic osteomyelitis requiring an amputation, etc. None of these complications are minor, therefore, 75% coverage is inadequate. We need 100% coverage empirically since osteomyelitis is a serious infection. Thus, IV vancomycin is the treatment of choice here. For the bacterial meningitis case, we need an antibiotic to effectively cover these organisms and additionally, we need an antibiotic that will penetrate the blood brain barrier into the CSF. Chloramphenicol would be satisfactory here, but we don't use this because of its side effects. IV ceftriaxone or cefotaxime would penetrate the CSF well and cover meningococcus and HiB, and most pneumococcus, but pneumococcus has a small frequency of high level resistance to cephalosporins, so vancomycin must be added.

5. What organism is most likely? Mycoplasma or viral. Pneumococcus is unlikely since she is afebrile. The best antibiotic choice would be an erythromycin.

6. Although trimethoprim/sulfamethoxazole (Bactrim or Septra) is commonly recommended because of its broad coverage for this indication, this drug causes Stevens-Johnson syndrome more commonly than others. If the parents accept this increased risk, then this

should be documented on the chart. Most parents are not willing to accept this increased risk since other antibiotics are available. Amoxicillin will probably work, but there is a high frequency of resistance which is generally not a probably for simple cystitis, but in a febrile 18 month old, there may be some degree of pyelonephritis as well. Resistance to cephalosporins is infrequent. Thus, an acceptable answer here would also be a first generation cephalosporin such as cephalexin. IM ceftriaxone can also be given at the initial patient encounter to ensure high initial antibiotic levels and initial compliance.

7. Cost, compliance, convenience, efficacy, etc. While EES is $10 and azithromycin is $70, some patients may choose to pay more if the more expensive drug has significant advantages. Additionally, since most patients have drug plans, the difference may be negligible (e.g., $5 vs. $10). Compliance is essential for the drug to be effective. EES must be taken four times a day for 10 days while azithromycin is once a day for five days. Additionally, EES may have more GI side effects. Clearly a once a day medication is more convenient than a q.i.d. medication. If both medications are efficacious, perhaps it is best to discuss these differences with the patient and give them some input in the decision.

Chapter VI.6. Otitis Media and Otitis Externa

Vince K. Yamashiroya, MD

A parent brings her two year old son to your office because of a chief complaint of fussiness and tugging at his right ear for the past two days. He has had coughing and runny nose for about 5 days that has been treated with an over-the-counter cold medicine. He also has a low-grade fever of about 101 degrees axillary for the past two days. Both parents smoke cigarettes. He attends daycare. His past medical history is significant for ear infections in the past, with his last otitis media being 5 months ago treated with amoxicillin. His immunizations are up to date, including heptavalent pneumococcal vaccine.

Exam: VS T 38.4, P 100, RR 28, BP 100/65. He is active, alert to his surroundings and otherwise in no distress. HEENT: Right tympanic membrane is erythematous and bulging with poor mobility on pneumatic otoscopy. Left TM is clear with good mobility. Throat is non-erythematous. There are shotty cervical lymph nodes. Lungs are clear to auscultation. The rest of the examination is normal.

He is diagnosed with acute right otitis media. He is prescribed amoxicillin and acetaminophen. A follow-up visit is scheduled in 10 days.

Otitis media (OM) is one of the most common diagnoses that pediatricians encounter. It is estimated that otitis media comprises 23% of all office visits in the first year of life, and 40% at four to five years when these children start Kindergarten. In the United States, OM was the most frequent diagnosis in office settings, and accounted for 24.5 million visits in 1990 according to a report published by the Centers for Disease Control and Prevention (CDC) (1).

The middle ear is a gas filled cavity in the petrous part of the temporal bone between the external auditory canal and the inner ear. It contains three ossicles called the malleus, incus, and stapes. These ossicles conduct sound from the external auditory meatus to the inner ear. Therefore, factors hindering the movement of these ossicles, such as pus or fluid in the middle ear, will adversely affect hearing. The middle ear is connected to the nasopharynx by the eustachian tube. The eustachian tube allows for ventilation and clearance of fluid from the middle ear. Compared to the adult, the infant's eustachian tube is shorter, has a more acute angle, and has a smaller luminal area. Also, the angle of the tensor veli palatini muscle to the cartilage around the tube is variable, compared to being stable in the adult. The significance of these characteristics is that there is a greater likelihood that nasopharyngeal secretions can reflux or insufflate into the middle ear, and that clearance of the middle ear cavity of these secretions is decreased (2). These differences are the reason why there are more middle ear infections in the infant compared to the adult and older child.

Otitis media is common in infants and young children with the peak age being between 6 to 18 months of age. This is due not only to anatomical factors, but immunologic as well since these children still lack many protective antibodies against viral and bacterial organisms. The incidence of OM decreases after the first year of life and then increases again when the child enters school. It becomes less common after 7 years of age. Factors that increase the risk for OM are attendance in day care, second hand cigarette smoke exposure, craniofacial abnormalities such as cleft palate, and immunologic deficiencies. A protective factor is breastfeeding, which may be due to immune factors (e.g., secretory IgA and IgG), non-immune factors (e.g., interferon, glycoproteins, lactadherin), and anti-inflammatory factors (e.g., antioxidants, TNF-alpha, lactoferrin). Also, babies are breast fed while in a vertical or semi-reclining position, compared to some babies who may be bottle-fed while in a horizontal position. The practice of bottle feeding in the supine position is thought to increase OM by reflux of fluids from the nasopharynx into the middle ear (1).

The diagnosis of otitis media is a challenging one for pediatricians because of difficulty obtaining an adequate examination of the tympanic membrane (TM). The presence of cerumen and uncooperative and frightened patients complicate this. Common symptoms of OM are otalgia, otorrhea, and hearing loss. However, infants may only manifest otalgia by fussiness in the presence of fever. Other less common symptoms of OM and its complications are vertigo, nystagmus (unidirectional, horizontal, jerk type), tinnitus, swelling in the posterior auricular area (associated with mastoiditis), facial paralysis (due to disease within the temporal bone), and purulent conjunctivitis (which is associated with non-typable Haemophilus influenzae) (3). The best tool for the diagnosis of OM is the pneumatic otoscope. Inspection of the TM should include four characteristics: position, color, degree of translucency, and mobility. Also by visualizing the TM, one notices several landmarks such as the malleus which is divided into the short process, manubrium, and umbo; the long process of the incus; and the pars flaccida on the superior aspect and the pars tensa on the inferior aspect (3). It should be noted, although controversial, that a tympanic membrane may become red in a crying child (4). Other methods of diagnosing OM include tympanometry and tympanocentesis (3). This chapter will focus on two types of otitis media, namely acute otitis media and otitis media with effusion.

Acute otitis media (AOM) typically presents as a sudden onset of otalgia, fever, and hearing loss, which are preceded by an upper respiratory tract infection lasting for several days. Fever occurs in about 30-50% of patients of AOM, and is usually less than 40°C. Fever over 40°C suggests bacteremia or another complication (4). Pneumatic otoscopy reveals the TM that is opaque and bulging with poor mobility. Erythema, is a characteristic finding, but it may be absent. There may be perforation. Otitis media with effusion (OME), on the other hand, is asymptomatic in most children. Some may complain of hearing loss and less commonly tinnitus and vertigo. Older children may complain of a "plugged" feeling or "popping" in their ears, which is usually bilateral. The TM commonly appears opaque, but may be

retracted or full. An air fluid level or bubbles may be seen. Mobility is also decreased. It is important to distinguish between the two diseases because the management of each is different, however, it is not easily done. Some key points would be that fever, irritability, definite redness and otalgia, and a bulging and opaque eardrum are associated with AOM, whereas absence of symptoms except for hearing loss, and a retracted eardrum are associated with OME. Both can present with middle ear effusion and decreased mobility of the TM (6,7).

If severe otalgia is present, then analgesia becomes a major therapeutic consideration. Minor pain can be treated with acetaminophen or ibuprofen in most instances. For more severe pain, topical anesthesia with benzocaine containing ear drops (e.g., Auralgan otic) can be administered in the office to see if satisfactory analgesia is achieved. If not, a stronger analgesic such as acetaminophen with codeine may be necessary. Although Auralgan otic is used for pain relief, one should be aware of allergic reactions and to make sure there is no perforation.

The management of otitis media is one of many controversial subjects in pediatrics. Most treat AOM with antibiotics as soon as it is diagnosed, whereas in OME, antibiotics may be deferred, unless it becomes chronic (3). The three most common organisms are Streptococcus pneumoniae, non-typable Haemophilus influenzae, and Moraxella catarrhalis. Other less common organisms are Streptococcus pyogenes, Staphylococcus aureus, gram negative enteric bacteria, and anaerobes (5). The choice of antibiotic is dependent on efficacy, palatability, side effects, convenience of dosing, and cost. The drug of choice against AOM remains amoxicillin, although bacterial resistance continues to be a problem. For this reason, it is recommended that the dose of amoxicillin be increased from 40-50 mg/kg/day to 80-90 mg/kg/day in two to three divided doses. However, children who are at low risk for resistant organisms may be treated with the lower dose of amoxicillin, being 40-50 mg/kg/day. Risk factors include young age (less than 2 years), recent antibiotic use (within the last month), and day care attendance (4). The consensus is less clear on second-line therapy if amoxicillin fails. The CDC suggests three drugs, amoxicillin-clavulanate (with the amoxicillin component of 80-90 mg/kg/day), cefuroxime axetil, and intramuscular ceftriaxone. In patients who are allergic to beta-lactam antibiotics, macrolides, like erythromycin plus sulfisoxazole, azithromycin, or clarithromycin, and trimethoprim-sulfamethoxazole may be used. The duration for treatment is 10 days, although azithromycin, cefpodoxime, and cefdinir are now approved for 5 days, and a single dose of intramuscular ceftriaxone is as effective as a 10-day course of amoxicillin. Also recently, azithromycin has been approved for a 30 mg/kg one time dose, or 10 mg/kg dose for three days. If the 30 mg/kg dose is used however, there is a 4.9% risk for emesis occurring, necessitating a repeat dose of medication. Other drugs that are recommended are cefprozil, ceftibuten, loracarbef, and clindamycin (6). The expected clinical course is improvement within 48-72 hours. Persistent otalgia, fever, and other systemic symptoms past 72 hours should be reevaluated. At times, tympanocentesis or myringotomy is necessary for resistant cases, at which time a culture can also be obtained. Follow-up visits are recommended 10-14 days later to determine the need for further antimicrobial treatment. Although a middle ear effusion may be present, an inflamed eardrum or persistent systemic symptoms at this follow-up visit may warrant changing the antibiotic therapy or performing a myringotomy/tympanocentesis. It is estimated that 30-70% of children will have a middle ear effusion 10-14 days later, and that without treatment, 6-26% will have a persistent middle ear effusion after 3 months, with the mean of resolution being about 23 days. Because middle ear effusions usually resolve spontaneously, the CDC and the American Academy of Pediatrics have recommended against re-treatment of infants and children who have persistent middle ear effusions and are asymptomatic. However, there is debate about what to do for children having OME for 2-3 months. An option is to treat non-surgically. Medications that have been studied are decongestants, antihistamines, oral corticosteroids, and antibiotics. The only drugs proved efficacious are oral corticosteroids and antibiotics; however, it is felt that the side effects from oral corticosteroids outweigh its benefits. Therefore, a ten-day course of amoxicillin remains as a reasonable treatment for chronic OME. Other antibiotics that have been recommended are cefaclor, erythromycin-sulfisoxazole, and ceftibuten, although these are either just as efficacious or less so than amoxicillin. Some of the decisions to treat chronic OME are significant conductive hearing loss; young infant since they cannot communicate their symptoms; associated suppurative upper respiratory tract infection; concurrent permanent conductive and sensorineural hearing loss; speech-language delay because of effusion and hearing loss; alterations in the tympanic membrane such as a retraction pocket; middle ear changes such as adhesive otitis media or involvement with the ossicles; previous surgery for otitis media; frequent recurrent episodes; and persistence of the effusion for 3 months or longer in both ears or 6 months or longer in one ear. If antibiotic therapy fails, then myringotomy with tympanostomy tube placement or myringotomy and adenoidectomy are recommended as the next step. Only ofloxacin otic solution is approved in children with acute otitis media with tympanostomy tubes or chronic suppurative otitis media with perforation (8).

Not only do we treat otitis media for symptomatic relief, but also to prevent its complications. The complications of OM include conductive and sensorineural hearing loss, mastoiditis, cholesteatoma, labyrinthitis, facial paralysis, meningitis, brain abscess, and lateral sinus thrombosis (9,10). Fortunately, because we live in the antibiotic era, these complications are rarely seen.

The prognosis for otitis media is excellent. In most children, otitis media resolves after antibiotic therapy. Only in a few children does medical therapy fail, and more aggressive measures are needed, such as myringotomy and tympanostomy tubes. Recently, a heptavalent pneumococcal conjugate vaccine (Prevnar) has been FDA approved and is a recommended childhood immunization by the AAP and CDC. This vaccine has been shown to reduce otitis media caused by pneumococcus; however, its greatest efficacy is in those patients with recurrent OM.

Otitis externa is another condition that is often seen in pediatrics. Four factors can lead to the development of otitis externa. They are excessive wetness (e.g., swimming), dryness (e.g., lack of cerumen and dry ear skin), other skin diseases (e.g., dermatitis, previous infection), and trauma (e.g., using cotton tipped applicators). It is also called swimmer's ear, although it can occur without swimming (4). The pathophysiology of otitis externa is the following. As the humidity in the outer ear increases, the stratum corneum in the cartilaginous portion of the ear absorbs water, which results in edema. Edema blocks the pilosebaceous units in the ear, thereby decreasing the excretion of cerumen. A decrease in cerumen causes an increase in the pH of the external ear, in addition to decreasing its water repelling covering. The exposed skin becomes susceptible to maceration and the higher pH becomes a favorable environment for bacteria such as Pseudomonas. Bacteria can then penetrate through the dermis after superficial breakdown or through minor trauma such as with cotton applicators. Inflammation and infection thus results. The most common organisms cultured in otitis externa are Pseudomonas and Staphylococcus aureus. Other organisms that can be cultured are Enterobacter aerogenes, Proteus mirabilis, Klebsiella pneumoniae, streptococci, coagulase-negative staphylococci, diphtheroids, and fungi such as Aspergillus and Candida. Symptoms initially include pruritus and aural fullness, which then progresses to ear pain that may be severe and out of proportion to its appearance. Purulent otorrhea and hearing loss from edema of the canal may be present as well. Examination shows an inflamed and erythematous cartilaginous canal, with variable involvement of the bony canal. Manipulation of the pinna and pressure on the tragus elicits pain. Although the tympanic membrane is not affected, it and the medial portion of the canal can become involved and often look granular. When this happens, pneumatic otoscopy is needed to rule out concomitant otitis media. Tender and palpable lymph nodes may be present in the periauricular

and preauricular areas. Treatment includes the use of ototopical drops, such as a combination of polymyxin B, neomycin, and hydrocortisone (Cortisporin otic). Polymyxin B is active against gram negative bacilli such as Pseudomonas, neomycin is active against gram positive organisms and some gram negatives especially Proteus, and the corticosteroid reduces inflammation and edema. Fluoroquinolones are a new class of antibiotics for otitis externa; ofloxacin and ciprofloxacin are both currently available. If there is a lot of fluid drainage, it may be preferable to wick out most of the fluid prior to instilling the drops. If there is severe edema preventing effective instillation of drops, a wick can be placed in the membranous canal with otic drops applied several times a day, the wick can be replaced every 48 to 72 hours until the edema resolves (11). After 2-3 days, the edema of the ear canal is usually markedly improved. Analgesics such as ibuprofen and codeine can be used to treat severe pain. Cleaning the ear canal such as irrigating with 2% acetic acid to remove debris can be a useful adjunct to therapy. Prevention may be necessary for those patients who suffer from recurrences. Dilute alcohol or acetic acid (2%) can be instilled immediately after swimming or bathing, and is the best prophylaxis. Patients should protect their ears from water when bathing and should avoid swimming until their otitis externa resolves (4).

Questions

1. When is the peak age of otitis media?
2. What are some risk factors for otitis media?
3. What is the BEST tool for diagnosing otitis media (not gold standard)?
4. What is the difference between acute otitis media and otitis media with effusion?
5. What are the three most common organisms that cause otitis media?
6. What antibiotic is the drug of choice against otitis media?
7. What are the three second-line antibiotics recommended by the CDC if amoxicillin fails?
8. What are some reasons to treat chronic otitis media with effusion with either antibiotics or tympanostomy tubes?
9. What are some complications of otitis media?
10. What is the most common organism cultured in otitis externa?
11. What are four factors that can predispose a patient to develop otitis externa?
12. What can be instilled in the ear to prevent otitis externa in an otitis externa prone child?

Answers to questions

1. 6 to 18 months of age.
2. Attendance in day-care, second-hand cigarette smoke exposure, craniofacial abnormalities, bottle-feeding in the horizontal position.
3. Pneumatic otoscopy (myringotomy/tympanocentesis is the gold standard, but not the best diagnostic tool because of its invasiveness).
4. AOM: otalgia, fever, hearing loss, associated with upper respiratory tract infection; TM that is opaque or erythematous and bulging with poor mobility, perforation. OME: commonly asymptomatic but may have hearing loss; retracted TM.
5. Streptococcus pneumoniae, non-typable Haemophilus influenzae, Moraxella catarrhalis.
6. Amoxicillin
7. Amoxicillin-clavulanic acid, cefuroxime axetil, intramuscular ceftriaxone
8. Significant conductive hearing loss; young infant since they cannot communicate their symptoms; associated suppurative upper respiratory tract infection; concurrent permanent conductive and sensorineural hearing loss; speech-language delay because of effusion and hearing loss; alterations in the tympanic membrane such as a retraction pocket; middle ear changes such as adhesive otitis media or involvement with the ossicles; previous surgery for otitis media; frequent recurrent episodes; and persistence of the effusion for 3 months or longer in both ears or 6 months or longer in one ear.
9. Conductive and sensorineural hearing loss, mastoiditis, cholesteatoma, labyrinthitis, facial paralysis, meningitis, brain abscess, and lateral sinus thrombosis.
10. Pseudomonas aeruginosa.
11. Excessive wetness, lack of cerumen, preexisting skin problems, and trauma.
12. 2% acetic acid or dilute alcohol.

Chapter VI.7. Sinusitis
Kathleen A. Morimoto, MD

A 7 year old previously healthy female presents to her primary care physician with a 12 day history of persistent thick nasal discharge, nasal congestion, cough, and intermittent low grade fever. On further questioning, her parents reveal that the cough is worse at night but there is no wheezing, currently or in the past. She also seems to have one temperature spike daily to about 38.2 degrees (100.8 degrees F). She is not taking any medications. They deny the possibility of a nasal foreign body. She denies any vomiting, headache, earache, or rashes.

Her past medical history is negative for hospitalizations, asthma, allergic rhinitis, or cystic fibrosis.

Exam: VS T 37.2, P 90, R 15, BP 88/50. She is an alert, interactive female breathing comfortably. She has no eye abnormalities. Her tympanic membranes are clear. She has nasal congestion with thick yellow purulent mucus in the posterior nasal pharynx. Her nasal turbinates are red and swollen. Transillumination of her sinuses is equivocal. She has mild tenderness to palpation of her maxillary sinuses. Her oral pharynx is non erythematous. Her breath is malodorous. She has no obvious dental caries or pain on tapping of her teeth. Her lungs are clear. The rest of her exam is normal.

A diagnosis of acute bacterial sinusitis is made on the basis of history and physical exam. She is started on amoxicillin at 50mg/kg/day for 10 days. Her symptoms quickly resolve, and by day 3 of treatment she is asymptomatic.

Sinusitis is a common childhood disease which involves inflammation of the paranasal sinuses (frontal, maxillary, ethmoid, and/or sphenoid). There are many etiologies and forms of sinusitis, including the simple self limited viral rhinosinusitis, the acute bacterial, subacute, and chronic sinusitis. The differences between these designations lie largely in the duration of symptoms.

In acute bacterial sinusitis, nasal and sinus symptoms have been present for at least 10 days, but fewer than 30 days. Subacute sinusitis involves nasal and sinus symptoms lasting longer than 4 weeks but fewer than 12 weeks, and chronic sinusitis involve symptoms lasting at least 12 weeks (1).

Anatomically, the maxillary and ethmoid sinuses form during the third and fourth gestational month, but at birth are still very small. The frontal sinuses develops by one to two years of age and assume their final position above the orbital ridge by the fifth or sixth birthday. However, the frontal sinuses are not completely developed until late adolescence. The frontal, ethmoid, and maxillary sinuses all drain through the ostiomeatal complex located between the middle and inferior turbinates. This makes normal mucociliary motility imperative to preventing sinus infections. In the absence of effective clearing of secretions by the cilia, the sinuses become a medium for bacterial growth. Thus, anything that impairs normal ciliary function such as cigarette smoke exposure, viral infections, allergic rhinitis, cystic fibrosis, immunodeficiency, gastroesophageal reflux, and ciliary dyskinesia, can predispose patients to developing sinusitis. Nasal obstructions caused by foreign bodies, polyps, large adenoids, cleft palate, and trauma are also risk factors for sinusitis. However, viral infections represent the inciting event in about 80% of cases of acute sinusitis with allergic inflammation accounting for about 20% of acute sinusitis. It is estimated that the typical child has 6-8 viral URIs per year and approximately 10% of these may be complicated by secondary bacterial sinusitis.

The principle bacterial pathogens implicated in bacterial sinusitis are Streptococcus pneumonia (30%), non-typable Haemophilus influenzae (20%), and Moraxella catarrhalis (20%) (2). Viral isolates include adenovirus, parainfluenza virus, influenza, and rhinovirus, which account for 10% of sinusitis cases. In chronic sinusitis, results have been variable with alpha hemolytic streptococci, Staphylococcus aureus, anaerobes, and mixed colonies frequently recovered.

The most common presenting patient complaint is persistent nasal discharge which can be of any quality from thin, thick, clear, or purulent. Other common complaints include persistent cough which is worse at night, malodorous breath, low grade fever, dental pain, and sore throat. Older children, teens, and adults will have more specific complaints such as facial pain and pressure, and headaches.

On physical exam it is often difficult to differentiate between uncomplicated viral rhinosinusitis and acute bacterial sinusitis. Both conditions will have mild erythema and swelling of the nasal turbinates with mucopurulent nasal discharge. Sinus tenderness can be useful in the older child and adolescent, but is unreliable in younger children. Transillumination of the sinuses may be useful to assess the presence of fluid in the maxillary and frontal sinuses. However, this technique is difficult to perform correctly and has been shown to be unreliable in children less than 10 years old due to asymmetrical sinus development or lack of sinus development.

Sinus aspiration remains the gold standard for the diagnosis of acute bacterial sinusitis. However, it is invasive and requires a skilled ENT surgeon. Subsequently less invasive tests such as sinus x-rays, sinus CT scans, and MRI's have been used to help confirm the diagnosis of sinusitis. Radiographic findings of sinusitis are complete opacification, mucosal thickening of at least 4mm, or an air fluid level. However, even in the presence of these x-ray findings it will not help differentiate between viral rhinosinusitis, acute or chronic sinusitis.

In September 2001, the American Academy of Pediatrics published a clinical practice guideline for the management of sinusitis. Part of their recommendations include appropriate diagnosis and use of imaging studies to confirm sinusitis. In short, they recommend that for children <6 years of age, the diagnosis of acute bacterial sinusitis be based on clinical criteria rather than radiographic criteria. In this age group, there was an 88% correlation between history (persistent cough and nasal symptoms) and abnormal sinus radiographs, thus reducing the benefit of x-rays. Furthermore, the guidelines recommend reserving sinus CT scans for those patients requiring evaluation for surgery (2).

The treatment for acute bacterial sinusitis is antibiotics. In uncomplicated sinusitis the treatment is standard dose amoxicillin of 45-50 mg/kg/day. However, alternate dosing or medication should be considered if a patient fails to improve on conventional doses of amoxicillin, recent treatment with amoxicillin (<1 month ago) or attendance at day care. Alternate drug regimens recommended in these cases are high dose amoxicillin of 80-90 mg/kg/day and amoxicillin with clavulanate (1,2). Appropriately treated sinusitis patients will have a marked improvement in nasal discharge and cough within 48-72 hours.

The duration of antibiotic therapy has been controversial, between 10-28 days. Recent recommendations suggest continuing antibiotics until the patient is symptom free, plus an additional 7 days, but for a minimum of 10 days.

Surgical treatment is seldom indicated in acute sinusitis. However, in cases where patients fail to respond to aggressive antimicrobial therapy, or suffer from refractory chronic sinusitis, sinus aspiration may be indicated. Sinus aspiration is useful to both ventilate the sinuses and obtain cultures. Surgical intervention for chronic sinusitis involves endoscopic enlargement of the ostiomeatal complex and anterior ethmoidectomy. However, the actual outcome and benefit of sinus surgery is not well established.

The vast majority of acute bacterial sinusitis resolves without problems. The few reported complications associated with sinusitis involve contiguous spread of infection to the orbit, bone, or central nervous system. Orbital involvement is the most likely, and can lead to periorbital and orbital cellulitis, orbital abscess, and subperiosteal abscess. Other documented complications include frontal osteomyelitis (Pott's puffy tumor), epidural abscess, subdural empyema, cavernous sinus thrombosis, and meningitis.

Questions

1. What is the dose and drug of choice for uncomplicated sinusitis?
2. What percentage of viral URI's will progress to acute bacterial sinusitis?
3. Name some risk factors in the development of sinusitis.
4. What are some radiographic finding of sinusitis?
5. What is the most common complication of sinusitis?

Answers to questions

1. Amoxicillin 45-50 mg/kg/day.
2. Up to 10% will progress.
3. Allergic rhinitis, viral infections, cystic fibrosis, foreign body.
4. Mucosal thickening of at least 4mm, air fluid levels, opacification.
5. Periorbital cellulitis.

Chapter VI.8. Mastoiditis

Kathleen A. Morimoto, MD

A 7 year old male presents to the ER with a two day history of worsening ear pain and drainage. On the day prior to presentation, his parents noted redness behind his right ear, and that his right ear appeared to be sticking out. He had been well until 10 days ago when he started complaining of a cough and runny nose that progressed to include right ear pain and fever. He was evaluated in the clinic 5 days ago and diagnosed with an acute right otitis media. He was placed on amoxicillin and he initially appeared to improve until two days ago when his ear pain recurred and this is now accompanied by ear drainage, redness behind his right ear, and a prominent right pinna which is pointing up and out.

Exam: VS T 38.5, P 110, R 20, BP 100/60. He is non toxic, alert and responsive. His head is normocephalic. His eyes are normal. His left TM and ear are normal. His right pinna is upward and outwardly displaced with erythema and tenderness to the right mastoid. There is purulent drainage from his right ear which is obstructing visualization of tympanic membrane. His throat and neck are normal. Heart regular without murmurs. Lungs are clear. He has good strength (5/5) in all four extremities. His DTRs are 2+ in all four extremities. He ambulates well without ataxia

A CT scan of the mastoids is performed which demonstrates haziness and early bony destruction of the mastoid. No coalescence of air cells, empyema or subperiosteal abscess is noted. The patient is hospitalized for parenteral antibiotics. An ENT consult is obtained. The patient defervesces by 48 hours and he is then taken to the OR for myringotomy and tympanostomy tube placement. Long term IV access is placed and he receives 4 weeks of parenteral antibiotics. Following completion of therapy the patient does well without sequelae.

Mastoiditis is a suppurative infection of the mastoid air cells, and a potential complication of otitis media. Mastoiditis can basically be broken down into two types, acute and chronic. The acute form is defined as symptoms lasting less than one month and chronic for symptoms greater than one month. Within acute mastoiditis there are two pathologic forms, acute mastoiditis with periostitis, and acute mastoiditis with osteitis (with or without subperiosteal abscess). This section will be focusing on acute mastoiditis, as chronic mastoiditis is a unique entity in itself.

Prior to the antibiotic era, mastoiditis was a common complication of acute otitis media and frequently resulted in death. In 1938, the frequency of mastoidectomy for acute mastoiditis was 20%. With the advent of antibiotics, the frequency of mastoidectomy for acute mastoiditis had declined to 2.8% by 1948 with an almost 90% reduction in mortality rate (5).

The mastoid process is the posterior part of the temporal bone. At birth, the mastoid consists of a single cell called the antrum, which is connected to the middle ear by a narrow channel called the aditus ad antrum. Soon after birth, the mastoid undergoes pneumatization and by 2 years of age, is well pneumatized. Anatomically, the mastoid is surrounded by numerous vital structures, so if it become infected, this can lead to devastating results. Anterior to the mastoid lies the middle ear and ossicles, the facial nerve, the jugular vein, and the internal carotid artery. Posteriorly, lies the posterior cranial fossa and sigmoid sinus. Superior to the mastoid is the middle cranial fossa and medially the mastoid encases the cochlea and semicircular canals. Inferior to the mastoid are extensive soft tissue planes and muscles that are also potential areas for the spread of infection.

In acute otitis media, a certain amount of mastoid inflammation is observed because the mastoid air spaces and middle ear cavity are contiguous and they share the same modified respiratory epithelium. With appropriate antibiotic therapy, the inflammation within the middle ear and mastoid resolves. However, if the acute otitis media is not treated or inadequately treated, the inflammation within the mastoid persists. In acute mastoiditis, this persistence of inflammation results in accumulation of serous then suppurative material within

the mastoid. Accumulation of the purulent exudate leads to increased middle ear pressure resulting in possible tympanic membrane perforation. The increased pressure in the mastoid causes destruction of the bony septa between the air cells leading to formation of large cavities. Subsequently, osteomyelitis of adjacent bone may develop as well as abscess formation and bony erosion with extension of infection into surrounding structures.

The clinical manifestations of acute mastoiditis are largely dependent on the age of the patient and the stage of the disease. The classic presentation however, is a febrile child with otalgia, mastoid swelling and tenderness, and a history of acute otitis media days to weeks ago. The patient may have received antibiotics with some temporary improvement before becoming ill again. Other signs and symptoms of mastoiditis include mastoid erythema, displaced auricle either up and out in an older child or down and out in an infant, otorrhea, and a bulging immobile tympanic membrane.

The diagnosis of acute mastoiditis can be made on clinical findings alone. However, if radiographic imaging is indicated, CT scan is the test of choice over plain radiographs. CT scans done early in the course of mastoiditis reveal clouding of the mastoid, however this is not diagnostic as 50% of patients with uncomplicated acute otitis media will have similar findings. True CT evidence of mastoiditis is destruction of the mastoid outline, loss of bony septa within the air cells, "coalescence" of mastoid air cells (loss of bony septa between air cells), and hypoaeration of the mastoid (1,2). Additionally, CT scans with contrast are helpful in delineating possible intracranial complications.

Cultures of middle ear aspirates, ear drainage in the case of a perforated TM, and/or actual mastoid cultures may be helpful in optimal management of mastoiditis. If the TM is intact, cultures obtained from middle ear aspirates have been shown to correlate with actual mastoid cultures. However, if the TM is perforated, cultures obtained are often contaminated by ear canal flora. Consequently, in these cases, cultures should be obtained as close to the perforation site as possible. Optimally cultures should be obtained prior to the initiation of antibiotics. Unfortunately this is not always feasible particularly if the patient is not stable for surgery.

Although intuitively one would expect the same organisms that cause acute otitis media to also cause acute mastoiditis, the actual microbiology differs. The most common bacteria isolated in acute mastoiditis are Streptococcus pneumonia, Streptococcus pyogenes, and Staphylococcus aureus. Pseudomonas, enteric gram negative rods, and Staphylococcus aureus are the three most common organisms isolated in patients with chronic mastoiditis (2).

Initial antibiotic therapy in acute mastoiditis is empiric. Based on the most likely organisms, oxacillin and cefotaxime have been recommended (1). Vancomycin may be preferable since the frequency of oxacillin and cephalosporin resistant Staph aureus (MRSA) exceeds 25% in most areas. Additionally, emerging pneumococcal resistance may also benefit from vancomycin treatment. Ceftazidime or other anti-pseudomonas therapy may be indicated if pseudomonas is suspected. Duration of therapy is similar to that of osteomyelitis, and depends on the organism, extent of disease, and clinical response. However, a minimum of three weeks is recommended (1).

Surgical treatment of acute mastoiditis depends on the severity of the disease. In cases of simple uncomplicated mastoiditis (acute mastoiditis with periostitis), IV antibiotics and myringotomy and tympanostomy tube placement are recommended (5). If the patient fails to respond to the above therapy, or the mastoiditis is complicated by osteitis with or without subperiosteal abscess, the addition of a simple mastoidectomy is indicated (2,5). In a simple mastoidectomy, the mastoid air cell system is eviscerated although the canal walls are left intact. In severe cases refractory to simple mastoidectomy, a modified radical or radical mastoidectomy may be indicated. These surgical procedures involve complete removal of the mastoid air system including the posterior ear canal wall thereby creating a single cavity between the mastoid, middle ear, and external auditory canal. In addition, the radical mastoidectomy removes the tympanic membrane, malleus, and incus thereby leaving just the stapes or portion of the stapes intact.

The associated complications of acute mastoiditis are dependent on how and where the infection spreads. Pus that erodes through the lateral aspect of the mastoid produces a subperiosteal abscess. Clinically this child will present with redness, swelling, or pain behind the ear over the mastoid process. Pus can also spread medially to the petrous air cells resulting in petrositis or spread to the occipital bone posteriorly leading to osteomyelitis of the calvarium (Citelli abscess). Infection could also spread and involve the facial nerve, and central nervous system leading to meningitis, epidural and cerebellar abscesses, subdural empyema, or venous sinus thrombosis. The middle ear ossicles can also be destroyed resulting in conductive hearing loss. Rarely, mastoiditis is associated with abscess formation beneath the sternocleidomastoid and digastric muscles (Bezold abscess) (2,5).

The prognosis of mastoiditis depends on the extent of the infection. Fortunately, if detected early prior to intracranial involvement, the prognosis is very good. Even sensorineural and conductive hearing deficits associated with mastoiditis may be reversible if treated early. Therefore, prevention with early and adequate treatment for acute otitis media and early recognition of mastoiditis are key in decreasing the risk of serious suppurative complications.

Questions

1. What are the three most common organisms in acute otitis media?
2. What are the three most common organisms in acute mastoiditis?
3. Name a few intracranial complications of acute mastoiditis.
4. Name a few extracranial complications of acute mastoiditis.
5. Classically what is the difference in ear position in acute mastoiditis between the older child and young infant?
6. True/False: A CT scan image demonstrating clouding of the mastoid air cells is diagnostic of mastoiditis (acute or chronic)?
7. True/False: Plain film radiographs of the mastoid air cells often show mastoid clouding in acute otitis media without true mastoiditis.

Answers to questions

1. S. pneumonia, H. influenzae (non-typable), and M. catarrhalis.
2. S. pneumonia, S. pyogenes, and S. aureus.
3. Meningitis, epidural empyema, subdural empyema, venous sinus thrombosis.
4. Facial nerve paralysis, deafness, labyrinthitis, petrositis, Bezold abscess.
5. In the older child the ear is up and out and in the infant it is down and out.
6. False
7. True

Chapter VI.9. Oral and Upper Respiratory Infections
Joel Ruff, MD

A 15 year old boy comes to the office for a sore throat. His sore throat started three days ago but it was mild. He was unconcerned and did not seek medical attention. He denies any initial fever, vomiting, diarrhea, rash, rhinorrhea or cough. Last night, his sore throat became worse, seeming to be more painful on the right. This morning it was so sore he could hardly swallow or open his mouth and the pain is still worse on the right. He has been well otherwise and cannot remember when he last had a sore throat. His energy level is normal and he denies other symptoms except for the severe pain.

Exam: VS T 39.0, P 100, R 20, BP 130/84. In general, he looks uncomfortable although not toxic. He has difficulty opening his mouth wider than 2 cm. His speech has a "hot potato" (muffled) quality to it. His mucous membranes are moist. An asymmetric erythematous swelling (greater on the right) and deviation of the uvula to the left are seen. The right side of his soft palate is also noted to be slightly bulging. His neck is supple with tender adenopathy on the right side. The remainder of his general physical examination is normal including lungs, heart, abdomen, extremities and skin.

He is referred to the emergency room. A diagnosis of peritonsillar abscess is made and he undergoes incision and drainage, spending a few days in the hospital for IV antibiotics and pain control. He is discharged in good condition a few days later.

Upper respiratory infections include infectious conditions of the nose, adenoids, tonsils, pharynx, oral cavity and larynx. The following terms are often used: Rhinitis (nose), tonsillitis (tonsils), pharyngitis (pharynx), nasopharyngitis (nose and pharynx), stomatitis (mouth), gingivitis (gums), gingivostomatitis (gums and mouth), uvulitis (uvula), glossitis (tongue), laryngitis (larynx), parotitis (parotid gland). Sinusitis and otitis media are discussed in separate chapters.

Pharyngitis is a ubiquitous condition that accounts for a large number of visits to the physician. Fortunately, the majority of causes of sore throat have a benign course requiring only symptomatic treatment. It is important, however, to have an understanding of some of the less common, but potentially more serious etiologies of pharyngitis and their sequelae.

The tonsils are the site of most of the infections discussed below. They, along with the adenoids superiorly and lingual tonsils inferiorly, form a ring of lymphatic tissue known as the Waldeyer ring. What is referred to most commonly as "tonsils" are the palatine tonsils, the lateral limits of the ring. The tonsils are bounded by the palatoglossus muscle or "anterior pillar" and palatopharyngeal muscle or "posterior pillar." The structures have multiple folds which increase surface area available for antigenic stimulation. When an antigen is presented, it stimulates B cells that have congregated there. Migration of more lymphocytes to the site occurs and there they differentiate into immunoglobulin producing cells. Although IgM and IgG are found, the majority of the secretion consists of IgA. A wide variety of organisms can cause infection in this area, including viruses, bacteria, fungi and parasites (1,2).

Viruses cause the majority of pharyngitis with rhinovirus being the most common, followed by coronavirus and adenovirus in one series (3). Upper respiratory infection etiologies are frequently age dependent. For example, respiratory syncytial virus (RSV) will cause cold symptoms in teens and adults, while it causes bronchiolitis in infants and pneumonia in small and/or premature infants. Parainfluenza virus causes colds in teens and adults, while it causes croup in young children.

A long list of other viruses may also cause infection including influenza, herpes simplex virus (HSV), coxsackie virus, Epstein-Barr virus (EBV), cytomegalovirus (CMV) and human immunodeficiency virus (HIV). While the majority of viral infections have nonspecific symptoms, a few virus types give clues to their identity in how they present.

Adenovirus, for example may cause an associated conjunctivitis, the combination of which is known as "pharyngoconjunctival fever" (3,4). Herpes and coxsackie virus may produce ulcerations on the oral mucosa (stomatitis). HSV type 1 tends to be the more common subtype of HSV, but oral-genital exposure to HSV type 2 may also produce similar lesions. The lesions from HSV tend to, but not exclusively be more anterior in the mouth and often involve the gums (known as gingivostomatitis) (3). Lesions from coxsackie virus, which is a subtype of enterovirus, may appear similarly as multiple vesicles on an erythematous base (commonly seen on the palate), and are known as herpangina. The lesions in the latter may be associated with vesicles on the hands and feet and in this case are known as "hand-foot-and-mouth disease." Both types of oral ulcerations are very painful.

Epstein-Barr virus infection, also known as infectious mononucleosis, is manifested classically as exudative pharyngitis, fever, lymphadenopathy, hepatosplenomegaly and atypical lymphocytosis (4). The majority of patients are between 15 and 24 years old. Systemic symptoms may be the clue to diagnosis with lethargy and malaise commonly prominent. Differentiation from group A streptococcal pharyngitis may be difficult since both may have thick, exudative tonsillitis and palatal petechiae. Not only are anterior and posterior chain lymph nodes in the neck enlarged, but axillary and inguinal adenopathy often occurs. The spleen enlarges in about 50% of cases and the liver enlarges in 10-15% but frank jaundice is seen in only about 5%. A rash is classically elicited by ampicillin (hence, amoxicillin as well), but may be seen in about 5% of patients who do not receive antibiotics. The complete blood count may show thrombocytopenia (sometimes marked but usually mild). Lymphocytosis, often with more than 10% atypical lymphocytes can been see on the differential (3). Testing for EBV can be done with a "Monospot" test that actually tests for heterophil antibodies in the patient's serum that agglutinate sheep or horse erythrocytes. The sensitivity is about 90%, but it is often much less in infants and children less than 4 years old. Although several drugs have activity against EBV, none are effective for routine use. The mainstay of treatment is symptomatic

management. Advice to avoid vigorous activities for one month after onset of illness will help protect against possibly fatal splenic rupture (3). Corticosteroids should only be used to prevent occlusion of the airway by enlarged tonsils or in other special cases such as massive splenomegaly, myocarditis, hemolytic anemia and hemophagocytic syndrome (4).

A final virus that deserves to be included in the differential is HIV. After a period of incubation ranging from 6 days to 5 weeks, fever, nonexudative pharyngitis, lymphadenopathy, lethargy, myalgia and arthralgia develop in acute HIV infection. The higher incidence of rash in acute retroviral syndrome (40-80% versus 5%) and the occurrence of mucocutaneous ulceration may help differentiate the above from infectious mononucleosis, which can have similar constitutional symptoms and sore throat. Diagnosis is further complicated by the fact that tests for HIV antibody are often negative during this time, so assays for p24 antigen or HIV RNA must be used if the diagnosis is suspected. The diagnosis is important to make because during this period, the patient benefits from maximal therapy with antiretroviral agents (3).

Group A streptococcal (GAS) pharyngitis is the most common bacterial cause of sore throat, comprising 15-30% of children's sore throats and a smaller percentage in adults (5-10%). GAS pharyngitis is treated to shorten the course slightly (only if treatment is initiated early), to avoid suppurative sequelae, which include peritonsillar or retropharyngeal abscess, cervical lymphadenitis, mastoiditis, otitis media and sinusitis and non suppurative sequelae which include acute rheumatic fever. Although there is no evidence that treatment of GAS pharyngitis prevents the development of post streptococcal glomerulonephritis, a course of systemic antibiotics, usually penicillin, is recommended in patients with the latter condition when the diagnosis is made. This is generally to prevent the spread of nephritogenic strains and it has not been shown that antibiotics alter the course of the glomerulonephritis (3). Both post streptococcal glomerulonephritis and acute rheumatic fever can result from pharyngeal GAS infection but with skin infection (impetigo) the only non suppurative sequelae is post streptococcal glomerulonephritis.

Rheumatic fever deserves special mention since it historically was so significant in the U.S. It continues to be a significant cause of morbidity and mortality in many populations of the world. Around the year 1900, rheumatic fever and its sequelae were the leading causes of death among school age children. Although known to be associated with sore throat, the lack of identification of streptococci in damaged heart valves and elsewhere puzzled investigators until about 1930 when the association between antibodies and their effect on various tissues involved in the illness began to be elucidated. First with sulfa and subsequently with penicillin, streptococcal pharyngitis has been treated successfully since World War II. The decline in the incidence of acute rheumatic fever over the past 100 years, however, began before the advent of antibiotic availability and has been attributed to a decrease in the rheumatogenicity of streptococci (5). Astute observations in the 1980s of similarities in areas of the brain affected in Sydenham's chorea and obsessive-compulsive disorder (OCD) and exacerbation of OCD with GAS infection led to interest in pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections ("PANDAS") (7). Research continues to accumulate in this exciting field related to this disease.

Discussion on how to diagnose GAS pharyngitis clinically has never been definitively settled. Certain factors such as the typical age group of school age children, exudative appearance of tonsils, anterior cervical adenopathy, appropriate season (mid-winter to early spring) and absence of rhinorrhea and cough make the diagnosis of GAS pharyngitis likely (60-70% in children and 20-30% in adolescents) (3,6). Recommendations for whom to test vary and are defined in detail in the Red Book (4). Examples of factors to consider include viral symptoms such as coryza (acute inflammation of nasal mucosa with discharge, i.e., a cold), conjunctivitis, stomatitis, hoarseness, or diarrhea which make GAS pharyngitis less likely, or prior history in the patient or a family member of nonsuppurative sequelae which should cause stronger consideration for testing. GAS pharyngitis in children below 3 years old is very uncommon (4).

A properly done throat culture, which includes vigorous swabbing of both tonsils and the posterior pharynx remains the best diagnostic test available with about a 90% sensitivity (3,4). Newer rapid streptococcal tests that measure group A streptococcal carbohydrate antigen in a few minutes, as opposed to the 24-48 hours for a throat culture, have gained in popularity but have sensitivities that are 80-90% at best. A negative rapid streptococcal test is recommended to be followed up with a throat culture in suspicious cases. Neither test will differentiate a carrier from a patient with an acute infection (3).

Since most throat infections end up having a viral etiology, it is difficult to explain why one study showed that 70% of children and adolescents seen for sore throats in primary care settings received antibiotics (8). A study in military recruits in the 1950s showed that there is a window of 9 days from onset of pharyngitis during which administration of antibiotics is effective to prevent acute rheumatic fever. Since acute GAS pharyngitis lasts only 2 to 5 days without treatment, this means that rheumatic fever can still be prevented after the symptoms of pharyngitis are gone (6). Penicillin remains the drug of choice and should be continued for a full ten days or given intramuscularly in the procaine/benzathine formulation. A recent study looking at enhancing compliance with once daily amoxicillin, showed amoxicillin to be as effective once daily as three times daily penicillin, the implications being clear for compliance (9). The effectiveness of once daily amoxicillin, however, for prevention of rheumatic fever remains to be defined. Possible reasons for treatment failure include compliance issues, re-exposure, co-pathogens and carrier status (6).

Different types of streptococci including serogroups C and G may also cause pharyngitis via food and waterborne routes of infection. Although these types may cause glomerulonephritis, they are not associated with acute rheumatic fever. The infections tend to be milder than those with group A streptococci. Treatment, however, is recommended when these organisms are identified in symptomatic patients although the proven benefits are unknown. The same antibiotics that are used for group A streptococci are effective for types C and G (3).

Arcanobacterium haemolyticum is a rare cause of pharyngitis that usually occurs in adolescents or young adults. The illness may mimic group A streptococcal infection including a scarlatiniform rash. Erythromycin is the drug of choice (3). Neisseria gonorrhoeae may cause a pharyngitis if inoculated into the pharynx by oral contact with infectious material. Usually, the infection is asymptomatic but clinical pharyngitis and tonsillitis may develop. Disseminated disease should be suspected if Neisseria gonorrhoeae is found. Special media is required if the diagnosis is suspected. The treatment is the same as for genital disease (ceftriaxone 125mg IM, or single dose oral quinolone such as ciprofloxacin 500mg or ofloxacin 400mg plus azithromycin 1gm single dose or doxycycline 100mg bid for seven days) (3).

Diphtheria is now a rare disease in the US with only a single case reported to the Centers for Disease Control in the last few years. This disease has historical significance in the US, but currently has ongoing morbidity and mortality in other areas of world such the central Asian republics, Russia and Ukraine (3,4). The characteristic finding is the grayish brown diphtheric pseudomembrane which may involve the tonsils unilaterally or bilaterally and can extend to involve the soft palate, nares, pharynx, larynx or even the tracheobronchial tree (3). Case fatality rates range from 3% to 23%, the usual mechanisms of morbidity and mortality being upper airway obstruction from extensive membrane formation and myocarditis. Peripheral neuropathy may also occur (4). Edema of the soft tissues in the neck and prominent cervical and submental adenopathy may give the patient a "bull-neck" appearance (3). The disease is best prevented by

immunization, but if necessary, is treated with equine antitoxin and antibiotics, erythromycin or penicillin G intravenously. Antimicrobial therapy alone is not a substitute for antitoxin (4).

Mycoplasma pneumoniae may cause pharyngitis, but since it is also commonly isolated from controls, the significance of such infections remains unknown. Chlamydia pneumoniae has also been reported to cause pharyngitis either by itself or preceding a pneumonia. Since routine testing does not diagnose either of these organisms, treatment is not likely to be offered. The incidence of these organisms is likely seen in only a small percentage of infections and since serious complications are not commonly observed, it is likely that these infections resolve without treatment in most instances. (3,6)

Peritonsillar abscess is one of the listed suppurative sequelae of group A streptococcal infection but may also occur as a result of infection from other oral anaerobes. Acute tonsillopharyngitis precedes the formation of abscess, usually with an afebrile period noted or unresolving fever before the onset of severe throat pain. There may be trismus (pain on opening the mouth) and refusal to speak or swallow because the pain may be so intense. On exam, one of the tonsils is usually markedly swollen, with effacement of the anterior tonsillar pillar and deviation of the uvula to the opposite side. Untreated abscesses may rupture into the airway. Treatment involves incision and drainage of the abscess and intravenous antibiotics. Penicillin may be used although some prefer clindamycin for better anaerobic coverage. Without a history of chronic tonsillitis, there is a 10% recurrence rate. Authorities vary on whether tonsillectomy should be performed after the initial episode (2,10).

Retropharyngeal abscess can also manifest as a complication of bacterial pharyngitis or less commonly from extension of vertebral osteomyelitis or penetrating injury to the posterior pharynx. The potential space between the posterior pharyngeal wall and the prevertebral fascia contains lymphatic tissue that involutes around age 3 to 4 years, making infection less common after that age. A child with a preceding acute nasopharyngitis or pharyngitis who refuses to eat, has high fever, severe distress, hyperextension of the neck or noisy gurgling respirations may have a retropharyngeal abscess. Imaging (lateral neck radiographs) is essential to confirm the diagnosis, although in an uncooperative child, a bulge in the posterior pharynx may be seen. To obtain a proper soft tissue lateral neck x-ray, the neck should be in full extension (lordotic) and the x-ray should be taken in end-inspiration. False positive x-rays (false widening of the prevertebral soft tissue) may occur with poor positioning. Untreated retropharyngeal abscesses may rupture into the airway or spread down the fascial planes to the mediastinum. Treatment includes incision and drainage under general anesthesia and empiric intravenous antibiotics with coverage for Staphylococcus aureus until culture and sensitivity information is available (2,10). A "cold" abscess with tuberculosis may present as a retropharyngeal abscess (11).

Candida may cause infection of the pharynx under conditions of altered immunity such as HIV infection, immunodeficiency or diabetes (11). Thrush (mild oral candidiasis) is common in healthy infants. White plaques may be seen on the buccal mucosa and the tongue. Initial treatment is with oral nystatin.

Mechanical problems such as tonsillar hypertrophy leading to obstructive sleep apnea and chronic mouth breathing may cause pharyngitis. Foreign body must always be included in the differential of sore throat that does not appear infectious. Asymmetric swelling of the tonsils without infection may be a clue to malignancy (2,11). Adult type epiglottitis should be considered in older children and teens complaining of a severe throat without much clinical findings.

Diagnoses such as chronic fatigue syndrome contain sore throat as part of their criteria but continue to be controversial. Emerging entities such as periodic fever syndrome (PFAPA) which include sore throat (pharyngitis), fever, aphthous stomatitis and adenopathy in the cervical region may be more common that initially thought (12). The latter symptoms occur for 3 to 6 days with three weeks during which the patient is entirely well interspersed with clockwork periodicity. As one author puts it, is periodic fever an infectious disease or immune dysregulation? The answer is easy: no one knows (13).

Pharyngitis can have a myriad of causes, but for the most part, the causes are easily managed viral infections. The physician has to have a certain awareness of the more serious problems which can present as pharyngitis and the appropriate workup and management once the diagnosis is suspected. Certain clues can help the physician diagnose the more serious causes of sore throat and treat them appropriately.

Questions

1. A 12 year old male with 4 days of sore throat comes into the office. He has been afebrile, has rhinorrhea, cough and one day of diarrhea associated with his sore throat. The throat is mildly erythematous with otherwise normal appearing tonsils. The best course of action is (this may be a controversial question depending on your practice setting):

a. Swab his throat and give a 10 day course of antibiotics, you will call him if the culture is negative for group A strep so that he can stop antibiotic treatment.
b. Swab his throat, withhold antibiotics unless his culture is positive.
c. Advise him on symptomatic treatment.
d. Give him antibiotics without testing for group A strep.

2. A 14 year old boy who you know is homeless and possibly engaging in prostitution comes into clinic complaining of sore throat, rash and pronounced fatigue. One exam, he has an exudative pharyngitis. Tests to consider include (choose all that apply):

a. Throat swab for group A strep
b. HIV test for antibody
c. Throat swab for Neisseria gonorrhoeae
d. Monospot for EBV infection

3. A 3 year old is very fussy, febrile and has profuse rhinorrhea. On exam, shallow ulcers are noted on the soft palate and vesicles are noted on one palm and both soles of the feet. The etiology of this infection is likely:

a. Group A streptococci
b. Arcanobacterium haemolyticum
c. Coronavirus
d. Coxsackievirus

4. A 6 year old child recently adopted from somewhere in Russia complains of sore throat and is noted by the parents to have a lot of "grayish junk" in his mouth and nose. Exam shows an adherent grayish-white membrane over both tonsils and the soft palate that, when removed, leaves an edematous, bleeding area of tissue. After calling your state health department, you initiate therapy with:

a. Intravenous erythromycin or penicillin G.
b. The above antibiotics plus antitoxin.
c. Antitoxin alone.
d. IVIG.

5. In children, nonsuppurative sequelae of group A strep infection of the pharynx include (circle all that apply):

a. Post streptococcal glomerulonephritis.
b. Acute rheumatic fever.
c. Periodic fever syndrome.
d. PANDAS (maybe).

Answers to questions

1. any of the answers may be correct depending on your practice setting.
   a. for difficult to reach families or someone you don't trust to follow up.
   b. is probably what you would do for most families you felt comfortable with follow up (i.e., you could reach them on the phone if you needed to).
   c. is what you might do if you are playing the odds; it's probably viral.
   d. is what you might do during an epidemic.
2. a, c and d (b - HIV antibody test - is usually negative during this period and PCR for p24 antigen, RNA or reverse transcriptase is required).
3. d
4. b (antitoxin must be given with antibiotics)
5. a, b and d (no one is sure what causes PFAPA)

Chapter VI.10. Pertussis
Leo U. Pascua, MD

In December, a 2 year old female presents to the office with a chief complaint of afebrile nocturnal coughing for 3 days. Her past medical history is significant for atopic dermatitis (uses topical hydrocortisone), as well as multiple visits for wheezing episodes which respond well to nebulized albuterol. Gastroesophageal reflux had been explored and ruled out based on history. The family history is positive for maternal, paternal and sibling asthma. She is a recent immigrant and may not have had all her immunizations.

Exam: VS T37.0, P110, R40, BP 100/60, oxygen saturation 97% in RA. All growth parameters are at the 10th percentile. She is somewhat tired and clingy but alert. HEENT significant for mild nasal congestion. Heart regular without murmurs. Extensive and diffuse biphasic wheezing is heard in the lungs. Occasional coughing is heard in the office during the clinic visit. No flaring, retractions or cyanosis is observed. She has lichenified skin over her extremities.

A presumptive diagnosis of reactive airway disease is made, and he is discharged to home on oral albuterol and prednisone. She returns 2 days later, without much improvement. A CXR is unremarkable. Amoxicillin is empirically added to her regimen. She returns 2 days later with increased coughing and tachypnea with an oxygen saturation of 94% in room air. A repeat CXR shows a suggestion of a RLL infiltrate. A presumptive diagnosis of pneumonia is made and she is admitted to a general hospital for further evaluation and management of pneumonia and asthma exacerbation. CBC is normal. RSV ELISA and pertussis fluorescent antibody from the nasopharynx are negative. A pertussis culture is obtained. She improves and is discharged home in 3 days on amoxicillin/clavulanate.

She returns to the office 3 days later with increasing coughing and hypoxia (oxygen saturation 92%). She is admitted to a tertiary care hospital for management. An RSV ELISA and pertussis fluorescent antibody are again negative. Her earlier pertussis culture is negative. An infectious disease consult is obtained. Based on her clinical presentation of hypoxia and repetitive coughing; a working diagnosis of pertussis is made. Erythromycin and supportive care are initiated. A report is made to the Department of Health. Household contacts are subsequently interviewed, and erythromycin prophylaxis is started in all contacts.

After 7 days, she improves and is discharged to home to complete her course of erythromycin.

Bordetella pertussis is a gram negative coccobacilli that is the cause of an acute respiratory illness initially characterized by protracted coughing. With respect to the differential diagnosis, protracted coughing can also be caused by Mycoplasma, parainfluenza or influenza viruses, enteroviruses, respiratory syncytial virus, or adenoviruses. The majority of cases occur from July through October. Pertussis is extremely contagious, with attack rates as high as 100% in susceptible individuals exposed to aerosol droplets at close range. Day care centers have the potential for high exposure rates. B. pertussis does not survive for prolonged periods in the environment. Although a person may be fully immunized, either actively or passively, the rate of subclinical infection is as high as 50%. Neither natural disease nor vaccination provides complete or lifelong immunity against reinfection or disease (1). Protection against typical disease begins to wane 3-5 years after vaccination and is unmeasurable after 12 years. Adults in the United States, e.g., day care center operators, baby-sitters, etc., have inadequate antibody to B. pertussis (2).

B. pertussis produces an array of biologically active substances which are responsible for attachment to ciliated respiratory epithelial cells, inhibited clearance of organisms and local epithelial damage. In addition, pertussis incites histamine sensitivity, insulin secretion and leukocyte dysfunction. There are 3 post-incubation stages: 1) catarrhal, 2) paroxysmal, and 3) convalescent.

After an incubation period from 3 to 12 days, the catarrhal stage is marked by: congestion, rhinorrhea, low-grade fever, sneezing, and lacrimation. As symptoms wane, the paroxysmal coughing stage begins which can be characterized by one or more of the following: 1) Intermittent, irritative hacking paroxysmal coughing, 2) Choking, gasping, eyes watering and bulging, 3) Occasional coughing up of mucous plugs, 4) Post-tussive exhaustion, 5) Coughing in long spasms with the face turning red, or sometimes blue. The coughing wanes and improves during the convalescent stage. Each stage lasts about 2 weeks. However, immunized children do better, with shortening of all stages. Conjunctival hemorrhages and petechiae on the upper body are common due to all the coughing,

Pertussis should be suspected in a patient who complains of incessant coughing for 2 weeks, especially if nothing else shows up on the physical exam. Fever, sore throat, and conjunctivitis usually accompany adenoviral infections. Mycoplasma usually has a history of fever, headache, and rales. Chlamydia trachomatis presents with purulent conjunctivitis, tachypnea, rales or wheezes. Leukocytosis (normal small cells, rather than the large atypical lymphocytes seen with viral infections) due to absolute lymphocytosis occurs in the late catarrhal and paroxysmal stages. Neutrophilia would suggest a different diagnosis or secondary bacterial infection.

The chest radiograph shows perihilar infiltrates or edema and variable degrees of atelectasis. Parenchymal consolidation also suggests secondary bacterial infection. Pneumothorax, pneumomediastinum, and air in soft tissues sometimes occur. Isolation of B. pertussis in a culture is the gold standard and is a more sensitive and specific method of diagnosis than direct fluorescent antibody (DFA) testing of nasopharyngeal secretions. Cultures are positive during the catarrhal stage and escalating paroxysmal stage. However, a false negative can occur in those who have received amoxicillin or erythromycin. A flexible swab kept in the posterior nasopharynx until the patient coughs, is one way to obtain the specimen. DFA testing of nasopharyngeal secretions is rapid, but is highly dependent on the experience of the lab technician.

Infants under 6 months of age have a higher morbidity and mortality risk. Those under 2 months of age have the highest reported rates of pertussis-associated hospitalization (82%), pneumonia (25%), seizures (4%), encephalopathy (1%), and death (1%). The principal complications of pertussis are: apnea, secondary infections (such as otitis media and pneumonia), and physical sequelae of forceful coughing.

PICU care with artificial ventilation is usually limited to infants under 3 months of age, and is suggested with the presence of apnea and cyanosis. Secondary bacterial pneumonia (Staphylococcus aureus, S. pneumonia, mouth flora) is another cause for admission and his heralded by fever, tachypnea, respiratory distress between paroxysms, and absolute neutrophilia.

Coughing transiently increases the intrathoracic and intra-abdominal pressure resulting in conjunctival hemorrhages, petechiae on the upper body, epistaxis, hemorrhage in the central nervous system and retina, pneumothorax and subcutaneous emphysema, and umbilical and inguinal hernias.

CNS abnormalities occur and are almost always the result of hypoxemia and hemorrhage associated with coughing or apnea in young infants (due to laryngospasm, vagal stimulation just before a coughing episode, from obstruction during an episode, or from hypoxemia following an episode). Seizures are usually the result of hypoxemia. Also, pneumonia can precipitate SIADH, resulting in hyponatremic seizures.

Reversible bronchiectasis or pseudobronchiectasis occurs commonly after pertussis. The bronchi may appear cylindrically dilated on bronchography, but usually resolved in about 4 months.

Patients with significant respiratory infections should be hospitalized if they are less than 3 months of age, (other causes of pneumonia presenting during the first weeks of life include C. trachomatis, genital Mycoplasma, Ureaplasma urealyticum, and occasionally bacteria such as Haemophilus species, streptococci, and Bordetella pertussis. Other indications for hospitalizations include: severe coughing paroxysms, cyanosis, poor social support, or an infection in a high risk patient (prematurity, cardiac disease, chronic pulmonary disease, neuromuscular disorder, etc.).

Admission orders should include:

Cardiorespiratory monitoring, continuous pulse oximetry, apnea monitor.

Detailed cough records (cyanosis, tachycardia, bradycardia, presence of coughed up mucus plug; post-tussive exhaustion and/or unresponsiveness).

Documentation of feeding, vomiting, and weight change.

Prn oxygen, stimulation, or suctioning (note: suctioning of nose, oropharynx, or trachea always precipitates coughing, occasionally causes bronchospasm or apnea, and should be done prn only).

Avoidance of large volume feedings.

Medication order should include: erythromycin (estolate form preferred) 40-50 mg/kg/day div qid (max 2 g/day 24 hr) x 14 days.

Nursing orders should include:

Respiratory isolation for at least 5 days after start of erythromycin.

Restricting visitation of coughing family members who might be spreading pertussis to others in the hospital (until they have taken erythromycin for 5 days).

Management orders of household close contacts should include:

Erythromycin, 40-50 mg/kg/day divided qid (max 2 g/day 24 hr) for 14 days to all household and close contacts, i.e., day care, regardless of age, history of immunization, or symptomatology.

Pertussis-containing vaccine to all unimmunized contacts younger than 7 years.

Hospital discharge criteria should include clinical improvement plus: no intervention required during coughing, adequate nutrition, absence of complications, and the parents are prepared for further home care.

Primary prevention with pertussis vaccine is key. The vaccine currently used in the primary immunization series is a safer acellular vaccine composed of a suspension of inactivated B. pertussis, combined with diphtheria and tetanus (DT) toxoids and aluminum-containing adjuvants (DTaP vaccine).

For historic purposes, the adverse effects of the older whole cell vaccine (DTP, which is no longer used) are mentioned below. It resulted in more frequent pain, swelling, erythema, and systemic reactions, such as fever, fretfulness, crying, drowsiness, and vomiting. Febrile seizures, albeit rare, occurred within 48 hr and were brief, generalized, self-limited, and occurred more commonly in those with a history of seizures. Collapse or shock-like state (hypotonic-hyporesponsive episode) was rare, uniquely associated with pertussis vaccine, and has no permanent neurologic sequelae. Very rarely, pertussis vaccine was associated with acute neurologic illness in children who were previously normal. Severe adverse events, such as death, encephalopathy, onset of a seizure disorder, developmental delay, or learning or behavioral problems, have occurred in individuals temporally associated with pertussis immunization or alleged to be causally associated. These adverse effects are less likely to occur with the generation of the currently used acellular vaccine (DTaP), which has supplanted the DTP series.

Some parents have refused pertussis vaccine because of its adverse effects. Many parents believe that herd immunity will protect their children. The concept of herd immunity is that if 99% of the population is immune, then the infection can never find enough susceptible hosts to sustain itself and the few susceptible individuals within the population are unlikely to be exposed to the infection. However, herd immunity does not apply to pertussis since pertussis immunity declines substantially with age. Most teens and adults are susceptible, even if they were immunized as children. Although teens and adults with pertussis will manifest with only mild to moderate respiratory symptoms, they represent a large population of susceptible individuals who can sustain an epidemic, and thus expose unimmunized infants and children, who may have more severe infections and complications.

Questions

1. In the case, the patient's presentation and clinical course were consistent with pertussis, yet the pertussis culture was negative. Why?
   a. A false negative can occur in those who have received amoxicillin.
   b. A false negative can occur in those who have received albuterol.
   c. A false negative can occur in those who have a history of asthma.
   d. Direct fluorescent antibody (DFA) testing of nasopharyngeal secretions is the gold standard and is a more sensitive and specific method of diagnosis than culture.
   e. Cultures usually become positive only during the latter convalescent phase.

2. What etiology of sudden onset of coughing in an active infant can be effectively ruled out with a CXR?
   a. Mycoplasma
   b. Parainfluenza
   c. Enterovirus
   d. Respiratory syncytial virus
   e. Foreign body aspiration
   f. None of the above

3. Match the clinical manifestation to the disease process

a. Fever, sore throat, and conjunctivitis	1. Mycoplasma
b. Fever, headache, and rales	2. Adenovirus
c. Purulent conjunctivitis and tachypnea	3. Chlamydia
d. Choking, gasping, eyes watery and bulging.	4. Pertussis

4. An experienced ward nurse asks you to correct an admission order for pertussis. Which component is incorrect ?
   a. "Continuous cardiorespiratory monitoring".
   b. "Document episodes of cyanosis or post-tussive exhaustion".
   c. "Daily weights".
   d. "Deep suctioning q 3h".
   e. "Instruct parent regarding maximal size of feedings.

5. Case management dilemma scenario: You are the admitting intern on the wards. It is 3 PM on a Friday afternoon. A patient is transferred from a neighbor island with a diagnosis of pertussis, complete with positive direct fluorescent antibody (DFA). The summary of PE findings by the community PMD includes petechiae on the upper body, epistaxis, and umbilical hernia. Upon admission to the ward you repeat the physical exam and also note retinal hemorrhages, which are confirmed by an ophthalmologist who just happens to be around. The parents have returned to the neighbor island for the weekend to fulfill important obligations and have already made arrangements to return on Monday. Given the presence of retinal hemorrhages, do you make a referral to Child Protective Services?

Answers to questions

1.a. A false negative can occur in those who have received amoxicillin.

2. None of the choices are correct. Choices a and e are the closest to being correct, but technically, these answers are incorrect. Mycoplasma pneumonia might show up as a pneumonia on a CXR, but this would be non-specific for mycoplasma. Additionally, some mycoplasma infections may not cause a pneumonia. Foreign body aspiration might show up on a CXR, but these often require special views such as an expiratory view or a lateral decubitus view. Foreign body aspiration is frequently occult.

3. a-2, b-1, c-3, d-4

4.d. Suctioning of nose, oropharynx, or trachea always precipitates coughing, occasionally causes bronchospasm or apnea, and should be done prn only.

5. Increased intrathoracic and intra-abdominal pressure during coughing can result in conjunctival hemorrhages, petechiae on the upper body, epistaxis, hemorrhage in the central nervous system and retina, pneumothorax and subcutaneous emphysema, and umbilical and inguinal hernias. A child protective services report is not necessarily indicated since pertussis could cause this. Other clinical or psychosocial findings inconsistent with pertussis may lead one to report this to child protective services.

Chapter VI.11. Pulmonary Infections
Kimberly N. Otsuka, MD

A previously healthy 4 year old boy is brought to an urgent care center by his mother for difficulty breathing for one day. Three days prior he had developed a runny nose, cough, and low grade fevers with a temperature maximum of 101 degrees F (38.3 degrees C). He continued to take liquids well, but his solid intake has decreased. His temperature this morning was 103 degrees F (39.4 degrees C) and he was breathing fast and working hard to breathe. He does not have any ill contacts. He has never been hospitalized or had any surgeries. He was born at term without any complications. He is not taking medications other than acetaminophen. His immunizations are up to date for his age (except he had not received the pneumococcal conjugate vaccine). His parents and 10 year old sister are healthy and the remainder of his family history is non-contributory. There are no smokers in the household, and he has not traveled recently. He does not have a history of choking or vomiting. He has not had frequent ear or skin infections. He does not have a history of foul-smelling stools.

Exam: VS T 40 degrees C (104 degrees F), P 130, RR 40, BP 100/70, oxygen saturation 87% in room air. His height and weight are in the 50th percentile for his age. He is awake and alert, in moderate distress. His conjunctiva and TMs are normal. His nasal mucosa is erythematous with yellowish discharge. His lips and mucous membranes are dry. His neck is supple, with several small anterior cervical lymph nodes. Lungs: Moderate subcostal, intercostal, and supraclavicular retractions, symmetric expansion, dullness to percussion at the right base, increased vocal fremitus over the right base, decreased air entry over right lower lobe with crackles, no wheezes. Heart: Tachycardia, regular rhythm without murmur. Pulses are 2+, and capillary refill time is 3 seconds. His abdomen, skin, and neurological examinations are unremarkable.

CBC WBC 20,000, 70% segs, 11% bands, 15% lymphs, 3% monos, 1% eos. Hemoglobin 12.4, platelet count 280,000. Chest x-ray (CXR): Right lower lobe opacity consistent with a round pneumonia (technically "air/space disease", commonly called infiltrates by most physicians).

Because of the hypoxia, he is given supplemental oxygen (with subsequent improvement in oxygen saturation), as hospitalization arrangements are made. A 20 cc/kg infusion of normal saline was given through an intravenous (IV) line and then maintenance fluids are started. A blood culture is obtained and he is started on IV cefuroxime. He improves over the next day. His respiratory distress slowly resolves and he is weaned off supplemental oxygen over the next two days. His blood culture shows no growth. He is discharged home on high dose amoxicillin for a total of 10 days of therapy. His discharge diagnosis is probably pneumococcal pneumonia.

Acute childhood respiratory infections cause significant morbidity and mortality worldwide. Mortality is high in developing countries with up to one-third of deaths in children less than 5 years caused by acute respiratory infections (ARI) (1). The disparity in mortality is due to the severity of infection (perhaps due to differences in nutrition, overall health, immunization practices, and medical care availability) since the incidence of acute respiratory infections is similar between developed and developing countries with infants experiencing about 4-8 episodes per year (1). In the US, mortality from ARIs has declined since 1968 (1,2).

There are 2 basic classification systems used for acute respiratory tract infections: the case-management classification system used by the World Health Organization (WHO) and the "traditional" clinical classification system (1). The case management system divides ARIs by symptoms (i.e., stridor, wheezing, and no wheezing) and their severity (i.e., mild, moderate, severe, and very severe). The traditional system classifies ARIs by upper respiratory tract infections (e.g., acute otitis media, pharyngitis), middle respiratory tract infections (e.g., croup and epiglottitis), and lower respiratory tract infections (e.g., bronchiolitis, bronchitis, pneumonia). Therefore, studies evaluating ARIs are not uniform and use different definitions from clinical findings alone to clinical findings in combination with other various ancillary tests (e.g., chest radiography).

Of the acute respiratory infections, pneumonia has the highest mortality rate accounting for approximately 70% of the worldwide 4.5 million deaths from acute respiratory infections (4). Although mortality from pneumonia in children in the United States has declined by 97% between 1939 and 1996 (5), pneumonia continues to be a leading cause of morbidity in children. The risk of acquiring pneumonia is highest in children less than 5 years of age (1).

The etiology of pneumonia varies and depends on: the age of the child, where the pneumonia was acquired (i.e., community vs. nosocomial), local epidemiology (e.g., influenza epidemics), host factors (e.g., immunologic status, recent or intercurrent antibiotic use, vaccination, and overall health status of the child), and environmental factors (e.g., travel, season of the year, daycare, or crowded living conditions) (4,6-9). Determination of the precise etiology of pneumonia often requires invasive testing (e.g., lung biopsy), and therefore, this is done infrequently. Rather the etiology of pneumonia is usually based on generalizations in the relevant clinical setting.

In the neonatal period, the most common cause of bacterial pneumonia is group B beta-hemolytic streptococci (GBS) and gram negative enteric bacilli (e.g., E.coli), the same organisms associated with neonatal sepsis (4). In infants and children outside of the neonatal period, viruses are the most common cause of pneumonia (4,6,10-11) and respiratory syncytial virus (RSV) is one of the most common causes in infancy, especially in premature infants (9,12). Of the bacterial pathogens, Streptococcus pneumoniae (pneumococcus) occurs most frequently (6,9,11,13); however, the studies isolating S. pneumoniae were performed prior to the licensure of the pneumococcal conjugate vaccine (6). Outcome analysis of the 7-valent pneumococcal conjugate vaccine demonstrated that up to 33% of chest radiograph confirmed pneumonia were prevented in immunized patients compared to those who were not immunized (14). Therefore, a different bacterial pathogen may supersede S. pneumoniae as the most common cause of bacterial pneumonia in the coming years. Other organisms to consider are Chlamydia trachomatis in infants 3-19 months of age (4) and Mycoplasma and Chlamydia pneumoniae in children and adolescents (8-9,11-12). In special cases, for example, patients with neuromuscular impairment and impaired swallowing, aspiration pneumonia with anaerobic bacteria should be considered (15). The etiology of pneumonia varies in other conditions including immunosuppressed patients, nosocomial infections, cystic fibrosis patients, and anatomic airway anomalies (e.g., tracheostomies). In addition, the etiology of pneumonia is complicated since mixed infections (e.g., viral-bacterial) can occur in 16-34% of patients (7,11,13).

The lower respiratory tract in healthy persons is sterile (16). Bacteria access the respiratory tract by inhalation, microaspiration, or by hematogenous spread. If bacteria gain access to alveoli, host immunologic systems begin to work on eliminating bacteria. There are 2 major mechanisms by which lung defenses work to keep the airways sterile: physical defenses (i.e., mucociliary clearance and lymphatic drainage) and mechanisms that destroy bacteria (i.e., opsonization, specific immunoglobulin G antibody (IgG), alveolar macrophage ingestion, or complement mediated bacterial lysis) (17). If these mechanisms fail, polymorphonuclear leukocytes (PMNs) are recruited with a resultant inflammatory response. Perpetuation of this inflammatory response leads to pneumonia. There are 4 major histologic

steps seen in pneumococcal pneumonia described by Tuomanen, et al (18): engorgement, red hepatization, grey hepatization, and resolution. Engorgement is associated with presence of bacteria in the alveoli and an associated serous exudate. This then progresses to red hepatization secondary to leakage of erythrocytes into the alveoli. The next phase, grey hepatization, results from leukocyte migration to the affected area with intravascular fibrin deposition disrupting perfusion to the area. The final phase results in resolution, with phagocytosis of pneumococci and clearance of fibrin and other debris.

Outside of the neonatal period, pneumonia is suspected in patients with clinical signs and symptoms suggestive of impairment of the lower respiratory tract. Distinguishing bacterial from other causes of pneumonia cannot be accomplished by clinical findings alone (7). Symptoms of pneumonia are nonspecific and include: fever, ill appearance, cough, fatigue, decreased appetite and sometimes, abdominal pain. Signs of lower respiratory tract involvement include: tachypnea (greater than 50 breaths/minute in children less than 12 months, and greater than 40 breaths/minute for older children) (4), cyanosis, increased work of breathing (i.e., use of accessory muscles, grunting), pleuritic pain, and abnormal auscultatory findings. These signs do not differentiate a viral from bacterial process. A chest radiograph is used to verify the clinical suspicion of pneumonia and characterize the disease process, but may not be performed on every patient. Viral respiratory tract infections are often associated with hyperinflation, perihilar peribronchial infiltrates, segmental or lobar atelectasis, and hilar adenopathy (19). Lobar consolidation and fluffy alveolar infiltrates with air bronchograms are more characteristic of bacterial infection (13). However, there is overlap between these two groups (13). Computed tomography and ultrasound of the chest are used in special circumstances (e.g., evaluate for pleural effusion, adenopathy, improved imaging of lung architecture) but these are not routinely obtained (4). Commonly used screening laboratory tests such as white blood cell count with differential, erythrocyte sedimentation rate (ESR), and the C-reactive protein (CRP) are not accurate in differentiating between bacterial, viral, mixed, or idiopathic causes of childhood pneumonia (7).

Determination of precise etiology of pneumonia is difficult due to the lack of sensitive and specific tests. Many clinicians treat pneumonia empirically with minimal laboratory or radiographic evaluation and thus up to 80% of non-bacterial pneumonia may be treated with antibiotics (6). This approach is satisfactory when clinical risk is deemed to be low. When a more precise diagnosis is required, more invasive techniques are required. Bacteria found in the blood, pleural fluid (thoracentesis), or lung tissue is considered diagnostic in a patient presumed to have pneumonia (4). Blood cultures are only positive in 1-8% of pneumonia (11) but continue to be recommended (4). Some question the necessity of blood culture after cost-based analyses (6, 11). Transthoracic needle aspirates, transtracheal aspirates, and open lung biopsy (the gold standard for diagnosis) are rarely performed due to the risk involved for these procedures (11,20), except in severe cases or in immunocompromised hosts (4). Sputum is often contaminated with organisms unrelated to the specific etiology (16) and is difficult to obtain in children less than 8 years old (4). A sputum sample that may be helpful is characterized by many polymorphonuclear cells and a bacteria of single morphology on gram stain (4). Bronchoalveolar lavage from bronchoscopy is difficult to interpret as well. The results are non-specific (i.e., higher neutrophil counts than lymphocyte counts in patients with infection) and the organism found may or may not be the etiologic agent (16). Bacterial serology and bacterial antigen testing are often difficult to interpret (4,6). Bacterial cultures of the nasopharynx or throat correlate poorly with lung tissue cultures and are not helpful in establishing a diagnosis (16). Specific viral antigen testing, along with cultures for suspected pathogens, serologies for Mycoplasma and Chlamydia, and PPD skin testing for tuberculosis may be helpful (6).

Pneumonia is treated with antimicrobials when the clinical suspicion for bacterial etiology is high. Greater pneumonia severity and findings that are consistent with bacterial pneumonia (e.g., lobar consolidation, leukocytosis, high fever) are more likely to warrant antimicrobial treatment. Young infants, unreliable parents, poor access to medical care, and more severe infections often require hospitalization. Treatment of pneumonia is often empirically based and thus, information on antibiotic resistance patterns and mechanisms of resistance is important to determine the most appropriate treatment. For S. pneumoniae, the most common mechanism of resistance to penicillins is alteration of penicillin-binding sites that can be overcome with higher doses of the drug (6). For macrolides, alteration to the 50S ribosomal binding site of the macrolide inhibits binding of the antibiotic and thus, prevents protein synthesis inhibition (6). In addition, there is also an increase in efflux pumps for macrolides and this property can be overcome by using macrolides that achieve high tissue concentrations at the site of infection (e.g. azithromycin) (6). Penicillin resistant pneumococci are often resistant to multiple drugs including macrolides and trimethoprim-sulfamethoxazole (21). Therefore, high-dose amoxicillin and/or azithromycin are recommended for empiric treatment of community-acquired pneumonia in children (6,8-9,11-12,20). Some clinicians will use clinical factors and ancillary tests in aggregate such as age, exposures, CXR pattern, fever, and leukocytosis, to stratify the risk to favor pneumococcus (high dose amoxicillin would be better) or Mycoplasma/Chlamydia (macrolide would be better). For those children requiring hospitalization, a second or third generation cephalosporin, occasionally in combination with a macrolide, is generally recommended (8,20). Most treatment regimens are continued for a total of 7-14 days although this is based on little evidence (4).

Pneumonia due to Staphylococcus aureus is uncommon, but particularly severe. S. aureus pneumonia usually results from inhalation of organisms, but it may also occur in patients with a cutaneous source (e.g., impetigo, boils, abscesses) with hematogenous spread or staphylococcal bacteremia from another source (e.g. osteomyelitis, central line infection). If S. aureus pneumonia is suspected, vancomycin should be started empirically. Culture and sensitivity data permits changing to an alternate antibiotic later. Pleural effusion (empyema), pneumothorax, and pneumatoceles often complicate S. aureus pneumonia.

Pleural effusions can be classified in several ways. They can be a transudate or an exudate based on their protein content. A subpulmonic effusion versus an empyema is more clinically relevant. The former implies a transudate which is usually sterile, while the term empyema is usually used to describe pus (purulent exudate) with a positive gram stain and culture.

The overall outcome in children with pneumonia is excellent. The majority of children will recover without complications (11). Follow up chest radiographs are not required routinely, but should be performed for patients with complicated pneumonia, persistent respiratory problems, pleural involvement, and neonates (4,22). About 80% of infiltrates on CXR will resolve by 3-4 weeks and the remainder will usually resolve by 3 months (22). Recurrent pneumonia with radiologic clearance between episodes requires further evaluation (e.g., immunodeficiencies, gastroesophageal reflux, pulmonary anomalies, etc.) (4).

Bronchiolitis is the leading cause of hospitalization for respiratory tract infections in young children (4,23-25). Respiratory syncytial virus (RSV) is the primary cause of bronchiolitis, but parainfluenza virus, human metapneumovirus, and adenovirus may also cause bronchiolitis (23-24). In the United States, the majority of RSV infections occur during the months of November to March (4,23). RSV infections account for a significant amount of morbidity and health care expense in the young age group (24).

RSV is transmitted by direct contact with large droplets or fomites. Transmission can be limited by good handwashing (23). RSV bronchiolitis results from the spread of RSV to the lower respiratory tract after an incubation period 2-8 days where the virus undergoes replication in the nasopharynx (23). The infection results in infiltration of the respiratory epithelium with resultant inflammation and

necrosis, sloughing of the epithelium and increased mucus production causing airflow limitation in the small airways leading to the hallmarks of the disease (23). Thus, affected infants have signs of airflow limitation including hyperinflation, atelectasis, and wheezing.

The diagnosis is often made on clinical grounds during the RSV season. Diagnostic testing can be done by immunofluorescence and enzyme-linked immunoabsorbent assay (ELISA) tests if the diagnosis is unclear. Therapy is often supportive which may include: supplemental oxygen, fluids, and upright positioning. Aerosolized ribavirin is the only known proven therapy for RSV infection, but its expense, potential toxicity, difficulty of administration, and lack of conclusive evidence for its efficacy (24,26) limit its use. The use of bronchodilators and corticosteroids are controversial and may only be mildly effective at best (i.e., not been proven to be highly efficacious) (24-26). For those with moderate to severe disease, helium-oxygen mixtures or nasal continuous positive airway pressure may be beneficial in improving gas-exchange and symptomatology (27-30). Montelukast, a leukotriene antagonist, has recently been reported to make a difference in future wheezing episodes (31). Prophylaxis with palivizumab (RSV monoclonal antibody) or RSV-IVIG is given to select pediatric populations recommended by the American Academy of Pediatrics during RSV season to reduce RSV infection risk (32). Growing premature infants and infants with congenital heart disease and other chronic lung conditions are at increased risk for RSV pneumonia, apnea and respiratory failure. Healthy term infants with RSV usually develop mild bronchiolitis. Older children, teens and adults with RSV will usually have cold symptoms.

Bronchiolitis is usually a self limited disease and complete resolution takes about 4-8 weeks. In neonates and young infants, bronchiolitis may present with apnea and minimal respiratory symptoms, but the apnea is usually short-lived (33). Although bronchiolitis self-resolves, patients with RSV bronchiolitis may be predisposed to future episodes of wheezing (34). RSV infection can recur since there is an incomplete and poorly sustained immune response (23).

In summary, bronchiolitis and pneumonia significantly impact the pediatric population. Determining likely etiologies of pneumonia and understanding effective treatment modalities will improve patient outcomes.

Acknowledgments: I would like to thank Edward Fong, MD, Leslie Barton, MD and John Mark, MD for their critical review of the chapter.

Questions

1. Which of the following is the most common cause of pneumonia outside of the neonatal period?
    a. S. pneumoniae
    b. Mycoplasma
    c. Viruses
    d. Chlamydia

2. S. pneumonia resistance to penicillins is due to:
    a. Production of beta-lactamase
    b. Alteration of penicillin binding proteins
    c. Increased efflux pumps
    d. Low tissue bioavailability

3. True/False: Nasopharyngeal and throat cultures are useful in determining etiology of bacterial pneumonia.

4. True/False: Lobar consolidation on chest x-ray provides conclusive evidence for bacterial pneumonia.

5. Which factor does not appear to affect the etiology of pneumonia?
    a. Age
    b. Vaccination status
    c. Current antibiotic use
    d. Birth rank

6. The most common cause of bronchiolitis is:
    a. Respiratory syncytial virus
    b. Human Metapneumovirus
    c. Parainfluenza
    d. Adenovirus

7. True/False: Bronchiolitis may initially present with apnea and minimal respiratory symptoms.

8. Treatment of bronchiolitis should include all of the following except:
    a. Supplemental oxygen for infants with hypoxia.
    b. Intravenous fluids and close monitoring of nutritional status.
    c. Good handwashing.
    d. Antibiotics.

9. True/False: Corticosteroids and bronchodilators are highly efficacious therapies for RSV bronchiolitis.

Answers to questions

1.c. Overall, viruses cause the majority of pneumonias in children; however, the incidence of viral pneumonia decreases with age, becoming less common in older children and adolescents.

2.b

3.False
4.False. Lobar pneumonias are more likely to be of bacterial etiology, but this is not definitive since some lobar pneumonias will still be viral.
5.d
6.a
7.True
8.d
9.False

Chapter VI.12. Croup and Epiglottitis
Paul J. Eakin, MD

This is a 20 month old male who presents to the emergency department with a chief complaint of cough. Two days ago he developed rhinorrhea, fever, a hoarse cry and a progressively worsening, harsh, "barky," cough. Today he developed a "whistling" sound when he breathes, so his parents brought him to the emergency department. His past medical history is unremarkable. His 6 year old brother also has cold symptoms.

Exam: VS T 37.5, P 140, R 36, BP 90/64, oxygen saturation 96% in room air. He is alert, with good eye contact, in mild respiratory distress. He has a dry barking cough and a hoarse cry. He has some clear mucus rhinorrhea but no nasal flaring. His pharynx is slightly injected, but there is no enlargement or asymmetry. His heart is regular without murmurs. His lung exam shows good aeration and slight inspiratory stridor at rest. He has very slight subcostal retractions. No wheeze or rhonchi are noted. His abdomen is flat, soft, and non-tender. His extremities are warm and pink with good perfusion.

He is treated with nebulized racemic epinephrine and his coughing subsides and his stridor resolves. A lateral neck X-ray reveals no prevertebral soft tissue widening or evidence of epiglottitis. The subglottic region is mildly narrowed. He is treated with oral dexamethasone. He is discharged home after one hour of monitoring and his parents were instructed to treat him with humidified mist therapy.

Croup, which is derived from an Anglo-Saxon word meaning "to cry out", is a common respiratory illness in childhood. Croup is also known as laryngotracheitis and laryngotracheobronchitis (LTB). These terms will be used interchangeably in this chapter. The diagnosis describes a disease with some degree of laryngeal inflammation; resulting in hoarseness, a barking cough and varying degrees of respiratory distress over time. There are different etiologies encompassed in the diagnosis of croup, but the most common cause is viral, and this will be the focus of this chapter. The entity known as spasmodic croup is not easily distinguished from viral croup except that spasmodic croup has a greater tendency to recur. The treatment and evaluation are similar. When evaluating a child with croup, it is important to rule out epiglottitis, so this will be discussed as well.

Croup occurs most commonly between the ages of 1 and 6 years, with a peak incidence being around 18 months of age and the majority of cases below 3 years of age. It is more common in boys than girls. In temperate climates, it is most common during the late fall and winter, although cases can occur throughout the year.

Parainfluenza viruses are the most frequent cause of croup, accounting for more than 60% of cases. Less frequently associated with croup are influenza A and B, respiratory syncytial virus, adenovirus and measles. Bacterial superinfection can occur in cases of laryngotracheobronchitis and laryngotracheobronchopneumonitis.

Like most respiratory infections, the initial site of infection is thought to be the nasopharynx with subsequent spread to the larynx and trachea. The respiratory epithelium becomes diffusely inflamed and edematous, resulting in airway narrowing and stridor. Reduced mobility of the vocal cords results in a hoarse voice or cry.

Laryngotracheitis generally starts with several days of rhinorrhea, pharyngitis, low-grade fevers and a mild cough. Over the next 12 to 48 hours, a progressively worsening "barky" cough, hoarseness and inspiratory stridor are noted, secondary to some degree of upper airway obstruction and laryngeal inflammation. The speed of progression and degree of airway obstruction can vary widely. The onset is often rapid and typically in the early morning hours (e.g., 2:00 am). Croup symptoms appear to subside during the day (possibly because of positioning), only to recur the following night. Thus, a child with significant stridor presenting during daylight, may be more seriously affected. On examination, the child will be noted to have coryza, a hoarse voice, and varying degrees of pharyngeal inflammation, tachypnea, and stridor. More severe cases may involve nasal flaring, moderate tachypnea, retractions and cyanosis. Some children with croup may not be able to maintain adequate oral intake of fluids. Alveolar gas exchange is usually normal, with hypoxia seen only in severe cases. Symptoms of croup usually normalize over 3-7 days, although in severely affected children, this may take 7-14 days.

