5. Which of the following lesions frequently cause symptoms by mass effect?
   a. Bronchogenic cyst
   b. Congenital cystic adenomatoid malformation
   c. Both of the above
   d. Neither of the above

6. Which type of CCAM has the best prognosis?
   a. Type 0
   b. Type I
   c. Type II
   d. Type III
   e. Type IV

7. Which type of CCAM is most common?
   a. Type 0
   b. Type I
   c. Type II
   d. Type III
   e. Type IV

Chapter VIII.10. Congenital Airway Problems
Winona K. Lee, MD

This is a 4 week old male who has been brought to your office with a one week history of "noisy breathing." His parents note that his noisy breathing is worse when they lay him down or with crying. It is most noticeable when he takes a breath in. There has been no history of fever, coughing, runny nose, change in his cry, apnea, or feeding difficulties. He has been gaining weight appropriately. Prenatal course was uneventful and he was delivered at 38 weeks gestation by spontaneous vaginal delivery without complications. Family History is unremarkable.

Exam: VS T 37.0, P 120, RR 48, oxygen saturation 98% in room air. Weight and height are at the 50%ile. He is alert, active, in no acute distress. There is audible inspiratory stridor noted in the supine position, which is improved with extension of his neck. His anterior fontanel is soft and flat. His eyes and ears are normal. No nasal flaring is visible and his nares appear patent. His throat shows no erythema or lesions. His lips are moist and pink. There are no retractions or pectus abnormalities. His lungs are clear to auscultation throughout once the stridor clears with airway repositioning (no wheezes or rales). Aeration is good. He has noisy referred upper airway sounds when he is supine with his neck flexed. His heart is regular without murmurs. His color, perfusion, capillary refill and pulses are good.

He is referred to ENT for a flexible fiberoptic laryngoscopy, which confirms the diagnosis of mild laryngomalacia. His status is monitored clinically. He continues to feed well and gain weight appropriately. All his symptoms resolve by 18 months of age.

Laryngomalacia

Laryngomalacia is the most common congenital anomaly of the larynx. It represents 60% of all congenital laryngeal anomalies (1). Males are affected twice as often as females. It is generally self-limiting, however, severe cases of laryngomalacia can lead to failure to thrive and life-threatening apnea (2).

The exact etiology is unclear, however, theories include maldevelopment of the cartilaginous structures of the airway and immature neuromuscular control. The epiglottis is derived from the 3rd and 4th brachial arches. An overgrowth of the 3rd arch results in an elongated and laterally extended epiglottis (1). Neuromuscular immaturity may contribute to the prolapse of the arytenoids observed in laryngomalacia; however; there is no increase in the incidence of laryngomalacia in premature infants with classic hypotonicity (1).

Symptoms of laryngomalacia are typically absent at birth, arising at 2 to 4 weeks of age. Common symptoms include inspiratory stridor, which is worsened with supine position and with agitation or excitement (3). Feeding difficulties, exacerbated by gastroesophageal reflux, may occur due to the increased negative intrathoracic pressure created by a partially obstructed airway (2). Patients have a normal cry and rarely present with respiratory distress or cyanosis. Rare complications include chest deformities, obstructive apnea, and failure to thrive (1).

The classic history will guide one to the diagnosis of laryngomalacia; however, diagnosis is confirmed by flexible laryngoscopy while the patient is awake (3). Laryngoscopy typically reveals an elongated and laterally extended (omega shaped) epiglottis that falls posteriorly on itself on inspiration. Visualization also reveals inward collapse of the aryepiglottic folds (cuneiform cartilages) on inspiration and bulky arytenoids that prolapse on inspiration (1).

Management is expectant with simple reassurance for parents. Patients are observed for adequate growth. Symptoms of gastroesophageal reflux should be monitored since this can aggravate symptoms and can be improved with anti-reflux precautions. In patients with failure to thrive or obstructive apnea, surgical interventions such as epiglottoplasty (dividing the aryepiglottic folds and trimming the epiglottis) may be required (2).

Vocal Cord Paralysis (also known as Vocal Fold Paralysis)

The second most common congenital anomaly of the larynx is vocal cord paralysis, accounting for 20% of laryngeal lesions. The paralysis can be unilateral or bilateral. In general, bilateral paralysis is usually due to a central nervous system problem, while unilateral paralysis is typically caused by an injury to the peripheral nervous system (2). Specific causes of vocal cord paralysis include meningomyelocele with Arnold-Chiari malformation, hydrocephalus, birth trauma, and surgical trauma (4).

Infants with vocal cord paralysis may present at birth or within the first few weeks of life. Symptoms include a weak or breathy cry, noted typically in unilateral vocal cord paralysis. Patients may also present with inspiratory or biphasic stridor, aspiration or feeding difficulties, and occasionally respiratory compromise (3).