The diagnosis is usually made on clinical grounds. Laboratory studies add little to the diagnosis of croup if bacterial infection is not suspected. White blood cell counts may be elevated above 10,000 with a predominance of polymorphonuclear cells. White blood cell counts greater than 20,0000 with bandemia may suggest bacterial superinfection. Chest radiographs may show subglottic narrowing (in 50% of children with croup), but this can also be seen in normal patients. Lateral neck radiographs are often obtained, not as much to confirm the diagnosis of croup, but to rule out other causes of stridor such as soft tissue densities in the trachea, a retropharyngeal abscess and epiglottitis.

The most important diagnostic consideration is distinguishing acute epiglottitis from acute laryngotracheitis. Epiglottitis describes a bacterial infection of the epiglottis. It is most commonly caused by H. influenzae type B, and occasionally by S. pneumoniae and group A Streptococcus. The prevalence of epiglottitis has decreased markedly (almost non-existent) since the widespread use of H. influenzae B vaccine.

The peak incidence of epiglottitis is between the ages of 3 and 7 years, with cases described in infants and adults as well. It occurs throughout the year, but is more common in winter months. Children with epiglottitis do NOT have a "croupy" cough. They appear more toxic, stridorous, apprehensive, have higher fever (e.g., 40 degrees C, 104 degrees F) and will often be drooling. Patients will often be tachycardic and tachypneic. The child with epiglottitis may prefer to adopt a position of sitting up, leaning forward, with their chin pushed

forward and they may refuse to lie down. They will have a very inflamed, swollen epiglottis. Lateral neck radiographs may be helpful in making the diagnosis. X-rays are usually deferred if this diagnosis is suspected, owing to the critical clinical condition of the patient. The three characteristic findings on lateral neck X-ray are: a swollen epiglottis (thumb sign), thickened aryepiglottic folds and obliteration of the vallecula (pre-epiglottic space). Lab work is usually not done, but if done generally reveals elevated white blood cell counts with a left shift and blood cultures are positive in 80-90% of cases.

Other entities on the differential include bacterial laryngotracheobronchitis and laryngotracheobronchopneumonitis, which will have signs of lower respiratory involvement such as, wheezing and/or changes on chest x-ray. Often they will have hypoxia secondary to the lower airway disease. Retropharyngeal or peritonsillar abscess can cause upper airway obstruction, with soft tissue swelling evident on lateral neck x-ray (widening of the prevertebral soft tissue) or physical exam respectively. These children will often have high fever, drooling and be more toxic in appearance. Laryngitis can be seen in older children and adults, with a similar prodrome and cough, but lacking the inspiratory stridor. Foreign body aspiration should be considered in cases of sudden onset stridor without cough or fever. Acute angioneurotic edema, can cause acute swelling of the upper airway, but usually presents with external evidence of swelling of the face and neck. Laryngeal diphtheria (sometimes presents with a croup like syndrome known as membranous croup), although rare, should be considered and is another reason to assess the immunization record.

Once the diagnosis of croup is made, mist therapy, corticosteroids and epinephrine are the usual treatments. Since croup is chiefly viral in etiology, antibiotics play no role. Historically, mist therapy has been the mainstay of croup therapy, yet in small empiric trials, mist therapy has shown little benefit. Mist therapy (warm or cool) is thought to reduce the severity of croup by moistening the mucosa and reducing the viscosity of exudates, making coughing more productive. For patients with mild symptoms, mist therapy may be all that is required and can be provided at home.

For more severe cases, further intervention may be required. Oxygen should be provided to patients with hypoxemia. Racemic epinephrine, given by nebulizer, is thought to stimulate alpha-adrenergic receptors with subsequent constriction of arterioles and decreased laryngeal edema. Nebulized epinephrine may have marked effect to decrease inspiratory stridor and the work of breathing. Adverse effects include tachycardia and hypertension. The effects of this medication last less than two hours and children need to be monitored (not necessarily in the hospital) serially for the return of symptoms. Racemic epinephrine is a mixture of 50% biologically active epinephrine and 50% inactive epinephrine. The usual dose is 0.5cc of the 2.25% concentration diluted with 2cc of saline. 0.5cc of the 2.25% is equal to 11 mg of racemic epinephrine or 5.5 mg of plain epinephrine (0.5 cc of 2.25 gm/100cc = 11 mg). Thus, 5cc of 1:1000 epinephrine solution is pharmacologically similar and can also be used for inhalation therapy with a nebulizer if racemic epinephrine is not available.

Corticosteroids provide benefit for children with viral croup by reducing the severity and shortening the course of the symptoms. Dexamethasone is the most commonly used, with the dose being 0.6 mg/kg (maximum 10 mg) by mouth or intramuscularly. Clinical improvement from corticosteroids is usually not apparent until 6 hours after treatment. More recent studies have shown high dose nebulized budesonide to be as effective as dexamethasone, with more rapid onset of effect.

Endotracheal intubation is reserved for children with severe symptoms who do not respond to the previous therapies. This decision should be based on criteria such as hypercarbia, impending respiratory failure and changes in mental status.

If epiglottitis is suspected, the most serious complication is sudden airway obstruction. Because of this, airway management becomes the most important consideration. Visualization of the epiglottis should not be attempted, unless clinical suspicion is low or respiratory failure occurs. Assistance from a surgeon, intensivist, anesthesiologist, etc. (more than one is better), should be sought immediately since patients with epiglottitis may arrest at any time. Intubation is difficult so preparation should be made for intubation or tracheostomy. If the child is stable, it may be possible to start at intravenous line and obtain radiographic studies. Once the airway is secure, IV antibiotic therapy with either ceftriaxone or cefotaxime should be initiated. In the event of a respiratory arrest, mask ventilation with 100% FiO2 should be attempted using a two-person technique with one person ensuring a tight mask fit and the other squeezing the ventilation bag hard enough to drive air through the narrowed airway. Placing the patient prone (instead of the usual supine position) may improve ventilation by utilizing gravity to lift the epiglottitis off the larynx.

Most children with croup do extremely well and do not require hospitalization. Most children can be discharged from the emergency department after receiving dexamethasone and epinephrine therapy if they have no stridor at rest, normal color, aeration and level of consciousness and have been monitored for a period of time. 3-4 hours of observation is often recommended, but this is rarely followed in actual practice since most families are reluctant to remain in the emergency department during the early morning hours if their child is now sleeping comfortably.

Questions

1. Which of the following viruses are most commonly associated with viral croup?
    a. Adenovirus.
    b. Human papilloma virus
    c. Varicella virus
    d. Parainfluenza viruses
    e. RSV

2. True/False: An acutely ill child presents to the emergency department with the signs and symptoms of acute epiglottitis. The diagnosis should be confirmed with direct visualization of the epiglottis?

3. Which of the following is/are true?
    a. There is good evidence from randomized controlled trials that mist therapy is effective for the treatment of croup.
    b. Antibiotics are indicated in the treatment of croup.
    c. Nebulized albuterol is effective in the treatment of croup.
    d. Dexamethasone has been shown to be effective in the treatment of croup.

4. Which of the following is/are true?
   a. Croup affects more girls than boys.
   b. Croup shows no seasonal prevalence.
   c. Most cases occur in teenagers.
   d. It is a common respiratory infection in children.

5. True/False: Once a child with croup has been given corticosteroid treatment and racemic epinephrine, they may safely be discharged home after 20-30 minutes of monitoring.

Answers to questions

1. d.

2. False. Routine airway visualization is stressful and may precipitate respiratory arrest. If epiglottitis is unlikely, then airway visualization appears to be safe. In the event of respiratory arrest, laryngoscopy will be necessary for tracheal intubation.

3. d is the best answer. c is also correct in that nebulized albuterol does have some efficacy in croup, but nebulized epinephrine is better.

4. d.

5. Most textbooks would suggest that this is false in that a longer observation period is generally recommended. However, most patients are low risk and can be discharged soon after dexamethasone and epinephrine are administered. Severe patients or those who do not respond as well should be observed for longer periods of time.

Chapter VI.13. Cellulitis
Leo U. Pascua, MD

A 2-year-old male presents to the emergency department with a chief complaint of left thigh swelling, fever, irritability, and unwillingness to stand upright for the last 2 days. He has been scratching at mosquito bites that he had gotten while weekend camping about 1 week ago.

Exam: VS T 39.5, P 110, R 26, BP 120/70. Growth parameters are normal for age. He is fussy, somewhat distractible, but clearly uncomfortable. He is continuously scratching at a left upper inner thigh lesion measuring 6 x 3 cm. The skin over the area is indurated, erythematous and tense, and tender. No fluctuance or wound drainage is noted. There is no joint involvement. Some tender lymph nodes are palpable in the left inguinal region.

He is prescribed cephalexin and anti-pyretics. In follow-up the next day, the erythematous region is slightly darker (a shift from red toward a shade of purple). Tiny blisters are also noted over the area. These changes are expected and treatment is continued. On follow-up day 2, the fever has resolved and the cellulitis appears to be clearly improving. His parents are instructed to finish the course of antibiotics. He is next seen in follow-up 7 days later, at which time, his cellulitis is resolved.

The basic response to infection is fever. The local, dermatological acute inflammatory reaction of cellulitis stems specifically from granulocytic infiltrations, hyperemia, and capillary leakage. This is the basis for the skin disruption inherent in cellulitis. The patient may guard the tender area. If the cellulitic area overlies a mobile area such as a joint, the patient may display resistance or anxiety with limb movement, either passive or active.

The specific visual characteristics (appearance) of the cellulitic region can provide important clues as to the organism(s) involved, with implications for treatment and prognosis. Clinical presentation, treatment, and prognosis differ depending on the causative organism and the location of the cellulitis. The remainder of this chapter will be stratified by these factors.

Group A strep cellulitis

Generally, cellulitis suggests the presence of a skin infection due to group A beta-hemolytic streptococci (GABHS, also known as Strep pyogenes). GABHS cellulitis is a painful, erythematous, indurated infection of the skin and subcutaneous tissues. It is classically described as large lesions, erythroderma in color (magenta), slightly raised at the border, with a small, central open skin lesion (frequently an insect bite). It is common for varicella lesions to become secondarily infection with GABHS. GABHS cellulitis may present with scarlet fever. Abscess formation beneath the cellulitis is very uncommon. GABHS is penicillin and cephalosporin sensitive.

Staph aureus cellulitis

Staph aureus is commonly cultured from impetigo lesions, albeit usually as a secondary pathogen, along with GABHS. Some of these lesions develop into cellulitis, which may be primarily caused by GABHS or alternatively, caused primarily by Staph aureus. Staph aureus cellulitis is typically smaller (than the larger GABHS cellulitis) and is frequently associated with an abscess or pustule. In many of these cases, the abscess is the major problem (i.e., incision and drainage is required), as opposed to the cellulitis which is relatively less of a problem.

H. flu type b cellulitis

H. influenzae type b (Hib) used to account for in 5-14% of the cellulitis cases in young children. More than 85% of children with H. influenzae type b cellulitis are 2 years of age or younger. Hib is a particularly virulent organism which is frequently associated with sepsis. A common location for Hib cellulitis was the periorbital and buccal region. Cellulitis is a complication of H. influenzae septic arthritis 10-30% of cases. Fortunately, there has been a substantial decline in the incidence of invasive infection caused by Hib with the practice of routine immunization of infants against this organism, to the point where Hib infection is almost non-existent. Hib is covered by high generation cephalosporins (e.g., ceftriaxone) and by broad spectrum oral drugs such as amoxicillin-clavulanate and cefuroxime.

Pasteurella/animal bite cellulitis

Cellulitis and lymphangitis typically appears 24-36 hours after mammalian bite injuries. The etiologies of infections following mammalian bites are polymicrobial and consist of mixed anaerobic and aerobic bacteria. In one study, an average of three different bacterial species was isolated from infected dog bites while a mean of five different species was recovered from infected human bites. Because of the numerous bacterial species in mammalian oral cavities and on the victim's skin, contamination of bite injuries is universal. Pasteurella multocida is sensitive to penicillins, but it is less sensitive to cephalosporins. Amoxicillin-clavulanate is generally used for animal bites to cover Pasteurella, staph aureus and anaerobes.

Orbital and periorbital cellulitis

Periorbital (preseptal) cellulitis involves inflammation of the lids and periorbital tissues without signs of true orbital involvement, such as proptosis or limitation of eye movement. It presents as a red and swollen infection limited to the superficial tissue layers anterior to the orbital septum. History usually yields an antecedent respiratory infection or bacteremia. Historically, H. influenzae type b was an important cause, and presented with fever, edema, tenderness, warmth of the lid, and, occasionally, purple discoloration (violaceous hue). However, streptococcal organisms are the most common cause of bacteremia associated with periorbital cellulitis in the post Hib-vaccinated era (9). S. pneumonia, Staphylococcus aureus, and group A beta-hemolytic streptococci cause clinically indistinguishable preseptal cellulitis (2). The latter two pathogens are more likely when fever is absent and with an interruption of the integument (e.g., an insect bite) (1).

Distinguishing periorbital from orbital cellulitis can be difficult. If proptosis, extraocular movement dysfunction, or visual deficits are clearly present, then orbital cellulitis is likely. However, in the absence of these findings, the diagnosis is unclear. In periorbital cellulitis, the lid swelling may be so severe, that it is not possible to tell if proptosis is present. A CT scan of the orbits will reliably distinguish periorbital from orbital cellulitis. Since the difference between the two can be important, a CT scan of the orbits has become routine in the evaluation of most patients with severe periorbital cellulitis and/or suspected orbital cellulitis.

Orbital cellulitis refers to a condition involving not only edema of the conjunctiva (chemosis), and inflammation and swelling of the eyelids, but also involvement of the tissues of the orbit, with subsequent proptosis (limitation of movement of the eye). In general, orbital

cellulitis may follow direct infection of the orbit from a wound, metastatic deposition of organisms during bacteremia, or direct extension or venous spread of infection from contiguous sites such as the lids, conjunctiva, globe, lacrimal gland, nasolacrimal sac, or paranasal sinuses. The most common cause of orbital cellulitis in children is paranasal sinusitis, with the most frequent pathogenic organisms being Haemophilus influenzae, Staphylococcus aureus, group A beta-hemolytic streptococci, and Streptococcus pneumonia. Orbital cellulitis must be recognized promptly and treated aggressively. Hospitalization and systemic antibiotic therapy are usually indicated. In some cases surgical intervention is necessary to drain infected sinuses, or a subperiosteal or orbital abscess. Intravenous treatment for 10 to 14 days is highly recommended, along with repeated eye exams (visual acuity, pupillary reactivity, extraocular movements, and visual fields) to evaluate possible progression of infection and/or involvement of the optic nerve (10). As a worst case scenario, orbital cellulitis can lead to the complication of brain abscess, especially in the frontal lobe.

Finally, orbital cellulitis is an infrequent presenting sign of retinoblastoma. The severe clinical implications of retinoblastoma (enucleation may be inevitable) warrants vigilance for a white pupillary reflex (leukocoria, the reflection of light off the white tumor), pseudohypopyon (tumor cells layered inferiorly in front of the iris caused by tumor seeding in the anterior chamber of the eye), and hyphema (blood layered in the anterior chamber) secondary to iris neovascularization or vitreous hemorrhage.

Erysipelas

Erysipelas is an acute, well-demarcated aggressive infection of the skin with lymphangitis involving the face (associated with pharyngitis) and extremities (wounds). The skin is erythematous and indurated. The advancing margins of the lesions have raised, firm borders. The skin lesion usually is associated with fever, vomiting, and irritability. In some cases, streptococci break through the lymphatic barrier (lymphangitis), and subcutaneous abscesses, bacteremia, and metastatic foci of infection are observed. Bacteremia and death have been associated with streptococcal cellulitis, and progression may be so rapid that there may be no response to treatment with penicillin. The popular press has termed severe cases of GABHS cellulitis (necrotizing fasciitis) as "flesh eating bacteria".

Lymphangitis

Lymphangitis is an inflammation of the lymphatics draining an area of infection (i.e., a cellulitis site). On exam, tender red streaks extend proximally from the infected site. S. aureus and group A strep are the most frequent pathogens. A history of impetigo is also suggestive of cellulitis, in that, cellulitis has been reported in approximately 10% of patients with nonbullous impetigo but rarely follows the bullous form. There is no correlation between the number of lesions and clinical involvement of the lymphatics or development of cellulitis in association with streptococcal impetigo. The history is consistent with pruritic lesions subject to frequent scratching and secondary infection (including insect bites, pediculosis and scabies). This is followed by the development of a vesicle or vesiculopustule with an erythematous base that erodes through the epidermis into the dermis to form an ulcer with elevated margins. A dry crust that contributes to the persistence of the infection obscures the ulcer. Lesions may be spread by autoinoculation, may be as large as 4 cm, and occur most frequently on the legs or pruritic areas within reach.

Risk of osteomyelitis and septic arthritis

Although the risk of osteomyelitis and septic arthritis is fairly rare unless a penetrating wound is present, the relationship between osteomyelitis and cellulitis deserves special attention, in that a progression to osteomyelitis from cellulitis mandates a far more aggressive and prolonged antibiotic course, not to mention possible orthopedic surgical debridement. Thus, when a diagnosis of cellulitis is made, the comorbid presence of osteomyelitis must also be strongly considered especially when corroborated by a history of a penetrating wound. At the very least, cellulitis accompanied by point tenderness or joint pain is highly suggestive of osteomyelitis. Attempts at diagnosis are complicated by the fact that cellulitis of structures in proximity to bone can mimic osteomyelitis.

To effectively discern cellulitis with possible underlying osteomyelitis, combining technetium bone scanning with other radionuclide scanning techniques or MRI scanning may be useful. In a three phase bone scan, focal increased uptake in the initial phase, with subsequent decline in the later phases (especially the bone phase), is suggestive of cellulitis without osteomyelitis. In osteomyelitis, localized uptake is seen in all three phases, especially in the bone phase.

If the history, physical exam, or radiological studies suggest deep cellulitis near a joint, the level of suspicion is raised with regard to an infection in the respective joint, not to mention osteomyelitis, synovitis, septic bursitis and pyomyositis in nearby muscles. Deep cellulitis is also consistent with psoas or retroperitoneal abscesses. Cellulitis overlying a joint can interfere with studies crucial to the diagnosis of septic arthritis. If a cellulitic area is traversed during arthrocentesis for a workup for septic arthritis, the results can be confounded if organisms are introduced into a previously sterile uninvolved joint.

Cellulitis and immunodeficiency

The presence of cellulitis in the face of concomitant immunodeficiency requires inpatient treatment. Deficient expression of leukocyte adherence glycoproteins can present as cellulitis or small (<1 cm) necrotic abscesses on any area of the body. In such cases, puncture wounds or skin surface trauma often precipitates cellulitis and abscess formation.

Defects in the normal host response may be reflected in study findings that are disproportionately severe when compared to relatively benign findings on the physical exam. For example, deep cellulitis may be quite impressive on a CT of a neutropenic patient who has only mild superficial swelling or erythema. Indeed, surface pus formation is unusual at sites of even severe cellulitis in such patients.

Cellulitis in children with burns illustrates not only the acute effects of interrupted skin and mucous membrane barriers, presence of necrotic tissue, long-term administration of antibiotics and prolonged intravenous or urinary catheterization, but also the concomitant abnormal immune response to infection, including neutrophil dysfunction. The resulting neutrophil chemotactic defect, combined with an associated hypogammaglobulinemia is a perfect scenario for cellulitis with Pseudomonas aeruginosa being the most common organism.

In the neonatal period, cellulitis can be a manifestation of invasive infection, as is bacteremia with a septic-like clinical picture, pneumonia, respiratory distress syndrome with shock, conjunctivitis, scalp abscess, or meningitis. Cellulitis may be the presenting sign of immunodeficiency in an infant. Cellulitis, delayed separation of the umbilical cord and gingivitis is consistent with an infant with leukocyte adhesion deficiency. Cellulitis of the labia majora, pyogenic skin infections, oral ulcerations, or abscesses has been the presenting manifestations of autoimmune neutropenia of infancy.

Cellulitis of the perirectal area, sites of iatrogenic puncture (central venous catheter insertion, venipuncture, lumbar puncture, and bone marrow biopsy), or abrasions is a setup for gram negative dissemination. In the context of vaginitis, beta-hemolytic streptococcus is

a common cause in prepubertal girls and may present with perianal cellulitis with local itching, pain, blood-streaked stools, erythema, and proctitis (3).

Rarely, cellulitis or skin discoloration overlying a fluctuant mass might be the presenting finding in tuberculosis of the superficial lymph nodes, often referred to as scrofula, the most common form of extrapulmonary tuberculosis in children. The tonsillar, anterior cervical, submandibular, and supraclavicular nodes become involved secondary to extension of a primary lesion of the upper lung fields or abdomen. The nodes usually enlarge gradually in the early stages of lymph node disease. They are firm (but not hard), discrete, and nontender. The nodes often feel fixed to underlying or overlying tissue. Disease is most often unilateral, but bilateral involvement may occur because of the crossover drainage patterns of lymphatic vessels in the chest and lower neck.

Cellulitis of the sublingual and submandibular spaces (Ludwig angina) tends to spread rapidly without lymph node involvement or abscess formation. It is an acute, life-threatening entity that may require tracheostomy in the event of respiratory obstruction.

Cellulitis of the auricle and external auditory canal is usually caused by S. pyogenes (GABHS) or occasionally by S. aureus. The skin is red, hot, and indurated, without a sharply defined border. Fever may be present with little or no exudate in the canal.

Cellulitis can be a complication of hidradenitis suppurativa, a chronic, inflammatory, suppurative disorder of the apocrine glands in the axillae or anogenital area, and occasionally, the scalp, posterior aspect of the ears, female breasts, and around the umbilicus. Cellulitis of the lateral nail fold can occur as spicules that have separated from the nail plate, penetrate the soft tissue. Predisposing factors include compression of the side of the toe from poorly fitting shoes, particularly if the great toes are abnormally long and the lateral nail folds are prominent, and improper cutting of the nail in a curvilinear manner rather than straight across. Oral antibiotics are necessary to treat cellulitis of the lateral nail fold.

Lab tests are generally not very helpful in cellulitis. A CBC might help to assess infection severity. A blood culture may be indicated if bacteremia or sepsis is suspected. A gram stain of a leading edge aspirate is done by injecting a small amount of non-bacteristatic saline into the leading edge of the cellulitis, then aspirating back the saline. Leading edge cultures have a low yield and they are usually not obtained. Since introduction of the Hib vaccine, the most common organisms are streptococci. In a series of 243 children admitted with cellulitis, Sadow and Chamberlain (1998) contend that, given a treatment threshold based on a band-to-neutrophil ratio of 0.20 on a CBC differential, routine cultures contribute little to the decision to treat (7). Most cases of early or mild cellulitis, especially those without fever, do not require laboratory testing. Empiric antibiotic treatment is successful in most instances.

Antibiotic treatment is targeted mainly against the usual pathogen, group A strep. Staph aureus is uncommon (unless an abscess is present), but difficult to exclude without a leading edge aspirate culture. GABHS is sensitive to penicillin and cephalosporins. Staph aureus used to be sensitive to anti-Staph aureus penicillins (cloxacillin, dicloxacillin, methicillin, oxacillin, nafcillin) and cephalosporins. However, currently, 25% of Staph aureus are resistant (i.e., methicillin and cephalosporin resistant). If GABHS is very likely, then utilizing a cephalosporin or penicillin is acceptable. However, if Staph aureus is suspected, then there is a 25% failure rate for cephalosporins and anti-Staph aureus penicillins. There is less Staph aureus resistance to clindamycin (also covers GABHS) and trimethoprim-sulfamethoxazole (does not cover GABHS as well). Thus, clindamycin is generally indicated if Staph aureus is suspected. Vancomycin and aminoglycosides are parenteral and can only be used for inpatient treatment of staph aureus. Erythromycin has been used in the past, but GABHS and Staph aureus have high resistance rates to erythromycin. If a satisfactory clinical response is not achieved within 7 days, a culture and sensitivity should be taken of a leading edge aspirate. If a resistant organism is detected, an appropriate antibiotic should be given for an additional 7 days.

Young children (<36 months of age) with pneumococcal facial lesions cellulitis are at risk for pneumococcal bacteremia, and usually present with fever and leukocytosis. With regard to prevention, a recent study noted that 96% of the pneumococcal serotypes causing facial cellulitis are included in the heptavalent-conjugated pneumococcal vaccine recently licensed in the United States (8).

Finally, aggressive attempts to restore skin integrity should be initiated. The skin should be gently moistened and cleansed. Impetiginous crusts should be softened with warm compresses and removed with an antibacterial soap. Application of an emollient provides lubrication and decreases discomfort. Topical antibiotics are unnecessary once systemic intervention is started.

Questions

1. A three-phase bone scan is being used to determine if osteomyelitis is coexisting in a cellulitis patient. Which finding would be consistent with the presence of osteomyelitis ?
   a. Focal increased uptake in the initial phase, with subsequent decline in the bone phase.
   b. Localized uptake in all three phases.

2. You are managing a serious pediatric burn victim who has developed cellulitis after repeated procedures for debridement of necrotic tissue. The patient has been on IV antibiotics and urinary catheterization since admission one month ago. Recent labs show hypogammaglobulinemia. The most likely pathogen is
   a. Pseudomonas aeruginosa
   b. Pasteurella multocida
   c. E. coli
   d. Herpesvirus
   e. Cryptosporidium

3. You are investigating a case of cellulitis secondary to a bite wound. The study shows seven different bacterial species isolates. The bite was most likely from:
   a. a human
   b. a cat
   c. a dog
   d. rat
   e. a pig

4. Which antibiotic class is NOT considered appropriate for outpatient treatment against cellulitis?
   a. Clindamycin
   b. Penicillin
   c. Cephalosporin
   d. Aminoglycoside

5. You have obtained a CT scan on a toxic-appearing patient, and the radiologist calls you to report a finding of an extensive deep cellulitis. A re-examination of the area shows only slight erythema superficial to the area of extensive deep cellulitis as seen on CT. A CBC of the patient is likely to show:
   a. neutropenia
   b. thrombocytopenia
   c. absolute lymphocytosis
   d. monocytosis
   e. increase red cell distribution width

Chapter VI.14. Meningitis
Raul Rudoy, MD, MPH

Case 1

A six month old male presents to the emergency department with a history of lethargy. He was seen 3 days ago with fever and URI symptoms, diagnosed with otitis media and treated with oral amoxicillin. This morning he had become irritable and was less active than usual. He has vomited three times and his urine output is noticeably decreased. He has no diarrhea.

Exam: VS T 40.0, P 90, R 30 (irregular), BP 120/90, weight 8kg. He is lethargic and arousable only to painful stimuli. His anterior fontanel is full and tense, and he has questionable neck rigidity. His TMs are red and bulging. His pupils are reactive, but his eyes do not focus well on his parents. His heart, lungs and abdomen are normal. His color and perfusion are good. He has no petechiae. He moves all his extremities weakly and his DTRs are hyperactive.

A CBC, blood culture and chemistry panel are drawn. An IV is started. Since an increased ICP (intracranial pressure) is suspected, a lumbar puncture (LP) is initially delayed and he is immediately given 500 mg of ceftriaxone IV. A stat CT scan of the brain is normal, so an LP is done and the CSF (cerebrospinal fluid) is visibly hazy. An infectious disease consultant is called to inquire about IV dexamethasone and vancomycin. Both are recommended and given. The CSF results return 1 hour later showing 450 WBCs, 95% segs, 5% monos, total protein 75, glucose 25 mg/dl. Gram stain of the CSF shows many WBCs with few gram positive cocci. He is admitted to the pediatric ICU.

The clinical presentation of this patient, with a very rapidly evolving febrile illness, changes in sensorium and evidence of increased intracranial pressure, is very compatible with a diagnosis of CNS (central nervous system) infection. Bacterial meningitis occurs more frequently between the ages of 2 months and two years. Acquisition of infected aerosolized particles, with initial colonization of the nasopharynx, is followed by subsequent replication in the regional lymph nodes, invasion, septicemia and CNS infection. The lack of anticapsular antibodies increases the risk of invasion. Rarely, the infection is due to spread from a contiguous focus such as the sinuses, the middle ear, or the mastoids. Bacterial meningitis secondary to otitis media is an uncommon phenomenon, but when it does occur, it is usually septicemic in origin, rather than due to direct extension.

Manifestations of bacterial meningitis are variable and depend upon the child's age and the duration of illness. In young infants, evidence of meningeal inflammation may be minimal and only irritability and poor feeding may be present. Body movements of infants with meningitis result in pain, accordingly a strong suspicion of CNS infection is aroused when the child does not wish to be handled but prefers to remain motionless. Such paradoxical irritability (which worsens when the child is carried, rocked or gently bounced), is highly suggestive of meningitis.

The older child will present with more clinical findings, such as nuchal rigidity, vomiting, lethargy and photophobia. Most cases of meningitis will be either of bacterial or viral etiology. Common bacterial causes in this age group include Streptococcus pneumonia

(pneumococcus) and Neisseria meningitidis (meningococcus). The advent of a very efficacious vaccine against H. influenzae type B, has resulted in an almost complete disappearance of meningitis due to this etiological agent. Prior to this vaccine, this was the most common cause of bacterial meningitis.

An LP is indicated in patients with clinical findings compatible with meningitis. Strong consideration should be given to delaying the LP in patients with clinical findings of increased intracranial pressure. However, antibiotic administration should not be delayed by this. Antibiotics must still be given immediately once bacterial meningitis is suspected. The patient in our case has evidence of increased intracranial pressure since he has decreased sensorium, a bulging tense fontanel, hyperactive reflexes and changes in the vital signs such as a decreased pulse rate, hypertension and irregular respirations (Cushing's triad). Accordingly, caution should be taken before performing the LP due to the possibility of precipitating herniation. A CT scan of the head is a very rapid and accurate means to confirm increased intracranial pressure and if present, measures such as the administration of mannitol and hyperventilation, after rapid sequence intubation, should be instituted before the LP is done. Analysis of the CSF is usually very useful in confirming the diagnosis of bacterial meningitis. Acute bacterial meningitis is characterized by an elevated CSF white count with a predominance of polymorphonuclear cells (neutrophils), a decreased CSF glucose level, an increased protein value and a positive gram strain and culture. Administration of oral antibiotics prior to the LP, do not greatly modify the LP results, except for a slight decrease in the rate of identifying the organism on gram strain and cultures.

The treatment of meningitis is directed at reducing the damage produced by the inflammatory response by maintaining adequate cerebral perfusion with the use of adequate amounts of intravenous fluids and agents that reduce intracranial pressure and by treating the infection. The use of a third generation cephalosporin such as cefotaxime (50 mg/kg dose every 6 hours) or ceftriaxone (100 mg/kg day in one dose) provides coverage for most of the agents responsible (pneumococcus, meningococcus, H. influenzae type B) for meningitis except for penicillin-resistant pneumococcus which require the addition of vancomycin. Antibiotics used to treat meningitis must reliably penetrate the blood brain barrier in addition to reliably cover the organisms involved. The duration of treatment is dictated mostly by the clinical course but usually is 5 to 7 days for meningococcal infections and 10 days for infections due to pneumococcus. Neonatal meningitis has a different group of etiologic bacteria and antibiotics which are covered in the chapter on neonatal sepsis.

The survival of patients with bacterial meningitis has improved but it still remains a disease with high morbidity. Approximately half of those with S. pneumoniae and 15 percent of those with H. influenzae meningitis will develop neurological sequela. Cerebral infarction occurs in 5 to 20 percent of the patients as a result of localized inadequate perfusion due to local thrombosis, arteriolar vasculitis and phlebitis secondary to the inflammatory response. Sensorineural hearing loss is the most common sequela occurring in approximately 15 percent of cases. The hearing loss is usually severe, bilateral and permanent, and it occurs during the first few days of the infection. Penetration of bacteria through the internal auditory canal results in inflammation and destruction of the auditory nerve. Reduction in the incidence of hearing loss was reported with the use of corticosteroids (dexamethasone) for cases of H. influenzae meningitis, but proof supporting the benefit of corticosteroids with other causes of bacterial meningitis is not as evident. The use of corticosteroids is currently controversial due to the decrease in cases of H. influenzae meningitis (due to routine H. influenzae vaccine) and the fact that most cases of bacterial meningitis are now caused by pneumococcus and meningococcus, for which the benefit of corticosteroids is less proven.

Primary prevention of meningitis is accomplished by the administration of H. influenzae type B and S. pneumoniae vaccines to infants. Meningococcal vaccine is also available, but it is not routinely recommended, except adolescents and adults residing in dormitories or military barracks. Secondary prevention, with antibiotics such as rifampin is recommended for close contacts of patients with invasive H. influenzae type B and N. meningitis disease (but not for pneumococcal meningitis).

Case 2

A three year old female presents to the emergency department with a two day history of headache, nausea, vomiting and fever. She was seen by a physician two days ago who diagnosed otitis media and prescribed amoxicillin. She has taken six doses. Her immunizations are up to date. She is conscious, alert and complains of pain over the neck area. On examination she has pain on flexion of the neck. An LP showed 453 WBCs with 75% neutrophils and a glucose of 50 mg% (blood glucose 90 mg%) and a protein value of 55 mg%. A gram strain is negative for bacteria. Her headache improves and she appears less ill following the LP. She is admitted to the hospital with the diagnosis of viral meningitis. A repeat LP done 20 hours after the initial LP, shows 315 WBCs with 83% lymphocytes and a glucose value of 75 mg%, blood glucose of 89 mg%, and protein of 30 mg%. She is largely asymptomatic following the second LP. CSF cultures remain negative. A CSF PCR for enterovirus is positive.

Aseptic meningitis is characterized by lymphocytic/monocytic predominance of the CSF differential. The CSF protein is not as high and the glucose is not as low, compared to bacterial meningitis. Aseptic meningitis is almost always due to viral etiologies; however the rare case of tuberculous and fungal meningitis will present as an aseptic meningitis as well. Patients with viral meningitis can have all of the signs and symptoms of patients with bacterial meningitis; however, their findings are less severe. The classic patient with bacterial meningitis is toxic in appearance, irritable, and/or lethargic, possibly with other signs of sepsis. The typical patient with viral meningitis is alert and cooperative, but uncomfortable and mildly ill. Young infants are the most difficult to assess. Older cooperative children who can speak and express their symptoms are easier to evaluate. A lumbar puncture has two advantages in cases of viral meningitis in that it will usually ascertain a firm diagnosis and it will usually provide some degree of headache relief.

CSF neutrophil predominance can be initially seen in up to two thirds of cases of meningitis due to enterovirus and a slight decrease in the CSF blood glucose ratio occurs in one fourth of pediatric enteroviral meningitis. The low protein value and the relative low WBC are also indicative of a viral etiology. Enteroviruses are the leading cause of aseptic meningitis and account for 90 percent of all cases in which a pathogen is identified. Infants and children are most commonly affected and the prognosis is generally excellent. A CSF PCR for enterovirus is highly accurate in making an etiological diagnosis and will be positive in the great majority of cases. The repeated LP done 12 to 24 hours after the first will show a rapid shift in the CSF differential count from neutrophils to mononuclear predominance.

Questions

1. A three year old male presents with a bad headache, nausea, photophobia and fever (temp 38 degrees). His immunizations are up to date. He is not toxic in appearance. He is alert and cooperative. He has mild photophobia and mild nuchal discomfort without rigidity. He can speak and ambulate normally. The remainder of his exam is unremarkable. If this patient has meningitis, does he/she have bacterial or viral meningitis? What factors suggest one or the other?

2. An LP is done on the patient in question #1. The results show the following: 3 RBCs, 200 WBCs, 70% segs, 10% lymphs, 20 % monos, total protein 45, glucose 50. Gram stain of the CSF shows many WBCs and no organisms seen. Is this CSF analysis consistent with bacterial or viral meningitis? Which factors suggest one or the other?

3. What are the three most common bacteria that cause meningitis and what antibiotic covers them with close to 100% certainty?

4. Match the CSF results with the diagnosis (normal CSF, viral meningitis, bacterial meningitis). Validate your answer. Assume that the patient is 6 months old.

CSF	CSF 1	CSF 2	CSF 3	CSF 4
White cells	1243	5	190	250
%Neutrophils	94%	1%	60%	86%
CSF Glucose	23	65	50	47
Blood Glucose	78	85	87	90
Protein	62	21	48	49

Answers to questions

1. This is most likely a viral meningitis. He is older, so his risk of bacterial meningitis is lower. He has been fully immunized, which presumably means that he has had H. influenzae, type B vaccine. He has probably had pneumococcal vaccine, but this can't be automatically assumed. He is alert, ambulatory, and not toxic in appearance, which all suggest that he does not have an overwhelming infection such as bacterial meningitis.

2. This is most consistent with viral meningitis. Although he has a high percentage of segs, this is still consistent with early viral meningitis. Cases of bacterial meningitis which have not been pre-treated with antibiotics almost always have more than 90% segs. The gram stain does not show any organisms which makes bacterial meningitis less likely. This laboratory analysis of his CSF suggesting viral meningitis, is consistent with his clinical appearance which also suggests viral meningitis (see the answer to #1 above).

3. Pneumococcus, meningococcus and Haemophilus influenzae type B. Pneumococcus is usually sensitive to penicillins and cephalosporins, but some resistance has emerged so vancomycin should be given in addition to cefotaxime or ceftriaxone. Meningococcus is sensitive to penicillin so cefotaxime or ceftriaxone provides sufficient coverage. H. influenzae type B is sensitive to cefotaxime and ceftriaxone, but this organism is not a common cause of bacterial meningitis due to widespread immunization against this organism.

4. CSF 1 shows bacterial meningitis. The increased number of cells in the CSF with a predominant number of neutrophils makes this a strong likelihood possibility. In addition, he also has a very low glucose CSF level (CSF, blood glucose ratio of 25%) and an increased protein value sometimes. Cases of early viral meningitis can present with an increased number of cells and neutrophils but usually the CSF glucose is normal or not lower than 40% of the blood CSF value.

CSF 2 is normal. The normal number of WBCs in the CSF depends upon the age of the patient. The younger and more immature the infant is, the higher the value is. CSF glucose value depends upon the value of glucose in the blood and upon the integrity of the blood brain barrier. In patients with normal meninges the CSF value is usually about 75% of the blood level. When the meninges become inflamed, the active transport of glucose across the blood brain barrier becomes altered and the ratio drops proportionately to the degree of inflammation. Most viral meningitis produce less changes than bacterial meningitis accordingly CSF glucose values are lower in bacterial meningitis.

CSF 3 shows viral meningitis. Most cases of viral meningitis will present with a moderate increase in the number of white cells and a percentage of neutrophils not higher than 60-70%.

CSF 4 is inconclusive. The high percentage of neutrophils indicates that bacterial meningitis is possible. It would be wise to administer antibiotics until more information can be obtained. The gram stain result will be helpful. If it is positive for organisms, then this indicates bacterial meningitis. If the gram stain is negative, bacterial meningitis still cannot be totally ruled out. The child's clinical condition is not part of this table, but in reality, a child who is alert, active and playful is more likely to have viral meningitis, as opposed to a lethargic, toxic child who is more likely to have bacterial meningitis. This will probably turn out to be a case of viral meningitis despite the high percentage of neutrophils, since an early viral meningitis will often have high neutrophil percentages. A repeat LP 12 to 24 hours from the first LP will be helpful. A repeat LP which demonstrates a clear shift toward mononuclear cells, is consistent with viral meningitis, while no shift, or only a slight shift would suggest bacterial meningitis. Culture of the CSF will be most definitive if it is positive, but this result will not be available for at least 24 hours.

Chapter VI.15. Encephalitis
Jonathan K. Marr, MD

This is a healthy 11 year old male who is taken to his PMD for persistent headaches for the last 4 days despite treatment with acetaminophen and ibuprofen at home. He has had intermittent emesis and tactile fever for the last three days and has had minimal oral intake over the last 36 hours. There was no history of trauma, but he has had recent URI symptoms 2 weeks ago. After evaluation by his PMD, he is sent to the lab for tests when his mother notes that he is more sleepy and unresponsive. While going to the lab for tests, he develops shaking movements on the left side of his body. 911 is called and he is taken to an emergency department via ambulance. An IV is started and he is given diazepam IV which promptly stops the seizure activity.

VS: T 38.6, P 136, R 15 (shallow), BP 108/65, oxygen saturation 100% with mask. Wt 40kg. He is unresponsive to voice commands and he has shallow respirations. His head shows no signs of trauma. His pupils are equal at 3 mm and reactive to light. No papilledema on funduscopic exam is noted. His oral mucosa is moist with no oral lesions. His neck is supple without adenopathy. Heart is regular. Lungs are clear with shallow aeration. His abdomen is normal. His pulses, color and perfusion are good. He has several bug bites on his extremities without signs of cellulitis, petechiae, or bruises. He has increased tone to the left side of his body and brisk reflexes L>R. He is nonresponsive to voice commands, but he withdraws to pain. He exhibits no purposeful movements or signs of posturing. His corneal reflex, oculocephalic, and oculovestibular responses intact.

Encephalitis is suspected. He is given IV loading doses of fosphenytoin, acyclovir, and ceftriaxone. Lab studies show a normal CBC, chemistry, and liver function studies. Urine and serum toxicology screens are pending. A head CT without contrast shows no evidence of intracranial mass, ventriculomegaly, or intracranial bleed. A lumbar puncture is done. Opening pressure is 10 cm H20. CSF analysis shows 58 WBC (65% segs, 26% lymphs, 9% mono), protein 95, glucose 40, 4th tube on hold. Gram stain of the CSF shows few WBCs, but no organisms seen.

He is transferred to the PICU for further management.

Encephalitis is defined as an acute infection with focal or diffuse inflammation of brain parenchyma usually from viral etiologies, but it may also be associated with bacterial, fungal, protozoan, and autoimmune processes. Most often, encephalitis is an unusual complication of common systemic infections. Clinical manifestations reflect damage to neural cells that impair neural cell function through immune responses (1). The probability and severity of encephalitis can often be determined by: seasonality, age of infected groups, geographic distribution, availability of vaccines, animal or insect vector involvement, and immune-competency of the host.

The estimated incidence of viral encephalitis in the United States according to the Center for Disease Control (CDC) is 20,000 cases per year (5). It is an infrequent disease, occurring predominantly in children (16 per 100,000), elderly, and immunocompromised hosts (1). The incidence is highest in the second year of life (17 per 100,000 child years) and declines to 1 per 100,000 at age 15 (2). Overall mortality is 3 to 4% and morbidity is 7 to 10%. Endemic causes of encephalitis in the United States include herpes simplex virus (HSV), rabies virus, and La Cross virus. HSV is the most common cause of severe encephalitis in children and accounts for approximately 10% of all cases of encephalitis in the United States (2,4,5). Neonatal HSV-2 encephalitis with treatment, has a mortality of 14% (compared to 85% without treatment) and severe neurological dysfunction is found in 50 to 70% of affected individuals (2). HSV-1 encephalitis in older children represents the commonest cause of nonepidemic fatal viral encephalitis with a mortality of 30 to 50% and major neurological sequelae in 40 to 50% (2,6). Rabies virus infection accounts for several thousand deaths per year in Asian countries. In contrast, rabies virus is a rare cause of death or encephalitis in the United States due to the mandatory vaccination program of domestic canines. There are less than 5 indigenous cases of human rabies per year in the United States. One article, however, has suggested that the incidence in the United States may be increasing because of the changing epidemiology of infection in animal populations (5).

Arthropod-borne viruses (arboviruses) are agents of several virus families that can replicate in both invertebrate and vertebrate cells. Replication and infection of the hematophagous host must occur prior to injection of the vertebrate host. Over 400 arboviruses produce four major clinical syndromes associated with human arboviral infections: 1) encephalitis, 2) yellow fever, 3) hemorrhagic fevers, and 4) undifferentiated tropical fevers (6). La Cross virus is the most common cause of endemic arboviral encephalitis. St. Louis encephalitis is geographically the most widespread arbovirus in the United States and the commonest cause of epidemic viral encephalitis. The CDC receives reports of 200-500 cases of arboviral encephalitis per year. Encephalitis due to La Cross virus characteristically affects males (male:female ratio 2:1) 5-15 years of age in Wisconsin and Ohio, occurs from June to early October, and has less than 1% mortality (2,4,5). St. Louis encephalitis, in contrast, causes large urban epidemics among the elderly and occurs more frequently in the lower socioeconomic groups in the Midwestern and southeastern United States in late August and September following heavy spring rains and summer droughts. The virus is more common in urban environments where there is stagnant water with high organic content, particularly poorly draining sewage (6). Mortality ranges from 3 to 20%. Worldwide, Japanese encephalitis is the most common cause of arthropod-borne encephalitis with over 50,000 cases reported per year in China, Southeast Asia, and India (5). During epidemics, mortality ranges from 20 to 40%, with death usually occurring in the first week of illness (4). Eastern Equine encephalitis has peak activity from August to September and is geographically located along the eastern coast from Massachusetts to Florida. Compared to other arboviral encephalitides, Eastern Equine encephalitis symptoms are more severe and mortality is greatest at 50 to 75%. Mosquito-borne viruses peak in late summer in temperate regions, whereas tick-borne diseases occur in spring and early summer.

Post-infectious encephalomyelitis is an acute, inflammatory, demyelinating disease affecting multiple levels of the central nervous system (brain, optic nerves, and spinal cord) and occurs after a respiratory tract infection, viral exanthem, or an immunization. Synonymous names include: acute disseminated encephalomyelitis, acute demyelinating encephalomyelitis, and postviral encephalomyelitis. Occurrence is rare before 1 year of age, and it accounts for 10-15% of acute encephalitis cases in the United States (1) with peak incidence at 5 to 6 years of age. Historically, postinfectious encephalomyelitis was a complication of vaccinia immunization and measles virus infections; however, the discontinuation of vaccination against smallpox has eliminated the former, and immunization against measles has greatly reduced the later. Currently, post-infectious encephalitis in the United States is most commonly associated with varicella-zoster virus and influenza virus (5); although true postinfectious encephalomyelitis as a complication of varicella or influenza are rare (6). Other infections associated with postinfectious encephalomyelitis include: rubella, Mycoplasma pneumoniae, EBV, mumps, and human herpes virus 6 (HHV-6) (2,6). Worldwide there are over 100,000 cases that occur secondary to measles infection (5). Encephalitis from measles in the United States, in contrast, occurs in one per thousand cases (2). The incidence of post-infectious encephalitis has declined precipitously in countries following implementation of vaccination against measles, mumps, and rubella.

Viral encephalitis can be transmitted in one of two ways: via animal or insect vectors that transmit viruses maintained in environmental reservoirs or by human transmission via direct contact with human blood or body fluids. Epidemiologically, this is important since environmentally derived viral pathogens display relatively uniform epidemiologic characteristics. Furthermore, human disease correlates with the life cycle of the vector (spring and summer) and exhibits a geographic distribution that parallels with the habitat of the vector. In contrast, viruses transmitted human-to-human display few seasonal, temporal, or geographic predilections.

Central nervous system (CNS) infection depends, in large measure, on the magnitude and duration of the viremia, which reflect, in turn, the efficiency of the viral replication at extraneural locations and the ability to evade host defense mechanisms. The spectrum and severity of neurological signs and symptoms depends on neurovirulence (the capacity to cause disease within the CNS) and neurotropism (the propensity to infect specific cell groups of the CNS) (1). In human disease, the difference in neurovirulence between viruses is striking. For example, mumps is very highly neuroinvasive, but its neurotropism appears limited to ependymal cells, which may account for the low level of neurovirulence. In contrast, herpes simplex virus is thought to be relatively nonneuroinvasive, but when the CNS is infected, neurons, glial cells, pia-arachnoid cells, and endothelial cells are all affected and, without appropriate treatment, a 70% mortality bespeaks a very high degree of neurovirulence (6).

Infectious encephalitis is the result of direct invasion of any cell type in the brain and gains entry via hematogenous or neuronal routes. Most viral CNS infections are acquired hematogenously and current evidence indicates that most viruses grow at some extraneural site (usually the reticuloendothelial system), establish a viremia, and cross from blood to brain or cerebrospinal fluid by varied pathways: 1) via cerebral capillaries, 2) transfer via pinocytotic vesicles across capillary endothelial cells, and 3) via the fenestrated vascular endothelial cells of the choroid plexus (6). Hematogenous spread is exemplified by neonatal (HSV-2) herpes encephalitis and arthropod-born viral disease. Transmission of virus into the brain through neural pathways include 1) bidirectional axonal transport, and 2) cell-to-cell infection (6). Rabies, HSV-1, and varicella-zoster virus exemplify neural transmission of viruses into the CNS.

Post-infectious encephalitis is likely an autoimmune cell-mediated immune process characterized by perivenulitis and contiguous demyelination (1) caused by derangement and dysregulation of the immune system following either respiratory or intestinal tract infections. A viral infection may activate myelin-reactive T-cells that migrate to the CNS. These cells may activate other mediators of inflammation, including inflammatory cytokines that trigger demyelination.

Clinical manifestations of encephalitis in the neonatal period are often nonspecific and include: fever, poor feeding, irritability, lethargy, and sepsis. Apnea, focal or generalized seizures, paralysis, or coma may appear with progressive neonatal herpes simplex encephalitis. The mean age at onset of neonatal HSV encephalitis is 11-14 days after birth. HSV-2 is usually the etiological agent in 3/4 of cases and is acquired either by intrapartum contact of the fetus with maternal genital secretions (85-95%) or in utero (5-15%). Primary maternal genital HSV infection poses a much greater risk to the fetus than recurrent genital infection, since the initial viremia and the lack of protective antibodies against HSV are more likely to result in disease. The risk of transmission from mother to fetus is 30-50% with maternal primary infection, as compared with <3% with recurrent infection (4). Overall, 50% of infants with neonatal HSV infection will have encephalitis as a component of their disease (1,2). The presence of microcephaly, hydranencephaly, microphthalmia, chorioretinitis, cataracts, intracranial calcifications, intrauterine growth retardation, and vesicular rash are characteristic of in utero acquisition of HSV-2. This latter presentation is due to congenital infection (hematogenous exposure during early gestation usually from primary maternal HSV), as opposed to the former presentation which is a perinatal infection acquired close to the time of delivery.

In older children, the clinical manifestations of the inflammatory response are initially subtle and diverse. Specific neurological findings vary according to which areas of brain parenchyma are affected and also the degree of increased intracranial pressure. Some features of acute encephalitis are similar to those found in aseptic meningitis and include headache, stiff neck, photophobia, fever, vomiting, and irritability; however, the hallmark of disease is alteration of higher cerebral function, characterized by change in level of consciousness, psychiatric and behavioral abnormalities, and/or seizure activity. Predominant cortical involvement may lead to disorientation and confusion. Basal ganglia involvement may lead to movement disorders and brainstem involvement may lead to cranial nerve dysfunction. Occasionally, spinal cord involvement (myelitis) may accompany the encephalitis with findings of flaccid paraplegia and abnormalities of the deep tendon reflexes.

HSV encephalitis in the older child may represent primary infection, reinfection, or reactivation of latent infection. Most cases (about 70%) are the due to reactivation in the olfactory bulb or trigeminal ganglia and resultant spread into the CNS. Encephalitis may begin suddenly or after a brief influenza-like prodrome. Initial symptoms include: fever (always present) with headache, vomiting, malaise, behavioral changes, and speech difficulties. Consciousness decreases with progression and focal seizures are prominent (40%). Focal neurological signs, such as hemiparesis, dysphagia, or visual field defects develop and likely reflect selective involvement of the temporal or frontal lobes. The clinical course of HSV encephalitis can be rapidly progressive, with refractory seizures (status epilepticus), coma, increased ICP, and death within 2 weeks. The clinical course, however, may become more chronic and result in seizures, memory loss, and behavioral disturbances. Pathological studies have shown localized inflammation, necrosis, and inclusion bodies, with strikingly unilateral frontal-temporal localization (6). This pathologic finding suggests that the virus is spread from cell to cell along the base of the brain within the middle and anterior fossae.

Of the nearly 100 known herpesviruses of non-humans, eight human herpesviruses (HSV 1 & 2, cytomegalovirus (CMV), varicella-zoster virus, Epstein-Barr virus (EBV), and human herpesvirus 6, 7, & 8) are prevalent in all human populations and seven are capable of persisting for life. All eight human herpesvirus infections are associated with acute encephalitis. Acquired cytomegalovirus (CMV) infections in immunocompetent hosts are rarely associated with neurological complications, but when they occur, the encephalitis is often mild, and self-limited. Encephalitis from varicella-zoster virus usually appears 3-7 days after onset of the rash and consists of headache, fever, seizures, paralysis, and coma (1). Epstein-Barr virus (EBV) encephalitis accounts for 5% of cases of acute encephalitis and is the most common infectious agent mimicking HSV encephalitis (1). Clinical manifestations of acute encephalitis include: fever, headache, altered consciousness, and seizures, including status epilepticus. EBV infection also produces the "Alice-in-Wonderland" syndrome characterized by bizarre personality changes and perceptual misinterpretation (metamorphosia of size, shape, and or distance) (1). Human herpes virus type 6 and 7 (HHV-6 and HHV-7) causes roseola (exanthem subitum) in young children and account for a substantial proportion of febrile seizures of childhood. HHV-6 or HHV-7 have been linked with acute encephalopathy and encephalitis in young children with symptomatic infections having high fevers and seizures that are usually generalized. Hemiparesis (transient or permanent) and coma may be additional clinical features (1).

Encephalitis from arboviruses in pediatrics are usually the result of La Cross virus, a California serogroup virus, which is transmitted from the vector, Aedes triseriatus, a forest dwelling mosquito residing in wooded areas of the midwestern and mid-Atlantic United States. The virus is maintained in the wild through a mosquito and small woodland mammal (chipmunks, rabbits, and squirrels) cycle. Unlike eastern, western, and St. Louis encephalitis, the transmission cycles do not involve an avian reservoir (6). There are

approximately 100 cases per year in children 5 to 11 years of age. The clinical course is mild and characterized by headache, fever, malaise, abdominal pain, and vomiting for 3 to 7 days after exposed to the virus. Lethargy, behavioral changes, and/or brief seizures follow with clinical improvement over a 7 to 8 day period. Focal neurological signs are present in 16 to 25%, suggesting a diagnosis of HSV encephalitis and may necessitate initiation of treatment. Fifty percent develop seizures and 10 to 15% of children develop status epilepticus. Mortality is less than 1% (4).

St. Louis encephalitis virus is endemic in the midwestern United States and is maintained in a mosquito-bird cycle involving Culex tarsalis mosquitoes, pigeons, sparrows, and doves. Most infections are asymptomatic; however, two-thirds of symptomatic infections present with encephalitis. Children have a biphasic illness first with low-grade fever, diarrhea, vomiting, and malaise followed by the rapid onset of headache, vomiting, fever (as high as 41 C), neck stiffness, lethargy, and/or agitation. Tremors may be present, but focal neurological findings are infrequent. Clinical improvement begins within 7 to 10 days of disease onset. Syndrome of inappropriate antidiuretic hormone (SIADH) with hyponatremia, dysuria with pyuria, opsoclonus, myoclonus, and oculomotor paralysis are unique clinical features of this form of encephalitis (6). Mortality ranges from 8 to 20% with most deaths within the first 2 weeks. Approximately 10% of survivors experience sequelae of memory loss, chronic fatigue, sleeplessness, headaches, and occasionally seizures or motor deficits.

Japanese encephalitis causes more neurologic morbidity and mortality than all of the other arboviruses combined and is the most common arthropod-borne encephalitis worldwide with over 50,000 cases per year in Asia. The virus is maintained in a bird-vertebrate cycle involving Culex tritaeniorhynchus mosquitoes that breed in rice fields, domestic pigs, young water buffalo, herons and other wading birds (1,6). Children affected are usually under 15 years of age and have an abrupt, fulminant illness with rapid depression of consciousness, fever, vomiting, increased muscle tone, convulsions, and coma. The virus may infect brain stem nuclei, leading to acute respiratory failure and death. Infection of the basal ganglia and thalamus presents as tremors during the acute disease and result in parkinsonian mask-like facies, rigidity, tremor, and dystonia in survivors (4). Decorticate and decerebrate posturing are notorious clinical features in Japanese encephalitis. Mortality ranges from 25 to 40% with the majority of survivors having mental retardation, seizures, motor deficits, or subtle behavioral and intellectual abnormalities. Infection may be prevented with an inactivated Japanese encephalitis virus vaccine prepared by infected mouse brains.

Eastern equine encephalitis virus has the lowest incidence in North America, but has the highest mortality rate. Geographically, the eastern encephalitis virus is found in the eastern half of the United States primarily along the freshwater marshes of the Atlantic and Gulf coasts from Massachusetts to Florida. Peak activity occurs in August and September. The rarity of human disease is explained by the cycle of the virus that is usually transmitted between marsh birds and Culiseta melanura mosquitoes, which do not feed on large vertebrates. Only with alterations in the conditions of the marshes, changes in rainfall, different bird populations, and variations in mosquito breeding, can the virus spill over into other mosquito vectors that feed on mammals. Human outbreaks usually are heralded by deaths among horses and pheasants (4,6). Although the disorder usually begins with abrupt onset high fever, lethargy, vomiting, and convulsions, some have a prodromal phase of fever, headache, malaise, and myalgia. Signs are usually diffuse, but some may have focal findings suggesting focal encephalitides, such as HSV. Mortality ranges from 50 to 75% with neurological sequelae of mental retardation, seizures, spastic paralysis, and behavioral abnormalities (1). The Asian Tiger mosquito (Aedes albopictus) was imported into Houston, Texas in 1985 in a shipment of used tires. In 1991, Eastern encephalitis virus was recovered in the Asian Tiger mosquito and has raised major concerns since the mosquito is an aggressive biter of humans which thrives in suburban and forest habitats and could become a treacherous host for the eastern encephalitis virus (6).

The differential diagnosis for acute encephalitis includes: bacterial meningitis, Rocky Mountain spotted fever, brain abscesses, drug intoxication, lead encephalopathy, Reye's syndrome, hepatic coma, uremia, organic acidemias, amino acidemias, urea cycle defects, intracranial neoplasms, systemic lupus erythematosus, cerebrovascular accidents, pseudotumor cerebri, trauma, and post-infectious encephalopathies. The presence of fever is helpful in distinguishing encephalitis from encephalopathies due to toxins or inborn errors of metabolism.

Evaluation of an infant, child, or adolescent with signs of neurological dysfunction with or without fever requires a thorough neurodiagnostic assessment that may include: cerebrospinal fluid (CSF) examination, electroencephalogram (EEG), and imaging studies of the brain and/or spinal cord. The sequence of these studies will depend on severity of condition and concerns regarding possibility of CNS mass lesion, presence of increased intracranial pressure, or other acute neurological conditions requiring specific intervention.

In general, there is little correlation of CSF abnormalities with clinical or histologic severity of encephalitis. The CSF is usually clear and colorless, but may be xanthochromic when blood has been in the CSF for some time. The CSF cell count and protein are frequently normal or slightly elevated, and the glucose concentration remains normal. In the early phase of viral infection, there is often a mixed pleocytosis with both polymorphonuclear (PMN) and mononuclear cells that typically shifts to a lymphocytic pleocytosis over time (1,2). Subsequent lumbar punctures can be helpful in demonstrating pleocytosis. Eastern equine encephalitis has CSF parameters which appear more "bacterial" than "viral," with a predominance of PMN pleocytosis that persists throughout the illness (1,2). Although HSV-1 typically produces lytic infection of neuronal cells and causes hemorrhagic necrosis of the brain (1), the presence of red blood cells in the CSF is a late and inconsistent indicator of HSV encephalitis. Consideration must also be given to subarachnoid hemorrhage from occult trauma or vascular malformation. Vasculitis or tissue necrosis elicits CSF leukocytosis with increased PMN cells and also causes extravasation of red blood cells into CSF (2).

Cell culture provides direct evidence of infection by detecting viral pathogens from CSF, blood, or other body fluids. Viruses that can be detected via this diagnostic approach include herpesvirus, enterovirus, adenovirus, HIV, and rabies. Yields typically are very poor: viral CSF cultures are positive in less than 30% of neonatal HSV encephalitis or disseminated disease (5). Additionally, CSF viral cultures for HSV-1 are almost always negative (4) for older children with HSV encephalitis (2). As for the arboviruses, La Cross virus, St. Louis, and eastern equine encephalitis virus are not typically isolated.

Polymerase chain reaction (PCR) is an inexpensive, rapid, molecular genetic assay that detects specific organism DNA sequences and provides confirmatory viral isolation and thus a specific etiologic diagnosis. PCR affords rapid diagnosis of infections with HSV, CMV, EBV, enterovirus, JC virus, HHV-6, varicella-zoster virus, B. burgdorferi (Lyme disease), Bartonella henselae (cat scratch disease), and HIV. The specificity of PCR in HSV encephalitis approaches 100% and the sensitivity ranges from 75 to 95% depending on the quality of the laboratory (1). PCR has become the gold standard for evaluation of infants and children with suspected HSV encephalitis.

Immunoglobulins and antibodies have limited usefulness for early diagnosis because of poor specificity and sensitivity. Additionally, the antibody response in the CSF does not appear before the fifth day of illness. Finally, acute and convalescent serum antibody titers generally take 3 to 6 weeks to develop.

Electroencephalography (EEG) is usually abnormal in infants and children with encephalitis and shows slowing and epileptiform discharges that can be diffuse or focal. HSV encephalitis classically produces slowing, sharp-wave discharges, or periodic lateralizing epileptiform discharges localized to the temporal or frontal lobe (2). EEG however, is not specific for HSV encephalitis since only 50% exhibit the classic EEG findings. Similar EEG findings have been found with infectious mononucleosis.

Neuroimaging studies, such as computed tomography (CT) or magnetic resonance imaging (MRI), have major roles in evaluating infants and children with presumed or proven CNS infections. Large mass lesions, such as tumors, hemorrhages, and brain abscesses, can be excluded reliably with CT, especially when obtained with contrast enhancement. CT is a better imaging modality for infants with suspected intrauterine viral infections, since small intracranial calcifications are better detected by CT compared to MRI or ultrasound (1). MRI is the preferred imaging modality in children with suspected viral encephalitis and post-infectious encephalomyelitis (1). Herpes simplex encephalitis in older children reveals T2 prolongation on MRI in the medial temporal lobe, orbitofrontal region, or cingulate gyrus, as well as cortical enhancement in these regions when gadolinium is administered intravenously (1,2). In contrast, neonatal herpes simplex encephalitis in the acute stages reveals diffuse brain edema that is consistent with the hematogenous transmission of the virus to the brain. Subsequent imaging shows atrophy, parenchymal calcifications, or cystic encephalomalacia (1).

The definitive diagnostic test of encephalitis, however, is brain biopsy for tissue histology and culture. The utility, however, of routine brain biopsies in children is controversial. Improved neuroimaging techniques and low adverse effects from current antiviral therapy have made empiric therapy the usual practice. Brain biopsy has utility if patients have atypical features or the disease progresses despite empiric therapy (1,2).

Encephalitis and other non-infectious conditions that suggest the presence of CNS infection severe enough to alter the state of consciousness, should be admitted to a Pediatric Intensive Care Unit (PICU) for initial evaluation and supportive care. Severe encephalitis can lead to extensive areas of perivascular infiltrates and diffuse cerebral edema with elevation in ICP and cerebral herniation (2). Frequent assessments of responsiveness, neurological exam, anticipatory monitoring for seizures, and signs of increased intracranial pressure can all be provided in the PICU.

Since antiviral therapy has decreased the mortality for HSV infections by nearly 40% from the pre-antiviral era, acyclovir is the treatment of choice for herpes simplex encephalitis. Antivirals inhibit viral infection by binding with viral nucleic acid and prevent viral replication. The currently approved dose is 30 mg/kg/day IV divided every 8 hours for 14 to 21 days, but some experts recommend increasing the total daily dose to 45-60 mg/kg/day IV divided every 8 hours. Acyclovir has also been effective against varicella zoster virus, while other antiviral agents such as ganciclovir and foscarnet have been used for CMV infections. Unfortunately, antiviral therapy has essentially no impact on morbidity among survivors of CNS disease. Approximately two-thirds still suffer neurological impairment such as major motor and sensory deficits, aphasia, and amnestic syndrome (Korsakoff's psychosis) despite antiviral agents during the acute CNS infection.

Encephalitis from arthropod-borne viruses cannot be treated with specific therapy and typically resolve with conservative management, antipyretics, intravenous fluids, and antiepileptic drugs. Seizures, a frequent complication of viral encephalitis, can be treated acutely with lorazepam and may need maintenance antiepileptic drug therapy with phenobarbital or phenytoin in standard doses.

Potentially life-threatening complications of encephalitis are increased intracranial pressure (ICP), seizures refractory to antiepileptic therapy, and neuronal destruction of the brainstem leading to respiratory compromise or hemodynamic instability. Treatment for increased ICP often requires routine head positioning, osmotic diuresis, fluid restriction, and assisted mechanical ventilation with hyperventilation. Long-acting neuromuscular paralytics for intubation and mechanical ventilation should be avoided since clinical manifestations of seizures will not be evident. Furthermore, neuromuscular blocking agents in patients with impairment of consciousness does not permit repetitive neurological exams and the development of raised ICP may not be evident until intracranial hypertension causes Cushing's triad and possible herniation (2).

Overall, the mortality and morbidity for encephalitis is 3 to 4% and 7 to 10%, respectively. Severity is inversely correlated with the age of onset. Children under the age of one year have a mortality of 40 to 50% (2). Death usually results from cerebral edema or vasomotor instability. Generally, improvement occurs over days to weeks, while focal deficits resolve over a period of months. Neurological morbidity includes: personality changes, behavior disorders, mental retardation, blindness, movement disorders, paretic syndromes, spasticity, and persistent ataxia (1-4). Significant neurological sequelae are more likely to occur if the patient presents with lethargy, coma, or with seizures. Mortality for neonatal HSV encephalitis is 14% with treatment and the outcome is worse for infants with HSV-2 infection (1,3). Older children with HSV encephalitis have mortality at 28% and 40-50% have significant neurological impairment. Of all arboviral encephalitides, Eastern equine encephalitis has the greatest mortality at 50 to 75% with neurological damage in most survivors. In contrast, La Cross encephalitis has the lowest mortality, but seizures develop in 10% of survivors (2).

Questions

1. Encephalitis is usually the result of which of the following:
    a. viral
    b. bacterial
    c. protozoa
    d. autoimmune
    e. fungal
    f. all of the above

2. What are the endemic forms of encephalitis in the United States?

3. Which viral infection involving the CNS is likely to present with focal neurological findings?
    a. HSV
    b. Coxsackievirus
    c. Enterovirus
    d. Rabies virus
    e. St. Louis virus

4. Match the following encephalitis (first column) with the appropriate clinical characteristic (second column):

Japanese encephalitis	SIADH
Eastern equine encephalitis	Decorticate or decerebrate posturing
Post-infectious encephalitis	Aedes triseriatus
St. Louis encephalitis	Multiple levels of CNS involved
La Cross encephalitis	Highest mortality

5. Polymerase chain reaction (PCR) is the diagnostic method of choice for confirming the cause of encephalitis for all of the following except:

a. Cytomegalovirus
b. Enteroviruses
c. HHV-6 and HHV-7
d. HSV 1 and 2
e. Rabies virus

6. True/False: Antiviral therapy has decreased the morbidity and mortality for HSV encephalitis.

Answers to questions

1. a. viral
2. HSV, St. Louis encephalitis, and rabies virus.
3. a. HSV
4. Japanese encephalitis-decorticate or decerebrate posturing, Eastern equine encephalitis-highest mortality, Post-infectious encephalitis-involvement of multiple CNS levels, St. Louis encephalitis-SIADH, La Cross encephalitis-Aedes triseriatus.
5. e. Rabies virus
6. False. Antiviral therapy has only decreased mortality, NOT morbidity.

Chapter VI.16. Sepsis
Guliz Erdem, MD

A 13 month old infant presents to the emergency department with a 2 day history of low-grade fevers, runny nose and increasing fussiness. She also developed a rash and vomiting. Her mother notes that the red-purple lesions on her legs have increased in number since this morning.

Exam: VS T 39.6, P 170, R 50, BP 80/50. She is weak, poorly responsive and sick (toxic) appearing with occasional grunting. Her oral mucosa is sticky. Lungs are clear. Heart is tachycardic. Abdomen is scaphoid, without hepatosplenomegaly. Her extremities are slightly mottled with asymmetrical maculopapular and few petechial lesions over upper and lower extremities. Her capillary refill time is delayed (about 3 seconds).

You are worried about meningococcal disease and explain to her parents that you must start parenteral antibiotic treatment and fluid replacement immediately. While trying to obtain IV access, the infant becomes more lethargic and her blood pressure drops further. You place an intraosseous needle and administer fluids, pressor medications and ceftriaxone (a third generation cephalosporin). Despite these measures, she continues to deteriorate, developing large purpuric lesions on her lower extremities. Her laboratory findings reveal thrombocytopenia, prolonged PT/PTT and increased fibrin degradation products (indicative of disseminated intravascular coagulation - DIC). You intubate the patient and transfer her to the ICU. You notice that it has been less than 40 minutes since you first saw this patient (i.e., the deterioration has been quite rapid).

Her blood culture later grows Neisseria meningitidis. Her antibiotic coverage is changed to high dose, intravenous penicillin. A lumbar puncture is normal indicating that she does not have meningitis. She is successfully extubated on the third day of her hospitalization. Most of the purpuric lesions have regressed but she develops necrosis of the 4th and 5th toes of her right foot, which requires amputation.

Meningococcemia is a classical example for severe sepsis. It is classically said that, patients are well at 12 o'clock and dead by 3 o'clock. Early diagnosis and immediate empiric treatment are life saving as in this case. Patients with severe sepsis can develop complications and die even with appropriate antimicrobial and supportive treatments. Each year, sepsis develops in more than 500,000 people in the United States with a mortality rate of 35-45% in adults (1). Sepsis is estimated to be the 13th leading cause of death overall in patients older than 1 year of age. The highest mortality rates in children are among infants. Approximately two thirds of the cases occur in patients hospitalized for other illnesses (e.g., cancer). There are several definitions used to describe the conditions associated with sepsis (1-3):

Bacteremia (or fungemia) is the presence of viable bacteria (or fungi) in the blood. Septicemia is a systemic illness caused by the spread of microbes or their toxins via the blood stream. This means that septicemia is worse than bacteremia. The two terms are not synonymous.

Systemic inflammatory response syndrome (SIRS) is characterized by at least two of the following :

- Oral temperature of >38C (>100.4F) or <36C (<96.8F).
- Tachypnea (Respiratory rate of >60 breaths/min for infants, >50 breaths/min for children) or PaCO2 of <32 torr.
- Tachycardia (Heart rate of >160 beats/minute for infants, >150 beats/minute for children).
- Leukocyte count of >12,000/L or <4,000/L or >10% bands.

SIRS may have an infectious or noninfectious etiology. SIRS that has a proven or suspected etiology is called sepsis. Sepsis syndrome is sepsis with one or more signs of organ dysfunction, hypoperfusion, or hypotension, such as metabolic acidosis, acute alteration in mental status, oliguria, or ARDS (adult respiratory distress syndrome). Septic shock is sepsis with hypotension that is unresponsive or poorly responsive to fluid resuscitation plus organ dysfunction or perfusion abnormalities.

Noninfectious etiologies of SIRS that need to be considered include trauma, adrenal insufficiency, anaphylaxis, burns, bleeding, cardiac tamponade, dissecting or ruptured aortic aneurysm, drug overdose, neoplasms, myocardial infarction, pancreatitis, post-cardiopulmonary bypass syndrome and pulmonary embolism.

The causative organism varies considerably by age. Streptococcus pneumoniae, Neisseriae meningitidis, Staphylococcus aureus, and group A streptococci are major causes of sepsis in children beyond the newborn period. Blood cultures yield bacteria or fungi in 20-40% of cases of severe sepsis and in 40-70% of cases of septic shock.

Although the infection is an essential part of the development of sepsis, the septic response occurs when immune defenses fail to contain the invading microbe(s). Sepsis due to gram negative microorganisms and endotoxic shock are major triggers for the septic syndrome. The lipopolysaccharide (LPS or endotoxin) of gram negative bacteria is transferred to CD14 on the surfaces of phagocytic and polymorphonuclear cells by a LPS binding protein. This interaction triggers the release of mediators, such as TNF-alpha, that further amplify this signal and transmit it to other cells and tissues. Gram positive microorganisms, especially Staphylococcus aureus can elaborate exotoxins, which appear to act through a similar signal pathway to that of endotoxins, triggering the release of inflammatory mediators. How these signals initiate inflammation and how the host responds to them are active areas of research. It has been shown that the inflammation signals are specific to the plasma membranes and a family of proteins named "toll-like receptors" (TLR) are shown to be cellular components of host defense against bacterial challenge. Toll receptors were initially described in Drosophila and shown to activate host defenses against fungal infection in the adult fruitfly. Subsequently, mammalian homologs of these proteins were shown and named as toll-like receptors (TLR). Different members of TLR family may have different roles in inflammation and sepsis. TLR4 appears to confer responsiveness to bacterial lipopolysaccharide (gram negative infections) and TLR2 appears to mediate stimulation by gram positive, gram negative microorganisms and mycobacteria. These proteins basically help the host in transduction of inflammatory signals and they share these pathways (due to their high homology) with the IL-1 receptor in humans. IL-1 is also a critical component of the general inflammatory response.

The septic response then involves complex interactions among microbial signal molecules, leukocytes, humoral mediators and vascular endothelium. Inflammatory cytokines amplify and diversify the overall response. Microbial toxins stimulate the production of cytokines like TNF-alpha and IL-1-beta, which in turn promote endothelial cell-leukocyte adhesion, release of proteases and arachidonic acid metabolites and activation of clotting. IL-8, a neutrophil chemotaxin, may have an especially important role in perpetuating tissue inflammation. IL-6 and IL-10, which are counter-regulatory, inhibit the generation of TNF-alpha, augment the action of acute phase reactants and immunoglobulins, and inhibit T-lymphocyte and macrophage function. IL-6 along with other mediators can also promote intravascular coagulation.

Many tissues may be damaged by the septic response. The probable underlying mechanism is widespread vascular endothelial injury, with fluid extravasation and microthrombosis that decrease oxygen substrate utilization by the affected tissues. Additionally, stimuli such as TNF- alpha induce vascular endothelial cells to produce and release cytokines, procoagulant molecules, platelet activating factor (PAF), endothelium derived relaxing factor (nitric oxide) and other mediators. Moreover, vascular integrity may be damaged by neutrophil enzymes (such as elastase) and toxic oxygen metabolites so that local hemorrhage ensues (4). Nitric oxide is implicated as a mediator septic shock in animals.

The manifestations of sepsis are usually superimposed on the symptoms and signs of the patient's underlying illness and primary infection. Symptoms can be variable. Nonspecific mental status changes and hyperventilation are often the early findings in older children and adults. Irritability, lethargy or confusion can be seen even if meningitis is absent. Young children can exhibit signs of diminished perfusion while maintaining a normal blood pressure, such as delayed capillary refill, weak peripheral pulses, and cool extremities. Nausea, vomiting, diarrhea and ileus can be present. Cholestatic jaundice with elevated levels of serum bilirubin (mostly conjugated) and alkaline phosphatase may precede the other signs. Blood glucose concentration often initially increases as a stress response.

While most patients have fever, some have a normal temperature or are hypothermic. Tachypnea and tachycardia are common signs. Hypotension and DIC, which can complicate sepsis, predispose to cyanosis and ischemic necrosis of peripheral tissues. Other skin lesions such as ecthyma gangrenosum (Pseudomonas aeruginosa), petechial rash (meningococcemia, rarely H. influenzae type B), and purpura fulminans can be suggestive of specific pathogens. The skin and mucosa should be examined carefully and repeatedly for lesions.

Cardiac output is initially normal or increased (the "hyperdynamic phase") in sepsis and helps in distinguishing septic shock from other types of shock. A definitive diagnosis requires the isolation of the microorganism from blood or a local site of infection. At least two and probably three sets of cultures should be obtained. Buffy-coat smear of peripheral blood is a quick and inexpensive method and can assist in more effective therapy; however it is not very sensitive. In early sepsis, abnormalities may include leukocytosis or leukopenia, left shift (with or without toxic granulations), thrombocytopenia, increased lactic acid levels and proteinuria. Active hemolysis suggests clostridial bacteremia, malaria, a drug reaction, or DIC.

With the critically ill child, as in the case scenario, time must not be wasted on performing an extensive diagnostic evaluation. Obtaining a blood culture before initiating antibiotic therapy may be prudent in these children. Other diagnostic labs and a lumbar puncture may be delayed so that antimicrobial treatment can be started immediately in critically ill patients. Severe coagulopathy, as frequently seen in meningococcemia, may also delay lumbar puncture because of the risk of spinal epidural hematoma and bleeding.

Risk factors and prognostic factors include host related factors such as malnutrition, splenectomy, HIV infection, burns, hematologic malignancies and neoplasms; or treatment related factors such as surgical invasive procedures, high dose of corticosteroids or other immunosuppressive drugs, mechanical ventilation, neutropenia and presence of indwelling mechanical devices.

Numerous sepsis scoring systems have been developed in adults and children, particularly for meningococcemia. The best indicator of sepsis and poor outcome is the presence of shock (5). Multiorgan failure is the leading cause of mortality in sepsis patients. The outcome is influenced by the patient's underlying disease and by the microorganism. The outcome is worse in bacteremia caused by Candida and enterococcus species when compared with the coagulase negative staphylococci. Recently, several polymorphisms in genes coding for key inflammatory molecules have been identified and suggested as a risk factor in sepsis and adverse outcomes.

Cardiopulmonary complications include ventilation-perfusion mismatching which produces a fall in arterial pO2 early in the course of sepsis. Increasing alveolar capillary permeability results in an increased pulmonary water content, which decreases pulmonary compliance. Progressive diffuse lung infiltrates and hypoxemia indicate the development of acute respiratory distress syndrome (ARDS). ARDS develops in up to half of adult patients with severe sepsis. Depression of cardiac function (diminished contractility) develops within 24 hours in most patients with advanced sepsis. Although myocardial dysfunction may contribute to hypotension, refractory hypotension is usually due to a low systemic vascular resistance. Death results from refractory shock or the failure of multiple organs.

Renal complications include renal failure following acute tubular necrosis. In some patients glomerulonephritis, renal cortical necrosis or interstitial sepsis can also cause renal failure.

Thrombocytopenia occurs in up to one-third of the patients. Disseminated intravascular coagulation (DIC) may be seen. Prolonged or severe hypotension may induce acute hepatic injury or ischemic bowel necrosis.

If sepsis lasts weeks to months, critical-illness polyneuropathy may develop as a neurologic complication.

Sepsis is a medical emergency and urgent measures for the treatment of infection as well as hemodynamic and respiratory support need to be taken. Priorities in resuscitation of the child who has septic shock mirror those with any other type of shock (6). All children should receive supplemental oxygen. The child in respiratory distress should be intubated. Drugs that cause vasodilation or myocardial depression should be avoided. At least two separate IV lines are required to administer fluids and medications. Intraosseous infusion may be used when peripheral vascular access cannot be obtained rapidly. Cardiovascular support using inotropic medications such as dopamine, dobutamine, and possibly epinephrine, is necessary in almost all patients with severe sepsis.

Empiric antimicrobial therapy should be initiated as soon as blood and other relevant sites are cultured. However, difficulty obtaining cultures should not delay antibiotic administration which must be started as soon as possible. Maximal recommended doses of drugs should be given parenterally. The immune status of the patient, the underlying condition (including illicit injecting drug abuse, splenectomy) are important in deciding the appropriate treatment. Removal of indwelling intravenous catheters and removal or drainage of a focal source of infection are essential. The duration of treatment is influenced by factors such as the site of tissue infection, the adequacy of surgical drainage, the patient's underlying disease and the antimicrobial susceptibility of the pathogen. A typical empiric treatment regimen in children usually includes a third generation cephalosporin and further coverage for gram negative bacteria may be needed such as aminoglycosides, anti-pseudomonal penicillins, extended-generation penicillin with beta-lactamase inhibitor or carbapenems. In areas with increased pneumococcal or staphylococcal resistance or for patients who have received frequent antibiotic therapy (sickle cell anemia) vancomycin can also be started for suspected gram positive infections

Despite aggressive management, many patients with severe sepsis or septic shock will die. Two types of agents that may help in preventing these deaths are being investigated:

1. Drugs that neutralize bacterial endotoxin, thereby potentially benefiting the patients who have gram negative infection.
2. Drugs that interfere with one or more mediators of the inflammatory response and may benefit all patients with sepsis. Recently, activated protein C is approved by FDA for treatment of selected patients with sepsis.

Questions

1. Which one of the following is not a parameter in the definition of SIRS?
    a. Hypotension
    b. Tachycardia
    c. Tachypnea
    d. Leukocytosis
    e. Hypothermia

2. Which is an early finding in septic shock?
    a. Decreased urine output
    b. Increased cardiac output
    c. Decreased blood pressure
    d. Diffuse lung infiltrates

3. A number of different principles apply to the immediate management of a child in septic shock. In general, management should be prioritized in order of urgency. Which of the following is not an immediate priority in the resuscitation phase of a child in septic shock (2)?
    a. Ensure adequate airway support
    b. Correct anemia
    c. Administer volume resuscitation
    d. Cardiovascular support
    e. Empiric antibiotic treatment

4. Which microorganism is a common etiology in endotoxic shock?
    a. Staphylococcus aureus
    b. Streptococcus pyogenes
    c. Streptococcus pneumoniae
    d. Escherichia coli

5. Which of the following skin examination findings is generally not associated with sepsis?
    a. Pyogenic granuloma
    b. Ecthyma gangrenosum
    c. Purpura fulminans
    d. Petechiae

Chapter VI.17. Kawasaki Disease

Kara S. Yamamoto, MD
Marian E. Melish, MD

This is a 2 year old Japanese-Korean male presenting with 5 days of fever up to 39 degrees C (102.2 degrees F). On the second day of illness, he developed red lips and an erythematous maculopapular rash over his torso. By the third day of illness, his conjunctivae were injected without exudates, his rash involved his extremities, and he developed a strawberry tongue. On the fourth day of illness, he had edema to his hands and feet with a diffuse red-purple discoloration over the palms and soles. His lips were now cracked and bleeding. He was noted to be irritable and fussy, with decreased oral intake.

Exam: VS T 39.5, P 130, RR 40, BP 100/60, oxygen saturation 100% in room air. Weight and height are at the 25th percentile. He is alert and slightly fussy, but he consoles easily and he is not lethargic. His bulbar conjunctivae are injected with limbal sparing (less injected around the limbus where the cornea fuses with the conjunctiva), but no exudates. His lips are red and cracked. His tongue is bright red. His neck is supple with bilateral small lymph nodes. Heart is slightly tachycardic, with no murmurs or gallop. Lungs are clear. Abdominal exam finds no abnormalities. He has some mild edema of his hands and feet with some red-purple discoloration of the palms and soles wrapping partially around the dorsum with a sharp demarcation at the wrists and ankles. He has a generalized deeply erythematous rash which is flat with irregularly shaped pink-red lesions ranging from 1 to 7 cm in diameter, with some areas coalescing. The lesions blanch. No joint swelling is noted. He moves all extremities well.

He is admitted to the hospital for further management and treatment of suspected Kawasaki Disease (KD). Lab: CBC WBC 19,500 with 75% segs, 20% lymphs, 5% monos. Platelet count 475,000. Hgb 10. AST 56, ALT 62, bilirubin 1.2, albumin 2.8. Urinalysis with WBC 5-10, no organisms, negative for protein, blood, leukocyte esterase or nitrites. Urine and blood cultures are obtained. Echocardiogram and EKG are both normal.

He is treated with IVIG (IV gamma globulin) and aspirin. His fever defervesces after 24 hours with improvement in his rash, lips, extremities and conjunctivae. He is discharged after the completion of IVIG treatment. Follow-up echocardiograms demonstrate no abnormalities.

Kawasaki Disease (KD) is an acute multisystem vasculitis that almost exclusively affects young children. First described by Dr. Tomisaku Kawasaki of Tokyo, Japan in 1967, it occurs in all regions of the world among children of diverse ethnicity. Significant adverse cardiac effects were recognized in untreated patients, particularly the development of coronary artery aneurysms leading to myocardial infarction (thrombosis) and sudden death. The clinical criteria he described remains the basis of all clinical and epidemiologic descriptions used today (see Table 1).

The etiology of KD remains unknown. The acute, febrile, and self-limited nature of KD and its clinical manifestations of rash, meningeal, hepatic, joint, and mucous membrane inflammation strongly suggest an infectious etiology or trigger. The predominance of cases in children under 12 years of age and the occurrence of community-wide epidemics further suggest that the etiologic agent may be common and widely distributed. Despite lack of the identification of an etiologic agent, intravenous gamma globulin (IVIG) has been discovered as a remarkably effective treatment resulting in rapid clinical improvement and prevention of coronary artery sequelae.

KD has a peak incidence in the first two years of life. In our experience here in Hawaii, peak incidence occurs between 1 to 2 years of age. Fifty percent of patients are younger than 2 years of age and 80% are younger than 4 years (1). The disease infrequently occurs in children greater than 8 years of age. Boys are affected more often than girls by a ratio of 1.5 to 1. Although classic symptoms can occur in children as young as several weeks old, diagnosis within the first 3 months of life is uncommon, perhaps because of passive protection from maternal antibodies or because these children tend to have atypical or mild clinical manifestations.

Children of Japanese and Korean ancestry are at greatest risk for KD. Children of other Asian or African ancestry have also demonstrated significantly higher incidence rates than those of European ancestry. In Hawaii, the rate for children of European ancestry is 9 per 100,000 per year; for children of African-American ancestry 20 per 100,000 per year; and for children of Japanese and Korean ancestry 145 per 100,000 per year (1).

KD occurs more frequently in the winter and the spring than in the summer and fall. Community-wide outbreaks have been noted, but there is little evidence of person-to-person spread or of point source exposure in these outbreaks.

Pathologically, KD is a multisystem vasculitis with a predilection for the coronary arteries. The acute phase (first 10 days of illness) is characterized by an intense inflammatory infiltrate in the vasa vasorum of the coronary arteries with infiltration and hypertrophy of the intima. Pancarditis may be present and the pericardium may also inflamed, often with effusion. Some patients may develop congestive heart failure and myocardial dysfunction, but death during this phase is usually sudden and thought to be due to arrhythmia. During the convalescent phase (10-40 days after the onset of fever) the inflammatory infiltrate matures from predominantly polymorphonuclear leukocytes to a predominance of mononuclear cells. Fragmentation of internal elastic lamina and damage to the media can result in aneurysm formation. Coronary artery involvement is usually bilateral and most severe near the origin (proximal). Death is most frequently due to acute myocardial infarction due to acute coronary artery thrombosis during this stage.

Late changes (>40 days) involve healing and fibrosis in the coronary arteries. There may be organizing thrombosis within aneurysms with recanalization, calcification and stenosis. Fibrosis can also occur in the myocardium from old myocardial infarction. Death during this stage most often occurs from acute myocardial infarction or chronic myocardial ischemia.

The immunologic mechanisms causing KD vasculitis are partially understood involving abnormalities of T cells, B cells, cytokines, autoantibodies, macrophages, monocytes, and blood vessel associated matrix metalloproteinases.

There is no pathognomonic diagnostic test for Kawasaki syndrome. The diagnostic criteria for the diagnosis of KD as established by Dr. Kawasaki have stood the test of time and are listed in Table 1 and described in detail below.

Table 1 - Diagnostic Criteria for Kawasaki Disease

1. Fever
2. Conjunctival vascular injection
3. Mouth changes:
   a. Erythema, cracking and bleeding of lips
   b. Strawberry tongue
   c. Oropharyngeal erythema
4. Polymorphous erythematous rash
5. Changes in the hands and feet consisting of:
   a. Indurative edema
   b. Diffuse erythema of the palms and soles
   c. Convalescent desquamation after day 10
6. Unilateral lymphadenitis (>1.5 cm diameter)

Clinical Course: The onset of illness is often abrupt with fever as the initial sign. The fever is typically persistent and high ranging between 38 and 41 degrees C (101 to 106 degreesF). Initially the criteria stated that fever should exceed 5 days before making the diagnosis. With recognition of serious sequelae if therapy is delayed, we now stress making the diagnosis as early as possible, disregarding the 5 day provision. In untreated patients, the mean duration of fever is 11 days with a range of 5 to 33 days. Within 2 to 5 days of fever onset, the child develops the other diagnostic signs of KD. These children are often exceedingly fussy or irritable. The eye involvement consists of discrete vascular injection of the bulbar conjunctiva most marked in the periphery with relative sparing around the limbus (known as limbic or perilimbic sparing). Exudate is absent while photophobia may be present. Mild anterior uveitis may be present. Mouth changes include initial bright red erythema of the lips (progressing to swelling, cracking and bleeding), prominent papillae on the tongue with erythema (strawberry tongue), and diffuse erythema of the oropharynx without vesicles, ulcers or erosion. The rash can takes many forms (which is why the term "polymorphous" is used) but it is never vesicular or bullous. The most common form is deeply erythematous with papules varying from 2-3 mm to large, coalescent plaques covering several centimeters. Frequently it is pruritic and appears urticarial. A diffuse maculopapular measles-like rash is also commonly seen. Erythema marginatum and diffuse scarlatiniform erythroderma are seen less frequently (<5%). Rash distribution is variable. It frequently involves the face, often coalescent and mask-like around the eyes, nose and mouth. It can involve the perineum with later peeling. It may be distributed more prominently on the trunk or the extremities. The rash is not fixed and can clear then reappear in new areas. It may be more prominent with high fever. Changes in the hands and feet consist of firm, indurative edema with diffuse red-purple discoloration of the palms and soles, usually with sharp demarcations at the wrists and sides of the hands and feet. In early convalescence (10-20 days after onset of fever), desquamation starts just under the nails and progresses to involve the entire palms and soles, with skin peeling in sheets. Cervical lymph node involvement occurs in approximately 50 % of patients, characterized by a sudden onset of unilateral firm swelling measuring more that 1.5 cm in diameter. Occasionally the cervical adenopathy can be diffuse and massive, even causing tracheal shift. It can be moderately tender, with or without erythema, and non-fluctuant.

Associated findings include aseptic meningitis with CSF pleocytosis in 25% of patients. CSF counts range between 50-150 per cubic mm (mostly mononuclear). CSF protein levels are normal to slightly elevated, with normal glucose. Urethritis and sterile pyuria are present in approximately 60% of patients. Some hematuria may be seen, but urinary protein is usually normal. A small meatal ulcer or meatitis (redness) of the urethra is often seen in males. Prior to the use of IVIG, approximately one third of patients developed arthritis. During the first week of illness, arthritis was usually polyarticular of large and small joints. Oligoarthritis of large weight bearing joints was noted more in the second week of illness. Late onset arthritis has been virtually eliminated with the use of IVIG. Severe abdominal pain, often associated with diarrhea can be seen in the first few days of illness. Occasionally it may present as an acute abdomen. Amylase and lipase levels may be elevated, suggesting an acute pancreatitis. Liver involvement occurs in 40% of patients, including liver enzyme and bilirubin elevations. The direct fraction of bilirubin can be elevated suggesting a primarily obstructive pattern. Gallbladder hydrops can be seen with elevated bilirubin levels and findings of a right upper quadrant mass. Ultrasonography can confirm the diagnosis. This is usually a self-limited complication and does not require surgery, resolving within 2 weeks with IVIG and aspirin therapy.

A wide spectrum of cardiac abnormalities has been identified. Many children have tachycardia. Some develop signs of congestive heart failure ranging from mild pulmonary vascular congestion and a gallop rhythm to cardiogenic shock. About a third of patients may have pericardial effusions during the first week of illness. Mitral and tricuspid insufficiency have also been noted. Echocardiography may demonstrate some degree of myocardial involvement in the majority of patients. Prolongation of the PR interval and first-degree heart block are common, but more significant arrhythmias are rare. Many of these abnormalities resolve rapidly after IVIG therapy.

Coronary artery abnormalities can be detected by echocardiography at the end of the first week to the second week of illness (range 7-28 days after onset of illness). Progressive dilatation and aneurysm formation may occur with a peak incidence and severity at approximately 1 month after the onset of disease. Prior to the use of IVIG therapy, about 18-25% of patients developed coronary artery aneurysms, with the highest risk in males and children under the age of 1 year. Transient coronary artery dilatation is even more common affecting at least 60%. Regression of aneurysms is common for all but giant aneurysms. Approximately 2/3 of children with aneurysms at 8 weeks post onset have regression by 1 year on echocardiography. Although the aneurysm may appear to have regressed by echo, the vessel walls are not normal and no longer dilate in response to exercise or drugs. These patients may still develop stenosis, tortuosity, and coronary artery thrombosis. Some of these children will develop giant coronary aneurysms (>8mm). Children with coronary abnormalities are at high risk for myocardial infarction, sudden death, coronary thrombosis, and myocardial ischemia within the first year after onset and have a higher lifetime risk in the long term. Giant aneurysms (greater than 8 mm or the diameter of the aorta) pose a most severe problem. These occur in 3% to 7% of untreated patients, are correlated with duration of fever >2 weeks and have a poor prognosis. Children with giant coronary aneurysms are at the highest risk for early myocardial infarctions and sudden death due to coronary thrombosis or rupture. Progression to significant coronary stenosis with resultant myocardial ischemia occurs in a very high percentage over the next 20 years.

Some patients may have more severe vasculitis with acute KD. Aneurysms in vessels other than the coronary arteries, such as axillary, mesenteric, and renal arteries have been noted in severe cases. Some cases develop peripheral gangrene due to severe vasculitis and thrombosis. In infants, fatal KD is indistinguishable from infantile polyarteritis nodosa.

Laboratory findings in KD are nonspecific but consistent with significant inflammatory indices. There is no diagnostic test for Kawasaki disease. Erythrocyte sedimentation rate, C-reactive protein, and alpha-1-antitrypsin are elevated. White blood cell count (WBC) is often elevated with a polymorphonuclear cell predominance and sometimes, a left shift. The WBC rises through the first two weeks of illness, peaking between 7-12 days. By day 5 of illness, 50% of patients have platelet counts greater than 450,000 per cubic mm. By day 10, nearly all have elevated platelet counts which may peak at 650,000 to 2,000,000 per cubic mm between days 10 and 20. Mild to moderate anemia is common. Liver enzymes are moderately elevated (over twice the upper limit of normal) in 40% of patients in the first week. Bilirubin may be elevated in 10% of patients. Hypoalbuminemia is common. Urinalysis shows sterile pyuria in 60%.

Work up of patients suspected of KD should include the above lab studies, and a cardiovascular evaluation including EKG, echocardiography, and chest x-ray.

The differential diagnosis for KD includes staphylococcal and streptococcal toxic shock syndromes, streptococcal scarlet fever, staphylococcal scalded skin syndrome, measles, febrile viral exanthems, adenovirus infection, hypersensitivity reactions (including Stevens-Johnson syndrome, erythema multiforme minor and serum sickness), and systemic onset juvenile rheumatoid arthritis. When KD is suspected, appropriate testing for viral and bacterial infection are indicated in addition to laboratory testing described above.

The diagnosis of KD relies primarily on clinical features and a pattern of non-specific laboratory tests. Since there is no specific diagnostic test available, patients who have a milder illness or an incomplete/atypical pattern of symptoms, may not be diagnosed with KD, but are still at risk for coronary artery disease. These "incomplete" cases are at risk for coronary complications, especially since they may not be diagnosed or treated with IVIG. Infants younger than 6 months of age, and older children are at particular risk. If a child has fever and 2 or 3 of the other criteria PLUS compatible laboratory findings KD should be considered and if needed, expert consultation sought. KD should also be considered in all younger children with fever of unknown origin.

Patients with KD who present with fever and lymphadenitis as the first sign may also pose a diagnostic problem. These patients may be initially diagnosed with lymphadenitis and are treated with antibiotics. The subsequent development of rash, conjunctival injection, mouth, hand and feet changes, may be mistakenly attributed to antibiotic hypersensitivity.

The child who is not of Asian ethnicity may not be diagnosed even with complete clinical signs. Many physicians consider KD to be a disease occurring only in Asians or in high risk areas. KD is severely underdiagnosed across the world where it occurs in children of every racial and ethnic group.

Laboratory tests can be very helpful in the diagnosis although none provide definitive answers. By day 5 of illness, most patients have WBC of 15,000 or more, significantly elevated sedimentation rate (ESR) and C reactive protein (CRP), and platelet count of >400,000. Sixty percent have sterile pyuria with >10 WBC/hpf and 40% have liver enzyme values equal to or greater than 2X the upper limit of normal. Most viral illnesses and serum sickness have normal or low WBC, and normal or near normal ESR and CRP values. Creatinine elevation is unusual in KD and usually suggests another diagnosis.

Since the late 1980s multiple studies have shown that the use of high dose IVIG given in the first 10 days of illness has dramatically altered the clinical and pathologic course of the illness. Prompt clinical improvement follows IVIG: 60% become afebrile within 12 hours of IVIG, and 90% within 48 hours. The risk of coronary aneurysms has been lowered from 18-25% to 2-4%. Infants younger than 1 year of age have the highest risk of coronary abnormalities when untreated. Even with IVIG treatment, the risk of coronary abnormalities at 8 weeks is 15%. For all age groups treated with IVIG, the incidence and severity of any coronary disease and the frequency of giant aneurysms has been greatly reduced.

Once a diagnosis of KD is made, therapy consists of intravenous infusion of IVIG 2 gm/kg given over 10-12 hours. Heart rate and blood pressure should be monitored closely. Patients who remain febrile or have recurrent fevers 48 hours after the end of the initial IVIG infusion, may require an additional infusion. In our experience, approximately 10 % of children require second doses. Expert opinion should be sought for patients who are unresponsive to IVIG as this is the group who develop coronary disease.

Aspirin therapy should be instituted on the day IVIG is given. In the United States, a dose of 100 mg/kg to a maximum of 4 grams per day is given until a few days after defervescence or until the 14th day of illness. This is followed by a daily dose of 3 to 10 mg/kg/day (one half to one 81 mg tablet) until the ESR and platelet counts return to normal, usually about 2-3 months after onset of illness. Aspirin has been shown to result in a more rapid defervescence, lower frequency of relapse of fever and shorter hospital stay. Anti-coagulation with low dose aspirin therapy helps prevent the thrombosis in the setting of vascular inflammation and elevated platelet counts. Serum salicylate levels should be obtained if symptoms of salicylate toxicity develop. Aspirin therapy can be interrupted in children who develop varicella or influenza during the follow-up phase to decrease the risk of Reye syndrome.

There is no data to guide therapy of patients suspected of having KD who present more than 10 days after onset of illness. If patients are still febrile or have other signs of active disease such as progressive coronary artery dilatation, IVIG therapy may result in prompt clinical improvement. Patients who have become afebrile and have normal coronary arteries by 3-4 weeks after illness onset are unlikely to benefit from IVIG and should be placed on low dose aspirin. In patients who have already developed coronary aneurysms without active inflammation, there appears to be no beneficial effect of IVIG.

In summary, KD is a severe acute febrile exanthematous illness of young children, who are usually under the age of 6 years. Cardiovascular damage sustained during the acute and early convalescent phases of KD occurs in over 30% and may be serious, causing lifelong coronary abnormalities including premature myocardial infarction, coronary and myocardial insufficiency or coronary artery rupture. KD is fatal in 2-4% of undiagnosed and untreated patients. Early IVIG therapy results in prompt clinical improvement and prevents coronary artery damage and long term cardiovascular complications. Therefore KD must be recognized, diagnosed and treated early and aggressively. If there is any question about the diagnosis of KD or if a patient thought to have KD does not respond to IVIG and aspirin therapy within 48 hours, expert consultation with a local or national expert is indicated on an urgent basis.

Questions

1. What are the diagnostic criteria for KD?
2. What change in the treatment of KD has been primarily responsible for decreasing the incidence of coronary artery aneurysms in KD?
3. Which children are at higher risk for coronary artery aneurysms?
4. Name some common allergic reactions that may resemble KD?
5. Name some common infections that may resemble KD?

Answers to questions

1. Presence of fever ranging between 38 and 41 degrees C, and four out of five principal diagnostic criteria which include: discrete conjunctival injection without exudates, changes in the mouth, polymorphous erythematous rash, changes in the hands and feet, and unilateral cervical lymphadenopathy.
2. Intravenous gamma globulin treatment.
3. Children <1 year of age and those untreated with IVIG.
4. Stevens-Johnson syndrome, erythema multiforme, serum sickness.
5. Measles, adenovirus, toxic shock syndrome, scarlet fever, staphylococcal scalded skin syndrome.

Chapter VI.18. Staphylococcal and Streptococcal Toxic Shock Syndromes

Judy Makowski Vincent, MD

A 16 year old girl in previously good health became ill 2 days ago with fever to 39 degrees, myalgias, abdominal pain, and profuse vomiting and diarrhea. Yesterday she noticed a sunburn-like rash that covered her entire body but was most intense on her inner thighs and her palms and soles. This morning she was unable to get out of bed due to feeling "too sick", and when she was helped to stand, she nearly fainted from "light-headedness". She is having her menstrual period and is wearing a tampon.

Exam: T 32.2, P 160, RR 30, BP 60/40 supine. She is an ill-appearing adolescent female who is poorly oriented to her surroundings and only responds to questions with much coaxing, and her answers are incoherent. Her conjunctivae are injected. She has oral mucosal hyperemia and hypertrophy of her tongue papillae. Her tonsils are not enlarged. Total body erythroderma is noted, most pronounced on the inner thighs, and palms and soles, with prolonged capillary refill time of about 6 seconds. Her neck is supple. Her heart exam demonstrates tachycardia with a I/VI systolic ejection murmur without radiation. S1 and S2 are normal with no gallops. Her lungs are clear. Her abdomen is soft and nontender, with hyperactive bowel sounds. She is drowsy and disoriented. Her strength is weak, but her DTR's are normal. Her genitalia exam (normal Tanner 4) is significant for a tampon in the vagina and menses are noted without any other type of discharge. The tampon is removed and sent for culture.

Labs: CBC with WBC 16,000, H/H: 12/36, 50% segs, 30% bands, 15% lymphs, 5% monos, platelet count 70,000. Na 140, K 4.0, Cl 110, bicarbonate 12, BUN 20, Creatinine 0.6, AST 30, ALT 40.

She is given an IV fluid bolus and a dopamine infusion. Her blood pressure, perfusion and mentation improve. IV clindamycin and vancomycin are administered. She is hospitalized in the ICU, where her condition gradually improves. Culture of her tampon grows 4+ Staphylococcus aureus the next day. Her blood cultures are negative.

Simple or trivial skin infections or mere colonization with Staphylococcus aureus may produce toxin-mediated life-threatening disease known as staphylococcal toxic shock syndrome (TSS). This syndrome was first described by Todd et al. in 1978 who reported seven children aged 8 to 17 years who had high fever, headache, vomiting, watery diarrhea, oliguria, and a propensity to acute renal failure, hepatic abnormalities, disseminated intravascular coagulation, and severe prolonged shock (1). S. aureus related to phage-group I was isolated from mucosal (nasopharyngeal, vaginal, tracheal) or sequestered (empyema, abscess) sites, but not from blood. The illness was associated with the isolation of Group 1, type 29 staphylococci from skin, abscesses, empyema fluid or mucous membranes, and Todd named the disease "toxic shock syndrome" (1).

Between 1980 and 1986, 2960 cases of staphylococcal TSS were reported to the CDC, 90% of which were associated with menses. In 1980, a link was discovered between the use of newly introduced superabsorbent tampons and staphylococcal TSS. One brand was removed from the market and all tampons containing superabsorbent polyacrylate fibers were removed in 1985. Non-menstrual staphylococcal TSS also occurs in women, men and children (2,3). Menstrual and non-menstrual TSS are similar in their clinical appearance, but they differ in their target populations and in their outcomes. The prevalence of menstrual TSS has decreased markedly with the institution of preventive measures. Non-menstrual TSS has decreased less dramatically, and now accounts for about one-third of all staphylococcal TSS cases (3).

Menstrual TSS occurs at a rate of 1 per 100,000 menstruating women per year, and 99% of menstrual TSS occurs in women who use tampons (2). The current incidence of staphylococcal TSS has decreased greatly from the early 1980's, which is probably due to greater awareness of its presentation and the removal from the market of hyperabsorbent tampons (4). Risk factors for menstrual TSS include adolescence, lack of antibody to TSST-1 or staphylococcal enterotoxins, Caucasian ethnicity, continuous tampon use, and high absorbency potential of the tampon. Risk factors for non-menstrual TSS include any interruption of the integrity of the skin, mucous membrane colonization with a toxin-producing S. aureus isolate, or any S. aureus infection (2,3).

Todd et al. realized that their patients had clinical features similar to other known staphylococcal toxin related diseases, such as staphylococcal scalded skin syndrome and staphylococcal food poisoning (1). Also, S. aureus was isolated from 2 patients at foci of infection but not from the blood, cerebrospinal fluid, or urine, and an association with staphylococcal toxin was investigated. All staphylococcal strains isolated by Todd elaborated a previously undescribed epidermal toxin which produced a cleavage at or below the basal layer of the skin. Unlike exfoliatin, this new toxin was inactivated by heating to 60 degrees C for 30 minutes and was neutralized by staphylococcal antitoxin, but not by exfoliatin antitoxin (1). All of the staphylococcal isolates in Todd's patients reacted with group-I phages. This unique epidermal toxin has been named staphylococcal toxic shock syndrome toxin-1 (TSST-1). Expression of TSST-1 is determined by oxygen, temperature, pH, and glucose levels (5). It belongs to a large family of toxins called pyrogenic toxin superantigens which are potent stimulators of the immune cell system (i.e., cell mediated immunity), pyrogenicity, and enhancement of endotoxin shock.

Eighteen percent of healthy children and 1% to 5% of healthy menstruating women are colonized with TSST-1-producing strains of S. aureus. These healthy individuals have antibody to TSST-1, but patients with staphylococcal TSS have decreased or absent levels of anti-TSST-1 or anti-enterotoxin antibody, suggesting that anti-TSST-1 and anti-enterotoxin antibodies are protective or mitigating against staphylococcal TSS (2).

Staphylococcal toxic shock syndrome is an illness with the following clinical manifestations (6):

1) Fever with a temperature greater than 38.9 degrees (102.0 degrees F).

2) Rash, which is a diffuse macular erythroderma. In some patients with tampon-associated menstrual TSS, the rash is more intense on the medial aspect of the thighs.

3) Desquamation which occurs 1-2 weeks after onset of illness, particularly on the palms and soles.

4) Hypotension with a systolic blood pressure less than 90 mmHg for adults or less than the 5th percentile for children, or an orthostatic drop in diastolic blood pressure greater than 15 mmHg from lying to sitting, orthostatic syncope, or orthostatic dizziness.

5) Multisystem involvement with three or more of the following: a) Gastrointestinal: Vomiting or diarrhea at the onset of illness. b) Muscular: Severe myalgia or creatine phosphokinase level at least twice the upper limit of normal. c) Mucous membranes: Vaginal, oropharyngeal, or conjunctival hyperemia. d) Renal: Blood urea nitrogen or creatinine at least twice the upper limit of normal, or urinary sediment with pyuria in the absence of urinary tract infection. e) Hepatic: Total bilirubin, alanine aminotransferase or aspartate aminotransferase enzyme levels at least twice the upper limit of normal for laboratory. f) Hematologic: Platelet count less than 100,000. g) Central nervous system: Disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent.

6) Laboratory Criteria: Blood and CSF cultures are generally negative if done. Positive cultures for S. aureus may identify the source of the toxin-producing staph. Serologic tests for Rocky Mountain spotted fever, leptospirosis, or measles are negative.

7) A case is classified as probably TSS if five of the six clinical findings described above are present. A case is classified as confirmed if all six of the clinical findings described above are present, including desquamation, unless the patient dies before desquamation occurs.

The focus of the staphylococcal infection may appear surprisingly normal or may have only minimal signs of inflammation or purulence, such as with impetigo or paronychia. The toxin interferes with the release of inflammatory mediators, so signs of inflammation may be absent (2). Thus it is very important to carefully inspect the skin to identify a possible focus of staphylococcal infection that lacks the typical erythema, warmth, and edema of these infections. Bass et al. have speculated that formes frustes, or mild versions of staphylococcal TSS may exist, which may not have hypotension, for example, but do have the other clinical features of staphylococcal TSS (7).

Five to 7 days after the onset of symptoms, patients with staphylococcal TSS exhibit a desquamating rash. It progresses to full thickness peeling by days 10 to 12. The desquamation begins on the trunk and extremities before localizing to fingers, palms, toes and soles. This desquamation is at or below the basal layer. It may be helpful diagnostically when desquamation occurs, since S. aureus is almost never cultured from the blood or CSF of patients with staphylococcal TSS, and it may not be recovered from any site.

The differential diagnosis of a severe systemic illness with fever and erythematous rash includes: invasive group A streptococcal diseases, Staphylococcal toxin-mediated diseases, septic shock of other bacterial etiologies including meningococcemia, scarlet fever, Rocky Mountain spotted fever, Kawasaki syndrome, leptospirosis, measles, systemic lupus erythematosus, Stevens Johnson syndrome, Epstein-Barr virus, adenovirus infection, enterovirus infection, human parvovirus B19 infection, Yersinia pseudotuberculosis infection (Izumi fever), drug reactions, juvenile rheumatoid arthritis, polyarteritis nodosa, Reiter's syndrome, mercury poisoning, etc.

Early recognition of staphylococcal toxic shock syndrome with intervention by removing the focus of infection and providing intravenous fluids and appropriate antibiotics before shock develops may preclude the development of shock and multiple organ failure, which in this disease appears to be secondary to shock (7). With this approach, mortality has decreased significantly below the 10% level observed in the epidemics reported in the early 1980s. The presence of cardiovascular compromise with either myocardial depression and or vascular instability should be treated with appropriate inotropes and/or vasoactive pressors in addition to fluids in an intensive care unit. Antimicrobial therapy should be selected with knowledge of the local rate of methicillin resistance. If the rate of methicillin resistance is significant, IV vancomycin and clindamycin are preferred over anti-staphylococcal penicillins and cephalosporins. Additionally, anti-ribosomal antibiotics such as clindamycin inhibit protein synthesis which may reduce the rate of toxin excretion.

Non-menstrual TSS has a higher mortality rate than menstrual TSS (3,8). Multiorgan failure, particularly renal failure and adult respiratory distress syndrome, are major sequelae of staphylococcal TSS. Unlike streptococcal TSS, in which multiorgan failure is present on admission or within a few hours of admission, multiorgan failure due to staphylococcal TSS tends to occur slightly later in the course of hospitalization. It may occur well after the acute phase of illness. Death is usually due to shock, cardiac arrhythmias, or bleeding abnormalities. In cases of non-fatal staphylococcal TSS, the patient usually improves quickly. After hypotension responds to therapy, respiratory, cardiac, renal and hepatic abnormalities improve quickly and without permanent sequelae (2,3). In cases of prolonged hypotension, chronic renal failure may result. Patients may experience persistent pain, weakness, and fatigue. There may be permanent cognitive impairment, such as memory loss, distractibility, emotional or personality alteration, and persistently cyanotic extremities (2,3).

Menstrual TSS has a risk of recurrence (2). It may recur multiple times in a patient, with each recurrence of decreasing severity. This phenomenon may be due to a delayed or low-level expression of anti-TSST-1 or anti-enterotoxin antibody (2). Women who have had a previous episode of menstrual TSS should be advised to discontinue tampon use and barrier contraceptive methods such as diaphragms. Additionally, some physicians prescribe prophylactic antibiotics to these women during menstruation. Recurrence after non-menstrual TSS is uncommon (2,3).

Since staphylococcal toxic shock syndrome and streptococcal toxic shock-like syndrome are both serious life-threatening diseases that can develop from minor skin infections and fatal consequences can develop in hours, constant vigilance and concern must be maintained when treating staphylococcal and streptococcal skin infections. The serious consequences of staphylococcal and streptococcal toxic shock syndromes demand early recognition of symptoms and aggressive treatment.

A common scenario is a febrile child with impetigo or secondarily infected varicella lesions, who presents with an erythroderma. Early toxic shock syndrome should be considered. Laboratory studies should be obtained, but these may not be very helpful in diagnosing early toxic shock. It may be best to administer parenteral antibiotics in the outpatient setting and observe the patient for several hours in the office or emergency department. Any worsening would suggest toxic shock syndrome. If any uncertainty exists, it is reasonable to hospitalize these patients.

Streptococci can also cause toxic shock syndrome. Virulent group A beta-hemolytic streptococci (GABHS) strains were prevalent in the early part of this century in the pre-antibiotic era when fatal scarlet fever was common. These virulent strains became less prevalent after the 1950s, then recently reappeared. In the late 1980s several reports of outbreaks of rheumatic fever occurred across the United States after a marked decline in the incidence of the disease over the previous four decades. Along with these outbreaks came reports of numerous individuals who had invasive fulminant infections with GABHS with septicemia, shock, and multiple organ failure. A high mortality was reported. Some of the individuals had skin and mucous membrane findings similar to those seen in staphylococcal TSS, and subsequently streptococcal TSS was identified (9,10,11).

To determine whether these isolated reports represented an increasing incidence of invasive GABHS disease, Hoge et al. performed a retrospective review of invasive cases of GABHS disease in Pima County, Arizona over a 5-year period (12). Reporting an annual incidence of 4.3/100,000, they found that the incidence of severe infection and death due to GABHS disease was increasing, and that those affected tended to be younger and healthier than in the past. In a prospective, population-based study, Zurawski et al. reported similar results in Atlanta with a 5.2/100,000 annual incidence (13).

Hoge's study resulted in a clinical case definition for invasive GABHS disease, which has recently been updated (14). Risk factors for invasive GABHS disease are diabetes, cardiovascular disease, alcoholism, neurologic disease (paraplegia, dementia), chronic pulmonary disease, intravenous drug use, cirrhosis, malignancy, dialysis, use of corticosteroids or other immunosuppressive medications, rheumatoid arthritis, recent varicella infection, human immunodeficiency virus infection, lack of skin integrity, recent surgery, abortion, childbirth, and obesity (12,15).

Most outbreaks of invasive GABHS disease in communities do not represent common-source outbreaks, but rather are a clustering of sporadic cases (15). These severe, invasive forms of GABHS disease do not usually follow episodes of acute GABHS pharyngitis (10,16). No focus of infection is identified in 20-25% of cases. Zurawski et al. determined that use of nonsteroidal anti-inflammatory drugs (NSAIDS) in the week prior to the diagnosis of invasive GABHS disease was statistically associated with mortality (13); however other studies have not established this relationship.

The pathogenic mechanisms of invasive GABHS infections are complex and have not yet been completely defined (10,13,17,18).

Streptococcal TSS is a severe illness associated with invasive or noninvasive group A streptococcal (Streptococcus pyogenes) infection. Streptococcal TSS may occur with infection at any site but most often occurs in association with infection of a cutaneous lesion. Signs of toxicity and a rapidly progressive clinical course are characteristic, and the case-fatality rate may exceed 50% (19).

The prodromal illness of streptococcal TSS is nonspecific and includes symptoms such as fever and myalgia. Therefore clinicians may not have reason to suspect group A streptococcal infection when they are confronted with a patient appearing to have signs of toxicity with shock and multiorgan failure following a nonspecific prodromal illness. This may lead to delay in the diagnostic workup and institution of definitive therapy.

There is often a history of minor trauma preceding the prodromal illness. This trauma is of such a minor nature as to seem inconsequential, such as falling off a small children's swingset or tripping over a toy while running. It has been postulated that this minor trauma may become a locus minoris resistensiae, a site of lessened resistance, allowing GABHS in the bloodstream to focalize and multiply (20).

The earliest clue that a patient has streptococcal TSS is often the presence of multiorgan failure either at the time of presentation or soon after admission to the hospital. The kidneys are among the first organs to fail. Renal impairment is present early in the hospital course and precedes hypotension in 40-50% of patients (10). The physical examination is remarkable for shock. Examination of the skin initially reveals cool, clammy skin with poor perfusion, which progresses to mottling and purpura. Worsening of perfusion and shock may lead to tissue necrosis and frank gangrene.

Early clues in the laboratory evaluation of streptococcal TSS are hemoglobinuria and serum creatinine values that are on average more than 2.5 times normal (10). Hypocalcemia and hypoalbuminemia are present on admission and coexist throughout hospitalization (10). Serum creatinine kinase may be helpful in detecting underlying tissue involvement and destruction; when the level is elevated or rising, there is good correlation with underlying necrotizing fasciitis or myositis (10). Blood cultures are usually positive for GABHS within 24 hours or less after collection.

The prodrome of staphylococcal TSS nearly always includes gastrointestinal symptoms such as vomiting, diarrhea, and abdominal pain; the prodrome of streptococcal TSS only rarely includes these symptoms.

Patients with staphylococcal TSS are less likely to have multiorgan failure at the time of hospital admission, whereas multiorgan failure on or within hours of hospital admission occurs frequently with streptococcal TSS. We believe that with early recognition of a staphylococcal toxin-related illness, hypotension may be averted by administration of fluids and antibiotics. However, fluids and antibiotics do not appear to prevent shock in streptococcal TSS. We believe that the multiorgan failure of staphylococcal TSS may be a secondary effect of hypoperfusion due to shock, whereas the multiorgan failure of streptococcal TSS may be due to a primary effect of the toxin.

Streptococcus pyogenes remains exquisitely sensitive to penicillin. However some studies have reported mortality rates from invasive GABHS disease as high as 80% despite treatment with penicillin. In 1952 Eagle demonstrated a reduced efficacy of penicillin with high inoculum size (21). This has subsequently been named "the Eagle effect". In 1988 Stevens et al. compared the use of penicillin, erythromycin and clindamycin in GABHS myositis in mice and demonstrated that penicillin-treated mice fared no better than untreated controls if penicillin treatment was delayed for as little as 2 hours (22). Erythromycin-treated mice fared better than penicillin-treated mice and untreated controls, but only if treatment was started within 2 hours. However clindamycin-treated mice had survival rates of 100%, 100%, 80%, and 70%, even if treatment was delayed for 0, 2, 6, and 16.5 hours respectively (22).

Clindamycin is superior to penicillin in the treatment of invasive GABHS disease (10) because its efficacy is not affected by inoculum size or stage of growth. Clindamycin is a potent suppressor of bacterial toxin synthesis and it facilitates phagocytosis of GABHS by inhibiting M-protein synthesis. Clindamycin suppresses synthesis of penicillin-binding proteins and it has a longer post-antibiotic effect than beta-lactams. Clindamycin suppresses lipopolysaccharide-induced monocyte synthesis of TNF-alpha.

The patient with suspected invasive GABHS disease should be admitted to the intensive care unit for monitoring and treatment with intravenous fluids and pressors. With use of vasoconstrictors such as epinephrine, gangrene of the digits and toes often develops (10). It is not clear whether this gangrene is due to the pressors, the GABHS infection, or both.

Most patients with streptococcal TSS have fulminating septicemia with severe multiple organ failure, frequently before shock develops. These events appear to be toxin-mediated, and by the time the diagnosis is suspected and treatment is initiated, the outcome may

already be determined, since streptococcal TSS has a 30-70% mortality rate (9,10,11). Complications of streptococcal TSS include shock (100%), acute respiratory distress syndrome (55%), renal impairment (80%), amputation (10%) and death (30%).

Questions

1. True/False: The prevalence of menstrual TSS has decreased markedly with the removal from the market of superabsorbent polyacrylate fiber tampons.
2. True/False: Vomiting, diarrhea, and abdominal pain are nearly ALWAYS seen in staphylococcal TSS but are rare in streptococcal TSS.
3. True/False: Oral mucosa hyperemia and hypertrophy of the tongue papillae are often seen in staphylococcal TSS but are seen in few patients with streptococcal TSS.
4. True/False: Blood cultures are usually positive in streptococcal TSS, but are usually negative in staphylococcal TSS.
5. True/False: Mortality for both staphylococcal and streptococcal TSS is about 50%.
6. True/False: In both staphylococcal and streptococcal TSS, desquamation of the hands and feet begins at about day 5-7, and is complete by day 10-12.
7. True/False: Multiorgan failure is usually present at the time of admission with streptococcal TSS, but appears later in the course with staphylococcal TSS.
8. True/False: Even though GABHS are sensitive to penicillin, the efficacy of penicillin may be reduced during overwhelming streptococcal sepsis due to the Eagle effect.
9. True/False: The prodrome of streptococcal TSS is very vague and may be associated with some seemingly unrelated minor trauma.
10. True/False: The source of staphylococcal TSS may be a superficial skin or mucocutaneous lesion which appears insignificant.

9. True
10. True. Examples include impetigo and paronychia.

Chapter VI.19. Tuberculosis
Wallace J. Matthews, Jr., MD

La Boheme - Poverty and TB
La Traviata - Prostitution and TB
Long Days Journey Into Night - Foreign Born and TB
Moulin Rouge - Alternate Life Style and TB
And The Band Played On - AIDS and TB

A 2 year old girl is seen for irritability and fever. Her family had moved to Hawaii from the Marshall Islands 6 months ago. She had presented with anemia and malnutrition at the age of 9 months and her PPD (purified protein derivative) skin test had 17 mm of induration at 48 hours. Her chest film showed increased markings but no cavitary lesions. The radiologist was not certain if hilar adenopathy was present. She was treated with INH for 3 months and was scheduled to continue receiving INH therapy twice weekly but was lost to follow-up.

She is not as alert as usual and has a stiff neck. Her present chest film shows hilar adenopathy with multiple small lesions throughout all lung fields. A head CAT scan demonstrates enlarged lateral ventricles, enhancement of the meninges at the base of the brain and small vessel brain stem infarcts with possible pons involvement. There are no suggestions of significantly increased intra-cranial pressure. A lumbar puncture is performed. The opening pressure is 21 cm, white cell count 525, 85% lymphs, protein 86, glucose 55 (blood glucose 92). Cultures are sent which later grow Mycobacterium tuberculosis.

Known as "consumption", the white plague, and the white death, tuberculosis is perhaps the earliest, documented bacterial disease of humanity. Because of its characteristic pulmonary scarring and bony changes, it has been documented in human remains as ancient and diverse as the Egyptian and Incan mummies to the sand preserved natural remains found in the Chinese deserts of Asia Minor.

In the late part of the 19th and early part of the 20th century, almost all adults showed evidence of exposure and immune response to Mycobacterium tuberculosis. The recognition of TB as a major health issue is even becoming known in the popular press. In a special on War on Disease, National Geographic reported that one third of humanity are now carriers of tuberculosis (1). TB exposure was determined by a positive OT (old tuberculin) skin test. Skin testing by PPD (purified protein derivative) is now the standard (available since the 1930s) (1,2).

In the United States in general, and Hawaii in specific, there has been a rapid decrease in tuberculosis because of dramatic improvement in the living conditions of city dwellers (sociologic), the recognition of the means of spread the disease (epidemiological), isolation of contagious individuals in sanatoriums, as well as the development of anti-tuberculosis chemotherapy (bacteriologic and anti-microbial). There has been a 9-fold decrease in reported TB cases in Hawaii from 1060 cases in 1930 to 136 cases in 2000. This is in spite of a dramatic increase in population over that same time span. Indeed, tuberculosis was considered a vanishing disease and the medical specialists in this field and the public health resources spent on it were vanishing as well. It was thought of as a residual third world problem.

Hawaii has always had rates of infection much higher than the rest of the country. The case rate of TB in Hawaii is now about 2 times the national average 11.2 vs. 5.8 cases per 100,000 population (4). It is also clear that most newly diagnosed cases are imported and occur in foreign-born individuals (4). The spike in cases in 1992 was due to World War II Philippine veterans being required to come to the US to register for veteran benefits and having their TB recognized while here. Foreign born TB cases in Hawaii account for 83% of all cases as compared to 46% of cases on the mainland (1). In Hawaii, these are patients are from Southeast Asia and the West Pacific Islands. Patients from the Philippines account for 63% of TB cases while native born cases account for only 16%. Pacific Island immigrants from COFA (Compact of Free Association) (former trust Territories, Republic of Marshall Islands, Federated States of Micronesia, Palau) made up 44% of the cases from 1995-2000. In the rest of the United States, TB is also found among foreign born, but these individuals are from Mexico and South America in addition to Asia (5). The length of residence in Hawaii at the time of a TB diagnosis was <1 year whereas on the mainland it occurred somewhat later at 1-5 years of residency (6). From these data, the highest risk individuals are foreign born and are diagnosed soon after coming to Hawaii.

The diagnosis of TB depends upon clinical suspicion, isolation of the organism or its specific DNA, the tuberculosis skin test (PPD) or the response to therapy. It can involve any organ, can range from having no symptoms to overwhelming symptoms, progress indolently or become rapidly fatal, can be local or systemic. These facts make it clear that the slogan "Think TB" is correct, especially here in Hawaii.

The TB skin test is the only available standardized method for identifying latent TB infection. It consists of injecting 0.1ml of intermediate PPD (5 TU) intracutaneously into the volar surface of the forearm. It is to be read at 48-72 hours although a positive result can be read up to 7 days after testing. It must be read by a trained health professional. Self-reading is not allowed. Induration, not erythema, is measured in millimeters. The cutaneous reaction depends on an intact cellular immune response to the TB antigens. Tine or multiple puncture tests are no longer allowable. False positive tests do occur with other non-TB mycobacterium antigens. False negatives occur both with improper placement of the antigen as well as when immunity decreases or is interfered with by other disease. The Center for Disease control has suggested different cut off levels for different populations. Positivity is based on a statistical probability that a reaction reflects true Mycobacterium tuberculosis infection. A 5 mm test is considered positive in cases of close contact with a confirmed case, in patients with an abnormal chest film consistent with old or active TB, on immigration visa adjustment examination and in patients with HIV (a 5mm test might still be falsely negative in HIV patients with a CD4 count of less than 100). A 10 mm reaction is considered

positive in areas of high TB incidence such as Hawaii. It includes most TB positive patients with a relatively small number of false positives. In all other groups, a 15 mm test is considered positive. This higher level is especially useful in areas that have a high incidence of exposure to atypical Mycobacterium. A booster phenomena is known where the initial test is negative but reverts to its correct positive status with repeat testing in 1-4 weeks. Individuals who are truly negative will not boost. Repeated testing does not sensitize uninfected individuals. Anergy panel skin testing (testing for anergy) is no longer recommended. It was unreliable due to non-standardized antigens and did not seem to have clinical relevance.

BCG (Bacille Calmette-Guerin) vaccination is still used in some other countries. It is effective in preventing disseminated tuberculosis, especially tubercular meningitis in infants. Its efficacy in preventing pulmonary tuberculosis is debated. It is still used in countries with high rates of tuberculosis. It is also recommended as part of a treatment program for newborns of mothers with active pulmonary tuberculosis. It is a live vaccine derived from Mycobacterium bovis strains. The current recommendation is that individuals who have received BCG should have this fact ignored and their PPD tests interpreted the same as other individuals. The only exception is if the immunization was given less than 1 year previously.

Replacement tests for the PPD skin test have been sought to help with the difficulty of correct placement, having the patient return for a reading of the test, correct reading of the PPD and correct evaluation of these results. A newer test, Quantiferon, is a blood test that is in the final stages of FDA testing and will, in all likelihood, replace PPD testing. It recognizes Mycobacterium TB specifically and eliminates the cross-reactions in patient who have been exposed to atypical organisms as well as those who have received BCG immunizations.

Because of all of the problems noted above and because of the emergence of multiple drug resistant TB, it is very important to isolate the organism in suspected cases of tuberculosis. Children rarely produce sputum and this makes the isolation of organisms especially problematic.

Asymptomatic primary tuberculosis (7) is the most frequent clinical presentation in pediatrics. It is recognized during contact work-up or routine tuberculin testing. The child is asymptomatic. The chest film is usually normal but might have some hilar adenopathy. A 25 year study of TB in Baltimore documented the morbidity and mortality of non-treated, asymptomatic TB (8). For this reason, adults with asymptomatic TB are treated with INH for 6 months. The duration of therapy in children is longer than in adults. Converters are treated with INH for 9 months. This minimizes the occurrence of more progressive TB infections. In our case example, the positive PPD led to treatment as is appropriate but the therapy was discontinued. This results in the risk of drug resistance as well as subsequent disease as noted above.

Because treatment with INH for 9 months is associated with completion rates as low as 5-25% (9,10) shorter duration regimes have been advocated for latent TB including a 2 month schedule of rifampin and pyrazinamide. The reports of death from hepatitis associated with this regime have brought this practice into question (11). In addition, because of the compliance issues noted above, direct observed therapy has become more common.

Our patient might well have pulmonary tuberculosis. Pulmonary tuberculosis can be seen in children as well as adults. In adults, sputum smears are positive in 40-60% (i.e., organisms are identified on an acid fast stain of the sputum) of confirmed cases of pulmonary TB. Most cases of TB in adults have positive cultures or smears (82%). 96% of cases with cavitary pulmonary lesions on CXR will have a positive culture, as will 70% of cases with focal infiltrates. A positive smear requires 10,000 to 1,000,000 organisms/ml of sputum. In cavitary disease, the smears are usually positive and a negative smear strongly suggests another etiology. The culture, of course, is the gold standard for tuberculosis. Cultures are usually positive in 4-8 weeks although BACTEC liquid cultures may be positive in 2-4 weeks (12). In these studies, antibiotics to suppress all other growth are added and radiolabeled carbon-14 substrates are used. Radiolabeled carbon dioxide is measured as an indication of the presence of Mycobacterium tuberculosis.

Other technologies have the possibility of more rapid diagnosis for tuberculosis. Nucleic Acid Amplification Tests (NAATs) are available in 2 probes, Gen-Probe MTD and Roche Amplicor. Guidelines for the use of these tests as well as an algorithm are available (13). They are licensed for use on respiratory samples only and are limited to patients who have not been on anti-TB treatment for more than 7 days or who have been treated within the past 12 months. They do not replace cultures. In smear positive cases, they have a sensitivity of 95% and specificity of 98%. In smear negative cases, they have a sensitivity of 50% and a specificity of 95%. If cultures and NAATs are discordant, the cultures remain the gold standard. Additional means of obtaining specimens include fine needle aspiration, bronchoalveolar lavage or transbronchial biopsies. These tests are also useful to uncover a different diagnosis.

Since children do not produce sputum, isolation of the organism is much more difficult. Gastric washings may be used as a specimen source. Even after this, the organism may not be recovered. When all of these tests fail in a pediatric patient, a search should be undertaken for the organism from the person infecting the child. This organism, if found, can serve as a surrogate specimen for drug sensitivity testing.

Pleurisy with effusions, although rare in young children, may be seen in older children and is more common in boys than in girls. Its onset is rapid with signs of pneumonia. Fever is usually present and can last for weeks. Thoracentesis yields fluid with a low glucose, high protein and predominantly lymphocytic cells. Smears of the effusion are frequently negative for TB, as are cultures. Pleural biopsy, perhaps by a thorascope these days, increases the yield of both of these studies (7).

TB by diagnostic site shows that pulmonary makes up of 87% of cases, pleural 3%, lymphatic 6%, bone/joint <1%, genitourinary <1% and meningeal 2%. In pediatric patients, all of these infections are possible but the most likely are pulmonary TB and meningitis.

Our patient has confirmed tubercular meningitis. Note that the cell count is largely mononuclear/lymphocytic, similar to viral meningitis in this regard. The CAT scan noted above is virtually diagnostic. Isolation of the organism is crucial as in all cases of TB. Drug therapy is aimed at the isolated organism but until that occurs 4 or 5 drugs are used.

Multiple drug resistant TB is the major concern. Primary drug resistance to anti-TB medications occurs in nature. For INH, the rate of resistance is 1 in 1 million, for rifampin 1 in 100 million and for both INH and rifampin 1 in 100 trillion. Since cavitary lung lesions contain approximately 1 billion organisms, naturally occurring, primary resistance has not been a real problem. However, partially treated infections either due to inadequate length of therapy or lack of compliance, results in selecting multiple drug resistant TB organisms which is a major issue in treating TB patients and public health prevention programs. The standard treatment now consists of 4 drugs, INH and rifampin for 6 months and pyrazinamide and ethambutol for 2 months. Streptomycin can be substituted for ethambutol. Further treatment is based on cultures and sensitivity. In pediatric patients, treatment is more likely to be empiric. Some providers avoid ethambutol because of the difficult of monitoring for ethambutol associated optic neuritis. There have been no documented cases of optic neuritis in children. Because of this, many still use ethambutol.

Those with meningeal, bone or otherwise disseminated disease are treated for 12 or more months. All patients should receive directly observed therapy. In patients with confirmed drug resistance, changes in their regimes are required such that second and third line drugs are substituted (e.g., ethionamide, cycloserine, PAS, quinolones, clofazimine, amikacin, kanamycin, capreomycin). The length of treatment is also prolonged. These recommendations have changed frequently and it is best to get recommendations from the Department of Health or infectious disease experts.

The long-term consequences of TB meningitis are real and hydrocephalus and decreased functioning are almost universally seen.

TB requires vigilance both for the individual patient and the community. The rule is THINK TB.

Questions

1. True/False: Tuberculosis is a disease of the past and no longer a major health care issue.
2. True/False: Testing with PPD is a useful screening test for patients suspected of having tuberculosis.
3. True/False: A history of BCG vaccination makes PPD testing contraindicated and the results unreliable.
4. True/False: Children with a positive PPD skin test and a positive chest film should be treated with INH alone for 9 months.
5. True/False: The risk of multiple-drug resistant TB is much higher in patients that did not complete initial TB therapy.
6. True/False: Immigrants are at greater risk of having TB than native-born Americans.
7. True/False: Patients with HIV/AIDS have a higher rate of acquiring pulmonary TB than the general population.
8. True/False: Health care workers are at a greater risk of acquiring TB than the general population.
9. True/False: Ethambutol cannot be used in pediatric patients since vision testing is often impossible.
10. True/False: Hawaii has a lower rate of TB than the rest of the US.

Chapter VI.20. Human Immunodeficiency Virus (HIV) Infections

Guliz Erdem, MD
Cecilia M. Shikuma, MD

An 18 year old student has a three week history of worsening headache, myalgias and fever not responding to acetaminophen (Case scenario is adapted from reference 1). His primary care physician diagnosed him to have a "viral syndrome". He was noted to have oral thrush and was advised to undergo HIV testing (which he did 10 days ago) because he admitted to being bisexual and engaging in unprotected sex. He also had a truncal rash and arthralgias 5 days previously (currently resolved). He denies illicit drug use.

Exam: VS T 39, P 118, RR 24, BP 110/74. He is mildly ill appearing. His head, ear, heart and lung exams are normal. His oral exam is significant for thrush. His abdomen is nontender, liver edge palpable 3 cm below the right costal margin (liver span 11 cm), moderate splenomegaly is present. Skin without rash. Small, nontender anterior/posterior cervical and occipital lymphadenopathies are present. No focal neurologic findings are present, but he has some meningeal signs.

Lab: CBC: WBC: 11,500, 93% neutrophils, 3% lymphocytes, 1% monocytes, 3% atypical lymphocytes, Hct 45. Serum transaminases slightly elevated. Heterophil antibody (Monospot) negative. Serum RPR negative. HIV ELISA (performed 10 days earlier) was negative. A lumbar puncture is performed. CSF analysis shows 22 WBC, 95% lymphocytes and 5% PMNs. The CSF protein is mildly elevated. CSF VDRL is negative.

His symptoms gradually improve after initiation of treatment with several antiretroviral medications. You thought that this patient is recently infected with HIV and his symptoms are consistent with HIV aseptic meningitis and a mononucleosis like syndrome. This phenomenon is also called acute retroviral syndrome and occurs 2-8 weeks after exposure. The HIV ELISA tests can be initially negative as it was in this patient. The decrease in the absolute lymphocyte count and increase in serum transaminases are common. CSF lymphocytic pleocytosis can be seen at any stage of HIV disease. CSF pleocytosis diminishes and protein elevation persists as HIV disease advances. The finding of pleocytosis in advanced disease warrants exclusion of other etiologies.

Since AIDS was recognized as a distinct disease in 1981, over 50 million individuals worldwide have been infected by HIV-1 (2). An estimated 1.3 million children under 15 are living with HIV/AIDS. As of January 1, 2000, 8718 cases of AIDS in children <13 years old had been reported, and approximately 60% of these children have died (3).

HIV is transmitted by both homosexual and heterosexual contact, by blood and blood products, by infected mothers to infants either intrapartum, perinatally or via breast milk. Heterosexual transmission is the most common mode of infection worldwide. The presence of other sexually transmitted diseases in the partners increases the risk of transmission. The risk of HIV transmission following skin puncture from a needle that was contaminated with blood from a patient with HIV infection depends on multiple factors (such as the viral load of the patient, the amount of the blood on the needle, etc.) and without antiretroviral therapy, the transmission risk is about 0.3%.

Women, in whom HIV infection is most often acquired via heterosexual sex, now comprise the group in which HIV infection is increasing most rapidly in the United States. About 25% of the infants born to HIV-seropositive mothers who are not receiving antiretroviral therapy are infected by HIV-1 (4,5). Perinatal transmission can occur during pregnancy, during labor and delivery and after delivery through breast-feeding. In the absence of breast feeding, 60-75% of transmission occurs during labor and delivery. Among women who breast feed, breast feeding is responsible for 10-15% of transmission. Clinical factors that increase the likelihood of perinatal transmission include immunologically or clinically advanced HIV disease in the mother, high plasma viral load, maternal injection drug use during pregnancy, preterm delivery, non-receipt of antiretroviral treatment and breast-feeding. Obstetric factors are also important. Delivery >4 hours after the rupture of fetal membranes can double the risk of transmission. Chorioamnionitis and maternal infection with another sexually transmitted disease during pregnancy increase the risk. Most of these risk factors have been identified before the use of zidovudine chemoprophylaxis and their effects are unknown now, since most pregnant infected women are receiving treatment. Reducing the exposure of the infant to the maternal blood and secretions during the intrapartum period as in cesarean section can prevent HIV transmission. The birth of every perinatally HIV-infected infant signals either a missed prevention opportunity (no prenatal care, HIV testing is not offered or obtained, no prophylaxis) or, more rarely, a failure of prophylaxis.

The term HIV syndrome is used to describe the cellular and humoral immunodeficiency and the numerous complications that result from the HIV-1 and HIV-2 infections. Acquired immunodeficiency syndrome (AIDS) is the spectrum of disorders (HIV-wasting, opportunistic infections, certain malignancies) resulting from advanced HIV infection.

Also, any HIV-infected child with less than 15% of circulating lymphocytes as CD4+ T-lymphocytes (CD4 cell) has severe suppression regardless of the presence of symptoms or opportunistic infections. The CD4 cell counts may differ in children depending on their age and accordingly, the definitions for the immunosuppression level may differ between different age groups.

Etiology and establishment of infection

HIV is a RNA virus whose hallmark is the reverse transcription of its genomic RNA to DNA by the enzyme reverse transcriptase. HIV belongs to the family of human retroviruses and the subfamily of the lentiviruses. The four recognized human retroviruses belong to two distinct groups as the human T-lymphotropic viruses (HTLV-1 and HTLV-II) and the human immunodeficiency viruses (HIV-1 and HIV-2). HIV-2 was originally confined to West Africa, but a number of cases have been recently identified in other parts of the world.

The HIV viral envelope proteins (such as gp120 protein) have a high affinity (tropism) for the CD4 lymphocytes. In order for HIV to fuse to and enter its target cell (mostly CD4 cells), it must also bind to one of a group of co-receptors. The two major co-receptors are CCR5 and CXCR4. Both of these receptors belong to the family of G protein-coupled cellular receptors, and the use of one or the other or both receptors by the virus is an important determinant of the cellular tropism of the virus.

After HIV binds to CD4 cells, the viral and cellular membranes fuse via the gp41 molecule and the HIV nucleoprotein complex enters the cytoplasm. The RNA viral genome then undergoes transcription by the virally encoded reverse transcriptase. The double stranded viral DNA enters into the nucleus, where integration of the DNA provirus into the host chromosome is catalyzed by the enzyme "integrase". This provirus may remain transcriptionally inactive (latent) or it may manifest varying levels of gene expression.

When a CD4 cell with the integrated provirus is activated, the viral particles are assembled and virions are released from the cell by budding. Productive viral replication is lytic to the infected T cells. Rapid production and turnover of CD4 cells occur throughout the course of HIV infection. Although a highly dynamic, complex equilibrium between HIV and CD4+ cells may be maintained for several years, eventually a decline in circulating CD4 cells occurs. A decrease in function as well as number of CD4 cells is central to the immune dysfunction in HIV infection.

The events associated with primary HIV infection are likely critical determinants of the subsequent course of HIV disease. In particular, the dissemination of the virus to lymphoid organs is a major factor in the establishment of a chronic and persistent infection. It is uncertain which cell in the blood or lymphoid tissue is the first to actually become infected; however, studies in animal models suggest that dendritic lineage cells may be the initial cells infected. These cells pass the virus on to CD4 cells in the draining lymph nodes of the animals. In humans this mechanism probably operates when the virus enters "locally" (such as vagina, rectum, upper gastrointestinal tract and breast milk) as opposed to directly into the blood.

In primary infection, virus replication in CD4 cells intensifies prior to the initiation of a virus specific immune response, leading to a burst of viremia and then to a rapid dissemination of the virus to other lymphoid organs, brain and other tissues. Two to eight weeks after initial exposure, up to 70% of the patients experience this immune response as a mononucleosis-like syndrome. These acute symptoms may last 3 days to 3 weeks and can include arthralgias, fever, headache, lymph node enlargement, maculopapular rash and sore throat. Ten percent to 20% of patients have neurologic involvement, usually presenting as aseptic meningitis with possible cerebrospinal fluid pleocytosis. The progression of diseases varies greatly among individuals and the route of HIV transmission does not influence the rate of progression. Generalized lymph node enlargement occurs in 35 to 60% of asymptomatic HIV-infected persons.

Despite the initial immune response, once infection is established, the virus is virtually never cleared from the body. A median of approximately 10 years passes before the patient becomes clinically ill. This period is shorter in perinatally infected children. HIV successfully evades elimination by the immune system in order to establish chronicity and the mechanisms of this evasion are not clear. This goes along with the establishment of a pool of latently infected, resting CD4 cells. These cells can remain in this state until an activation signal drives the expression of the replicating virus. This persistent pool of cells is a major obstacle to any goal of eradication of virus from the infected patients. Some degree of viremia is present in all untreated patients and the level of this "steady-state" viremia, called the "viral set point", at approximately 1 year has important prognostic implications. If the patients have a lower set point, it can be said that the disease progression will be much slower. Several genetic mutations can be responsible for this delay in the progression of the disease (as in certain deletions of the CCR5 co-receptor gene).

Diagnosis

In most centers, enzyme-linked immunosorbent assay (ELISA) is used as the primary screening test. If the test is reactive, it is repeated in duplicate and if either or both repeat tests are reactive, the sample is considered positive and a western blot or indirect immunofluorescence assay is done on the sample for confirmation. The western blot detects antibodies to specific denatured HIV-1 proteins. The absence of all bands in western blot is considered a negative test.

This protocol has a 3-4 week "window period" prior to seroconversion, during which results can be negative or indeterminate. Most experts suggest the use of plasma viral load (PVL) for patients that may be in the window period (as in the case scenario). In addition to PVL, very sensitive virological assays (RT-PCR, bDNA) are also used for diagnosis. However, one frequent consequence of using highly sensitive tests will be the loss of specificity, meaning that false-positive results will occur. For this reason, ELISA with a confirmatory western blot remains the "gold standard" for the diagnosis of infection in adults and older children. Rapid tests for expedited screening can be used in selected patients such as pregnant women.

The diagnosis of HIV infection in newborns and infants <18 months of age is different. Nearly all infants born to infected mothers passively acquire maternal antibodies and in some instances will test positive regardless of whether they are infected. Definitive diagnosis in this age group requires virological tests as PCR or viral culture. Two positive assays on two separate specimens are required for diagnosis. Infant HIV testing should be done as soon possible. The infant who has two negative virological tests, both of which are performed at 1 month of age or older and one of which is performed at 4 months of age or older, is considered to have had HIV infection reasonably excluded in the absence of any clinical illness.

T cell counts are important for the diagnosis and laboratory monitoring of the patients. Generally, along with a decrease in the CD4+ levels, an increase in CD8+ levels is observed. This decrease in CD4+ to CD8+ ratio can also occur with other viral infections, such as those caused by CMV or EBV. CD4 count is generally accepted as the best indicator of the immediate state of immunologic competence of the patient.

Response of T-lymphocytes to plant lectin mitogens (pokeweed) are decreased or absent and patients may be anergic to skin tests. Serum immunoglobulins, particularly IgG and IgA are frequently elevated during the early stages of HIV infection.

Clinical manifestations

The clinical manifestations can be due to HIV or its complications. The disease spectrum changes from primary infection with or without the acute syndrome to the asymptomatic stage and to advanced disease. Approximately 50% of untreated patients develop AIDS within 10 years. An additional 30% will have mild symptoms of immunodeficiency and fewer than 20% will be entirely asymptomatic.

The pediatric manifestations usually include generalized lymphadenopathy, hepatomegaly, splenomegaly, failure to thrive, oral candidiasis, recurrent diarrhea, parotitis, cardiomyopathy, hepatitis, nephropathy, CNS disease (including developmental delay), lymphoid interstitial pneumonia, recurrent invasive bacterial infections, opportunistic infections and malignancies. Fever is common and can be due to Mycobacterium avium complex, toxoplasmosis, CMV infection, tuberculosis, Pneumocystis carinii infection, salmonellosis, cryptococcosis, histoplasmosis, medications or malignancies. Acute bronchitis and sinusitis are more prevalent during all stages of disease. The most common causes of pneumonia are the bacterial infections and Pneumocystis carinii pneumonia (PCP). PCP occurs most frequently in infants between 3 and 6 months of age who acquire infection before at birth. In addition to these pulmonary manifestations, another important clinical feature in children is lymphoid interstitial pneumonitis (LIP). LIP is a benign lung infiltrate and is felt to be part of the polyclonal activation of lymphocytes. It is generally self-limited and no specific treatment is necessary. HIV infected patients appear to be particularly prone to infections with encapsulated microorganisms such as S. pneumoniae and H. influenzae type B.

Malignancies in pediatric HIV infection have been relatively uncommon, but leiomyosarcomas, CNS lymphomas, and Burkitt lymphomas occur much more frequently in children with HIV infection than in nonimmunocompromised children. The development of opportunistic infections, particularly PCP, progressive neurologic disease, and severe wasting is associated with a poor prognosis.

HIV pediatric findings have been revised into 4 categories (4):

Category N: Not symptomatic. These children may have only one of the conditions from category A. These patients have CD4 cells >25%.

Category A: Mildly symptomatic. They can have 2 or more of the following conditions: lymphadenopathy, hepatomegaly, splenomegaly, dermatitis, parotitis, recurrent or persistent upper respiratory tract infections.

Category B: Moderately symptomatic. Findings may include but are not limited to: anemia, neutropenia, single episode of meningitis, pneumonia, recurrent or chronic diarrhea, HSV infections, lymphoid interstitial pneumonitis, persistent fever (>1 month). Category C: Any condition listed as "AIDS defining conditions" including serious multiple and recurrent bacterial infections, candidiasis, disseminated coccidioidomycosis and histoplasmosis, extrapulmonary cryptococcosis, cryptosporidiosis >1 month, CMV infection developing after 1 month of age. It also includes wasting syndrome (persistent weight loss >10% of baseline or downward crossing of at least 2 of the following percentile lines on the weight for age chart in a child >1 year of age or <5th percentile on weight for height chart on 2 consecutive measurements plus chronic diarrhea or documented fever), encephalopathy, Kaposi's sarcoma, lymphomas. These patients usually have circulating CD4 cells of <15%.

Treatment

Initiation of antiretroviral treatment (ART) depends upon virologic, immunologic and clinical criteria. The CD4+ lymphocyte count or percentage value is used in conjunction with viral load to guide treatment decisions and primary prophylaxis of PCP after age 1 year. Expert opinions and knowledge about diagnostic and therapeutic strategies are changing rapidly and these can be followed from several resources such as: www.hivatis.org (posts federally approved treatment guidelines), www.actis.org (information on federally funded and privately funded clinical trials), www.cdcnpin.org (updates on epidemiologic data from the CDC), www.cc.nih.gov/hiv-mgt (online images of HIV drugs and information regarding dosing). If enrollment into clinical trials is possible, enrollment of the HIV-infected child into an available clinical trial should be encouraged. There are several groups of drugs used in ART.

Nucleoside analog reverse transcriptase inhibitors (NRTIs): zidovudine (ZDV-Retrovir), didanosine (ddI-Videx), lamivudine (3TC, Epivir), stavudine (d4T, Zerit), zalcitabine (ddC, Hivid), abacavir (ABC, Ziagen).

Non-nucleoside analog reverse transcriptase inhibitors (NNRTIs): nevirapine (NVP, Viramune), efavirenz (EFV, DMP-266, Sustiva).

Protease inhibitors (PIs): ritonavir (Norvir), indinavir (Crixivan), nelfinavir (Viracept), saquinavir (Invirase, Fortovase), amprenavir (Agenerase), ABT-378/r (Kaletra).

Fusion inhibitors: T-20.

Antiretroviral therapy has provided substantial clinical benefits to HIV-infected children with immunologic or clinical symptoms of HIV infection. Studies have demonstrated substantial improvements in neurodevelopment, growth, and immunologic and/or virologic status with initiation of ZDV, ddI, 3TC, or stavudine monotherapy . More recent pediatric trials of symptomatic children who have not previously received antiretrovirals have demonstrated that combination therapy with either ZDV and 3TC or ZDV and ddI is clinically, immunologically, and virologically superior to monotherapy. When compared with monotherapy, combination therapy: a) slows disease progression and improves survival, b) results in a greater and more sustained virologic response and c) delays development of virus mutations resistant to the drugs being used. Data from clinical trials that address the effectiveness of antiretroviral therapy in asymptomatic infants and children with normal immune function are not available. However, initiation of therapy early in the course of HIV infection, including during the period of primary infection in the neonate, is theoretically advantageous. Antiretroviral treatment is definitely required in the presence of any AIDS-definitive infection (Category C), wasting or failure to thrive, HIV encephalopathy, AIDS-associated malignancy and two episodes of meningitis or sepsis. Several ART drugs are not approved for use in children. ART should be initiated by a pediatric infectious diseases specialist with expertise in HIV infection and its treatment. Generally, the combination of a protease inhibitor and two non-nucleoside RTIs is recommended for initial antiretroviral therapy. If the patients cannot swallow pills, the PIs nelfinavir or ritonavir can be used. If they can swallow pills, indinavir can also be used. Another recommended alternative to this treatment is nevirapine with two NRTIs or abacavir with ZDV and 3TC. Monotherapy, d4T/ZDV, ddC/ddI, ddC/d4T, ddC/3TC treatments are not generally recommended.

Adherence to treatment can be increased by use of suitable formulations, use of G-tubes, and directly observed therapy. Drug concentrations should be monitored. Viral assays can be done to assess resistance. ART may have serious side effects and patients should be carefully monitored. There are currently no data available that define the threshold at which a change in therapy should occur. If the PVL is above detectable limits on two determinations or if the PVL exceeds the arbitrary figure of 10,000 to 20,000 copies/mL, a change in therapy may be considered. PVL assays and CD4 cell counts should be repeated at 3 to 4 month intervals during therapy.

Early diagnosis and aggressive treatment of opportunistic infections may prolong survival. Four major opportunistic infections need to be considered for prophylactic treatment: bacteremia/sepsis, Pneumocystis carinii infection (PCP), tuberculosis and mycobacterium avium/m. intracellulare infection. For infants younger than 1 year of age with possible or proven HIV infection, PCP prophylaxis should be administered at 4 to 6 weeks of age and continued for the first year of life unless infection is excluded.

IVIG can be given in addition to ART to children with hypogammaglobulinemia, recurrent, serious bacterial infections, children who fail to develop antibodies to common antigens and to children living in areas where measles is highly prevalent who have not developed an antibody response after two doses of MMR.

Treatment of HIV-infected women with zidovudine during the second and third trimester of pregnancy and during delivery, followed by zidovudine treatment of the infant for 6 weeks is shown to decrease maternal-fetal transmission to 8%.

Following significant exposure of health care employees (needle-stick injuries) prompt administration of a combination regimen of indinavir, zidovudine, and lamivudine, significantly decreases the likelihood of HIV infection.

Immunizations

In general, live virus (OPV) vaccines and live bacterial (BCG) vaccines should not be given to patients with AIDS or other clinical manifestations of HIV infection indicative of significant immunosuppression. An exception is MMR vaccine which can be given to patients who are not severely immunocompromised. Other routinely recommended vaccines, should be given according to the usual immunization schedule. Pneumococcal vaccine and influenza vaccination are also recommended. Varicella vaccine can be administered to asymptomatic patients if the benefits of vaccination outweigh its risks.

Control measures

In addition to the measures for the reduction of perinatal HIV transmission and counseling of HIV-infected women to not breastfeed; education, counseling, behavior modification are the cornerstones of infection prevention. Another important point is that HIV infected children should not be excluded from day-care centers or schools for the protection of other children or personnel. The need for a more restricted environment should be evaluated on a case by case basis with consideration of conditions that may pose an increased risk to others, such as aggressive biting behavior or the presence of exudative, weeping skin lesions that cannot be covered. Only the child's parents, guardians, and physician have an absolute need to know that the child is HIV infected. The number of personnel aware of the child's condition should be kept to the minimum needed to ensure proper care of the child.

HIV vaccines using viral surface proteins, non-HIV live vector viruses, combination of several viral elements, naked DNA and HIV protein fragments are studied and in some instances clinical trials are being performed.

Questions

1. Which one of the following is not a finding in HIV wasting syndrome?
   a. <5th percentile on weight-for-height chart on 2 consecutive measurements.
   b. Chronic diarrhea.
   c. Temperature of 38.5 °C, intermittently during the last 2 months.
   d. Persistent weight loss.
   e. Thrombocytopenia.

2. Which one of the following is used as a screening test in HIV infection diagnosis?
   a. Enzyme immunoassay
   b. Polymerase chain reaction
   c. Western-blot
   d. Immune fluorescence assay
   e. Viral culture

3. Which of the following vaccines is not routinely recommended in HIV infected asymptomatic children?
   a. IPV
   b. MMR
   c. Hib
   d. Pneumococcal
   e. Varicella

4. Which of the following is a definite indication to start antiretroviral treatment in HIV infected children?
   a. CD4 cell counts >1500 in a 4 year old asymptomatic child.
   b. Pneumocystis carinii pneumonia.
   c. Recurrent otitis media but no other symptoms.
   d. Bilateral anterior cervical lymphadenopathy.

5. Which one of the following is/are not shown to be a transmission route for HIV infection?
   a. Vertical transmission
   b. Breast feeding
   c. Vectors
   d. Blood transfusion
   e. Heterosexual sex

6. Which of the following enzymes have critical importance in the establishment of HIV infection?
   a. Neuraminidase
   b. DNA polymerase
   c. Protein kinase
   d. RNA polymerase
   e. Reverse transcriptase

Answers to questions

1.e, 2.a, 3.e, 4.b, 5.c, 6.e

Chapter VI.21. Sexually Transmitted Infections
Reina M. Ahern, MD

This is a 17 year old female who presents to the ER with a chief complaint of abdominal pain and vaginal discharge. She noticed a yellow-green vaginal discharge approximately three days prior, with cramping. She is experiencing worsening lower abdominal pain beginning yesterday, which is now 5/10 in intensity. She is having some nausea, but no vomiting or changes in bowel movements. LMP was two weeks ago. She recently began dating a college senior whom she met at a university party 4 months ago. She admits to having unprotected sex with him three times in the last month. She also recalls that he had some burning with urination a few days ago. Her past surgical history is significant for a previous ITOP (intentional termination of pregnancy) at age 16. Otherwise, she does not have any medical problems or take any medications.

Exam: VS T 38.7, P 95, R 20, BP 130/86. HEENT, neck, cardiac, and lung exams are unremarkable. Abdominal exam is significant for mild right upper quadrant tenderness and moderately severe lower abdominal (pelvic region) tenderness. Pelvic exam reveals mucopurulent vaginal discharge, right adnexal tenderness, and severe cervical motion tenderness. A urine sample tests negative for beta-hCG and it is sent for a DNA amplification assay for Chlamydia. A cervical swab and gram stain of the vaginal discharge demonstrates many WBCs and multiple intracellular gram negative cocci. Transvaginal ultrasound shows thick, fluid filled fallopian tubes with free fluid in the cul-de-sac. She is hospitalized and treated with IV cefotetan and oral doxycycline.

Sexually transmitted infections (STI), also known as sexually transmitted diseases (STDs), are a significant cause of morbidity and mortality in the world, particularly in adolescents who are prone to adopting high-risk behaviors. Epidemiologic studies show teenagers initiating sexual activity earlier than before, with nearly half of all adolescents sexually active by age 17 (1). Adolescents who initiate sexual intercourse at younger ages are more likely to have multiple partners, thus increasing their chances of becoming infected. Experimentation with alcohol and drugs may compromise an adolescent's ability to make sound judgments about sex and contraception. Those particularly at risk for STIs include homosexual males, street youth, incarcerated adolescents, teens engaged in prostitution, and injection drug users (1,2). Adolescents, in particular, face obstacles in utilizing health care services. Embarrassment about discussing sexuality with health care providers may discourage adolescents from seeking care. Limited financial independence and transportation barriers for teenagers may also reduce access to health care. Consequently, the incidence of STIs among adolescents is increasing with 3 million American teenagers infected each year (3). These numbers are difficult to estimate accurately, but suffice it to say, that STIs are common and a major health care concern.

Primary prevention of STIs is the chief goal for health care providers, with emphasis on safe sexual practices or abstinence. When condoms are used correctly and consistently, they are highly effective in preventing spread of STIs. However, condoms may not provide complete protection against human papillomavirus, herpesvirus type 2, and C. trachomatis (3). As younger adolescents engage in high-risk sexual activity, early recognition of the various clinical syndromes may further decrease the long-term health consequences associated with STIs. The number of identified STIs has increased to more than 20 pathogens, 8 of which have been newly recognized since 1980 (1,3). Fortunately, there is a limited set of clinical presentations. Genital ulcers occur with both Treponema pallidum (syphilis) and herpes simplex type 2 (genital herpes), as well as the rarer Haemophilus ducreyi (chancroid) and Calymmatobacterium granulomatis (granuloma inguinale). Certain serotypes of human papillomavirus cause nonulcerative genital warts (condyloma acuminata). Pubic lice, caused by Phthirus pubis, manifest as pruritus and may demonstrate eggs at the base of pubic hairs. Vaginal discharge may be noted with Candida albicans (vulvovaginal candidiasis, white cottage cheese discharge) and Gardnerella vaginalis (bacterial vaginosis, fishy foul odor), which are not considered to be sexually transmitted, but also with Trichomonas vaginalis (trichomoniasis), which is. Urethritis in the male and cervicitis or PID in the female can result from infection with Neisseria gonorrhoeae (gonorrhea) and/or Chlamydia trachomatis (chlamydia) (2). The Centers for Disease Control and Prevention (CDC) also require physicians in every state to report syphilis, gonorrhea, chlamydia, and AIDS.

STIs with serious long-term sequelae include: 1) human papillomavirus (HPV) infection, which leads to an increased prevalence of cervical neoplasia in adolescents and cervical cancer in adults; 2) chlamydia and 3) gonorrhea, which are the leading causes of pelvic inflammatory disease, tubal infertility, and infant pneumonia; 4) herpes simplex, which can result in recurrent painful episodes and subsequent neonatal infection; and 5) syphilis, which can be passed to offspring, resulting in congenital syphilis (1).

Of note, STIs diagnosed in preadolescent children (beyond the neonatal period) suggests sexual abuse. Acquisition of HIV, gonorrhea, chlamydia, and syphilis in the post-neonatal period is almost indisputably indicative of sexual contact (2). Other diseases are not as clearly connected, but sexual abuse should be suspected in infants and prepubertal children with trichomoniasis, genital herpes, and condyloma acuminata. Findings should be confirmed, and evidence should be reported to the appropriate community agency for child abuse or neglect (2).

Human Papillomavirus (HPV)

Papillomaviruses are members of the papovavirus family. They are non-enveloped, have an icosahedral virion capsid, and contain a double-stranded DNA genome. It is postulated that the virus gains entry into the body through microscopic abrasions of the surface epithelium, leading to transformation of basal cells. The natural history of HPV infection ranges from spontaneous regression to persistent infection and/or neoplastic progression (4). HPV transmission is very common, perhaps the most common sexually transmitted infection among young, sexually active people in the United States (5,6). There are multiple subtypes, e.g., subtypes 6 and 11 cause 90% of genital warts (condyloma acuminata). Nearly all cases of cervical cancer or squamous intraepithelial neoplasia are associated with HPV, particularly subtypes 16, 18, 31, 33, and 35 (5).

HPV produces subclinical infection in 70% of cases and overt infection in 30% (4). Condyloma acuminata or genital warts are the most widely recognized manifestation of HPV infection, often described as cauliflower-like in gross appearance. The most common sites of these lesions are the posterior fourchette, adjacent labia and perineum, introitus, vagina, and cervix (4). Depending on the size and location, genital warts can be painful, friable, and pruritic (2). Conversely, cervical intraepithelial dysplasia is asymptomatic, but can be detected by a Pap smear.

Traditionally, the diagnosis of HPV in sexually active adolescents is made by visual inspection, often with colposcopy. Tissue infected with HPV often undergoes epithelial hyperplasia and has a shiny white appearance (acetowhitening) after being soaked with acetic acid (4). Biopsy of lesions can be sent for light microscopy or DNA subtyping (4). The use of DNA testing of vaginal swabs to detect HPV in high risk individuals is being evaluated in screening for cervical cancer (5). Cytology of cervical scrapings (Pap smear)

permits the detection of cervical neoplasia, widely believed to be triggered by certain serotypes of HPV. However, screening with the Pap smear results in a significant number of false negatives. For patients who have a Pap test indicative of low-grade SIL (squamous intraepithelial lesion) or ASCUS (atypical squamous cells of undetermined significance), follow-up with repeat Pap tests every 6 months for 2 years may be acceptable without colposcopy. If repeat tests show persistent abnormalities or if compliance is an issue, colposcopy and directed biopsy may be indicated (2).

HPV spontaneously resolves in many patients (4). Therefore, the goal of therapy should target symptomatic manifestations. In general, there are patient-applied and provider-applied modalities of treatment. Patients may apply podofilox solution or gel or imiquimod cream to visible lesions. Alternatively, condyloma can be managed by topical application of trichloroacetic acid (TCA), cryotherapy, or podophyllin by a health professional. Surgical removal is indicated if topical therapy fails, for extensive lesions, or for a young patient who requires general anesthesia (4). No clear evidence exists to determine whether treatment of genital warts will reduce transmission (2). All adolescent women with anogenital warts should have a Pap smear, with follow-up recommended every 6 months (4).

Chlamydia

C. trachomatis is an obligate intracellular organism that does not gram stain. Infected cells contain cytoplasmic Giemsa stain-positive inclusions. C. trachomatis has at least 15 different immunotypes. Types D through K are responsible for the majority of genital infections, including mucopurulent cervicitis, urethritis, proctitis, epididymitis, salpingitis, endometritis, and perihepatitis. Types L1 through L3 are associated with lymphogranuloma venereum. Ocular trachoma (a chronic follicular keratoconjunctivitis which is a common cause of acquired blindness in other countries), is caused by types A-C (4).

Chlamydia is one of the most prevalent bacterial STIs in the United States, accounting for an estimated 3-4 million new cases each year, more frequently diagnosed in adolescents than gonorrhea (4,6). Up to 85% of women and 40% of men who are infected with chlamydia are asymptomatic (3). Yet if recognition and treatment are inadequate, pelvic inflammatory disease (PID) will develop in 20-40% of women with chlamydia (3). As with some other inflammatory STIs, transmission of HIV can be facilitated by chlamydial infection.

C. trachomatis infects the endocervix most often, in addition to the urethra, anus, Bartholin's glands, and fallopian tubes. The most common signs of C. trachomatis cervicitis include yellow/green mucopurulent endocervical discharge and an edematous, friable cervix (hypertrophic ectropion) which may present with abnormal vaginal bleeding (4). A wet-mount or gram stain of the discharge usually reveals greater than 30 polymorphonucleocytes (PMN) per high power field and absence of gonococci (although the presence of gonorrhea does not rule out concurrent chlamydia infection). Chlamydia urethritis should be suspected in sexually active females with prolonged dysuria (greater than 7-10 days) unresponsive to traditional treatment for bacterial cystitis (J). In males, chlamydial infection can also cause non-gonococcal urethritis, acute epididymitis, or proctitis. Chlamydial pharyngitis or conjunctivitis can occur in both males and females.

Chlamydia is diagnosed by cervical culture, antigen detection techniques (e.g., enzyme immunoassay, direct fluorescent antibody test), or DNA based testing (e.g., nucleic acid hybridization probe, DNA amplification). Although cervical culture for chlamydia is costly and technically difficult (it requires cell media culture because it is an obligate intracellular organism similar to a virus), it remains the gold standard and the procedure against which new diagnostic methods are measured (4). Tests for detecting chlamydial antigen have a sensitivity of approximately 60-80% (7). DNA amplification tests are the most recent development, including polymerase chain reaction (PCR) and ligase chain reaction (LCR). Both PCR and LCR are highly sensitive and specific with endocervical, urethral, and urine specimens from men and women (5,7,8). The U.S. Preventive Services Task Force strongly recommends that "all sexually active women 25 years and younger and other asymptomatic women at increased risk of infection" be routinely screened for chlamydial infection. This was based on evidence that screening women at risk reduces the incidence of PID (9). Urine-based home testing for chlamydia is expected to increase availability of low-cost screening (7). Shafer et al. reported that urine-based LCR screening, rather than routine pelvic examinations, was the most cost-effective strategy in asymptomatic sexually active adolescent girls because of greater acceptance of urine testing (10).

A single dose of azithromycin (1 gram) has been shown to be equally effective in treating chlamydia but at a modestly greater cost than a 7-day course of doxycycline (100 mg BID) (5). Azithromycin is an alternative regimen for pregnant women or patients for whom compliance is an issue (2). Either regimen is recommended for children older than 8 years of age (2). Patients should be encouraged to refer their sexual partners for diagnosis and treatment to prevent reinfection (2). A test of cure should be performed approximately 6 weeks after completion of treatment (7).

Pelvic inflammatory disease (PID) results from ascension of infection from the endocervix to the upper genital tract (e.g., endometritis, salpingitis). This is suggested by the triad of: 1) abdominal pain, 2) uterine/adnexal tenderness on bimanual exam, and 3) cervical motion tenderness. Symptoms often begin a few days after menstruation. Empiric treatment should be initiated if no other cause for these symptoms can be identified. Other findings that support the diagnosis (2) include: fever, abnormal cervical/vaginal mucopurulent discharge, presence of WBCs on saline microscopy of vaginal secretions, elevated acute phase reactants (WBC, ESR, CRP), laboratory documentation of cervical infection with N. gonorrhea or C. trachomatis.

If necessary, the diagnosis can be confirmed by: a) endometrial biopsy showing endometritis; b) transvaginal sonography demonstrating fluid-filled fallopian tubes, free pelvic fluid, or a tubo-ovarian complex (abscess); or c) laparoscopy. Differential diagnosis may include acute appendicitis, ectopic pregnancy, ruptured corpus luteum cyst with hemorrhage, diverticulitis, septic abortion, adnexal torsion, leiomyoma degeneration, endometriosis, or ulcerative colitis.

Criteria for hospitalization (2) include: surgical emergencies (e.g., appendicitis) that cannot be ruled out, pregnancy, failure to respond to outpatient treatment, suspected noncompliance or intolerance to outpatient treatment, nulligravid status, severe illness (including nausea, vomiting, or high fever), suspected tubo-ovarian or other pelvic abscess. Aggressive antibiotic usage for at least 24 hours is warranted as PID accounts for 15% of female infertility and increases the risk of ectopic pregnancy and chronic pelvic pain (3). A common regimen includes cefotetan (2 g IV every 12 hours) or cefoxitin (2 g IV every 6 hours); plus doxycycline (100 mg PO or IV every 12 hours) (2). A combination of clindamycin, gentamicin, and doxycycline is an alternative regimen (2). Mild PID is often treated as an outpatient with single dose IM/IV ceftriaxone and PO doxycycline or azithromycin.

Gonorrhea

Neisseria gonorrhoeae, a gram-negative intracellular diplococcus, is a commonly found co-infection with chlamydia. Gonorrhea infects the urethra, Bartholin glands, Skene's glands, cervix, epididymis, prostate, anus, pharynx, and conjunctiva. Hematogenous dissemination to joints, skin, meninges, and endocardium may occur (4).

Gonorrhea is one of the most commonly reported bacterial STIs in adolescents (chlamydia is more common, but chlamydia is not a true bacteria). Estimates of 600,000 new infections occur in the U.S. each year in all age groups (2). Overall, the rates of diagnosis are declining, but still remain high among adolescents aged 15 to19 of all racial and ethnic groups (2). In addition to its role in pelvic inflammatory disease, gonorrhea infection also facilitates HIV transmission (2).

Males infected with gonorrhea often present with symptomatic urethritis within 2 to 5 days of exposure, with urethral discharge or dysuria (7). Other manifestations in the male include epididymitis, lymphangitis, or prostatitis. In young women, the endocervical canal and urethra are the primary sites of infection. However, like chlamydia, they are often asymptomatic. If left untreated, it can lead to PID or disseminated infection. Only 10-20% of infected females are likely to present with increased vaginal discharge, dyspareunia, abnormal vaginal bleeding, or signs and symptoms of ascending infection (4). Physical exam may reveal mucopurulent discharge, erythema of the ectropion, and a friable cervix. Ten to 20% of females with acute gonococcal infection will develop PID (7). Individuals with gonococcal salpingitis, as compared to non-gonococcal salpingitis, are more likely to appear more ill, have a fever, and present within 3 days of symptom onset (7). Peritonitis and perihepatitis (right upper quadrant pain and elevated liver enzymes) characterize the Fitz-Hugh-Curtis syndrome, commonly associated with gonorrhea-caused PID.

Disseminated gonococcal infection (DGI) occurs in 0.5 % to 3% of untreated patients (4). DGI is often manifested by polyarticular septic arthritis (joint pain, swelling, tenderness) and skin lesions. Most commonly, the wrist, ankle, knee, and metacarpophalangeal (MCP) joints are involved in an asymmetric and/or migrating fashion. Skin lesions present as a tender, necrotic pustule on an erythematous base over the distal extremities (7).

Gonorrhea can be confirmed by culture, immunochemical, or DNA testing. Gram stain of cervical or urethral discharge generally reveals gram-negative diplococci within or closely associated with PMN leukocytes. Gram stain has a high sensitivity and specificity for males, but the test has a poor sensitivity for females at 30% to 60% because of vaginal bacterial contamination (2,4). Culture is the gold-standard, using antibiotic-containing selective media (e.g., Thayer-Martin medium), which has sensitivities from 80 to 90% (7); however, gonorrhea is fastidious, requiring a special transport and incubation conditions. The non-amplified DNA probe is reported to have sensitivities and specificity up to 97% and 99%, respectively (7). The LCR amplification assay is found to have sensitivities of 95% (7). A test of cure should be performed at approximately 6 weeks after completion of treatment (7).

As gonorrhea has become increasingly resistant to penicillin, quinolone-resistant N. gonorrhoeae (QRNG) is becoming more common in parts of Asia and the Pacific, including Hawaii (2). The CDC's 2002 STD Treatment Guidelines recommend that quinolones no longer be used to treat gonorrhea for infections acquired in Hawaii and California (2). The CDC recommends second- and third-generation cephalosporins such as cefixime (400 mg PO, single dose) or ceftriaxone (125 mg IM, single dose). Partners of patients suspected of having gonorrhea should also be treated to prevent re-infection.

Because patients with gonorrhea are often concomitantly infected with chlamydia, many physicians treat women with mucopurulent cervicitis with an additional regimen of doxycycline or azithromycin to prevent sequelae such as PID. The best prevention of PID is prevention of lower genital tract infection by C. trachomatis and N. gonorrhea (4).

Genital Herpes

Herpes simplex virus (HSV) is a member of the herpesvirus family which includes the Epstein-Barr virus, varicella-zoster virus, and cytomegalovirus. HSV-2 is responsible for most of the genital infections. HSV-1 primarily causes oral infections, but it has been isolated in 10-25% of genital lesions with first-episode genital herpes. HSV infections are transmitted by viral shedding through a peripheral site, mucosal surface, or in genital or oral secretions. Between recurring episodes, HSV virus ascends peripheral sensory nerves and enters nerve root ganglia (7), persisting in a dormant state. The frequency of recurrence of genital lesions after a symptomatic first-episode of genital herpes is high for HSV-2 and less for HSV-1 (2).

At least 50 million people in the U.S. have genital HSV infection (2). In a major study published in the New England Journal of Medicine, 22% of Americans over 12 years old have positive test results for antibodies against HSV-2, the major cause of genital herpes (3,11). This represents a 30% overall increase in the prevalence of HSV-2 since the late 1970s. Furthermore, individuals with HSV-2 are more susceptible to contracting HIV from a HIV-positive partner (3). Most individuals with genital herpes have not been diagnosed (2). Therefore, the disease is often transmitted from asymptomatic individuals, even those who have never had any symptoms (3).

Genital herpes is a life-long, recurring infection. Yet, symptoms vary greatly, both on an individual basis as well as between episodes for the same individual. The primary episode of herpes infection may present with vulvar pain, dysuria, and occasionally urinary retention (4). Systemic symptoms are common such as flu-like symptoms, with malaise, headache, fever, and body aches. Severe complications such as herpes meningitis/encephalitis are rare (4), except in neonates when the risk is much higher.

The most frequent presenting sign of infection is an exquisitely painful pustular, vesicular or ulcerative lesion that spreads rapidly over the external genitalia. In females, lesions may be hidden intravaginally, and patients may not even be aware of its existence. HSV cervicitis occurs in 70-90% of women with their first episode of HSV infection (7). Examination may reveal cervical erythema and friability. Ulcerative lesions may last up to two weeks until crusting or re-epithelialization occurs.

Adolescents should be counseled that genital herpes transmission can occur even when they are asymptomatic. Asymptomatic individuals may shed the virus at the same rate as symptomatic individuals. Recurring infections are generally localized to the genitalia with fewer systemic symptoms.

Diagnosis of herpes infection is best confirmed by viral culture of the lesions (1). However, the sensitivity of the culture declines within a few days of onset as lesions begin to crust and heal. HSV antigen detection tests do not distinguish between HSV-1 and HSV-2 (2). Cytologic detection via the Tzanck smear of the ulcer discharge may demonstrate multinucleated giant cells, though the test itself is not highly sensitive and also does not distinguish between viral types.

During the first several weeks of a primary infection, both type-specific and nonspecific antibodies develop. Type-specific antibodies to HSV-2 are virtually indicative of sexual transmission. Serologic tests may show that the current infection is primary, suggested by a rise in IgM antibodies followed by a rise in IgG antibodies. Because false-negative HSV cultures are common, HSV-2 type-specific serologic tests are useful in determining a diagnosis of genital herpes (2). However, serologic screening for genital herpes in the general population is not indicated (2).

Systemic antiviral drugs partially control the symptoms of herpes episodes for both primary and recurrent disease. Antivirals such as acyclovir, valacyclovir, and famciclovir have demonstrated decreased shedding when taken regularly. However, these medications do not permit a lasting effect. Once the treatment stops, the disease resumes typical pre-treatment frequency and severity of recurrences (2).

Patients with first-episode herpes may eventually develop severe or prolonged symptoms, so treatment is indicated. Recommended regimens include acyclovir, famciclovir, or valacyclovir for 7 to 10 days (2). Treatment for recurrent disease may be administered

episodically or continuously as suppressive therapy. Episodic therapy requires initiation within 1 day of lesion onset. Suppressive therapy reduces the frequency of genital herpes recurrences by 70 to 80% for patients normally with 6 or more recurrences a year (2). Thus, quality of life is often improved in these patients. Suppressive therapy reduces subclinical viral shedding, but does not eliminate the risk.

Counseling is also critical to the management of herpes, to help patients cope and to prevent sexual and perinatal transmission. Patients should be informed that transmission of HSV can occur during asymptomatic periods. Condoms may help reduce the risk, especially when infected areas are covered (2).

Syphilis

Syphilis is caused by Treponema pallidum (subspecies pallidum), a spirochete that cannot be seen by light microscopy. It is identified by darkfield microscopy examination by its characteristic corkscrew motility (4). T. pallidum is transmitted via breaks in the skin or mucus membranes, perinatal transmission, or rarely blood transfusion.

Though syphilitic disease has been significantly curtailed by its sensitivity to penicillin, the incidence has been rising since the 1980s (4). In addition, the rate in adolescent females has increased since the 1990s (4). This is of particular concern considering the high teen pregnancy rates in today's population. Syphilis may be passed to the fetus, resulting in congenital syphilis, which affects brain development and growth. Furthermore, genital ulcer disease increases the risk of HIV transmission (4).

Syphilitic disease is divided into three symptomatic stages: primary, secondary and tertiary syphilis. Primary syphilis presents as a chancre, approximately 1 to 3 weeks after inoculation. A chancre is a highly infectious, painless, ulcerative lesion with well-defined raised borders and an indurated base. It contains large numbers of spirochetes that cannot be visualized by gram stain, but can be seen by darkfield microscopy (4).