The diagnosis of vocal cord paralysis can be made at the bedside with direct visualization of the vocal cords using a laryngoscope (direct laryngoscopy), but is confirmed by rigid endoscopy under anesthesia while the patient is breathing spontaneously. Alternatively, flexible laryngoscopy while the patient is awake to assess vocal cord mobility can be used. Imaging may be utilized to rule out associated CNS lesions (4).

Initial management includes stabilization of the airway and support for feeding and nutrition (3). In most cases of unilateral vocal cord paralysis, no intervention is needed since compensation by the opposite vocal cord occurs over time and most cases resolve within the first few weeks of life. In bilateral vocal cord paralysis, tracheostomy is generally required to stabilize the airway. Bilateral vocal cord paralysis secondary to a neurological problem often improves once the neurological problem is addressed. In cases of idiopathic bilateral vocal cord paralysis, symptoms may spontaneously resolve by age of 2. If not, it is unlikely to do so. Surgical methods have had moderate success in improving the airway and promoting decannulation (removal of tracheostomy) by age 4 to 5 years (2).

Congenital Subglottic Stenosis

Congenital subglottic stenosis is the third most common congenital anomaly of the larynx. It accounts for 15% of all cases. Males are affected twice as often as females (5). Congenital subglottic stenosis is usually associated with a small or malformed cricoid cartilage with or without thickening of the underlying submucous layer.

Patients with subglottic stenosis may be asymptomatic until an upper respiratory infection causes further narrowing of the airway. The patient may present with biphasic stridor and a barking cough may be noted. Many patients are diagnosed with recurrent croup prior to a final diagnosis of subglottic stenosis. With severe subglottic stenosis, patients will present with dyspnea and marked suprasternal and subcostal retractions. The patient's cry remains unaffected (2).

A history of recurrent croup may support the diagnosis of congenital subglottic stenosis. Subglottic narrowing may be noted on plain lateral and AP x-rays and the diagnosis is made with rigid bronchoscopy. The length and diameter of the stenosis is measured and

congenital subglottic stenosis is diagnosed when the lumen diameter is less than 4 mm in a term infant or less than 3 mm in a preterm infant (1).

In the majority of patients with subglottic stenosis, respiratory problems resolve with growth of the child. However, endotracheal intubation and tracheostomy may be needed in patients with significant airway compromise. Decannulation by age 3 to 4 years is usually possible when the subglottic space widens. Laryngeal reconstruction to enlarge the lumen of the stenotic airway has proven successful in severe cases of congenital subglottic stenosis (4).

Tracheomalacia

In tracheomalacia, the trachea lacks firmness, causing the anterior and posterior walls to come together during respiration, decreasing the tracheal lumen. Tracheomalacia occurs in 2 forms: primary and secondary. Primary tracheomalacia is rare and is caused by a congenital deformity of the supporting tracheal rings. Secondary tracheomalacia is due to external compression from lesions such as vascular anomalies (e.g., vascular ring), tumors or hemangiomas. It can also result from surgical intervention such as tracheoesophageal fistula repair (5).

Patients with tracheomalacia can present with inspiratory or expiratory stridor, wheezing, and a barking cough. Dramatic "dying spells", in which the patient undergoes reflex apnea, progressing to cardiac arrest can also occur. Patients can also present with recurrent pneumonitis secondary to chronic obstruction and difficulty clearing bronchial secretions (5).

Direct endoscopy is the only reliable method to diagnosis tracheomalacia. Both types of tracheomalacia are typically self-limited, but in severe cases a tracheostomy may be needed to stent the trachea during development. In the secondary form, correction of the underlying lesion to alleviate external compression is associated with a good outcome (3).

Congenital airway anomalies must be considered when evaluating stridor of infancy. The key is to separate life-threatening conditions from those which are self-limited. With a thorough history and physical examination, one can establish the initial diagnosis, make the appropriate referral to the ENT specialist, and support the infant until a diagnosis is confirmed.

Questions

1. What is the most common cause of laryngeal anomalies in infants?

2. Classically, the stridor in laryngomalacia is:
   a) inspiratory b) expiratory c) biphasic

3. The secondary form of tracheomalacia is usually due to:
   a. a congenital deformity of the supporting tracheal rings.
   b. an extrinsic compression such as a vascular anomaly.
   c. surgical intervention such as tracheoesophageal fistula repair.
   d. b and c.
   e. all of the above.