Secondary syphilis develops between 4 and 10 weeks after the primary chancre appears. Infected individuals may have systemic complaints such as low-grade fever, malaise, myalgia, arthralgia, and generalized adenopathy. A nonpruritic maculopapular rash may develop on the trunk or extremities, especially the palms and soles. Other anogenital lesions include condyloma lata, which are highly infectious, flat, beefy-like lesions with a broad base (4).

Latent syphilis describes the period after which these systemic symptoms resolve. This period is further divided into early and late phases. Early latent syphilis is defined as less than a year, whereas late latent is longer than 1 year (4). Infectivity is thought to be significantly decreased during the late latent phase, and prolonged antibiotic therapy may be required to adequately manage the slower replicating treponemes (2).

Tertiary syphilis is rarely encountered in adolescents, but serious complications may occur in approximately one-third of patients who enter late latency even though they may no longer be contagious (4). Tertiary syphilis may present with cardiovascular, gummatous and/or neurologic manifestations. Common cardiovascular manifestations of tertiary syphilis include thoracic aortic aneurysm, aortic insufficiency, and coronary ostial occlusion. Chronic inflammatory lesions of tertiary syphilis, called gummas, affect the skin, subcutaneous tissue, and bones. Neurosyphilis, which can occur during any stage, usually includes tabes dorsalis, affecting the spinal tracts controlling proprioception and vibratory sense, and is associated with the Argyll-Robertson pupil (accommodation reflex is intact, but there is no response to direct light).

Diagnosis of early syphilis is done clinically, serologically, or most accurately, by direct visualization on darkfield microscopy. T. pallidum is best visualized by darkfield microscopy of the lesion exudate. Alternatively, direct fluorescent antibody tests can also be used to visualize the treponemes in ulcer smears (2).

During primary and secondary stages, nonspecific serologic tests for non-treponemal (cardiolipin) antibody such as the RPR (rapid plasma reagin) or VDRL (Venereal Disease Research Laboratory) are used as screening tests (RPR has now largely replaced the VDRL test for serum, but not for CSF). Positive results are confirmed with more specific antibody tests including the fluorescent treponemal antibody absorption (FTA-Abs) test, the microhemagglutination-T. pallidum test (MHA-TP), or the hemagglutination treponemal test for syphilis (HATTS). False positive results may occur in patients with various medical problems (e.g., false positive VDRL/RPR occurs with systemic lupus). The differential diagnosis of a positive specific treponemal antibody test includes other treponemal diseases such as pinta, yaws, and endemic syphilis. Yaws is an infection with Treponema pallidum pertenue (T. pallidum, subspecies pertenue), while syphilis is an infection with Treponema pallidum pallidum (T. pallidum, subspecies pallidum). Thus, even the MHA-TP (a specific test for T. pallidum) can be positive in yaws, making the definitive diagnosis of syphilis in yaws endemic areas (e.g., Micronesia), very difficult. According to the CDC, all patients diagnosed with syphilis should be tested for HIV (2).

Diagnosis of neurosyphilis may be difficult as the VDRL test for CSF is high in specificity but low in sensitivity (more false-negatives). In other words, a reactive test would indicate syphilis, but the test may not be reactive in a mildly affected person. Some specialists recommend performing an FTA-Abs test for CSF which is higher in sensitivity (2).

Penicillin is the treatment of choice for syphilis, even for pregnant women (2). Standard treatment for primary, secondary, and early latent syphilis includes parenteral (longer acting) benzathine penicillin G. Late latent and tertiary syphilis requires a longer course of therapy. A test for cure (with the same serologic test) should be performed 3, 6, and 12 months after treatment with a four-fold decline in titer considered to be clinically significant (e.g., from 1:16 to 1:4) (4). Furthermore, patients should be cautioned about the Jarisch-Herxheimer reaction after treatment for early syphilis, due to the sudden rupture of cells containing T. pallidum. Patients may experience self-limiting symptoms such as fever, myalgias, chills, headache, and postural hypotension for the first 24 hours. Management consists of hydration and NSAIDs (4). Identification of sexual partners at risk for contracting syphilis should be directed for serologic testing and/or treatment.

Questions

1. What is the triad of symptoms that suggests pelvic inflammatory disease?

2. What is likely to be the most common STI in adolescents in the United States?

3. Why are adolescents more susceptible to acquiring STIs than adults?

4. What treatment regimen would not be appropriate for an adolescent in Hawaii with confirmed gonococcal cervicitis?
    a. doxycycline 100mg PO BID x 7 days
    b. ceftriaxone 125mg IM x 1 day
    c. cefixime 400mg PO x 1 day; plus azithromycin 1g PO x 1 day
    d. ciprofloxacin 500mg PO x 1 day

5. True/False: Suppressive therapy for genital herpes with acyclovir effectively eliminates viral shedding.

6. Which test is more specific for syphilis? RPR, VDRL, or FTA-Abs (fluorescent treponemal antibody absorption)?

7. What are the criteria for hospitalization of a patient with suspected pelvic inflammatory disease?

Answers to questions

1. Abdominal pain, adnexal tenderness on bimanual exam, and cervical motion tenderness.

2. Human papillomavirus (HPV) is estimated to be the most common STI among young, sexually active people in the United States, though many HPV infections are asymptomatic. According to the CDC, an estimated 5.5 million people of all ages contract HPV each year in the United States. On the other hand, chlamydia is the most commonly reported infectious disease in the United States.

3. Adolescents adopt high risk behaviors including early onset of sexual activity, multiple sexual partners, or drug/alcohol use which may impair judgment. Adolescents generally are less able to access health care due to embarrassment about their condition, financial constraints, or transportation barriers.

4. d. Quinolones are no longer recommended for the treatment of gonorrhea in Hawaii or infections acquired in Asia. In 2000, the CDC collected 5,461 isolates for its Gonococcal Isolate Surveillance Project (GISP). 14.3% of the GISP isolates in Hawaii were found to be quinolone-resistant N. Gonorrhoeae (QRNG), compared to 0.2% of samples collected within the continental United States and Alaska. Furthermore, since QRNG is becoming more common in West Coast areas, the use of fluoroquinolones in California is probably inadvisable.

5. False. Acyclovir and other antivirals only reduce viral shedding, but they do not eliminate the risk of transmission. Suppressive therapy reduces the frequency of symptomatic genital herpes recurrences by 70% to 80% for patients with 6 or more recurrences a year.

6. FTA-Abs is more specific, but it is still not totally diagnostic of syphilis since patients with yaws will still have a positive FTA-Abs. Other false positive results of FTA-Abs may occur with patients with various medical problems. The differential diagnosis of a positive treponemal antibody test includes other treponemal diseases such as pinta, yaws, and endemic syphilis.

7. Criteria for hospitalization include: surgical emergencies (e.g., appendicitis) that cannot be excluded, pregnancy, failure to respond to outpatient treatment, suspected noncompliance or intolerance to outpatient treatment, nulligravid status, severe illness (including nausea, vomiting, or high fever), suspected tubo-ovarian or other pelvic abscess.

Chapter VI.22. Common Viral Exanthems
Kalamaoka'aina Kil Soon Niheu, MD

This is a 5 year old male who is referred to your clinic by the school nurse for suspicion of child abuse. The report states that the child's face appears to have been "slapped" repeatedly. From the chart, you note that the patient has no history of trauma or suspicious incidents. He has been seen regularly for well child exams and is up to date on immunizations. The distraught parent states that there have been no recent changes among the family and that the patient has been doing well, other than a moderate tactile fever for two days, alleviated by acetaminophen.

Exam: VS T 38.2, P 95, R 26, BP 110/68, oxygen saturation 99%. Weight and height are at the 50th percentile with normal progress on his growth curve. He is alert, and cooperative in no distress. HEENT exam is significant for slight erythema of his oropharynx. His neck is supple without lymphadenopathy. Heart and lung exams are normal. Examination of his skin is only significant for some slight edema and pinkish red color of his cheeks ("slapped cheek" appearance). There are no bruises or other rashes detected. Exam of his extremities are negative for any signs of injury. Neurologic examination does not reveal any abnormalities.

Following your examination, further questioning reveals an ill cousin with a "rash." Over the next several days, the malar erythema begins to fade and a faint pink rash appear on his trunk and extensor surfaces of his upper extremities. The truncal rash becomes confluent, creating a lacy appearance. Both the fever and rash disappear without any further problems.

An exanthem, originating from the Latin anthos, meaning flower, is a skin eruption occurring as a symptom of an acute infection (1). More than 50 agents (viral, bacterial, or rickettsial) that cause exanthems in children have been identified (2). Therefore, it is not surprising that the febrile child presenting with a "rash" is a diagnostic challenge to many physicians. The goal of this chapter is to provide a systematic framework to approach patients similar to the case outlined above. An accurate diagnosis is possible when close attention is paid to the pattern of patient age, immunization status, prodromal symptoms, character of fever (high-grade, prolonged, chronological relationship to rash, etc), associated manifestations, and the characteristic exanthem. The natural history of each disease is also unique, therefore an attempt has been made to organize the clinical manifestations in chronological order. Several diagnostic lab studies are available, such as specific serologies and rising titers.

Due to the wide differential diagnosis, the scope of this chapter will be limited to common viral exanthems, namely measles, rubella, hand-foot-mouth disease, erythema infectiosum, roseola infantum, and varicella.

Measles (rubeola) is caused by a paramyxovirus which is spread by respiratory droplets produced by sneezing or coughing. Infected persons are contagious for several days before the onset of rash and up to 5 days after the lesions appear. It is highly contagious, resulting in 90-100% transmission among those who are susceptible (2). Prior to the use of the measles vaccine (one component of the MMR), the peak age of incidence was 5-10 years. In underdeveloped countries, up to 45% of cases occur before the age of 9 months. Since widespread immunization began in 1963, measles occurrence is rare. Current small outbreaks in the U.S. occur in unimmunized preschool children and school-aged persons immunized at an early age (who often have not received a second MMR). In Hawaii, most index cases occur in Asian tourists who are not immunized. In the 1980's, there were several outbreaks. The revised recommendation (requirement) for two doses of MMR vaccine prior to school entry has resulted in less than 70 cases of measles in 1998 and 1999 in the U.S. (2). Worldwide, measles is endemic (3).

The measles incubation period is 8-15 days. Measles is rare among immunized patients, especially those who have had two MMR doses. Susceptible individuals exist since some parents have chosen to refuse MMR vaccine for their children. Classically, measles is preceded by the three C's: a hacking cough, coryza (nasal rhinorrhea and congestion), and conjunctivitis, plus photophobia, malaise, and a high fever persisting for several days. The enanthem (mucus membrane eruption) of measles is pathognomonic. Part of the enanthem is called Koplik's spots which appear on or after the second day of fever. The lips, tongue and oral mucosa are hyperemic (red). The Koplik's spots can be described as white spots over the red buccal mucosa (so called, grains of sand in a sea of red) (3). Although pathognomonic, their absence does not exclude measles since this finding is transient, disappearing within 48 hours after onset of the rash (2). The exanthem classically appears on the fourth day of fever. The rash is called "morbilliform" (which means measles-like). This can best be described as non-elevated red spots of varying sizes with a few areas of coalescence. They spread centrifugally and inferiorly to involve the face, trunk, and extremities. Lesions may become confluent, especially on the face, then gradually fade in order of appearance with subsequent residual yellow-tan stain. As the exanthem progresses, systemic symptoms subside (3). There is generalized lymphadenopathy. Otherwise, the exam is unremarkable.

Differential diagnosis includes drug reactions (e.g., Stevens Johnson syndrome), Kawasaki disease, other viral exanthems, secondary syphilis, or scarlet fever (3).

Prevention through prophylactic immunization is the primary approach to measles in the United States. Treatment is otherwise symptomatic (3). In areas of vitamin A deficiency, the World Health Organization (WHO) recommends 200,000 IU of oral vitamin A in three doses over the course of the illness. Immunoglobulin (gamma globulin) is recommended for household contacts, particularly infants less than one year, pregnant patients, and the immunocompromised (2).

Measles is a self-limited infection in most patients. The mortality rate is 0.3% in the United States but ranges from 1-10% in developing countries. Complications are more common in malnourished children, and in those who are immunocompromised. Acute complications include pneumonia (due to measles or a secondary bacterial infection, such as Staph aureus), and measles encephalitis (1 in 800-1000). Subacute sclerosing panencephalitis is a chronic complication (3).

Measles also presents is two other fashions: modified and atypical measles. Modified measles occurs in partially immune individuals. It is characterized by a shorter prodrome and a less severe rash. Atypical measles presents with abrupt onset of high fever, myalgias, and cough. A papular or papulovesicular rash in the extremities begins 2 to 5 days later and spreads centrally. The rash is frequently hemorrhagic and a lobar pneumonia may be present (2).

Rubella, also known as German measles or 3-day measles, is caused by the rubella virus. Transmission is via inhalation of aerosolized respiratory droplets and the period of infectivity is from the end of the incubation period to the disappearance of the rash (3).

Before widespread immunization, this disease was found in children younger than 15 years. Currently it occurs primarily in young adults in hospitals, prisons, colleges, and prenatal clinics. The incidence has decreased by 99% since immunization began in 1969. Rubella is endemic worldwide causing epidemics every 6 to 9 years during the spring.

The incubation period lasts from 14-21 days (2). In 60-90% of adolescents and young adults the exanthem is preceded by anorexia, malaise, conjunctivitis, headache, low-grade fever, mild upper respiratory symptoms, or Forchheimer's sign (petechiae on the soft palate) (3).

The exanthem is characterized by pink macules or papules which appear initially on the forehead, spreading inferiorly to the face, trunk, and extremities in the first day. By the second day, the facial exanthem fades. Truncal lesions may become confluent, creating a scarlatiniform eruption. By the third day the exanthem fades completely (3). On physical examination, lymph nodes are enlarged, particularly postauricular, suboccipital, and posterior cervical, and possibly tender during prodrome. Splenomegaly may also be present (2,3). The differential includes measles, rubella, scarlet fever, erythema subitum, enteroviral infection, and drug reactions.

Rubella is preventable by immunization. If antirubella antibody titers are negative in young women, rubella immunization should be given. In adolescents, pregnancy should be ruled out due to the possible adverse effects of the vaccine on the fetus. Otherwise treatment is symptomatic (2).

In most cases rubella is a mild, self-limiting infection. However, when rubella occurs in the first trimester of pregnancy, infection can be passed transplacentally to the fetus. Of all mothers infected during pregnancy, approximately 50% of fetuses will have manifestations of congenital rubella syndrome, including congenital heart defects, cataracts, microphthalmia, deafness, microcephaly, and hydrocephalus (2,3).

Hand-foot-mouth disease (HFMD) is caused by coxsackie virus. The primary strain is A16 but sporadic cases have been reported with coxsackie viruses A4-7, A9, A10, B2, B5 and enterovirus 71. Highly contagious, it is transmitted from person to person by oral-oral or fecal-oral routes (3). Incubation is 3 to 6 days

The age of onset is usually in children younger than 10 years old, but may occur in young and middle-aged adults. Epidemic outbreaks occur every 3 years. In temperate climates, outbreaks occur during the summer. The prodrome is 12-24 hours of low-grade fever, malaise, and abdominal or respiratory symptoms. Oral mucosal lesions are macules or grayish vesicles (small, less than 0.5 cm circumscribed elevation containing fluid) that evolve to punched-out, painful ulcers that may result in refusal to eat in children. The cutaneous lesions appear on the palms or soles together or shortly after the oral lesions. The sides of the fingers, toes, and buttocks may also be involved. Pink to red macules or papules appear, 2-8 mm in diameter, in a characteristic linear arrangement. They quickly evolve to form vesicles with a clear, watery appearance or yellowish hue. Lesions on the palms and soles usually do not rupture, but other sites may with formation of erosions and crusts (3). The sudden onset of oral and distal extremity lesions is pathognomonic for HFMD. In the absence of an exanthem, the differential diagnosis includes herpes simplex virus, aphthous stomatitis, and herpangina.

Management is symptomatic treatment, including optional topical applications of various local anesthetics to reduce oral discomfort. A diet of vanilla ice cream is the easiest to tolerate. Most commonly, HFMD is a self-limited disease with resultant acquired immunity. A few cases have been prolonged or recurrent. Serious complications are rare, but coxsackie virus has been implicated in myocarditis, meningoencephalitis, aseptic meningitis, paralytic disease, and a systemic illness resembling rubeola. Infection acquired in the first trimester or pregnancy may result in spontaneous abortion. Cutaneous lesions heal without scarring (3).

Erythema infectiosum (EI), also known as Fifth disease, is caused by parvovirus B19. Transmission is via respiratory droplets, with attack rates among close contacts up to 50%. Incubation is 4-14 days. This disease typically affects children 3 to 12 years old but may also appear in non-immune adults. In 20-60% of children, a prodrome of fever, malaise, headache, and coryza appears two days before the rash. Headache, sore throat, fever, myalgias, nausea, diarrhea, conjunctivitis, and cough may coincide with the rash. Pruritus is variably present. Arthralgias may occur but are uncommon. Presentation may differ considerably in adults.

The exanthem has a characteristic "slapped cheeks" appearance. An erythematous, edematous, confluent plaque on the malar face appears first which fades over 1 to 4 days. Erythematous macules and papules then appear on the extensor surfaces of extremities, trunk, and neck. These become confluent causing a lacy or reticulated appearance. Less commonly, lesions may be morbilliform (measles-like), circinate, annular, or rarely form pustules, vesicles, or palmoplantar desquamation. The eruption lasts 5 to 9 days but can characteristically recur for weeks to months, triggered by sunlight, exercise, temperature change, bathing, or emotional stress. Uncommonly, an enanthem with glossal and pharyngeal erythema and red macules on buccal and palatal mucosa may be present. The differential diagnosis includes measles, rubella, scarlet fever, roseola, enteroviral infection, Hemophilus influenza cellulitis, or drug reactions.

Management of EI is symptomatic and is usually a self-limited disease. In patients with hemoglobinopathies or RBC defects, human parvovirus may cause a transient RBC aplastic crisis, manifested by fatigue, pallor, and worsening anemia. Fetal infection may be complicated by fetal hydrops secondary to infection of erythroid precursors, hemolysis, severe anemia, tissue anoxia, and high-output failure. This is a serious concern in schools since children may commonly expose young women who are potentially pregnant (e.g., teachers) to this.

Roseola infantum (exanthem subitum, sixth disease) is caused by human herpes virus 6. This disease usually affects patients under the age of 3 years (2). The incubation period is 5-15 days. The prodrome consists of constant or intermittent high fever with malaise and irritability lasting 3 to 5 days. Occasionally, periorbital edema and febrile seizures are also associated. The exanthem appears after an abrupt defervescence (2). Erythematous to pink macules and papules appear, often arranged in rosettes, mainly involving the trunk with extension to the neck and proximal extremities lasting for 1 to 2 days (2). Treatment is symptomatic (4). Most infants are affected subclinically with two studies showing only 9-17% developing clinical roseola infantum (4). The course is generally benign, but febrile seizures, meningitis, and encephalitis are well-recognized complications. Several case reports have described fulminant hepatitis in primary HHV-6 infection (4).

Varicella (chicken pox) is caused by the varicella-zoster virus (VZV). The period of infectivity extends from the beginning of the prodromal illness through the time that the uncrusted lesions are present (2). Transmission is via respiratory secretions and the fluid produced by skin lesions, either airborne or through direct contact. In the United States pre-vaccine era, 90-95% of individuals acquired VZV infection in childhood with epidemics occurring in the winter and spring. Transmission to susceptible individuals occurred at a rate of 80-90% for household members. Casual contact (e.g. the classroom setting) is associated with attack rates of less than 30% (5).

The incubation period is 14 to 16 days and initial symptoms typically consist of fever, malaise, headache, anorexia, or abdominal pain (2). Temperature elevation is usually moderate but may be as high as 41 degrees C (106 degrees F) (5). The skin lesions appear 24 to 48 hours after the prodromal illness has begun. They begin as intensely pruritic, erythematous macules which rapidly evolve into vesicles containing serous fluid. The exanthem first appears on the face, scalp, or trunk and spreads peripherally. Over a 24 to 48 hour period, the

vesicles umbilicate, the fluid clouds, then transforms into crusts before finally resolving. Healed lesions may leave residual hypopigmentation lasting weeks, but scarring is uncommon. The number can vary from as few as 10 to as numerous as 1500 (5). Ulcerative lesions of the oropharynx and vagina commonly develop concurrently with the exanthem.

Prevention is currently available with the varicella vaccine. The vaccine has reduced the historical transmission rate from 87% to 7% (6). Acyclovir and varicella-zoster immune globulin have been effective in the prophylaxis and treatment of progressive disease, as described below. The course is generally benign, although in certain populations it may be associated with several complications. Perinatal transmission can cause life-threatening infection in the fetus. Progressive varicella is characterized by visceral organ involvement, coagulopathy, severe hemorrhage, and continued lesion development. Severe abdominal pain and the appearance of hemorrhagic vesicles in otherwise healthy adolescents, immunocompromised children, pregnant women, and the newborn may be a red flag for this serious complication (5).

Delivery within one week before or after the onset of maternal varicella frequently results in the newborn developing varicella, which may be severe and requires the administration of varicella-zoster immune globulin and acyclovir. Those who receive prompt treatment have an excellent prognosis. Mothers who had varicella between 8-20 weeks of pregnancy may demonstrate congenital varicella syndrome, characterized by interruption of organogenesis, in particular, the CNS, limbs, and eyes. A characteristic zig-zag scarring, often in a dermatomal distribution, can sometimes be seen (5).

Herpes zoster (also called shingles), due to reactivation of latent VZV, is uncommon in childhood, but more common in teens and adults. When it occurs, it originates in a single dermatomal pattern (e.g., T10), preceded by pain within the dermatome, followed by a dense collection of vesicles within the dermatome. Immunosuppressed children (those receiving immunosuppressive therapy for diseases like malignancy or with HIV) are at higher risk for developing herpes zoster in childhood. The lifetime risk for those with a history of varicella is 10%, with 75% of cases occurring after 45 years of age (5).

Other viruses which commonly cause exanthems include adenovirus (rash, conjunctivitis), echovirus ("Boston exanthem" similar to roseola), and Epstein-Barr virus (see chapter on Epstein-Bar virus). A common rash associated with amoxicillin use is probably related to a viral etiology. Commonly called an "amoxicillin rash", this is a non-allergic rash which occurs when amoxicillin is used in conjunction with some viruses (which are poorly defined). Later, when the viral infection is resolved, amoxicillin use does not result in a rash. This is similar to infectious mononucleosis which results in an impressive rash with amoxicillin/ampicillin use, but no recurrence of a rash with the same antibiotic use, once the viral infection has resolved. Patients are commonly labeled as amoxicillin allergic because of this phenomenon. Most amoxicillin rashes are non-urticarial which is the best (though not perfect) clue that this is probably not due to an allergic mechanism.

Questions

1. Name the type of exanthem depicted in the case described at the beginning of this chapter.
    a. Exanthem infectiosum
    b. Exanthem subitum
    c. Hand-foot-mouth disease
    d. Varicella
    e. Measles

2. Symptoms of congenital rubella include all of the following EXCEPT
    a. congenital heart defects
    b. hydrocephalus
    c. deafness
    d. microphthalmia
    e. zig-zag scarring

3. The mother of a patient comes in to your office stating that she has read terrible things about the vaccinations and doesn't want to give her child any. Which of the following statements is FALSE regarding vaccinations.
    a. The risk of acquiring chicken pox after exposure in the healthy, varicella immunized child is less than 10%.
    b. Vaccines have no adverse affects.
    c. Many vaccines need to be administered more than once.
    d. Rubella incidence has decreased 99% since 1969.
    e. Adverse effects of illnesses prevented by vaccines include death and damage to the central nervous system.

4. A 3 year old patient is seen for several days of fever and refusal to eat. Physical examination reveals a slightly dehydrated child with punched out, painful oral ulcers with associated small red macules on the palms and soles. What type of treatment would you recommend?
    a. Rest and fluids
    b. Rest, fluids, and amoxicillin
    c. Rest, fluids, acetaminophen, and vanilla ice cream
    d. Rest, fluids, acetaminophen, and acyclovir
    e. Rest, fluids, acetaminophen, and ciprofloxacin

5. Your patient has been diagnosed with varicella. Her aunt is pregnant and is not immune to chicken pox. When is the soonest that the aunt can visit the patient?
    a. Immediately, if she is his favorite aunt.
    b. When the lesions crust over.
    c. When the lesions are completely healed.
    d. Two months after the lesions heal.
    e. After the delivery of the fetus.

Chapter VI.23. Epstein-Barr Virus Infections
Jhoanna D. Mabutas, MD

An 18 year old freshman college student presents to the health center complaining of sore throat and fever for 3 days. She also states that she has been feeling tired for the past week. On physical exam, she is tired and subdued but not toxic in appearance with a temperature of 38 degrees C. Her tonsils are enlarged and erythematous. She has enlarged posterior cervical lymph nodes bilaterally, which are mildly tender to palpation. She has no supraclavicular, axillary, or inguinal lymphadenopathy. Her spleen tip is palpable below the left costal margin. A throat swab is obtained to test for group A streptococcal antigen, which is negative. Laboratory testing reveals a mild leukocytosis with the presence of atypical lymphocytes. A Monospot test is positive. She declines a course of corticosteroid therapy. Her symptoms improve in a week.

The Epstein-Barr virus (EBV) causes a broad spectrum of disease in humans with several clinical syndromes. Perhaps the best known is the one illustrated in the case above, the syndrome of infectious mononucleosis. This is an acute illness that results from primary infection with the virus. It is characterized by the triad of sore throat, fever, and lymphadenopathy. The name is derived from the mononuclear lymphocytosis with atypical appearing lymphocytes that accompany the illness.

The EBV virus is ubiquitous, infecting more than 95% of the world's population. Its clinical manifestations depend on the age when the infection is first acquired. Most infections occur during infancy or early childhood. These are often asymptomatic or indistinguishable from other childhood illnesses. Among affluent communities, however, primary infection may be delayed until adolescence or young adulthood. This is when the classic syndrome of infectious mononucleosis often manifests. Almost all adults over age forty have been infected with EBV and show serologic evidence of prior infection.

The EBV virus is a member of the herpes virus family. EBV is also known as human herpes virus-4 or HHV-4. Like other herpes viruses, it establishes a lifelong latent infection. The virus is transmitted in oral secretions and is acquired from close contact such as kissing or exchange of saliva between children. It initially infects epithelial cells in the oropharynx, where viral replication occurs and lysis of the epithelial cell results in release of new virions into the circulation. The virus then infects B lymphocytes in the peripheral blood and the reticuloendothelial system, including the liver, spleen, and lymph nodes. It is in these cells where the virus establishes latency, via formation of a viral episome. The host mounts a cell-mediated immune response to control the number of proliferating infected B lymphocytes. The atypical lymphocytes seen in infectious mononucleosis are activated CD8 T-cells, which exhibit suppressor and cytotoxic functions in response to the infected B cells. Infection is thus controlled but not abolished. Reactivation may occur intermittently with viral shedding in oral secretions of affected individuals.

The incubation period of infectious mononucleosis is 30-50 days. The onset of symptoms is often insidious, with a prodrome of malaise, headache, fatigue, fever, sore throat, anorexia, and myalgia. Patients seek medical attention with worsening sore throat and fever. On physical exam, the most common finding is lymphadenopathy, which is present in 90% of cases. It often occurs in the cervical region, particularly the posterior cervical chain, but may also be generalized with involvement of submandibular, epitrochlear, axillary, and inguinal lymph nodes. Lymph nodes are not spontaneously painful but may be mildly tender to palpation. Fever and pharyngitis occur in most patients. Pharyngitis may be moderate to severe with tonsillar enlargement and exudate. Abdominal exam may reveal splenomegaly in 60% and hepatomegaly in 10%. Patients treated with ampicillin/amoxicillin for presumed bacterial infection characteristically develop a maculopapular rash, which may be useful in diagnosis, but it is also an annoying adverse effect that often results in an inappropriate diagnosis of penicillin allergy.

The diagnosis of infectious mononucleosis may be made by clinical history, physical exam, and typical laboratory findings. Greater than 90% of patients will have leukocytosis, with white blood cell counts ranging from 10,000 to 20,000. Atypical lymphocytes usually account for 20-40% of the total number. These cells appear larger, with eccentrically placed nuclei and a larger amount of cytoplasm compared to typical lymphocytes. Mild elevation of liver enzymes occurs in 50%.

EBV-associated infectious mononucleosis is associated with the transient production of heterophil antibodies. These are IgM antibodies from the patient's serum that cause agglutination of red cells from sheep or horse serum. The most widely used test is the Monospot (trademark), a qualitative rapid slide test which detects horse red cell agglutination (i.e., the modern equivalent of the heterophil antibody). The sensitivity and specificity of this test is greater than 95% for diagnosing EBV-associated infectious mononucleosis. Children with symptomatic primary EBV infection are often heterophil negative. Ten percent of EBV-associated infectious mononucleosis may be heterophil- negative. Certain organisms may cause an infectious mononucleosis-like syndrome but are not associated with formation of heterophil antibodies, such as cytomegalovirus, T. gondii, adenovirus, viral hepatitis, HIV, and rubella.

The host also produces antibodies specific to the EBV virus. These are unnecessary for the diagnosis of infectious mononucleosis when the Monospot test is positive. These may be useful to clarify the diagnosis of heterophil-negative cases, or for atypical EBV infections when the Monospot test is often negative. Multiple EBV-specific antibody tests are available, including tests for viral capsid antigen (VCA), early antigen (EA), and EBV nuclear antigen (EBNA). The presence of IgM antibodies against viral capsid antigen signifies acute infection, while the presence of IgG antibodies signifies recent or past infection.

Infectious mononucleosis usually resolves in 2-3 weeks, although malaise may persist for weeks to months. Treatment is primarily supportive, with rest during the acute stage of illness and symptomatic care. Contact sports should be avoided while splenomegaly is present due to the risk of splenic rupture, although the incidence of this is low at less than 0.5%. Treatment with acyclovir or corticosteroids has not been proven to be of benefit in uncomplicated cases. Corticosteroids may be considered for severe complications of EBV infection, which are rare. Complications may include marked tonsillar inflammation with impending airway obstruction, massive splenomegaly, myocarditis, autoimmune hemolytic anemia, aplastic anemia, thrombocytopenia, neutropenia, hemophagocytic syndrome, meningitis, and encephalitis. EBV infection has been identified as a possible causative agent for chronic fatigue syndrome, but there is no strong evidence to support this.

EBV has been linked with benign and malignant proliferative disorders, particularly in patients with immunodeficiencies such as HIV, transplant recipients, severe combined immune deficiency, or Wiskott-Aldrich syndrome. The absence of an intact cell-mediated immunity in these patients allows the uncontrolled proliferation of EBV-infected B lymphocytes. Examples of benign disorders include oral hairy leukoplakia, which occurs primarily in adults with HIV and presents with raised, white lesions on the tongue, and lymphoid interstitial pneumonitis, which occurs primarily in children with HIV and is characterized by the presence of diffuse interstitial pulmonary infiltrates. Examples of malignant disorders that have been associated with EBV include nasopharyngeal carcinoma, the most prevalent cancer among adult males in southern China, and African Burkitt lymphoma, the most common childhood cancer in equatorial east Africa. Genetic and environmental factors may play a role in the increased incidence of these diseases in these areas. EBV has also been associated with lymphoma in immunosuppressed patients.

Questions

1. A 16 year old male presents with sore throat, fever, and cervical lymphadenopathy. A throat culture is done which is positive for group A streptococcus. Treatment is initiated with penicillin. He returns two days later with worsened symptoms, despite taking the medicine. Which of the following is the most appropriate step to do next?
   a. Switch to azithromycin.
   b. Obtain a CBC and Monospot.
   c. Check anti-VCA, anti-EA, and anti-EBNA titers against EBV.
   d. Assume the patient has infectious mononucleosis and start acyclovir and prednisone.

2. Which of the following is FALSE regarding EBV infection in young children?
   a. Primary infection is usually asymptomatic.
   b. Heterophil antibodies are usually positive.
   c. Immunocompromised patients are at risk for lymphocytic interstitial pneumonitis
   d. Complications are less common than in adults.

3. Which syndrome has NOT been found to be associated with EBV?
   a. Nasopharyngeal carcinoma
   b. Oral hairy leukoplakia
   c. Aplastic anemia
   d. Kaposi's sarcoma

4. An 18 year old female presents with malaise, fever, sore throat, and lymphadenopathy. Her CBC reveals atypical lymphocytosis, but her Monospot test is negative. Which of the following statements is TRUE?
   a. The Monospot test is not a highly sensitive test.
   b. Her symptoms may be due to primary infection by cytomegalovirus (CMV).
   c. There is no role for EBV-specific antibodies in making the diagnosis.
   d. The atypical lymphocytes represent circulating infected B lymphocytes.

5. Which of the following statements about EBV infection is TRUE?
   a. The syndrome of infectious mononucleosis results from primary infection with the virus.
   b. Infection usually occurs via contact with the blood of an affected person.
   c. About 25% of older adults show serologic evidence of prior infection.
   d. Splenic rupture is a frequent complication in EBV-associated infectious mononucleosis.

Answers to questions

1. The answer is b. In this case, the group A streptococcus probably represents colonization rather than the etiology of the patient's symptoms. Infectious mononucleosis may have a similar presentation to streptococcal pharyngitis, and must be considered if a patient is not responding clinically to treatment with antibiotics. Diagnosis may be made with a Monospot test as well as the presence of atypical

lymphocytes on CBC. EBV titers are not usually needed in diagnosis, but may be considered if the Monospot is negative and EBV infection is to be ruled out. Treatment with acyclovir or corticosteroids has not been proven to be of clinical benefit in uncomplicated cases of infectious mononucleosis.

2. The answer is b. Primary EBV infection occurs more commonly in childhood and is often asymptomatic. In children who do develop symptomatic EBV infection, heterophil antibodies are more often negative. Lymphocytic interstitial pneumonitis may occur in children with HIV. Complications occur less commonly in children than in adults.

3. The answer is d. The first three have all been found to be associated with EBV infection. Kaposi's sarcoma is associated with a different human herpes virus, referred to as human herpes virus-8 or HHV-8.

4. The answer is b. The Monospot test is a highly sensitive test, although ten percent of EBV-associated infectious mononucleosis may be negative. There are also a number of organisms that may cause an infectious mononucleosis-like syndrome but are not associated with formation of heterophil antibodies. The most common cause of a heterophil-negative infectious mononucleosis-like syndrome is CMV, which this patient likely has. Obtaining antibody titers specific against EBV and CMV may clarify the diagnosis. The atypical lymphocytes that may be seen with either EBV or CMV infection represent activated T lymphocytes, which proliferate in response to infected B lymphocytes.

5. The answer is a. The syndrome of infectious mononucleosis results from primary infection with EBV, particularly when it is delayed until adolescence or young adulthood. It is usually transmitted through close contact with oral secretions of an infected individual. The virus is ubiquitous, and almost all adults over age 40 show serologic evidence of prior infection. Splenic rupture is a rare complication of EBV-associated infectious mononucleosis.

Chapter VI.24. Polio
Rodney K. Yamaki

This is a 4-1/2 month old female who presents to the ER with weakness in her right leg. She is afebrile and does not appear to have any difficulty breathing. Her right leg appears flaccid and no DTR or Babinski can be elicited although sensation is intact. The tone, movement, sensation, and reflexes of her other limbs are normal. Her cardiovascular, respiratory and abdominal examination are normal. Upon further investigation, her father reports that she had a cough and fever of 38.3 C that resolved one week prior to presentation. Her father also notes both a normal birth history and appropriate well baby check ups. Her immunization records are up to date and at her 4 month visit (2 weeks prior to presentation), she received her 2nd doses of HiB, DTaP, OPV and pneumococcal vaccine.

CBC and Serum IgG/IgA/IgM are normal and CSF demonstrates elevated protein with normal glucose. Radiographs of her spine and right lower extremity are unremarkable. Electrophysiological studies (electromyography and nerve conduction studies) show absent motor responses to stimulation of her right tibial nerve. Fecal samples culture the Poliovirus type 3. It is then sent to the CDC where the poliovirus is identified as a vaccine strain of poliovirus (not the "wild-type" strain).

She is admitted to the hospital for monitoring. Her immunocompromised grandfather who changes diapers occasionally is informed about her spinal polio and encouraged to seek medical attention. During her inpatient care, mechanical ventilation is not required and she does not experience any urinary or fecal difficulties. One week after admission, she is discharged with mild residual weakness of her right leg.

Poliomyelitis is a disease that can be traced throughout recorded history. Egyptian murals note a man with an atrophied, shortened leg that appear to describe the late effects of polio. However, its first clinical description occurred in 1789 when Michael Underwood ascribed this condition to the disease that affected the lower extremities of children. Polio epidemics plagued the world over the next centuries. It is difficult for those of us living in the post-vaccine era to imagine the extent of these outbreaks, but an example is the 1952 epidemic that infected more than 50,000 Americans with a mortality rate of about 12% (1). Fortunately, the incidence of polio finally peaked in the 1950s and 1960s with the vaccine discoveries of Jonas Salk and Albert Sabin. The widespread use of these vaccines has dramatically decreased its incidence and has allowed us to target polio for global eradication.

Poliomyelitis is a highly contagious and infectious illness that exclusively affects humans. It is caused by 3 different serotypes of the poliovirus: P1 (majority of cases), P2, and P3. All of the poliovirus subtypes are included in the Picornaviridae family (pico=small, RNAviridae=RNA virus). Similar to other enteroviruses, the poliovirus is a transient inhabitant of the gastrointestinal system and is able to tolerate low pH settings. As the family name suggests, the poliovirus is relatively small. It is non-enveloped and its protein capsid of icosahedral symmetry measures less than 30 nm in diameter. Furthermore, its family name describes its genome as being RNA; specifically, it is single and positively stranded.

After the poliovirus attaches to specific human cell receptors, this single, positive stranded RNA is uncoated in the cytoplasm where it can be directly translated into products such as progeny protein capsids and replication enzymes. The replication of the genome itself is through a complementary negative strand. Once the genome is replicated, it is assembled into the protein capsids where the virions accumulate until they are released upon the death of the host cell.

The communicability of the poliovirus is mainly through the fecal-oral route, but oral-to-oral transmission is possible. Following exposure, the poliovirus infects the tissues of the oropharynx. It is then secreted into saliva and swallowed, allowing the virus to spread to the gastrointestinal system. There, the virus replicates and can subsequently invade the local lymphoid tissue, the bloodstream, and the CNS. The response to the infection is variable as seen in the range of clinical presentations. In a minority of patients, the virus can spread to the nervous system possibly through viremia or through retrograde transport along motor axons. Poliomyelitis has a selectivity toward the motor neurons of the anterior horn and the brain stem. It is the cell destruction at these sites that cause the paralysis that is associated with polio.

There are various responses to polio infections. The first subgroup encompasses the vast majority of polio cases. Up to 95% of polio patients have inapparent or asymptomatic infections (2). While these patients have no symptoms, they are infectious and briefly shed the virus in their stool to their contacts. The second subgroup is the abortive poliomyelitis which occurs in 4-8% of the cases (2). This subset is also spared CNS complications but can present with symptoms of malaise, anorexia, nausea, vomiting, headache, sore throat,

constipation, and diffuse abdominal pain. These patients usually undergo a complete recovery in less than a week. The third subgroup is the nonparalytic aseptic meningitis form of poliomyelitis which includes 1-2% of all cases (2). This group exhibits prodromal symptoms that are similar to those in abortive poliomyelitis but is complicated by posterior muscle stiffness of the neck, back, and limbs which can be accompanied by paresthesias. These signs of meningeal irritation and muscle spasm will typically resolve after 2-10 days. The final subgroup conjures up images of what most people think as the typical polio patient. Less than 2% constitute this form of poliomyelitis (2). Paralytic symptoms can present 1-10 days after initial prodromal symptoms. These paralytic symptoms are usually asymmetrical and include decreased deep tendon reflexes with no changes in cognition or sensation. Paralytic polio can be further separated into three types: spinal polio, bulbar polio, and bulbospinal polio. Spinal polio is the most common form and usually involves an asymmetric involvement of the legs. Cranial nerves can also be involved along with the muscles of respiration. Of historical interest, the "iron lung" was a negative pressure ventilator fitted outside the patient's body to chronically ventilate patients with respiratory paralysis. Of contemporary concern is that patients who contracted paralytic polio as children can develop a post-polio syndrome decades later.

Polio has been eradicated from North America so it is unlikely that we will ever see a case. In regions where polio still exists, poliomyelitis should be considered in an unimmunized or partially immunized patient with the clinical symptoms listed in the prior section. The choice of diagnostic tests include stool and throat cultures with greater success in isolating the virus from the stool. If the paralytic form of the polio is suspected, two or more samples are collected at least 24 hours apart and should be obtained within the first 14 days of symptoms. If the poliovirus is identified through the cultures, the isolate should then be sent to the Centers for Disease Control and Prevention to differentiate the naturally occurring "wild type" from the oral attenuated vaccine strain (which can cause poliomyelitis, rarely). In the absence of an isolate, poliomyelitis can be diagnosed with paired measurements of acute and convalescent sera. It is possible to witness a four fold or more increase in antibody titers. However, these results do not differentiate the "wild type" from the vaccine strain and can at times be equivocal. If CSF is obtained in the workup, it rarely isolates the poliovirus, but it can demonstrate pleocytosis with mildly elevated protein.

Treatment involves isolation of the hospitalized patient, strict bed rest, symptomatic pain relief, respiratory support as needed, and subsequent rehabilitation of affected muscles.

The last case of "wild type" poliomyelitis in the United States occurred in 1979. Through the efforts of the Global Polio Eradication Program, the number of endemic countries has decreased from 125 in 1988 to 10 as of 2001. In addition, the number of reported polio cases has substantially decreased over the same period (3). These efforts now focus on eliminating the virus from the Indian subcontinent and Africa through the use of the polio vaccine.

The dramatic decreases in the incidence of polio are attributed to the two types of vaccines that are currently available in the United States: the inactivated poliovirus vaccine (IPV) and the oral poliovirus vaccine (OPV).

IPV is also known as the Salk vaccine. Because it contains the inactivated forms of all three serotypes, it confers effective immunity to the polioviruses. Furthermore, since it does not contain the live virus, it is safe for use in immunocompromised patients and their contacts. It also does not cause the vaccine associated paralytic poliomyelitis (VAPP) seen with the oral vaccine. The disadvantages of the IPV are the exclusive administration through injection, less gastrointestinal immunity, and an unknown duration of immunity (4). Decreased gastrointestinal immunity could allow possible infection of the "wild type" strain through the GI tract. While the immunized person would be protected from the paralytic form of poliomyelitis, the patient would shed the poliovirus to other contacts. This lack of gastrointestinal immunity is part of the reason that the OPV is used by the World Health Organization for its global eradication efforts.

OPV is also referred to as the Sabin vaccine. OPV also provides effective immunity against all three serotypes of the poliovirus. The advantages of the oral vaccine include easier administration, probable lifelong protection, and better gastrointestinal immunity (4). The main disadvantage of the OPV is the risk of VAPP. Vaccine Associated Paralytic Poliomyelitis occurs when the live oral virus reverts to a virulent form. The risk of this occurrence is estimated to be 1 per 2.4 million doses distributed (125 cases for 303 million doses distributed) with most cases usually occurring after the administration of the first dose (4). This translates to five cases of VAPP reported in 1997 and two cases in 1998 (5). VAPP is also associated with patients who are immunocompromised. Because of this risk, the Advisory Committee on Immunization Practices (ACIP), the American Academy of Pediatrics (AAP), and the American Academy of Family Physicians (AAFP), now recommend an all-IPV schedule for routine childhood polio vaccination in the United States. All children should receive four total doses of IPV with single doses at ages: 2 months, 4 months, between 6-18 months, and between 4-6 years.

There are special circumstances that allow the use of the oral vaccine. These include: 1) Mass vaccination campaigns to control paralytic poliomyelitis outbreaks; 2) Unvaccinated children traveling to endemic or epidemic areas without enough time to administer 2 doses of the IPV; 3) Children whose parents do not accept the immunization schedule can receive the OPV for the third and/or fourth doses only; 4) Depletion of remaining supplies of OPV to children for their third and/or fourth doses although it is preferred that the OPV reserves be used preferentially on 4-6 year old for their fourth dose (6).

There are certain precautions and contraindications to childhood polio immunization. Immunocompromised patients should only receive IPV. Similarly, household contacts (immunocompromised patient in the household) should not receive the OPV because of the risk of excreting live polio vaccine virus and exposing household contacts. If these people happen to be vaccinated with the OPV, they should have minimal close contact with the immunocompromised person for between 4-6 weeks after immunization. Immunization should also be avoided during pregnancy because of the possible adverse effects of the vaccine on the fetus. If vaccination is required during pregnancy, IPV is recommended. Finally, since IPV contains trace amounts of streptomycin, polymyxin B, and neomycin, IPV is contraindicated for those with reactions to these antibiotics or those who have had prior reactions to previous doses. Both vaccinations can be used with breastfeeding and during bouts of mild diarrhea (7).

Those affected with acute paralytic poliomyelitis can experience Post-Polio syndrome (PPS) an average of 35 years after an infection. It was first described in the French medical literature in 1875. In a commentary on one of these cases, neuropathologist Jean Martin Charcot astutely hypothesized that one spinal disorder laid a patient more susceptible to a subsequent spinal disorder due to the overuse of the involved limbs. For reasons unknown, the late sequelae of paralytic poliomyelitis were not investigated further and prior to 1980, there was not even a name associated with this condition. In 1987, the National Health Interview Survey estimated more than 640,000 survivors of paralytic polio in the United States with more than half of these survivors demonstrating new late manifestations of post-polio syndrome (8). It is unclear how many of these polio survivors are still alive today, nor is it clear the added contribution of immigrants, refugees, and illegal aliens moving to the United States who are also survivors of paralytic polio.

Risk factors for PPS include: the severity of the acute poliomyelitis paralysis, age at onset of the acute poliomyelitis (higher risk with adolescent and adult onset), the amount of recovery, and greater physical activity during the intervening years (8). In a summary of four major studies, the frequency of symptoms were consolidated into the following data: fatigue 62-89%; weakness in previously affected muscles 54-87%; weakness in previously unaffected muscles 33-77%; muscle pain 39-86%; joint pain 51-79%; cold intolerance

29-56%; muscle atrophy 28-39%; new difficulties with walking 52-85%; new problems with climbing stairs 54-83%; new difficulties with dressing 16-62% (9).

Although there is no definitive origin of PPS, one leading hypothesis suggests that once the motor neurons are reinnervated, the excessive metabolic stress over the years eventually leads to the eventual dropout of the motor neurons. Many of us associate The March of Dimes with preventing birth defects and infant mortality. However, The March of Dimes was originally created to combat the polio epidemics. The March of Dimes continues its polio efforts as evidenced by its involvement in the 2000 International Conference on Post Polio Syndrome which developed the following diagnostic criteria (10).

1. Prior paralytic poliomyelitis with evidence of motor neuron loss, as confirmed by history of the acute paralytic illness, signs of residual weakness and atrophy of muscles on neurologic examination, and signs of denervation on EMG.
2. A period of partial or complete functional recovery after acute paralytic poliomyelitis, followed by an interval (usually 15 years or more) of stable neurologic function.
3. Gradual or sudden onset of progressive and persistent new muscle weakness or abdominal muscle fatigability (decreased endurance), with or without generalized fatigue, muscle atrophy, or muscle and joint pain.
4. Symptoms persist for at least a year.
5. Exclusion of other neurologic, medical and orthopedic problems as causes of symptoms.

It is very unlikely that we will witness patients with acute poliomyelitis. The wild-type poliovirus has nearly been eradicated from the globe, and due to current vaccination recommendations, VAPP can be avoided by using IPV. Although this discussion of Post-Polio Syndrome is beyond the scope of a pediatrics textbook, modern experiences with poliomyelitis will more likely to be with adults with post-polio syndrome.

Questions

1. The 3 serotypes of the poliovirus belong to which family of viruses?

2. Of the 4 acute clinical presentations (asymptomatic, abortive, nonparalytic aseptic meningitis, or flaccid paralysis poliomyelitis) which is the most common?

3. What are the AAFP, AAP, ACIP childhood immunization schedule recommendations for polio vaccination?
   a. Exclusive OPV
   b. Exclusive IPV
   c. Mixed IPV/OPV (first two doses being with IPV)
   d. Four doses of the Sabin vaccine

4. Which vaccination (OPV or IPV) should be used for the following clinical situations?
   a. Vaccination of children in an endemic country.
   b. Doctor has remaining OPV supplies. Third does for an infant living with an agammaglobulinemic Grandpa.
   c. Doctor has remaining OPV supplies. Third dose for a child whose parents refuse any more injections.
   d. Doctor has remaining OPV supplies. 2 month old's first polio immunization.
   e. Outbreak of "wild type" polio in the United States

5. Describe the proposed pathophysiology of post-polio syndrome.

6. True/False: The March of Dimes is named after the campaign where Americans mailed in their dimes to fight polio.

Answers to questions

1. Picornaviridae family (Pico=small, RNAviridae=RNA virus).
2. Asymptomatic presentation is up to 95% of the cases.
3. The correct answer is b, exclusive IPV immunization.

4a. OPV (for endemic countries).
4b. IPV (Household contact, especially since Grandpa might be changing the diapers).
4c. OPV (May receive 3rd and/or 4th oral doses).
4d. IPV (Immunization through all IPV schedule).
4e. OPV (Mass vaccination campaign to control outbreaks).

5. The proposed mechanism includes the dropout of neurons that were reinnervated after the initial paralytic poliomyelitis infection due to increased metabolic stresses.

6. True. The March of Dimes was originally named the National Foundation for Infantile Paralysis.

Chapter VI.25. Rabies
Grant L.Y. Chen, MS

An 8 year old male presents to the ER with headache, temperature of 39.5 C, chills, and vomiting. His mother reports that he had experienced worsening headache over the past 2 days. Meningitis is a concern, so an LP is performed which shows 20 RBCs, 0 WBC, a mildly elevated protein and normal glucose. Therapy is started with broad spectrum antibiotics, and he is admitted to the floor. Two days later, his mental status worsens in spite of therapy, so a repeat LP is performed. The repeat reveals: opening pressure of 28 cm water, clear fluid, 6 WBC, (84% lymphs), glucose 92 mg/dl and an elevated protein. There are no focal deficits on neurological examination, but since he is agitated and combative, he is sedated and intubated. Acyclovir is added to his therapy for the possibility of encephalitis.

Two days later, his fever drops, and he became alert at times, but he is still agitated. Further history from the mother reveals that the family had recently moved from the Philippines. The mother denies a history of dog bites, but notes that the child would occasionally play with bats that were caught by his grandparents for him to be used as pets. She denies bat bites, but states that there may have been skin to bat contact when the bat would land on the child. Based on this history, his saliva is sampled, along with a skin biopsy from his neck. Immunofluorescent staining of the skin reveals the presence of rabies antigen, and rhabdovirus is present in his saliva after reverse transcription and PCR testing. The family is notified of the diagnosis and he continues to progressively deteriorate, passing away 10 days after admission. Postmortem autopsy of cerebellar tissue reveals the presence of basophilic inclusion bodies. The brain is soft and edematous. PCR analysis of the tissue at the CDC implicates a strain of the rabies virus associated with the Philippines.

Rabies is a disease whose presence has been noted throughout recorded history. Rabies is inevitably fatal by the time that significant symptoms appear, which is why prophylaxis must be started before symptoms appear. It causes a highly fatal acute encephalitis, causing approximately 35,000 deaths each year worldwide. Rabies virus belongs to the Rhabdoviridae family. Animal cases of rabies have been reported in all states with the exception of Hawaii, which continues to be rabies free. Human acquisition of rabies in the United States is a relatively rare occurrence, as only 32 cases of rabies were recorded between 1980 and 1996, occurring in 20 states (1). However, the yearly mortality rate in the Philippines is approximately 340, and in India, more than 25,000 people fall victim to rabies each year.

The normal mode of transmission of this disease has been by direct contact between animal and man. The animal implicated most frequently has been the dog, but other common zoonotic reservoirs of the disease include raccoons, bats and skunks. It is estimated in the Philippines that 10,000 dogs are infected each year (3). The primary wild reservoir of rabies in the United States is the raccoon. The rabies virus reproduces in both human and animal reservoirs, and is found in not only nervous tissue, but also in saliva, which provides the primary method for transmission of the virus. It is notable that the titer of rabies virus is much higher in skunks than other animals (5). Also, cats, while less frequently infected, have sharper teeth that cause deeper puncture wounds. In the case of transmission from bats, it is believed that transmission may occur through inhalation of aerosolized bat feces (highest risk in caves with high bat populations), and also through direct skin-to-skin contact. Non-animal associated transmission of rabies is extremely rare, and has occurred by means of corneal transplantation from an unknowingly infected donor who died from rabies (diagnosed after the corneal transplant recipients were diagnosed with rabies at post-mortem).

Rabies spreads centripetally from the bite wound (usually an extremity) into the CNS, moving at an estimated rate of 1-2 cm/day (8). The period between the inoculation of the virus into the victim and its invasion of the CNS is the incubation period. The median incubation period is 85 days (range 53-150 days) (1), although molecular biological analysis reveals that the incubatory stage can last up to 7 years (5). It is not known what mechanism modulates the rate of rabies virus travel from the periphery to the central nervous system. It is believed that the primary factor involved in determining whether or not the bitten individual is inoculated with the virus is whether or not the virus makes contact with muscle. Prior to the invasion of the nervous system, the virus reproduces in the muscle tissue, subsequently invading the motor neurons. Bat rabies, unlike canine rabies, possesses the ability to replicate in skin and connective tissue, explaining why non-bite inoculation is prevalent in bat exposures (8).

The first signs and symptoms of rabies are often nonspecific, including fever, sore throat, chills, malaise, anorexia, headache, nausea, vomiting, dyspnea, cough, and weakness. A characteristic symptom is the presence of paresthesia in the area local to the bite. This is thought to be early ganglionic invasion of the virus.

There are two presentations of canine rabies, a "furious" (encephalitic) or "dumb" (paralytic) form. Both forms are invariably fatal, with the furious form causing death within a week, and the dumb form causing death within 2 weeks. Characteristic of furious rabies is high fever, hyperactivity, hypersexuality, including an increase in sexual appetite and priapism of several days, along with autonomic dysfunction, piloerection, and pupillary abnormality (1,5,6,8). The autonomic dysfunction also includes excess salivation, which can produce the "foaming at the mouth" that is often said to accompany rabies. The dumb form progresses from the peripheral weakness to a generalized craniospinal weakness (1,6,8). The late features of dumb rabies are typically encephalitic.

Bat rabies differs from canine rabies not only in method of inoculation, but also in presentation. Patients with bat rabies have a high incidence of focal brainstem signs and myoclonus, and may display hemiparesis, hemisensory deficits, ataxia, chorea, or Horner's syndrome (1,8). In contrast, victims of canine bite rabies display only focal weakness, usually in the limb that was bitten.

In addition to the clinical findings of rabies, a histopathologic finding is the presence of Negri bodies. These are inclusion granules found in cells of the CNS, most often within the pyramidal cells of Ammon's horn, or the Purkinje cells in the cerebellum. They are described in the literature as either eosinophilic or basophilic inclusions, and are cytoplasmic inclusion bodies containing viral nucleoprotein. The presence of Negri bodies is variable, as non-rabid tissues have displayed inclusions that are indistinguishable from Negri bodies, while rabid tissue from animals have shown Negri bodies in only 50% of samples taken.

Thus, the most reliable test for rabies prior to the appearance of symptoms remains the direct fluorescent antibody test (DFA). However, the DFA requires brain tissue, and is therefore performed post-mortem. It is the test of choice for the testing of rabid animals. For humans, it is necessary to perform multiple tests to diagnose rabies before death. The two main tests are testing for the virus in saliva by PCR, or testing the blood serum or spinal fluid for antibodies to rabies virus. Additionally, skin biopsy specimens may display rabies antigen within cutaneous nerves (10). The small number of rabies cases in the United States undoubtedly contributes to the lack of clinical suspicion by the physician, but it is important to remember that any patient presenting with encephalopathy of unknown cause should be considered to potentially have rabies, even in the absence of known exposure to the virus through animal bites. The validity of this statement is further justified by noting that 12 of the 32 deaths (37.5%) in the US attributable to rabies were not diagnosed until after the death of the patients, and of these 12 cases, 6 were not diagnosed until several weeks after death (1). Additionally, while all 32 fatal rabies cases in the US between 1980 and 1996 were seen by their physicians on an outpatient basis prior to the onset of terminal symptoms, not one of them received a complete set of rabies prophylaxis post-exposure. As a further reminder of the importance of clinical suspicion for pediatricians, a 1990 study showed that animal bites were the fourth leading cause of accidents in children 9 years old or less.

As rabies is a uniformly fatal disease once the symptomatic stage of the disease has developed, it is important to provide pre-exposure, and if necessary, post-exposure prophylaxis for patients. The origins of modern rabies treatment lie in Louis Pasteur's work with live attenuated rabies virus in the 19th century. After discovering the transmissibility of rabies by nervous tissue inoculation, Pasteur determined that passage of the virus from dogs to monkeys attenuated the virus, while transmission from rabbit to rabbit increased the virulence of the strains. By utilizing his attenuated strain on 9 year old Joseph Meister, he was able to attain "the happy outcome" now known to all.

Following Pasteur's work, the duck embryo rabies vaccine was produced in 1955, and was used for prophylaxis for more than 25 years, proving effective when combined with equine rabies immunoglobulin (RIG). However, this therapy caused allergic reactions in response to the avian antigens, required 21-23 doses, was very painful, and the equine origin of the RIG could cause serum sickness (5).

Modern rabies immunization consists of two types of products: Active immunization with rabies vaccine (HDCV-human diploid cell vaccine, PCECV-purified chick embryo cell vaccine, or RVA-rabies vaccine adsorbed), and rabies immune globulin (RIG). The modern version of the RIG is derived from the plasma of hyperimmunized human donors, thus eliminating the equine antigens present in the previous version of the RIG. RIG produces a rapid, passive immunity with a half-life of approximately 21 days. On the other hand, rabies vaccine creates an active immune response that takes 7-10 days to produce, and lasts for 2 or more years. The recommended pre-exposure vaccination is three 1.0 ml injections of HDCV IM (deltoid) on days 0,7, and 21 or 28. Should immunosuppressed individuals become exposed to rabies, they should be treated as indicated, and titers should be taken to confirm development of rabies antibodies. Booster doses of the vaccine may be given every 2 years if the antibody titers in the patient are decreased. Should pre-vaccinated persons become exposed to rabies, they should NOT be given RIG, as an amnestic response will develop. Treatment of persons known to be exposed to rabies is threefold: First, there should be an immediate and thorough cleansing of the wound with soap and water. If virucidal agents such as povidone-iodine are available, they should be used for irrigation. Secondly, RIG should be administered, 20 IU/Kg of body weight. If feasible, the FULL DOSE should be administered (infiltrated) around the wound(s). If there is any remaining volume, it should be administered IM at a site distant from the vaccine administration site. To note, RIG should not be administered in the same syringe as the vaccine, and as it may suppress formation of antibody, it should not be administered in excess of the recommended dose. Lastly, HDCV should be administered in the same dosage as mentioned for pre-exposure prophylaxis.

The efficacy of the recommended prophylaxis is evidenced by the fact that of the millions of doses administered worldwide, there have been only 13 reported failures, and all of the failures have been associated with deviation from the recommended treatment protocol. The rate of systemic allergic reaction to the rabies vaccine is approximately 11 per 10,000 vaccinations, which has resulted in a few hospitalizations, but no deaths. It is currently the recommendation of the Advisory Committee on Immunization Practices (ACIP) that persons in high risk groups, such as veterinarians, animal handlers, and certain lab workers be treated with pre-exposure vaccine. Additionally, rabies prophylaxis is recommended that persons traveling (for more than 30 days) into areas where rabies is endemic and medical care is limited.(2,8). It is also recommended that even immunosuppressed patients receive prophylaxis if exposed to rabies. While pre-exposure prophylaxis is recommended, it is important to note that it does not negate the need for post-exposure. Pre-exposure prophylaxis negates the need for RIG immunization after exposure, but does not alter the remainder of the post-exposure prophylaxis schedule.

Far more effective than medical prophylaxis are the recommendations of the national working group on prevention and control of rabies in the United States. Their recommendations include:

1. Vaccinate all dogs and cats against rabies. Do not keep wild animals as pets.
2. Do not feed or pet stray animals; avoid animals you do not know.
3. Report any animals that are acting sick or strange to local animal control authorities.
4. Keep pets indoors at night. Feed pets indoors.
5. Keep pets fenced in or leashed.
6. Do not handle dead, sick, or injured wild animals. If necessary, use sticks or shovels and wear heavy gloves.
7. Remove roosting bats from homes and barns.
8. Keep all trash container lids tightly closed. Keep compost piles away from buildings.

Since the prognosis for patients displaying symptoms of rabies infection is invariably fatal, it is of the greatest importance for all possible measures to be taken to avoid the transmission of rabies, both through the application of animal vaccination and public health awareness. It is also vital for physicians to recognize individuals at risk for rabies exposure and treat them with both pre and post-exposure prophylaxis.

Questions

1. Which animals are most frequently reported rabid in the United States? (select all true answers)
    a. Squirrels
    b. Raccoons
    c. Rabbits
    d. Hamsters
    e. Skunks

2. Which of the following would provide the best method for ante-mortem diagnosis of rabies in a human?
    a. Identification of clinical symptoms.
    b. Direct fluorescent antibody testing.
    c. Identification of Negri bodies.
    d. Observation of the animal in question to be rabid.
    e. PCR of isolate from the saliva of the victim.

3. True/False: Inoculation of rabies from animal to human requires a physical animal-human contact.

4. In which of the following cases would post-exposure rabies prophylaxis be appropriate (select all appropriate):
    a. A tour group observes a large colony of bats emerge from a cave.
    b. While cleaning out the attic, a man removes a dead bat without using gloves.
    c. A child is bitten by his pet dog in Hawaii.
    d. A dead bat is removed from the crib of a child.

5. Which animal is most likely to transmit rabies to humans by mere contact (as opposed to a bite)?
    a. Bat
    b. Racoon
    c. Skunk
    d. Coyote
    e. Cat

Chapter VI.26. Rocky Mountain Spotted Fever
Douglas K. Kwock, MD

This is a 12 year old male who presented to the office 2 days ago with a 2 day history of fever, headaches, malaise, and generalized myalgias. He was diagnosed with a "viral syndrome" and given instructions for home symptomatic care. He is now in the emergency department with a rash that started on his hands and feet, spreading up his arms and legs. The fever, headaches, and myalgias have persisted. Mother states that today her son seems "out of it ".

Exam: VS T 40.2 C, P 100, R 26, BP 115/70. He is laying in a hospital gurney, awake and responsive, but tired and ill appearing. His skin has a maculopapular rash that blanches under pressure on the upper and lower extremities, including his palms and soles, and a few scattered macular lesions located on the upper trunk and back. There is a small 3mm round healed scab lesion on the left calf. His head is atraumatic and nontender. He has no mucosal (eye, nose, mouth, and throat) lesions. He does not exhibit any meningeal signs. His heart, lung, and abdominal exams are normal. There is tenderness to gentle palpation of his thigh and calf muscles. He is oriented and responds appropriately.

Laboratory studies reveal a normal white blood cell count that is slightly left shifted. He has a platelet count of 105,000. His serum sodium is 132mEq/L. Cerebrospinal fluid is normal.

The patient is asked about the scab on his calf. Four days prior to the onset of illness, while deer hunting with friends, he noticed an engorged tick on his calf. The tick was removed by "squeezing and scratching" causing a small abrasion that he soon forgot about. He is started in doxycycline. Rocky mountain spotted fever serologies are ordered on his blood.

Rocky mountain spotted fever (RMSF) is a tick-borne disease caused by the gram-negative intracellular bacterium Rickettsia rickettsii. It is the second most common tick transmitted disease in the United States. Among the rickettsial illnesses, it is the most common and severe in the United States (1).

The disease was first recognized in Idaho and Montana in the late 1800s and initially thought to be limited to the Rocky Mountain region. Today RMSF is seen in all geographic areas of the continental United States. Over half of reported cases are concentrated in the south-Atlantic and south-central regions. The highest rates of disease are reported in North Carolina and Oklahoma (2). Though historically significant, the "Rocky Mountain" moniker is misleading relative to the current disease epidemiology.

Males have a higher incidence of disease than females. RMSF is of pediatric concern because children <15 years of age account for the majority of infections with the highest incidence in children age 5 to 9 years (2).

The wood tick (Dermacentor andersoni) found in the Western and Rocky Mountain States and the dog tick (Dermacentor variabilis) found east of the Rocky Mountains are the primary hosts and vectors of R. rickettsii. Infected female ticks can transmit infection transovarially and lay infected eggs, perpetuating infection from generation to generation. Ticks can acquire the infection while feeding on an infected rickettsemic host. Tick nymph and larva stages primarily feed on small mammals. Adult ticks feed on large domestic mammals, including humans. Once a tick becomes infected, it will maintain the infection for life even across molting stages.

Cases can occur throughout the year but the majority (90%) occur during April through September (2). This seasonality correlates with periods of heightened outdoor human activity, and increased tick feeding activity amplifying the likelihood of exposure. Ticks transmit infection during a blood meal. Transmission usually occurs after the tick has been attached for a minimum of 6 to 10 hours. A history of tick bite or exposure to tick infested areas is often not recalled on initial evaluation and is obtained in only 60% of RMSF cases.

Prior to the advent of effective therapy, 30% of RMSF cases were fatal. Currently, the mortality rate is 2 to 4% despite available appropriate treatment (1). Poor outcome is usually the result of delayed diagnosis and the subsequent delay in initiating appropriate antimicrobial therapy (3).

The average incubation period of RMSF is 5 to 7 days (range 2 to 14 days). Early signs and symptoms of RMSF are nonspecific. Prominent features of RMSF are fever, headaches, myalgias, and malaise. The onset of fever is usually abrupt. Headaches in older patients are intense, persistent, and refractory to relief efforts. Gastrointestinal complaints (nausea, vomiting, abdominal pain) are common.

The most characteristic feature of RMSF is a rash that develops on days 2 to 4 of illness. It appears as a discrete macular or maculopapular rash that blanches with pressure. The ankles and wrists are initially involved. Rash on the palms and soles is characteristic of RMSF. The rash spreads proximally up the arms and legs and eventually involves the trunk. Petechial and hemorrhagic lesions develop giving the classic "spotted" appearance of the illness. However, there have been reports of "spotless" or "almost spotless" RMSF illnesses. During convalescence, desquamation may occur in the most affected skin areas.

Fever, rash, and a history of tick bite comprise the "classic triad" of RMSF. This triad is seen in two-thirds of patients. Because the rash typically appears late in the course of illness, the classic triad is rarely useful in assisting with an early diagnosis which is critical to successful management.

Central nervous system involvement may develop in severe RMSF with symptoms of disorientation, meningismus, seizures, and coma. Cardiac complications include arrhythmias and congestive heart failure. Other less frequent signs and symptoms are pneumonitis, hepatosplenomegaly, edema, and conjunctivitis (4).

The initial presentation of RMSF is nonspecific and can mimic any generalized febrile illness. The maculopapular rash of measles and non-polio enteroviruses can resemble the rash of RMSF. A petechial rash necessitates the consideration of meningococcemia or septic shock (staphylococcus or streptococcus). Ehrlichiosis shares many similar features with RMSF.

There is no laboratory test that definitively diagnoses RMSF in the early phase of illness. Thus, an early diagnosis depends on a high index of suspicion, a compelling clinical presentation, and suggestive ancillary laboratory data.

The CBC WBC may be high, normal, or low but is usually left shifted. Thrombocytopenia is common in RMSF. Mild thrombocytopenia is probably related to platelet adherence to affected endothelial cells. Severe thrombocytopenia usually represents a consumptive coagulopathy. Hyponatremia is common. CSF is usually normal but may demonstrate a mild pleocytosis.

Diagnosis is made by serologic studies. The most sensitive and specific tests are indirect immunofluorescent antibody (IFA), enzyme immunoassay (EIA), and compliment fixation (CF). Other available serologic studies are latex agglutination (LA), indirect hemagglutination (IHA), and microagglutination (MA). Antibodies can be detected 7 to 10 days from disease onset. A single serum IFA titer of 1:64, CF titer of 1:16, or LA, IHA, or MA titer of 1:128, are highly suggestive of RMSF. A 4-fold rise between acute and convalescent antibody titers is diagnostic (5).

Early treatment is necessary and often empiric based on index of suspicion considering history, clinical course, and epidemiology. Treatment should not be withheld until a definitive diagnosis is made. Delay in initiating treatment leads to a poorer prognosis. Without treatment, RMSF can be fatal. Chloramphenicol, tetracycline, and doxycycline are effective against R. rickettsii. Doxycycline is the drug of choice for treatment of RMSF in patients of any age. Historically, chloramphenicol was recommended for children <8 years of age. Tetracycline and doxycycline were not favored because they bind to calcium of developing teeth and bones causing permanent discoloration. However, there are several reasons why doxycycline is the recommended first-line therapy. It does not bind to calcium as readily as tetracycline. A single course of doxycycline treatment carries little risk of teeth staining. Chloramphenicol has been associated with the development of irreversible aplastic anemia, and has been shown to be less effective than doxycycline for treatment of RMSF (2). Doxycycline is also active against ehrlichiosis, which may be clinically indistinguishable from RMSF. The efficacy of chloramphenicol in ehrlichiosis has not been established. Doxycycline is given at a dose of 2 to 4 mg/kg/day, divided every 12 hours, with a maximum dose of 200mg/day. The dose is the same regardless of oral or intravenous administration. Duration of therapy is for a minimum of 5 to 7 days and until the patient has been afebrile for at least 48 hours (5).

Limiting exposure to ticks is the most effective method of decreasing the risk of disease. If tick exposure is anticipated, there are several suggested means of protection. Clothing should cover a maximal amount of surface area to minimize exposed skin and should be light-colored allowing easy tick detection. Long pants should be tucked into socks or boots. Tick or insect repellants should be applied to clothing and exposed skin. Thorough body checks should be performed after exposure to a tick infested area. Particular attention should be paid to the head and scalp where ticks may be difficult to find. Proper skin removal of ticks is important in decreasing the risk of infection. Squeezing, crushing, pinching, or the folk remedy of burning the tick with a cigarette may actually facilitate rickettsiae transmission. The tick should be removed with a fine-tipped tweezer grasped as close to the skin as possible and pulled upward with a slow steady pressure. The skin site should be cleaned and disinfected. If possible, the tick should be saved for identification if illness develops.

There is no licensed vaccination for prevention of RMSF. Prophylactic therapy for asymptomatic individuals with a recent tick bite or exposure to a tick infested area is not recommended.

Full recovery is the rule with administration of appropriate antibiotics within 5 days of disease onset. Fulminant fatal RMSF has been associated with glucose-6-phosphate dehydrogenase (G6PD) deficiency (6), possibly related to increased hemolysis due to infection.

Questions

1. True/False: RMSF is most prevalent in the Rocky Mountain states.

2. True/False: RMSF can be "ruled out" based on a lack of history of tick bite.

3. True/False: Treatment of RMSF is often empiric.

4. True/False: Rash typically starts on the trunk and spreads distally.

5. Which is the preferred method of removing an attached tick?
   a. Use a lit match or cigarette to burn the tick stimulating it to detach and flee.
   b. Gently pinch the body of the tick with fingers and lift straight off.
   c. Use fine-tipped tweezers to grasp the tick as close to the skin as possible and pull upward with slow steady pressure.
   d. Apply petroleum jelly (Vaseline) over the tick and wait for the tick to suffocate or detach for air.
   e. Don't remove, leave the tick alone.

6. Which of the following is NOT a recommended means of RMSF prevention?
   a. Insect or tick repellants to clothing and exposed skin.
   b. Prophylactic doxycycline prior to exposure to tick infested areas.
   c. Minimize exposed skin with light [Note spelling change]-colored clothing.
   d. Avoid known tick infested areas.
   e. Survey skin and scalp after exposure to tick infested areas.

Answers to questions

1. False. Primarily south-Atlantic and south-central states.

2. False. A history of tick bite or exposure is obtained in only 60% of cases.

3. True. Therapy should never be withheld until a definitive diagnosis is made. Poorer outcome with increased mortality is associated with delay in initiating treatment.

4. False. Rash typically starts on the hands/wrists and feet/ankles. Involvement of the palms and soles is classic.

5.c, 6.b

Chapter VI.27. Lyme Disease
Judy Makowski Vincent, MD

A 7 year old boy is brought to the pediatric clinic in August with the chief complaint of a large, red circular rash on his left thigh. The rash has been present for 2 weeks and has been enlarging. His father states that 3 weeks ago, the family was visiting relatives at a rural farm in Connecticut, and one day after playing outside in the woods, the boy was found to have a tick attached to his thigh. His father had removed the tick with tweezers; however a red macule remained at the site where the tick had been attached. One week after the tick was removed, a red ring developed around the macule, and then the ring appeared to grow larger by expanding outward, leaving an area of central clearing. The boy has had a mild headache and myalgia, but has been afebrile.

Exam: VS T 37.1, P 90, RR 20, BP 100/70. He is alert, active, in no distress, and is non-toxic. Over the anterior surface of his left thigh, there is a red ring, 20 cm in diameter, with central clearing, and a central brownish-red macule that is 3 mm in diameter. The thigh is non-tender. All joints are non-tender and non-swollen. His neck is supple without lymphadenopathy. The remainder of his exam is unremarkable.

No laboratory tests are performed. The skin lesion is diagnosed as erythema migrans (EM), and a diagnosis of Lyme disease is made. He is judged to have early localized infection. He is treated with amoxicillin, 50 mg/kg/day po divided tid for 21 days. His headache and myalgia resolve within one week, and the EM resolves completely by the end of amoxicillin treatment.

A zoonosis is a disease of animals that may be transmitted to man. A vector is a carrier that transfers an infectious agent from one host to another. Lyme disease is the most common vector-borne zoonosis in the United States and is caused by the spirochete Borrelia burgdorferi. It is a multisystem, multistage, inflammatory illness affecting primarily the skin, nervous system, heart and joints. If you have difficulty remembering this, note that these affected systems are identical to those affected in rheumatic fever.

Lyme disease was recognized as a distinct disease in 1977 after a group of children in Old Lyme, Connecticut was diagnosed as having "juvenile rheumatoid arthritis". Two mothers of children with arthritis contacted the Connecticut State Department of Health and reported the occurrence of arthritis in 12 children in Old Lyme; of these, 4 lived on the same street. The mothers also reported arthritis in several members of their families and in families living in the neighboring towns of Lyme and East Haddam. An epidemiologic investigation was begun and has resulted in the knowledge of Lyme disease today.

B. burgdorferi is transmitted to humans by the ticks of the Ixodes ricinus complex. I. scapularis (the black-legged or deer tick) is the vector in the eastern United States, while I. pacificus (the western black-legged tick), transmits B. burgdorferi in the western United States (1). In the spring, the adult ticks lay eggs, from which larvae emerge. On the east coast of the United States, the larvae become infected when they feed on the reservoir, the asymptomatically-spirochetemic white-footed mouse. Since the spirochete infection is not transmitted from mother tick to their eggs, the tick larvae are not infected until they feed on this mouse. On the west coast, Lyme disease occurs sporadically, due to the fact that I. pacificus larvae feed more often on non-spirochetemic lizards than on white-footed mice (1). In the nymphal stage, the ticks feed predominantly in the spring and early summer, and two-thirds of cases of Lyme disease cases are reported from July to October. It is the nymphal stage that transmits the infection most often to humans. Since the nymphs are small, they often go undetected. The adult tick survives the winter by attaching to a host mammal, which is not involved in the life cycle of the spirochete, but merely allows the tick to survive over the winter (1). If white-tailed deer live in the environment, they are the host of choice; however at least 30 types of wild mammals and 49 species of birds may be host to the tick (2).

The number of cases reported annually has increased approximately 25-fold since national surveillance was begun in 1982 (1). During 1993-1997, a mean of 12,451 cases were reported by states annually to CDC. In the United States, the disease is primarily localized to states in the northeastern, mid-Atlantic, and upper north-central regions, and to several areas in northwestern California. Most cases of Lyme disease result from exposure to infected ticks during activities such as property maintenance, recreation, and leisure activity. Therefore persons who live or work in wooded areas or areas with overgrown brush infested with vector ticks are at risk for acquiring Lyme disease.

The B. burgdorferi spirochete is transmitted by infected ticks, which transmit the organism into the blood vessels in the skin of its host. The tick must attach to the host for 48 to 72 hours for the risk of transmission of B. burgdorferi to become substantial (3). The majority of patients with Lyme disease do not recall a tick bite, which means that with an unrecognized tick bite, these individuals are at greater risk to acquire Lyme disease, because unrecognized ticks may feed longer (3).

The incubation period from infection to onset of symptoms is 7 to 14 days, with a range of 3 to 30 days. B. burgdorferi spreads locally into the skin from the site of the tick bite, which results in a single EM lesion in approximately two-thirds of patients who become symptomatic. Days to weeks later, the spirochete may disseminate via lymphatic or blood-borne routes to other areas of the skin, causing multiple EM lesions, and to the eye, muscle, bone, synovial tissue, central nervous system and heart (2,3,4).

Lyme disease occurs in stages, and this is useful to remember when considering the diagnosis (2,3,4). The stages are: early localized (stage 1); early disseminated (stage 2); and late disseminated (stage 3).

Early localized infection (stage 1) occurs 3 to 32 days after the tick bite (3). It usually manifests as the characteristic EM rash, and may be accompanied by fever, malaise, headache, fatigue, myalgia, and arthralgia. EM by itself is diagnostic of Lyme disease, and a positive Lyme serology is not required. Indeed, most patients have negative serology in this stage (3). Thirty to fifty per cent of persons with evidence of recent infection are asymptomatic (3). The rash is usually annular, spreading from a central lesion, which is the tick bite. It may be solidly erythematous, may be a target lesion, or may have a vesicular or necrotic center. The rash may be pruritic, painful, or asymptomatic. Without treatment, the rash expands in size; hence the name migrans. The average size is 15 cm, however the lesions may be as large as 30 cm in diameter (4). A patient may have multiple EM lesions.

Early disseminated infection (stage 2) begins 3-10 weeks after the appearance of the EM lesion (3,4). Patients may develop secondary EM lesions which are not at the site of the tick bite. These lesions are often accompanied by the same systemic symptoms as primary EM. Focal neurologic involvement, the most common of which is isolated seventh cranial nerve or (Bell's palsy), is also a manifestation of early disseminated disease. This may be the presenting, as well as the only, manifestation of Lyme disease and is relatively common, affecting about 3% of children (3). Antibiotic treatment has no effect on the clinical course of the Bell's palsy, which completely resolves in 2 to 8 weeks. Lyme-related Bell's palsy should not be treated with corticosteroids (3). Other complications in stage 2 may be aseptic meningitis, carditis, radiculoneuropathy, lymphadenopathy, conjunctivitis, neck pain, fever, headache, arthralgia, myalgia, and fatigue. Radiculoneuropathy is more common in European adults, but is also seen in children in the United States (3,4).

If the patient is untreated or is inadequately treated, late-disseminated (stage 3) Lyme disease may develop 2 to 12 months after the tick bite (2,3,4). The most common manifestation of late disseminated Lyme disease in children is arthritis. Large joints are affected most often, with the knee being involved in >90% of cases (3). The involved joint is tender, erythematous and swollen; however the clinical findings are not as marked as in bacterial arthritis. With treatment, the joint shows signs of improvement in 4 to 7 days, with complete resolution in 2 to 6 weeks. Occasionally symptoms will recur after treatment, requiring another course of antibiotics. Chronic arthritis occurs primarily in patients with DR-2, DR-3, or DR-4 HLA types (2).

The most common mistake in diagnosis, is the overdiagnosis of Lyme disease by obtaining Lyme serology in patients who have vague, nonspecific symptoms, but who do not have risk factors for Lyme disease (i.e., patients who do not live or work in heavily wooded areas or areas that have dense underbrush infested with vector ticks and who do not have frequent or prolonged exposure to tick-infested habitats) (5). The ELISA serologic test for Lyme disease has high sensitivity but low specificity, and positive results in patients at low risk of disease are likely to be false positive results. At this time, diagnostic tests, including the polymerase chain reaction, based on the identification of antigens or DNA of B. burgdorferi lack sufficient specificity or sensitivity to be clinically useful (3).

Early and uncomplicated infections in children and adolescents usually respond well to orally administered antibiotics (3,4,6). Treatment of Lyme disease is outlined in Table 1. Parenteral antibiotics are generally recommended for treating meningitis, carditis, later-stage neurologic Lyme disease, and complicated Lyme disease arthritis. Late, complicated Lyme disease may respond slowly or incompletely, and more than one antibiotic treatment course may be required to eliminate active infection (2).

Table 1. Treatment of Lyme Disease (3)

Stage 1 - Early localized disease (EM):

Children <9 years old: amoxicillin, 50 mg/kg/day po divided tid (maximum dose 500 mg/dose) for 21days.

Children ≥9 years old: doxycycline, 100 mg po bid for 21 days. Alternatives for those who cannot take amoxicillin or doxycycline include: cefuroxime axetil, 30-50 mg/kg/day po divided bid (maximum dose 500 mg/dose) for 21 days, or erythromycin, 30-50 mg/kg/day po divided qid (maximum dose 250 mg/dose) for 21 days.

Stage 2 - Early disseminated disease:

Uncomplicated: Treat as for EM

Bell's palsy or other cranial nerve palsy: Treat as for EM, but for 21-30 days. Do not use corticosteroids.

Carditis: Treat as for late neurologic disease.

Meningitis: Treat as for late neurologic disease

Stage 3 - Disseminated disease:

Neurologic disease with isolated cranial nerve palsy: Treat as for EM but for 21-30 days.

Other: ceftriaxone 50-80 mg/kg/day in a single dose (maximum dose 2 g) for 14-21 days IV or IM; or penicillin G, 200,000-400,000 units/kg/day (maximum 20 million units/day) divided q 4 hrs, for 14-21 days IV.

Arthritis: Initial treatment same as for EM except treat for 30 days. If symptoms recur or fail to resolve after 2 months, then treat as for late neurologic disease. Some experts give a second course of oral antibiotics before using a parenteral agent.

The prognosis for Lyme disease in children and adolescents is excellent. Gerber et al. (6) reported a prospective, longitudinal, community-based cohort study of children with Lyme disease in southeastern Connecticut which studied 201 children enrolled over a period of 20 months, with a mean age of 7 years and a range of 1 to 21 years. All but 3 of the 201 patients were treated for 2 to 4 weeks with conventional antibiotic therapy, which was administered orally in 96% of cases. All had prompt clinical responses. After 4 weeks, 94% were completely asymptomatic. At follow-up, a mean 25.4 months later, none of the patients had evidence of either chronic or recurrent Lyme disease. Six patients subsequently had a new episode of EM. No patient progressed from early to late disease.

Parents may fear that their children and adolescents will acquire complications from Lyme disease that are debilitating, chronic, or fatal (6). They may question whether orally administered antimicrobials can be as effective as intravenously administered antimicrobials. In addition, if a child or adolescent later has vague, nonspecific symptoms after completing an appropriate course of antimicrobials, parents often worry that the antimicrobial therapy has been inadequate and request that additional antimicrobial therapy be prescribed. The information gathered by Gerber et al. can be used to reassure parents that Lyme disease in children and adolescents has an excellent prognosis and responds well to appropriate antimicrobial therapy.

Prevention is best achieved by avoidance of tick habitats. Whenever possible, persons should avoid areas that are likely to be infested with ticks, particularly in spring and summer when nymphal ticks feed. Ticks favor a moist, shaded environment, especially that provided by leaf litter and low-lying vegetation in wooded, brushy or overgrown grassy habitats (1).

Persons who are exposed to tick-infested areas should wear light-colored clothing so that ticks can be spotted more easily and removed before becoming attached. Wearing long-sleeved shirts and tucking pants into socks or boot tops can help keep ticks from reaching the skin. Applying insect repellents containing DEET (n,n-diethyl-m-toluamide) to clothes and exposed skin, and applying permethrin, which kills ticks on contact, to clothes, should also help reduce the risk of tick attachment. Because transmission of B. burgdorferi from an infected tick is unlikely to occur before 36 hours of tick attachment, daily checks for ticks and their prompt removal will help prevent infection (1).

The number of ticks in endemic residential areas can be reduced by removing leaf litter, brush, and woodpiles around houses and at the edges of yards, and by trees and brush to admit more sunlight, thus reducing deer, rodent, and tick habitats. Tick populations have also been reduced by applying pesticides to residential properties.

In general, antibiotic prophylaxis after a tick bite is not recommended. Persons who are bitten by a deer tick should remove the tick and seek medical attention if any of the signs and symptoms of Lyme disease develop (1,4).

A vaccine consisting of recombinant B. burgdorferi outer-surface lipoprotein A (OspA) with adjuvant (LYMErix) was licensed by the U.S. Food and Drug Administration for use in the United States in 1998. A placebo-controlled trial of the vaccine revealed that pain at the injection site was the most common side effect, reported by 24% of vaccine recipients vs. 8% of controls (7). The efficacy of the vaccine in protecting against symptomatic Lyme disease was 49% in the first year (after the first 2 doses) and 76% in the second year (after the third dose). Vaccine efficacy in preventing asymptomatic B. burgdorferi infection was 83% in the first year and 100% in the second year (7).

The cost effectiveness of vaccinating against Lyme disease has been analyzed by Meltzer et al. (8). A single answer regarding the cost effectiveness of vaccinating a person against Lyme disease cannot be calculated. The tables and figures in the study by Meltzer et al., also reprinted in the MMWR (1), will assist physicians, health care decision makers, and public health authorities to determine the cost effectiveness of vaccination for their specific situations.

Assessing the risk for Lyme disease (1) This is primarily determined by the following:

1. Density of vector ticks in the environment, which varies by place and season.
2. Prevalence of B. burgdorferi infection in vector ticks.
3. Extent of person-tick contact, which is related to the type, frequency, and duration of a person's activities in a tick-infested environment.

Questions

1. True/False: Over 90% of children with Lyme disease can be treated successfully with oral antibiotics.
2. True/False: Children with Bell's palsy should be treated with corticosteroids.
3. True/False: Multiple EM lesions are a sign of late disseminated Lyme disease.
4. True/False: Lyme vaccine is recommended for persons aged 15-70 years whose exposure to a tick-infested habitat is frequent and prolonged.
5. True/False: If a patient has an EM lesion, a diagnosis of Lyme disease can, and should, be made without serologic testing.
6. True/False: Most patients with Lyme disease do not recall having had a tick bite.
7. True/False: Patients with uncomplicated early disseminated disease should receive 30 days of antibiotics.
8. True/False: Lyme vaccine is a live-virus vaccine.
9. True/False: Lyme disease occurs most commonly in spring and summer, when nymphal ticks feed.
10. True/False: Lyme serology is so highly specific that positive results always predict the presence of Lyme disease, even in patients at low risk for the disease.
11. True/False: The number of cases reported annually has increased approximately 25-fold since national surveillance was begun in 1982.

Answers to questions

1. True.
2. False. Bell's palsy due to Lyme disease should NOT be treated with corticosteroids.
3. False.
4. True.
5. True.
6. True.
7. False.
8. False.
9. True.
10. False. Positive Lyme serology in low risk cases are usually false positives.
11. True

Chapter VI.28. Leptospirosis
Selina S.P. Chen, MD, MPH

A 14 year old male, previously healthy, presents to the emergency department with a one week history of fever, malaise, abdominal discomfort, calf pain and a mild sore throat. He denies any cough, hemoptysis, dyspnea, chills, night sweats, anorexia, nausea, vomiting, or dysuria. His urine output is good. There is no history of trauma, blood transfusions, or recent travel.

He lives with his parents. His father is a fisherman and his mother is a housewife. He is in the 9th grade with a 3.1 GPA. He is the captain of the school swim team. He also swims in streams and canals. He denies substance abuse and sexual activity.

Exam: VS T 38.4C, P 110, RR 18, BP 130/80 mm Hg. Height and weight are at the 50th percentile. He is alert in no acute distress. He is noted to have a moderate conjunctival suffusion (redness of the conjunctiva), with scleral icterus. His pharynx is injected, but his tonsils are not enlarged. His neck is supple with 1 cm anterior lymphadenopathy. Heart is regular with no murmur. His lungs are clear. His abdomen has normoactive bowel sounds with tender hepatomegaly; but no rebound or guarding. His extremity muscle strength is 4/5. His lower extremity muscles are tender to palpation. Homans sign is negative. No nodules are palpable.

Labs: WBC 9,000 with 80% polymorphonuclear leukocytes, hemoglobin 14 g/dL, platelet count 60,000. Coagulation times are normal. BUN 70 mg/dL, creatinine 3 mg/dL, total bilirubin 10 mg/dL, direct bilirubin 8 mg/dL, AST 80 UI/L, ALT 70 U/L. CPK 1,800 UI/L. UA shows ketones >160mg/dL, >100 red blood cells per high-powered field. No pyuria, organisms or casts are seen on UA. Chest and abdominal radiographs are normal.