4. Anatomically, congenital subglottic stenosis is usually associated with what other airway malformation?

5. As the second most common laryngeal anomaly, vocal cord paralysis accounts for what percentage of laryngeal lesions?

6. A child with a diagnosis of recurrent croup may suggest which airway anomaly?

7. Most cases of laryngomalacia resolve by what age?
   a. 6-12 months old
   b. 12-18 months old
   c. 18-24 months old
   d. 24-36 months old

8. In general, bilateral vocal cord paralysis can be attributed to a _____nervous system problem, while unilateral vocal cord paralysis is usually caused by an injury to the ___nervous system.

Answers to questions

1. Laryngomalacia
2. a. inspiratory
3. d. b and c
4. small or malformed cricoid cartilage
5. 20%

6. congenital subglottic stenosis
7. c. 18 to 24 months old
8. central, peripheral

Chapter VIII.11. Sleep Disorders
Sze Mei Chung

This is a 4 year old boy who is brought to the office by his single mother with a chief complaint of screaming at night for about a year. He has been in good health otherwise with no recent history of otitis or respiratory infection. There is no history of nervous system malformation, seizure, or sleep walking. According to his mother, she would hear a chilling scream, rush to her son, and find him sitting up in bed, sweating with a glassy stare. There is no response when she talks to him, and when she tries to hug him, he usually resists. But when her son does answer after more vigorous shaking, he seems confused and disoriented. This mostly happens approximately at midnight, 2-3 hours after his bedtime. In the morning he would seem fine and not remember having any nightmares or screaming.

Exam: VS T 37.5, P 90, R 24, BP 92/53. He is a shy, healthy looking boy in no apparent distress. His examination is normal.

He is referred to a sleep specialist who assesses the boy as having sleep terrors. His mother is taught to help avoid stresses and fatigue for her son during the daytime. Short naps of 30-60 minutes in late afternoon are suggested. His mother is told that diazepam may be prescribed if his problem worsen, but most of the time, children will outgrow this disorder.

When children present with sleep problems, a careful history should be taken (1). This includes age of onset, patterns of daytime sleepiness and napping, questions about snoring and apnea, sleep related behaviors such as talking and head banging, psychiatric assessment regarding separation anxiety and nightmares, relevant medical/neurological conditions such as headaches, and mental retardation, and family histories of sleep disorders.

Studies such as polysomnography (PSG), limb actigraphy, and multiple sleep latency test (MSLT) can be useful in diagnosing the cause of the sleep problem. PSG includes measurements of eye muscle movement, EMG, EEG, EKG, respiratory measurements (i.e., thoracic/abdominal excursion, air flow, and oximetry) during sleep. MSLT is based on PSG that objectively measures daytime sleepiness by recording sleep onset and type of sleep with 5 regularly spaced daytime naps. Limb actigraphy uses an instrument resembling a wrist watch that detects body movements continuously for 3 days. However, for disorders that are more sporadic, PSG may not be definitive. In cases of arousal disorders (sleep terror and sleep walking), having the parents record the episodes on a video camcorder may be more useful. Sleep disorders can be categorized into dyssomnias, parasomnias, and sleep disorders due to medical or psychiatric conditions (2).

Normal sleep is composed of rapid-eye-movement (REM) and non-REM (NREM) types. REM sleep is the dreaming stage of sleep, whereas NREM is sleep that is further divided into 4 stages depending on the PSG readings. Stage 1 NREM sleep can be defined as "drowsiness" where alpha waves of wakefulness are replaced by theta waves in EEG, and during which slow, rolling eye movements are observed with slightly decreased tonicity in EMG recordings. This is followed by K complexes characteristic of Stage 2 NREM sleep. Stages 3 and 4 of NREM sleep are known as slow-wave sleep where delta waves on EEG dominate. In stage 3, delta waves are present in 20-50% of the EEG, while in stage 4, delta waves are present in >50% of the EEG (3,4).

Dyssomnias are disturbances of normal sleep or sleep rhythm pattern. This disorder is characterized by not enough, too much, or inefficient sleep. Dyssomnias can be broken down into 3 categories: intrinsic dyssomnias, extrinsic dyssomnias, and circadian dyssomnias (5).

Intrinsic dyssomnias are due to causes within the body and include breathing related sleep disorders (sleep apnea) and narcolepsy. Sleep apnea occurs when air flow is completely stopped and is diagnosed when there are 5 apneas or 10 apnea-hypopnea episodes per hour of sleep. Compared to apnea, hypopnea is shorter duration of decreased ventilation. However, the precise criteria for defining hypopnea is controversial. In general, hypopnea can be thought of as episode where airflow is reduced by one-half to two-thirds (6). Audio tape recording of the episode can also aid in the diagnosis. Apnea by itself is not a problem except when it exceeds 10 seconds in duration. Patients are not aware of their apneas but sometimes do wake up with a choking feeling.