He is admitted to the hospital and started on IV penicillin empirically for possible leptospirosis. Culture and serology studies are pending.

Leptospirosis (from Greek leptos, meaning "fine," and speira, meaning "a coil") is a zoonosis, which was first discovered as a disease of sewer workers by Landouzy in 1883. However, Adolf Weil of Heidelberg reported the clinical entity of fever, jaundice, hemorrhage, and renal failure in 1886. The causative organism was independently isolated in 1915 by German and Japanese investigators. The cause of many diseases was then discovered to be due to leptospira species. These diseases include pretibial fever, swineherd's disease, canefield fever in Australia, seven-day fever in Japan, swamp or mud fever in Europe, and Fort Bragg fever in the United States. The same Japanese investigators shortly discovered the role of rats as carriers. Rats are the most common reservoirs; however, many mammals have since been identified as reservoirs, especially cattle and feral pigs in Hawaii. Spread of leptospirosis can occur by contact with urine, blood or tissues from infected persons. The organisms enter the body through breaks in the skin or through mucous membranes. Infection is commonly acquired by bathing in contaminated water or by drinking contaminated water.

Leptospirosis presents with great clinical variability from a mild flu-like illness to an acute life-threatening condition, known as Weil's syndrome. Two major clinically recognizable syndromes are observed: anicteric leptospirosis (90%) and the more severe and potentially lethal form, icteric leptospirosis or Weil's syndrome (10%). The incubation period lasts 1-2 weeks.

Each syndrome has two distinct phases: the septic phase and the immune phase. The septic phase lasts 4-7 days, consisting of a flu-like syndrome. Leptospira can be found in the bloodstream and cerebral fluid. The immune phase lasts 4-30 days, consisting of aseptic meningitis, uveitis, iritis, rash, hepatic, and renal involvement. Leptospira can then be found in the urine and aqueous humor.

In anicteric leptospirosis, the septic phase is characterized by fever, headache, abdominal pain, anorexia, nausea, vomiting, and myalgia. The most common physical finding is conjunctival suffusion (reddening of the eye surface) without purulent discharge. Other signs include maculopapular skin rashes, pharyngeal injection, lymphadenopathy, hepatomegaly, and splenomegaly. The immune phase is characterized by less prominent fever, more intense headache, aseptic meningitis, conjunctival suffusion, uveitis, hepatosplenomegaly, rash, and pulmonary involvement.

Icteric leptospirosis, previously known as Weil's syndrome, is a more serious and potentially fatal syndrome. The septic and immune phases are not as distinct. The septic phase resembles anicteric leptospirosis. The immune phase is characterized with hepatorenal and vascular dysfunction. Jaundice and azotemia may develop.

Most cases of leptospirosis are self-limited, but complications include uveitis, renal failure, hemorrhage, DIC, acute respiratory distress syndrome, myocarditis, and rhabdomyolysis. Liver failure is generally reversible. In the absence of jaundice, the disease is rarely fatal. Oliguria is the only independent factor which adds to mortality risk. Other risk factors include dyspnea, alveolar infiltrates on chest radiography, repolarization abnormalities on electrocardiogram, and leukocytosis. Deaths have been attributed to myocarditis, irreversible septic shock, acute respiratory failure, and multiple organ failure.

Routine laboratory findings in leptospirosis are often non-diagnostic. CBC often reveals normal leukocyte counts (usually <10,000, but may range between 3,000 to 26,000), with neutrophilia in two-thirds of patients, and an elevated erythrocyte sedimentation rate. Anemia occurs with later presentations. Thrombocytopenia is seen most commonly in patients with azotemia. Urinalysis may show microscopic hematuria, proteinuria, pyuria, and granular casts. Aseptic meningitis is the hallmark presentation of the immune stage of anicteric leptospirosis. CSF examination shows a pleocytosis (<500) with an early neutrophilic or lymphocytic and late mononuclear cell predominance, normal glucose, and mildly elevated protein (50-110 mg/dL).

Jaundice is only observed in patients with Weil's syndrome. These patients can develop hepatic and renal dysfunction and hemorrhage. Serum bilirubin is usually <20 mg/dL, but can reach up to 60-80 mg/dL, predominantly as conjugated bilirubin. Liver function test can be elevated twofold to threefold. Hypoprothrombinemia occurs in a minority of patients. Myositis with elevated creatinine phosphokinase occurs in half of the patients.

Chest radiographs may reveal small nodular densities that can progress to infiltrates or consolidation. Pathologically, infiltrates are caused by hemorrhagic pneumonitis.

The diagnosis of leptospirosis is confirmed by isolation of the organism from any clinical specimen or seroconversion or fourfold increase in antibody titers. Leptospira can be cultured with special media from blood or CSF in the first 10 days and urine cultures are positive during the second week of illness and remain positive for up to 30 days after the resolution of symptoms. Growth in culture requires special semisolid, protein-supplemental media and takes at least one week (up to three months). Therefore, the diagnosis is made more frequently by serologic testing. A number of serologic tests are employed including micro-agglutination test (MAT), macroscopic agglutination test, indirect hemagglutination, and ELISA. Although MAT is considered the gold standard, it is not readily available in many institutions. ELISA is typically first performed and if suggestive, MAT can then be sent to the CDC in Atlanta. Newer studies utilizing polymerase chain reaction (PCR) are being investigated.

Differential diagnoses include dengue fever, hemorrhagic yellow fever, malaria, influenza, Louse-borne epidemic relapsing fever, tick-borne endemic relapsing fever, arthropod-borne and rodent-borne pathogens. Although dropped from the list of national notifiable diseases since 1994, leptospirosis remains a reportable illness in Hawaii.

Penicillin or tetracycline-based antibiotics, preferably doxycycline, are the antibiotics of choice even when treatment is delayed. In less ill patients, an oral dose of doxycycline for one week shortens the course of early leptospirosis. Intravenous penicillin used in severely ill patients reduces the duration of fever and renal dysfunction. In the most severe forms, patients must be admitted to an ICU for supportive therapy and close observation. Close monitoring and management of electrolytes, dehydration, hypotension, and hemorrhage are the mainstay of therapy. Although renal failure often resolves spontaneously, some patients may require temporary hemodialysis. Administration of vitamin K can help correct hypoprothrombinemia.

Doxycycline can prevent infection; however, exposure is difficult to predict. Prevention is best accomplished by effective rat control and avoidance of known contaminated water sources or infected urine.

Questions

1. The most specific physical finding of leptospirosis include:
    a. fever
    b. conjunctival suffusion
    c. renal failure
    d. myalgia

2. More characteristic findings in the immune phase of anicteric leptospirosis include:
    a. fever
    b. jaundice
    c. renal failure
    d. aseptic meningitis

3. Good prognostic factors for the patient in our case include all of the following, except:
    a. good urine output
    b. normal leukocytes
    c. normal coagulation tests
    d. no infiltrates on chest radiography

4. Leptospira are best cultured from:
    a. blood
    b. plasma
    c. urine
    d. CSF
    e. none of the above

5. Therapy of leptospirosis may include all of the following except:
    a. alkalinization of urine
    b. supportive therapy
    c. doxycycline
    d. penicillin

6. Which clinical factor best distinguishes the life threatening form of leptospirosis from the more common self-limited form of leptospirosis?
    a. azotemia
    b. pneumonia
    c. meningitis
    d. dehydration
    e. jaundice

Answers to questions

1.b, 2.d, 3.c

4.e. None of the above. Leptospira are difficult to culture. Culture requires special laboratory techniques not available at most clinical labs. Thus, the diagnosis is usually confirmed by serology.

5.a

6.e. Jaundice indicates icteric leptospirosis, which is a more serious condition which has a higher mortality rate. Azotemia is an additional marker of severity.

Chapter VI.29. Cat Scratch Disease
Judy Makowski Vincent, MD

A four year old girl presents to the pediatric clinic with a chief complaint of a slowly enlarging mass in her right armpit for the past two weeks. She has had no fever, but has had some loss of appetite. The mass was initially small and did not hurt; however, it has now grown to the size of an orange and has become painful. She cannot lower her arm due to the pain from the mass, and she carries her arm extended at 90 degrees to her body. Movement of her arm exacerbates the pain. She does have a 3 month old kitten at home that she "rescued from a sewer". It was covered with fleas when she found it. It playfully bites and scratches her. Three weeks ago it scratched her right thumb. The scratch healed, but a small "wart" has developed in the line of the scratch. There is a scab on the wart and her mother has tried to squeeze the wart, but no pus has come out.

ROS: Non-contributory. No cough. No weight loss. No change in activity other than being unable to use her right arm well.

Exam: VS T 37.2, RR 18, P 102, BP 100/60. She is alert and very cooperative. HEENT is negative. Neck is supple without adenopathy. Chest is clear. Heart regular without murmur. Abdomen exam is normal without hepatosplenomegaly. Neurologic exam is normal (mental status, gait, strength, and reflexes). Her right axilla reveals an 8x8 cm firm, tender, mobile, warm, non-erythematous, non-fluctuant mass that is consistent with an enlarged axillary lymph node. Her right thumb has a 1 cm linear, non-inflamed, healing scar that is consistent with a kitten scratch. In the middle of the linear scar, there is a 3 mm brownish-red papule with a small central crust.

Lab: CBC WBC 8.0, 62% segs, 10% bands. Ultrasonography of the mass reveals that it is a matted group of about 5 lymph nodes which are mostly solid in appearance. There is evidence of a small amount of necrosis at the periphery of one of the lymph nodes.

Impression: Lymphadenopathy due to cat scratch disease.

Clinical course: Because the axillary node is enlarged and painful, you elect to treat her with oral azithromycin at a dose of 10 mg/kg/day for the first day and 5 mg/kg/day for the next 4 days. Serology for Bartonella henselae is obtained, and the result returns one week later with an IgG of 1:512 (a positive result is a value greater than 1:64). The node remains the same size for a week and then begins to get smaller. The adenopathy resolves in one month.

It is now known that cat scratch disease (CSD) is a multisystem disease caused by a small Gram negative bacillus named Bartonella henselae, formerly known as Rochalimaea henselae. As early as 1932, physicians in the United States recognized patients with CSD, but the cause of the disease eluded detection until 1983 when researchers at the Armed Forces Institute of Pathology at Walter Reed Army Medical Center in Washington, D.C. detected the organism in lymph node tissue from patients with clinical CSD. Identification of the causative organism has allowed researchers to identify the epidemiology and transmission of the disease, identify atypical forms of CSD, develop serologic diagnostic tests, and perform placebo-controlled treatment trials.

Jameson et al, recently reported the results of a survey of 33 geographic regions throughout North America and showed that increasing prevalence of antibody to B. henselae in cats paralleled increasing climatic warmth and annual precipitation (1). Seroprevalence was highest in regions with warm humid climates which also have a higher incidence and degree of cat flea infestation. The southeastern United States, Hawaii, coastal California, the Pacific Northwest and the south central plains had the highest average B. henselae antibody prevalences. Alaska, the Rocky Mountains-Great Plains region, and the Midwest had the lowest average B. henselae antibody prevalences.

CSD is generally a benign, self-limited disease in immunocompetent hosts. Although CSD may be associated with significant morbidity, no deaths have been reported in immunocompetent persons with typical CSD proven by positive skin test, positive serology, or by DNA testing (2). Deaths have been reported rarely in immunocompromised patients. Several members of a family may develop clinical CSD, whereas some have asymptomatic infection as evidenced by development of B. henselae antibody. Infection appears to confer lifelong immunity, because reports of recurrences of clinical CSD are rare (2).

B. henselae bacteremia occurs in flea-infested well appearing kittens usually less than one year old, and less commonly in older cats. The organism is transmitted among cats by the cat flea. It is transmitted to humans by a cat scratch, bite or other intimate contact. The pathologic response to infection with B. henselae varies significantly with the status of the host immune system. In immunocompetent hosts, the response is granulomatous and suppurative. In immunocompromised hosts, the response is vasculoproliferative (2).

Organisms are not seen in routinely stained tissue preparations. In Warthin-Starry or Brown-Hopp's tissue-stained CSD lymph node preparations, Gram negative argyrophilic (i.e., it takes up silver stains, so it shows up better with silver staining) non-acid-fast, pleomorphic bacilli may be seen in the tissues. The bacilli are very small and are seen primarily in the walls of blood vessels, in macrophages lining the sinuses, in or near germinal centers, and in microabscesses. Here they may appear as single organisms, or in chains, or clumps.

B. henselae may be grown in standard microbiology laboratories by plating the sample (patient's lymph node aspirate or blood from suspected-bacteremic kittens) directly onto chocolate agar, then streaked and incubated under 6% CO2 at 35 degrees C for 60 days. The organism is fastidious in its growth. Therefore the plates should be left in the CO2 incubator and not examined or exposed to room air for the first 14 days. After 14 days, B. henselae manifests as grayish-yellow pinpoint-sized colonies that are best seen when the plate is held tangentially to the light. If no growth occurs within 60 days, the results may be interpreted as negative.

CSD occurs as both typical and atypical disease (2). Typical CSD in an immunocompetent host is manifested by a characteristic and highly predictable clinical course. In nearly all cases, patients give a history of a scratch, bite, contact or intimate association with a cat, most often a newly acquired kitten. In some patients, a round, red-brown, nontender papule develops in the scratch line after 3 to 10 days. It may vary in size from 1 to several millimeters and may persist for only a few days or for as long as 2 to 3 weeks. In the next 1 to 2 weeks, one or more regional lymph nodes gradually enlarge. The most commonly involved lymph nodes are the anterior cervical, axillary, inguinal, femoral, preauricular, supraclavicular, and epitrochlear nodes; however any node can be involved if it is in the path of lymphatic drainage from a site that has been inoculated with B. henselae.

CSD lymph nodes tend to be large with an average diameter of 4 to 6 cm at the time of maximum size, but can be as large as 10 to 13 cm. After 1 to 2 weeks of growth, they remain the same size for 2 to 3 weeks and then resolve over an additional period of 2 to 3 weeks, with the usual course of the disease lasting for 2 to 3 months. Some cases are more severe and more protracted, lasting up to 6 to 7 months. Although most of the nodes are moderately tender, some are nontender. Most patients with typical CSD remain afebrile and are not ill-appearing. Some patients experience anorexia, malaise, headache, arthralgia, and abdominal, neck, back or extremity pain.

A very useful clinical feature that distinguishes CSD from acute pyogenic lymphadenopathy, is that CSD lymphadenopathy only rarely develops overnight. In our experience, most patients with CSD tend to seek medical care after lymphadenopathy has been present

for 7 to 14 days. In contrast, most patients with acute pyogenic adenopathy present for care within 24 hours of onset of the adenopathy. CSD lymphadenopathy is unilateral and isolated to a regional group of lymph nodes in immunocompetent patients. Therefore, if a patient has disseminated lymphadenopathy, or bilateral lymphadenopathy, a diagnosis other than CSD should be sought.

Late in the course of CSD, about 10% of lymph nodes develop overlying erythema and fluctuation and may suppurate if they are not drained. Needle aspiration usually provides satisfactory drainage for suppurative CSD. If pus reaccumulates, the nodes may require open surgical drainage. The incision should be left open, with closure by granulation. Chronic fistulous tracts do not develop if CSD lymph nodes are incised and drained. This is a common misconception. In Hawaii where CSD is highly prevalent, we have followed many patients with large CSD-infected lymph nodes that progressed to suppuration, reaccumulated after needle aspiration, and required open surgical drainage. All CSD-infected lymph nodes treated with incision and drainage have healed completely without fistulae.

CSD can be diagnosed reliably with serologic testing. In a seroepidemiologic study of CSD, rigid criteria were applied for the clinical diagnosis of CSD, and all of 38 patients had positive serology (sensitivity 100%), compared to only 1 of 48 controls with no direct cat exposure in the previous 2 years who had positive serology (specificity 98%) (3). Serology was performed by the CDC. In this study, 24 of 38 patients (84%) had positive titers in their initial serum obtained 1 to 2 weeks after onset of clinical CSD; the other 6 patients (16%) developed positive titers in serum obtained 4 to 8 weeks later.

Prior to the development of a confirmatory serologic test for CSD, intradermal skin testing was used for the diagnosis of CSD. However with the development of specific laboratory tests to confirm the diagnosis, the CSD skin test is no longer recommended (which was less sensitive, less specific, poorly standardized, not readily available, not approved by regulatory authorities, and is considered by some to be unsafe).

Primary care physicians should be familiar with the atypical forms of CSD, as well as the typical form. A fairly common presentation of atypical CSD is Parinaud's oculoglandular syndrome (POGS), which consists of unilateral conjunctivitis with adjacent preauricular lymphadenopathy. The palpebral conjunctivae of the involved eye displays a characteristic granulomatous lesion that measures 2 to 3 mm to >1 cm in diameter, or there may be a scratch near the eye. Although POGS can be caused by other infections, including tuberculosis, tularemia, syphilis, and lymphogranuloma venereum, it has become well established that POGS is a common form of atypical CSD (2). Infection of the eye with B. henselae may be contracted with inoculation of the organism indirectly into the eye, rather than by direct contact through a scratch, as in typical CSD. POGS is a predictable self-limited infection with a good outcome in essentially all cases.

Hepatosplenic CSD is an atypical form of CSD which occurs in immunocompetent patients who present with fever of unknown origin (4). These patients have daily high fevers, often in the range of 40 degrees (104 degrees F), and some patients will have been febrile for a month before the diagnosis is finally made. Many of these patients complain of abdominal pain. In many cases, the care provider has neglected to ask about cat exposure until the patient has been febrile for several weeks. Physical examination is remarkably benign. Although these patients usually have a few well-healed cat scratch scars, these are often overlooked. Only about half of these patients have lymphadenopathy. They do not have hepatosplenomegaly or jaundice, and liver function tests are usually normal. The ESR may be moderately elevated, in the range of 40 to 70 mm/hr, but other screening laboratory tests are usually normal. Diagnosis is made by the presence of lytic lesions in the liver and/or spleen on ultrasound or CT scan, and B. henselae titers are positive, often markedly so. Fever usually resolves with a day or two of starting treatment with an intravenous aminoglycoside; however fever may not resolve for a month, even with adequate treatment (2).

CSD encephalopathy (CSDE) was first reported in 1952 and has recently been extensively reviewed (2). Convulsions occur in about half of cases, and may last only a few minutes or may last 3 to 4 hours, requiring intubation and intensive care. Another neurologic form of atypical CSD is a distinctive type of neuroretinitis, called Leber's stellate neuroretinitis. It presents with painless unilateral, rarely bilateral, loss of vision with central scotomata, optic disc swelling, macular star formation and complete recovery of vision within 1 to 3 months (2).

Both CSDE and CSD neuroretinitis are unusual forms of atypical CSD and are not well known to the average clinician. Immunosuppressed patients with B. henselae infection may have widespread and occasionally fatal disease (2). As these clinical syndromes become better known, along with the knowledge that laboratory tests are now available to confirm the diagnosis, these and other atypical manifestations of CSD may become more widely appreciated.

Typical CSD is a self-limited disease in immunocompetent hosts and will usually resolve spontaneously in 1 to 3 months. Recently we performed the first double-blind placebo-controlled antibiotic trial for treatment of CSD at Tripler Army Medical Center (5). Lymph node volume was measured by clinical measurement with palpation and a tape measure and by ultrasonography. This study showed that 7 of 14 (50%) azithromycin-treated patients had significant resolution of lymphadenopathy at 30 days compared to 1 of 15 (7%) of placebo-treated controls (p=0.026), as measured by ultrasonography. It should be noted that the two treatment groups had no difference in lymph node volume until the fourth week of treatment, and that clinical response at 30 days was only observed in 50% of patients in the azithromycin group. Therefore if a clinician makes a clinical diagnosis of CSD and elects to offer treatment with azithromycin (standard 5 day course), he or she should instruct the patient not to expect overnight resolution of symptoms. Azithromycin-treated patients have a 50% likelihood of having significant lymphadenopathy for 2 months or longer, despite treatment (5).

B. henselae has been reported to be sensitive to gentamicin in vitro, and anecdotal reports have supported its use in hepatosplenic disease; however the only placebo-controlled efficacy study has been with azithromycin for typical CSD lymphadenopathy.

The only way to prevent CSD is to avoid exposure to cats, particularly flea-infested cats that have had exposure to other cats, and kittens less than one year of age. There is currently no CSD vaccine for cats or humans, and antibiotic prophylaxis of humans or cats is not recommended.

Questions

1. True/False: Cat scratch disease is usually transmitted by flea-infested kittens.
2. True/False: Cat scratch disease is more common in dry, desert-like areas, as compared to humid climates.
3. True/False: Adenopathy due to cat scratch disease usually develops rapidly, within a few hours.
4. True/False: When patients have hepatosplenic cat scratch disease, their liver function tests are always abnormal, and they always have concomitant lymphadenopathy.
5. True/False: Azithromycin is the only antibiotic that has been shown to be effective in the treatment of typical CSD lymphadenopathy in a double-blind, placebo-controlled trial.
6. True/False: Serology is the diagnostic test of choice for cat scratch disease.

Answers to questions

1. True.
2. False. Cat scratch disease is more common in humid climates because humidity is necessary for the existence of cat fleas.
3. False. Cat scratch disease adenopathy develops slowly, usually over 10-14 days.
4. False. With hepatosplenic CSD, LFTs are usually normal, and only 50% of patients have concomitant lymphadenopathy.
5. True.
6. True.

Chapter VI.30. Malaria
M. Scott Hickman, MD

This is a 10 year old male who presents to the ER with a two-month history of fever. The fever occurs every 48 hours, reaching up to 40 degrees centigrade (104 degrees F), and is often associated with a headache. Before the onset of fever, he experiences chills, nausea and vomiting. The fever resolves in two hours, followed by diaphoresis and fatigue. In between these episodes he feels well. He denies any abdominal pain, hematuria or any neurological symptoms such as a change in consciousness or seizure activity. His travel history is significant for a one month trip to Africa with his family eight months ago. His vaccinations are up-to-date, and his father states that he took prophylactic chloroquine before, during and after his trip, as well as avoiding mosquito bites at night.

Exam: VS T 38.0, P 89, RR 16, BP 100/60. Height and weight are at the 25th percentile. He is alert and active in no distress. Skin exam shows no jaundice. HEENT, neck, heart, lung and neurologic exams are normal. His abdomen exam is notable for moderate splenomegaly.

Labs: WBC 10,000, 68% segs, 20% lymphs, Hgb 10, Hct 29, platelet count 140,000, reticulocyte count 1.8%. A blood smear shows mature trophozoites and schizonts, enlarged erythrocytes and Schuffner dots, with no banana shaped gametocytes. Parasitemia is estimated at 7%.

He is hospitalized for malaria. During the night he develops a fever of 40.5 degrees. Blood cultures are negative. Anti-malarial treatment is begun with mefloquine. He responds clinically in 24 hours to treatment, with a drop in parasitemia to 5%. Primaquine is also begun for the suspected hepatic source of presumed Plasmodium vivax.

Malaria is an infectious disease caused by a protozoa (single-celled eukaryotes). It impacts an incredible toll on humanity, with an estimated 300 to 500 million world-wide cases occurring annually (1). There are an estimated 1 million deaths, most of which occur in children (2,3) between the ages of 1 and 5 years (1,4) in Africa (5). In the United States, 1000 cases of malaria are diagnosed each year with 5 to 10 deaths (6). Patients usually have traveled to endemic areas, or they are recent immigrants from these areas. In addition, physicians are often asked for advice on prophylaxis for travelers visiting malaria endemic countries.

There are four Plasmodium species of malaria in humans: P. falciparum, P. vivax, P. malariae, and P. ovale. P. vivax is the most common. P. falciparum is the most dangerous being associated with cerebral malaria. P. falciparum is different from other species in that it can cause infected red blood cells to adhere to the capillary endothelium, enabling it to evade destruction by the spleen and also causing microvascular obstructive disease.

The malaria life cycle begins when the Anopheles mosquito vector takes a blood meal (a vector transfers the infectious agent from one host to another). By doing so it releases malarial sporozoites from its salivary gland into the blood of the human host. In the pre-erythrocytic phase of the cycle, these sporozoites travel in the blood and invade hepatocytes in the liver. Here the sporozoites can take two paths. One path for sporozoites in the liver is to form trophozoites, which then undergo nuclear division to form into schizonts. Schizonts are factories of merozoites, with each schizont producing 10,000-30,000 merozoites for each infected hepatocyte. This amplifies the infectious process. The liver cells become overloaded with merozoites and burst, with merozoites spilling over into the blood stream. Merozoites then infect erythrocytes once they are released into the circulation. Hypnozoites, the other path that sporozoites can take in the liver, are found in only P. vivax and P. ovale. Hypnozoites can remain dormant in the liver for 6-11 months. When hypnozoites subsequently mature into schizonts, they produce a delayed infection and will also release merozoites into the blood to infect erythrocytes. Thus, travelers who have taken prophylactic malarial agents, as in the case above, can still become infected with malaria if the dormant liver stage is not treated for these two species. This occurs because prophylactic agents such as chloroquine or mefloquine are ineffective against the hypnozoites.

After the merozoite leaves the hepatocyte, the erythrocytic cycle begins as merozoites invade erythrocytes. The merozoite also forms into a schizont in the erythrocyte. The schizont undergoes nuclear division and merozoites are formed from this RBC schizont. The erythrocyte lyses, with merozoites released into the blood stream ready to infect other erythrocytes. The process of red blood cell invasion, merozoite formation, and erythrocyte rupture takes two to three days depending on the malarial species.

In addition, some intraerythrocytic parasites develop into sexual (gametocyte) forms, which is necessary for the completion of the sexual phase of the life cycle in the mosquito. The cycle is completed when the male and female gametocytes are taken up by the female anopheline mosquito during a blood meal from an infected individual. Fertilization takes place in the stomach of the mosquito by the formation of a zygote. This zygote divides until a oocyst develops, which eventually ruptures and releases sporozoites which find their way to the salivary glands of the mosquito. Here the sporozoites remain, ready to reinfect another human and begin the cycle once again.

P. falciparum is the most severe infection of the different plasmodium species, and it produces a microvascular disease, unlike the other species which do not. Erythrocytes infected with P. falciparum adhere to the endothelial lining of small blood vessels, causing blockage and a decrease in tissue perfusion with a resulting metabolic acidosis. Lysis of erythrocytes and the release of merozoites causes an immune response with the production of cytokines (TNF-alpha), giving rise to the characteristic fever of malaria. The anemia is caused by the lysis of red blood cells as well as by the suppressive effect that TNF- alpha has on erythropoiesis. Hypoglycemia is often seen in patients with P. falciparum. This is caused by the depletion of liver glycogen from decreased intake, glucose consumption by the parasites, and increased levels of TNF- alpha. The main organs involved include the brain, kidneys, liver, spleen, lung and GI tract, although any organ can be affected. The brain in cerebral malaria is edematous and hyperemic, with small blood vessels filled with parasitized erythrocytes (7), giving rise to the impaired consciousness and seizures of cerebral malaria. Renal failure secondary to tubular necrosis is due to increased circulating free hemoglobin (hemoglobinuria), as well as due to hypovolemia and microvascular disease. Excess hemoglobin that is spilled into the urine gives malaria one of its names: blackwater fever. The spleen, which is responsible for filtering out the deformed erythrocytes, is enlarged, congested, and at times may rupture. The liver also enlarges, as it too has reticuloendothelial function. Parasitized RBCs sequestered in the pulmonary vasculature can cause cough, respiratory distress and pulmonary edema. In the gastrointestinal tract, it can cause gastroenteritis.

Infected erythrocytes in the placenta can cause increased mortality, premature delivery and low birth weight. Congenital infections in newborns are also seen if erythrocytes cross the placenta. Anemia in the mother is further worsened by malaria. P. vivax, P. ovale and P. malariae do not cause a microvascular disease because they do not cause erythrocytes to adhere to vascular endothelial cells. They do cause hemolysis and an inflammatory response, giving rise to a less severe form of the disease than that seen with P. falciparum. Sickle-cell anemia, beta-thalassemia and glucose-6-dehydrogenase deficiency are thought to offer resistance to malaria in the heterozygote forms. This protection is believed to come from the shortened RBC life-span with increased RBC susceptibility to lysis from oxidative stress (interrupting the Plasmodium reproductive cycle) and the fact that the hemoglobin with these genetic variants denatures preferentially with malaria infection, releasing toxic forms of heme that damage the parasites. In addition, P. vivax requires the Duffy blood group antigen to bind to the RBC and cause an infection. West Africans and many Americans of African descent are often missing this blood group antigen, rendering them resistant to this species. Acquired resistance comes about with IgG and IgM, with IgG giving protection against merozoites, preventing them from invading susceptible erythrocytes. This immune response renders individuals resistant to symptomatic disease. They are not however immune, as their body still can harbor parasites even though they are non-symptomatic.

The clinical manifestations of fever coincide with the rupture of the red blood cells and the release of merozoites, stimulating the production of TNF-alpha. Different malarial species have different patterns of growth, with erythrocytic schizogony and the release of a brood of merozoites occurring approximately every 48 hours (called tertian malaria) for P. falciparum, P. vivax, and P. ovale, and 72 hours (called quartan malaria) for P. malariae. If there is more than one brood of parasites developing in the blood at one time, then the fever can occur daily, obscuring the diagnosis. P. falciparum in particular is known for causing any pattern of fever. The pre-erythrocytic phase is asymptomatic, as sporozoites are released from the mosquito and pass to the hepatocytes.

An attack classically starts with the "cold stage", with chills lasting from minutes to an hour. Nausea, vomiting and frequent micturition are often seen during this phase. Following the cold stage, the "hot stage" begins with fevers between 40 (104 F) to 41 (106 F) degrees C lasting between 2 to 6 hours, associated with a severe headache, tachycardia, delirium, epigastric pain, nausea, vomiting and diarrhea. Despite the high fever, there is minimal diaphoresis. After the hot stage, the third "sweating phase" is entered lasting 2 to 3 hours, with diaphoresis, resolution of the fever, and fatigue that gives way to sleep. In children less than 5 years of age, the signs may be non-specific: fever, vomiting, abdominal pain and diarrhea. Older children may only complain of fever, headache and joint pain. For these reasons, fever in a child that has visited or lives in a malaria endemic area is considered to be due to malaria until proven otherwise.

The clinical manifestations of cerebral malaria include altered consciousness, seizures, symptoms of raised intracranial pressure, opisthotonos, decorticate or decerebrate posturing, hypotonia and conjugate eye movements. It has a high case fatality rate (8). On physical exam, signs of anemia should be sought. Respiratory distress and splenomegaly may be present. Dehydration due to decreased PO intake and increased losses from diaphoresis or diarrhea can give rise to hypotension, tachycardia and shock.

Besides having 4 different species of malaria, there are also many strains of malaria, (except for P. malariae which has only one). This diversity makes vaccine development for malaria very difficult. As stated above, in areas where malaria is endemic, repeated infections cause the development of acquired immunity from symptomatic disease (they are still susceptible to asymptomatic parasitemia). For this reason, most cases of fatal malaria occur in the first 5 years of age in these areas. In contrast, in areas with no endemic infection (such as the United States), acquired immunity is not developed and fatal malaria can occur at any age.

Laboratory findings include a decreased hemoglobin, hematocrit, thrombocytopenia and increased bilirubin due to the lysis of red blood cells. Hyponatremia, hypokalemia, and hypercalcemia may be seen. Acute renal failure with increased creatinine, proteinuria and hemoglobinuria may be present. Diagnosis is made by examination of the thick and thin smears. Thick smears allow the detection of the parasite in small numbers, while the thin smear allows one to identify the species. Classically the ring form of P. falciparum is seen. Microscopic examination can give a quantitative value to the parasitemia, with more than 5% to 10% of erythrocytes being infected associated with high mortality rate. Following the percentage of infected erythrocytes serially, is useful to evaluate treatment. PCR and ELISA can also be used in the diagnosis.

P. falciparum differs from P. vivax and P. ovale in several ways (9):

	P.falciparum	P.vivax/P.ovale
Multiple infected erythrocytes:	common	rare
Mature trophozoites or schizonts:	absent	common
Schüffner dots:	absent	common
Enlarged erythrocytes:	absent	common
Banana-shaped gametocytes:	common	absent

The correct diagnosis of P. falciparum is important. Looking at the table above, you would expect the more severe infection of P. falciparum to have multiple infected erythrocytes, with the more mild infection of P. vivax and P. ovale to have rare infected erythrocytes. Mature trophozoites and schizonts are not seen with P. falciparum because they are sequestered in the peripheral microvasculature. P. vivax preferentially infects a reticulocyte, so infections with P. vivax show large erythrocytes. Schüffner dots are due to pigment accumulation in infected erythrocytes, and appear blue on microscopic examination. They are characteristic of P. vivax and P. ovale infections. P. falciparum can be distinguished by its early trophozoites called ring forms (signet-ring appearance), and by the sausage or banana shape of its gametocytes.

The differential diagnosis of malaria is broad, including leptospirosis, yellow fever, juvenile rheumatoid arthritis, Hodgkin's disease, brucellosis, borreliosis, pneumonia, meningitis, tuberculosis, influenza and bacteremia (9).

Uncomplicated malaria is defined as a child with fever and a positive blood smear, but without evidence of altered consciousness, hypoglycemia, respiratory problems, jaundice or severe anemia. Severe malaria includes the fever and positive blood smear as above, but also involves mental status changes, convulsions, hypoglycemia, acidosis, jaundice, weakness or parasitemia greater than 15%. Uncomplicated malaria can be managed on an outpatient basis for a child who has lived in an endemic area all of their life. The management of an infected patient who has visited an endemic area for the first time, or a patient with severe malaria, involves hospital admission. Patients suspected of having P. falciparum should always be hospitalized, with early initiation of therapy. Conventional treatment of dehydration, hypoglycemia, anemia, seizures, pulmonary edema and renal failure is required. The selection of an antimalarial depends on the species identified or suspected, the possibility of resistance, and the ability of the patient to take oral medications. Chloroquine is the drug of choice for plasmodia sensitive to this drug. For chloroquine-resistant P. falciparum, oral therapy includes quinine with pyrimethamine-sulfadoxine, tetracycline, doxycycline or clindamycin. Mefloquine is another alternative. Chloroquine-resistant P. vivax should be treated with mefloquine. Primaquine is effective against the liver forms of P. vivax and P. ovale. A new anti-malarial drug with fewer side effects than mefloquine is atovaquone/proguanil (Malarone). Exchange transfusion can be considered in patients with severe disease. Most patients treated with chloroquine respond within 24 hours, and usually recover by the third or fourth day (12). The case fatality rate for cerebral malaria even with optimal therapy, is 15-30%, with 10% of survivors of cerebral malaria having residual signs of ataxia, hemiparesis and spasticity.

Prevention involves an assessment of the risk of the country one is visiting, along with chemoprophylaxis and methods to limit mosquito bites by Anopheles (which feed primarily from dusk to dawn). Permethrin-impregnated mosquito nets, long-sleeve shirts, and 35% DEET repellant sprays, limit exposure to Anopheles. Chloroquine can be taken on a weekly basis for chemoprophylaxis. It is taken 2 weeks before departure (to monitor for side effects), continued for the duration of the trip, and 4 weeks after leaving the endemic area. It is the drug of choice for chemoprophylaxis because it is safe for all ages and during pregnancy. Mefloquine (taken once weekly) is used for areas suspected of having chloroquine-resistant P. falciparum (Southeast Asia, the Amazon region of South America, and sub-Saharan Africa). In patients weighing less than 15 kg or for pregnant women, chloroquine combined with proguanil can be used. Doxycycline is an alternative for those older than 8 years (10,11). A newer alternative is atovaquone/proguanil, but this must be taken daily.

Questions

1. The species of malaria associated with adherence to endothelial walls, cerebral malaria, and a high mortality rate is:
    a. P. falciparum
    b. P. vivax
    c. P. malariae
    d. P. ovale

2. The fever of malaria:
    a. can be tertian (occurring every 48 hours).
    b. can be quartan (occurring every 72 hours).
    c. occur with no pattern at all.
    d. all of the above.

3. The clinical manifestations of the cyclic fever of malaria are caused by the:
    a. pre-erythrocytic phase
    b. hepatic stage
    c. erythrocytic stage
    d. sexual stage

4. Liver hypnozoites (dormant form) can be effectively treated with:
    a. chloroquine
    b. mefloquine
    c. primaquine
    d. doxycycline

5. The pathogenesis of malaria can affect which of the following organ systems:
    a. liver
    b. brain
    c. lungs
    d. kidneys
    e. spleen
    f. GI tract
    g. all of the above

6. Prophylaxis for malaria includes all of the following except:
   a. chloroquine
   b. mefloquine
   c. permethrin impregnated mosquito nets
   d. 35% DEET
   e. avoiding mosquitoes during the day

Answers to questions

1. a. P. falciparum is unique among malarial species in that it has mechanisms to adhere to vascular endothelial walls. This produces a microvascular disease, leading to poor perfusion and metabolic acidosis. This hypoperfusion can affect almost any organ in the body, but this is of greatest significance in that it can cause cerebral malaria, which can cause a change in consciousness and seizures. Long-term affects due to cerebral malaria can also be seen. P. vivax is the most common form of malaria, but produces a more milder form of the disease.

2. d. The fever of malaria can produce any pattern of fever, with P. falciparum most known for its lack of recognizable fever patterns. Classically, the release of merozoites from red blood cells all in one group at similar times causes an inflammatory response, the production of TNF-alpha, and a characteristic pattern of fever depending on the particular species. The fever occurs approximately every 48 hours (called tertian malaria) for P. falciparum, P. vivax, and P. ovale, and 72 hours (called quartan malaria) for P. malariae.

3. c. The life cycle of malaria is very complex. It starts with malarial sporozoites being released from the anopheles mosquito. In the pre-erythrocytic stage sporozoites travel to the liver, with the patient being asymptomatic during this time. Sporozoites form schizonts, which eventually produce thousands of merozoites. These merozoites are released from hepatocytes, and infect red blood cells, giving rise to the erythrocytic stage of the life cycle. The erythrocytes burst after infection, releasing merozoites, which is the major cause of the cyclical fever. These merozoites can infect new blood cells, or form gametocytes. Male and female gametocytes are taken up by the mosquito, where they reproduce and form new sporozoites, completing the life-cycle during the mosquito's next blood meal.

4. c. Sporozoites infecting the liver can form into schizonts and can also form hypnozoites. These can remain dormant in the liver, causing an infection months later. The dormant liver-stage of the malarial life cycle, seen in P. vivax and P. ovale, is effectively treated with primaquine.

5. g. The microvascular disease of P. falciparum can affect almost any tissue of the body, giving rise to the many clinical features of malaria.

6. e. Prophylaxis for malaria includes using permethrin impregnated mosquito nets, avoiding mosquito bites using 35% DEET, and chemoprophylaxis most commonly with chloroquine or mefloquine. The anopheles mosquito usually bites from dusk to dawn, not during the day, and it is during these times that travelers should be particularly careful.

Chapter VI.31. Protozoans and Parasites
Loren G. Yamamoto, MD, MPH, MBA

A 2 year old boy from in a war refugee camp is treated for dehydration secondary to vomiting and foul diarrhea. After rehydration, the staff suspects that he may have Hirschsprung's disease based on his history and growth pattern. He is flown to your hospital for surgical evaluation. He is obviously malnourished and underweight, but he improves clinically. After eating lunch, the boy vomits and the nurses note the presence of several large worms in the vomitus. They later note that he has a visible worm in his stool. A stool sample is sent for ova and parasite analysis which identifies Giardia cysts and ascaris eggs. He is treated with albendazole which covers both the Giardia and ascaris.

Protozoans and parasites are less common in the United States. Many of them require fecal-oral transmission or vectors (insects and rodents). Proper public health measures which are taken for granted in the U.S. are responsible for minimizing our exposure to these infections. These measures include regulations and laws ensuring clean water, agriculture and livestock, proper food handling, sanitation (sewage and trash disposal), vector control (insects and rodents), and housing. American lifestyle factors including good nutrition, footwear and skin care also reduce the risk of infection.

Protozoans are eukaryotic large single celled organisms. Parasites are organisms which live in or on another organism, which would include viral and bacterial infections as well. However, the general understanding when one refers to parasites, is that these include "worms" such as roundworms and flatworms. Since many of these organisms are gastrointestinal, common presentation patterns include gastroenteritis, failure to thrive, weight loss, edema, and or abdominal discomfort. The immune system has a difficult time eradicating protozoans and parasites. Eosinophilia is often associated with parasites, but eosinophilia is only present in the presence of invasive worms.

Protozoans can be classified into ameba, flagellates and sporozoans. Pneumocystis used to be considered a protozoan, but it now classified as an opportunistic fungi.

Ameba include Entamoeba histolytica often called amebiasis, which classically causes bloody diarrhea (amebic dysentery), but it may also present with non-specific gastroenteritis, edema, failure to thrive or an amebic liver abscess. The diagnosis can be made by finding organisms in the stool or by serology. Naegleria fowleri is a rare and fatal infection. Naegleria live in hot springs, so most infections are acquired by swimming or diving in hot springs. Naegleria enter the body and infect the brain rapidly resulting in encephalitis, coma and death (often despite treatment).

Flagellates include giardia, trichomonas, trypanosomes and leishmania. Giardia lamblia causes diarrhea, malabsorption and abdominal discomfort. Giardia organisms are generally not found in stool samples, and Giardia cysts are only sometimes found in the stools. Giardia organisms were most commonly identified by having the patient swallow a gelatin capsule on a string which is then retrieved and analyzed. Giardia serology has now replaced these other methods of identifying giardiasis.

Trichomonas vaginalis (trich for short) is a sexually transmitted motile protozoan which causes vaginitis. Clinically, a pruritic vaginal discharge results, with or without dysuria. Motile protozoans are seen on a microscopy wet mount of the vaginal discharge. Males are often asymptomatic.

Trypanosomiasis can be of the African or the South American type. African sleeping sickness is caused by Tryp. brucei rhodesiense and Tryp. brucei gambiense, which are both spread by the biting tsetse fly vector. Symptoms of infection include fever, headache, malaise, rash, lymphadenopathy, etc. Spontaneous remission or coma and death may follow. American trypanosomiasis (also known as Chagas disease) is cause by Tryp. cruzi which is spread by the reduviid bug. Cardiomyopathy may classically result, but other presentations include malaise, fever, lymphadenopathy, encephalitis and death.

Leishmania infections are transmitted by sandfly vectors. Leishmania donovani causes visceral leishmaniasis (also known as kala-azar) which results in fever, malaise, lymphadenopathy, organomegaly, anemia and weight loss. Leishmania tropica cause cutaneous leishmaniasis. Leishmania braziliensis causes mucocutaneous leishmaniasis.

Sporozoans include cryptosporidium, plasmodium and toxoplasma. Cryptosporidium may be a contaminant in some water systems. It is resistant to chlorination, but many home filtration systems will filter out the cysts. Infection with cryptosporidium results in self limited diarrhea in healthy persons (no treatment required), but in immunocompromised individuals, it may cause fever, chronic diarrhea, weight loss, and death.

Malaria is caused by the various Plasmodium species (ovale, vivax, falciparum, malariae). Malaria is a complex infection which is described in a separate chapter. It is transmitted by anopheles mosquito vectors and it can be prophylaxed and treated to a limited extent with chloroquine and primaquine.

Toxoplasma gondii is harbored by cats. Infection can be acquired by exposure to cat feces (by touch or through contaminated food). Most healthy adults have an asymptomatic or a non-specific illness similar to infectious mononucleosis. Infection in pregnant mothers during early gestation puts the fetus at risk of congenital toxoplasmosis which may result in brain injury, microcephaly and chorioretinitis. Immunocompromised patients may develop chorioretinitis and focal brain lesions.

Trematodes (also called flukes) are unsegmented flatworms which contain the groups fasciola, clonorchis, paragonimus, and schistosoma. Intestinal flukes include fasciolopsis buski found in Asia. Clonorchis sinensis (the Asian liver fluke) is acquired by eating raw or undercooked freshwater fish. Fasciola hepatica (another liver fluke) is found in sheep raising areas and infection is acquired by eating organisms which have contaminated agriculture. Paragonimus westermani is a lung fluke found in Asia and Africa. It is acquired by eating contaminated shellfish. Schistosomes are classified as blood flukes because they spread through the circulation. Schistosoma species include mansoni, japonicum, and haematobium. These organisms can penetrate the skin directly when exposed to contaminated water. S. mansoni and S. japonicum cause intestinal symptoms. S. haematobium causes bladder symptoms including bladder carcinoma.

Cestodes (also called tapeworms) are segmented flatworms. Taenia solium is the pork tapeworm and Taenia saginata is the beef tapeworm. Humans acquire these when ingesting undercooked pork and beef that are contaminated with larval forms known as cysticerci. In most instances, intestinal infection with large tapeworms result. In some instances, cysticerci invade the eye or brain resulting in focal brain lesions which often leads to seizures known as neurocysticercosis. This is very common in countries where livestock raising conditions are not well regulated and undercooked pork is frequently consumed. The southern U.S. regions encounter frequent cases of neurocysticercosis in Mexican immigrants and visitors. The fish tapeworm, Diphyllobothrium latum, is found in undercooked freshwater fish. This organism has largely been eliminated from previously endemic areas in Minnesota (the land of lakes) and the Great Lakes. Raw

salmon ingestions may be a source of D. latum, because even though salmon are salt water fish, they may acquire the infection when they return to freshwater.

Nematodes are roundworm groups which can be remembered by the mnemonic NEMATODES (with 2 As and 3 Ts). These stand for Necator, Enterobius, Mosquito borne (Wucheria and Brugia), Ascaris, Ancylostoma, Trichuris, Trichinella, Toxocara, Onchocerca, Dracunculus, Eye worm (Loa loa), and Strongyloides. They infect humans via ingestion (EATT: Enterobius, Ascaris, Trichuris, Trichinella) or by skin penetration (SAN: Strongyloides, Ancylostoma, Necator).

Necator americanus and Ancylostoma duodenale are hookworms which are endemic in warm moist climates. N. americanus is endemic in the southeast U.S. Larvae in the soil attach (hook) between the toes and penetrate the skin into the bloodstream. They migrate into the lungs causing an eosinophilic pneumonia. Organisms are coughed up and swallowed where they enter the GI tract. They attach (hook) to the intestinal wall where they cause a chronic infection.

Enterobius vermicularis (pinworms) are the most common parasite in the U.S. Many children are said to have these and they are usually asymptomatic. It is likely that spread occurs among young children with poor oral hygiene habits in group settings (e.g., preschool). These worms are about 0.7 cm long and they resemble moving pieces of white thread. They are usually found in the perianal area. These worms reside in the rectum. They exit the anus and lay eggs at night when the child is asleep. The worms then reenter the anus. Some advocate obtaining a perianal sample by applying sticky tape or an adhesive plastic paddle to the anus several hours after the child has fallen asleep. Alternatively, visual inspection at night will often identify the worms. In girls, the worms may enter the vagina instead of the anus. This will cause dysuria or vaginal pruritus. This is commonly seen in emergency departments at night. If the parent brings the child in early, the moving worms are usually still visible in the perineal area. If the parent brings the child in late, dead degenerating worms may be visible in the perineum. Otherwise, a chief complaint of sudden onset of dysuria or vaginal discomfort in the absence of urinalysis evidence of a UTI, is suggestive of pinworms. These can be eradicated with a single dose of mebendazole. This can be repeated in two weeks to reduce the likelihood of reinfection.

Ascaris lumbricoides is probably the most common parasitic worm in the world. If you see a large intestinal worm, odds are this is what it is. They are large and pink resembling smooth earthworms. Ascaris worms survive and grow in the intestine. Infection may be asymptomatic or they may grow large enough to cause a bowel obstruction. Newly hatched larvae may migrate throughout the body into the liver, heart and lungs. Eosinophilic pneumonia is caused by migrating ascaris larvae as they invade the lungs.

Mosquito borne nematodes include Wucheria bancrofti and Brugia malayi which both cause elephantiasis. These are difficult to treat. These infestations are referred to as filariasis, which also includes Loa loa (an African eye worm, which is spread by the Chrysops fly vector) and Onchocercal volvulus (also known as river blindness, which is spread by the Simulium blackfly).

Trichuris trichiura (whipworm) is found in tropical regions. The infestation can be asymptomatic or the usual GI chronic infestation symptoms. Trichinella spiralis is the pork roundworm, which is acquired by eating poorly cooked contaminated pork. The larvae initially cause GI infestation symptoms. As maturing worms lay new eggs, these larvae hatch and migrate into the bloodstream where they lodge in muscle tissue forming calcifications which cause fever and myalgia. Toxocara canis and Toxocara cati are dog and cat parasites which may be asymptomatic or cause visceral larvae migrans.

Dracunculus medinensis is known as the Guinea worm. Larvae in tiny aquatic crustaceans are ingested in contaminated water. Over time, adult worms grow subcutaneously (nearly one meter long), which are classically removed through the skin by gradually pulling them (rolling them onto a stick).

Strongyloides stercoralis (threadworm) is another parasite that enters the body through exposed feet stepping over contaminated soil.

Commonly used antiparasitic drugs include albendazole, pyrantel pamoate, mebendazole and metronidazole. It should be noted that this chapter is written for general background information only. Therapeutic decisions should be based on more comprehensive information describing each infection type. Some parasitic infections do not benefit from treatment.

Albendazole is a relatively new drug which covers a broad range of parasitic infections. Mebendazole (Vermox) and pyrantel pamoate are older drugs which are also highly efficacious. Metronidazole (Flagyl) and tinidazole have activity against many protozoans. Many parasites respond to albendazole and pyrantel pamoate. Diethylcarbamazine is used for filariasis parasites (and dog heartworms). Praziquantel works for most flatworms (flukes and tapeworms).

Summary of Protozoans and Parasites (Treatment agents in parentheses. Alb=albendazole, Pyr=pyrantel pamoate, Meb=mebendazole, Metr=metronidazole) [Route of infection in brackets]. [FO] = fecal-oral transmission. The purpose of this summary is to provide a general educational overview. Note that treatment alternatives, doses and durations are not provided here. Please use a current authoritative reference for clinical therapeutic decisions.

I. Protozoans
- A. Ameba
  1. Entamoeba histolytica (Metr) [FO]
  2. Naegleria fowleri (amphotericin) [hot springs]
- B. Flagellates
  1. Giardia lamblia (Metr) [FO, contaminated water]
  2. Trichomonas vaginalis (Metr) [sexually transmitted]
  3. Trypanosomes
     a. Tryp cruzi (nifurtimox or benznidazole) [reduviid bug vector]
     b. T. rhodesiense, T. gambiense (pentamidine) [tsetse fly vector]
  4. Leishmania (stibogluconate) [sandfly vector]
- C. Sporozoans
  1. Cryptosporidium (paromomycin, amphotericin) [drinking water]
  2. Plasmodium-Malaria (complex treatment) [anopheles mosquito vector]
  3. Toxoplasma (pyrimethamine) [cat feces, contaminated food]

II. Trematodes (flukes)
- A. Intestinal: Fasciolopsis buski (praziquantel) [FO]
- B. Liver
  1. Clonorchis sinensis (praziquantel) [raw freshwater fish],
  2. Fasciola hepatic (triclabendazole) [sheep-raising area, contaminated agriculture]
- C. Lung: Paragonimus westermani (praziquantel) [shellfish]
- D. Blood: Schistosoma (praziquantel) [skin penetration in contaminated water]

III. Cestodes (tapeworms)
- A. Beef: Taenia saginata (praziquantel, albendazole) [ingesting contaminated raw beef]
- B. Pork: Taenia solium (praziquantel, albendazole) [ingesting contaminated raw pork]
- C. Fish: Diphyllobothrium latum (praziquantel) [ingesting infected raw freshwater fish]

IV. Nematodes (roundworms): NEMA(2)T(3)ODES
- A. Necator (albendazole) [FO, skin]
- B. Enterobius (mebendazole) [FO]
- C. Mosquito borne
  1. Wucheria bancrofti (diethylcarbamazine) [mosquito vector]
  2. Brugia malayi (diethylcarbamazine) [mosquito vector]
- D. Ascaris (pyrantel pamoate, albendazole) [FO]
- E. Ancylostoma (albendazole) [FO, skin]
- F. Trichuris (mebendazole) [FO]
- G. Trichinella (mebendazole) [poorly cooked pork]
- H. Toxocara (albendazole) [dog and cat feces]
- I. Onchocerca: river blindness (ivermectin) [Simulium blackfly vector]
- J. Dracunculus: Guinea worm (metronidazole) [contaminated water]
- K. Eye worm: Loa loa (diethylcarbamazine) [Chrysops fly]
- L. Strongyloides: threadworm (ivermectin) [FO, skin]

Questions
1. Name two parasites which are associated with the ingestion of uncooked freshwater fish?
2. What is the most common parasitic worm in American children?
3. Name two parasites associated with the ingestion of poorly cooked pork?
4. Name two motile (flagellated) protozoans infections commonly found in the U.S.
5. Name two types of hookworms.
6. Name four protozoans and two parasites transmitted by mosquito vectors.
7. Name 3 or 4 protozoans and parasites that are transmitted by biting flies.
8. Name 2 or 3 protozoans and parasites that invade the brain.

Answers to questions
1. Diphyllobothrium latum (fish tapeworm), Clonorchis sinensis (Asian liver fluke),
2. Pinworms (Enterobius vermicularis).
3. Trichinella spiralis, Taenia solium.
4. Trichomonas vaginalis, Giardia lamblia.
5. Ancylostoma duodenale, Necator americanus
6. Malaria (Plasmodium vivax, falciparum, haematobium, malariae), filariasis (Wucheria bancrofti, Brugia malayi).
7. Tryp cruzi [reduviid bug vector, which is not really a fly, but it is a biting bug], T. rhodesiense and T. gambiense [tsetse fly vector], leishmania [sandfly vector], Onchocerca [Simulium blackfly vector], loa loa eye worm [Chrysops fly].
8. Taenia solium (neurocysticercosis), Naegleria fowleri, Toxoplasmosis, Loa loa (eye).

Chapter VI.32. Candida and Fungal Infections
Wendy C. Matsuno, MD

This is a 14 year old male who presents to the office with tender, itchy feet. He has been having persistent itchiness of his toes, particularly between the fourth and fifth toes for the last week. He has been otherwise healthy, and even boasts that he is playing for the community football team.

Exam: VS T 37.0, P 74, R 12, BP 118/64. Ht/Wt at the 50th percentile. The patient is alert, active and in no distress. His physical exam is unremarkable except for his feet. The toes on both feet are inflamed and some scaling of the skin is noted. The interdigital space, between the fourth and fifth toes, appears to be the most affected. There is some cracking and thickening of the anterior plantar surfaces.

A culture of the area is taken and he is prescribed topical tolnaftate cream. He is also advised to use slippers when in the locker room showers, and to wash his feet well when he bathes at home. A week later, he returns with some relief of his symptoms. The results of the culture identify Trichophyton rubrum and Candida albicans. His topical therapy is changed to clotrimazole cream (an imidazole) applied twice daily for 3-4 weeks, since tolnaftate does not cover Candida albicans.

Superficial fungal infections of the skin, nails and hair are common (1). The fungi causing these infections are one of three types: dermatophytes, Candida species or Malassezia furfur. The recent increased incidence has been attributed to a greater number of immunocompromised hosts, use of chemotherapeutic agents, lifestyle changes (increased use of health clubs) and the large elderly population (1). Superficial infections can progress to systemic infections, but systemic and disseminated fungal infections are serious infectious which require inpatient care by infectious disease specialists, that are beyond the scope of this chapter.

Dermatophytoses is a common fungal infection caused by three genera of filamentous fungi: Trichophyton, Microsporum, and Epidermophyton. These organisms can infect any keratinized epithelium, nail and hair follicle because they utilize keratin as a nutrient. Trichophyton species infect skin, nails and hair, with T. rubrum the most common organism (2). Microsporum species primarily invade the hair, while Epidermophyton species invade the intertriginous skin.

Dermatophytoses are classified by the natural habitat in which they grow. Anthropophilic dermatophytes are those acquired from humans and can cause chronic low-grade infections to acute inflammatory disease. Geophilic dermatophytes infect humans sporadically causing an inflammatory reaction and are acquired from the soil. Zoophilic dermatophytes are acquired from animals through direct or indirect contact. The name of the infection itself is determined by the word 'tinea' followed the Latin word for the site of involvement.

Tinea capitis is a dermatophyte infection of the scalp (3). Prior to the 1900s, the most common cause of tinea capitis was Microsporum canis (4). In 1900-1940, M. audouinii was found to be the prominent cause of tinea capitis in North America and Western Europe (4). Since 1952, however, the incidence of tinea capitis caused by T. tonsurans has steadily risen and is now the primary cause of tinea capitis in the United States (4).

The presentation of tinea capitis caused by T. tonsurans can be of either the inflammatory or non-inflammatory type. The inflammatory type occurs in about 40% of cases, and can be accompanied with a kerion (edematous boggy nodule) or dermatophytid "id" reaction (fungus-free, papular eruption, usually on the trunk) (5). The non-inflammatory type occurs in the remaining 60% of cases (5). It presents with scaling in a dandruff-like manner or in a "black-dot" pattern with well demarcated areas of hair broken off at the orifice leaving the appearance of black dots. Posterior occipital and cervical adenopathy may be present.

The differential diagnosis of tinea capitis includes seborrheic dermatitis, psoriasis, alopecia areata, trichotillomania and some dystrophic hair disorders. With the presence of a kerion, a bacterial infection must be considered. In high risk individuals, the presence of patchy, moth-eaten alopecia could be a sign of secondary syphilis. Also, in cases with chronic tinea capitis, the diagnosis of discoid lupus and lichen planopilaris is also possible.

The diagnosis of tinea capitis must be done by potassium hydroxide (KOH) preparation or culture. Wood's light examination is not used because T. tonsurans, the most common causal organism in the US, does not fluoresce. In doing a KOH mount, "black dots" or scrapings from scaly areas should be collected, mixed with 10-20% KOH solution, heated and examined under the microscope. A KOH mount may give a false negative in the case of early or inflammatory lesions. Thus, a culture should be done. The most popular method to collect the culture is by the brush technique where a toothbrush is run over the scalp to pick up scales and hair debris. The culture is then plated on Sabouraud's dextrose agar with cycloheximide and chloramphenicol or on dermatophyte test medium. The culture will usually show growth in 7-10 days.

Topical therapy alone is ineffective in the treatment of tinea capitis (3). Topical therapy with 2.5% zinc sulfide or zinc pyrithione shampoo is helpful in decreasing the shedding of spores, but oral therapy is also needed to eradicate the infection. Oral therapy is often done with griseofulvin, which is currently the only drug approved by the U.S. Food and Drug Administration for the treatment of tinea capitis in children (4). In 1997, the recommended dose and duration of treatment with griseofulvin by the Infectious Disease Committee of the American Academy of Pediatrics was 10-20 mg/kg/d (using the microsize formulation of griseofulvin) for 4 to 6 weeks, with the intention of treatment continuing until 2 weeks after clinically asymptomatic (4). If the ultramicrosize formulation of griseofulvin is used, 5-10 mg/kg/day in a single or two divided doses is the recommended dosage (not to be used in children under 2 years of age). However, most experts use a dose of 20 mg/kg/d (microsize). "Microsize" refers to the product formulation of griseofulvin. The other preparation is ultramicrosize. The difference is that microsize has an absorption of 25-75% after an oral dose vs ultramicrosize which is almost completely absorbed. So an oral concentration of 500 mg of microsize griseofulvin produces similar serum concentrations to 250-330mg of ultramicrosize griseofulvin. The Microsporum species that were the primary causes of tinea capitis in past years, are more sensitive to griseofulvin than T. tonsurans, which explains why tinea capitis is currently more difficult to treat.

Three other agents are also being investigated: terbinafine, itraconazole, and fluconazole. Terbinafine at a dose of 5-11 mg/kg (depending on level of involvement) was used for 1, 2 and 4 weeks with an overall cure rate of 44%, 57%, and 78% respectively (1). In a comparison of terbinafine with griseofulvin, the primary response rates in 50 patients treated for 8 weeks were found to be 72% and 76%, respectively (4). However, at 12 weeks, fewer recurrences were seen with terbinafine with an efficacy of 76% as compared to griseofulvin with an efficacy of 64% (4). In cases of tinea capitis caused by Microsporum species, terbinafine was found to be less effective than griseofulvin with only a 32% cure rate 14 weeks after a 6-week course of therapy (4). Disadvantages of terbinafine include its decreased effectiveness against Microsporum species (compared with griseofulvin), gastrointestinal disturbances seen in 5% of patients and the potential for interactions with other drugs, such as rifampin and cimetidine (4).

Studies are also being conducted with itraconazole and fluconazole. The dosing for itraconazole is 5 mg/kg or 100 mg/day for 2-6 weeks (4). A 6-week course of itraconazole was found to be comparable to a 6-week course of griseofulvin (4). For fluconazole, a study

of 44 children infected with T. tonsurans, demonstrated that a dose of 6 mg/kg for 20 days was found to be safe with an efficacy of 89% (1). Itraconazole and fluconazole were found to cause minor gastrointestinal side effects in 5% of patients and cause a reversible, asymptomatic elevation in liver function tests in 1 of 17 patients (4).

Tinea pedis, more commonly known as athlete's foot, is the most common fungal infection (1). The usual etiologic agents are T. rubrum (most common), T. mentagrophytes and E. floccosum (1). Non-dermatophytes and candida species can coexist or produce similar infections. Predisposing factors include occlusive footwear, hot, humid weather, and walking barefoot on contaminated floors. Arthrospores are able to survive for 12 months in flakes of human skin cells.

Tinea pedis is usually seen in preadolescent and adolescent males, and less likely in younger children (3). The toe webs and soles of the feet, most commonly the lateral toe webs, are usually affected. Patients often present with severe tenderness, pruritus, foul odor, fissuring, scaling and maceration of the surrounding skin. In some cases, a diffuse hyperkeratosis of the sole of the foot with mild erythema is seen. In infections with T. mentagrophytes, usually in young children, an inflammatory vesicular reaction is seen on the dorsal surface of the foot. Breaks of the skin may occur leaving a pathway for bacterial infection with group A streptococcus or Staphylococcus aureus. The infection may also spread to the inguinal area (tinea cruris), trunk (tinea corporis), hands (tinea manuum), or nails (tinea unguium).

The differential diagnosis includes normal peeling of the interdigital spaces and infection by Candida or other bacterial organism. Contact dermatitis, atopic dermatitis, and dyshidrotic eczema can also mimic tinea pedis (3).

The diagnosis of tinea pedis can be made by KOH slide examination or by culture. On KOH microscopic examination, fungal mycelia or hyphae are seen. Fungal culture can also reveal the diagnosis. The use of a Wood's lamp can demonstrate erythrasma (coral red fluorescence under the Wood's lamp), but does not provide definitive diagnosis of tinea pedis.

The treatment of tinea pedis involves topical and systemic agents to cure and to prevent recurrence. Topical therapy with tolnaftate, imidazoles (e.g., miconazole or clotrimazole), ciclopirox, etc., can be used once or twice daily for 1-4 weeks (1). Tolnaftate, however, can only be used in uncomplicated cases, since it is not effective against Candida species (3).
Systemic therapy with an imidazole (e.g., oral ketoconazole, itraconazole) is usually sufficient. In one study of 484 patients enrolled in 15 different studies, itraconazole, 200mg twice a day for one week, was found to be highly effective with a cure rate of 85% (1). Thus, this is the recommended regimen for plantar type tinea pedis.

Secondary prophylaxis of tinea pedis is important because recurrences are common. Preventive measures include avoidance of occlusive footwear, use of footwear when bathing in public showers, and complete drying of the area between the toes after bathing. The use of absorbent anti-fungal powder, such as zinc undecylenate (Desenex), which does not cover Candida species, is also helpful (3).

The dimorphic yeast of the genus Candida causes candidal infections. Candida is ubiquitous and may be present on the skin. Beyond the neonatal age, however, C. albicans is considered as part of the normal oral and intestinal flora (6). Environmental factors such as elevated temperature and increased humidity, as well as a decrease in the normal bacterial flora (e.g., due to antibiotics use) can lead to the overgrowth of the yeast. Candida albicans is the primary species that causes candidiasis in children (3). Many candidal infections clear spontaneously, and are relatively minor, such as oropharyngeal candidiasis (thrush) and candidal diaper dermatitis; however, systemic candidiasis can occur, which is serious and beyond the scope of this chapter. Chronic mucocutaneous candidiasis is due to a T-cell deficiency and a specific anergy which is also beyond the scope of this chapter.

Oropharyngeal candidiasis, also known as oral thrush, is rare in the first week of life. When it does appear in the neonate, it is most commonly acquired during passage through the birth canal from the mother's infected vaginal mucosa (vaginal candidiasis). In neonates of mothers with vaginal candidiasis, oral thrush was 35 times more common than in those of non-infected mothers (6). It was found that 20% of mothers with positive vaginal cultures had neonates with positive oral cavity cultures and 11% went on to develop oropharyngeal candidiasis (6). It is important to note that approximately 31% of women with positive vaginal cultures for C. albicans do not complain of discharge (6). Oropharyngeal candidiasis in neonates usually develops an average of 8 days after birth (6). The average interval between a positive C. albicans culture to clinical findings is about 3 days (6).

In addition to being transmitted via the birth canal, C. albicans can also be transmitted from incomplete sterilization of babies' bottle feeding or from the mother's breast. The incidence of oral thrush is higher in bottle-fed infants than in breast-fed infants (6). Neonates and young children are often affected because of the immaturity of host defenses and incomplete establishment of the gastrointestinal flora.

Oropharyngeal candidiasis (thrush) often presents as whitish patches on the tongue, gums and buccal mucosa. The soft palate, uvula and tonsils may also be involved. The patches are adherent (but can be removed revealing a erythematous base, unlike leukoplakia which is not able to be removed) and are made of epithelial cells, leukocytes, keratin, food debris and C. albicans in blastospore and pseudohyphae forms. The patient may exhibit decreased appetite and poor nursing due to pain and/or discomfort, but they are often asymptomatic. Patients taking antibiotics are at higher risk of developing thrush.

Treatment varies from no treatment, to absorbed agents and non-absorbed agents. In untreated cases in newborns, oral thrush has been found to clear on its own in 23-59 days (6). Absorbed agents, such as fluconazole and ketoconazole, are effective, but the non-absorbed (topical) agents are preferred because they are equally effective.

The classically used non-absorbed agents are gentian violet and nystatin. Gentian violet is a non-absorbed agent composed of formaldehyde and mercurochrome. It is effective in inhibiting the growth of C. albicans in the mouth, but not in the bowel. This agent is unfavorable because recurrences are common, with the additional adverse effects of ulceration and irritation of the oral mucosa, staining of tissue and clothing, and the possibility of being carcinogenic (6). Nystatin comes as a suspension. It is usually applied topically three times a day. Older children and teens can swish it in their mouth, but it should be applied with a cotton applicator onto the lesions in infants and young children. Nystatin has activity against candida only (i.e., no activity against tinea and other dermatophytes).

Newer non-absorbed agents, miconazole and clotrimazole, have also been studied. Miconazole is a first generation imidazole that has in vitro activity against yeast, dermatophytes and some Gram positive bacteria. Miconazole oral gel has been studied and found to be more effective than nystatin suspension. In a study of 183 ambulatory infants with no other underlying disease, 85% of infants treated with miconazole oral gel and 21% of infants treated with nystatin suspension were cured on day 5 (6). Miconazole has a superior cure rate and a lower rate of recurrence (6).

Candidal diaper dermatitis is a benign condition that often occurs concomitantly with oropharyngeal candidiasis. Since infants with oropharyngeal candidiasis have C. albicans in their gastrointestinal tract, they inevitably excrete it as well. Infants with oropharyngeal candidiasis have been found to have candidal diaper dermatitis in about 57% of cases (6). However, many infants have candida diaper dermatitis without thrush. Patients on antibiotics are at higher risk of developing candidal diaper dermatitis.

Candidal diaper dermatitis often presents in the perianal area as erythematous (classically described as beefy red), confluent plaques with well defined edges and a scalloped border. There are often satellite lesions (red spots), which are the primary lesions, and are

considered the hallmark of localized candidal infections. Candidal diaper dermatitis often extends to the perineum, upper thighs, lower abdomen and lower back. The diagnosis of candidal diaper dermatitis can be established by culture of the area. However in most instances, the diagnosis is made clinically by its characteristic appearance. Treatment of candidal diaper dermatitis involves topical therapy such as nystatin, miconazole or clotrimazole. These agents are usually applied with each diaper change or four times a day.

In patients that have frequent recurrences of candidal diaper dermatitis, oral therapy may be used. Since C. albicans is often harbored in the gastrointestinal tract, oral treatment along with topical treatment may be beneficial. In one study of infants less than three months of age with feces positive for C. albicans, oral plus topical nystatin was compared to oral placebo plus topical nystatin. The mycologic cure rates were the same, but oral nystatin reduced the recurrence rate to 16%, compared to 33% for topical nystatin alone (6).

Tinea versicolor is a chronic fungal infection of the stratum corneum. The dimorphic yeast, Malassezia furfur (previously known as Pityrosporum ovale and Pityrosporum orbiculare), is the infecting organism. The yeast form is present as part of the skin's natural flora, but the filamentous form is seen in the disease state. This organism is more commonly seen in areas of the skin with sebum production capabilities and infection is seen more commonly in adolescents and young adults (3). Tinea versicolor presents with a lesion of varying color depending on the individual's skin type. In lighter skinned individuals, the lesions are typically seen as reddish-brown macules with fine scales. In darker skinned individuals, the lesions may appear as hyperpigmented or hypopigmented macules. The lesions usually start in a perifollicular area then coalesce to form the macular, scaly lesions. The common locations are the neck, upper chest, upper back and upper arms. Involved areas are usually not pruritic and they do not darken after sun exposure.

The diagnosis of tinea versicolor is usually made by clinical appearance, but confirmatory evidence can be obtained with a Wood's lamp, KOH preparation, and skin biopsy. Wood's lamp examination reveals a yellowish gold fluorescence. When examining KOH prepared scrapings from the lesion, a "spaghetti and meatballs" appearance is seen. The "spaghetti" are the thick, angular hyphae and the "meatballs" are the spores. Skin biopsy with culture and periodic acid-Schiff staining for fungi may be necessary to diagnose cases with principally follicular involvement. Under examination, M. furfur is seen in the follicle.

The differential diagnosis of tinea versicolor includes dermatophytoses, seborrheic dermatitis, pityriasis alba and secondary syphilis. Post-inflammatory pigment changes, although they usually do not have scales, may mimic tinea versicolor.

The treatment of tinea versicolor involves topical and oral therapy. Topical agents include selenium sulfide suspension, sodium thiosulfate lotion, and 3-6% salicylic acid applied once or twice daily for 2-4 weeks. Imidazoles such as, miconazole, clotrimazole and ketoconazole can be used twice daily for 2-4 weeks. Terbinafine cream is also effective when used for 2-4 weeks twice a day. When topical therapy fails, oral therapy can be used. Ketoconazole, fluconazole and itraconazole are commonly used oral therapy agents.

M. furfur is a normal saprophyte of the human skin, thus it is not eradicated. Tinea versicolor infections can, therefore, recur in susceptible individuals. Some risk factors of developing a tinea versicolor infection include being in a warm, humid environment, immunosuppression, malnourishment, high plasma cortisol levels, genetic predisposition, and poor skin hygiene. In most individuals, good hygiene and a healthy diet can prevent recurrences.

Antifungal agents can be summarized as follows. Tolnaftate covers only tinea. Nystatin covers only candida. Imidazoles (clotrimazole, miconazole, ketoconazole, etc.) cover both tinea and candida. Amphotericin is generally given IV for systemic fungal or candidal sepsis or disseminated infection.

Questions

1. The most common cause of Tinea capitis in the United States is:
    a. M. canis
    b. T. tonsurans
    c. M. audouinii
    d. T. capitatans

2. True/False: Tinea Capitis, "black dot" pattern, is best diagnosed with Wood's lamp.

3. True/False: Tinea pedis is most commonly seen in infant females.

4. True/False: Oropharyngeal candidiasis and candidal diaper dermatitis often occur together because of C. albicans colonization of the gastrointestinal tract.

5. Tinea versicolor lesions appear as:
    a. Hyperpigmented macules
    b. Reddish brown macules
    c. Hypopigmented macules
    d. All of the above

6. Indicate whether the following agents are active against tinea, candida or both:
    a. tolnaftate
    b. nystatin
    c. clotrimazole
    d. miconazole
    e. amphotericin
    f. ketoconazole

Answers to questions

1. b. T. Tonsurans is the most common cause of tinea capitis in the United States.
2. False. Tinea capitis, "black dot" pattern, is caused by T. tonsurans. This is an endothrix infection, thus would not be visible by Wood's lamp. Diagnosis is best done with KOH prep or culture.
3. False. Tinea pedis is most common in preadolescent and adolescent males.
4. True. C. albicans often colonizes the gastrointestinal tract. In 57% of patients with oropharyngeal candidiasis, candidal diaper dermatitis is also seen (6).
5. d. All of the above. Tinea versicolor lesions present differently depending on the individual's natural skin color. In light skinned individuals they often appear as reddish brown scaly lesions. In darker skinned individuals they can appear as either hyperpigmented or hypopigmented macules.

6a. tinea only.
6b. candida only.
6c. both.
6d. both.
6e. both.
6f. both.

Chapter VI.33. Necrotizing Fasciitis
Chad S.D. Sparks

This is an 11 year old, previously healthy male who presents to the office with a chief complaint of extreme pain from a 3 day old puncture wound on his right calf. He also reports fever, redness, and swelling for one day. The height of his fevers is not measured. He was given acetaminophen for fever and pain. The fever improved, but the pain has worsened.

Exam: VS T 39 degrees C, HR 132, RR 26, BP 105/78. He is alert and in obvious pain. HEENT exam is negative. Lungs are clear. Breathing is tachypneic. Heart is tachycardic, without murmurs or extra sounds. Abdomen is soft and non-tender. A round puncture wound measuring 0.3 cm in diameter is noted on his right lateral calf with erythema and edema extending distally for 3 cm. Palpation of this area results in severe tenderness. The capillary refill of the skin overlying this region is slightly delayed.

A wound culture is obtained. A CBC and blood culture are drawn. IV ceftriaxone is administered and he is admitted to the hospital. Over the next 36 hours, the skin near his wound progressively develops a bluish discoloration, blisters, and bullae. Group A-beta hemolytic streptococci (GABHS) is isolated from the wound culture and blood culture. Ceftriaxone is discontinued and he is started on IV penicillin G and clindamycin for necrotizing fasciitis (NF). On the second day of hospitalization, an MRI finds fluid in a fascial plane of the lateral compartment of the lower leg. Surgical debridement is performed and brown serous fluid is removed and cultured. The surgeon confirms the diagnosis of NF. GABHS grows from the serous fluid the next day.

He continues to require daily surgical debridement until the sixth day of hospitalization, but he slowly improves. He is discharged on day ten. Follow-up for the next month shows good recovery.

Necrotizing fasciitis (NF) is a group of infections that present in any age group as an abrupt, rapidly advancing soft-tissue infection with systemic toxicity and high mortality (1). It is characterized by microbial spread along the fascial planes into deep tissue, which results in necrosis of the superficial tissue.

The classification of NF is ambiguous because of its similarity to other syndromes and its numerous etiologies. Often, the diagnoses will overlap as infection spreads to adjacent tissue. For example, necrotizing cellulitis may involve the fascial planes secondarily or vice versa. Several studies have tried to classify NF based on anatomic location, bacterial flora, presence or absence of crepitance, and clinical progression.

NF falls under the general category of necrotizing soft tissue infection (NSTI). There are three types of NSTI: 1) NF, 2) necrotizing cellulitis, and 3) myonecrosis. However, NF is often used in clinical settings as a broadly inclusive term for overlapping types of NSTI. Clinically, there are three syndromes of NF that are often described and easy to conceptualize: Type I is polymicrobial and includes saltwater NF due mainly to marine Vibrio species. Type II is group A streptococcal NF. Type III is clostridial myonecrosis or gas gangrene (2). The most common form of NF is the polymicrobial Type I. In one pediatric study, 75% of children developed NF with polymicrobial etiology (Type I) (3). The most common species of bacteria cultured from a study of 182 subjects in Maryland were Streptococcal species, Staphylococcal species, Enterococcal species, and Bacteroides species. Anaerobes such as Clostridia were also common in type I NF and could be differentiated by gas production visible on imaging studies. The most common bacteria in type I NF is Bacteroides, which is a gram-negative anaerobic bacillus. Fournier's gangrene is a variant of polymicrobial NF usually found in the scrotum or penis of older, often immunocompromised individuals. This variant is rare in children.

Type II infection with GABHS is probably the most extensively studied type of NF and is common in children (4,5). However, Type II NF has received extra attention in the lay press recently and is referred to as the "flesh-eating" bacterial infection (6). In cases where only one bacterium was present on culture, group A beta hemolytic streptococcus (GABHS) was the most common. In addition, GABHS (also known as Strep pyogenes) has been increasing in frequency since 1990 (7,8). The reason for this increase is unknown, but it may be related to the increasing incidence of other types of invasive streptococcal infections since 1985 (9).

The invasive nature of some GABHS infections and their increasing prevalence has been linked to several virulence factors. It should be noted that NF is rare compared to the total number of non-NF GABHS cellulitis infections which are much more common. The M protein has been found responsible for protecting the bacteria from phagocytosis by polymorphonuclear leukocytes (10). There are over

80 distinct M proteins, but the two most often isolated in NF are the M-1 and M-3 subtypes of S. pyogenes (8). Another important virulence factor is the exotoxin. There are five different exotoxin proteins: A, B, C, D, and E. Most commonly noted in NF are the streptococcal (scarlatina) pyrogenic exotoxins (SPE) types A, B, and C. Exotoxins recruit T cells and increase production of tumor necrosis factor alpha, interleukin 1-beta, and interleukin 6. The effects are characterized by fever, shock, edema, and multiple organ failure (11). The streptococcal superantigen (SSA) can also play a role in this process. Although these proteins are unique to the Streptococcal species, the clinical picture is often difficult to distinguish from other types of NF (4).

Type III NF is most often associated with crepitus due to growth of clostridium perfringens. This is often referred to as gas gangrene. The gas produced can often be seen on various imaging modalities such as x-ray, MRI, or CT.

The differential diagnosis of severe pain and inflammation of the skin includes cellulitis, erysipelas, acute febrile neutrophilic dermatosis, acute hemorrhagic edema of infancy, drug reactions, and vasculitis. NF is regularly confused with cellulitis because its early clinical presentation is also pain, erythema, and edema. However, cellulitis extends only to the subcutaneous tissue and is poorly demarcated. An experienced clinician is usually able to make an accurate diagnosis. Definitive differentiation from necrotizing cellulitis is generally established with surgical incision and probing. If any question remains after probing, a biopsy should be obtained (12). Erysipelas is red, raised, well-demarcated areas of induration and usually involves only the superficial cutaneous tissue. Ecthyma gangrenosum may also present as NF, but is due to Pseudomonas and appears ulcerated rather than bullous (13).

Although there are several distinct etiologies of NF, the clinical presentations are very similar. The clinical picture of NF is significant for pain, erythema, and swelling that progressively extends from the site of trauma, surgery or other provoking insult. The clinician's history should include questions regarding any inciting event such as a small wound or traumatic occurrence at the site of infection. On the other hand, the absence of an initiating event does not rule out NF. Common initiating events depend on the age group as well as the patient's immune status. In the newborn, NF can be a serious complication of omphalitis. It may begin as swelling and erythema around the umbilicus and progress to a purplish discoloration and periumbilical necrosis during the subsequent hours or days (13). In older children, NF may present after trauma, surgery, or with resolving varicella lesions. In a study, almost 50% of pediatric cases were superimposed upon varicella in its 3rd-4th day of progression (8). The history frequently reveals a persistent fever after the third day of rash, associated with severe, localized pain, over an area of swelling, erythema, and possibly necrosing skin (14). The mechanism of how varicella increases the risk for NF is unknown. An association has been shown between NF and NSAID use with varicella. Numerous studies examined this relationship, but the results have been mixed. Most believe these studies do not prove a causal relationship. However, physicians may consider recommending acetaminophen instead of ibuprofen for children with varicella (15).

Pain in an extremity is usually the presenting symptom. It is extreme and often out of proportion with the physical findings. NF has a propensity for the extremities, but can occur anywhere there is deep fascia (16). In the first 24-48 hours, it is associated with edema, erythema, and warmth of the skin overlying the necrotizing tissue. After that point, the skin will become dusky and discolored. It will develop blisters and bulla over the next seven to ten days. During that time, the discoloration will become sharply demarcated. Its tenderness will also disappear as the superficial nerves experience ischemia (17). This progression is both faster and more severe than that seen in cellulitis or erysipelas (18). If not addressed, NF can quickly progress to multi-organ failure, acute respiratory distress syndrome, renal impairment, coagulopathy, liver abnormalities, and generalized erythroderma (19).

Although the diagnosis of NF is primarily clinical, laboratory workup and imaging may be helpful. Surgical probing and frozen section biopsy are used for diagnosis of NF, but they are invasive and take time to complete. There must be a high index of suspicion for NF to move straight to surgery. Therefore, the most important first steps of medical management are probably the gram stain and cultures of both the blood and the wound, if one is present. This will help guide antibiotic therapy over the course of the disease. In addition, routine blood work such as a CBC and chemistry panels may be helpful.

Imaging can also be very useful in differentiating NF from cellulitis. Crepitus or soft tissue gas on plain x-rays are pathognomonic for NSTI. However, they are only found in 37%-57% of the cases (20). More recently, MRI and CT scans have been investigated to identify NF. Contrast enhanced images may show asymmetric thickening of the deep fascia and/or gas bubbles in the deep tissue. However, MRI may overestimate the extent of disease and intravenous contrast may be contraindicated in some patients in shock or with renal failure. In most cases, however, empiric treatment should be initiated as soon as possible, even prior to obtaining imaging results (21).

The mainstays of treatment for NF are intravenous antibiotics and surgical debridement. Generally, broad antibiotic coverage is necessary for empiric therapy. A study by Elliot suggested a combination of ampicillin, gentamicin, and clindamycin or ampicillin/sulbactam for broad coverage (4). Penicillin covers GABHS and most anaerobes. Clindamycin covers all anaerobes and it inhibits bacterial protein (toxin) synthesis in organisms that are not multiplying. However, anaerobic infections are frequently polymicrobial necessitating broad spectrum coverage. Specific antibiotic therapy can be employed after cultures return and bacterial sensitivities are known. Recent studies indicate clindamycin treatment produces better outcomes and decreases mortality in streptococcal disease. In fact, a combination of the two drugs is currently advocated in the literature (3,22). In the pediatric setting, there is no current recommendation for length of antimicrobial treatment, but it should be continued as long as there are signs of infection. Treatment for cellulitis is continued for at least three days after the acute inflammation has subsided (22). Therapy for NF should be continued for at least as long as for severe cellulitis.

Surgical debridement is recommended every day until the patient is stable and without signs of infection or sepsis. Debridement should cover the infected area as well as a margin of healthy tissue to prevent reoccurrence of infection. As a result, the patient may need extensive skin grafting to cover the debridement area. During recovery, frequent dressing changes are necessary. Unfortunately, scarring and disfigurement are very common after NF debridement and grafting. In addition, physical therapy and rehabilitation will be needed for those with extensive skin grafts (20).

Mortality is always worse if there is significant delay in therapy or inadequate surgical debridement. Unfortunately, NF is often diagnosed at a very late stage because the clinical presentation initially appears to be an ordinary cellulitis or wound infection. Therefore, management should begin as soon as possible with intravenous antibiotics and surgical debridement.

Hyperbaric oxygen (HBO) therapy has been evaluated as an adjunctive therapy. Treatment with HBO has not been examined adequately in randomized trials, but some studies have shown benefit in preventing the extension of NF. It may accomplish this by increasing the oxygen tension in the surrounding tissue (23). In fact, HBO has become standard treatment in clostridial myonecrosis (24). Unfortunately, HBO is difficult to obtain and is rarely utilized. Other management concerns are the systemic effects of NF. Organ system problems that need to be addressed may include respiratory insufficiency, transient renal failure, and blood pressure support.

Mortality in the literature ranges from 12% with early, aggressive treatment (1) to nearly 100% for those without surgical debridement (8). Prognosis depends most heavily on the patient's age. In one study, NF patients younger than age 35 had no fatalities. In

contrast, mortality was 61% in the age group above 65 years. This difference may be explained by the various predisposing factors in the older group, such as diabetes mellitus. In fact, 62% of all NF patients had predisposing factors, but none were present in the younger group. However, the younger group was also more likely to have undergone surgery, which may indicate more intense therapy for the younger group. Other important factors impacting disease outcomes are the development of bacteremia, shock or hypotension, use of antibiotics other than clindamycin, or lack of adequate surgical debridement (8). Complications with toxic shock syndrome occurred in 50% of cases in one study (25). However, there was no correlation between increased mortality and specific M-serotype or the presence of SPE (streptococcal pyrogenic exotoxins) A or C (8).

Questions

1. The most common species of bacteria isolated from Type I NF is:
    a. Staphylococcus
    b. Streptococcus
    c. Bacteroides
    d. Clostridium

2. Which imaging modality is most useful in differentiating cellulitis from NF?
    a. Plain radiograph
    b. MRI
    c. CT
    d. Ultrasound

3. The virulence factor which has been found to protect streptococcal species from phagocytosis is:
    a. Streptokinase
    b. M-protein
    c. Streptococcal pyrogenic exotoxins
    d. Streptolysin O
    e. Hyaluronidase

4. Type III NF is most often caused by:
    a. Clostridium perfringens
    b. Group A beta-hemolytic streptococcus
    c. Bacteroides
    d. Campylobacter

5. First line treatment for streptococcal NF is:
    a. Erythromycin
    b. Gentamicin
    c. Doxycycline
    d. Penicillin

Answers to questions

1.c. Bacteroides is the most common bacteria isolated in polymicrobial NF. Staphylococcus, streptococcus, and clostridium are also commonly found.

2.a. Plain films are routinely used to differentiate cellulitis and NF. MRI and CT are currently under investigation for utility, however, they are costly and time consuming. Answers b and c could be correct, but ultrasound (answer d) is not useful. If NF is suspected, surgical exploration is necessary and will yield the same information.

3.b. The M protein inhibits the activation of complement and prevents phagocytosis. The other virulence factors listed belong to the streptococcal species, but have different roles in causing infection.

4.a. Clostridium causes gas gangrene and crepitus, which characterizes Type III NF. The other bacteria listed are causes of Type I or Type II NF.

5.d. First line therapy for streptococcal NF is penicillin according to current guidelines. Unfortunately, one does not initially know that the NF is due to GABHS. Most anaerobes are penicillin sensitive. Adding clindamycin may be useful even if the organism is penicillin sensitive since it may inhibit protein synthesis (toxin production) in non-replicating organisms. For other organisms, anti-microbial therapy should be based on culture and sensitivity results when they are obtained.

Chapter VI.34. Lymphadenitis and Lymphangitis

Teresa M. Bane-Terakubo, MD

A 3 year old female presents to her primary care physician with a chief complaint of a neck mass that has been present and getting worse over 4 days. The mass started as a small lump that has enlarged to the size of a walnut and is now becoming painful, and warm to touch with overlying redness. She has had 2 days of fever up to 104 degrees (40 degrees C). She is also complaining of a runny nose, cough and sore throat for 1 week. Her appetite for solid foods is down but she is drinking fluids well and her urine output is normal. She has not been as active as usual and has not slept well due to the fever. No one at home has been ill but she does attend pre-school and several children have been ill recently with sore throats and URI symptoms. Her history is negative for recent skin infection, skin rash, weight loss, dental problems or cavities, nausea, vomiting or diarrhea. There is no exposure to cats or other animals. Her past medical history, family history and social history are unremarkable.

Exam: VS T 40, P 110, RR 20, BP 80/40, oxygen saturation 100% in room air. Height and weight are at the 50th percentile. She is tired appearing but in no acute distress. Pupils are equal and reactive. Sclera is white and conjunctiva are clear. TMs are normal. Her throat is erythematous with patches of exudate on both tonsils. Some clear nasal mucus is noted within her nares. Her neck is supple with tender bilateral cervical lymphadenopathy. There is a 2 cm x 3 cm tender, warm anterior cervical lymph node on the right with overlying erythema. Fluctuance is present. No axillary or inguinal lymphadenopathy is appreciated. Heart is regular without murmurs. Lungs are clear. Abdomen is nontender and nondistended. No hepatosplenomegaly or masses are noted. Her extremities are warm with full pulses and capillary refill time of one second. No skin rashes or impetigo scars are noted. Neurologic exam is normal.

A throat swab is sent for beta hemolytic strep culture. CBC shows WBC of 25,000 with a left shift. She is started on IV clindamycin empirically. An ultrasound study shows abscess formation. A surgeon is consulted and the abscess is incised and drained (I&D) for a moderate amount of pus. Gram stain shows numerous WBCs and gram positive cocci. Culture of the pus grows out Strep pyogenes (group A strep) within 24 hours. Her throat culture also grows group A strep. Her antibiotics are changed to IV penicillin. She responds to the antibiotics and I&D with dramatic improvement. She is discharged after 3 days of hospitalization to complete a 10 day course of penicillin.