There are 3 types of sleep apnea: central, obstructive, and mixed sleep apnea. Central apnea results from no respiratory effort because of brainstem respiratory neuronal immaturity, which is commonly seen transiently in premature babies and newborns. Obstructive sleep apnea is caused by airway obstruction. In young children, the obstruction is most often due to enlarged tonsils and adenoids and not usually from severe obesity (2). Surgical removal of the enlarged tonsils and adenoids may be curative. Apnea is accompanied by increased thoracic and diaphragmatic respiratory effort without air exchange due to upper airway obstruction. Mixed sleep apnea combines features of both central and obstructive causes.

Because of apneic episodes, the patient experiences many short arousals to restore adequate oxygenation. These arousals can severely interrupt the sleep cycle. Thus, symptoms of daytime sleepiness and inattention are evident. In toddlers, growth retardation similar to that seen in failure to thrive can be observed possibly associated with disruption of growth hormone secretion during fragmented sleep.

A related disorder in children is central hypoventilation syndrome (or Ondine's curse) caused by central chemoreceptor impairment leading to nocturnal seizures and hypoxia (7). Treatment includes mechanical ventilation or phrenic nerve pacing (3). Other hypoventilation syndromes include Pickwickian syndrome (named for the Joe, the fat boy in Dickens' Pickwick Papers), a rare complication of extreme obesity characterized by hypersomnolence with apneic pauses, polycythemia, and eventual right-sided heart failure (8,9). Likewise Prader-Willi syndrome can also cause obstructive sleep apnea (10). Prader-Willi syndrome is a genetic disorder due to deletion of q12 in the long arm of the paternal chromosome 15. Initially, the infant presents with hypotonia followed by rapid weight gain after 1 year of age leading to morbid obesity (11,12, 13). In cases of Pickwickian and Prader-Willi syndromes, reducing weight is of primary importance and should be achieved as fast as is feasible (14). Examples of other conditions predisposing to obstructive sleep disorders are Down syndrome, craniofacial anomalies, mucopolysaccharidoses, and neuromuscular disorders.

Narcolepsy is the only REM sleep dyssomnia. Its peak incidence (<1%) is between 15 to 25 years of age (5). Its etiology is unknown, but there is strong genetic predisposition (with HLA-DR2 and HLA-Dqw1, and first degree relatives of affected individuals

being eight times more likely to suffer from REM sleep disorders) (2). In severe cases, narcolepsy consists of a clinical tetrad: 1) sleep attack characterized by an irresistible urge to sleep for 5-20 minutes, 2) cataplexy (or an intrusion of REM atonia while awake), manifested as an abrupt muscle tone loss (total loss of whole body muscle tone) triggered by strong emotions such as anger (the patient may be fully awake, but is unable to move), 3) sleep paralysis, which is REM atonia at sleep-wake transition (when falling asleep or waking up) when the patient briefly cannot move, and 4) hypnagogic hallucinations in which dreams continue into the waking state resulting in illusions or hallucinations.

PSG is required for the diagnosis of narcolepsy. Treatment is symptomatic. Regular sleeping and rising times are recommended with scheduled naps 2-3 times a day. Psychosocial counseling and support are important as narcolepsy is a debilitating life-long condition once diagnosed. Stimulants maybe indicated by excessive daytime sleepiness. For treating cataplexy, tricyclic antidepressants and clomipramine have been successful.

Unlike intrinsic dyssomnias, extrinsic dyssomnias are due to external causes and includes protodyssomnias (an inability to fall asleep and stay asleep) of infancy and insomnias of childhood (2). Examples include night waking, and difficulty falling asleep. Predisposing factors include previous behavior reinforcement patterns, child temperament (e.g., ADHD), poor nutrition, milk allergy, marital dispute, and physical discomfort. Currently, it is not known whether these protodyssomnias progress to true dyssomnias later on (2). Individualized bedtime habits such as reading or playing a quiet game can also help.

Circadian rhythm dyssomnias are characterized by inappropriate timing of sleep. This is more likely to occur in adolescence when bedtime is pushed back later. The teenager then tries to make up for the lost sleep by sleeping long periods during the weekend. Thus, this irregular sleep pattern leads to biologic clock disruption over time resulting in circadian rhythm dyssomnias characteristic of delayed sleep phase syndrome. This syndrome presents with an inability to sleep and wake at a customary time, excessive daytime sleepiness, and many naps with no difficulty in maintaining sleep once asleep. Diary/sleep logs reveal irregular sleep times, and MSLT is helpful in quantifying sleep debt. Treatment consists of eliminating sleep debt and reinforcing appropriate bedtime and rise time. When supportive or behavioral therapy fails, chronotherapy is indicated. Chronotherapy (phase delay treatment) allows the biological clock to reset by delaying sleep and rising times by 2 hours each day until the time of sleep onset is shifted back to a more reasonable hour.

Unlike dyssomnias in which the sleep process is disrupted, parasomnias represent behavioral intrusions upon ongoing sleep. These behaviors are caused by CNS arousal, especially activation of motor and autonomic components. Parasomnias are more likely to occur in males than females, and a patient suffering from one parasomnia is likely to exhibit another. For example, a child with sleep terror may also experience sleepwalking. Parasomnias can be divided into the following categories: arousal disorders, sleep-wake transition disorders, REM parasomnias, and other miscellaneous parasomnias.

Arousal disorders include sleep terror disorder and sleepwalking. Arousal disorders occur at transition from NREM stage 4 to REM sleep, which usually occurs 1-3 hours after sleep onset. Problems occur when this normally smooth transition is characterized by autonomic activity. In sleep terror, the child typically sits up, screams, and has a glassy, unseeing gaze associated with autonomic symptoms of palpitations, diaphoresis, and irregular breathing. This lasts for about 1 to 5 minutes until the child calms down and continues to sleep. A child in this condition is difficult to wake up and appears disoriented and confused when he does awaken. Unlike nightmares, the child does not recall the incident or any dreams in the morning (15,16). Sleepwalking may accompany sleep terrors and can be dangerous. The body movements that occur during sleepwalking are purposeless and uncoordinated. Locking the doors and windows and installing alarms that alert the parents when the child rises from bed are some of the safety measures (17).

Sleep lab studies may not be helpful since arousal disorders occur sporadically. Rather, having the parents videotape the episode of attack can be more diagnostic. As daytime stress and fatigue are known precipitators of arousal disorders, they should be avoided. Short naps can reduce NREM stage 4 sleep which reduces the likelihood of sleep terrors. Benzodiazepines can reduce numbers of attacks but drug tolerance develops. In severe cases or if the onset occurs in adolescence, it is important to rule out sleep-related seizures.

Sleep-wake transition disorders occur at transitions between sleep and waking. Examples of this category of parasomnias are rhythmic movements, nocturnal leg cramps, and sleep talking. Rhythmic movements include head banging, sleep starts (defined as sudden muscle jerks at sleep onset that may involve the limbs, neck, or entire body), and body rocking that usually occurs at sleep onset for <15 minutes duration. Prevalence decreases with age, and generally, measures to prevent self injury are sufficient.

Nightmares are by far the most common of REM parasomnias. Onset occurs at 3-6 years of age and up to 50% of this age group experience nightmares severe enough to worry their parents. Nightmares are terrifying arousals from REM sleep associated with anxious dream reports. Unlike sleep terrors, a child with nightmares can recall the event well in the morning. Also, nightmares typically take place in the last third of sleep when REM sleep dominates compared to sleep terror occurrences in the first 1-3 hours after sleep onset (NREM stage 4) (18). Treatment of nightmares mainly focuses on providing comfort and reassurance during the incident and reducing daytime stress. Withdrawal from certain medications such as beta-blockers and other drugs that suppress REM sleep (including tricyclic antidepressants and alcohol) can also trigger nightmares.

There are many other miscellaneous parasomnias. But the two most common ones in children are sleep bruxism and sleep enuresis. Sleep bruxism is stereotypic mouth movements in sleep that results in teeth grinding. Dentists are usually the first one to notice this problem. Bruxism is strongly related to stress and strained emotions. Management consists of dental interocclusal appliances (to prevent enamel wear), behavioral therapies, and night alarms. Sleep enuresis, or bed wetting, is diagnosed in the absence of urologic, medical, or psychiatric conditions in children after 5 years of age.

In studying sleep in the younger age groups, one should consider the age related differences in sleep stages and their implications. During the 1st year of life, REM sleep associated with arousals is dominant. Thus, infants are more likely to suffer from dyssomnias with sleep maintenance. During the preschool years, NREM stages predominate. Because NREM arousal parasomnias more often occur at the transition from deep to REM sleep, these sleep problems are more commonly seen in the preschool to primary school years and tend to disappear by teenage years. Adolescents, on the other hand, are more likely to be sleep deprived due to increasing workloads from school, sports, and social activities and events. The disruption of regularly sleep schedules and decrease in total amount of sleep predispose them to circadian rhythm dyssomnias.