Lymphadenopathy is a common complaint that brings children to see a physician. Fortunately, most of these children will have a benign, self-limited process. However, some children with serious systemic disease or malignancy may present with lymphadenopathy. It is therefore important to understand the differential diagnosis, perform a thorough history and careful physical exam and be aware of the appropriate work up to undertake in a timely manner. Enlargement of a lymph node (lymphadenopathy) may be caused by proliferation or invasion of inflammatory cells (lymphadenitis) or by infiltration of malignant cells. The location of the enlarged lymph node can be helpful in the differential diagnosis. It is normal for healthy children to have palpable lymph nodes in the anterior cervical, axillary and inguinal areas. Palpable lymph nodes in the supraclavicular region; however, often reflect mediastinal malignancy.

Important questions to ask the patient/caregiver include location and duration of the enlarged lynch node (acute vs. chronic, localized vs. generalized), history of prolonged fever, weight loss, arthralgias, skin lesions/infections or rashes, history of recurrent infections, immunization status, contact with sick persons, recent travel, exposure to animals and insects, URI symptoms, sore throat and dental problems/cavities. On physical exam, pay particular attention to location, consistency (solid or fluctuant, smooth or nodular, movable or fixed), number, distribution and size. The appearance of the overlying skin should be noted (red and warm in infection, violaceous coloration in nontuberculous mycobacteria). Hepatosplenomegaly, bruises, petechiae, conjunctivitis, pharyngitis, periodontal disease, and signs of systemic disease should be looked for.

The term "shotty" is commonly used to describe lymphadenopathy. Shotty means shot-like, which refers to bird shot (tiny beads) or buck shot (bigger beads). Shotty lymphadenopathy could refer to a matting of lymph nods with tiny bumps, medium bumps or big bumps. This term is vague and it may be preferable to use more accurate terminology.

Most patients with lymphadenopathy clinically assessed to be due to a minor infection do not require any laboratory testing. Laboratory work up to consider in a patient with a potentially more serious presentation of lymphadenopathy includes PPD, HIV screening, throat culture, CBC, blood culture. Serologic studies for EBV (Epstein-Barr virus), CMV (cytomegalovirus), HIV, Treponema pallidum, Toxoplasma gondii, or Brucella can be helpful in selected cases. For a patient with a fluctuant node where an abscess is suspected, ultrasound may be helpful. Needle aspiration of a suspected abscess may negate the need for an ultrasound but this approach is more invasive. Although a needle aspirate can yield the organism contained within an abscess, most abscesses will have to be surgically drained anyway. Occasionally, a lymph node biopsy may be needed. This tissue is usually sent for gram stain, bacterial culture, acid fast stain, mycobacterial culture, or Bartonella henselae (cat scratch disease) PCR. A chest x-ray evaluation should also be considered to rule out mediastinal masses/malignancy.

The differential diagnosis for lymphadenopathy is best based upon the presentation as either acute bilateral cervical lymphadenitis, acute unilateral pyogenic (suppurative) lymphadenitis, and chronic cervical lymphadenopathy. The most common causes of acute bilateral cervical lymphadenitis are URI viruses such as adenovirus, influenza and RSV. Viruses that typically cause generalized lymphadenopathy such as EBV and CMV may also present as acute bilateral cervical lymphadenitis. The most common causes of acute unilateral pyogenic (suppurative) lymphadenitis are Staph aureus and group A strep. Most of these children are 1-4 years of age. The typical clinical course of lymphadenitis due to group A strep, is manifested in association with group A strep tonsillitis, both of which respond to penicillin. Abscess formation and the need for surgical drainage are uncommon with group A strep. However, Staph aureus more commonly forms abscesses and I&D will almost always be necessary. If there is a prior history of dental problems or a dental abscess, anaerobic oral flora may be the cause. The differential diagnosis for chronic cervical lymphadenopathy is more extensive. The most common causes of prolonged cervical lymphadenopathy are infectious such as atypical mycobacterial infections, mycobacterium tuberculosis, cat scratch disease, EBV, CMV, toxoplasmosis, histoplasmosis and HIV. Noninfectious etiologies for chronic cervical lymphadenopathy include malignancy such as leukemia, lymphoma, metastatic solid tumors such as neuroblastoma, rhabdomyosarcoma and nasopharyngeal carcinoma. One other important etiology that does not fall into the above categories is Kawasaki disease. Kawasaki disease is associated with a single, nontender, nonpurulent enlarged cervical lymph node.

Since most cases of acute bilateral cervical lymphadenitis are viral in etiology and self -limited, only symptomatic treatment is recommended. For children with acute unilateral pyogenic (suppurative) lymphadenitis caused by Staph aureus or group A strep who do not appear toxic and have no apparent abscess or cellulitis oral empiric therapy with cephalexin, oxacillin or clindamycin is recommended. For ill appearing children who have abscess formation or cellulitis, needle aspiration or I&D and IV therapy with clindamycin or vancomycin is recommended. For children who have cervical lymphadenitis associated with periodontal disease, needle aspiration or I&D and therapy with penicillin or clindamycin are optimal. For suspected nontuberculous mycobacteria infection, surgical excision of the infected lymph node without antibiotic therapy is optimal. For cat scratch disease following needle aspiration and PCR diagnosis of Bartonella infection, no antibiotic therapy is routinely recommended, although this is controversial since azithromycin has some clinical efficacy.

The prognosis for lymphadenopathy and lymphadenitis depends upon the etiology. In general, since most childhood acute bilateral cervical lymphadenopathy is viral in etiology, the prognosis is good. Since most acute unilateral pyogenic (suppurative) lymphadenitis is caused by Staph aureus and group A strep, and is easily treatable, the prognosis is also good. Since the differential diagnosis for chronic cervical lymphadenopathy is more extensive, generalized statements about prognosis are difficult to make.

Lymphangitis is the inflammation of the lymphatic vessels. The etiology of lymphangitis can be neoplastic or benign. If the lymphatic vessels are infiltrated by tumor cells, surrounding fibrosis takes place producing visible or palpable cords. Lymphangitis is sometimes seen proximal to areas of cellulitis (especially those caused by group A strep) as red streaks extending from the cellulitis proximally. Such cases are treated similar to cellulitis alone.

Questions

1. What are the indications for biopsy of a lymph node?
2. What is the most common cause of acute bilateral cervical lymphadenopathy in children?
3. What is the most common cause of acute unilateral cervical lymphadenitis associated with fever and suppuration?
4. What is the most appropriate treatment of suppurative cervical lymphadenitis caused by nontuberculous mycobacteria?
5. What are some causes of prolonged cervical lymphadenitis in children?

Answers to questions

1. Persistent enlargement despite empiric therapy, persistent enlargement or no improvement with negative laboratory work up, solid fixed mass, mass located in the supraclavicular area, accompanying constitutional signs of persistent fever or weight loss.
2. Self limited, systemic viral infections such as adenovirus, influenza, and RSV are most common. EBV and CMV also can present as acute bilateral cervical lymphadenitis.
3. Staph aureus and Strep pyogenes (group A strep). Suppuration is more likely to be present with Staph aureus.
4. Complete surgical excision of the node is required to avoid development of a draining fistula.
5. Nontuberculous mycobacteria and cat scratch disease are common. EBV, CMV, toxoplasmosis, histoplasmosis, HIV are other infectious etiologies. Malignant diseases such as leukemia, lymphoma and solid tumors such as neuroblastoma, rhabdomyosarcoma and nasopharyngeal carcinoma also need to be considered.

Chapter VII.1. Congestive Heart Failure
Lance K. Shirai, MD, MS

This a 6 week old female who presents to the emergency room with the chief complaints of lethargy, poor feeding, and respiratory distress. She was well until 2 weeks prior to presentation when she developed a febrile illness with cough, rhinorrhea, and emesis. She subsequently developed progressive respiratory distress. Her parents report that she sweats a lot on her forehead when feeding. Her parents have also noted her to be increasingly lethargic, with tachypnea, and retractions.

She is the product of a G3P2, full term, uncomplicated pregnancy. Delivery was unremarkable except for meconium stained fluid. She did well at delivery and in the nursery. Her pediatric follow-up has been poor.

Exam: VS T 36.8, RR 72, HR 160, BP 92/68. Oxygen saturation in room air is 99%. She is a mildly cachetic, acyanotic infant who was pale, lethargic, and tachypneic, with mild to moderate subcostal and intercostal retractions. HEENT exam is unremarkable. Neck is supple without lymphadenopathy. Her skin is clear with no rashes or other significant skin lesions. Her lungs have scattered crackles with slightly decreased aeration in the left lower lobe. The precordium is mildly active. Her heart is of regular rate and rhythm, with a Grade II/VI holosystolic murmur at the mid lower left sternal border with radiation to the cardiac apex. The S1 is normal and the S2 is prominent. An S4 gallop is noted at the cardiac apex. There are no rubs or valve clicks. Her abdomen is soft, non-distended, and non-tender. The liver edge is palpable 3 to 4 cm below the right costal margin. There are no palpable masses or splenomegaly. Bowel sounds are hypoactive. Her extremities are symmetric and cool, with peripheral pulses 1+/4+ in all extremities with no radial-femoral delay. The capillary refill is 4 to 5 seconds (delayed).

A chest x-ray shows moderate cardiomegaly with a moderate degree of pulmonary edema. There are no pleural effusions. A 12 lead electrocardiogram shows a sinus tachycardia, normal PR and QTc intervals, and a left axis deviation. Voltage evidence of biventricular hypertrophy is present. No significant Q-waves or ST segment changes are noted. An echocardiogram reveals a large perimembranous ventricular septal defect with non-restrictive left to right shunting. All cardiac chambers are dilated. Left ventricular contractility is at the lower range of normal. There is no pericardial effusion.

She is admitted to the hospital and loaded with digoxin, and also started on diuretics and afterload reduction. Her symptoms improve and she is discharged on 24 calorie/ounce formula due to poor weight gain on standard 20 calorie/ounce formula. She continues to have poor weight gain on higher caloric density formula and continues to have symptoms of heart failure on medical management. She is referred for surgical correction of the ventricular septal defect at 6 months of age.

Heart failure (or congestive heart failure) is defined as the inability of the myocardium to meet the metabolic requirements of the body. This may arise as a consequence of excessive work or volume load imposed on the myocardium, primary alterations in myocardial performance, metabolic derangements, or a combination of these elements. Heart failure leads to a neurohormonal response, which contributes to the symptoms associated with heart failure and increased morbidity and mortality.

In the pediatric age group, the underlying abnormality is often a large left to right intracardiac shunt, most commonly a ventricular septal defect, or an obstructive lesion, such as an aortic coarctation. In contrast to heart failure in adults, pediatric patients often have normal left ventricular function. Exceptions to this may include patients with myocarditis, dilated cardiomyopathy, ischemia-reperfusion injury following cardiopulmonary bypass, or a congenital coronary artery anomaly.

.

Heart failure can be classified into 4 functional classes:

1) Volume overload: Large left to right shunts, valvular insufficiency, or systemic arteriovenous fistulae.

2) Pressure overload: Outflow or inflow obstruction.

3) Disorders affecting the inotropic state: Myocarditis, electrolyte disturbances, hypoxia, acidosis, various cardiomyopathies, coronary artery lesions, endocrine or metabolic derangements, septic shock, toxic shock.

4) Alterations in the chronotropic state: Supraventricular or ventricular tachycardia, complete heart block.

To better understand congestive heart failure in pediatric patients, especially infants, one must have an understanding of the developing heart. Fetal and newborn hearts function at a high diastolic volume (high on the Frank-Starling contractility curve) and therefore have limited diastolic reserve. As afterload or volume load on the young heart increases, there is relatively limited ability to develop additional contractility. This is thought to be, at least in part, due to a relative paucity of the contractile mass in the developing heart, incomplete neural innervation, and low norepinephrine stores. An increase in heart rate is the dominant mechanism to increase cardiac output in all patients with heart failure, but this is especially important in infants and younger children.

There are several neurohormonal and biochemical derangements in congestive heart failure, which perpetuates its symptomatology and leads to chronic heart failure. Alterations in calcium handling occur within the myocardium secondary to impairment of sarcoplasmic reticulum function, anaerobic metabolism, and developing acidosis. The fall in cardiac output and changes in regional circulation accompanying heart failure leads to an activation of the renin-angiotensin-aldosterone system and the sympathetic nervous system. Activation of these systems can lead to direct myocardial toxicity, peripheral vasoconstriction, and increased renal sodium and water reabsorption. Cardiac beta-receptors are down-regulated causing a reduced inotropic response to beta-adrenergic stimulation. Myocardial remodeling including hypertrophy, cell injury, and fibrosis, interferes with normal myocyte function and increases susceptibility to arrhythmias.

Clinical findings in congestive heart failure can be broken down into signs and symptoms of impaired myocardial performance, pulmonary congestion, and systemic venous congestion.

The signs and symptoms of impaired myocardial performance include:

1) Cardiomegaly: Represents ventricular hypertrophy and/or dilatation.

2) Tachycardia: Mediated by an increased adrenergic drive. This is the body's attempt to improve cardiac output and oxygen delivery.

3) Gallop rhythm: Represents either increased flow across the AV valves in the presence of a large left to right shunt, or rapid filling of a non-compliant ventricle.

4) Atrioventricular valve regurgitation: Due to ventricular dilatation, decreased ventricular contractility, and at times infarction of papillary muscles.

5) Decreased or increased arterial pulsations depending on the lesion leading to heart failure. Extremities are usually cool, with weak peripheral pulses secondary to systemic vasoconstriction. Arterial pulses may be bounding with lesions causing a large diastolic runoff as seen with large arteriovenous fistulas, patent ductus arteriosus, or an aortopulmonary window (other aorto-pulmonary communication).

6) Growth failure: A consequence of decreased systemic perfusion and raised energy requirements.

7) Diaphoresis (especially with feeding): Represents increased adrenergic activity.

The signs and symptoms of pulmonary congestion include:

1) Tachypnea: Secondary to interstitial and bronchiolar edema.

2) Wheezing: Due to external compression on airways, e.g., from an enlarged left atrium.

3) Rales: Implies the process is severe, with involvement of the alveolar spaces.

4) Mild cyanosis: Secondary to impaired gas exchange (pulmonary edema).

5) Dyspnea.

6) Orthopnea.

7) Persistent cough.

The signs and symptoms of systemic venous congestion include:

1) Hepatomegaly: This may be associated with a mild elevation in the bilirubin level and liver function tests.

2) Jugular venous distention: Seen only in older children and adolescents.

3) Peripheral edema: Facial edema is most common in infants and children. Extremity edema may be seen in older children and adolescents. Ascites is usually only seen in older age groups with very advanced heart failure.

It must be remembered that the signs and symptoms of congestive heart failure in pediatric patients with congenital heart disease will begin at varying ages depending on whether the patient has a ductal dependent lesion or a left to right shunt. Patients with large left to right shunts, such as those with a large ventricular septal defect or atrioventricular canal, may not present with symptoms until 4 to 6 weeks of age when the pulmonary vascular resistance has decreased sufficiently to allow development of interstitial and alveolar pulmonary edema. Ductal dependent lesions (e.g., hypoplastic left heart syndrome, aortic coarctation, pulmonary atresia) most often will present in the newborn period as cyanosis. Occasionally these patients will not present until 1 week or more of life after the ductus arteriosus has closed and the patient presents in a shock-like state.

There are several laboratory studies utilized in the diagnosis and assessment of congestive heart failure in the pediatric patient. A chest x-ray is one of the more useful studies in the initial assessment of a patient with suspected heart failure. This allows evaluation of heart size and contour, pulmonary vascularity, presence of pleural effusions, abdominal and cardiac situs (i.e., whether situs inversus or dextrocardia is present), aortic arch sidedness (occasionally, since the X-ray sign of a right or double aortic arch is very subtle), and lung expansion. An electrocardiogram is most useful in instances where heart failure is secondary to an arrhythmia, anomalous coronary artery, or myocarditis. Echocardiography is useful in all patients with heart failure to assess for structural anomalies, cardiac function, and cardiac chamber sizes. Since filling chamber enlargement is one of the initial abnormalities in heart failure, the earliest sign of heart failure will be cardiomegaly (before pulmonary edema) on chest x-ray (CXR), and the earliest sign of heart failure on an echocardiogram will be enlargement of the filling chambers (left atrium for left sided heart failure, right atrium for right sided heart failure) and/or decreased ventricular contractility.

Other useful laboratory studies may include an arterial blood gas (in very ill patients), serum electrolytes (including calcium and magnesium levels), and a complete blood count (to help rule out the presence of anemia). Pediatric patients with heart failure will often have a mild hyponatremia, resulting from increased renal water retention rather than a true negative sodium balance. Mild hyponatremia, therefore, does not need to be treated. Administering supplemental sodium may actually worsen the patient's fluid retention and heart failure.

The major goals in the treatment of congestive heart failure include relief of pulmonary and systemic venous congestion, improvement of myocardial performance, and reversal of the underlying disease process (if possible). Historically, digoxin has been one of the most widely used pharmacologic agents in the treatment of heart failure in infants and children. In addition to its positive inotropic effect, digoxin exerts beneficial effects via sympathetic-inhibiting actions via baroreceptor, central, and adrenergically mediated mechanisms. Other inotropic agents used in the treatment of acute heart failure include dopamine, dobutamine, and phosphodiesterase inhibitors (milrinone and amrinone).

Diuretic therapy plays an integral part in the treatment of pediatric patients with congestive heart failure. The three most commonly utilized classes of diuretics include the loop diuretics (furosemide-Lasix, bumetanide-Bumex), potassium sparing diuretics (spironolactone), and thiazide diuretics (hydrochlorothiazide). The benefits of diuretic therapy include improvement in systemic, pulmonary, and venous congestion. Spironolactone may exert additional beneficial effects by attenuating the development of aldosterone-induced myocardial fibrosis, and catecholamine release. This currently remains under investigation. Potential complications of diuretic therapy include volume contraction, electrolyte abnormalities (hyponatremia, hypo- or hyperkalemia, hypochloremia), and metabolic alkalosis or acidosis. Electrolyte balance should be carefully monitored, especially during aggressive diuresis, as the failing myocardium is more sensitive to arrhythmias induced by electrolyte dyscrasias.

The use of afterload reduction is one of the newer concepts in the management of heart failure. Relaxation of arteriolar smooth muscle helps to decrease the systemic vascular resistance and augment cardiac output. Venodilatation exerts its effect on preload by increasing venous capacitance, thus lowering filling pressures. The angiotensin-converting enzyme (ACE) inhibitors decrease systemic vascular resistance and have a favorable effect on the body's neurohormonal response to heart failure and cardiac remodeling. Several adult studies have demonstrated improved symptoms and survival with the use of ACE inhibitors in patients with heart failure. Their role in the treatment of heart failure in children is less well defined. They are thought to have beneficial hemodynamic effects in patients with decreased systemic ventricular contractility, and those patients with large left to right shunts. ACE inhibitors should be started at a low dose then gradually increased, especially in infants. The phosphodiesterase inhibitor milrinone is often used in the intensive care setting of acute, new onset systemic ventricle dysfunction (e.g., myocarditis), and in the immediate post-operative setting following cardiopulmonary bypass (ischemia-reperfusion injury).

Treatment of chronic heart failure with the use of beta-blockers, such as carvedilol, is now an accepted practice in the adult population. Several studies have shown a reduction in both hospitalization and mortality. The beneficial effects are thought to be derived

from the reversal of myocardial dysfunction occurring secondary to sympathetic activation and down-regulation of beta-adrenergic receptors, coronary artery vasodilatation, and possible anti-oxidant effects. The present state of knowledge for use in the pediatric population is based on anecdotal experience from unblinded, non-randomized studies of small sample size. Therefore, beta-blockers should be used with caution in infants and children with chronic heart failure until more experience is gained with these agents.

Other non-pharmacologic therapeutic measures that may be considered in patients with congestive heart failure include elevation of the head and shoulders to 30 to 45 degrees, bedrest, dietary changes (higher caloric intake, and a low sodium diet in older children and adolescents), packed red blood cell transfusion, iron supplementation, and the administration of supplemental oxygen. It must be remembered that oxygen is a pulmonary vasodilator, therefore in patients with known large left to right shunt lesions, administration of oxygen will decrease pulmonary vascular resistance, increase the degree of left to right shunting, and worsen the degree of pulmonary edema.

For acute pulmonary edema, several treatment methods are used which help to understand the underlying pathophysiology. Within the alveolus, the major force which holds water in the interstitial and vascular space is the plasma oncotic pressure. The force attempting to push water out into the alveolar space is the hydrostatic fluid pressure. Pulmonary edema basically occurs when the hydrostatic force pushing the fluid out, exceeds the oncotic force holding the fluid in. The air pressure within the alveolus has some effect as well. It is slightly positive (pushing the fluid out of the alveolus into the interstitium) when we exhale, since we exhale against partial resistance. The air pressure is negative when we inhale (which favors drawing fluid into the alveolus). To treat acute pulmonary edema, the hydrostatic force pushing the fluid out into the alveolar space can be reduced by reducing back pressure (preload and afterload reduction) by the following therapeutic measures: 1) diuresis, 2) vasodilation (increases vascular capacitance), and 3) augmenting contractility (reduces back pressure). An alternative means to treat acute pulmonary edema is to increase the pressure within the alveolus to counterbalance the excessive hydrostatic pressure with positive pressure ventilation via mask CPAP (continuous positive airway pressure) or through an endotracheal tube with a ventilator. This literally pushes the fluid out of the alveolus back into the interstitium and vascular space. The most important parameter to increase to reverse pulmonary edema is the PEEP, which is the positive end-expiratory pressure. With a ventilator, inspiration is under positive pressure driving the fluid out of the alveolar space. However, during exhalation, the positive pressure declines permitting the fluid to return. A high PEEP (10 to 20 mmHg) will prevent this and keep the lungs clear until other measures can be taken to control the pulmonary edema.

Other measures of historical interest only, include phlebotomy (to balance the humors) and rotating tourniquets. These measures are not as effective as the other therapies mentioned.

In patients with heart failure, the treatment plan should ultimately deal with the underlying condition. This may include surgical repair of a shunt lesion or valvular anomaly, interventional cardiac procedures, radiofrequency ablation, control of hypertension, anti-inflammatory treatment for rheumatic carditis, pacemaker implantation, carnitine supplementation, adenoidectomy and weight loss for patients with airway obstruction, pulmonary hypertension and right heart failure, or cardiac transplantation.

The prognosis of the pediatric patient with heart failure depends largely on the primary condition. In those patients with large left to right shunts, such as a ventricular septal defect, medical therapy will often maintain the patient in a well compensated state until the VSD spontaneously begins to close or it is decided the defect needs to be surgically repaired. Repair of congenital heart defects with large left to right shunts (VSD, ASD, AV canal), or those with valvular abnormalities carry a low surgical mortality in the hands of an experienced pediatric cardiovascular surgeon. The majority of patients with myocarditis, who present in heart failure, will improve with medical management. Patients with cardiomyopathies or hypoplastic left heart syndrome will occasionally require a heart transplant as a last resort. In these cases, the prognosis is much more guarded. Those patients with arrhythmia induced heart failure will often respond well to anti-arrhythmic therapy and/or electrophysiology study and radiofrequency ablation.

Questions

1. What is the most common congenital heart defect with a left to right shunt causing congestive heart failure in the pediatric age group?
    a. Atrial septal defect
    b. Atrioventricular canal
    c. Ventricular septal defect
    d. Patent ductus arteriosus
    e. Aortopulmonary window

2. True/False: Jugular venous distention is a common finding in infants with heart failure.

3. What is the most likely age an infant with a large ventricular septal defect will begin manifesting symptoms of congestive heart failure?
    a. 1 day
    b. 1 week
    c. 1 month
    d. 6 months
    e. 1 year

4. True/False. Administration of supplemental oxygen to a child with a large left to right shunt lesion will help improve the degree of congestive heart failure.

5. What is the dominant mechanism with which infants and young children increase their cardiac output?
    a. By increasing ventricular contractility
    b. By increasing heart rate
    c. By increasing ventricular end-diastolic volume
    d. By decreasing heart rate
    e. By increasing respiratory rate

6. True/False: All neurohormonal and sympathetic responses of the body to heart failure are beneficial.

7. The earliest sign of congestive heart failure on a chest X-ray is:
    a. Increased heart size.
    b. Kerley B lines.
    c. Central pulmonary vascular congestion.
    d. Pulmonary edema.
    e. Pleural effusion.

Chapter VII.2. Acyanotic Congenital Heart Disease

Edgar C.K. Ho, MD

A 4 year old male presents in the office for a preschool physical examination. In the course of the interview, his mother mentions that he seems to get short of breath with exercise recently. It is especially noticeable during his swimming lessons when he tires before the other children do in his class. He has otherwise been in good health since his last physical exam in the previous year. His records for the past year show 3 office visits for minor upper respiratory illnesses, and no emergency room visits. He has never had wheezing during his colds.

Exam: T37.5, P92, R25, BP right arm 97/70, oxygen saturation 98% in room air. Height and weight are at the 25th percentile. He is cooperative and well nourished in no distress. HEENT and neck exams are normal. His chest is symmetrical. Heart: No palpable thrill, normal 1st and 2nd heart sounds; no clicks or rubs; grade 1/6 ejection systolic murmur heard along the left sternal border with radiation to the back between the scapulae; no diastolic murmur. Lungs are clear to auscultation. Abdomen without no organomegaly or masses palpable. Genitalia: normal male. Extremities: Femoral pulses are slightly diminished to palpation; no peripheral edema, clubbing or cyanosis of the nail beds. His neurological is normal.

He receives his immunizations, and tuberculin skin test, and because of the new onset heart murmur, a chest x-ray and EKG are ordered. He returns in 3 days to have his skin test read and to review his cardiac tests. Before entering the exam room the nurse remeasures his vital signs and records in his chart: BP left arm 127/86, P88, R24. His chest x-ray shows a cardiac/thoracic ratio of 0.55, normal cardiac configuration, and normal pulmonary vasculature. His EKG has tall R waves of 40 mm in lead V5, and 35 mm in lead V6. An echocardiogram is performed the following day and demonstrates a coarctation of the aorta, and bicuspid aortic valve. A MRI shows a discrete narrowing of the distal aortic arch just beyond the origin of the left subclavian artery and also reveals an aberrant right subclavian artery originating from the proximal descending aorta below the coarctation.

Coarctation of the aorta is classified as an acyanotic congenital heart defect and belongs to that group of cardiac anomalies that is the result of abnormal fetal cardiac formation, that does NOT cause shunting of blood from the venous to the systemic side of the heart (i.e., it does NOT cause right to left shunting), and that may be manifested and clinically detectable some time after birth. With the advent of fetal echocardiography, these lesions are sometimes detected before birth.

A list of the acyanotic lesions can be made by enumerating the structures encountered by the flow of blood through the different parts of the heart beginning with the venous side. The most common anomalies would thus include: tricuspid valve stenosis/regurgitation, Ebstein's anomaly of the tricuspid valve (can be cyanotic in infants), pulmonic valve stenosis/regurgitation, subvalvular and supravalvular pulmonic stenosis, partial anomalous pulmonary venous drainage to the right side of the heart, atrial septal defect (secundum, primum, sinus venosus), mitral valve stenosis/regurgitation, ventricular septal defect, aortic valve stenosis/regurgitation, subvalvular and supravalvular aortic stenosis, patent ductus arteriosus, and coarctation of the aorta.

Acyanotic congenital lesions account for 70% of all congenital heart disease, the most common of which, as isolated lesions, are ventricular septal defects (most common), patent ductus arteriosus, atrial septal defect and pulmonic stenosis. Coarctation of the aorta accounts for (6%) of all congenital heart disease (1). Patients with Turner syndrome have coarctation more commonly than the general population.

Coarctation of the aorta results from constriction of the tissue of the distal aortic arch at the junction with the descending aorta and near the insertion of the ductus arteriosus. Various theories have been proposed to explain this maldevelopment. One popular theory associates the presence of ductal tissue encircling the aorta at the site of the coarctation suggesting a constrictive effect of the ductile tissue (2).

Although present at birth, coarctation of the aorta may not cause symptoms until early childhood and sometimes not until late childhood, depending on the severity of the coarctation, and the presence of associated cardiac lesions. If a ventricular septal defect is also present and is large, the coarctation of the aorta will cause increased left to right shunting across the defect, producing congestive heart failure within the first few months of life as the pulmonary resistance decreases after birth. A patent ductus arteriosus located proximal to

the coarctation would likewise increase pulmonary shunting through the ductus resulting in congestive heart failure. If the ductus is located distal to the coarctation, signs and symptoms may be delayed.

Other anomalies associated with aortic coarctation include a bicuspid aortic valve (85%) (3) that may obstruct left ventricular output, and an aberrant origin of the right subclavian artery distal to the coarctation (1%) (4). The latter will cause the blood pressure of the right arm to be equal to the leg, and may mislead one from the correct diagnosis. It is important to measure the blood pressure in both arms and at least one leg in order to detect the blood pressure differential caused by an aortic coarctation.

If coarctation of the aorta is an isolated lesion, the typical symptoms may include: shortness of breath with exertion, leg pain with exercise, and rarely, chest pain with exercise. Physical findings include: upper extremity hypertension with a blood pressure differential between arm and leg (obtain BP in both arms and one leg), a systolic murmur heard along the left sternal border and especially well over the back between the scapulae, and diminished and delayed pulses in the lower extremities when compared with the upper extremities. A chest x-ray may display cardiomegaly with a left ventricular hypertrophy configuration. In long standing cases, rib notching due to erosion of the lower anterior portion of the rib by dilated collateral arteries can be appreciated. The echocardiogram demonstrates narrowing of the distal aortic arch with increased velocities on pulsed and color Doppler. The pulsed Doppler waveform has a typical prolonged systolic phase extending throughout systole. The MRI produces a static but clearer picture, than the echocardiogram, of the anatomy of the coarctation. An angiogram is sometimes necessary to clarify associated cardiac lesions.

There are several surgical techniques used to repair a coarctation of the aorta. Each technique has had its own proponents at one time or another. If the coarcted segment is short and discrete, resection and end to end anastomosis of the proximal and distal ends is possible. If the coarctation is a long tubular obstruction, resection with interposition of a tube graft would be necessary. Some surgeons favor a longitudinal incision with insertion of a synthetic graft to enlarge the diameter. In the young infant, sacrificing the left subclavian artery, and using the transected blood vessel as a graft by turning it down and sewing it into the aortic wall was popular at one time (5).

Catheter balloon dilatation of native coarctations has not been as successful as dilatation of postoperative restenosis of a coarctation. The former technique has resulted in late appearance of aneurysms. The use of stents to reinforce the arterial wall is now preferred to balloon dilation alone.

A postoperative complication that is now rare is the syndrome of mesenteric arteritis (6), caused by reflex spasm of mesenteric arteries that are suddenly exposed to higher pressures after the coarctation is removed. The spasm can be severe enough to result in bowel ischemia. Patients are being operated on at a younger age now so that the mesenteric arteries do not have as long a period of exposure to low pressures and are therefore less reactive.

Ventricular septal defects (VSD), atrial septal defects (ASD), and patent ductus arteriosus (PDA) account for a large percentage of all congenital heart defects. They share common physiologic hemodynamics and will be discussed together.

These defects represent abnormal communications between the high pressure left side of the heart and the low pressure right side of the heart. The pressure differential results in a left-to-right shunting of blood through the defect. The consequences of this shunting of blood are: turbulence of abnormal blood flow producing a heart murmur in systole and sometimes in diastole; excessive blood flow into the lungs causing shortness of breath and increased pulmonary vascularity on a chest x-ray; and increased volume overload of the myocardium resulting in hypertrophy of myocardium and chamber dilatation.

The murmur of a VSD is located at the lower left sternal border and is dictated by the anatomic location of the defect in relation to the chest wall. Since flow across the VSD occurs as long as there is a pressure differential between left and right ventricles, the timing of the murmur in this lesion is pansystolic. The high pressure turbulence of the shunted blood produces a harsh quality to the murmur. When the pulmonic flow exceeds the systemic flow by a ratio of 2:1, an apical diastolic murmur is produced due to excessive flow during recirculation across the mitral valve. Frequently, a VSD murmur is not heard at birth (day 1 of life) since pulmonary vascular resistance and pulmonary pressure may still be high, limiting left to right shunting through the VSD. As pulmonary vascular resistance drops further, more left to right shunting through the VSD occurs, making the murmur audible on day 2 or day 3 of life.

The murmur of an ASD is produced by excessive flow across the pulmonic and tricuspid valves resulting in a systolic murmur at the second left intercostal space and a mid-diastolic murmur over the lower right sternal area. Note that this is a flow murmur and NOT a murmur due to turbulent flow across the ASD. Flow across the ASD is low velocity and not turbulent and therefore produces no audible murmur itself.

The flow through a PDA is continuous due to the existence of a constant pressure differential between aorta and pulmonary artery in both systole and diastole. The machinery quality of the murmur results from the rhythmic variation of the pressure differentiation during the cardiac cycle. The location of the murmur is at the upper left sternal border.

A small shunt produces only a murmur but no symptoms. With increasing defect size and pulmonary flow, signs and symptoms of congestive heart failure occur: shortness of breath with exertion and in severe cases, also at rest; cough and susceptibility to pulmonary infections; hepatomegaly, splenomegaly, and lower extremity edema result from retrograde extension of the systemic venous congestion into the liver, spleen and legs.

The chest x-ray in a left-to-right shunt lesion will demonstrate congested pulmonary vessels. Enlargement of specific cardiac chambers is due to excessive volume overload. The left atrium and ventricle are dilated in VSD and PDA, and the right heart chamber is dilated in ASD. The EKG reveals hypertrophy of the corresponding cardiac chambers.

Untreated defects with large shunts will eventually result in injury to the pulmonary arterioles, vascular obstruction, and pulmonary hypertension. The development of permanent injury to the pulmonary vessels is a function of the duration of the exposure to excessive blood flow and the anatomy, occurring more rapidly in VSD and PDA than in ASD. If this process is not reversed, Eisenmenger's complex of right to left shunting may occur as the right sided pressures (pulmonary hypertension) exceeds left sided pressures.

Intracardiac repair of a VSD and ASD require cardiopulmonary bypass. Repair of a PDA is extracardiac and is achieved without cardiopulmonary bypass. The intracardiac defects can be closed by primary suturing of the edges of the defect if small, or by covering with a patch material if large. The PDA is usually tied off and divided.

Complete heart block secondary to injury to the conduction system during repair of a VSD may require a pacemaker in the postoperative period. The knowledge of the location of the conduction system in relationship to the defect now makes this a rare complication. The mortality rate in experienced hands should be less than 5% if all ages are considered, with infants carrying a higher mortality rate especially if pulmonary hypertension is present.

Questions

1. True/False: Congenital heart disease is always detectable at birth.
2. True/False: Equal blood pressures in the right arm and left leg rule out the diagnosis of coarctation of the aorta.
3. Which are the three most common acyanotic congenital heart lesions?
4. True/False: The presence of palpable femoral pulses rules out the diagnosis of aortic coarctation.
5. True/False: Surgical repair of PDA does not require cardiopulmonary bypass.
6. Explain how a child with an isolated VSD (classified as an acyanotic lesion) could become cyanotic?
7. True/False: Medical students and residents will typically not hear the murmur of a VSD during the initial newborn assessment in the nursery because the murmur of a VSD is subtle and low pitched.

Answers to questions

1. False. The physiologic pulmonary hypertension present in a newborn can prevent blood flow across a septal defect or PDA. These can be detected several hours after birth or several days after birth. Other congenital heart disease lesions may remain occult for longer period of time.
2. False. An aberrant right subclavian artery originating below a coarctation will produce equal pressures in the right arm and leg.
3. VSD, ASD, PDA. Of these, VSD is the most common.
4. False. Development of collateral vessels to the lower body can produce palpable femoral pulses.
5. True.
6. Congestive heart failure and pulmonary edema may cause hypoxia. If the hypoxia is severe enough, visible cyanosis will result, although this can be overcome with oxygen and other treatments for pulmonary edema and congestive heart failure. Long standing excessive pulmonary blood flow leads to pulmonary hypertension and Eisenmenger's complex, right to left shunting and cyanosis.
7. False. They cannot hear the murmur of a VSD on day 1 because on day 1, pulmonary vascular resistance is still high, which restricts left to right flow through the VSD. On day 2, pulmonary vascular resistance is lower, so left to right shunting through the VSD increases making the murmur louder.

Chapter VII.3. Cyanotic Congenital Heart Disease
D. Venu Reddy, MD, MPH

This is a 3 month old male infant who presents to the emergency department with a history of having episodes of excessive crying followed by limpness, cyanosis and fainting. He was born at 41 weeks of gestation by C-section because of failure to progress to a 23 year old mother G1P0. Apgar scores of 7 and 8 at 1 and 5 minutes, respectively. He had a two vessel cord and acrocyanosis. His cyanosis increased with crying and he had a grade 3/6 ejection systolic murmur along the upper left sternal border (ULSB). His oxygen saturations were 95% and stable. He was discharged from the hospital and followed in the office until this episode. He is now being hospitalized.

Exam: VS T 37, P164, RR 64, oxygen saturation 83% on oxygen by nasal prongs. Weight 50th percentile. He is alert and active in mild respiratory distress, with visible cyanosis. HEENT exam is negative. His heart rhythm is tachycardic. He has a mild right precordial heave with a grade 3/6 ejection murmur at ULSB and a diminished 2nd heart sound. His lungs are clear. Liver and spleen are not enlarged. He has normal peripheral pulses with cyanotic nail beds and mucous membranes.

An echocardiogram is obtained which identifies cyanotic congenital heart disease. This is confirmed at cardiac catheterization. He subsequently undergoes palliative surgery with improved oxygenation and appearance of a continuous murmur. He is discharged in stable condition to be followed on an outpatient basis and to undergo further corrective surgery at a later date.

Cyanosis is a bluish discoloration of skin and mucous membranes. It results from reduced hemoglobin in blood of at least 3-5 gm/dL (1). Cyanosis can be secondary to cardiac, respiratory, hematologic and metabolic causes. Methemoglobinemia, decreased alveolar hypoventilation secondary to depressed respiratory center or obstruction of the respiratory passages, polycythemia, and hypoglycemia, shock, and sepsis may also cause cyanosis, or at least something that resembles cyanosis. It can be central or peripheral. Peripheral cyanosis is secondary to low cardiac output, in which acrocyanosis usually occurs with cool extremities and small pulse volume with bluish discoloration at the tip of the nose and fingers, and less in the mucous membranes. It is often difficult to differentiate pulmonary from cardiac causes of cyanosis in the newborn. A hyperoxy test may be helpful, whereby an arterial pO2 is measured in room air, which is then compared to a arterial pO2 measured in an FiO2 of about 90%-100% for about 10-15 minutes. Respiratory problems with alveolar hypoventilation usually improve with paO2 measurements well above 100-150 mmHg, whereas in right-to-left shunt cardiac lesions, the improvement in arterial pO2 is very minimal. Echocardiogram and chest x-ray are useful in differentiating these causes.

The above mentioned case represents a diagnostic and management problem. Classifying cyanotic congenital heart defects into those with increased vascularity with an accentuated second heart sound and those with decreased blood flow with a diminished second heart sound, can simplify the differential diagnosis to an extent. Chest x-ray findings and attention to the second heart sound may help. Lesions with increased or normal blood flow with accentuated second heart sounds include transposition of the great vessels, truncus arteriosis, total anomalous pulmonary venous return, single ventricle, single atrium, and hypoplastic left heart. Eisenmenger syndrome also falls into this category, but this is an acquired condition in which a patient with a left-to-right shunt and chronic CHF develops pulmonary hypertension and a subsequent right-to-left shunt. Those lesions with decreased blood flow and diminished second heart sound include tetralogy of Fallot or tetralogy of Fallot-like lesions, pulmonary atresia, tricuspid atresia, and Ebstein's malformation.

Transposition of the great vessels is the most common cyanotic congenital heart disease in the newborn infant (tetralogy of Fallot is more common overall, but many tetralogy of Fallot cases present after the newborn period). Transposition represents 4%-5% of all congenital heart defects (2). The aorta arises from the right ventricle and pulmonary artery from the left ventricle, with the aorta positioned anterior and to the right of the pulmonary artery. It is incompatible with life unless a communication exists between systemic and pulmonary circulation, as the two circulations are in parallel (and independent). During the newborn period, the PDA and patent foramen ovale (PFO) maintain this communication. As the PDA starts to close and the PFO by itself is inadequate in size, the patient develops intense cyanosis, and the patient becomes tachypneic. On auscultation, the second heart sound is greater in intensity, as the aortic valve is anterior. A heart murmur may not be present unless other associated lesions are present. An electrocardiogram may show right ventricular hypertrophy, but this is non-specific since RVH is present in normal newborns. Chest x-ray shows increased pulmonary vascular markings and a narrow mediastinal shadow secondary to a small thymus, sometimes giving the appearance of "egg on side" or "apple on a string" appearance. Echocardiography confirms the diagnosis and delineates the other associated lesions. Inadequate mixing between systemic and pulmonary circuits represents a medical emergency and a prostaglandin E1 infusion which maintains ductus arteriosus patency (to preserve mixing) may be lifesaving, followed by balloon atrial septostomy (Rashkind procedure). Surgical management consists of an arterial switch procedure (aorta and pulmonary artery are anastomosed to the correct ventricle), which is the operation of choice. The atrial switch (atrial baffling) such as Senning or Mustard procedures are no longer done because of the development of later complications. Survival without surgery is unlikely. The arterial switch procedure offers the best prognosis with a mortality of about 5%.

Tetralogy of Fallot constitutes 4%-9% of congenital heart disease and is the most common cyanotic congenital heart disease when considering all age groups together. Tetralogy of Fallot and pulmonary atresia with ventricular septal defect consist of: a) ventricular septal defect, b) pulmonary stenosis, c) overriding of the aorta, and d) right ventricular hypertrophy. Approximately 25% have a right-sided aortic arch, and about 4% have a coronary artery anomaly. The degree of cyanosis depends on the degree of pulmonic outflow obstruction. This is quite variable, from a slight obstruction, to severe obstruction with pulmonary atresia. Pulmonary atresia constitutes about 18% of the children with tetralogy of Fallot (3). The major right ventricular outflow obstruction in tetralogy of Fallot is infundibular stenosis. With mild stenosis, there may be congestive heart failure in infancy, also known as "pink tetralogy of Fallot." As infundibular stenosis increases, progressive cyanosis develops (due to less pulmonary blood flow), and infants and children may develop cyanotic or hypoxic spells, which consist of sudden onset of increased cyanosis, excessive crying, hypoxemia, acidosis, dyspnea, fainting, rarely seizures, and occasionally death if untreated. During these episodes (called "Tet" spells), there is increased right-to-left shunting (with less pulmonary flow), and decreased systemic vascular resistance. Older infants and children may assume a squatting position during playtime or long walks which increases systemic vascular resistance and decreases right to left shunting, increasing their oxygenation.

Clinical examination shows a loud systolic ejection murmur from the right ventricular outflow obstruction at the left sternal border conducted to the upper sternal border towards the suprasternal notch. The second pulmonary sound may be diminished, but the aortic component may be loud, as the aorta is anterior.

The electrocardiogram shows the non-specific right ventricular hypertrophy. Chest x-ray shows decreased pulmonary vascular markings (reduced pulmonary perfusion) and right ventricular hypertrophy with a leftward apex. There is an absence or decreased main pulmonary artery segment, which may give the appearance of a "boot shaped heart." Echocardiography demonstrates a ventricular septal defect with an overriding of the aorta, pulmonic stenosis, right ventricular hypertrophy, and in about 25% of cases, a right aortic arch (i.e., the aorta goes over the right mainstem bronchus instead of the left) is also present. Cardiac catheterization is done in cases in which the anatomy of the defect is not clear on echocardiogram.

Management during the newborn period consists of administration of prostaglandin E1 when the infant is markedly cyanotic and pulmonary blood flow is ductus dependent. This is followed by a systemic artery to pulmonary artery shunt (Blalock-Taussig shunt). Treatment of hypercyanotic spells is directed towards improving pulmonary blood flow. These include oxygen, knee/chest position, morphine, intravenous fluids, sodium bicarbonate, propranolol (beta-blocker), or increasing systemic vascular resistance by administration of drugs, such as phenylephrine. Total surgical correction of the defect is performed under cardiopulmonary bypass, and it can now be performed in young infants from 3-6 months of age or earlier (4). Prognosis is good with total correction. However, the majority of them still have residual defects and some of them may need reoperation and life long medical follow up.

Truncus arteriosus consists of a single arterial vessel arising from the heart, positioned over a ventricular septal defect, supplying systemic, coronary and pulmonary circulations. It accounts for about 1%-4% of the congenital heart defects. Associated anomalies are common, such as DiGeorge syndrome. Symptomatology depends upon the amount of pulmonary blood flow. With increased blood flow, symptoms of congestive heart failure such as tachypnea, cyanosis, retractions, etc., develop. There may be a systolic murmur at the left sternal border or an apical aortic ejection click. A diastolic murmur of truncal insufficiency may be heard along the left sternal border. The electrocardiogram may show right or left or combined ventricular hypertrophy. Chest x-ray shows an enlarged heart and increased pulmonary vasculature. There may be a right aortic arch (25%). The echocardiogram shows a truncal root overriding VSD, and pulmonary arteries arising from the trunk. Cardiac catheterization may be indicated when the anatomic features are not clear on echocardiography. Management consists of treatment of congestive heart failure followed by surgery. Surgical correction consists of closure of the VSD, separation of the pulmonary arteries from the trunk and anastomosing them through a conduit from the right ventricle (Rastelli procedure). The prognosis is poor in untreated cases. After surgery, they will need long term follow up as they will eventually need to have the conduit graft replaced.

Total anomalous pulmonary venous return (TAPVR) occurs in about 1%-2% of patients with congential heart disease. There are four types of TAPVR causing left-to-right shunt: Supracardiac, cardiac, infracardiac, and mixed. In the supracardiac type, pulmonary veins join to form a common vein which drains into the SVC. In the cardiac type, the common pulmonary veins drain into the right atrium directly or via the coronary sinus. In the infracardiac type, the common pulmonary vein courses downward through the diaphragm into the portal vein, which then drains via hepatic veins into the inferior vena cava.

Anomalous pulmonary venous return could be total or partial. An atrial septal defect is necessary for survival, since the oxygenated blood (from the pulmonary veins) must somehow reach the left side of the heart. Symptomatology depends on the amount of mixing and whether or not the pulmonary veins are obstructed. Cyanosis and signs and symptoms of congestive heart failure develop and progress rapidly. There may be a grade 2/6 systolic ejection flow murmur heard along the left sternal border, or it may be absent. The electrocardiogram shows right ventricular hypertrophy and right atrial hypertrophy. Chest x-ray shows increased pulmonary vascular markings or even edema, and the heart may be normal in size or minimally enlarged. The echocardiogram may show right ventricular volume overload, and a color-flow Doppler study may help in locating the common pulmonary venous channel and its drainage. If the resolution is poor, cardiac catheterization and angiocardiography may help in delineating the anomaly further. Treatment consists of correction of the defect by surgery. If surgery is delayed and there is inadequate mixing, palliative balloon septostomy may be performed. Prognosis is good after surgery. Prognosis is poor in neonates with obstructive TAPVR. Long term follow up is needed to assess restenosis and late arrhythmias.

Tricuspid atresia consists of an absence or atretic tricuspid valve and a hypoplastic right ventricle. Blood from the right atrium enters the left atrium through an atrial septal defect or foramen ovale. They may have associated lesions such as TGA, VSD, PDA, right aortic arch, pulmonic stenosis or atresia. Communication between right and left circulation is essential to sustain life. Symptomatology depends on the amount of pulmonary blood flow. In the absence of a VSD, as the PDA closes, patients may develop intense cyanosis, tachypnea and tachycardia. The electrocardiogram usually shows left axis deviation (very unlike the RVH seen in normal newborns) and right atrial hypertrophy and left-ventricular hypertrophy. Chest x-ray may show increased or decreased pulmonary blood flow depending on the shunt and a normal or mildly increased heart size. Echocardiography usually delineates these abnormalities and very rarely a cardiac catheterization may be needed. Prostaglandin E1 may be life saving in infants with low oxygen saturation with duct dependent pulmonary blood flow. This is followed by a modified Blalock Taussig anastomosis. If the interatrial communication is narrow (small PFO/ASD) then a balloon or blade atrial septostomy is performed (5). Surgical correction initially consists of a bilateral Glenn procedure (superior vena cava to right pulmonary artery shunt) followed by an inferior vena cava anastomosis to the right pulmonary artery through an intra or extra cardiac baffle (modified Fontan procedure). Prognosis is good after surgery but patients will need multiple surgeries with associated morbidity such as pleural effusion, ascites, arrhythmia and mortality.

Ebstein anomaly is characterized by downward displacement of the septal and posterior leaflets of the tricuspid valve which are attached to the right ventricular septum. The anterior leaflet is elongated and is displaced downward within the right ventricular cavity causing "atrialization of the right ventricle" (i.e., the right ventricle is small). There is usually a PFO or an ASD or PS (pulmonic stenosis). Cyanosis depends up on the right to left shunt. Auscultation may reveal a triple or quadruple gallop rhythm and a split second heart sound. A pansystolic murmur of tricuspid insufficiency or an ejection murmur of PS may be heard. The electrocardiogram shows a right bundle branch block pattern, giant P waves and sometimes first degree AV block or WPW syndrome (delta wave). Chest x-ray shows a huge right atrium and gross cardiomegaly. Echocardiography reveals the lesions of Ebstein anomaly and only rarely is cardiac catheterization needed. Treatment is mainly palliative and there are no good surgical options. In older patients, tricuspid annuloplasty and rarely tricuspid valve replacement may be performed. Prognosis depends on the severity of the lesion. Prognosis is good with mild lesions and poor with severe lesions with other associated anomalies/malformations.

Hypoplastic left heart syndrome consists of a combination of mitral stenosis or atresia, severe aortic stenosis or atresia, and a small left ventricle. Systemic circulation depends on the patency of the ductus. These infants may appear reasonably well at birth until either the pulmonary vascular resistance drops or the PDA closes. They then present with shock, variable cyanosis, poor pulses, poor perfusion and

CHF. A systolic murmur may or may not be present. Chest x-ray shows increase vascularity and EKG may show RV hypertrophy. Echocardiography is diagnostic. Early management consists of administration of PGE1 and treatment of CHF. Surgery consists the Norwood surgical procedure and a few centers perform cardiac transplantation for this lesion. Prognosis is guarded.

Questions

1. A two day old cyanotic infant with a grade 3/6 ejection systolic murmur is noted to have decreased pulmonary vascular markings on chest x-ray and left axis deviation on EKG. The most likely diagnosis is:
   a. Tetralogy of Fallot
   b. Transposition of Great Vessels
   c. Truncus Arteriosus
   d. Tricuspid Atresia

2. A 2 year old infant is noted to have mild cyanosis who assumes a squatting position during long walking. He is noted to have increasing fussiness followed by increasing cyanosis, limpness and unresponsiveness. The most likely underlying lesion is:
   a. Hypoplastic left heart
   b. Transposition of the Great Vessels
   c. Anomalous Pulmonary Venous Return
   d. Tetralogy of Fallot
   e. Aspiration with obstruction to air passages

3. An infant with a marked cyanotic congenital heart defect with decreased pulmonary vascularity should be treated with:
   a. Digoxin
   b. Indomethacin
   c. Prostaglandin E1
   d. Epinephrine

4. Cyanosis is produced by the presence of deoxygenated hemoglobin of at least:
   a. 1-2 gm/dL
   b. 3-5 gm/dL
   c. 6-8 gm/dL
   d. 9-10 gm/dL

5. A "tet spell" or "blue" spell of tetralogy of Fallot is treated with all of the following except:
   a. oxygen
   b. knee chest position
   c. morphine
   d. digoxin
   e. propranolol
   f. phenylephrine
   g. sodium bicarbonate

6. Pulmonary vascularity is increased in all of the following except:
   a. TAPVR
   b. Tricuspid atresia
   c. TGV
   d. Hypoplastic left heart

7. Pulmonary vascularity is decreased in all of the following except:
   a. Tetralogy of Fallot
   b. Pulmonary atresia
   c. TAPVR
   d. Tricuspid atresia

Chapter VII.4. Rheumatic Fever
David K. Kurahara, MD

An 11 year old Polynesian male presents with fever up to 39 degrees (102 degrees F), joint pain and swelling, along with shortness of breath. The fever comes and goes at random times of the day. The symptoms have been present now for 4 days. Two days ago, his right knee was painful and swollen, but today it has improved. The joints involved today include the right ankle and left knee. They are quite tender, painful and also swollen. The shortness of breath occurs with walking, but he is now unable to walk because of the joint pain. He also has some shortness of breath with lying down flat when he is trying to sleep.

Exam: VS T 38.2, P 160, RR 32, BP 100/60, oxygen saturation 94% in room air. He is tired appearing with tachypnea and tachycardia. HEENT: Enlarged, erythematosus tonsils with exudates. Lungs are clear but with tachypnea. Heart sounds are tachycardic with a holosystolic murmur 3/6 heard at apex with radiation to axilla. No gallops are heard. His PMI is prominent (size of silver dollar) at the 7th intercostal space in the mid-axillary line. His abdomen is soft with normoactive bowel sounds. His liver edge is 6 to 7 cm below the RCM. His left knee is swollen and extremely tender with warmth. He has difficulty with range of motion but can flex his knee 30 degrees passively. His right ankle is very swollen and warm. He has limited subtalar motion. Both his knee and ankle are very tender even to touch. Neuro: No abnormal movements of arms, hands, or tongue are noted. He is unable to walk due to pain.

Clinical course: The child is admitted to the hospital. Initial laboratory work includes a erythrocyte sedimentation rate of 110, a CRP of 9.5, and a chest X-ray with cardiomegaly present. EKG reveals a prolonged PR interval. ASO titer is 754 and streptozyme is 1:600. The diagnosis of acute rheumatic fever (ARF) is made and he is initially started on salicylate therapy at 75 mg/kg/day, and his arthritis improves dramatically. However, the next day an echocardiogram confirms severe mitral insufficiency. Due to the significant cardiac disease with elements of congestive heart failure he is switched to corticosteroids and improves. His heart size decreases over the next 2 weeks, and when it normalizes he is switched back to salicylates for a total treatment duration of 8 weeks. He does have a persistent murmur after this time however. He is started on intramuscular benzathine penicillin, which is given every 4 weeks for streptococcal prophylaxis.

The terms of Acute Rheumatic Fever and Rheumatic Heart Disease are sometimes confused. Proper use of these terms requires some knowledge of the disease entities even though their pathogenesis and relation to streptococcal infection is nearly identical. ARF is usually used to describe the initial or acute onset of the disease. In our case, this being the first initial presentation of the disease, it would be correct to call this ARF. The case fulfills modified Jones criteria as will be discussed below. However, as time goes on it is found that this child has a persistence of the murmur. He also had severe carditis which caused his acute congestive heart failure, as manifestations of ARF, but he subsequently develops chronic heart disease as a sequelae of the ARF carditis and thus it would also be correct to describe him in terms of a more chronic form of the disease, namely Rheumatic Heart disease (RHD). This term implies there has been significant valvulitis, enough to cause valvular scarring. This child is at an increased risk of requiring a valve replacement in the future, especially if he develops another episode of the disease, which puts great emphasis on him receiving long term penicillin prophylaxis, to prevent him from getting streptococcal disease and possible reoccurrence of ARF with worsening RHD.

The study of ARF and RHD parallels the history of modern medicine. At one time in the early 1900s children filled the beds of hospitals dedicated to treat only rheumatic fever. The treatment at that time was simply bed rest, sometimes for up to a year. With improvements in living conditions, reduction of crowding, and industrialization, ARF incidence has steadily decreased in the United States (1). When the link to streptococcal infection was found, the usefulness of using penicillin to prevent future attacks was also established, and ARF incidence decreased further.

However, certain areas of the country and large parts of the under-developed world, including India, Sub-Saharan Africa, Turkey, Australia, New Zealand, and Tonga, still experience many cases of ARF (2). In the United States, there remains a high incidence of ARF in Hawaii and Utah (3-6). In Hawaii, the ethnic groups at greatest risk are those of Polynesian heritage, with Samoan children being at greatest risk (4-6). The Samoan children also appear to be at greater risk of developing carditis (4,5). More than 75% of patients with ARF, in Hawaii, have Polynesian ethnicity within their heritage.

To accurately diagnosis ARF, one should adhere to the modified Jones criteria (7). These criteria have been modified over the years since it was first developed by T. Duckett Jones. The last modification removed the minor criteria of "a history of ARF", since there are fewer cases seen on the continental United States, and the authors wanted to concentrate on first time cases, rather than recurrent ones (8). These criteria were developed to accurately diagnose ARF. It is very important to use these criteria when making the diagnosis. If the criteria are not used, and the patient is misdiagnosed, you may be subjecting the patient to needless penicillin injections for years. It is sometimes difficult for ARF patients to get life insurance and medical insurance later, due to the implications of the cardiac disease. Therefore, the diagnosis must fulfill the modified Jones criteria.

The modified Jones criteria are categorized into Major and Minor criteria. These criteria are based on how specific the manifestation is to the diagnosis of ARF. In other words, a Major criterion is much more specific to ARF than the Minor criteria. Therefore, if a child that has two Major criteria, they can fulfill Jones criteria for the diagnosis, as long as they have some evidence of streptococcal disease. On the other hand, if there is evidence of only one Major criterion, they need two minor criteria to fulfill the diagnosis, along with evidence of streptococcal infection. Since the minor criteria are less specific for the diagnosis of ARF, you cannot make the diagnosis of ARF with just minor criteria. The symptoms may be dampened by giving aspirin or other non-steroidal anti-inflammatory medications too early, thus not allowing the manifestations to fully develop.

Modified Jones Criteria (two majors or one major + two minors required) (7)

Major criteria: carditis, migrating polyarthritis, chorea, erythema marginatum, subcutaneous nodules.

Minor criteria: fever, arthralgia, elevated acute phase reactant (CRP or ESR), prolonged PR interval (i.e., first degree AV block). Leukocytosis used to be a minor criterion, but it no longer is.

Plus: All must have evidence of streptococcal infection (positive ASO titer, Streptozyme, positive streptococcal throat culture.

The polyarthritis must be migratory. This manifestation is one of the most common of the major criteria in ARF. Usually one joint becomes involved and over a few days resolves, then another joint(s) becomes involved as demonstrated in our case. Occasionally, the first joint does not resolve completely by the time the second joint becomes involved, and this is termed "additive arthritis", and also fulfills a diagnosis of migrating polyarthritis. In ARF, two or more joints are considered polyarthritis. If migrating polyarthritis is present

you cannot use the minor criteria of "arthralgias", as virtually all the children with polyarthritis from ARF have a significant amount of pain. The most common joints involved are large joints, usually those that weight bear. Knees and ankles are most often involved, although elbows and wrists can also be involved. Metatarsophalangeal joints can be involved and one can screen for their involvement by squeezing them together, across the foot, and eliciting pain. The joint pain of ARF is typically very severe even if the visual findings are not very impressive. Merely touching the joint often elicits severe pain. Lower extremity joint involvement renders these patients non-ambulatory.

The presence of a new murmur due to cardiac disease (i.e., carditis) is always sought on physical exam of a child that presents like our case. A very careful cardiac examination should include a description of the PMI and its location (for evidence of congestive heart failure). Our case had an enlarged PMI that was displaced to the lateral side indicating cardiomegaly. The enlarged liver size gave further evidence of congestive heart failure. These findings are important to note, especially in a child with possible symptoms of orthopnea. Congestive heart failure is a severe form of carditis in ARF, and is managed more aggressively, often needing corticosteroids, diuretics, digoxin, and occasionally inotropic agents.

More often, the carditis of ARF is not quite this severe, but can be problematic. The most common valve involved is the mitral valve. The second most common valve involved is the aortic valve. Classic mitral insufficiency sounds like a holosystolic murmur heard at the apex which radiates to the axilla. There are very few cardiac lesions that can be heard in the axilla. Besides mitral insufficiency, a ventricular septic defect could be heard in the axilla, but this murmur is usually heard all over the precordium. The murmur of aortic insufficiency is a diastolic murmur (difficult to hear) that is usually heard best at the upper left sternal border. There is often a decrescendo component to this murmur that is sometimes very high pitched. One should also listen for a rub which would indicate pericarditis and a gallop for evidence of congestive heart failure.

The initial valvulitis of ARF results in valvular insufficiency. Subsequently as RHD develops, if enough inflammation has occurred on the valve leaflets of the mitral valve, the leaflets may scar and become adherent to each other, resulting in mitral stenosis (usually seen late in the patient's course, sometimes after repeated episodes of ARF). The murmur of mitral stenosis is a diastolic murmur, although it is described as occurring in mid-diastole, rather then later in diastole like aortic insufficiency. Similarly, aortic stenosis may subsequently result from initial aortic insufficiency.

The other major criteria describe manifestations that are less often seen in ARF. These manifestations are usually seen in less than 20% of cases. Chorea is the more common of these three, and is often difficult to diagnosis. It is also known as Sydenham's chorea or St. Vitus dance, and causes purposeless and involuntary movements. The hands and tongue are often involved. Parents may also notice the child having mood swings or just "not acting right". Emotional lability is often seen with this manifestation of chorea. Occasionally, chorea occurs so late in the illness that the laboratory tests including ASO titers, ESR, and CRP titers may all be normal. Thus, chorea is often termed a "subacute" phenomenon of rheumatic fever (as opposed to acute rheumatic fever). Despite this lack of evidence of inflammation these patients can develop cardiac disease. Typically, the chorea is not present while sleeping. The chorea usually resolves with time.

Both subcutaneous nodules and erythema marginatum are less common in ARF, but if they are seen there, there is a greater chance of the patient developing carditis. The nodules are usually small being <0.5 cm in diameter, and are seen in <20% of patients with ARF. They are located over areas that tend to be more prominent and rub against surfaces causing microtrauma. For example, they can be located at the tips of the elbows, around the joints, and the bony prominences of the spinal column. It is worthwhile spending some time looking for the nodules as their presence heralds severe carditis (9).

Erythema marginatum is the most rare of the major signs/criteria seen in ARF. It occurs in 5 to 10% of cases. It is a rash usually present over the trunk, and almost never seen over the face. The erythema is described as an evanescent pink eruption with irregular but well-demarcated borders (9). Individual lesions usually last for hours and then disappear, which is why it seen so infrequently. If this rash is found, careful cardiac exams should be done, as these children are at greater risk to develop carditis.

When evaluating a child with acute onset arthritis, the differential diagnosis can be quite overwhelming. Certain elements of the history and physical can help lead to the correct diagnosis. In ARF, the modified Jones criteria are very helpful, but there are other findings which can also help confirm your suspicion of ARF. For example, you should be able to describe the type of arthritis you are observing. Are the joints swollen and without much tenderness, but very stiff in the morning like is seen in Juvenile Rheumatoid Arthritis? Are the effusions rather bland and non-tender lasting for a few days as they are in Systemic Lupus Erythematosus? Is the joint so tender and swollen it can not be moved even a few degrees as is seen in a septic joint? In ARF the joints are usually somewhere between these extremes of pain/tenderness. They can be very painful, but yet if you do not move them, the child is still fairly comfortable. In a septic joint, the child usually has pain even at rest. The classic ARF joint is very warm, only sometimes erythematosus, and very tender. Even the weight of the bed-sheet can cause pain, and this finding is sometimes called the "bed-sheet sign". The tenderness is almost hyper-esthetic, with light pressure causing pain.

The treatment of ARF and RHD is often confusing for the medical students and housestaff. If it is confusing to such well trained individuals, just think of the frustration parents may feel when trying to understand the treatment regiment. To simplify the treatment we will separate the regimen into acute management of the inflammatory condition of ARF, and prevention of further episodes of ARF or antibiotic prophylaxis. With any good treatment plan a "healthy" amount of translating medical jargon into simple terms for the parents is needed, which will help compliance issues. This is especially important when dealing with a long term treatment like benzathine penicillin injections on a monthly basis.

The acute arthritis of ARF will normally respond very dramatically to high dose salicylate therapy. The aspirin dose is 70-100 mg/kg/day divided into QID dosing with a maximum dose of 975 mg QID. Aspirin tablets come in 81 mg, 325 mg, and 975 mg. Use enteric coated tablets if available, and ask patients to eat prior to taking the aspirin. Monitor salicylate levels and liver function tests while on aspirin. Be very careful with ARF patients who have some elevation in liver function tests prior to being put on aspirin, since a low grade inflammatory hepatitis can be seen in ARF. The aspirin could aggravate this problem. The treatment duration is usually 4 to 6 weeks or until the ESR or CRP returns to normal. If it is stopped too early, the arthritis usually returns.

If the carditis is mild and the child is asymptomatic from a cardiovascular standpoint, then salicylate therapy is usually given. However, if there is evidence of severe carditis, then corticosteroids are indicated. Severe carditis is manifested by evidence of congestive heart failure (e.g., gallop rhythm, cardiomegaly, etc.) or severe myocardial disease (e.g., two valve disease or a new or a worsening arrhythmia). Close follow-up and evaluation by the cardiology service is warranted. Repeat echocardiograms will be needed. Corticosteroids are indicated for severe carditis under the direction of a cardiologist. Prednisone is usually given for 2 to 3 weeks followed by aspirin while the corticosteroids are tapered.

Some RHD patients will develop an indolent flare-up of their cardiac disease which is far removed in time from their first episode of ARF. These patients are extremely challenging. During this indolent flare-up, they develop no fever or arthritis, but just present with worsening cardiac disease. Sometimes, this is found on repeat echocardiograms, or by symptomatic CHF returning without other warning signs of a reoccurrence of rheumatic fever. Often an increase in the ESR, CRP, and ASO titer is also seen, indicating a sub-clinical case of streptococcal infection leading to the recurrence of the immune reaction in ARF. These patients may respond to another course of corticosteroids. This underscores the importance of close follow up by the cardiology service.

Antibiotic prophylaxis against streptococcal infections is utilized to prevent a recurrence of ARF, and thus prevent further damage to the valves. Long term prophylaxis needs to be carefully described to the parent and child. Many of the families do not understand why the child needs penicillin injections when he or she feels fine, following the episode of ARF. Many mistakenly think the injections are for the arthritis and therefore do not comply with this regiment once the arthritis has resolved.

There is currently some debate about whether the penicillin injections should be given every 3 or 4 weeks, as well as, the length of treatment (10), but these arguments are beyond the scope of this article. Suffice it to say, these children require the prophylaxis as long as they are at greatest risk of contracting streptococcal infection, which means at least until adulthood, and some require it for their lifetime. We have recommended that our patients receive it every 4 weeks, partly due to compliance concerns. With every 3 weeks it is difficult for families to remember when to get their injection, and this has an increased negative effect on compliance.

Oral antibiotics can also be used but have higher recurrence rates of ARF, than the intramuscular injections. If the child forgets one or two days of oral antibiotics, they are at risk of contracting streptococcal infection, and this is the reason for the higher recurrence rates with oral antibiotics. In penicillin allergic patients, the only option is to utilize oral antibiotics.

It is important to counsel families on the importance of preventing subacute bacterial endocarditis (SBE) from occurring in RHD patients. Like children with other cardiac malformations, once a child is diagnosed with RHD, they are at similar risk of developing SBE. Antibiotics for prophylaxis against alpha-hemolytic viridans streptococci valvular infection is important prior to and following any dental or gastrointestinal procedure. These recommendations can be found elsewhere in this textbook.

The development of persistent cardiac disease is dependent on the amount of inflammation suffered by the cardiac structures during the acute period of disease and by the number of recurrences. Each recurrence will cause increased damage to valvular components and an increased likelihood of mitral stenosis, and the need for valve replacement. The mortality from ARF and RHD probably lies somewhere between 1 to 5 %, although most of the prognostic studies were done decades ago. A classic study demonstrated that with increased carditis severity, there is an increased risk of subsequent cardiac disease (see below).

Estimated occurrence of Rheumatic Heart Disease 5 years after ARF (11,12)
Initial clinical status (%risk of subsequent cardiac disease)

No carditis (4%)
Soft apical murmur (18%)
Loud apical murmur (32%)
Diastolic murmur (47%)
CHF or pericarditis (100%)

Few prognostic studies have been done in the recent past, and should probably be repeated to understand the current risk to children with ARF developing chronic cardiac disease and RHD.

The diagnosis of ARF can be challenging and difficult to make. However, the modified Jones criteria can be extremely helpful in assisting the clinician in this process. It is important to verify the development of the major criteria before starting treatment, because treating too early may stop migration of the arthritis and make fulfilling Jones criteria more difficult. Without fulfilling Jones criteria it is difficult to justify long term penicillin prophylaxis, which may last decades, to patients and their families.

Questions (authored by Neal Rojas, MD-UCSF Residency Program)

1. What is the main difference between Rheumatic Heart Disease (RHD) and Acute Rheumatic Fever (ARF)?
    a. In ARF there is an elevated ESR
    b. In RHD there is a prolonged P-R interval
    c. In ARF there is a history of arthralgias
    d. In RHD there is evidence of chronic heart disease
    e. In ARF there is evidence of erythema marginatum

2. All of the following are included in the revised Jones Major criteria EXCEPT:
    a. New murmur (carditis)
    b. Migrating polyarthritis
    c. Chorea
    d. Maculopapular rash
    e. Subcutaneous nodules

3. A 7 year old girl presents with a tender and swollen right knee as well as a more recently appearing swollen left wrist. She also has a fever. This patient fulfills which of the following modified Jones criteria?
    a. 1 Major 1 minor
    b. 1 Major 2 minors
    c. 2 Majors
    d. 2 Minors
    e. 1 Major only

4. Which of the following symptom lists of ARF are in the correct order of most common' least common?
    a. Erythema marginatum, subcutaneous nodules, carditis, fever
    b. Arthritis, carditis, chorea, erythema marginatum
    c. Chorea, erythema marginatum, subcutaneous nodules, carditis, fever
    d. Arthritis, chorea, fever, carditis, subcutaneous nodules
    e. Fever, chorea, carditis, erythema marginatum

5. Salicylates are directed primarily at what symptom in ARF?
    a. Rash
    b. Fever
    c. Arthritis
    d. Chorea
    e. Carditis

6. Corticosteroids are directed primarily at what symptom in ARF?
    a. Rash
    b. Fever
    c. Arthritis
    d. Chorea
    e. Severe Carditis

Chapter VII.5. Carditis
David K.M. Wong, MD

This is a 12 year old boy with a 2 day history of fever, nausea, vomiting, anorexia, chills, and night sweats. During the last 24 hours, his symptoms not only worsened, but he started complaining of shortness of breath. At this time, he is brought to the Emergency Department. His past medical history is only remarkable for a small ventricular septal defect which has never bothered him before. He denies any surgical history or past hospitalizations. Family history and social history are noncontributory.

Exam: VS T 38.5, pulse 140, BP 90/45, RR 40, oxygen saturation 92% on room air. Weight and height are at the 50th %ile. He is alert, subdued and somewhat toxic in appearance. Eyes are clear (no conjunctival hemorrhages). ENT exam is normal. His neck is supple without adenopathy. Lung exam reveals tachypnea and coarse bibasilar breath sounds, but no dullness to percussion or pleuritic chest pain. Cardiac exam reveals tachycardia, and a loud, harsh, blowing, grade 3/6, holosystolic murmur, heard best over the lower left sternal border, but no frictional rubs and no gallops. His abdominal exam is normal. No rashes or ecchymoses are noted. No neurological abnormalities are noted.

Chest x-ray identifies multiple delicate nodular opacities bilaterally. A CBC shows a WBC 25,500, with 22% bands, 63% segs, 10% lymphs, and 5% monos. Hgb 14.5, Hct 44%, platelet count 300,000. ESR is elevated at 92. Chemistry panel is within normal limits. Urinalysis reveals microscopic hematuria. Two blood cultures, each more than 12 hours apart, are still pending. EKG reveals a sinus tachycardia. An echocardiogram reveals a small VSD with minimal left-to-right shunt, but no vegetations or pericardial effusion. Ventricular and valvular function are normal.

Clinical course: He is admitted to the hospital for possible endocarditis. IV antibiotics (vancomycin and gentamicin) are started. A CT of the chest reveals evidence of septic emboli in both lungs. On the second hospital day, both blood cultures grow out Staph aureus. On hospital day 3, the Staph aureus is methicillin/oxacillin sensitive, so his antibiotics are changed to oxacillin. On hospital day 8, his temperature returns to normal and by the 6th week of IV antibiotic therapy, his subsequent blood cultures are negative and he is discharged home.

Carditis (inflammatory conditions of the heart) includes myocarditis, pericarditis and endocarditis. Endocarditis includes valvular inflammation (often called valvulitis). Aortitis is sometimes included in carditis. Endocarditis may be infectious or due to rheumatic fever. Pericarditis and myocarditis are usually viral or post-viral, but they may be due to rheumatic fever as well. Autoimmune conditions may also cause carditis. Rheumatic fever and autoimmune conditions are covered in separate respective chapters.

Infective Endocarditis

Prior to the era of antibiotics, patients suffering from infective endocarditis had mortality rates of nearly 100%. However, with the introduction of antibiotics, the present day mortality rate for this disease in the pediatric population ranges between 20-30%. The present trend for this disease has the average pediatric age of onset increasing from 5 to 12 years old. Some hypothesize the reason for this is due to the current increase in survival rate of children with congenital heart disease.

It is theorized that the cause of infective endocarditis stems from the hemodynamically turbulent flow which causes endothelial thickening that provides a place for a platelet and fibrin thrombus to develop. This site becomes the nidus of bacterial growth for susceptible adhesive microorganisms. Therefore, conditions which predispose turbulent blood flow in the heart are risk factors for infective endocarditis. Such conditions include ventricular septal defects (VSD), patent ductus arteriosus (PDA), aortic valvular disease, atrioventricular septal defect (AVSD, also known as endocardial cushion defect or AV canal), prosthetic valves, tetralogy of Fallot, and chronic rheumatic heart disease. In underdeveloped countries where rheumatic heart disease is common, it is the most common cause for infective endocarditis. However, congenital heart disease is the most common risk factor in pediatric practices of the United States. The mitral valve is the most commonly affected, followed by the aortic valve, then the tricuspid valve. Other risk factors include situations which increase the risk of bacteremia, such as: IV drug use (which predisposes infective endocarditis to the right side of the heart), indwelling IV catheters, intraarterial catheters, severe burns, dental procedures, or recent cardiac surgery.

It is estimated that 80% of all pediatric infective endocarditis are due to alpha-hemolytic streptococci and S. aureus. Alpha-hemolytic streptococci (which includes strep viridans) are responsible for 75% of subacute endocarditis and S. aureus is responsible for 50-70% of acute endocarditis.

The clinical course of infective endocarditis varies from an acute to subacute course and is usually based on the offending microorganism. Traditionally, the microorganisms which are responsible for acute infective endocarditis include Staphylococcus aureus, Streptococcus pyogenes, or Neisseria gonorrhoeae. Microorganisms usually responsible for subacute infective endocarditis are the less virulent Streptococcus viridans (alpha strep). These distinctions, though useful clinically, do not always hold. Therefore, S. aureus may cause a subacute course, and S. viridans may be responsible for an acute endocarditis. In the pediatric setting, the clinical distinctions are still useful, perhaps more so than in the elderly population.

Acute infective endocarditis is characterized by a rapidly progressive clinical picture of sepsis, high fever, headaches, nausea, vomiting, diarrhea, cough, shortness of breath, and early cardiac decompensation. On the other hand, the subacute course is characterized as an insidious, flu-like syndrome, associated with malaise, anorexia, +/- fever. In the pediatric population, it is rare to find splinter hemorrhages, Osler nodes (painful, red, nodular lesions most commonly found on fingers), Janeway lesions (small, erythematous, nontender areas of the palms and soles), and Roth spots (retinal hemorrhages with central clearing). If the course is prolonged, then splenomegaly, weight loss, night sweats, anemia, or petechiae may develop. In 20% of infective endocarditis, a new cardiac murmur or change in a preexisting murmur occurs. A subacute course of infection is unusual under the age of 2 years old. Most patients with endocarditis younger than 2 will have an acute fulminating disease.

Embolic episodes may also be a part of the clinical course, however this is more common in adults than in children. Emboli originating from left-sided endocarditis may cause renal infarcts resulting in frank hematuria, splenic infarcts resulting in left flank pain, or stroke-like symptoms resulting from cerebral emboli. Emboli from right-sided endocarditis may cause chest pain and shortness of breath due to pulmonary embolism.

Several sources describe a diagnostic criteria (the Duke criteria) to allow early recognition of endocarditis, when vegetations are still too early to detect. A patient is considered to have infective endocarditis if 2 major criteria or 1 major plus 3 minor criteria are met. The major criteria are: positive blood cultures x2 and endocardial abnormalities on echocardiography. The minor criteria are: presence of a

predisposing condition (i.e., valve abnormality), fever greater than 38 degrees C, embolic episode (i.e., splenic infarct), and immunologic phenomena (i.e., Osler nodes).

Blood cultures are the most valuable laboratory tests in making the diagnosis of infective endocarditis. Controversy lingers as to the exact number of cultures that should be obtained for each patient with suspected infective endocarditis. However, the collection of 2 to 3 blood cultures over a 24 hour period will suffice in most cases. Approximately 5% of patients with endocarditis will have negative blood cultures. In some cases, the microorganism contained in the vegetation are unexposed, encased in fibrin and platelets. Antibiotic therapy prior to obtaining blood cultures will reduce the likelihood of recovering the organism in the blood. Therefore, it is very important to obtain blood cultures prior to antibiotic treatment. Fungi or candida can cause endocarditis rarely, but these will eventually grow out of most blood cultures (though very slowly).

Other laboratory tests are not as helpful in making the diagnosis of infective endocarditis, but they may be helpful in monitoring clinical progress. Elevated erythrocyte sedimentation rate (ESR) is commonly found in both acute and subacute endocarditis. During antibiotic therapy, a decrease of the ESR signifies that the treatment is most likely effective. Like many other infectious diseases, a leukocytosis with an accompanying left shift may be seen, although this is more common in the acute setting than the subacute course. Microscopic or macroscopic hematuria is also a common laboratory finding. Microscopic hematuria is most likely due to immune complex depositions in the glomeruli, whereas macroscopic hematuria is most likely a result from renal embolization. If the course is chronic, such as in the subacute cases, normocytic/microcytic anemia may occur.

The most helpful diagnostic procedure is echocardiography. Echocardiography is most helpful in children with normal cardiac anatomy or with isolated valvular abnormalities. However, this procedure is not 100% sensitive or specific, therefore a negative echocardiogram does not rule out endocarditis. Recently, transesophageal echocardiography (TEE) has had better results than the transthoracic approach in adults. Although, TEE is currently used intraoperatively in children, the usefulness for this procedure in children with endocarditis remains uncertain.

The differential diagnosis for infective endocarditis is complex since this disease has variable clinical presentations. Because infective endocarditis commonly presents with fever, arthralgias, and a positive rheumatoid factor; juvenile rheumatoid arthritis, Kawasaki's disease, rheumatic fever and other connective tissue disorders should be considered in the differential diagnosis. Neurologic manifestations from infective endocarditis may also mimic that of meningitis, cerebritis, or toxic encephalopathy. If hematuria is present, one must also consider other renal diseases. If S. aureus bacteremia along with an increasing ESR is present in a patient with infective endocarditis, one must consider osteomyelitis or septic arthritis. Cardiac myxomas or rheumatic carditis must also be considered if a patient presents with a new or changing heart murmur. The diagnosis of infective endocarditis should be considered in any child with persistent unexplained fevers especially if they are considered at high risk such as history of congenital heart defects or IV drug use.

Isolation of the infecting microorganism by blood culture is extremely important, not only in making the diagnosis, but also in planning for treatment. The microorganisms that are revealed from the blood cultures will strongly determine the type of antibiotic regimen to be used. The physician must be guided by the antibiotic susceptibility pattern. Although antibiotic regimens vary depending on the infective microorganism, one general principle is true in the treatment of infective endocarditis: complete eradication of the infecting microorganism with bactericidal agents will usually require weeks of therapy. For example, patients with blood cultures that grow out Streptococci will require 4 weeks of penicillin G and patients with Staph. aureus will require 6 weeks of oxacillin (if they are methicillin/oxacillin sensitive). Initially when blood cultures are still pending, empiric antibiotics should be started. Empiric therapy includes coverage for the common, Streptococci and S. aureus, but also for the less common MRSA (methicillin resistant Staph aureus) and Gram negatives, therefore vancomycin and gentamicin are the preferred regimen.

Determination of MIC and MBC levels for the causative bacteria will assist in determining the potential for outpatient treatment with oral antibiotics (refer to the chapter on MIC and MBC levels).

Obtaining occasional blood cultures during the first 8 weeks after cessation of treatment is warranted, because most relapses occur during this period. There are several common indications for surgery. These include a significant embolic event, persistent infection, and progressive congestive heart failure especially when the aortic or mitral valve is involved.

Prophylactic antibiotics are recommended for children who are at risk to develop infective endocarditis, while undergoing procedures that may induce a bacteremia. At risk patients include those who have significant heart defects associated with turbulent blood flow (e.g., VSD, mitral valve prolapse, etc.), prosthetic conduits, or prosthetic heart valves. The recommended antibiotic regimens for prophylaxis include amoxicillin 50mg/kg PO 1 hour before the procedure or ampicillin 50mg/kg IM or IV within 30 minutes of the procedure. If the patient is allergic to penicillin, an alternate drug may include clindamycin 20 mg/kg PO 1 hour before procedure or cefazolin 25mg/kg IM or IV within 30 minutes of the procedure. In general, any dental or surgical procedure involving the respiratory, gastrointestinal, or genitourinary tract that induces bleeding from the gingival or mucosal surface, can predispose at risk patients to bacteremia. Therefore, antibiotic prophylaxis should be considered in these situations. The maintenance of optimal dental care and oral hygiene is also important for children at risk for infective endocarditis.

At present, the mortality rate is between 20 and 30%. Mortality rates are slightly higher in patients with acute staphylococcal infection, fungal infection, and prosthetic valve endocarditis. Mortality may be caused by sudden perforation of the aortic valve with severe aortic insufficiency, chordal rupture with resultant mitral insufficiency, myocardial infarction, or intramyocardial abscess formation with the development of a myocarditis.

Myocarditis

Myocarditis is defined as an inflammatory response within the myocardium. The categories of myocarditis are divided into infectious myocarditis and generalized autoimmune myocarditis. In either case, the histological features of the myocardium reveal myocardial necrosis with accompanying inflammatory reactions.

The most common cause of pediatric infectious myocarditis in the western world is viral in nature. Any virus may cause this, but the most notable viruses are coxsackie viruses, echovirus, influenza virus, mumps, and rubella. Non-viral infectious myocarditis may include protozoan infections, Lyme disease, hemolytic uremic syndrome or complications from tuberculosis. Whatever the suspecting etiological may be, the pathophysiology remains unknown. Some speculate infectious myocarditis may result from toxins secondary to the infectious agent, others speculate the mechanism is secondary to an immune reaction.

The clinical manifestations of this disease, varies from the more common subacute course to the severe course which manifests as heart failure that may be accompanied by arrhythmias. There is no single characteristic profile for infectious myocarditis. A nonspecific systemic viral infection is usually followed by a latent period. The latent period is followed by variable nonspecific signs and symptoms such as fever, diarrhea, anorexia, pallor, mild jaundice, or lethargy. Diminished heart tones may be the only clinical clue pointing toward

myocarditis. If the disease progresses, cardiac enlargement may ensue, along with a nonspecific cardiac arrhythmia. The end result may eventually lead to symptoms of heart failure, such as tachypnea, dyspnea, and fatigue.

Much like the clinical manifestations, results from laboratory and investigational tests are often variable. Erythrocyte sedimentation rate, white blood cell count, and cardiac enzymes tend to vary from elevated to normal, depending on the severity of the disease. Chest radiographs may show an enlarged heart and depending on the severity of the heart failure, pulmonary venous congestion may be present. Electrocardiographic (EKG) abnormalities are common, but only nonspecific findings are present in infectious myocarditis. Often, a sinus tachycardia is present, with lowering of the QRS complexes in the standard leads and/or precordial leads. The T-waves may be flattened or inverted with changes in the ST segment. Echocardiography may reveal a nonspecific dilation of the heart chambers, most commonly the left ventricle. The left atrium may be enlarged if mitral insufficiency is present. The main importance of an echocardiogram is to exclude a pericardial effusion and to assess myocardial contractility. In addition to the echocardiogram, radionuclide angiography has been used to perform serial measurements of the left ventricular function. Controversy remains on routine endomyocardial biopsies for suspected myocarditis because the pathology is often patchy, therefore a negative biopsy cannot exclude the diagnosis. Essentially, the diagnosis of infectious myocarditis is a diagnosis of exclusion.

The treatment of myocarditis most often focuses on the treatment of arrhythmias and congestive heart failure. If an infectious agent is identified, then the appropriate therapy should be instituted, however in most cases no infectious agent will be found. Treatment of the heart failure consists of bedrest, oxygen, and congestive heart failure treatment (e.g., inotropes, diuretics and ACE inhibitors). Digoxin is controversial since this drug may induce ventricular arrhythmias. Other controversial and unproven treatment therapies include drugs that decrease the inflammatory response such as corticosteroids, immunosuppressive agents, and high-dose IV immunoglobulins.

The prognosis of the subacute course of myocarditis is good. Most patients will recover in several weeks to months with the heart size reverting back to normal within a year. However, in cases where heart failure recurs, the prognosis is poor.

Generalized autoimmune myocarditis is often one aspect of a syndrome secondary to a collagen or connective tissue disease. Autoimmune myocarditis is found infrequently in children. The more common cardiac finding in SLE is pericarditis.

Pericarditis

Pericarditis is defined as an inflammatory reaction of the pericardium. Etiologies include acute bacterial pericarditis, acute viral pericarditis, postpericardiotomy syndrome, acute rheumatic fever and uremia. Echocardiography is the most important diagnostic test, which will reveal the presence of a pericardial effusion surrounding the heart. Moderate pericardial effusion secondary to pericarditis may also show up on x-ray as an enlarged cardiac silhouette but the x-ray will not be able to distinguish pericardial effusion from myocardial dilation. In borderline cases, comparisons of previous x-rays may prove helpful. Electrocardiography (EKG) may be useful in the initial stage of the disease, when ST segments are elevated in all leads except V1 and aVR. After a few hours to days, the ST segments may return to baseline, and the T waves become flat. A low voltage (low amplitude) EKG may be seen if the pericardial effusion is large enough.

Much like infective endocarditis, the incidence of acute bacterial pericarditis has dramatically declined since the development of antibiotics. The most common settings for acute bacterial pericarditis include septicemia or hematogenous or direct spread into the pericardium from another site, such as with pyelonephritis, osteomyelitis, tonsillitis, bacterial pneumonia and empyema. The common microorganisms responsible for most acute bacterial pericarditis are Haemophilus influenzae type B, Staphylococcus aureus, pneumococcus, meningococcus, streptococcus species and tuberculosis infection. Patients with acute bacterial pericarditis will usually manifest with acute onset of chest pain, high fever, tachycardia, frictional rub, tachypnea and toxemia. Acute bacterial pericarditis often is associated with an infection elsewhere, therefore an intensive search for the primary source is essential. Blood cultures are important and it is recommended that three to five sets should be obtained in the first 1 or 2 days after admission. These blood cultures are positive 40-80% of the time and the appropriate antimicrobial agent given for 4 to 6 weeks should be chosen based on the susceptibility testing. Acid-fast stains for tuberculosis of the sputum, gastric contents, or urine are considered if blood cultures come back negative.

Acute viral pericarditis is often associated with the aforementioned viral myocarditis. And like the viral myocarditis, the most common viral agents responsible for viral pericarditis include group B coxsackie virus, echovirus, adenovirus, and influenza virus. The clinical manifestations of the viral myocarditis usually dominate over the clinical manifestations of the viral pericarditis. The typical signs and symptoms of acute viral pericarditis include a low-grade temperature, chest pain, and a frictional rub. The therapy for acute viral pericarditis is symptomatic. This includes bedrest, in particular patients who also have myocarditis. The prognosis of viral pericarditis is good and often self-limiting, with complete recovery in 3 to 4 weeks.

Similar to the adult pericarditis following a myocardial infarction, known as Dressler's syndrome, an episode of acute pericarditis in children following cardiac surgery which includes opening of the pericardium (post-pericardiotomy syndrome). The pathogenesis is unclear, however anti-myocardial antibodies and eosinophilia point toward an autoimmune etiology. Cardiac tamponade may occur, which may be treated with a pericardiocentesis, however in most cases of post-pericardiotomy syndrome, the disease is self-limiting in 2 to 3 weeks. The most important treatment is bedrest. Salicylates may be used to lower the temperatures and chest pain. In the severely ill child, a course of prednisolone may be effective.