Here is a summary outline of the sleep disorders discussed so far:

A. Dyssomnias
   1. Intrinsic dyssomnias
      a. Breathing related sleep disorder
         1) Central (prematurity, Ondine's curse, etc.)
         2) Obstructive (large tonsils/adenoids, Pickwickian, Prader-Willi, etc.)
         3) Mixed
      b. Narcolepsy
   2. Extrinsic dyssomnias
      a. Infant protodyssomnia
      b. Childhood insomnias (psychosocial and physiologic stress)
   3. Circadian rhythm disturbances (adolescents)

B. Parasomnias
   1. Arousal disorders
      a. Sleep terrors
      b. Sleep walking
   2. Sleep-wake transition phenomena
      a. Sleep talking
      b. Nocturnal leg cramps
      c. Rhythmic movement disorders
   3. REM parasomnias
      a. Nightmares
   4. Miscellaneous parasomnias
      a. Sleep bruxism
      b. Sleep enuresis

Disturbed sleep related to neurologic disorders can be due to diverse causes such as headaches, seizures, mental retardation, and cerebral degenerative disorders. The severity of the sleep problem is correlated to the extent of the neurologic conditions. Psychiatric problems can also lead to night time wakings, nightmares, or difficulty going to sleep. Examples are emotional trauma, stress, separation anxiety, attention deficit hyperactivity disorder, conduct disorder, and Tourette's syndrome. In older children, generalized anxiety disorder and major depression can play a role also. Thus, in assessing sleep disorders, the physician must distinguish between primary causes and sleep disturbances related to other medical or psychiatric disorders.

Questions

1. Which of the following helps to distinguish sleep terror from nightmares?
   a. Child does not recall the incident in the morning.
   b. Child is diaphoretic upon awakening.
   c. Common sleep disorder to occur in childhood.
   d. None of the above.

2. In which of the following cases would PSG (polysomnographic recordings) not be as helpful?
   a. Narcolepsy
   b. Sleep terror
   c. Sleep apnea
   d. a & b

3. Which of the following is NOT a primary sleep disorder?
   a. Tourette's syndrome
   b. Sleep bruxism
   c. Rhythmic movement disorder
   d. Protodyssomnia of infancy

4. Describe the clinical tetrad of narcolepsy?

5. Describe at least two causes of obstructive sleep apnea and two causes of non-obstructive sleep apnea?

6. Circadian rhythm dyssomnias typically occur in which age group?

Answers to questions

1.a, 2.b, 3.a

4. Sleep attack, cataplexy, sleep paralysis, hypnagogic hallucinations

5. Obstructive: Tonsillar enlargement, Prader-Willi syndrome, Pickwickian. Non-obstructive: Prematurity, Ondine's Curse.

6. Adolescence

Chapter VIII.12. Sudden Infant Death Syndrome (SIDS)

Mary Elaine Patrinos, MD

A 2-1/2 month old male infant presents to the emergency department via ambulance in full arrest. The baby has been well until 3 days prior when he developed a mild upper respiratory tract infection. On the day he presents to the ED, his appetite has been somewhat decreased, but there are no other symptoms. His mother left him with the sitter in the morning before going to work. After a feeding, the sitter put him down to sleep. She checked him approximately 30 minutes later, because of the recent URI, and found him apneic, pale, mottled, and limp. She attempted CPR briefly and called 911. CPR and resuscitation standing orders were implemented in transport. The patient arrives intubated with an intraosseous infusion. Two doses of epinephrine have been administered so far.

Birth History: Born at term with a birth weight of 3.3 kg (7 lbs. 4 oz). Uncomplicated perinatal and neonatal course; normal spontaneous vaginal delivery. Discharged from the hospital with his mother on day of life 3.

Exam: VS T 35 degrees C (95 degrees F), pulse and respirations with CPR, BP 100/50 with CPR. The infant is pale, mottled and cyanotic.

Clinical Course: CPR and resuscitation drug protocols are continued; however after 30 minutes of resuscitation, there is no response to these measures and the infant is pronounced dead.

Sudden infant death syndrome (SIDS) is defined as the sudden death of an infant (<1 year of age) that remains unexplained after review of the clinical history, a complete autopsy (including skeletal survey, metabolic and infectious disease assessment, and toxicology investigation), and examination of the death scene. It is a diagnosis of exclusion often affecting previously healthy infants. Despite a recent decline in SIDS deaths, it remains the number one cause of post-neonatal infant mortality with an incidence of 0.7-0.8 per 1000 live births (1). The incidence peaks between 2 and 4 months of age with 90% of SIDS deaths occurring before the age of 6 months. The etiology is unknown, however a number of risk factors have been identified which include: prone sleep position, sleeping on a soft surface, co-sleeping, maternal smoking, overheating, lack of adequate prenatal care, young maternal age, prematurity and/or low birth weight, and male sex. African Americans and American Indians have SIDS rates which are 2-3 times the national average (2).