Questions and Answers

1. What is the most common microorganism found in pediatric infective endocarditis?
    a. Staph aureus.
    b. Strep viridans
    c. E. coli
    d. Pneumococci
    e. Strep pyogenes

2. What is the preferred antibiotic treatment for the microorganism in question 1?
    a. Penicillin G x 2 weeks
    b. Penicillin G x 4 weeks
    c. Oxacillin x 6 weeks

3. Which microorganism(s) will most likely NOT manifest as an acute infective endocarditis in the pediatric setting?
   a. S. aureus
   b. Neisseria
   c. Strep. pyogenes
   d. HACEK (Haemophilus species (H. parainfluenzae, H. aphrophilus, and H. paraphrophilus), Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, and Kingella species).

4. Does the pediatric case presented at the beginning of this chapter meet the Duke Criteria for Diagnosis of infective endocarditis?
   a. Yes.
   b. No.
   c. Need more information.

5. What type of prophylactic antibiotic against infective endocarditis would you prescribe to a nine-year old female, with a past medical history only remarkable for an allergic reaction to penicillin, scheduled for a tooth extraction the next day?
   a. Amoxicillin.
   b. Ampicillin.
   c. Clindamycin.
   d. Cefazolin.
   e. None.

6. What is the most common microorganism that causes pediatric infectious myocarditis in the United States?
   a. Strep viridans.
   b. Tuberculosis.
   c. Staph aureus.
   d. E. coli.
   e. Virus.

7. Which of the following answer is the most severe clinical manifestation commonly found in pediatric myocarditis?
   a. Myocardial infarction.
   b. Heart failure.
   c. Pericarditis.
   d. SLE.
   e. None of the above.

8. Which is the most helpful test to diagnose pericarditis?
   a. Cardiac enzymes.
   b. EKG.
   c. Echocardiogram.
   d. X-ray of the heart silhouette.
   e. Answers b and d.

9. Which of the following is/are treatments options for pediatric postpericardiotomy syndrome?
   a. Salicylates.
   b. Pericardiocentesis.
   c. Bed rest.
   d. Prednisolone.
   e. All of the above.

Answers to questions

1. b.
2. b. Choice a is too short of a course and choice c is the preferred treatment for S. aureus infective endocarditis.
3. d.
4. a. The patient had positive blood cultures (1 major), and (3 minors) fever greater than 38 degrees C, a predisposing structural cardiovascular lesion (VSD), and evidence of an immunologic phenomenon (microscopic hematuria).
5. e. No antibiotics are needed, because this particular patient has no risk factors for infective endocarditis.
6. e.
7. b. Although c may be associated with viral myocarditis, viral pericarditis is most likely self-limiting.
8. c. Answers b and d may not show any abnormal findings.
9. e.

Chapter VII.6. Arrhythmias
Lance K. Shirai, MD

This is a 1 month old male who presents to the emergency room with a chief complaint of fever, lethargy, and poor feeding for the past 36 hours. He was well until he developed a tactile fever. His parents began noticing increasing lethargy and tiring with feeding and decreased oral intake for about 12 hours prior to presentation.

He is the product of a G2P1, full term, uncomplicated pregnancy. Delivery and stay in the nursery was uneventful.

Exam: VS T 38.0, HR 240, RR 72, BP 87/64, oxygen saturation 98% in room air. He is well developed, well nourished, but pale, lethargic and tachypneic, with mild subcostal retractions. HEENT exam is normal. Neck is supple without adenopathy. Lungs are clear to auscultation with good aeration. His heart is tachycardic with a regular rhythm. No murmur, rub, or valve clicks are heard. There is a soft S3 gallop that can be head from the lower left sternal border to the cardiac apex. His abdomen is soft, non-distended, non-tender, and without masses. His liver is 2 to 3 cm below right costal margin. His feet and hands are cool. His peripheral pulses are 1+ to 2+ (out of 4+) throughout. Capillary refill time is 3 to 4 seconds. He has no rashes or other significant lesions.

A chest x-ray shows mild cardiomegaly and mild pulmonary edema. A 12 lead electrocardiogram shows a narrow complex tachycardia (rate of 240 bpm) with no visible P-waves. Mild ST segment depression in the inferior-lateral leads is present.

The patient is felt to be in supraventricular tachycardia and mild congestive heart failure. A peripheral IV is started and he is given a rapid IV bolus dose of adenosine. The patient immediately becomes briefly bradycardic followed by resumption of a normal sinus rhythm at a rate of 140 beats per minute. He is admitted for overnight observation and initiation of an anti-arrhythmic medication. A 12 lead electrocardiogram following conversion shows no evidence of a delta-wave, so a loading dose of digoxin is administered.

An irregular heart rhythm is not an unusual finding in children with or without known cardiac disease. Some irregular rhythms are normal findings in healthy children. If the heart rate is not too slow or too fast, as to limit the cardiac output, then an arrhythmia may be well tolerated. Most children can be satisfactorily evaluated with a 12 lead electrocardiogram and rhythm strip, with possible supplementation by a chest x-ray, echocardiogram, Holter or event monitor, or an exercise study. There are several important determinants of arrhythmias, which should be considered. These include the arrhythmogenic substrate (e.g., accessory conduction pathway, automatic ectopic focus), modulating factors, and triggers of the arrhythmia.

Changes in sinus rhythm (P-wave preceding each QRS complex, with a normal P-wave axis) are most commonly seen with a sinus arrhythmia, sinus bradycardia, or sinus tachycardia. In pediatrics, a sinus arrhythmia is usually secondary to a variation in vagal tone during the normal respiratory cycle. This causes an increase in heart rate during inspiration and a decrease in heart rate during exhalation. It is most pronounced when the heart rate is slower and resolves with an increase in heart rate. Sinus bradycardia is a sinus rhythm with a rate below the lower normal limits for age and activity level. It is most often encountered in well conditioned athletes. Pathologic states in which sinus bradycardia may occur include increased intracranial, intrathoracic, or intraabdominal pressure, and systemic hypertension. Sinus tachycardia is a sinus rhythm with a rate greater than the higher limits for age and activity level. If the child is not active then the tachycardia usually has a secondary cause such as fever, heart failure, pain, anxiety, hypovolemia, anemia, myocarditis, or thyrotoxicosis.

Supraventricular tachycardia (SVT), also known as paroxysmal supraventricular tachycardia (PSVT) is a tachyarrhythmia manifesting with a narrow complex QRS duration (<0.08 sec). Many definitions of SVT exist, some of, which include all abnormal tachycardias originating in or around the atria (which would include PSVT, atrial fibrillation and atrial flutter). For the sake of this discussion, SVT will be defined as those narrow complex tachycardias involving the SA node and an accessory electrical pathway anywhere along the atrioventricular junction or very near the AV node itself (this definition excludes atrial fibrillation and atrial flutter). These are considered reciprocating tachycardias, as two discrete pathways are present, one with antegrade conduction and the other with retrograde conduction. One pathway is considered a "fast" pathway, with rapid conduction, and the other a "slow" pathway, with slower conduction. This creates the reentrant circuit. With orthodromic (conventional pathway) SVT, the antegrade conduction is down the "slow" pathway, usually the AV node, and the retrograde conduction is up the "fast" pathway, usually the accessory conduction tissue. Antidromic SVT is characterized by antegrade conduction down the "fast" pathway, and retrograde conduction up the "slow" pathway.

Supraventricular tachycardia is the most common abnormal tachycardia in the pediatric age group. The most common types of SVT in children include atrioventricular reentrant tachycardia (AVRT), which includes Wolff-Parkinson-White syndrome (WPW), and AV nodal reentrant tachycardia (AVNRT formerly called Lown-Ganong-Levine or LGL syndrome).

Supraventricular tachycardia usually has its onset at rest but may initiate during exercise. The precipitating factor(s) is often difficult to identify, but occasionally a febrile illness may precipitate an episode. The heart rate is usually in the 160 to 300 beat/min range. In general, the younger the patient the more rapid the SVT heart rate, but the longer the tachycardia is tolerated before symptoms (usually congestive heart failure) become obvious. As a rule, episodes of SVT onset and terminate abruptly, and may last anywhere from a few minutes to many hours, which is why it is called paroxysmal.

In infants, symptoms of SVT may not become apparent until the patient has been in SVT for 24 hours, or longer. They will often present with symptoms of congestive heart failure such as tachypnea, pallor, poor feeding, fussiness or lethargy.

In children and adolescents, symptoms may include palpitations, chest pain, shortness of breath, dizziness, syncope or near syncope, pallor, and diaphoresis. It is unusual for older patients to present in heart failure, as they will usually become symptomatic soon after the onset of SVT. They will often complain of intermittent episodes of palpitations, with mild associated symptoms.

Supraventricular tachycardia may present as syncope or near syncope. This may occur in patients with WPW who develop atrial fibrillation and rapid conduction down the accessory pathway to the ventricles. The onset of SVT can also cause a decrease in cardiac output with resultant hypotension, decreased cerebral perfusion pressure, and syncope. In the pediatric age group, the most common cause of syncope is neurocardiogenic syncope (also called a vasovagal faint). Syncopal episodes associated with palpitations should raise the suspicion of a possible tachyarrhythmia contributing to the patients symptoms. Nearly any type of cardiac arrhythmia can cause syncope if a sudden fall in cardiac output occurs. Cardiac dysrhythmias to consider should include SVT, ventricular tachycardia (in particular, long QT syndrome), advance degree AV block, sick sinus syndrome in patients with previous cardiac surgery, and pacemaker malfunction in those patients who are pacer dependent. Other cardiac related disease to consider in patients presenting with syncope include outflow tract obstruction (hypertrophic cardiomyopathy, aortic stenosis, pulmonic stenosis, pulmonary hypertension), coronary artery anomalies, cardiomyopathies, and mitral valve prolapse. The diagnosis can often be made with a thorough history and physical examination performed as close to the time of the syncopal episode as possible. Cases, which should arouse increased concern, include those not consistent with neurocardiogenic syncope, syncope with exercise, a family history of sudden death, and those patients with known

structural cardiac disease. All patients who present with syncope should, at the minimum, have an EKG performed. In most cases of neurocardiogenic syncope, symptoms will improve or resolve with increased fluid and salt intake. Treatment for other causes of syncope should address the underlying etiology.

The differential diagnosis of a pediatric patient who presents in a narrow complex tachycardia includes SVT, sinus tachycardia, atrial flutter, atrial fibrillation, junctional ectopic tachycardia, ectopic atrial tachycardia, and chaotic atrial rhythm. Some patients with SVT and a bundle branch block or antidromic WPW, may present with a wide complex tachycardia, which if often difficult to distinguish from ventricular tachycardia (VT).

Most of the narrow complex tachyarrhythmias may be distinguished from their electrocardiogram findings. Supraventricular tachycardia ranges in heart rate from 160 to 300 beats per minute. The diagnosis of AVRT or AVNRT requires the presence of 1:1 A-V conduction. The heart rate usually remains in a very narrow range regardless of the patient's physiologic state. P-waves, which are oftentimes retrograde, are visible only in 50% or less of cases. Upon conversion to a sinus rhythm, patients with WPW or Mahaim fibers (an accessory pathway able to conduct only antegrade, with slow conduction, connecting the atrium directly to a portion of the right bundle branch) will demonstrate the classical delta waves as evidenced by an upsloping or slurring of the initial portion of the QRS complex. Delta waves are secondary to rapid antegrade conduction from the atrium to the ventricles through the accessory pathway, thus causing ventricular pre-excitation. With WPW the PR interval is short, but with the presence of Mahaim fibers the PR interval is normal. Forms of SVT with concealed accessory pathways (i.e., those capable of only retrograde conduction), will not show evidence of a delta wave, and therefore most will have normal PR intervals. An exception is those patients with James fibers (a form of AVNRT), who have a short PR interval. Most patients with SVT have normal cardiac anatomy. Congenital heart defects in which SVT is most commonly encountered are Ebstein's anomaly and L-transposition of the great arteries.

Atrial flutter may present with a regular or regularly irregular tachycardia with an atrial rate in the range of 250 to 400 beats per minutes. The classic sawtooth flutter waves may be seen, or revealed following a dose of adenosine. The ventricular rate will depend on the degree of A-V conduction (e.g. 2:1, 3:1, etc.). Atrial flutter will most often be encountered in the setting of congenital heart disease, presence of significant mitral or tricuspid valve regurgitation with atrial dilatation, fetuses or newborns with normal hearts (i.e., it sometimes occurs in normal fetuses and newborns), or in patients with myocarditis.

Atrial fibrillation demonstrates a rapid atrial rate (300-500 beats per minute) with a very chaotic pattern, and an irregularly irregular ventricular rhythm. Atrial fibrillation is most often seen in older children following palliative surgery for congenital heart defects, especially those involving intra-atrial surgery (e.g., Fontan, Mustard, or Senning procedures), and those children with significant atrioventricular valve disease.

Ectopic atrial tachycardia and chaotic atrial rhythm are rare tachyarrhythmias in the pediatric age group. On EKG, ectopic atrial tachycardia will show the presence of a variable atrial rate with an abnormal P-wave axis indicating a single atrial focus. Chaotic atrial rhythm, also referred to as multifocal atrial tachycardia, typically demonstrates at least 3 non-sinus P-wave morphologies, an irregular ventricular response, and variable PR, PP, and RR intervals. Both types of dysrhythmias occur most often in patients with structurally normal hearts, at times with concomitant myocarditis.

Junctional ectopic tachycardia is most commonly encountered in children less than 2 years of age, in the immediate post-operative period following corrective surgery for a congenital heart defect involving the region around the AV node (e.g., a VSD or tetralogy of Fallot repair). This is one of the most common post-operative arrhythmias encountered. The EKG typically demonstrates a narrow complex tachycardia with a regular atrial and ventricular rhythm, and a ventricular rate, which is more rapid than the atrial rate. This dysrhythmia originates from a focus of enhanced automaticity in the peri-AV nodal region. The heart rate typically rises and decreases gradually (warms up and cools down). This feature helps differentiate it from a reentrant type of tachyarrhythmia.

Significant ventricular arrhythmias, such at ventricular tachycardia (VT) and ventricular fibrillation (VF), are rarely encountered in the pediatric age group. Benign premature ventricular contractions (PVC) are not uncommon in infants, older children, and adolescents. Patients with ventricular arrhythmias may be asymptomatic or they may present with symptoms of palpitations, chest pain, dizziness, and/or syncope. Ventricular tachycardia is defined at 3 or more consecutive abnormal QRS complexes at a rate greater than 120 beats per minute. As mentioned previously, SVT may occasionally present as a wide complex tachycardia, which may be difficult to distinguish from ventricular tachycardia. In these cases, the definitive diagnosis may not be known until the patient is converted to a sinus rhythm. In these situations the patient should be presumptively treated as having ventricular tachycardia (VT) until proven otherwise. It should be remembered that VT does not always present as a wide QRS complex tachycardia, especially in infants. Ventricular fibrillation displays unidentifiable QRS complexes due to an uncoordinated state of ventricular depolarization, resulting in a state of poor cardiac output. Significant ventricular dysrhythmias in the pediatric age range are most commonly encountered in the setting of congenital heart disease, myocarditis, cardiomyopathies, myocardial trauma, hypoxia, acidosis, and electrolyte abnormalities (most notably hypokalemia and hyperkalemia).

The prolonged QT syndrome causes a distinct type of VT called Torsades de Pointes characterized by a polymorphic VT, which oftentimes causes syncope or sudden death. Recent genetic linkage analyses have isolated a number of genetic foci associated with defects in cardiac ion channels (namely sodium and potassium channels). Prior to the advent of genetic analysis, patients with long QT syndrome were classified into two groups: Jervell-Lange-Nielsen (autosomal recessive, associated with congenital deafness) and Romano-Ward (autosomal dominant, without deafness). Prolongation of the QT interval may also develop secondary to drugs (anti-arrhythmic agents, antihistamines, antidepressants, antipsychotics, some antibiotics), CNS trauma, cardiomegaly, hypokalemia, and hypocalcemia.

Various forms of heart block are usually encountered in children with congenital heart defects, heart failure, or with congenitally acquired heart block. Congenital complete heart block is most commonly seen in the setting of a maternal collagen vascular disorder, namely systemic lupus erythematosus or Sjogren's syndrome. In nearly all cases, maternal SS-A/Ro and SS-B/La autoantibodies can be isolated. Conversely, not all fetuses whose mother is positive for these antibodies will develop heart block. The most common congenital heart defect associated with complete heart block is L-transposition of the great arteries. If the ventricular rate is too slow to maintain adequate cardiac output, heart failure may develop in utero or postnatally. Treatment involves permanent pacing. The decision to treat depends on the baseline ventricular rate and the likelihood of sudden death.

The management approach for SVT depends upon the age and condition of the patient on presentation. If the patient is clinically stable, vagal maneuvers may be initially attempted to convert the tachycardia. Such vagal maneuvers may include bearing down (as though having a bowel movement, i.e., Valsalva maneuver), or inducing the diving reflex using an ice bag to the face or submerging the patient's face into a container of ice water. Other vagal maneuvers such as eyeball pressure and unilateral carotid massage are less effective and may be harmful.

If the patient appears clinically unstable, then an intravenous line should be immediately started in a centrally located peripheral vein (antecubital preferred over a hand vein) through which an IV bolus of adenosine may be given. It must be remembered that this medication has a very short half life of approximately 10 seconds, therefore it should be administered via bolus injection followed by an immediate bolus of saline utilizing either a 3 way stopcock or simultaneous needles within the same IV hub (the IV push and immediate flush technique). A 12 lead electrocardiogram should be obtained before and after conversion, if possible, and a rhythm strip should be continuously run during attempted conversion. External pacing equipment should be available since some patients go into sinus arrest following administration of adenosine. Adenosine causes a transient AV block and sinus bradycardia thus interrupting the reentrant circuit involving the AV node and accessory pathway. Potential side effects with adenosine include hypotension, bronchospasm, and flushing.

In rare cases, a patient will present in very unstable condition. Immediate electrical cardioversion may be required in such cases, especially if an IV cannot be started in an expedient manner or the patient fails to convert with IV adenosine.

Other modes of acute treatment include use of digoxin, verapamil, propranolol, transesophageal or transvenous pacing. Conversion to a sinus rhythm with these medications will usually be slower, therefore most are utilized for chronic control once the SVT has been converted by other means. If adenosine fails to convert the SVT, but the patient is hemodynamically stable, they may be started on one, or more, of these medications (with the exception of verapamil which should be avoided in infants) and monitored for conversion. It is important to remember not to use digoxin on patients with ventricular pre-excitation (e.g., WPW), as it may increase antegrade conduction down the accessory pathway. Patients with WPW are more prone to develop atrial flutter or fibrillation, and are therefore at risk for 1:1 conduction to the ventricles while on digoxin, potentially sending the patient into ventricular tachycardia or fibrillation.

Long term management of SVT depends on the severity and frequency of episodes. In those patients with no ventricular pre-excitation and infrequent, mild episodes that can be converted with vagal maneuvers, no treatment is required. Patients with frequent episodes, or severe symptoms, and those with ventricular pre-excitation, medical management should be started with a beta-blocker, digoxin, or calcium channel blocker. Patients diagnosed in infancy often will not require continued treatment beyond 1 year of age, but may have recurrent episodes later in life. With the presence of severe symptoms, syncope, difficult to control SVT, or other situations, e.g., patient preference, an electrophysiology study and radiofrequency ablation can be performed with a high success rate for cure.

The majority of fetuses and infants who present in SVT will have no recurrences off medication after 6 to 12 months of age. Patients who present in later childhood or during adolescence will likely have recurrent episodes of SVT throughout their lifetime. Many of these patients will require medical treatment and will eventually seek curative treatment with radiofrequency ablation. Radiofrequency ablation involves mapping out accessory conduction pathways in the heart with the use of electrodes placed in the atria, coronary sinus, and ventricles through central venous access. Upon localization of the pathway a specialized ablation catheter (tip is heated using radiofrequency energy) is used to burn and cause irreversible tissue injury to the accessory conduction tissue.

With the recent advancements in pediatric electrophysiology, the prognosis for patients with SVT is very good. The success rate with radiofrequency ablation continues to improve, especially when performed at centers with experienced specialists. Death or significant morbidity is rare with the present state of medical management. Most patients can be expected to live a normal life expectancy with little or no lifestyle alteration due to this condition.

Questions

1. What are the two most common forms of SVT in the pediatric population?
2. What are the two most common types of congenital heart defects associated with SVT?
3. Name two instances in which SVT may present as a wide complex QRS tachycardia.
4. In a hemodynamically stable patient who presents with SVT, what are the two most commonly used methods for attempted conversion to a sinus rhythm?
5. True/False: Supraventricular tachycardia is the most common cause of syncope in the pediatric age group.

Answers to questions

1. Atrioventricular reentrant tachycardia (AVRT) and AV nodal reentrant tachycardia (AVNRT).
2. Ebstein anomaly and L-transposition of the great vessels.
3. With the presence of a bundle branch block or with antidromic conduction.
4. Vagal maneuvers and intravenous adenosine.
5. False.

Chapter VII.7. Vascular Rings and Slings
Cheryl M. Takao, MD

This is a 6 week old male with a previous diagnosis of laryngomalacia who presents with increasing stridor, respiratory distress and wheezing. There has been no associated apnea or cyanosis. He had been feeding well with no vomiting or choking. He has had no fever. Initial CXR revealed no acute infiltrates. He received albuterol but had a minimal response.

He was born at term via NSVD with 8 and 9 Apgars. No intubation required. Mild respiratory distress was noted on his first day of life. A CXR revealed fluid within fissures. O2 sat on RA was 98%, so transient tachypnea of the newborn was initially suspected. On the second day of life, he was noted to have stridor. He was evaluated by ENT surgeon with a flexible bronchoscopy which revealed mild laryngomalacia. His condition improved and he was discharged home in stable condition.

Family history: Father, 12 y.o. brother, 7 y.o. and 18 month old sister with asthma.

Exam: VS T 37.1, HR 160, RR 52, BP 109/56, oxygen saturation in RA 98%. Wt. 5.3kg (75%), ht 52.5cm (10%), HC 39.5cm (90%). He is lying in mother's arms, visibly tachypneic, with audible congestion. HEENT and neck exams are normal. Heart RRR, with gr II/VI systolic ejection murmur at the left sternal border. Lung exam shows inspiratory and expiratory stridor, coarse BS, diffuse wheezes, subcostal retractions. Abdomen is benign without organomegaly. Femoral pulses are 2+ bilaterally. No skin rashes are noted. His color is pink and his perfusion is good. No neurologic abnormalities are noted.

A CXR is obtained which shows clear lung fields. Close examination of the trachea on the lateral view shows that the trachea is narrowed and it appears to be bowed anteriorly. Coupled with the clinical findings (airway symptoms since birth, current presentation with stridor), these findings raise the suspicion of tracheal compression, such as with a vascular ring. He is treated with bronchodilators, racemic epinephrine and suctioning for his acute symptoms. A CT of the chest reveals findings suspicious for a double aortic arch and an esophagram reveals a posterior indentation on the esophagus. MRI and MRA studies confirm the diagnosis of a double aortic arch (the aorta ascends and splits such that one arch travels anterior to the trachea and over the left mainstem bronchus, while the other arch travels over the right mainstem bronchus and posterior to the esophagus and trachea, at which point, both branches join together to form the descending aorta). Echocardiography also suggests a double aortic arch. He undergoes a surgical correction and postoperatively he improves, but he continues to have mild stridor. Bronchoscopy reveals mild tracheal stenosis.

Vascular rings and pulmonary slings are congenital anomalies of the aortic arch and pulmonary artery. They are very important but rare causes for common respiratory symptoms. They arise from abnormal embryonic development of the aortic arches. When the abnormal blood vessels encircle the trachea and esophagus, it is termed a vascular ring. These rings may be complete or incomplete. The severity of symptoms depend on the degree of compression on the trachea and esophagus.

Multiple paired branchial arches and paired dorsal aorta sequentially fuse and resorb in embryonic development. This results in a left aortic arch (i.e., the aortic arch travels over the left mainstem bronchus) and left descending aorta. Failure of regression or persistence of normally regressed portions will result in one of many vascular rings or a pulmonary artery sling.

Paired right and left dorsal aorta are present in an embryo at approximately 21 days. They come together at the aortic sac. Six branchial arches form along with its own aortic arches that communicate with the aortic sac. The appearance and regression of the aortic arches follow the number they are assigned. The 1st aortic arch is the 1st to appear and the 1st to regress. The 1st and 2nd aortic arch form the maxillary and hyoid/stapedial arteries respectively. The 3rd arch becomes the common carotid arteries. The 4th arch forms the proximal portion of the subclavian on the right and the aortic arch segment on the left. The 5th arch has no known derivatives. The 6th arch develops into the pulmonary arteries.

Edwards was the first to describe embryonic pathophysiologic mechanisms in 1948. Vascular rings will result from disruption at 4 points in the normal development. The 1st point is at the right dorsal aorta. This normally will regress but if it persists, a double aortic arch will develop. The 2nd point is at the right 4th aortic arch. This normally will persist and develop into the proximal portion of the subclavian artery on the right. Failure of this to develop will result in the right subclavian artery to arise from the left aortic arch. The 3rd point is at the left dorsal aorta. This normally persists to form the left descending aorta. If this regresses, a right aortic arch will persist. The 4th point is at the left 4th arch. This normally persists and develops into a portion of the left aortic arch. If this regresses, a right aortic arch will persist and the left subclavian will arise from the right arch.

Vascular rings encompass only 1% of all congenital heart disease. Some vascular rings are associated with other congenital heart lesions while others are isolated defects. Tracheobronchial anomalies are seen with vascular rings but are more highly associated with pulmonary artery slings.

The most common symptomatic vascular ring is the double aortic arch. This results from persistence of the right dorsal aorta. The right and left aortic arches encircle the trachea and esophagus. 70-90% have a dominant right aortic arch with the left arch hypoplastic or atretic. The aorta ascends from the heart and splits such that one arch travels anterior to the trachea and over the left mainstem bronchus, while the other arch travels over the right mainstem bronchus and posterior to the esophagus and trachea, at which point, both branches join together to form the descending aorta. The double aortic arch forms a ring around the trachea and esophagus (hence the term vascular ring) compressing both the trachea and esophagus. Tracheoesophageal compression will result in early symptoms. This type of vascular ring is rarely associated with intracardiac defects.

The second most common vascular ring is the right aortic arch, aberrant left subclavian with a left ligamentum arteriosum. In this malformation, the aorta ascends from the heart anterior to the tracheal bifurcation, to arch over the right mainstem bronchus. It then descends posterior to the esophagus and trachea. The left subclavian comes off the descending aorta. The ligamentum arteriosum (remnant of the ductus arteriosus) connects the left subclavian or descending aorta (depending on its origin) to the left pulmonary artery. The trachea and esophagus are encircled by the ascending aorta anteriorly, the aortic arch on the right, the descending aorta posteriorly, and the ligamentum arteriosum and the left pulmonary artery on the left. This results from persistence of the right dorsal aorta, regression of the left dorsal aorta and regression at the left 4th aortic arch. Due to the regression of the 4th arch, the left subclavian develops from the right descending aorta. 10% of this type of ring will have associated intracardiac defects.

A third type of vascular ring is the right aortic arch with mirror branching vessels. It results from persistence of the right dorsal aorta and regression of the left dorsal aorta. A complete ring is completed only if the ductus arises from the upper descending aorta. If the ductus arises from the left subclavian, an incomplete ring is formed. This type of vascular ring has greater than 90% association with intracardiac defects. This can be explained by the hemodynamics in developing hearts. Normally, formation of a vessel occurs as a result of blood flow through it. In a normally structured heart, blood is ejected to the left side stimulating the formation of the left arch. If there

is abnormal blood flow due to internal structure such that blood is ejected to the right, persistence of the right arch will develop. Approximately 25% will have tetralogy of Fallot, 20% will have double outlet right ventricle and 25% will have truncus arteriosus.

A fourth type of vascular ring is the left aortic arch and aberrant right subclavian artery. This results from the regression of the right 4th arch which normally develops into the proximal portion of the right subclavian. The right subclavian now arises as the last branch on the left aortic arch. The aberrant right subclavian travels posterior to the esophagus to the right side. This type of vascular ring is incomplete and symptoms are minimal. It is occasionally associated with dysphagia occurring in adolescents or adulthood. This has a higher association with coarctation of the aorta.

A pulmonary sling is the left pulmonary artery arising from the right pulmonary artery. This is also known as anomalous pulmonary artery. This results from regression/failure of development of the left pulmonary artery. As the lung buds on each side develop, the right pulmonary artery is stimulated to form collaterals to the left lung. The collaterals eventually enlarge to provide blood flow to the developing left lung, acting as the left pulmonary artery. The pulmonary artery travels between the trachea and esophagus as it arrives on the left side. Most of these patients are symptomatic by 1 month of age. Respiratory symptoms predominate as the compression is most severe on the trachea. 50% of these patients also have severe tracheobronchial anomalies such as tracheomalacia, stenosis, webs, complete tracheal cartilage rings called "O" rings (as opposed to the normal "C" cartilage rings) or long segmental stenosis. This anomaly also is associated with intracardiac defects present in 10-20%.

Respiratory symptoms predominate in initial presentation. These symptoms occur from tracheobronchial compression from the vascular ring or pulmonary sling. The severity of compression determines the severity of symptoms. 70-97% of patients will have respiratory symptoms. Stridor is present in 97% of cases. 65% will present on the first day of life. Stridor may be more pronounced during feeding or activity. Wheezing, air trapping and hyperinflation are also common. Many infants may have recurrent pneumonias. Diagnosis is difficult due to the rarity of these anomalies and the common symptoms these infants exhibit. Many of the patients will have a delay in diagnosis due to attribution of symptoms to other more common etiologies and the difficulty of establishing this diagnosis without an advanced imaging study such as CT, MRI, echocardiography, or esophagram. Most infants are diagnosed by age 12 months. The most common cause of stridor is laryngomalacia. This also is seen at birth and can easily mask symptoms from a vascular ring.

Symptoms of dysphagia are less common. This occurs from compression of the esophagus posteriorly from the vascular ring. 5-15 % of patients will have dysphagia alone. Symptoms include slow breast or bottle feeding, fatigue with feeding, frequent regurgitation and aspiration pneumonias. Many times the diagnosis is made when solid foods are introduced and dysphagia symptoms are more pronounced.

Again, the more severe the compression, the more severe the symptoms and the earlier age of presentation. Double aortic arch, right aortic arch with left ligamentum arteriosum and anomalous pulmonary artery present early in infancy. Aberrant left subclavian artery may be clinically silent or present in adolescence/adulthood with dysphagia.

Evaluation of suspected vascular rings should include a chest x-ray, esophagram, echocardiogram and a CT or MRI. There is much debate on the radiographic evaluation for vascular rings due to the advancement in radiographic studies. While CXRs are frequently done, the signs of a vascular ring are usually too subtle to be routinely diagnostic. A positive esophagram may provide supporting evidence of a vascular ring, but the other imaging modalities are superior.

There are subtle characteristics of CXR findings for each type of vascular ring. An anterior indentation of the trachea at or above the carina on a lateral film suggests a complete ring or anomalous innominate artery (not discussed in this chapter). A right sided aortic arch may suggest a vascular ring and this can occasionally be suspected if the distal trachea is slightly deviated to the left (due to the aorta arching over the right mainstem bronchus). Hyperinflation of the left lung with the left hilum lower than the right suggests a pulmonary sling.

Echocardiography is useful in evaluating for associated intracardiac defects. It is possible but difficult to completely delineate the anatomy of the vascular ring on the echocardiogram alone.

Bronchoscopy is useful when there is suspicion of tracheobronchial anomalies. Identification of these associated anomalies may assist the surgeon if correction of tracheal anomalies will be performed at the same time. If bronchoscopy is done prior to diagnosis, there are some characteristics of vascular rings. A pulsatile indentation may be seen on the anterior wall of the trachea. In a pulmonary sling, the pulsatile indentation may be on the right side or posterior.

CT scan can be used to identify structures in the thoracic cavity. It is fast and no sedation is usually required. It is however difficult to identify the ligamentum or an atretic branch of the aortic arch. MRI can more definitively identify the vascular ring as well as the tracheoesophageal anatomy. This however requires sedation and more time.

Angiography was used prior to the advancement in CT and MRI. It provides anatomy of the abnormal vessels and also identifies associated congenital heart defects. It fails to show atretic portions of vessels and is unable to identify nonvascular anomalies.

Vascular rings are surgically corrected if the patient is symptomatic. If the patient is asymptomatic or has mild symptoms, he/she can be monitored and treated conservatively. Many mild symptoms will resolve with growth. It is however necessary to surgically correct patients with pulmonary slings, double aortic arch and right arch with a left ligamentum arteriosum. These patients will progressively become more symptomatic over time.

Postoperatively, many patients will have respiratory symptoms related to tracheomalacia and airway obstruction. 10% of patients have symptoms that persist for months. This is expected to resolve with growth. In 95% of patients, surgical correction of the vascular ring is curative. Patients with pulmonary slings have a much higher percentage of tracheobronchial anomalies. Some of these patients will need further surgery to correct their tracheal anomalies.

In summary, the diagnosis of a vascular ring or pulmonary sling requires a high index of suspicion. CXR and esophagram may be used for the initial work up, but further anatomic details are obtained by echocardiography, CT/MRI or bronchoscopy for tracheal anomalies. Early surgical correction is safe and effective. Mild respiratory symptoms persist postoperatively but are expected to resolve.

Questions

1. Which vascular anomaly will exhibit a complete vascular ring?
    a. right aortic arch, mirror branching, left ligamentum from left subclavian
    b. right aortic arch, aberrant left subclavian
    c. left aortic arch, aberrant right subclavian
    d. pulmonary sling

2. Which vascular anomaly may present in adolescence or adulthood with dysphagia?
    a. double aortic arch
    b. right aortic arch, aberrant left subclavian
    c. left aortic arch, aberrant right subclavian
    d. pulmonary sling

3. What vascular anomaly is most associated with severe tracheobronchial anomalies?
    a. Right aortic arch, left subclavian
    b. Double aortic arch
    c. Pulmonary artery sling
    d. All of the above

4. All of the following are common symptoms of vascular rings except:
    a. wheezing
    b. hoarse cry
    c. stridor
    d. dysphagia

5. All of the following studies could find evidence to support the diagnosis of a suspected vascular ring except:
    a. Esophagram
    b. Pulmonary function tests
    c. CXR
    d. Echocardiogram

6. Describe the structures which form the vascular ring in a double aortic arch.

7. Describe the differences between a vascular ring and a vascular sling.

Answers to questions

1.b, 2.c, 3.c, 4.b, 5.b

6. right aortic arch, left aortic arch, connecting to the descending aorta.

7. A vascular ring involves the aorta and its branches. A vascular sling involves the pulmonary artery. In the vascular sling, the left pulmonary artery arises from the right pulmonary artery and compresses the trachea posteriorly.

Chapter VIII.1. Interpretation of Blood Gases and Pulse Oximetry

Loren G. Yamamoto, MD, MPH, MBA

This is a 5 year old male with a history of fever and coughing. His temperature has been up to 40 degrees C (104 degrees F). He has been ill for three days. He has vomited 8 times today and 4 times yesterday. He is also weak and oral intake has been poor. His past medical history and family history are unremarkable.

Exam: VS T39.0, P140, R50, BP 100/70, oxygen saturation 93% in room air, height and weight 50th percentile. He is drowsy, in moderately severe respiratory distress, and mildly toxic in appearance. His eyes are clear but sunken. His TMs are normal. His oral mucosa is sticky. His neck is supple without adenopathy. Cardiac exam demonstrates tachycardia without murmurs. Lungs reveal coarse breath sounds without wheezing. Moderate retractions are present with obvious tachypnea. Abdomen is soft and non-tender. His color and perfusion are good. His neurologic exam is intact except for the fact that he is slightly weak.

A chest radiograph shows a right middle lobe infiltrate. A CBC is remarkable for a WBC of 28.5 with 15% bands, 65% segs, 15% lymphs, 5% monos. A chemistry panel shows Na 136, K3.6, Cl 100, bicarb 17, glucose 100. A blood culture is also drawn. An arterial blood gas obtained with the patient breathing room air shows pH 7.35, pCO2 33, pO2 80, BE -7, HCO3 16, O2sat 93%. He is placed on 6 L oxygen by mask, an IV fluid infusion is begun, and antibiotics are administered. His oxygen saturation increases to 100% while breathing supplemental oxygen.

A normal blood gas should be memorized using single values rather than a range: pH 7.40, pCO2 40, pO2 100, BE 0, HCO3 24. Our patient's arterial blood gas (ABG) shows that the partial pressure of oxygen (pO2) is slightly low, but satisfactory. Once supplementary oxygen is administered, his oxygenation improves as demonstrated by a rise in oxygen saturation. His ABG also shows that he has a metabolic acidosis (high negative base excess-BE and low bicarbonate). He has partial respiratory compensation since his low pCO2 partially offsets the metabolic acidosis.

An arterial blood gas (ABG) measures three components: pH, pCO2, pO2. All the other numbers on a blood gas are calculated. The bicarbonate (HCO3) value is calculated based on the measured pH and the measured pCO2, using the Henderson-Hasselbalch equation. The base excess (BE) is calculated using a similar equation. The oxygen saturation is calculated based on the assumption that normal adult hemoglobin (HgbA) is the dominant hemoglobin in the sample (using the oxygen hemoglobin dissociation curve).

The pH measures the net circulating acid/base level. The pH can be affected by ventilation and by metabolic factors. Although the Henderson-Hasselbalch equation relates the pH, pCO2 and the HCO3 (bicarbonate, bicarb for short) values, suggesting that the three are in a dynamic equilibrium, it is easiest to interpret a blood gas based on the assumption that pCO2 and HCO3 are independent contributors to the pH. As the bicarb goes up, the pH goes up (less acidic, more alkaline). As the pCO2 goes up, the pH goes down (more acidic). The pCO2 determines the respiratory component of the pH, while the bicarb determines the metabolic component of the pH. The pCO2 and the bicarb contribute to the acidosis in opposite directions.

Even though we learned in chemistry that a pH of 7.0 is neutral, this is not the same for biological systems. The human body functions best at a pH of 7.40. Human proteins, hence cellular function, have reduced bioactivity at a pH outside of this value. Anything less than 7.40 is an acidosis. Anything above 7.40 is an alkalosis.

Table 1 below lists several ABG examples to help us. The interpretation of blood gases should be done in conjunction with the patient's clinical status.

	pH	pCO2	pO2	Bicarb	BE
A	7.40	40	100	24	0
B	7.22	60	70	24	-3
C	7.04	60	70	16	-13
D	7.31	60	80	30	+4
E	7.26	34	100	15	-11

ABG-A is a normal blood gas in room air. ABG-B (pH 7.20, pCO2 60, pO2 70, bicarb 24, BE -3) shows a patient with acute respiratory failure. The pH is less than 7.40 which means that the patient has an acidosis. The pCO2 is very high so this is the respiratory component which contributes to the acidosis. The bicarb is normal (equivalent to saying that the base excess is 0). This is called a respiratory acidosis. The pCO2 is indicative of the minute ventilation, in other words, the amount of total air that is moved in and out of the lungs per unit time. The minute ventilation can be increased by increasing the respiratory rate or increasing the tidal volume or both. As the minute ventilation increases, the pCO2 will decrease. A high pCO2 signifies a decreased minute ventilation. Thus, in general, pCO2 = ventilation. A very high pCO2 in conjunction with a low pO2 (hypoxia) suggests acute respiratory failure. This patient is likely to be lethargic, with a poor respiratory effort. This patient requires prompt positive pressure ventilation by bag-mask ventilation and eventual tracheal intubation and mechanical ventilation.

If this patient is allowed to remain hypoxemic without any intervention, ABG-C (pH 7.04, pCO2 60, pO2 70, bicarb 16, BE -13) will result. Because the tissues are hypoxic for a prolonged period, they shift to anaerobic metabolism and generate lactic acid. Since bicarb is the dominant cellular and extracellular buffer, the bicarb will decline as metabolic acid levels increase. This ABG shows a worsening of the acidosis since both the respiratory and metabolic components are contributing to the acidosis.

ABG-D (pH 7.31, pCO2 60, pO2 80, bicarb 30, BE +4) shows a low pH, hence an acidosis. The pCO2 is high which causes an acidosis, so this is a respiratory acidosis. In chronic lung disease, such as in infants with bronchopulmonary dysplasia or adults with chronic emphysema, air exchange is chronically poor, thus pCO2 is chronically high. The kidneys sense the acidosis, and compensate by retaining bicarbonate to partially raise the pH. This is called metabolic (as opposed to respiratory) compensation. This does not occur acutely which is why ABG-B (acute respiratory failure) shows no metabolic compensation. Note that with the pCO2 of 60, and a normal bicarb (24), the pH is 7.22, but with the same pCO2 and a higher bicarb (30), the pH is closer to 7.40. ABG-D can be described as a respiratory acidosis with metabolic compensation.

Look at ABG-D again: pH 7.31, pCO2 60, pO2 80, bicarb 30, BE +4. Why couldn't we call this a metabolic alkalosis with secondary respiratory compensation? Because the pH is less than 7.40, this is an acidosis, not an alkalosis. Thus, since the metabolic factor should cause an alkalosis, but the pH shows an acidosis, this must be a respiratory acidosis, with secondary metabolic compensation.

ABG-E (pH 7.26, pCO2 34, pO2 100, bicarb 15, BE -11) is a patient with renal failure who requires hemodialysis every other day. Because his kidneys cannot excrete acid, he has a chronic metabolic acidosis (bicarb 15, BE -11). To compensate for this, the brain senses the acidosis and the brain's respiratory center stimulates the respiratory rate to cause a tachypnea, which increases the minute ventilation to increase the pH. ABG-E can be described as a metabolic acidosis with partial respiratory compensation. Why can't we call this a respiratory alkalosis with secondary metabolic compensation? Because the pH is less than 7.40, this is an acidosis, not an alkalosis. Thus, since the respiratory factor should cause an alkalosis, but the pH shows an acidosis, this must be a metabolic acidosis, with secondary respiratory compensation.

ABG-E, could also be seen in a dehydrated patient. The dehydration causes a metabolic acidosis, which causes some secondary tachypnea (respiratory compensation). The same thing occurs in diabetic ketoacidosis. But since the degree of acidosis is generally more severe, the degree of tachypnea is generally more exaggerated (Kussmaul respirations).

So far we have seen an example of: 1) a respiratory acidosis with metabolic compensation, and 2) a metabolic acidosis with respiratory compensation. Is it clinically possible to see other combinations? Specifically, could the following scenarios be possible: 3) a respiratory alkalosis with metabolic compensation and 4) a metabolic alkalosis with respiratory compensation.

A respiratory alkalosis could only be caused by increasing the minute ventilation. Clinically, this would have to be done by hyperventilating. Since metabolic compensation does not occur acutely, one would have to hyperventilate for a long time for metabolic compensation to occur. This would not be a realistic clinical condition. However, in a patient on a mechanical ventilator set such that the patient is deliberately hyperventilated for a prolonged period, the kidneys may sense the alkalosis and thus, excrete bicarb to partially compensate for this. An ABG example of this would be pH 7.41, pCO2 35, pO2 100, bicarb 22, BE -2. This would be an unusual case of a respiratory alkalosis with metabolic compensation.

The last possibility is a metabolic alkalosis with respiratory compensation. This is even less likely clinically. How can a patient develop a metabolic alkalosis? There are only a few possibilities: 1) The patient would have to take a drug which excretes chloride or retains bicarbonate. 2) The patient would have to consume excess amount of alkaline substances, such chronic antacid use. 3) The patient would have to be a chronic vomiter (e.g., bulimia nervosa) since chronic vomiting results in excessive hydrochloric acid loss. Do such patients develop respiratory compensation? To do this, they must hypoventilate!! This is possible, but not likely. This clinical situation is unlikely.

How do venous and capillary blood gasses differ from an arterial blood gas? Looking at the three blood gas measurements: 1) The venous bicarb and the arterial bicarb are roughly the same. 2) The venous pCO2 is slightly higher than the arterial pCO2 because additional CO2 is picked up from the tissues, but the difference between the two is rather small. 3) The venous pO2 is substantially lower than the arterial pO2.

Since only the pCO2 and the bicarb contribute to the pH, the venous pH and the arterial pH are roughly the same. A venous or a capillary blood gas very closely approximates the arterial pH, pCO2 and bicarb (or BE), under ideal conditions with well perfused tissues, but they do not approximate the arterial pO2. All that can be said about a venous pO2 is that it is lower than the arterial pO2. All that can be said about a capillary pO2 is that it lies somewhere between the venous pO2 and the arterial pO2. Fortunately, pulse oximetry accurately reflects the arterial pO2. Therefore, a venous blood gas or capillary blood gas done in conjunction with a pulse oximeter measurement, should accurately reflect the arterial blood gas as long as the capillary source is well perfused. Often, no blood gas is needed at all. The bicarb value can be obtained by ordering a standard set of electrolytes, the pO2 can be accurately estimated using a pulse oximeter, and the pCO2 can be clinically estimated using auscultation by listening for the degree of air exchange.

The arterial pO2 is frequently described as the paO2 to denote that this is an arterial sample, as opposed to a venous or capillary pO2. Blood gases and pulse oximeters can be occasionally fooled so it is important to know when these tests provide us with misleading information. It is important to understand the difference between the pO2, the oxygen saturation (often called SO2 or SaO2), the oxygen content and the oxygen delivery rate.

The pO2 represents the partial pressure of oxygen or the gas tension. This concept is difficult to visualize, but it can best be thought of as the force that the oxygen particles exert on the side of an enclosed container. Gases travel rapidly, so that the partial pressures of gases tend to be identical in samples that are next to each other for at least 5 seconds. Gas pressure or gas tension is measured in mmHg or Torr, which are exactly the same thing. The atmospheric pressure at sea level is 760 mmHg (or Torr) and the atmosphere contains 21% oxygen. Thus the pO2 that we breathe in is 160.

What is the pO2 in a cup of coffee? As the coffee sits on the table, its gas content rapidly equilibrates with the environment so the pO2 in the liquid coffee is 160 mmHg. If one sends a sample of coffee to the blood gas lab, the blood gas machine should measure a pO2 of 160. Normal pO2 in arterial blood is only 100 mmHg. If I replaced my blood with coffee, my brain and other tissues would not be happy since although the pO2 of the coffee may be 160, it does not contain much oxygen. Blood holds a lot of oxygen which is why we need blood. One ml of coffee contains only a few oxygen molecules, while one ml of blood contains many, many more oxygen molecules. Each hemoglobin molecule has four oxygen binding sites. Blood contains red blood cells and plasma. RBCs hold a lot of oxygen while the plasma contains only minute amounts of oxygen. The pO2 of RBCs is the same as the pO2 of the plasma, yet the oxygen content of the plasma is minute, compared to the oxygen content of RBCs. Substituting coffee for blood, is like removing all the RBCs and letting plasma alone flow though the body. This is the difference between pO2 and oxygen content. While many fluids may have reasonably good pO2s, only blood has a satisfactory oxygen content. The pO2 of a fluid sample is a measurement of its oxygen gas tension (or pressure), but it is not a measurement of oxygen content.

An oxygen saturation measurement can only be done on blood, as opposed to a pO2 which can be done on coffee or any fluid. The pO2 and the SaO2 are related to each other by the oxygen hemoglobin dissociation curve, which students learn in physiology. This curve plots the oxygen saturation (in %) on the vertical axis and pO2 on the horizontal axis. The oxygen saturation % steadily increases as the pO2 increases up to about a pO2 of 100 mmHg at which point the oxygen saturation is 99% to 100% (i.e., all the hemoglobin oxygen binding sites contain oxygen). If the patient breathes supplemental oxygen, the inspired pO2 increases to 200 mmHg, 400 mmHg or higher depending on how much oxygen is inhaled. Thus, a patient breathing supplemental oxygen may have a pO2 as high as 400 mmHg, but his oxygen saturation is still 100%, since it can't get any higher than this. So the typical appearance of an oxygen hemoglobin dissociation curve, has a steep rise at pO2s below 100 mmHg, at which point it becomes a plateau since the oxygen saturation cannot increase above 100%.

Oxygen saturation (SaO2) is a measurement of the percentage of oxygen binding sites that contain oxygen. If all the oxygen binding sites contain oxygen, then the oxygen saturation is 100%. An oxygen saturation measurement can only be done on blood, as opposed to a pO2 which can be done on coffee or any fluid. The pO2 and the SaO2 are related to each other by the oxygen hemoglobin dissociation curve, which students learn in physiology. This curve plots the oxygen saturation (in %) on the vertical axis and pO2 on the

horizontal access. The oxygen saturation % steadily increases as the pO2 increases up to about a pO2 nearing 90 to 100 mmHg at which point the oxygen saturation is 99% to 100% (i.e., all the hemoglobin oxygen binding sites contain oxygen). If the patient breathes supplemental oxygen, the inspired pO2 increases to 200 mmHg, 400 mmHg or higher depending on how much oxygen is inhaled. Thus, a patient breathing supplemental oxygen may have a pO2 as high as 400 mmHg, but his oxygen saturation is still 100% (it can't get any higher than this). So the typical appearance of an oxygen hemoglobin dissociation curve, has a steep rise at pO2s below 100 mmHg, at which point it becomes a plateau since the oxygen saturation cannot increase above 100%.

Oxygen saturation can be measured continuously and non-invasively by pulse oximetry. Pulse oximetry uses light absorption through a pulsing capillary bed usually in a toe or finger, but it will also pick up in the nose, ear, palm, side of the foot, etc. The probe looks red, but it actually uses two light sources; one is red and the other is invisible infrared. Absorption using these two wave lengths measures oxygen saturation for hemoglobin A. Pulse oximetry will not measure the oxygen saturation correctly for other hemoglobins such as methemoglobin or carboxyhemoglobin. However, for sickle hemoglobin or fetal hemoglobin, the measurement is nearly as accurate as for hemoglobin A. Oxygen saturation can be measured by co-oximetry but this requires a blood sample Co-oximetry is capable of determining the true oxygen saturation for methemoglobin and carboxyhemoglobin. If the true oxygen saturation is known, then the pO2 can be estimated or calculated using the oxygen hemoglobin dissociation curve assuming that the patient is circulating hemoglobin A (which is not always the case).

The oxygen content is determined by the oxygen saturation percentage and the hemoglobin concentration. A patient with a hemoglobin of 14 has twice as much oxygen per ml of blood compared to a patient with a hemoglobin of 7, assuming that they both have 100% oxygen saturations. Similarly, the visual presence of cyanosis is dependent upon the concentration of desaturated (blue) hemoglobin. Thus, a patient with a hemoglobin of 7 at 80% saturation has a deoxygenated hemoglobin concentration of 1.4. This patient will visually appear to be just as blue (though paler) as a patient with a hemoglobin of 14 at 90% saturation, since this latter person also has a deoxygenated hemoglobin concentration of 1.4. Additionally, a patient with a hemoglobin of 14 at 80% saturation will look more cyanotic than a patient with a hemoglobin of 7 at 80% saturation. In this comparison, the more cyanotic patient is doing better with a higher oxygen content and oxygen delivery.

The hematocrit is the percentage of the blood that contains RBCs. The hematocrit is directly proportional to the hemoglobin concentration. The hematocrit (in percent) is roughly three times the hemoglobin concentration (in gm per dl). Chronically hypoxic patients can survive by raising their hematocrit as a compensation maneuver. Chronic hypoxia stimulates erythropoietin which stimulates RBC production raising the hematocrit. Thus, a patient with a normal hemoglobin of 12 (hematocrit 36) and an oxygen saturation of 100%, has the same oxygen content as a patient with an oxygen saturation of 80% and a hemoglobin of 15 (hematocrit 45). The former patient looks pink, while the latter patient looks blue.

The last factor is the oxygen delivery rate. This is determined by the oxygen content and the cardiac output. Conceptually, imagine a patient with a weak heart and only half the cardiac output of a normal patient with signs of congestive heart failure. If pulmonary edema were not present, and such a patient had an oxygen saturation of 100%, their hemoglobin would have to be twice as high as another patient with a normal cardiac output to achieve the same oxygen delivery rate. This might be better understood by measuring a patient's venous blood gas. In room air, a normal arterial pO2 would be 100 mmHg, and the venous pO2 would be about 75 mmHg. However, if a patient had a very low cardiac output, the arterial pO2 might still be 100 mmHg, but the venous pO2 might be 50 mmHg. This occurs because the cardiac output is so low, that much more oxygen is extracted from the RBCs as they pass through the capillaries.

Pulse oximetry can be fooled by conditions with abnormal hemoglobin color. The major condition in this category is carbon monoxide (CO) poisoning. CO poisoning results in the formation of carboxyhemoglobin. Carboxyhemoglobin does not carry oxygen. It is really a hemoglobin molecule with all oxygen carrying sites occupied by CO. The CO has such a high affinity for hemoglobin, that oxygen cannot displace it. Consider carboxyhemoglobin totally useless in oxygen transport. CO poisoning results from CO exposure, most commonly exposure to fuel combustion (fuel burning heaters, stoves, automobile exhaust, etc.), so it most commonly occurs during cold periods where people are in closed quarters to conserve the heat originating from fuel combustion. Symptoms include headache, nausea, vomiting and weakness. The patient is classically described as cherry red, but in reality, they appear to be pink, which lowers the clinician's suspicion for hypoxia. Thus, these symptoms are commonly attributed to viral flu-like illnesses. If a patient has a carboxyhemoglobin level of 25%, and their hemoglobin is 12, this means that they effectively have a hemoglobin of only 9 (since 25% of their hemoglobin is useless). If the carboxyhemoglobin level is 25%, then the maximum oxygen saturation that can be attained is 75%. However, the pulse oximeter will read 100% because the color of carboxyhemoglobin is bright red, which is what the pulse oximeter reads. Thus, pulse oximetry measurements are fooled by CO poisoning. The arterial blood gas is not usually helpful either. Since the ABG measures oxygen gas tension (pO2) and not oxygen content or true oxygen saturation, the oxygen gas tension (pO2) will be normal. The only abnormality on an ABG may be metabolic acidosis, which is a consequence of inadequate oxygen delivery to the peripheral tissues, resulting an anaerobic metabolism and lactic acid production. If CO poisoning is suspected, one must order a CO level or a test called co-oximetry. Co-oximetry is done routinely in some blood gas analyzers, but most do not, so this must be specifically ordered. Co-oximetry is capable of measuring the true oxygen saturation percentage and the percentage of nonfunctional hemoglobins such as carboxyhemoglobin and methemoglobin. The treatment for CO poisoning is oxygen, but if the CO level is very high, or if the victim is pregnant, hyperbaric oxygen is indicated to more effectively displace the CO from the hemoglobin.

Similarly, methemoglobinemia is a condition in which there are high circulating levels of methemoglobin which does not carry oxygen. The major difference is that methemoglobin is brown in color. Patients with methemoglobinemia are classically "ashen gray" in color. Their pulse oximetry value will read LOW, so this condition does not fool the pulse oximeter as it does in CO poisoning. Another clue is that when supplemental oxygen is given to the patient, the pulse oximetry reading does not change. It will still be low. When an arterial blood gas is drawn, the blood appears to be a chocolate brown color which is quite eye opening. A simple bedside test can be done by taking a drop of the patient's blood on a filter paper or gauze. Get another drop of blood from a normal person (either your or your fellow residents and medical students). Blow oxygen over the surface of these two blood spots. The normal blood will become red or stay red, while the methemoglobinemia patient's blood will stay the same color (brown or dark) since the methemoglobin will not carry oxygen. This illustrates the fact that the oxygen gas tension (pO2) does not reflect the degree of oxygen carrying capacity. Co-oximetry or a methemoglobin level can be ordered to measure the severity of the methemoglobinemia, but the pulse oximeter will be able to estimate it also. Most symptomatic methemoglobinemia occurs in infants with diarrhea. The cause is usually idiopathic, but the ingestion of nitrites is one of the known causes. The condition is usually self-limited and resolves gradually with IV fluid hydration. IV methylene blue can be given for severe cases. Oxygen supplementation is somewhat helpful and PRBC transfusion can be used to increase the oxygen carrying capacity in severe cases.

The two common elements of CO poisoning and methemoglobinemia is that the pO2 does not identify the condition. You can think of carboxyhemoglobin and methemoglobin as useless hemoglobin, just like the coffee in the cup example. Coffee (or water) is capable of carrying oxygen, but very little. Just because the pO2 of the coffee or carboxyhemoglobin or methemoglobin is 150 Torr, this does not mean that it is carrying much oxygen at all. CO poisoning is a harder diagnosis to make, because the pulse oximeter reads falsely normal. A typical ABG in CO poisoning or methemoglobinemia patients is pH 7.26, pCO2 34, pO2 100, bicarb 15, BE -11, if the patient is breathing room air. If the patient is breathing supplemental oxygen, then the ABG will be pH 7.26, pCO2 34, pO2 400, bicarb 15, BE -11 (i.e., just the pO2 goes up), although this does not change the oxygen saturation much. Although the blood gas machine will calculate that the oxygen saturation is 100%, remember that the ABG machine did not measure this, but rather it calculates this based on the assumption that the sample contains normal hemoglobin (which is not the case if the patient has CO poisoning or methemoglobinemia). The paradox is that the ABG slip will indicate that the oxygen saturation is 100%, while the co-oximetry report will indicate that the oxygen saturation is very low (e.g., 70%).

In summary, CO poisoning has a low true oxygen saturation, red color, 100% oxygen saturation on pulse oximetry (which is false), and normal pO2 on ABG. Methemoglobinemia has a low true oxygen saturation, brown color, low oxygen saturation on pulse oximetry, and normal pO2 on ABG.

Questions

1. Which patient has a higher oxygen content? Patient A with a pO2 of 100 or patient B with a pO2 of 70?
2. ABG pH 7.31, pCO2 60, pO2 80, bicarb 30, BE +4. What is the best description for this ABG considering the concepts of metabolic or respiratory acidosis or alkalosis, and metabolic or respiratory compensation?
3. Describe a possible clinical situation which would yield the ABG in question number 2 above?
4. At what pO2 or oxygen saturation does cyanosis become visible?
5. Write an example of an ABG in a patient with moderately severe diabetic ketoacidosis.
6. In a cardiac arrest victim, you get an ABG which shows pH 6.72, pCO2 55, pO2 200, bicarb 7, BE -25. What can you do to reverse the acidosis?
7. Well oxygenated patients are pink and poorly oxygenated patients are cyanotic. Is there a stage in between these? What is the color of these patients if they aren't pink and they aren't cyanotic? The answer to this question is not found in the above chapter.
8. What condition would give you the following results in an ill appearing patient breathing supplemental oxygen: Pulse oximeter reading 100%, pO2 on ABG 350 Torr, co-oximetry (true oxygen saturation) 65%.

Answers to questions

1. This cannot be determined without knowing the hemoglobin or hematocrit of each patient. Patient A could paradoxically have a lower oxygen content if he has a substantially lower hemoglobin (severely anemic) than patient B.
2. This is a respiratory acidosis with metabolic compensation.
3. This patient has bronchopulmonary dysplasia (chronic lung disease) with chronic CO2 retention and metabolic compensation. An alternative answer would be an adult with chronic emphysema. An incorrect answer is acute respiratory failure, because if the respiratory failure were acute, the patient would not have enough time for metabolic compensation and his bicarb would be 24 or lower.
4. Visible cyanosis requires a certain amount of deoxygenated hemoglobin which is why the answer to this question depends on the hemoglobin or hematocrit. Patients with low hematocrits require a lower pO2 for visible cyanosis compared to patients which higher hematocrits. So there is no single answer to this question. For example, a patient with cyanotic congenital heart disease may have a high hemoglobin to compensate. If his chronic oxygen saturation is 80%, he can compensate by having a higher hemoglobin such as a hemoglobin of 16. He will be visibly cyanotic because 20% (100% minus 80% oxygen saturation) of his 16 hemoglobin is desaturated (i.e., 3.2 Hgb is desaturated). For a normal child with a hemoglobin of 13 to have 3.2 desaturated Hgb, this child would have to have 25% (3.2 divided by 13) desaturation (i.e., an oxygen saturation of 75%). Thus, one patient may look bluer at 80% saturation, while another would less blue at 80% because of different hemoglobins.
5. The pH should be low. The bicarb should be low (metabolic acidosis). There should be some respiratory compensation so the pCO2 should be low (hyperventilation or Kussmaul respirations). The pO2 should be fairly normal. So an example might be pH 7.14, pCO2 30, pO2 100, bicarb 10, BE -17.
6. This is a cardiac arrest so the patient is probably intubated. The high pCO2 indicates that the patient is being hypoventilated or the endotracheal tube is not in the trachea. Proper placement of the endotracheal tube should be confirmed. The tidal volume and respiratory rate need to be increased to increase the minute ventilation to decrease the pCO2. Better chest compressions to improve pulmonary blood flow will also facilitate the removal of CO2. The bicarb is low causing a metabolic acidosis. Sodium bicarbonate can be given intravenously to reverse the metabolic acidosis.
7. Their color is pale. Thus pallor can suggest anemia, poor skin perfusion or hypoxia.
8. CO poisoning.

Chapter VIII.2. Asthma
Franklin Y. Yamamoto, MD

A three year old comes in with a complaint of coughing for 2 weeks. Coughing is present every night. He has also had a mild fever, but his temperature has not been measured at home. His parents have been using a decongestant/antihistamine syrup and albuterol syrup which were left over from a sibling. Initially the cough improved but it worsened over the next 2 days. He is noted to have morning sneezing and nasal congestion. There are colds going around the pre-school. He has had similar episodes in the past, but this episode is worse. He has no known allergies to foods or medications.

His past history is notable for eczema and dry skin since infancy. He is otherwise healthy and he is fully immunized. His family history is notable for a brother who has asthma. In his home environment, there are no smokers or pets.

Exam: VS T 38.1, P 100, RR 24, BP 85/65, oxygen saturation 99% in room air. He is alert and cooperative in minimal distress if any. His eyes are clear, nasal mucosa is boggy with clear discharge, and his pharynx has moderate lymphoid hypertrophy. He has multiple small lymph nodes palpable in his upper neck. His chest has an increased AP diameter and it is tympanitic (hyperresonant) to percussion. Rhonchi and occasional wheezes are heard on auscultation, but there are no retractions. Heart is in a regular rhythm and no murmurs are heard. His skin is dry, but not flaky, inflamed or thickened.

He is initially felt to have moderately persistent asthma and possible asthmatic bronchitis. He is initially treated with nebulized albuterol and nebulized corticosteroids for bronchospasm and bronchial inflammation. He is also treated with an antihistamine at night to reduce his morning allergy symptoms. In follow-up, his cough does not improve and he is still having fever (T 38.2C, 101.0F). A chest X-ray is obtained, but no radiographic evidence of pneumonia is present. His cough persists, but only with exercise and drinking cold juice.

His chest now sounds clear in the office. After one week of no night cough, his nebulized albuterol+corticosteroid is reduced to 2 times a day. His exercise induced cough gradually resolves. His nebulized corticosteroid is replaced with nebulized cromolyn twice a day and oral montelukast (a leukotriene inhibitor) is added. He enrolls in a soccer league and plays with minimal coughing. His routine nebulized albuterol+cromolyn is stopped and is used only pre-exercise to prevent exercise induced bronchospasm. No cough is observed at night or with exercise. He is continued on nightly antihistamines, pre-exercise albuterol+cromolyn nebs, and once daily montelukast. He is given an asthma treatment plan which gives his parents clear instructions on which medications to start based on his symptoms and severity.

Asthma is by far, the most frequent respiratory diagnosis for children admitted to hospitals. It causes 5000 deaths annually in the United States despite the availability of excellent medications. Historically, asthma was characterized as a psychological illness, a surgical illness treated by removal of the carotid body, an environmental illness aggravated by air pollution, and an allergic illness or infectious illness. An allergy role in asthma, was legitimized by the discovery of IgE in 1965. Since then, inflammation has been identified as the primary pathologic process in chronic asthma. Because of the variety of asthma triggers, such as exercise, exposure to smoke, weather changes, and allergies, asthma is now considered to be a syndrome consisting of bronchospasm, airway hyperirritability, and inflammation. The popular term ROAD (reversible obstructed airways disease) or RAD (reversible airway disease) is not entirely accurate since this is only part of the disease process and reversibility may not always be evident. This is because obstruction of the airways may be secondary to mucous plugging or inflammatory changes decreasing the caliber of the airways, in which case, beta-2 bronchodilators are ineffective.

Currently the NIH Guidelines (1) have served as a standard for diagnosing and treating asthma. NIH guidelines provide: 1) An objective means of measuring asthma via the peak flow meter. 2) A way of objectively categorizing severity classes of patients based on symptoms and/or peak flow measurements. 3) A comprehensive pharmacologic plan primarily designed to treat inflammation, inclusive of provisions for acute and maintenance care, for each severity level. 4) For the identification and removal of (or control of exposure to) known triggers. 5) The direction for forming a partnership with the physician who uses education as a primary basis of this relationship.

The realization that IgE existed and could be found in allergic individuals propelled the field of allergy and understanding of asthma into a renaissance of elucidating the actual pathophysiology of allergic diseases. Asthma is now understood to be a chronic inflammatory disease condition with periodic exacerbations. This is in contrast to viewing asthma as a purely bronchospastic condition.

An acute asthma exacerbation is a biphasic process. Understanding the inflammatory process of asthma came about when it was observed that 4 to 8 hours following allergen exposure, wheezing would occur that was not responsive (or less responsive) to beta agonists but it was ablated by cromolyn and corticosteroids. However, beta agonists could easily neutralize the immediate reaction, occurring within minutes of the allergen exposure. This created a picture of a biphasic reaction to allergen (or infection) induced wheezing. The first phase was described as the immediate (bronchospastic) phase and the second phase as the late phase inflammatory response.

In the early phase of allergic inflammation, preformed mediators such as histamine and rapidly formed mediators such as leukotrienes are released and cause bronchospasm. Other mediators signal the late phase inflammatory cells. These cells (e.g., eosinophils) recruit other cells such as epithelial cells to participate in the resultant inflammatory damage of the airways and subepithelial structures. These events eventually result in extensive restructuring of the normal histology of the airways. This damage is not restored by beta-2 bronchodilators. An important immunologic occurrence is the activation of the Th2 helper cell, which is pivotal in the progression of the allergic immunologic process. The other helper designated Th1 cell does not enhance the allergic inflammatory process.

Asthma, whatever the severity, is a chronic inflammatory disorder of the airways. The characteristic features of asthmatic inflammation are: mast cell activation, inflammatory cell infiltration, eosinophils, macrophages, neutrophils (particularly in sudden-onset, fatal exacerbations), lymphocytes (TH2-like cells), edema, denudation and disruption of the bronchiolar epithelium, collagen deposition beneath the basement membrane (this is an irreversible process), goblet cell hyperplasia, mucous hypersecretion, and smooth muscle thickening. The primary clinical components of asthma include: bronchospasm, inflammation, airway hyper-reactivity, increased mucous production, and end expiratory hyperinflation ("air trapping").

There are many presentations of asthma. Asthma is present 24 hours a day, 7 days a week. It may not be in an easily identified form (i.e., there may be no obvious symptoms present). The most recognizable form is the acute episode in which the patient presents with acute shortness of breath. Depending on the underlying degree of inflammatory damage of the airways, the episode may have been festering with persistent cough and occasional bouts of shortness of breath for weeks. Failure to attend to these soft signs of "asthma in transition" may lead to an acute case of status asthmaticus. Hence, paying attention to signs of "silent asthma" (asthma not in an acute phase), can prevent costly and life threatening consequences. Asthma may appear solely as an event associated with work or exercise. Most asthma in childhood occurs as a result of encounters with respiratory viruses. If the asthmatic is already unstable because of a poor

maintenance regimen of the existing chronic asthma, the acute phase will begin simultaneously with the first signs of a "cold". If the asthma is managed well, then the cough and wheezing may occur several days after cold symptoms. Hence, early recognition of "asthma in transition" is a major point of cooperation involving the physician and patient. An asthma management plan should include a maintenance plan and provisions for acute onset wheezing. Asthma in its most manageable state, is outpatient asthma, as opposed to hospital status asthmaticus.

For most medical professionals, the first and everlasting impression of asthma is in hospital status asthmaticus. By far, the more common situation is asthma outside the hospital, in its non-acute form. Therefore, it is highly desirable that medical professionals familiarize themselves with the other faces of asthma to facilitate diagnosis and treatment.

The type of medication used to treat asthma reflects the mechanism of airway obstruction: bronchospasm versus inflammation. This is an extremely simplified version of what really goes on and new pieces of the intricate mechanism are being uncovered. However from a pragmatic standpoint, the logic for appropriate use of individual medications for asthma can be understood by recalling the biphasic reaction.

Based on this brief description of the mechanism of asthma, it is now possible to create an asthma treatment program. Genetics aside, elimination of triggers and aggravators of asthma such as allergens, cigarette smoke, and environmental and industrial pollutants, can prevent acute exacerbations of asthma and serve as the first line of defense. Conditions such as weather changes and respiratory infections fall outside of the readily controllable factors.

Approach to Asthma

1. Diagnose asthma and classify severity. Identify aggravating and triggering conditions.
2. Prepare an initial treatment plan to stabilize the acute condition. Instruct patient and parents on signs and symptoms which help to monitor the effectiveness of treatment. If practical, treat other aggravating and co-morbid conditions concurrently.
3. When asthma is stable, proceed to a maintenance plan to allow healing of the damaged airways. This may take weeks to months. Prepare an asthma action plan for up-regulation of medications for unexpected exacerbations.
4. When there are no signs of breakthrough cough or wheezing, indicating that the airway hyper-reactivity has subsided and is controlled, switch to a long term maintenance plan. This might be PRN use of bronchodilators, or pre-exercise use of preventive medications, or pulsing of medications for cold symptoms in short bursts.
5. Monitor asthma with periodic evaluations and reminder messages of avoidance and check on patients' inhalation technique of medication administration.

Inflammation in asthma contributes to: airway hyperresponsiveness, airflow limitation, respiratory symptoms, coughing, wheezing, shortness of breath, rapid breathing, chest tightness, persistent symptoms, and pathologic damage, even when symptoms are not present. It is often thought that periodic control of acute symptoms is sufficient, but this is suboptimal. Utilization of chronic anti-inflammatory agents result in better long term outcomes for all but the mildest asthmatics.

Co-morbid conditions such as allergic rhinitis, sinusitis, eczema, and gastroesophageal reflux have profound influence on asthma. Their presence makes asthma extremely difficult to control. The main goal is to keep the patient functional and free of side effects from medications. With this approach, asthmatics have been able to participate in a normal life style.

Asthma is more than an acute process. A large part of treating asthma successfully is to be able to recognize asthma in its early stages and to formulate an appropriate treatment plan before the asthma advances to a critical stage. It is simple to diagnose asthma when the patient is wheezing, displaying intercostal retractions and turning pale or blue. Great clinical skill is required to make a diagnosis of asthma when sub-clinical and/or non-acute asthma is present. A careful detailed history and physical exam are crucial to this end. Asthma is not the acute episode of wheezing as popularly described in lay journals and magazines, but a chronic condition of the airways of the lungs which exhibits recurrent bronchospasm. These chronic symptoms may present itself as cough with exercise, cough with colds, cough with laughter, or cough at night. A peak flow meter can consistently record airflow readings compared against normal values for sex and age.

Signs of "silent asthma" (when no wheezing is heard) include: persistent cough at night, cough with exercise, cough with laughter, cough when consuming cold foods or drinks, prolonged cough following or accompanying a cold, feeling of "tight chest" or difficulty breathing.

The peak flow measurement and FEV1 (forced expiratory volume over one second) are effort dependent measures. Full pulmonary function testing is desirable; however, the equipment is expensive compared to an inexpensive peak flow meter. The ultimate objective measurement for asthma is by body plethysmography (body box), which can measure the end expiratory residual lung volume as well as resistance to airflow. For those patients unable to perform peak flow measurements, clinical history is all you may have to base your conclusions. This includes a major group of younger asthmatics from infancy to 4 or 5 years old. Many children in this age group are unable to reliably perform peak flow measurements.

Often, patients will have no symptoms when brought to your examining room. The identification of the role of allergic diseases in asthma relies heavily on patient history. Physicians trained to respond to record what they feel, see, and hear may have a problem forming conclusions based on history alone. Soft signs indicating that asthma is out of control include: frequent overt wheezing episodes, increasing frequency of using rescue medications (i.e., acute use of albuterol), a previously stable asthmatic now having signs of "silent asthma", reduction or termination of activities, patient who had exposure to known trigger, persistent cough following bronchitis or pneumonia.

The National Institutes of Health (NIH) guidelines, list as one of several key objectives, forming a partnership with the patient to facilitate treatment of asthma. Good communication and availability to answer questions and concerns are basic to the partnership. Part of your efforts as the treating physician should be focused on getting the patient to respond in a logical manner to cope with changes in his/her clinical state. This is based on the patient understanding the principles of: triggers and aggravators, bronchodilation, inflammation, airway hyper-reactivity and healing. Patients must also understand mucous mobilization and signs and symptoms of asthma out of control which may lead to an acute asthma attack. For example, should the peak flow fall or cough increase, the patient is instructed to upgrade their medications according to a prearranged plan. As the acuteness of the situation resolves, the patient is advised to downgrade their medications back to their maintenance program. Should there be an unanticipated episode of wheezing, immediate activation of the action plan and consultation with the physician for additional treatment schemes is the next step. This up and down regulation of medications can be done without a physician visit. Phone calls, informing the physician's office of these maneuvers, are all that is normally required. Obviously, recurrent wheezing episodes, even if reversed easily might indicate the presence of an unstable condition requiring an

adjustment in the basic asthma management plan. Hence, the physician should be apprised of these changing conditions regularly. All asthma management plans should have common goals.

Asthma management plans depend on the severity of the asthmatic. Higher severity levels warrant greater use of corticosteroids and prophylactic medications such as leukotriene inhibitors and inhaled corticosteroids. The NIH guidelines categorizes severity levels into "steps" as follows:

Step 1 (mild intermittent): Day symptoms two days per week or less and night symptoms two nights per month or less. Chronic peak flow is 80% of expected or higher.

Step 2 (mild persistent): Day symptoms greater than two times per week, but less than once per day or night symptoms greater than nights per month. Chronic peak flow is still 80% of expected or higher.

Step 3 (moderate persistent): Day symptoms occur daily or night symptoms occur more than once per week. Chronic peak flow is 60% to 80% of expected value.

Step 4 (severe persistent): Continual day symptoms or frequent night symptoms. Chronic peak flow is less than or equal to 60% of expected value.

The use of peak flow in the above classification is not required in children 5 years and under. Peak flow data is useful but not required for classification in older age groups, but most children in this age range are capable of performing peak flows.

The major goal is to allow the child to express and achieve his or her maximum natural potential by not allowing the asthma to control him or her. This is a good way to view the end point in asthma management. Along the way, it is crucial to cradle the impressionable self image so that the child does not have a negative view of himself or herself. The very impressionable years are from about 3 to 10 years of age, when children form their life-long mental image of themselves. Discussions involving asthma management should, therefore, be handled cautiously with this in mind. Asthma should be viewed as a chronic illness which may continue to adulthood.

Bronchodilators

In 1896 Solis-Cohen published, "The use of adrenal substances in the treatment of asthma" (adrenalin or epinephrine is a fast and potent bronchodilator). Epinephrine (most commonly administered subcutaneously, but it could be inhaled as well) was the first line of treatment for acute asthma from the 1950s through the 1970s and early 1980s.

In 1924 ephedrine was isolated from Ma Huang (a Chinese root extract). For the next forty years, ephedrine would be the mainstay for asthma treatment in the USA. Ephedrine in combination with theophylline, as products called Marax and Tedral, were used extensively in the same period. Interestingly, the ancient Chinese boiled the ephedra root in strong tea for their concoction to treat asthma. The tea contained theobromine, a methylxanthine. Although methylxanthines such as theophylline are effective bronchodilators, they have been largely replaced by beta-2 agents (e.g., albuterol) which have a faster onset and less toxicity. Adding theophylline does not appear to acutely benefit most patients who are receiving high therapeutic doses of albuterol. Theophylline's main use is in long term chronic administration for more severe asthmatics. This change in therapeutic approach from methylxanthines to beta-2 agents did not further our understanding of the true pathophysiology of asthma, as bronchodilation was the only target of treatment. Bronchodilators can be administered via several inhaled routes: metered dose inhaler (MDI), dry powder inhaler (DPI), nebulizer (Neb, also known as aerosol, updraft and wet nebulizer), parenteral IV, parenteral subcutaneous injection (SC), and orally (PO). In general, inhaled medications have a faster onset, greater potency and less side effects.

Bronchodilators Used in Asthma

A. Beta-2 Agonists:
   - albuterol (Ventolin, Proventil, also called salbutamol outside the USA) - MDI, Neb, PO
   - L-albuterol (Xopenex - active isomer only) - Neb
   - terbutaline - MDI, Neb, PO, SC
   - formoterol (Foradil - very long acting) - DPI
   - salmeterol (Serevent - used for maintenance therapy) - DPI, MDI
   - epinephrine (alpha and beta) - MDI, Neb, SC

B. Anticholinergics
   - ipratropium bromide (Atrovent) -MDI, Neb
   - oxitropium bromide (Oxivent) - MDI
   - atropine -Neb

C. Methylxanthines
   - aminophylline - PO, IV
   - theophylline - PO, IV
   - oxtriphylline - PO

Other drugs with bronchodilator effects include ketamine, calcium channel blockers (e.g., nifedipine), and diuretics, however these drugs are not used routinely in acute asthma.

Anti-Inflammatory Drugs

Based on the biphasic mechanism, an anti-inflammatory drug (i.e., corticosteroids) is necessary for the complete treatment of asthma. Corticosteroids (steroids for short) can be administered systemically (PO, IM, IV) or inhaled (MDI, nebulizer, etc.). For asthma of a chronic nature, such as allergic asthma to house dust, a daily regimen of a long acting bronchodilator coupled with a steroid by inhalation would be effective. Steroids take hours to become engaged in its active phase. Their action does not take place directly on the inflammatory tissue but by modulating DNA production of pro-inflammatory cytokines. Their effects are very broad and nonspecific. Steroids affect virtually every phase of the inflammatory process. They have an array of impressive and undesirable side-effects, which cause hesitation in their use by physicians as well as patients. As in the use of any medication or therapeutic agent, the employment of steroids is subject to weighing the desired effects against the undesirable effects (benefit vs. risk). If the positive effects of using steroids have an overwhelming advantage over not using the drug, then it is justified to be used on a regular basis. This especially applies to children where growth suppression (in the order of 0.5 to 1.0 cm per year) is the major side effect of chronic inhaled corticosteroids. Catch-up growth occurs in most instances, if the child's condition improves to the point at which inhaled corticosteroids are no longer

needed. Many patients require more medications during the fall/winter/spring, and fewer medications during the summer. Occasional bursts of systemic corticosteroids have no significant long term side effects, but chronic or long term use of systemic steroids have major side effects (refer to the chapter on corticosteroids).

Corticosteroids used in Asthma
- beclomethasone (Beclovent, Vanceril) - inhaled
- triamcinolone (Azmacort) - inhaled, IM
- budesonide (Pulmicort) - inhaled
- fluticasone (Flovent) - inhaled
- flunisolide (AeroBid) - inhaled
- mometasone (Asmanex) - inhaled
- prednisone - PO
- prednisolone (Pediapred, Prelone, Orapred) - PO
- methylprednisolone (Medrol, Solumedrol) - PO, IV
- dexamethasone (Decadron) - PO, IV

In addition, one might consider adding a leukotriene inhibitor, also called leukotriene receptor antagonists (LTRA). These leukotriene inhibitors were developed to counteract the all important late phase inflammatory reaction caused by SRS-A (slow reacting substance of anaphylaxis), a compound which was eventually identified as leukotrienes. Their side effects are minimal. These are all given orally.

Leukotriene receptor antagonists (LTRA)
- montelukast* (Singulair)
- zafirlukast* (Accolate)
- pranlukast
- zileuton (Zyflo)

*(Some sources spell the suffix as "leukast" instead of "lukast". Roche and Astra Zeneca spell it as "lukast".)

Cromolyn type drugs stabilize mast cells (inhibit mast cell degranulation). They have less potent anti-inflammatory properties, but they have minimal side effects. Cromolyn (Intal) is available via nebulizer and MDI. Nedocromil (Tilade) is available via MDI.

Goals of Asthma Treatment
1. Prevent chronic and troublesome symptoms (e.g., cough or breathlessness in the night, in the early morning, or after exertion).
2. Maintain (near) "normal" pulmonary function.
3. Maintain normal activity levels (including exercise and other physical activity).
4. Prevent recurrent exacerbations of asthma and minimize the need for emergency department visits or hospitalizations.
5. Provide optimal pharmacotherapy with minimal or no adverse effects.
6. Meet patients' and families' expectations of and satisfaction with asthma care.

Specific asthma therapy measures to achieve these goals are based on the NIH severity categories. Step 1 (mild intermittent) requires no daily medications. ALL of the other categories (i.e., any category with the word "persistent"), requires a chronic controller anti-inflammatory medication.

Step 2 (mild persistent) recommends a low dose inhaled corticosteroid. Alternatively, a cromolyn medication or a leukotriene receptor antagonist may be used. Theophylline is another option, but only in children older than 5 years.

Step 3 (moderate persistent) recommends a low dose inhaled corticosteroid plus a long acting beta-2 agonist (salmeterol or formoterol). Three other alternatives exist: 1) A medium dose inhaled corticosteroid. 2) A low dose inhaled corticosteroid plus an LTRA. 3) A low dose inhaled corticosteroid plus theophylline.

Step 4 (severe persistent) recommends a high dose inhaled corticosteroid, plus a long acting beta-2 agonist.

In addition to the above chronic (long-term) recommendations, acute exacerbations are treated with quick relief (or rescue) medications, which is most commonly prn albuterol and optional short bursts of systemic corticosteroids. Albuterol can be given: 1) Orally at 0.1 mg/kg per dose every 6 to 8 hours. 2) Via nebulizer 2.5 mg unit dose every 4-6 hours. 3) Via metered dose inhaler (MDI) 2-4 puffs every 4-6 hours (however, most studies suggest that 5 to 10 puffs is more equivalent to the 2.5 mg nebulizer treatment).

Systemic corticosteroids are commonly administered as: 1) Oral prednisolone at 2 mg/kg/day given once daily or divided BID. 2) IV methylprednisolone 2 mg/kg, then 1 mg/kg every 6 hours. Systemic corticosteroids are usually given for 4 to 5 days and then discontinued if the patient improves. Systemic corticosteroids administered for longer than 7 days require a gradual taper of the medication. If the patient is on inhaled corticosteroids, these should be resumed once systemic corticosteroids are stopped or tapered. Some physicians continue inhaled corticosteroids during systemic corticosteroid bursts to avoid the confusion caused by modifying their chronic medications.

All patients should have a written asthma management plan that describes their chronic medications and a plan for the initiation of a rescue plan based on their symptoms and peak flow (if age >5 years). More detailed plans can include recommendations to step up or step down their chronic medications as their chronic symptoms worsen or improve.

If dyspnea still persists, despite rescue medications, then the asthma management plan should refer the patient to a source of immediate medical care (doctor's office during office hours, or emergency room after hours). Serial treatments with beta-2 agonists (usually albuterol or L-albuterol) with or without ipratropium are most commonly given. Inhaled beta-2 agonists can be given continuously for severely ill patients, or serially based on severity. Systemic corticosteroids can be started. Parenteral corticosteroids do not have an onset time advantage over oral corticosteroids; however, very ill children have a higher likelihood of vomiting oral prednisolone. Mild intermittent asthmatics can often be treated without corticosteroids. The decision to start systemic corticosteroids is based on their response to beta-2 agonists and their previous history which indicates their severity level. Those who do not respond well to beta-2 agonists should be started on systemic corticosteroids because, poor response indicates the presence of significant bronchial

inflammation Those who have required systemic corticosteroids in the past or who have other markers of more severe asthma should also be started on systemic corticosteroids.

Characteristics of good asthma control in children include: no coughing, no shortness of breath or rapid breathing, no wheezing or chest tightness, no waking up at night because of asthma symptoms, normal activities including play, sports, and exercise, no episodes of asthma that require a doctor visit, emergency room visit, or urgent care, no absences from school or activities, no missed time from work for the parent or caregiver, normal or near normal lung function, and a healthy self image (i.e., "nothing can stop me attitude").

Unfortunately, the death rate from asthma is not yielding to the introduction of many excellent and powerful treatments. This condition remains a challenge to the medical care team at all levels from physicians, nurses, emergency technicians, and respiratory therapists to psychiatrists and social workers. Family, school personnel, coaches, club leaders, and after hours activity supervisors, are all involved in delivering care to the asthmatic.

Risk factors for death from asthma include:

Past history of sudden severe exacerbations.
Prior intubation for asthma.
Prior admission to intensive care unit for asthma.
Greater than 2 hospitalizations for asthma in the past 12 months.
Greater than 3 emergency room visits for asthma in past 12 months.
Hospitalization or emergency care visit for asthma in the past month.
Use of more than 1 canister per month of inhaled short-acting beta 2 agonist.
Current chronic use of oral corticosteroids.
Difficulty perceiving airflow obstruction or its severity.
Low socioeconomic status and urban residence.
Illicit (illegal) drug use.
Serious psychosocial problems.

Acute signs of severe asthma and potential impending respiratory failure, warranting admission to an intensive care unit include: 1) Oxygen saturation less than 100% despite the administration of supplemental oxygen. 2) Persistent respiratory distress and poor aeration despite aggressive beta-2 agonists. 3) A pCO2 of 40 or greater on a blood gas. The treatment of severe status asthmaticus bordering on respiratory failure is controversial. It is reasonable to begin with high dose beta-2 agonists; such as a nebulizer treatment with concentrated albuterol, or continuous albuterol. In severe patients, aeration is poor, so inhaling albuterol by itself is usually insufficient. Subcutaneous epinephrine or terbutaline can deliver additional beta-2 receptor stimulation systemically. Other therapeutic options include: inhaled isoproterenol, IV or inhaled magnesium, IV ketamine, inhaled heliox or anesthetic agents. Such patients should be treated aggressively from the onset to prevent respiratory failure. If the patient fails to improve and respiratory failure ensues, positive pressure ventilation should be directed at maintaining oxygenation above 90% saturation if possible. Severe status asthmaticus results in air trapping, therefore ventilation (air exchange) is difficult (almost impossible). Although such patients have very high pCO2s because of air trapping and poor ventilation, the priority should focus on maintaining oxygenation. Attempting to normalize the pCO2 with aggressive positive pressure ventilation will increase the likelihood of a pneumothorax which will worsen the hypoxia. This strategy is known as "permissive hypercapnia" because hypercapnia is not as deadly as hypoxemia. Permissive hypercapnia is more likely to avoid a pneumothorax and thus, oxygenation is preserved, improving the overall outcome.

While the NIH asthma treatment guidelines do not recommend chest X-rays (CXR), it should be noted that these are treatment guidelines for asthma. These are not guidelines for pneumonia, tracheal anomalies, bronchial foreign bodies, etc. Thus, the CXR may be necessary in the process of evaluating some patients to be certain that the patient has asthma and NOT some other condition which can only be identified on CXR (i.e., to rule out other conditions).

Environmental measures to reduce asthma severity focuses on elimination of household smoking and the reduction of exposure to dust mite and cockroach microantigens in the environment. Wrapping mattresses with plastic casings, conversion of carpeted floors to tile floors, replacing drapes with blinds, and selecting home furnishings which avoid antigen accumulation, may result in improvement. Allergy testing and subsequent immunotherapy to desensitize a patient may be beneficial in some asthmatics.

In summary, asthma is a condition of multiple factors. It can be looked upon as a syndrome of multiple but related elements. It is basically a chronic condition with biphasic components which both result in airflow obstruction by different means. The treatment should take into account the various triggering factors, occupation, age, psychosocial, and economic factors.

Questions

1. How can you best describe asthma?
2. Can you describe the various medications to treat asthma?
3. Can you describe the parameters that are used to classify severity of asthma?
4. Describe clinical findings signifying the severity of an acute asthma exacerbation.
5. Discuss the approach to an asthmatic in relationship to formulating an acute asthma treatment plan. What questions do you ask, what physical findings do you look for, and what laboratory parameters are measured?
6. Formulate an asthma maintenance plan.
7. Describe various triggering factors and mechanisms by which they might exert their action.
8. Describe the immunologic chain of events that ultimately leads to bronchospasm and inflammation.
9. Discuss the pros and cons of corticosteroid use in children and compare them with use in adults.
10. How would you convince parents of asthmatics to use medications when their children are not openly symptomatic?

Answers to questions

1. Asthma is best thought of as a chronic inflammatory condition consisting of obstruction of the airways of the lung caused by spasms of the smooth muscle surrounding the airways which, in some cases, can be easily reversed by beta adrenergic bronchodilators. In other cases, corticosteroids may be necessary to reverse the airway obstruction by reducing the inflammatory changes responsible for the airway narrowing. These changes may be caused by a variety of different stimuli.