Many mechanisms have been proposed for SIDS, the most popular of which has been the apnea hypothesis. This theory assumes that infants with documented cardiorespiratory events are at increased risk of SIDS. It was this theory that prompted and has, to some extent, continued to support the long-standing use of home apnea monitors for certain high-risk patient populations such as preterm infants, infants with apparent life threatening events (ALTE), and siblings of SIDS victims. However, a recent study examining cardiorespiratory events in healthy term infants versus those at increased risk for SIDS demonstrated that preterm infants had the largest number of extreme cardiorespiratory events (apnea of at least 30 seconds and bradycardia of <60 bpm for >10 seconds) (3). By 43 weeks postconceptional age, the relative risk of having an extreme event was no longer significant in the preterm versus the full term group. Given the fact that the

incidence of SIDS peaks well beyond 43 weeks postconceptional age, it was concluded that prolonged apnea and significant bradycardia were not likely to be immediate precursors to SIDS.

It is currently believed that many mechanisms contribute to SIDS. A leading hypothesis maintains that many of these infants have an immature or abnormal arousal response. Postmortem examinations of the brainstems of infants dying of SIDS have revealed hypoplasia or decreased neurotransmitter binding of the arcuate nucleus. The arcuate nucleus is thought to be involved with the hypercapnic ventilatory response, chemosensitivity, and blood pressure regulation (2). Infants possessing this abnormality may be uniquely prone to central and cardiorespiratory depression resulting from hyperthermia, hypercarbia and hypoxemia during sleep. Death ensues due to failure of the arousal mechanism. This theory supports the notion of placing an infant in the supine (or non-prone) position during sleep, as prone positioning increases the likelihood of the nose and mouth becoming buried in the sleep surface.

Prior 1990, it was recognized that prone sleeping was one of several potential risk factors for SIDS (4). This association was strongly demonstrated in population based, case-control studies conducted in England, New Zealand and Australia. In 1992, the National Institute for Child Health and Human Development convened experts to deliberate on the potential relationship between prone sleeping and SIDS in the United States. Based on their opinion, the American Academy of Pediatrics (AAP) issued a recommendation that healthy newborns be placed on their side or back to sleep. In 1994 the "Back to Sleep" campaign was initiated to inform the public about the risks associated with prone sleeping. In the United States, the frequency of prone sleeping has declined from >70% to approximately 20% with a parallel decrease in the rate of SIDS by >40%. It has been demonstrated that non-prone positioning during sleep is beneficial to preterm/low birth weight infants as well as term infants (5). Current efforts are being made to target African Americans and other infant caregivers (sitters and daycare center personnel) with the "back to sleep" message as the incidence of SIDS still remains relatively high in these populations.

Another modifiable risk factor is the use of soft sleep surfaces and loose bedding (2). Polystyrene bead-filled pillows have been removed from the market. Pillows, quilts, comforters, sheepskins and porous mattresses pose additional risks particularly when placed under the infant. Although maternal smoking has been consistently identified in epidemiologic studies as a major risk factor for SIDS, changing behavior is difficult to accomplish. Bed sharing may pose an additional risk factor; the mechanisms of which include the presence of loose bedding, the possibility of the parent rolling onto the child, entrapment, and rolling of the infant to the prone position. The risk of SIDS associated with co-sleeping is significantly greater among smokers. No specific factors have been identified that are protective against SIDS.

There have been a number of other causes of infant death mistaken for SIDS, the most disturbing of which is infanticide (6). As the occurrence of cases of true SIDS decreases, the proportion of unexplained infant deaths attributable to fatal child abuse may be increasing. It is estimated that infanticide is the cause of 1% to 5% of cases identified as SIDS. In Great Britain, covert video surveillance revealed child abuse in 33 of 39 cases referred for evaluation of recurrent apparent life-threatening events (ALTEs). Intentional suffocation was observed in 30 patients. In addition, 12 out of 41 siblings of these patients had previously died suddenly and unexpectedly. Because autopsy findings cannot distinguish between deliberate asphyxiation and SIDS, certain circumstances should raise concern:

1. Previous recurrent cyanosis, apnea, or ALTE while in the care of the same person.
2. Age of death older than 6 months.
3. Previous unexpected or unexplained deaths of 1 or more siblings.
4. Simultaneous or nearly simultaneous death of twins.
5. Previous death of infants under the care of the same unrelated person.
6. Discovery of blood on the infant's nose or mouth in association with ALTEs.
7. Prolonged QT interval and short and medium chain acyl-CoA dehydrogenase deficiency (disorders of fatty acid oxidation) have also been identified in SIDS victims.

Managing the parents of the SIDS infant poses one of the greatest challenges to the health care provider. Most of these deaths occur at home. Parents are typically in shock, bewildered and very distressed. As in any infant death, guilt is often the prevailing response with the parent questioning what they could or should have done to prevent such a tragedy. Guilt is often compounded by anger and blame. The most appropriate professional response under these circumstances is to demonstrate compassion, empathy and support. It should be recognized that necessary medical questioning is likely to cause additional stress. Parental stress and feelings of guilt or paranoia have been further exacerbated by the professional and public awareness of infanticide as a contributing cause to sudden infant death. A SIDS training manual for emergency responders published by the Prince George's County, Maryland Police Department states the following "Do's" and "Don't's" which are equally relevant to the emergency department or primary care physician (7):

Do: Encourage the parent to be patient with him/herself and not expect too much.
Say you are sorry for what happened .
Allow the parents to express their grief as much as possible.
Reassure them that the child received the best care possible.