2. Medications are divided into groups directed towards relaxing bronchial smooth muscles (relievers) and reversing the inflammation (controllers).

3. This answer can be divided into two parts. The first is used to describe the degree of severity of the acute asthmatic episode. These would include rate and effort of respirations, ability to move air through a peak flow meter or spirometer, and oxygen and carbon dioxide concentration in the arterial blood. The second parameter involves the sensitivity of the airways (i.e., the chronic severity classification described in the chapter). Day symptoms, night coughing episodes, peak flow, coughing with exercise, prolonged coughing after upper respiratory infections, and coughing with drinking ice-cold beverages help to categorize the severity of asthma.

4. Wheezing may be heard but if the attack is very severe there may be no wheezing at all (due to poor air exchange). Aeration is a good indicator of acute severity. Evidence of respiratory distress (retractions, tachypnea) indicates increasing severity until respiratory failure occurs (at which point, the patient may tire and exhibit seemingly less respiratory distress). Hypoxemia is also indicative of severity. Peak flow is typically low for acute exacerbations. For mild cases, cough may be present at any phase of an asthmatic episode and may be the only sign that bronchospasm is occurring. A peak flow meter reading before and after a challenge of inhaled bronchodilator may reveal an increase in the airflow indicating the presence of bronchospasm.

5. Always consider the triggering event in formulating the treatment plan. Avoidance of the trigger can be very cost effective. Preventive use of medications can be very useful such as preemptive use of medication with first sign of a cold. Analysis of the symptom's response to initial treatment can guide you in up regulating or down regulating medications. Use of the peak flow meter can serve as an objective means of adjusting medications. If cough and wheezing occur often and there are signs/symptoms of chronic asthma, a maintenance plan of daily medication should be initiated. Efforts should be made to approximate the degree of inflammation in the airways. This estimation can serve to guide you in the type and dosage of anti-inflammatory medications to use. A contingency plan of what medications to use during an acute episode can be helpful and may help to avoid an unnecessary emergency visit to the hospital.

6. The asthma maintenance plans are dependent on the patient's severity class (step 1, 2, 3, or 4). For all "persistent" levels, a daily plan will usually involve a long-acting bronchodilator and corticosteroid, LTRA, cromolyn and/or theophylline two to three times a day. Regular monitoring with peak flow meter readings can help to determine if the treatment is helping to return the lungs to normal function. A "rescue" plan using short acting bronchodilators with optional systemic corticosteroids may be needed for breakthrough wheezing.

7. Allergen exposure is mediated through IgE with resultant immediate and late phase reactions. A variety of mediators are released and cause a cascade of immunologic events culminating in tissue edema, increased mucous production, and sloughing of the epithelial layer of the inner lining of the airways. This affects the free and easy movement of air to the alveoli, which affects air exchange and causes atelectasis as the smaller air ways are completely plugged by the thickened mucous.

8. Triggering mast cells cause release of mediators, which can cause immediate effects on the lung tissue and smooth muscles. Other mediators are formed and released later and serve primarily to attract inflammatory cells. Some of these late mediators help to capture the incoming cells. Other mediators recruit epithelial cells and transform then into participants of the reaction causing them to release more mediators (biologic amplification).

9. The critical issue of steroids in children is that of linear growth. It is now well established that the use of inhaled steroids has significantly less effect on growth than systemic corticosteroids. The length of steroid use (inhaled or systemic), may have some effect on growth but its effect is temporary and in many studies final growth of asthmatics is generally no different than in non asthmatics (i.e., catch up growth occurs if the corticosteroids can be stopped for a period of time long enough for this to occur). Chronic inflammatory suppression (long term use of inhaled corticosteroids) improves the long term outcome of asthma (i.e., less severity in the future).

10. This is where your ability to practice medicine is tested. You need to educate and persuade the parents that your recommendations are in the best interest of their child and that it is based on considering the risks against the benefits. This is ideally done without making the parents feel guilty or intimidated by the potential for fatal outcomes. While our goal may be to maintain the patient's lifestyle and lung function, patients may see their goal as getting off medications as soon as possible. For persistent asthmatics, they should be convinced that this is a chronic disease and long term medications will be required. Long term use of medications is generally very safe and not addictive.

Chapter VIII.3. Cystic Fibrosis
Wallace J. Matthews, Jr., MD

"The child who tastes salty will soon die" -- German folklore

An 8 month old child presents with a history of poor growth and a chronic cough. He was the product of a 21 year old Gravida 2 Para 1, Ab 0 mother and was born at 41 weeks of gestational age. Soon after birth, he developed respiratory distress and was admitted to the neonatal intensive care unit where he was mechanically ventilated for 1 day and discharged after 5 days. He was initially breast-fed, but due to frequent vomiting and loose bowel movements, he was changed to formula feeding. Despite trials of different types of formulas (soy, hypoallergenic, etc.), his clinical course was remarkable for bloating, diarrhea and failure to thrive. He developed a daily cough and some respiratory difficulty. At the age of 5 months he was hospitalized for respiratory distress and was diagnosed as having asthma. He continued to have loose, large, greasy, foul-smelling stools and failure to thrive. An iontophoresis of pilocarpine sweat test is now being obtained.

Family history: Mother (age 21), racially mixed Japanese, Chinese, English and Irish. Father (age 23), racially mixed, Portuguese. Hawaiian and Chinese. He has a sister (age 2). All three family members are alive and well.

Exam: VS T. 37.0 C. P120, R45, BP 80/60, oxygen saturation 97% in room air, weight 6.7 kg (<5th percentile). He is alert and active in no distress. He is small for his age. HEENT exam is significant for bilateral otitis media and mild nasal congestion. Neck supple without adenopathy. Heart regular. Lungs with good aeration and mild wheezing and rales. Abdomen soft, non-tender, active bowel sounds. Color and perfusion are good.

Chest radiographs: Some hyperexpansion with increased peribronchial markings.

Laboratory Results: Sweat test: Weight 120 micrograms; 105 mmol/L (normal <60). Deep throat culture after coughing induced by respiratory therapy using a suction trap collection unit (specimen treated by laboratory as a sputum culture): Klebsiella pneumoniae. AST 44 H (normal 0-37), ALT 49 H, (normal l0-40), Alk Phos 324 (normal 104-345). Cystic fibrosis mutation analysis (genetic testing): Positive for one copy of Delta F508 and one copy of R1066C.

A series of events that took place during the very hot summer of 1938 in New York City led to the recognition of a new disease, cystic fibrosis. Dr. Dorothea Anderson (1) noted that a number of children presented to Columbia Hospital with severe dehydration, but without diarrhea or vomiting. Several of these children had been followed in the GI clinic for failure to thrive and greasy stools. Many also coughed. Thus began the recognition of cystic fibrosis of the pancreas (CF). By 1946, the genetic nature of this autosomal recessive disease was described. In 1953, Dr. Paul di Sant'Agnese recognized that CF patients lost excessive salt in their sweat (2), forming the basis for use of the sweat chloride test as a cornerstone of the diagnosis of this disease. The chloride values for patients with cystic fibrosis were elevated and a clear separation from normal volumes was found to exist. Similar elevations for sodium as well as potassium exist but there is greater overlap with the normal population. Historically, obtaining a sweat test involved bundling the child to induce sweating. Sometimes children were even placed near furnaces to make them sweat more profusely. This resulted in some deaths. Informed consent for testing was not obtained in those days. Currently, the iontophoresis of pilocarpine (a cholinergic agent) is used to induce sweating (3). This is a safer and standardized method of obtaining a sweat sample for the sweat chloride test. Some causes of a false positive sweat test include conditions associated with serum electrolyte abnormalities or conditions associated with abnormal skin and sweating. These include adrenal insufficiency, anorexia nervosa, atopic dermatitis, ectodermal dysplasia, fucosidosis, mucopolysaccharidosis type 1, and nephrogenic diabetes insipidus among others. A positive sweat test in association with pancreatic exocrine dysfunction (maldigestion as opposed to malabsorption) and lung disease is the diagnostic triad of CF.

Cystic fibrosis is said to be the most common, lethal inherited disease of white people. Cystic fibrosis occurs in 1:2,500 whites in North America, 1:8,000 Latinos (4), 1:17,000 African-Americans (5) and 1:32,000 Asian-Americans (6). Since the life expectancy of patients with CF has increased to more than 30 years, some have called it a semi-lethal disease. A better term would be a disease associated with a dramatically decreased life expectancy.

The CF mutation (7) has been localized to chromosome 7, band q31 (8). This locus codes for a transport protein named the cystic fibrosis transmembrane conductance regulator (CFTR) (9). More than 800 mutations are now known. The Caucasian associated delta F508 defect is the most common mutation found. The R1066C identified in this child is one of the rarer CF genes. It is found in people of Portuguese decent. The CFTR protein functions as a chloride channel regulated by a cAMP dependent protein kinase phosphorylation. The genetic variations and molecular implications are becoming clearer (10). The clinical features associated with cystic fibrosis are listed in the table below:

Phenotypic Features Consistent With The Diagnosis of Cystic Fibrosis (11)

1. Chronic sinopulmonary disease manifested by:
   a. Persistent colonization/infection with typical CF pathogens including: Staphylococcus aureus, non-typable Haemophilus influenza, Pseudomonas aeruginosa, mucoid and non-mucoid, Burkholderia cepacia, E. coli mucoid type (12), other gram negative organisms.
   b. Chronic cough and sputum production.
   c. Persistent chest radiograph abnormalities (e.g. bronchiectasis, atelectasis, infiltrates, hyperinflation, peribronchial cuffing).
   d. Airway obstruction manifested by wheezing and air trapping.
   e. Nasal polyps: radiograph or CT abnormalities of the paranasal sinuses.
   f. Digital clubbing.
2. Gastrointestinal and nutritional abnormalities including
   a. Intestinal: meconium ileus, distal intestinal obstruction syndrome, rectal prolapse.
   b. Pancreatic: pancreatic insufficiency; recurrent pancreatitis, diabetes mellitus.
   c. Hepatic: chronic hepatic disease manifested by clinical, biochemical or histologic evidence of focal biliary cirrhosis or multilobar cirrhosis.
   d. Nutritional: failure to thrive (protein-calorie malnutrition), hypoproteinemia and edema; complications secondary to fat soluble vitamin deficiency.

3. Salt loss syndromes (acute salt depletion; hypochloremic metabolic alkalosis).
4. Male urogenital abnormalities resulting in obstructive azoospermia.

In a review of cystic fibrosis patients, the frequency of presenting signs and symptoms were: acute and persistent respiratory illnesses (51%), failure to thrive or malnutrition (43%), abnormal stool or steatorrhea (35%), meconium ileus or intestinal obstruction (19%), family history of CF (17%), electrolyte imbalance (5%), rectal prolapse (3%), nasal polyps/sinus disease (2%), hepatobiliary disease (1%), and prenatal diagnosis by chorionic villus sampling or amniocentesis (1%) (13). Almost all male CF male patients have azoospermia due to occlusion of the tubules in the testes. Adult men have been diagnosed with cystic fibrosis after being evaluated for infertility (no sperm found in their semen sample).

Gastrointestinal complications are the most obvious early presenting symptoms. Approximately 19% of babies with CF present with meconium ileus, an intestinal occlusion in neonates which results from thick, viscid meconium obstructing the small bowel. This frequently results in a distal microcolon that requires surgical intervention. Others present with rectal prolapse in association with failure to thrive. As in the case presented above, fat maldigestion, steatorrhea and failure to thrive are presenting features. Some degree of pancreatic enzyme deficiency is found in 80-90% of CF patients. It is important to note that 10-20% of CF patients do not have this component of the disease and its absence does not preclude the diagnosis of CF. Pancreatic replacement enzymes, dietary regulation and the replacement of the fat-soluble vitamins (ADEK) play a major role in treating these GI complications. Since better enzymatic preparations are now available, fat restrictive diets are rarely needed. Once this therapy begins, patients grow rapidly, with catch up growth and normal subsequent growth percentiles. Further growth failure is usually related to pulmonary disease and its complications, listed below. Hepatic involvement is usually limited to hepatic enzyme elevations as was seen in our case. This can progress over time to frank hepatic disease and cirrhosis. Blood flow can be diverted from the liver which results in esophageal varices which can present with bloody vomiting (hematemesis).

As CF patients get older, pancreatic complications include pancreatitis as well as the insulin deficient form of diabetes mellitus. This diabetes mellitus is rarely associated with ketoacidosis. In spite of this, insulin therapy is required to treat the caloric losses associated with this complication.

It soon becomes apparent, however, that the pulmonary aspects of this disease are the major, life-limiting process. It progresses from a bronchiolitic process with chronic bacterial colonization of the airway, to bronchiectasis and obstructive pulmonary disease. In infancy, the organisms are most frequently Staphylococcus aureus, non-typable Haemophilus influenza, and other gram negative organisms (14). These are often replaced by Pseudomonas aeruginosa (both mucoid and non-mucoid colony type). Once established in the airways, mucoid pseudomonas is almost impossible to eradicate. There seems to be a local environment in the CF airways that promotes the growth of pseudomonas. Whether this is due to the abnormally viscid mucus or the local calcium or chloride concentrations is uncertain. Colonization, which may not actually mean infection, with pseudomonas (mucoid colony type) leads to a state of chronic airway inflammation. This has been labeled frustrated phagocytosis. The inflammatory process directed against the pathologic organisms is incapable of eradicating the organisms and causes nonspecific damage to the airways that are "innocent" bystanders. Over time, this results in irreversible airway damage. This hyperimmune process is now known to be a major factor in the progressive lung disease that characterizes CF. Indeed, early studies showed that patients with hypogammaglobulinemia had less lung disease, fewer hospitalizations, and better oxygenation than those with normal or elevated levels of IgG (15). Indeed, those cystic fibrosis patients with the highest IgG levels had the worst prognosis and the shortest life expectancy (16). A study aimed at decreasing this hyperimmune process with prednisone therapy showed less progression of lung disease to controls (17). Unfortunately, the complications of steroid therapy were unacceptable. These include growth failure, development of cataracts and glucose intolerance. Further anti-inflammatory studies are underway.

The pulmonary disease is progressive, essentially unremitting and fatal. Therapy aimed at slowing this process includes mechanical mobilization of the thick secretions by chest physical therapy and postural drainage. This can be done by hand, mechanical percussors or by a vest percussion device. The use of nebulized rhDNase (Pulmozyme) (18) has been effective in decreasing the viscosity of CF mucus by aiding in the removal of the excessive DNA from the inflammatory cells destroyed in the airways. All of this is aimed at mobilizing secretions and encouraging expectoration.

Sputum cultures are used to define the organisms present. It is important to remember, however, that Staphylococcus aureus is frequently present in concentrations 100 to 1000 times less than that of the pseudomonas (19), such that Staph aureus is frequently undetected in routine (qualitative) sputum cultures. Quantitative culture, which would detect both organisms, remains a research tool unavailable to most clinicians. This could explain why CF patients with pseudomonas positive sputum cultures, improve on anti-staphylococcal antibiotics even after determining pseudomonas resistance to these antibiotics (20). In spite of this, antibiotic therapy aimed at specific organisms is a mainstay of therapy. Oral antibiotics are used when possible but hospitalization and intravenous antibiotics are frequently required. The timing of such intensive therapy in this chronic disease is best governed by symptoms as well as by objective pulmonary function data. Bacterial sensitivities are used to help select the best antibacterial agents. Usually, two antibiotics are used, an aminoglycoside and a anti-pseudomonal penicillin. Trials of single agents such as anti-pseudomonas cephalosporins (e.g. ceftazidime) continue. The aim is minimization of the yearly decrement in pulmonary function tests associated with the pulmonary deterioration. Nebulized therapy has offered an additional route for delivery of antibiotics (21). Twice daily aerosolized tobramycin (Tobi) has been used in a 28 day on, 28 day off pattern.

In spite of the large number of organisms present in the airways and sputum, CF patients rarely become septic and blood cultures are not helpful. It is an airway colonization process and not a pneumonic one.

One specific organism is known to be particularly worrisome. The acquisition Burkholderia cepacia is associated with rapid deterioration in pulmonary status and earlier death (22).

Other pulmonary complications include allergic bronchopulmonary aspergillosis (ABPA) (23) (another disease with airway colonization rather than tissue invasion), which requires corticosteroid treatment. Antifungal agents are not needed. Sinusitis is universally present in CF patients (24). Bronchospasm symptoms are treated with the usual medications outlined under asthma therapy. Pneumothoraces occur later in the disease and usually require chest tube drainage. Sclerosing agents, although effective in terminating persistent pneumothoraces (25), are relatively contraindicated since it may preclude lung transplantation (26). Hemoptysis is treated expectantly. Bronchial artery embolization has proven to be effective but has significant risks (27). Cor pulmonale is treated with oxygen therapy, diuretics and digoxin. Its presence is a sign of severe pulmonary disease and a poor prognosis sign (28).

Questions

1. The percentage of CF patients with pancreatic exocrine dysfunction (decreased lipase, amylase, etc.) is:
    a. 10%
    b. 25%
    c. 50%
    d. 85%

2. The carrier rate for the CF gene in the white population is:
    a. 1 in 10
    b. 1 in 15
    c. 1 in 25
    d. 1 in 50

3. The frequency of cystic fibrosis is:
    a. whites>blacks>latinos>asians
    b. whites>latinos>blacks>asians
    c. whites>asians>latinos>blacks
    d. latinos>whites>blacks>asians

4. An abnormal sweat test is:
    a. diagnostic of cystic fibrosis
    b. supportive of the diagnosis of cystic fibrosis
    c. has been replaced by genetic testing
    d. an abnormal sodium value

5. The most common CF gene is:
    a. R1066C
    b. Delta F508
    c. Not detected by genetic screening
    d. Present in less than 40% of patients

6. The percentage of CF patients with sinus opacification and/or infection is:
    a. 10%
    b. 25%
    c. 50%
    d. 75%
    e. 95%

7. What percentage of CF male patients have azoospermia
    a. 10%
    b. 25%
    c. 50%
    d. 75%
    e. 95%

8. The CFTR gene is located on chromosome:
    a. 5
    b. 7
    c. 9
    d. 11
    e. 13

9. The life expectancy of newly diagnosed patients with cystic fibrosis is:
    a. 5 years
    b. 10 years
    c. 15 years
    d. 20 years
    e. 30 years

10. Organisms characteristically isolated from the sputum of patients with cystic fibrosis includes all the following except:
    a. Staphylococcus aureus
    b. Streptococcus pneumoniae
    c. Klebsiella pneumoniae
    d. Pseudomonas aeruginosa
    e. Burkholderia cepacia

Chapter VIII.4. Chronic Lung Disease of Infancy (Bronchopulmonary Dysplasia)

Mary Elaine Patrinos, MD

This 3 month old, former 26 week gestation male, presents to his pediatrician's office with a 2 day history of cough and fever. He was stable until 3 days ago when he had an episode of emesis followed by choking. His parents witnessed the episode, patted him on the back, and increased his oxygen flow rate from 1/4 to 1/2 liter/min due to cyanosis during and after the event. His temperature peaked at 39.6 degrees C (103.4 F) today. There has been no diarrhea or rhinorrhea. Oxygen saturation readings (SpO2) at home have been in the mid 90s. His diet consists of BPD formula, thickened with rice cereal. He has a decreased appetite. He continues to have 1-2 episodes of emesis per day.

PMH is remarkable for delivery at 26 weeks gestation. His neonatal course was characterized by respiratory distress syndrome (RDS) treated with surfactant, a patent ductus arteriosus (PDA) requiring ligation at 5 days of age, coagulase negative staphylococcus bacteremia, and retinopathy of prematurity (ROP). He required mechanical ventilation for almost 5 weeks and was successfully extubated after a brief course of systemic corticosteroids. He was also diagnosed with gastroesophageal reflux (GER). He was discharged from the hospital 3 weeks ago at 36 weeks postconceptional age (PCA). His medications include: Albuterol aerosols 1.25 mg TID, furosemide 3 mg PO QD.

Exam: VS T 39.2, P 175, RR 73, BP 96/58, SpO2 94% on 1/2 liter/min O2 by nasal cannula. He is a pink, slightly pale infant in moderate respiratory distress with an intermittent cough. The remainder of his exam is remarkable for moderate subcostal, intercostal, and substernal retractions. Breath sounds demonstrate fair aeration throughout, but they are decreased in the right upper lung field. Diffuse, soft wheezing is heard bilaterally.

A chest x-ray shows bilateral interstitial infiltrates, flattened diaphragms, and consolidation of the right upper lobe.

Chronic lung disease (CLD) is a disorder that originates in the neonatal intensive care unit, but regularly presents in the outpatient arena. Therefore, knowledge of the clinical presentation, pathophysiology, management, and outcome of bronchopulmonary dysplasia (BPD) is equally essential to the intensivist as it is to the primary care physician. The case above underscores many of the common features of the infant with chronic lung disease or bronchopulmonary dysplasia. As discussed in detail below, BPD is a chronic illness that is seen primarily in preterm infants. Additional risk factors noted in this patient are biochemical immaturity (surfactant deficiency), patent ductus arteriosus, mechanical ventilation, and oxygen therapy (Table 1) (1). BPD is a serious and potentially life threatening disorder. Originally described in 1967 by Northway, a radiologist, radiographic findings remain a major feature of the diagnosis and staging of the disease process. The definition of chronic lung disease has changed over the years. The older definition describes infants who remain oxygen dependent at 28 days of age or more (typically following a course of mechanical ventilation) and with abnormal radiographic findings. The more recent definition uses oxygen dependency at 36 weeks postconceptional age (PCA) as opposed to 28 days postnatal age (age since birth) to identify infants with BPD. This change in definition reflects a change in the patient population that has occurred over the last 20 years with an increase in the survival of extremely low birth weight infants (ELBW, <1000 g). The need for respiratory support is common in ELBW infants at 28 days of age, often due to respiratory insufficiency/immature respiratory mechanics and not lung injury (BPD) per se.

Table 1. Major Risk Factors Associated with BPD
Prematurity (anatomical and biochemical lung immaturity; antioxidant insufficiency)
Genetic predisposition
Fluid overload
Patent ductus arteriosus
Lung infection/inflammation
Air leak
Mechanical ventilation (barotrauma, volutrauma)
Oxygen
Malnutrition

The incidence of BPD increases with decreasing birth weight and gestational age such that approximately 15% of infants <1500 grams (g) and 50% of infants <1000 g are diagnosed with the disorder (1). The pathophysiology is based on the developing lung's vulnerability to various forms of injury. With the understanding that it is not "normal" for a 26 week gestation fetus to be outside of a fluid filled intrauterine environment, it is easy to appreciate how endotracheal intubation and mechanical ventilation can "do harm". This is, indeed, the neonatologist's major dilemma; providing support to an infant with immature respiratory physiology while minimizing iatrogenic injury. All aspects of patient care, nutrition, fluid administration, respiratory, infectious disease, etc., must be meticulously managed to curb the incidence and severity of chronic lung disease. Early in the disease process there is injury, inflammation, and capillary leak. Ongoing inflammation leads to fibroblast proliferation and scarring. Barotrauma or volutrauma causes airway epithelial and alveolar necrosis. If continued unchecked, the final outcome is a chronic pulmonary condition with features that include increased airway resistance and reactivity, mucous production, cystic emphysema, scarring, and atelectasis.

The clinical manifestations of chronic lung disease also evolve over time. In the early stages, tachypnea, retractions, cyanosis, and occasional grunting are seen. Later, reactive airway disease associated with wheezing and hypercarbia develops. Coexisting conditions such as feeding difficulties, poor growth, and gastroesophageal reflux (GER) may further complicate the clinical picture making these infants uniquely challenging and often frustrating to manage.

Prevention strategies are by far the most effective and satisfying in decreasing the incidence and reducing the severity of chronic lung disease. It is reasonable, based on the pathophysiology of BPD, that one approach might be to reduce an infant's exposure to mechanical ventilation and oxygen. Nasal continuous positive airway pressure (NCPAP) has been increasingly used to provide non-invasive respiratory support in the preterm infant. In addition, non-invasive means of monitoring oxygenation through the use of pulse oximetry allows for titration and reduction of supplemental oxygen to meet the infant's needs. Permissive hypercapnia, accepting higher levels of CO2, is also employed to reduce (wean or discontinue) ventilator support. Other approaches to prevention are listed in Table 2 (2), the most recent of which has been vitamin A supplementation. Vitamin A, necessary for epithelial integrity and healing, is often

deficient in preterm infants, (as are other cofactors, antioxidants, minerals, and trace elements). Recent studies have shown that vitamin A supplementation is beneficial in ameliorating the development and progression of chronic lung disease (3).

Table 2. Prevention Strategies for BPD
Antenatal corticosteroids
Surfactant
Postnatal steroids
Vitamin A
Permissive hypercapnia
Alternative ventilation strategies (synchronized, high frequency)
Fluid restriction
Balanced nutritional support

Various therapies have been developed to reduce symptom severity in the infant with BPD (Table 3). It is, indeed, the infant's good fortune that time is on his/her side! Because lung growth and development continues throughout infancy and early childhood, this is a disease process that the patient literally (completely or partially) outgrows. The goals of effective supportive therapy are to achieve adequate nutrition and growth while limiting episodes of disease exacerbation. It is, therefore, easy to understand why nutritional support serves as the mainstay of treatment. Caloric requirements for these infants sometimes exceed 140-150 kcals/kg/day. Increased metabolic demands coupled with feeding problems and GER, make this an especially challenging aspect of care. Parents share in the frustration of providing these infants with enough calories to grow and often suffer feelings of guilt in the process. Special formulas have been developed to increase caloric density (and intake), provide a proper balance of carbohydrate, protein, and fat, and limit free water. Preterm infant formulas (already 24 kcals/oz) are commonly used as the "base" which is further supplemented with protein, polycose (carbohydrate) and medium chain triglyceride (MCT) oil or vegetable oil to provide 30 kcals/oz. Indwelling nasogastric feeding tubes, and in some cases, gastrostomy tubes, are placed to provide enteral calories in infants with varying degrees of feeding difficulties. Close monitoring of an infant's growth is critical and, like all children, growth charts should be meticulously kept.

Table 3. BPD Treatment Strategies
Nutrition
Diuretics
Corticosteroids
Bronchodilators
Sodium cromolyn
Immunization (specifically, against RSV, respiratory syncytial virus)
Respiratory support (oxygen, CPAP, mechanical ventilation)

Diuretic therapy is common in the treatment of chronic lung disease of infancy. The rationale for diuretic use early in the disease process is to treat the pulmonary edema that accompanies inflammation and capillary leak. Later in the course, the lungs of BPD patients remain hydrophilic due to impaired lymphatic drainage from distorted architecture and decreased plasma oncotic pressure related to malnutrition and/or fluid overload (1). Cor pulmonale (right ventricular hypertrophy secondary to pulmonary hypertension), an end stage complication of severe BPD, also responds to diuretic therapy. Furosemide is the first line and most popular diuretic due to its additional benefits of venodilation and diminished airway reactivity. However, because of the multiple untoward side effects of furosemide, chlorothiazide (with or without spironolactone) is frequently used in "maintenance" therapy. Careful monitoring of electrolytes is essential with diuretic use. Bronchodilators are widely used to treat the reactive airway component of BPD. Inhaled agents include albuterol and ipratropium bromide. Rarely, in the most severe cases, theophylline may be employed as an adjunct to inhaled agents. Wheezing and CO2 retention are two of the major clinical manifestations of reactive airway disease. It is often beneficial to auscultate the chest before and several minutes following an inhalation treatment to determine its clinical efficacy. Confirming therapeutic benefit in the individual patient is important for determining ongoing management. Airway disease in these infants may sometimes be unresponsive to bronchodilator therapy.

The most controversial, but most effective short term treatment for CLD is dexamethasone. Clinical trials of dexamethasone treatment began in the early to mid 80s (4,5). The anti-inflammatory and pro-surfactant properties of corticosteroids made them a logical focus of study. These and subsequent studies have repeatedly demonstrated the positive short term benefits of corticosteroids as manifested by dramatic weaning of ventilator and oxygen support. As with many clinical trials, dosing amount, frequency, and treatment duration varied widely among studies. Adverse side effects, including hyperglycemia and hypertension, have also been documented. Subsequent trials of early dexamethasone use (within the 1st week of life) have shown greater risk than benefit (6,7). Therefore, if dexamethasone therapy is being considered, its use should be reserved for those patients with established chronic lung disease or prolonged ventilator dependency, typically older than 1 week of age (8,9). Of great concern is evidence suggesting that dexamethasone treatment is associated with an increase in developmental disability and cerebral palsy. It is the knowledge of the many serious side effects associated with systemic dexamethasone that has prompted clinicians and investigators to consider the use of hydrocortisone and inhaled corticosteroids in the prevention and treatment of chronic lung disease. Inhaled corticosteroids have been used in the treatment of adult and childhood asthma for many years. Limited studies in neonates have demonstrated no significant benefit beyond a reduction in the need for systemic steroid therapy (10). Logistical issues surrounding dosing and drug delivery in infants has further complicated this matter. Inhaled steroids are safer, but not without serious systemic side effects, especially at higher doses. Further information is needed before inhaled steroids become incorporated into the routine treatment of CLD.

The prognosis for BPD is largely dependent on its severity and the coexistence of other morbidities of prematurity (intraventricular hemorrhage/periventricular leukomalacia, short bowel syndrome, GER, and failure to thrive). As mentioned above, most infants outgrow their disease at varying rates. Despite the lack of clinical symptomatology in older children and adolescents, abnormalities often persist on pulmonary function testing. Less than 1% of ventilated preterm infants remain ventilator dependent for months or years. Aggressive measures to prevent and treat acute (respiratory) infections (hand washing, immunization, prompt use of antibiotics) must be instituted for an optimal outcome. Outside of the concerns regarding dexamethasone, it has long been recognized that infants with CLD are at high risk for neurodevelopmental delay and cerebral palsy which may occur in up to 28% of the time (1).

Infants with BPD are at risk for serious infections when they encounter respiratory viruses. A good example is respiratory syncytial virus (RSV), which typically presents as an upper respiratory infection in older children and adults and bronchiolitis in healthy infants. However, in infants with BPD, RSV pneumonia often occurs, which may result in apnea and respiratory failure. Prophylaxis against RSV has been available for the last 5 years to reduce the severity of infection. Passive immunization is available in two forms, a monoclonal antibody (palivizumab) and RSV immune globulin (RSV-IGIV). Palivizumab is administered monthly to high risk infants as an IM injection during the peak of the RSV season (November thru March) (11).

In summary, BPD or chronic lung disease of infancy is a disorder with a multi-factorial etiology. The smallest preterm infants are at highest risk due to the anatomical and biochemical immaturity of their respiratory, antioxidant, and immune systems. Prevention is the key to dealing with this disorder, however, once BPD develops, nutritional, respiratory, and developmental supportive therapies are critical to the successful management of these patients. Research is ongoing to further characterize the pathogenesis and explore safer and more effective options for prevention and treatment.

Questions

1. True/False: BPD is a common condition affecting most preterm infants requiring mechanical ventilation.

2. All of the following factors are included in the pathogenesis of chronic lung disease except:
   a. infection
   b. antenatal corticosteroids
   c. oxygen toxicity
   d. patent ductus arteriosus

3. Chronic lung disease is defined as:
   a. ventilator dependency at 2 weeks of age
   b. oxygen dependency at 36 weeks postconceptional age
   c. oxygen dependency at 28 days postconceptional age
   d. oxygen dependency at 28 days postnatal age
   e. b and d

4. An effective prevention measure for BPD is:
   a. surfactant therapy
   b. vitamin A supplementation
   c. fluid management
   d. management of patent ductus arteriosus
   e. all of the above

5. For adequate growth, infants with chronic lung disease frequently require a caloric intake of:
   a. 80 kcals/kg/day
   b. 100 kcals/kg/day
   c. 120 kcals/kg/day
   d. 140 kcals/kg/day

6. True/False: Inhaled corticosteroids are as effective as systemic steroids in the treatment of BPD, but with reduced side effects.

Chapter VIII.5. Bronchiectasis in Children
Charles W. Callahan, DO

This is a 2-1/2 year old Polynesian male with a history of recurrent pneumonia who is now being hospitalized for symptoms of cough, wheezing and hypoxemia.

His past history is significant for dysmorphic features at birth which led to a diagnosis of a 5p chromosomal deletion consistent with Cri du Chat syndrome. He had difficulty in the neonatal period due to recurrent choking episodes and a presumed poorly coordinated swallow. He was initially discharged on oral feedings; however, he developed several episodes of pneumonia and reactive airway disease, for which he received treatment. At 15 months of age, an ambulatory evaluation for chronic aspiration was conducted because of recurrent wheezing. A modified barium swallow revealed mild dysfunction of the oral phase of swallowing with a delay in bolus transfer, especially evident with liquids. There was no pooling or aspiration noted. A nuclear scintiscan revealed eight episodes of gastroesophageal reflux (GER) to the hypopharynx, without evidence of aspiration. He was treated with cisapride and ranitidine. Despite this, he was hospitalized 4 more times for lower respiratory exacerbations. He is now being hospitalized for evaluation and treatment of an exacerbation consisting of coughing, wheezing and hypoxemia. A pediatric pulmonologist is consulted.

His family members are all healthy except for a family history of asthma.

Exam: T 37, P 97, R 40, BP 99/64, oxygen saturation 91% in room air. Weight 11 kg (<5%ile). He is alert in no acute distress but he is episodically tachypneic. Auscultation of his chest reveals heterophonous (small airway) and homophonous (large airway) wheezing with diffuse fine crackles. Examination of his upper and lower extremities reveals moderate digital clubbing. A chest radiograph shows bibasilar reticulonodular opacities that have been essentially unchanged for almost one year, with new right middle lobe disease.

A thin section, high-resolution computed tomography (HRCT) scan of his chest shows bibasilar thickened and dilated bronchi consistent with cylindrical bronchiectasis. CBC, electrolytes, UA, sweat chloride, ANA, immunoglobulins, alpha-one antitrypsin and fungal serology are all negative. Bronchoscopy with bronchoalveolar lavage reveals erythematous, friable airways with no obvious airway anomalies. Lavage revealed a cell count of 750 per microliter, of which 105 were red blood cells and the remainder white blood cells (70% neutrophils and 30% macrophages). Gram stain shows no organisms. Cultures are not definitive. Staining of the lavage fluid with oil red-O reveals numerous lipid-laden macrophages (a marker of chronic aspiration). A hemosiderin stain (evidence of chronic bleeding) is negative.

A nuclear scintiscan repeated on cisapride and ranitidine shows mid-esophageal GER. He is placed on cefuroxime for presumed bacterial bronchitis despite inconclusive cultures. More importantly, he is also started on nasogastric feeds and is not allowed to take anything by mouth. Within days, his pulmonary signs and symptoms improve markedly. He later undergoes a Nissen fundoplication with gastrostomy tube placement. After six months of gastrostomy feedings while remaining NPO, he is clinically improved, having gained weight and tolerated minor upper respiratory infections without hypoxemia. Seven months post-procedure, he has a follow up HRCT scan of his chest that shows near resolution of his bronchiectasis. His digital clubbing eventually resolves and a chest radiograph shows no suggestion of bronchiectasis.

Bronchiectasis is a chronic lung disease whose pathophysiology is poorly understood. It has traditionally been considered "permanent and irreversible" (1). Traction of airways from collapsed surrounding structures, bulging of the airways from retained secretions, weakening of the bronchial wall by infection or inflammation, or combinations of these factors are all suggested mechanisms (2). Single or repeated acute infections, chronic obstruction from congenital anomalies, tumors, cystic fibrosis, chronic asthma or immunodeficiencies may also predispose a patient to developing the disease (3). In addition, repeated airway injury from chronic aspiration, with or without gastroesophageal reflux (GER), has been implicated as another etiologic possibility (4,5).

Bronchiectasis has been termed an "orphan disease" which may not always be considered in the evaluation of children with obstructive pulmonary disease because it has become relatively uncommon in the antibiotic era (1,5). Fifty years ago, Field studied 160 children with bronchiectasis for almost 2 decades (6,7,8,9). In that period, she documented a fall in the annual hospitalization rate for bronchiectasis in five British hospitals (1952-1960) of approximately 48/10,000 to 10/10,000 (9). At our institution among children of American Military members, there have been 14 pediatric cases in the past 19 years including the present case, yielding an approximate rate of 0.2/10,000 (unpublished data).

The term "bronchiectasis" has traditionally implied permanent, irreversible alteration in the anatomy of the airways (1,10). It has been classified as cylindrical, varicose or saccular (1,10). The diagnosis should be considered in children with daily, productive cough of longer than 6 weeks duration, hemoptysis, children with persistent radiographic infiltrates, digital clubbing or isolated, persistent crackles on auscultation. (6,10). Traditionally, the diagnosis was made by bronchography (chest radiograph taken with inhaled contrast), as the plain chest radiograph is relatively insensitive for the detection of bronchiectasis (10). Most commonly today, the diagnosis is made by thin-section high resolution CT scan. The diagnosis is based upon the presence of an internal bronchial diameter greater than the adjacent pulmonary artery, lack of tapering of the bronchial lumina, and visualization of the bronchi within 1 cm of the pleura, although the use of the first of these criteria has been debated (11,12).

The combination of small airway obstruction coupled with chronic inflammation of the bronchial wall is most likely the mechanism in the development of bronchiectasis. The inflammation usually results from acute or chronic bacterial infection or "colonization" of the airways (7,10,13). The majority of cases of bronchiectasis follow severe pneumonia or other lower respiratory infection (10). In a series by Field fifty years ago, 24% of cases followed pneumonia, and 33% followed some combination of pertussis and/or measles infections (6).

Chronic aspiration, either from cricopharyngeal dyscoordination or gastroesophageal reflux, is a recognized condition that can lead to bronchiectasis in adults and children (5,10). It has probably emerged as a more common cause as antibiotics and vaccinations have diminished the other infectious etiologies. In addition, bronchiectasis has been shown to be more common in patients of Polynesian descent (13,14). A ciliary defect is thought to be the etiology but has not been consistently demonstrated (15). Bronchiectasis has also been reported with increased frequency in Native Alaskan children, although some theorize that the common thread is a low socioeconomic level (16,17).

Bronchiectasis, particularly the mildest of the pathologic forms, cylindrical bronchiectasis, may be reversible. When associated with pneumonia, it may resolve with treatment of the acute process (18). Resolution of post-obstructive bronchiectasis has even been reported after removal of a chronic foreign body (19). Some refer to this as "pseudobronchiectasis" (10).

Clubbing is reported in 37-51% of patients with bronchiectasis. In Field's series of 160 patients with bronchiectasis, clubbing was present in 78 cases (44%) (6). In many cases, the clubbing cleared after the affected section of the lung was removed surgically. In cases treated medically, occasionally the clubbing improved and in some cases it disappeared despite persistent bronchographic evidence of bronchiectasis (6). Of interest, Field concluded, "clubbing when present, usually signified irreversible bronchiectasis, providing there was no congenital cardiac lesion" (6).

In the same patient series, Field also described the condition of "reversible bronchiectasis," a temporary dilation of airways in areas of the lung that had been collapsed due to infection or atelectasis (7). She suggested that duration of cough and pulmonary symptoms was commonly of three months duration or less in children with reversible bronchiectasis and pulmonary collapse which reexpanded. In the same series, the majority of children with a history of symptoms for two years or more generally developed severe bronchiectasis (7).

The evaluation of a child with bronchiectasis should include an evaluation for any identifiable cause of the condition. Testing for cystic fibrosis with a sweat chloride test as well as genotype determination should be performed in select cases. Children in their first two decades do not usually develop lung disease from alpha-one protease inhibitor deficiency, but a level should be obtained. Other congenital conditions such as Mounier-Kuhn (congenital absence of airway muscle) and Williams-Campbell (congenital absence of airway cartilage) can usually be suspected from the radiograph and CT scan. Marfan's, Ehlers-Danlos, and the Yellow-Nail syndrome all have other phenotypic findings (5).

Post infectious causes of bronchiectasis are harder to prove. The child should have a PPD with anergy panel to assess for TB. Evaluation for allergic aspergillus or allergic fungal disease should be considered. Serum levels for pertussis, measles and adenovirus are probably not helpful in a child with bronchiectasis because of immunization and the possibility of previous, unrelated disease (5).

Basic aspects of the immune system should be evaluated including serum immunoglobulins and serum IgE. There are cases of bronchiectasis preceding other symptoms of rheumatic disease, sometimes by decades, so an anti-nuclear antibody and rheumatoid factor should be obtained. Finally, a thorough evaluation for gastroesophageal reflux should be undertaken including extended intraesophageal pH probe monitoring (5).

Children with bronchiectasis should be treated with antibiotics during symptom exacerbations based upon sputum culture results. Exacerbations should also be treated with increased frequency of the daily regimen of chest physiotherapy and postural drainage, usually conducted twice a day. Intense aerobic exercise is another, excellent means of pulmonary toilet. Bronchodilators are indicated where there is evidence of bronchial hyper-reactivity (8,9,10,13). There may also be a role for inhaled corticosteroids to modulate the host response and curb inflammatory damage to the lung (13). Therapy for an identified cause of bronchiectasis should be undertaken, including aggressive medical and perhaps even surgical therapy for gastroesophageal reflux.

When damage is severe and well localized, pulmonary segmental resection may be beneficial (8,9,10). However, Field demonstrated a gradual symptomatic improvement of children who did not have surgical therapy for bronchiectasis, even before the proliferation and availability of broad spectrum antimicrobials (9). Lewiston recommended that surgery be delayed unless symptomatically necessary, until the patient is 6-12 years, because of the possibility of clinical improvement (10).

Bronchiectasis has become an uncommon disease in the developed world, but it may often be unrecognized. It should be suspected in children with chronic respiratory symptoms, since it is often amenable to long-term medical management. Surgical therapy should be reserved for situations of recurrent pulmonary sepsis unresponsive to aggressive medical management.

Questions

1. True/False: Causes of bronchiectasis in childhood include cystic fibrosis, asthma and immunodeficiency.
2. True/False: Bronchiectasis has been traditionally classified as round, cylindrical or cavitating.
3. True/False: Most commonly today, bronchography is required for the diagnosis.
4. True/False: Chronic aspiration is a recognized cause of bronchiectasis in children.
5. True/False: Children of Polynesian descent are at no increased risk of bronchiectasis.
6. True/False: Therapy for bronchiectasis in children includes early surgical resection.

Chapter VIII.6. Foreign Body Aspiration
Edward W. Fong, MD

A mother brings her 14 month old son into the urgent care clinic with complaints of choking and gagging after eating potato chips 15-20 minutes ago at his grandmother's house. His mother is unsure if he had eaten anything else with the potato chips and does not think the child turned blue during the choking and gagging episode. He returned to his normal activity shortly after the episode occurred, but since then, he has had a few intermittent coughing spells. The patient has two older siblings who are still at the grandmother's house.

Exam: VS T 37.2, P 103, R 28, BP 98/55, O2 saturation 96% in RA, height/weight/head circumference are all 25-50%ile. He is walking around the exam room in no acute distress. He has a normal physical exam except for an occasional low-pitched, monophonic expiratory wheeze heard best over the sternal notch.

A CXR is obtained which appears normal. Since end exhalation films were unable to be obtained, decubitus films were performed. The right lateral decubitus film (right side down) shows air trapping on the right as evidenced by failure of the mediastinum to shift toward the dependent side. A pediatric surgery consult is obtained and they take the child to the OR for rigid bronchoscopy. They find a whole sunflower seed in the right main stem bronchus and remove it. The child is then hospitalized overnight for observation and chest physiotherapy (CPT) that is ordered for atelectasis seen on a post-op film. Upon arrival of the patient's grandmother to the hospital, further history elicited from her is significant for the older siblings eating sunflower seeds. The patient is discharged the next morning with follow up scheduled with his pediatrician in the next few days.

Foreign body aspiration is a very serious, often life-threatening, condition. According to the 1998 National Safety Council statistics for the United States, 3% of all unintentional deaths among children (<15 years old) were secondary to the inhalation/ingestion of food or objects (IOFO) (1). In fact, 5% of all IOFO deaths occur in this age group. IOFO is the 5th leading cause of death in the United States and Hawaii for all age groups (1). Of children younger than 15 years, toddlers seem to be the most vulnerable for foreign body aspiration (77% of deaths) (1). Some reasons for this are related to their developmental age such as: 1) exploration of their environment by putting objects into their mouths; 2) learning to walk and run; 3) inadequate dentition; 4) immature swallowing coordination; and 5) supervision by an older sibling. Baharloo, et al, found that 91% of foreign bodies aspirated by children (<8 years old) were organic in nature with peanuts accounting for 54% of that number (2). Meat (especially hot dogs) and other types of nuts are also frequently found on bronchoscopy. They also found that children, unlike adults, did not have a significant difference between the foreign body being found in the right or left bronchial tree (2). This may be explained by the fact that children have symmetric bronchial angles until about 15 years of age. At that time, the aortic knob has developed fully, causing the left mainstem bronchus to be displaced, which creates a more obtuse angle at the carina favoring the right mainstem for a foreign body (3).

There are three distinct clinical phases that occur after a foreign body is aspirated (4). The first phase occurs immediately following the incident. The patient will usually experience choking, gagging, coughing, wheezing, and/or stridor. There may also be an associated temporary cyanotic episode, usually perioral. The occurrence of death is very high during this first phase of aspiration. The second phase is the asymptomatic period that can last from minutes to months following the incident. The duration of this period depends on the location of the foreign body, the degree of airway obstruction, and the type of material aspirated. The ease with which the foreign body can change its location is also a factor in the duration of this period. The third clinical phase is the renewed symptomatic period. Airway inflammation or infection from the foreign body will cause symptoms of cough, wheezing, fever, sputum production, and occasionally, hemoptysis.

There are several conditions that could mimic an aspirated foreign body. Some of these illnesses are: asthma, croup, pneumonia, bronchitis, tracheomalacia, bronchomalacia, vocal cord dysfunction, or psychogenic cough (4).

The diagnosis and treatment of an aspirated foreign body depends on which clinical phase the patient has on presentation. History, as always, is the best determinant of how suspicious one should be of a potential aspiration. However, this is often complicated by the fact that the event may be unwitnessed, witnessed by a person not present for history taking, or witnessed by an older sibling who may have had a role in the aspiration and chooses not to say anything. On physical exam, the classic findings consist of cough, unilateral decreased breath sounds, and unilateral monophonic wheezing. Although 75% of patients have one or more of these findings, only 40% have all three (5). If stridor (inspiratory and/or expiratory), aphonia, or hoarseness is present, the foreign body is most likely in the larynx or cervical trachea. The usefulness of diagnostic imaging is variable. Since most foreign bodies are not radiopaque, one must rely on indirect findings suggestive of the presence of a foreign body such as: mediastinal shift, atelectasis, and hyperinflation. It has been reported that imaging studies have a sensitivity of 73% and a specificity of 45%, however, up to 20% of patients will have both negative history and radiographic evaluation (6).

For patients who present early, radiographic studies must look for evidence of air trapping. Some clinicians have been taught to look for asymmetry on an expiratory view. However, many foreign body aspirations involve both main stem bronchi or the foreign body is in the trachea. Thus, asymmetry is not seen in these instances. Identification of air trapping is the key. If the expiratory view looks the same as the inspiratory view, this implies bilateral air trapping. Asymmetry suggests unilateral air trapping. Expiratory views rely on timing, so these are sometimes deceiving (an "expiratory view" could have been really taken during inspiration). Decubitus views may be more reliable in this regard. In a lateral decubitus view, the mediastinum should shift downward toward the dependent side. Failure to see this implies air trapping on the dependent side. Thus, if a decubitus view looks the same as an upright inspiratory view, this suggests air trapping on the dependent side.

If the patient presents in the first clinical phase, the family and/or health care professional should be advised to follow the recommendations of the American Academy of Pediatrics and American Heart Association (7). Unless there is a complete airway obstruction, spontaneous coughing and respiration should be the only treatment encouraged. Blind finger sweeps should never be performed in infants or children since this may push the foreign body further downward into the airway. Infants with complete airway obstruction should have back blows and chest thrusts performed while children with complete airway obstruction should have abdominal thrusts performed in either the supine position or by the Heimlich maneuver. Once the patient is brought to the hospital, the patient will require rigid bronchoscopy for visualization of the airway and removal of the foreign body. Flexible bronchoscopy does not have a role in this situation because it is not the optimal tool for control of the foreign body or the safety of the patient during the removal procedure.

The other situation in which patients commonly seek medical attention is usually the third clinical phase. At this point in time, clinical suspicion based on the history, exam, and ancillary studies must be used to determine the appropriate course of action. Patients may present with signs and symptoms of pneumonia. In many such instances, a foreign body is not suspected and the foreign body remains untreated. Such patients return with "recurrent pneumonia" which is actually a pneumonia or atelectasis which has never resolved because the foreign body is still there.

If foreign body aspiration is suspected in this phase, the patient should undergo direct airway visualization by bronchoscopy (flexible or rigid). Even if the patient has expectorated a foreign body, direct visualization is recommended to ensure there are no additional foreign bodies present and to determine if there is any compromise of the airway from inflammation. Medical management (from expectant management to CPT with bronchodilator therapy) should not be done in this situation because the object could become dislodged causing a complete airway obstruction (4). However, once the foreign body is removed, CPT and bronchodilator therapy could help with complications such as atelectasis. If there is airway edema and/or inflammation present on direct visualization, a short course of oral corticosteroids may be useful. Unless there are signs or symptoms of an infection (tracheitis, pneumonia, etc.), antibiotics need not be used.

Complications arising from foreign body aspiration depend on the location and type of foreign body aspirated (organic vs. non-organic, sharp vs. dull), and the duration of time the foreign body remained in the airways. If the foreign body is successfully removed within 24 hours of the incident, the complication rate is very low. However, the longer the foreign body remains in the airways, the more likely inflammation and thus, complications will occur. Potential complications include: bronchial stenosis, bronchiectasis, lung abscess, tissue erosion/perforation, and pneumomediastinum or pneumothorax.

Questions

1. True/False: Foreign body aspiration is sufficiently uncommon that it need not be considered in a patient with a chronic cough.

2. Which radiographic imaging study would be the most helpful if a foreign body aspiration is suspected in a child (<3 y.o.)?
   a. PA
   b. Inhalation/Exhalation
   c. Lateral
   d. Decubitus

3. Describe the three clinical phases of foreign body aspiration.

4. What would be worse to aspirate: organic or non-organic material? Why?

5. True/False: Aspirated foreign bodies in children are more likely to be in the right main-stem bronchus than the left main-stem bronchus.

6. Why should a blind finger sweep never be done in a child with a foreign body aspiration?

7. What physical exam sign/symptom is most suggestive of foreign body aspiration?
   a. Fever
   b. Polyphonic wheezing
   c. Cough
   d. Stridor
   e. Monophonic wheezing

8. What physical exam sign/symptom is most worrisome in terms of degree of airway compromise?
   a. Fever
   b. Polyphonic wheezing
   c. Cough
   d. Stridor
   e. Monophonic wheezing

9. True/False: Nuts + Choking = Bronchoscopy

Answers to questions

1. False.
2. d.
3. First phase: Acute symptomatic period that immediately follows the incident. May see choking, gagging, coughing, and/or cyanosis. High risk of death. Second phase: Quiescent asymptomatic period. May last minutes to months depending on location, type, and ease of movement of the foreign body. Third phase: Renewed symptomatic period. May see wheezing, chronic cough, fever, hemoptysis. High risk of complication.
4. Organic material is worse to aspirate because it will cause a more intense inflammatory response, thereby increasing the risk for complications. Additionally, most organic material is non-radiopaque making it more difficult to visualize.
5. False. Right and left foreign bodies occur at roughly the same frequency.
6. A blind finger sweep may reposition the foreign body causing a complete airway obstruction.
7. d
8. d
9. True. Whenever a choking episode occurs while a young child is eating nuts, the risk of foreign body aspiration is high. Bronchoscopy should be highly considered here (9).

Chapter VIII.7. Pulmonary Hemosiderosis
Scott J. Sheets, DO

This is an 8 month old male referred to Pediatric Pulmonary Clinic with a chief complaint of chronic cough. The cough has been present for 7 weeks. Initially, it was attributed to a viral illness, but the viral cultures and screen for RSV were negative. The cough improved but did not clear with bronchodilators and an aggressive short course of oral corticosteroids which were instituted for suspected asthma. The symptoms had worsened again after the bronchodilator and steroid trial was discontinued. There is a low-grade fever but no evidence of a new upper respiratory infection. The chest radiographs performed by the patient's primary care physician shows worsening diffuse patchy consolidations with hyperexpansion. Review of systems reveals a slowing of growth from the 4 month routine well child visit to present. There is no family history of any respiratory disease, chronic or serious medical conditions.

Exam: VS T 37.0, P 140, R 50, BP 100/60, pulse oximetry showed oxygen saturations of 86% in room air. His weight is at the 5th percentile. He is thin, slightly pale, tachypneic with slightly labored breathing. HEENT exam is normal. His chest has symmetrical expansion. There are mild subcostal retractions, but no intercostal or supraclavicular retractions are seen. His heart is tachycardic but regular without murmurs. His breath sounds are coarse on inspiration and expiration throughout. The expiratory phase is slightly prolonged. There is good air exchange. His abdomen is soft, non-distended with normal bowel sounds and no hepatosplenomegaly.

Oxygen is started by mask and he is admitted to the hospital. Bronchodilators and antibiotics are initiated and corticosteroids are resumed. His oxygen saturation only improves slightly with supplemental oxygen. The arterial blood gas shows pH 7.35, pCO2 34, pO2 55 on 2 liters/minute of supplemental oxygen. His CBC shows a mild elevation of the white blood count, a normal platelet count, and an anemia with hematocrit of 26, a mean corpuscular volume of 76, and red cell distribution width of 15. His eosinophil count is modestly elevated. Iron studies show depleted iron stores. His chest radiograph still shows interstitial infiltrates.

His improvement over the next three days is gradual, and his chest radiograph still shows an interstitial pattern. Bronchoscopy is performed. The bronchoalveolar lavage demonstrates a large number of hemosiderin-laden macrophages. Cultures and lipid-laden macrophages are negative.

After further review of his history, he had been constipated on formula for the first few months of life, so he was switched to regular cow's milk and juice at 3 months of age. The serum IgG precipitins to cow's milk protein are strongly positive. The diagnosis of Pulmonary Hemosiderosis by Heiner's syndrome is made. All cow's milk and milk products are withheld. His clinical condition rapidly improves. His subsequent chest radiograph clears with only persisting streaky consolidations. After one week of corticosteroids, they are discontinued. He is continued on iron supplementation and his anemia slowly resolves. Growth also normalizes over the next 3 months.

Any bleeding from or into the lung will lead to hemosiderin deposits in the lung macrophages. Pulmonary Hemosiderosis (PH) is a term that should be reserved for chronic persistent or recurrent bleeding. It is a complex topic, covering a spectrum of different conditions and disease states. The clinical presentation and course is highly variable. Bleeding can be focal or diffuse. It can occur in the airways, alveoli or parenchyma. It can be from pulmonary (lower pressure) or bronchial circulation (higher pressure). It can be mild or life threatening. While there is no universal agreement in classification, it is useful to categorize PH as either primary or secondary (1-3). The following table categorizes the etiologies of Pulmonary Hemosiderosis in children from the standpoint of whether the lung insult is primary or secondary:

1. Primary Pulmonary Hemosiderosis (PPH)
   A. Idiopathic (IPH).
   B. Associated with certain molds or fungi (Stachybotrys atra) (4).
   C. Associated with cow's milk allergy (Heiner's syndrome) (5).
   D. Associated with antibody to basement membrane of lung (Wegener's granulomatosis) and kidney (Goodpasture's syndrome).
   E. Trauma including foreign body aspiration.
   F. Bronchiectasis and other chronic lung infections.
2. Secondary Pulmonary Hemosiderosis
   A. Pulmonary vascular disease including cardiac disease, pulmonary hypertension and arteriovenous malformations.
   B. Generalized systemic inflammatory disease.
   C. Generalized bleeding disorders, including purpuric syndromes and coagulopathies associated with sepsis.
   D. Ingestion of drugs or chemicals such as Trimellitic anhydride or D-Penicillamine.

The pathophysiology of pulmonary hemorrhage varies by the etiology. Bleeding can come from inherited or acquired weakness, inflammation or congestion of pulmonary blood vessels; immune reactions or antigen-antibody complex deposition in the lung; invasive or chronic infections, or toxic reactions. Regardless of the, any blood cells in the alveoli, airways or parenchyma, are broken down and the hemoglobin is ingested by local macrophages. Once ingested, the hemoglobin is converted to hemosiderin by lysosomal degradation. It may also activate the local macrophages, followed by an inflammatory cascade, including the recruitment of cells and production of cytokines. These events can produce all types of lung disease, pulmonary consolidations, and lymphadenopathy.

Obstructive disease can be seen as the airways narrow with an increase in edema, mucus production and shedding of epithelial cells into the airway. Bronchospasm (the contraction of smooth muscle surrounding the airways) can be seen. Chronic accumulation of fibrin and collagen deposits can lead to pulmonary fibrosis with decreased pulmonary compliance. This can manifest as a restrictive lung disease pattern.

Pulmonary hemosiderosis is an uncommon finding, but the true incidence is unknown. Primary PH is more common in children. The peak incidence of IPH (idiopathic) is between 1-7 years of age at diagnosis, but approximately 15% are diagnosed after 16 years of age. Below the age of 10, the incidence is equally divided between the sexes. After age 10, the male to female ratio is 2:1 (7). There are rare instances of familial clusters reported. In adults, PH is more likely to be secondary in nature.

The classic triad of findings includes pulmonary infiltrates, iron deficiency anemia and hemoptysis (although hemoptysis is seen less commonly in children). Approximately 50% of young children present without pulmonary complaints. When present, complaints include fever, pallor, dyspnea, cough, exercise intolerance and growth failure. Common findings are, tachypnea, tachycardia, cyanosis, clubbing, fine or coarse crackles, wheezing, and hypoxemia. In children with a significant hemorrhage, it may be difficult to determine

whether the blood is coming from the upper airway, lower pulmonary system or GI tract. Many patients will have melena from swallowed pulmonary blood.

The radiographic appearance may vary depending on the degree of involvement and chronicity. Plain film chest radiographs may range from normal to demonstrating focal lymphadenopathy or consolidations, or extensive bilateral interstitial disease. Pulmonary function testing may demonstrate an obstructive, restrictive or mixed pattern.

It is common for patients with PH to have a delay in diagnosis. Infectious pneumonia, bronchitis, aspiration, asthma and cystic fibrosis are more commonly seen with many of the same complaints and findings. Having a high clinical suspicion is necessary to make the diagnosis. While a bronchoalveolar lavage finding of a large number of hemosiderin-laden macrophages is diagnostic, it is not the end of the evaluation. Subsequent studies are needed for evaluation of the etiology. IPH is a diagnosis of exclusion, and is only appropriate after a thorough investigation is completed.

Complete blood counts, iron studies and a measure of renal function will be helpful to evaluate the patient's current status. ANA, rheumatoid factor, erythrocyte sedimentation rate, complement levels, immunoglobulins, anti-basement membrane antibodies, and serum precipitins to cow's milk protein should also be included in the evaluation for etiology. A cardiac evaluation including physical exam, EKG and CXR evaluation should be included. A referral to cardiology, rheumatology or hematology should be considered. Some experts advocate a lung biopsy for all patients, to include immunofluorescence and electron microscopy studies. Others reserve this for selected cases.

Each patient should have supportive measures as appropriate to their presentation, including supplemental oxygen, blood transfusion, and antibiotics for cases of secondary infection or suspected infection. Respiratory support includes chest physiotherapy to aid in clearing excess secretions, bronchodilators, CPAP or mechanical ventilation. Patients with ongoing bleeding may benefit from positive end expiratory pressure (PEEP).

Treatment has to be viewed in light of the etiology. For those with PH from exposure and toxins from Stachybotrys, the main treatment is elimination of the offending agent. Diet restriction, especially for those found to have serum precipitins to milk products, is essential. For those with secondary PH, treating the primary etiology is critical.

Medical therapy is typically aimed at controlling the inflammatory response. Corticosteroids are the mainstay, but there is no study comparing the dosing strategy. The dose is usually started at 2-5 mg/kg/day of prednisone or equivalent. This dose is used for several weeks, or until the hemorrhage is well controlled. The dose is then tapered, and there are many different protocols. Other immunosuppressive agents have been used in an attempt to reduce the prolonged corticosteroid effects, including azathioprine, chloroquine and cyclophosphamide.

If patients are having significant ongoing hemorrhage, a nuclear medicine study with labeled RBCs can be done to help locate the site. For life-threatening bleeds or those patients that don't respond to medical therapy, bronchial artery embolization may be required. For extreme cases removal of an affected segment or lobe may be necessary.

Close monitoring should include growth, oxygen saturation monitoring, hemoglobin and iron studies, chest radiographs, pulmonary function testing (if old enough), and renal function studies throughout recovery. Reinstitution of aggressive corticosteroid or immunosuppressive therapy is typical for breakthrough exacerbations.

The prognosis is variable, related to the cause. For secondary PH, it must include the natural history of the primary disease. A delay in diagnosis will yield a worse prognosis. Early studies showed a very poor prognosis for IPH. The average was approximately 2 years from diagnosis to death. More recent reports suggest an improvement in this statistic with more aggressive management (8,9). Additionally, newer technology has provided the means for more extensive evaluation, facilitating specific diagnostic determination (i.e., fewer diagnosis of IPH). Many patients can have sustained or complete remission with newer therapies. Although scarring and fibrosis may be permanent, full compensation is possible, especially in younger patients.

Questions

1. Which of the following findings are not usually present in a patient presenting with pulmonary hemosiderosis?
    a. Fever
    b. Parenchymal consolidations
    c. Hypercarbia
    d. Hypoxemia
    e. Cough

2. Why is it important to classify hemosiderosis as primary or secondary?

3. What kind of lung disease can be seen in pulmonary hemosiderosis?
    a. Obstructive disease
    b. Restrictive disease
    c. Mixed obstructive and restrictive
    d. Any of the above

4. Which of the following is not part of the classic triad of symptoms seen in pulmonary hemosiderosis?
    a. Pulmonary hemorrhage
    b. Anemia
    c. Hemoptysis
    d. Pulmonary infiltrates
    e. None of the above

5. True/False: Lung biopsy is the diagnostic test of choice for idiopathic pulmonary hemosiderosis.

Answers to questions

1. c. Hypercarbia is not usually seen because compensatory mechanisms usually overcome the problems of reduced gas exchange by increasing minute ventilation (either by increasing rate or depth of ventilation).

2. It is one scheme to help identify the etiology for a condition with numerous causes. Treatment is more likely to be successful after identifying and treating the primary cause.

3. d. Bronchospasm, edema, and mucus can narrow the airway causing obstructive disease similar to asthma. Chronic inflammation can increase interstitial fibrin and collagen deposits which then reduce compliance resulting in giving restrictive disease. Any combination of the two is possible.

4. a. The classic triad is iron deficiency anemia, pulmonary infiltrates and hemoptysis, although hemoptysis is seen less commonly in children. "Pulmonary hemorrhage" does result in hemosiderosis, but it is not part of the classic triad.

5. False. There is controversy over whether a lung biopsy should be undertaken for all patients with significant PH. It could be argued that all patients who have PH without a known etiology (suspected IPH) should have a lung biopsy. But since IPH is a diagnosis of exclusion, a lung biopsy doesn't preclude the other parts of the evaluation, including history, exam, radiology and laboratory studies. Pathology from lung biopsy is seldom diagnostic alone and can only be interpreted in light of the other information.

Chapter VIII.8. Pulmonary Vascular Anomalies
Jason H. Brown and Edward W. Fong, MD

This is a 5 year old female who presents to the clinic with shortness of breath, a cough with "lots of mucus" for the last two days, and fever as high as 39.0 degrees C two days ago to 37.0 degrees C this morning. Her parents are worried that she has been getting many chest colds with fevers for the last year and that she coughs and feels out of breath even when she isn't sick. Dextromethorphan cough syrups have not helped her symptoms. Exertion makes her cough worse. There are no other associated symptoms including muscle weakness, cyanosis, hemoptysis, chest pain or dizziness. Her past medical history shows no major illnesses or hospitalizations. Her growth and development have been good. Her family history is not contributory. Review of systems is non-contributory.

Exam: VS T 37.0, HR 85, RR 40, BP 110/68, oxygen saturation 97% in room air. Height and weight are at the 25th percentile. She is a pleasant, comfortable, alert, well-developed, well-nourished 5 year old who is non-toxic and in no acute distress. HEENT and neck exams are normal with no lymphadenopathy. Her cardiac exam is abnormal with the PMI 3 cm right of the midline of the sternum, a palpable sternal lift, a widely split S2, and a grade 2/6 systolic ejection murmur heard greatest over the pulmonic area. Some jugular venous distention is also present. Her respiratory exam shows moderate tachypnea with normal chest percussion and symmetrical chest movements. Some fine crackles are heard throughout the lung bases bilaterally. Her abdomen is soft and non-tender, but notable for hepatomegaly with the inferior liver margin extending 4 cm below the right costal margin. Her back is non-tender. Her extremities show normal muscle bulk, tone and strength, with normal DTRs and peripheral pulses.

A CXR shows dextrocardia, cardiomegaly, right lung hypoplasia, a dilated right main pulmonary artery, increased right pulmonary vascular markings, and right-sided pulmonary infiltrates versus atelectasis. A large vein in the right hemithorax raises the possibility of scimitar syndrome. An EKG shows right axis deviation (presumably due to dextrocardia), but is otherwise normal. An echocardiogram shows a dilated right atrium and right ventricle consistent with volume overload and 2 aberrant veins draining 70% of the pulmonary venous return into the vena cava instead of the left atrium. A large 1.5 cm artery off the aorta is present, feeding into the right lower lobe. No ASD (atrial septal defect) is found. CT scans confirm the findings of the echocardiogram. A cardiac catheterization is performed to determine the pressure in the left atrium, which is found to be elevated.

She is diagnosed with pneumonia and scimitar syndrome consisting of 2 anomalous pulmonary veins draining into the vena cava and a large systemic artery 1.5 cm in diameter originating from the aorta perfusing part of the lung. In addition, pulmonary pressure is elevated and with signs of right heart failure (including JVD and hepatomegaly) due to the increased pressure within the pulmonary system. Her pneumonia is treated with antibiotics.

Upon resolution of the pneumonia 2 weeks later, her pulmonary hypertension and CHF are determined to be improved enough for her to undergo surgical correction. The shunt and feeding artery are removed without complications and over time, her symptoms of CHF and pulmonary hypertension resolve.

Scimitar Syndrome (Partial Anomalous Pulmonary Venous Return):

Normal pulmonary venous circulation carries oxygenated blood from the alveolar capillaries to the left side of the heart for systemic distribution. In the Scimitar syndrome (approximately 1-3 per 100,000 births), an anomalous vein connects between the pulmonary venous circulation and systemic venous circulation which creates a left-to-right shunt that is determined by: 1) size and number of abnormal draining veins, 2) the source of venous blood flow (i.e., veins from the inferior lobe in an upright individual drains more blood than those of the superior lobe), 3) the level of pulmonary vascular resistance, and 4) the presence of other cardiovascular abnormalities. This anomalous pulmonary venous return can be either partial (PAPVR) or total (TAPVR), each with respective clinical presentations. The syndrome associated with PAPVR has been given many names in the past: pulmonary venolobar syndrome, pulmonary vascular syndrome, hypogenetic lung syndrome, and right pulmonary artery syndrome, but it is now more commonly known as "Scimitar syndrome" (1), due to the resemblance of the abnormal curvilinear pulmonary vein to a Turkish sword.

The anomalous venous connections and associated malformations are almost exclusively right-sided, with only a few reports of left-sided occurrence. The syndrome is composed of findings of: 1) An anomalous right pulmonary venous connection to the systemic venous circulation either above or below the diaphragm, most commonly to the inferior vena cava. This vein is what produces the characteristic "scimitar" shadow on X-ray. 2) Anomalous systemic arterial supply to the right lower lobe from the aorta. 3) Hypoplastic (or absent) right pulmonary artery. 4) Right lung hypoplasia with dextrocardia (the dextrocardia is typically the non-situs inversus type, and therefore, is usually a consequence of the right sided pulmonary hypoplasia). Other findings may include: a) Abnormal lobulation of the lung, b) Horseshoe lung, and c) Accessory hemidiaphragm.

Approximately 25% of presenting patients have an associated cardiac malformation, most often an ostium secundum defect (a type of ASD). Racial, sexual, and genetic predilections are largely unknown. PAPVR, was a diagnosis made at autopsy until the advent of echocardiography, cardiac catheterization, and CT/MRI scanning. The abnormal drainage of blood in the lungs can overload the right atrium and ventricle as well as decrease the preload for the left ventricle. This can lead to right ventricular dilation and decreased cardiac output. Additionally, flow from the perfusing artery stemming from the aorta may be greater than the outflow from anomalous veins, leading to increased left-sided volume loading, accelerated pulmonary hypertension, and associated symptoms of cardiac failure (2). This is not normally the case, as most symptoms arise from increased volume loading of the right heart (due to increased venous return) and pulmonary artery pressure is generally normal (3). The most common early clinical manifestation is an increased frequency of pulmonary infections.

Manifestation of clinical symptoms is dependent on the size of the shunt magnitude, expressed as pulmonary flow (Qp) to systemic flow (Qs), and can become serious when this ratio becomes >2:1. Clinical symptoms mainly manifest late in life, depending on the shunt magnitude, but occasionally they may present in childhood. These include: 1) symptoms of recurrent respiratory infections, 2) dyspnea, 3) exercise intolerance, 4) palpitations, 5) hemoptysis, 6) chest pain, 7) symptoms of associated abnormalities (e.g., ASD, pulmonary sequestration, etc.). Symptoms 2 through 6 are rare except in advanced cases where pulmonary hypertension and heart failure are present.

Physical exam reveals symptoms similar to an atrial septal defect:

1. A precordial bulge, which is a left parasternal lift due to right ventricular dilation, and possible pulsation in the 2nd intercostal space due to pulmonary artery dilation (in the absence of dextrocardia).
2. Systolic ejection murmur heard over the pulmonic area.
3. Widely split heart sound (S2) with possible normal respiratory variation.
4. This is usually a non-cyanotic condition unless there is the presence of ASD with pulmonary hypertension for shunt reversal.
5. Right-sided heart failure (include jugular venous distension, hepatomegaly, and peripheral edema).

The differential diagnosis includes: 1) atrial septal defect (clinical picture is almost indistinguishable), 2) total anomalous pulmonary venous return, 3) pulmonary sequestration, 4) ventricular septal defect.

The diagnosis of scimitar syndrome rests on demonstration of the aberrant pulmonary veins and associated abnormalities. Chest X-ray, ultrasound (echocardiography), and MRI are the choice imaging modalities for this purpose, with cardiac catheterization providing additional information in many cases. Treatment of PAPVR is symptomatic for resultant CHF, but the most definitive treatment for prevention of further complications is surgical correction of the shunt. A contraindication for surgical repair is the presence of pulmonary hypertension, which can increase the mortality rate to >50%.

A common complication of untreated PAPVR is recurrent pneumonia. The chronic, increased pressure within the pulmonary venous system can lead to pulmonary vascular and cardiac remodeling with complications of arrhythmias, right-sided cardiac failure and pulmonary vascular disease (rare). These manifest themselves to varying degrees throughout life depending on shunt size, and may be the cause of morbidity and mortality from the disease.

Pulmonary Sequestration:

Pulmonary sequestration is a segment of nonfunctioning lung tissue that usually does not associate with the tracheobronchial tree (airways within the sequestration rarely communicate with the trachea) and receives all of its blood supply from an anomalous systemic artery. The table below distinguishes Scimitar syndrome from pulmonary sequestration. The main distinguishing points are the tracheobronchial communication and the venous drainage. There are two different types of sequestrations: intrapulmonary (formerly called intralobar) and extrapulmonary (formerly called extralobar), which collectively make up approximately 6% of congenital pulmonary malformations. The development of these abnormalities is hypothesized to be from the development of a primitive lung bud from the foregut during embryonic development.

Table 1 - Comparison of Scimitar syndrome and pulmonary sequestration

	Scimitar syndrome	Pulmonary sequestration
Located within the lung	Yes	Intrapulmonary-Yes Extrapulmonary-Technically No
Arterial supply from systemic artery branch	Yes	Sometimes
Venous drainage into vena cava	Yes	Intrapulmonary-No Extrapulmonary-Yes (or right atrium or azygous vein)
Airways communicate with trachea	Yes	No
May involve the entire lung (13)	Sometimes	No
Dextrocardia (13)	Sometimes	No
ASD	Yes	No
Recurrent pulmonary infections	Yes	Intrapulmonary-Yes Extrapulmonary-Usually no
Hemoptysis	Yes	Intrapulmonary-Yes Extrapulmonary-Usually no

Intrapulmonary sequestrations are more common (75-90% of sequestrations) and are located within the lung tissue, usually in the posterior basal segment of the left lower lobe. This lesion usually occurs by itself with no associated congenital abnormalities and by definition, does not have a separate pleural covering. Communication with the tracheobronchial tree may occur via fistulas, but this is rare. 66% of lesions occur within the left lung and 99% are usually found in the posterior lung bases with venous drainage into the left atrium (4). The etiology of this lesion is unknown. Classically, intrapulmonary sequestrations do not present symptomatically until adolescence or adulthood. In fact, they are often an incidental finding on a chest X-ray performed for other reasons. When they do present clinically, it is with non-specific symptoms of cough, fever, wheezing, recurrent pulmonary infections, and rarely hemoptysis. Surgical resection of the lesion is curative and lobectomy is necessary because these are often poorly-defined masses.

Extrapulmonary sequestrations differ from intrapulmonary sequestrations in many respects: 1) the presence of a distinct and separate pleura, 2) the association with other congenital abnormalities (diaphragmatic hernia, colonic duplication, vertebral abnormalities, and pulmonary hypoplasia) (5), 3) >60% of cases present in infancy before age 6 months with a 4:1 male-to-female incidence, and 4) venous drainage is normally into the right atrium via the azygous system (11). The lesion is normally asymptomatic until associated abnormalities, infection, or shunting becomes severe. Although infants can present with cough, dyspnea, and difficulty feeding caused directly by the size of the lesion, a high degree of shunting will indirectly cause respiratory distress and CHF (7). Older children and adults usually present with chest pain and infection. Similar to intrapulmonary sequestration, if the patient is not diagnosed with an extrapulmonary sequestration during infancy because of no complications due to vascular causes (i.e., shunting), extrapulmonary sequestration will often be diagnosed as a result of an investigation for other associated anomalies. Complications are recurrent infection and hemorrhage in addition to those associated with other congenital abnormalities. Treatment is resection of the abnormality, which does not involve a lobectomy because it is a well-defined mass.

The anatomy can be further defined with the assistance of CT, MRI and angiography.

Physical examination reveals similar findings in both intra and extrapulmonary sequestrations:

1. Dullness to percussion over the lesion.
2. Decreased breath sounds over the lesion.
3. Rales may occur with a pneumonia.
4. A systolic murmur or continuous bruit associated with the arterial supply to the lesion may be present.

The differential diagnosis includes: 1) cystic adenomatoid malformation, 2) bronchogenic cyst, 3) bronchiectasis, 4) pulmonary atelectasis, 5) bronchial foreign bodies, and 6) pneumonia.

Scimitar syndrome and sequestration can both be categorized as venolobar syndromes. They both involve the lung, at least to some varying degree, and they both have cardiovascular involvement or at least the potential for cardiovascular involvement. However, while the cardinal cardiac lesion in Scimitar syndrome is partial or hemianomalous venous drainage, sequestration may not have an anomalous vascular connection. Sequestration is a disconnected or abnormally communicating bronchopulmonary mass or cyst with normal or anomalous arterial supply or venous drainage (12).

Sequestration is primarily considered to be a congenital lung malformation and because of the extra-parenchymal tissue, angiogenesis may occur causing an anomalous vascular supply. Scimitar syndrome, on the other hand, begins as a congenital cardiac malformation (usually an abnormal right pulmonary artery with or without other aberrant systemic arteries), which then causes abnormal lung development (ranging from minor abnormal bronchial branching all the way to a hypoplastic lung) and all of it is drained by the hallmark feature, an anomalous vein. In fact, bronchogenic cysts and extrapulmonary sequestrations have been found in association with Scimitar syndrome. It is because of these embryologic differences that on chest X-ray, sequestration usually appears as a cystic lesion or consolidation, while Scimitar syndrome has the characteristic Scimitar appearance with hypoplasia of the right lung.

For the above reasons, sequestration tends to be more of a condition for pulmonology specialists (pulmonology, CT, pediatric surgery), while scimitar syndrome tends to be more of a condition for cardiology specialists (cardiology, cardiac cath angiography, cardiovascular surgery).

Questions

1. What shunt fraction is considered clinically significant for the manifestation of symptoms in Scimitar Syndrome?
2. Why would you want to correct the underlying condition of scimitar syndrome early?
3. What are the complications of untreated pulmonary sequestrations?
4. What type of shunt is typical in extrapulmonary sequestration?
5. What type of sequestration is associated with a diaphragmatic hernia?
6. List three or more ways in which Scimitar syndrome differs from pulmonary sequestration.

Answers to questions

1. >2:1 pulmonary flow to systemic flow.
2. To prevent future complications such as: pneumonia, arrhythmia, and irreversible pulmonary hypertension (13).
3. Recurrent pulmonary infections, bronchiectasis and hemorrhage.
4. Typically, it is left-to-right venous drainage: pulmonary venous/systemic artery to the systemic venous system. Intrapulmonary sequestrations typically shunt systemic blood to the pulmonary vein (systemic artery to the pulmonary vein, which is left to left).
5. Extrapulmonary sequestration (30% are associated with diaphragmatic hernias).

6. 1) Sequestration contains bronchi that do not communicate with the trachea. 2) Two types of sequestration (intrapulmonary and extrapulmonary). 3) Dextrocardia and ASD usually accompany Scimitar syndrome. 4) Intrapulmonary sequestration venous drainage enters the left heart, while the venous drainage of Scimitar and extrapulmonary sequestration enters the right heart circulation.

Chapter VIII.9. Bronchogenic Cysts and Congenital Cystic Adenomatoid Malformations

Scott J. Sheets, DO

This is a newborn male infant born to a 25 year old G3P2 O+, rubella immune, group B streptococcus negative mother at 38 weeks gestation via spontaneous vaginal delivery. Pregnancy was complicated by ultrasound findings of mild polyhydramnios and an abnormal fetal chest finding. Apgars of 4 (-1 for respiratory effort, gag, tone and heart rate, -2 for color) and 7 (-1 for color, respiratory effort, tone) were given, at 1 and 5 minutes, respectively.

Exam: VS T 36.5, P 170, R 40, BP 80/40, oxygen saturation 90% on FiO2 of 1.00 (i.e., 100% oxygen), length 25%ile, weight 5%ile, OFC (head circumference) 50%ile. He is term in appearance, non-dysmorphic, thin appearing, in moderate to severe respiratory distress. HEENT exam is normal. His chest is slightly asymmetric, with his right hemithorax larger than the left. Suprasternal and intercostal retractions are present. Thoracoabdominal asynchrony ("belly breathing") is present. Heart is regular but tachycardic, with a grade II/VI systolic murmur best heard at the apex. Lung air exchange is moderate on the left but diminished on the right. There are no crackles or wheezing, but delayed air entry and prolonged expiration is present on the right. His abdomen is soft and non-distended, without palpable masses or hepatosplenomegaly. His extremities are symmetric, with mild acrocyanosis and no edema. Peripheral pulses are equal and within normal limits.

In the delivery room, he is given bag mask ventilation for the first minute of life with improvement in heart rate and color. He shows improved respiratory effort but remains in distress. He is intubated with a 3.5 endotracheal tube and transported to the NICU where he is placed on mechanical ventilation. A nasogastric tube is passed to decompress the stomach. A chest radiograph demonstrates cystic lesions occupying much of the lower right lung field. The mediastinum is shifted toward the left. One of the residents thinks that this is bowel in the chest (based on its appearance) with an associated diaphragmatic hernia. But the neonatologist cautions that a diaphragmatic hernia on the right is unusual. An emergent CT scan shows several small cysts within the right lower lobe with a prominent large cyst compressing the right mainstem bronchus, upper and middle lobes, and shifting the mediastinum. The left lung is small (slightly hypoplastic). Serial chest radiographs show that the lesions are stable over the first 24 hours. A cardiothoracic surgeon is consulted. The child is taken to surgery on the second day of life. Intraoperatively, it is apparent that the lesions are contained within the right lower lobe, so this lobe is resected. The pathologic examination of the resected lobe confirms a type I congenital cystic adenomatoid malformation (CCAM).

Immediately post-operatively, ventilation is improved. Chest radiographs show that the mediastinum has returned to midline, the right upper and middle lobes compensate to fill the hemithorax. The left lung, now no longer compressed, shows normal development. Over the following weeks, ventilation and oxygenation improve, and the infant is converted from high frequency oscillatory ventilation (HFOV) to a conventional mechanical ventilator with an emphasis on minimizing barotrauma. Breath sounds are symmetric. The child is weaned from the ventilator, and over time, he no longer requires supplemental oxygen.

Congenital malformations of the airways and lungs make up approximately 10-15% of all malformations and are often found with other congenital anomalies (18-20%). The following review includes a description of two of the more common lung malformations: bronchogenic cysts and congenital cystic adenomatoid malformations (CCAM). The vast majority of foregut cysts found in infancy are bronchogenic cysts (1).

Bronchogenic cysts are one type of a foregut cyst (a closed epithelial-lined sac developing abnormally from both the upper gut and respiratory tract). A bronchogenic cyst is thought to develop as a diverticulum of the primitive foregut. Since most form very early, usually 4-8 weeks gestation and before the development of distal airways, they rarely connect to a normal bronchus. Most are right sided, midline and in close proximity to the tracheobronchial tree. On rare occasions they can separate the connection to the airway and migrate to the periphery, parahilar area or even below the diaphragm. Five categories have been described by location: 1) paratracheal 2) carinal 3) para-esophageal 4) hilar and 5) other. They may contain normal tracheal tissue including mucus glands, elastic tissue, smooth muscle and cartilage. They are lined with ciliated epithelium. They range from 2-10 cm in diameter. The cyst may contain serous (with the consistency of water) or proteinaceous fluid (2,3).

Congenital cystic adenomatoid malformation (CCAM) is a congenital bronchopulmonary anomaly resulting from a maldevelopment of the lung bud in the fetus (1). CCAMs are a defect of non-cartilage containing terminal respiratory structures, resulting from an abnormality occurring in the mid to late stages of lung development. Although these lesions are frequently described as hamartomatoid, they are not true hamartomas because skeletal muscle can be found in the wall of the cyst. The following is a list of distinguishing features that define the group: 1) absence of cartilage, 2) absence of bronchial tubular glands, 3) presence of tall columnar mucinous epithelium 4) increased production of terminal bronchiolar structures without alveolar differentiation 5) increased enlargement of the affected lobe (4).

There are at least 4 subtypes described, although type 0 is not compatible with life. The different subtypes are primarily described by their gross physical appearance, but they also differ by their variations in microscopic findings and embryologic origin. Each subtype has differing prognostic indications. Type 0 (most rare) is tracheobronchial in origin, with small, firm and granular lungs. Microscopically there are bronchial-like structures separated by mesenchymal tissue.

Type I (macrocystic subtype) is the most frequent variant (60-70%). It has bronchial-bronchiolar origins and at least one prominent cystic structure, although several smaller cysts may also be present. Type I malformations have little adenomatoid component and are mainly lined by ciliated pseudostratified epithelium. They contain cysts interspersed with bronchiolar and alveolar tissue.

Type II (microcystic subtype) is the next most frequent variant (15-20%). Smaller cysts with ciliated cuboidal or columnar epithelium are the dominant feature. It has a mix of cystic and adenomatoid components and is bronchial in origin. Between the cysts are distended respiratory bronchioles and alveolar tissue. These may also contain skeletal muscle. This subtype is associated with a higher incidence of other anomalies.

Type III (solid subtype) is rare (8-10%). It is a bulky lesion, with thin walled cysts. Type III is almost entirely adenomatoid in make-up. It is an airless mass of bronchiolar elements, lined by patchy ciliated cuboidal epithelium mixed with alveolar elements.

Some describe Type IV (10-15%) as a large cystic lesion in the periphery of the lung, believed to be of acinar origin. Others do not describe this subtype and incorporate it into the others. These cysts are lined by flattened pneumocytes (5-6).

The clinical manifestations of a bronchogenic cyst depend on size, location and whether there is a communication with the airway or esophagus. They can present with fever, dyspnea, stridor, chronic cough, chest pain, dysphagia, cyanosis, crackles, wheezing, pulmonary sepsis or suppuration of the cyst, respiratory distress or swelling. Bronchogenic cysts can present as a draining sinus, typically located in the suprasternal notch or supraclavicular area. Superior vena cava syndrome has been seen. They are asymptomatic in up to 30% (7).

CCAMs present early in the newborn period with respiratory distress (dyspnea, tachypnea, grunting, retractions or cyanosis) in approximately 75% of cases. The mass lesion comprised of growing cysts can compress the surrounding structures. Compression during development of the surrounding lung can cause pulmonary hypoplasia, maldevelopment of the heart and great vessels (may cause fetal hydrops), or hypoplasia of the airways (can lead to respiratory distress). For those who do not present in the newborn period, they may present at any point in life. The lesions can develop infections, as they do not have normal clearance mechanisms, leading to recurrent pulmonary sepsis. A higher percentage of these lesions are being diagnosed or suspected prenatally by ultrasound.

On chest radiographs, bronchogenic cysts usually appear as a spherical or ovoid mass close to the carina or mainstem bronchus. CCAMs appear as obvious solid or cystic masses with or without pleural effusion. Diagnosis is suspected by CXR, CT, MRI, endoscopy or fluoroscopy, but is confirmed by pathologic evaluation of tissue.

Bronchogenic cysts are most commonly confused with the other main type of foregut cysts, esophageal duplication cysts. The rest of the differential diagnosis includes cystic hygroma, thymoma, thyroid tumors, dermoid cyst, congenital lung emphysema, pulmonary abscess, pneumatocele, thyroglossal duct cyst, bronchial duct cyst, teratomas, necrotic cervical lymphadenopathy, neurogenic tumors, primary malignancy, lipoma and leiomyoma.

CCAMs are most frequently mistaken for congenital diaphragmatic hernia (since the cysts can resemble bowel gas in the chest on CXR) but the differential includes simple parenchymal cysts, infections, sequestration, mesenchymal cystic hamartomas, mesothelial cysts or cystic lymphangiectasis (8-10).

The treatment of choice in all forms of bronchogenic cysts and CCAMs is surgical excision, which also provides confirmation of the diagnosis. Bronchogenic cysts may rupture into a bronchus or pleura, bleed profusely or become infected. These complications can cause problems at the time of surgical excision or produce sudden death. If they have already been secondarily infected, the excision may have to be delayed until antibiotic treatment can clear the area of infection. If resection is not complete, recurrence is possible. For CCAM, early resection will allow for compensation of lung growth from the remaining sections, and prevents secondary infections, that otherwise commonly occur.

Left untreated, bronchogenic cysts may develop malignancy including rhabdomyosarcoma, leiomyosarcoma, or anaplastic carcinoma. In one study of symptomatic infants, there was 100% mortality without surgery. Of those infants undergoing surgery, mortality rates were reported to be 0-14%. The prognosis for those surviving surgery was good. In some, residual tracheomalacia or bronchomalacia may be present.

CCAM Type 0 is not compatible with life and these infants are usually stillborn, or spontaneously aborted. Type I lesions have the best prognosis. For those surviving surgical resection, the prognosis is excellent with compensatory lung growth of the remaining segments. Type II has a worse overall outcome compared to Type I, largely because of the other associated anomalies. Type III has a poor prognosis, due to the degree of hypoplasia frequently seen in the other lung segments. If untreated, there is also a potential for malignant transformation in CCAM.

Another important consideration for those patients with either type of lesion is air travel, when transport to a tertiary care center is needed for further management. The cystic lesions have been known to expand 30% in size during flight, which may cause a significant mass effect and further compression of vital structures. Care must be taken to avoid significant pressure changes by flying at low altitudes, or in special aircraft capable of pressurization to sea level.

Questions

1. Which of the following lesions contain no cartilage?
    a. Bronchogenic cyst
    b. Congenital cystic adenomatoid malformation
    c. Both of the above
    d. Neither of the above

2. Which of the following lesions is a form of foregut cyst?
    a. Bronchogenic cyst
    b. Congenital cystic adenomatoid malformation
    c. Both of the above
    d. Neither of the above

3. Which of the following lesions is usually associated (has a direct connection or communication) with the tracheobronchial tree?
    a. Bronchogenic cyst
    b. Congenital cystic adenomatoid malformation
    c. Both of the above
    d. Neither of the above

4. In symptomatic lesions, both CCAM and bronchogenic cysts should be resected. In which of the following, can asymptomatic lesions be followed clinically?
   a. Bronchogenic cyst
   b. Congenital cystic adenomatoid malformation
   c. Both of the above
   d. Neither of the above