Don't: Tell the parents that you know how they feel.
Change the subject when the parent mentions their deceased infant.
Avoid mentioning the child's name.
Try to find something positive about the child's death.
Say the parent can always have another child.
Make comments that [previous] medical care may have been inadequate.

Parental anxiety and stress may be further heightened by naive and uninformed, yet well-intentioned family members. It is important to recognize that SIDS has a significant and life-long impact on parents and siblings, possibly leading to chronic emotional illness, divorce, or even suicide.

A recent AAP Policy Statement on SIDS, sleeping environment and sleep position states (2):

1. Infants should be placed for sleep in a nonprone position; supine preferred.
2. A crib that conforms to recognized safety standards is a desirable sleeping environment for infants.
3. Infants should not be put to sleep on waterbeds, sofas, soft mattresses, or other soft surfaces.
4. Avoid soft materials in the infant's sleeping environment.
5. Bed sharing or co-sleeping may be hazardous under certain conditions.
6. Overheating should be avoided.
7. Prone positioning is acceptable when the infant is awake and being observed so that issues related to development and positional plagiocephaly (head asymmetry and deformity) may be addressed.
8. Devices to maintain sleep position or to reduce the risk of rebreathing are not recommended.
9. Home monitors are available to detect cardiorespiratory arrest and may be of value for monitoring selected infants who have extreme cardiorespiratory instability. However, there is no evidence that such monitoring decreases the incidence of SIDS.
10. There is concern that the annual rate of SIDS appears to be leveling off as is the percentage of infants who sleep prone. Thus, the Back to Sleep campaign should continue and be expanded. Avoidance of maternal smoking, overheating, and certain forms of bed sharing should be included as important secondary messages.

In summary, although SIDS remains an enigma, it is reasonable to state that its etiology is multi-factorial and that an abnormal arousal response likely serves as the common denominator. The identification of a number of modifiable risk factors such as sleep position has effectively and dramatically reduced the incidence of SIDS through the application of prevention strategies. Other diagnoses, such as metabolic disorders, prolonged QT syndrome and infanticide account for a percentage of deaths mistaken for SIDS. Due to the unique nature of a SIDS death, sensitivity and compassion for parents and other caregivers is essential while thoroughly investigating the cause(s) of death.

Questions

1. True/False. Sudden Infant Death Syndrome has been nearly eradicated due to changes in infant positioning.

2. Which of the following disorders may mimic SIDS:
   a. galactosemia
   b. disorders of fatty acid oxidation
   c. maple syrup urine disease
   d. hypothyroidism

3. True/False. Co-sleeping is an acceptable practice if a mother is breast-feeding.

4. Infanticide should be considered in dealing with a SIDS death when:
   a. the parents are adolescents
   b. the infant is younger than 2 months of age
   c. previous ALTEs have occurred while under the care of the same person
   d. intrathoracic petechiae are present on post-mortem

5. True/False. Supine or non-prone positioning is beneficial in reducing the incidence of SIDS in infants born at <32 weeks gestation.

6. An appropriate response to a parent who has lost their child to SIDS is to:
   a. reassure them that they can always have another child
   b. use their infant's name often when speaking with them
   c. tell them you know how they feel
   d. speak critically about the previous medical management of their infant

7. True/False. Home cardiorespiratory monitors do not prevent SIDS.

Answers to questions

1.False, 2.b, 3.False, 4.c, 5.True, 6.b, 7.True

Chapter IX.1. Infant Colic
Rodney B. Boychuk, MD

This is a 20 day old newborn that is brought to the emergency department at 10 pm with a chief complaint of extreme fussiness. His parents think he has abdominal pain as he is "gassy" and pulls his legs up as if he is trying to stool. He passes a lot of gas from his rectum and his parents can hear his stomach gurgling a lot. Tonight's episode has lasted for 4 hours with intractable crying, and his parents are very distraught. They have tried feeding, a pacifier, rocking, burping, changing the diaper, and inserting a rectal suppository but nothing has relieved the crying. He is currently feeding a standard cow's milk formula with iron without vomiting or diarrhea. Further questioning reveals this is the fourth day in a row that this has happened on a daily basis, usually in the evening, but the baby usually cries for about 2 to 3 hours.

He was born at term with no prenatal problems or infection at time of birth. No maternal use of illegal drugs. He has been feeding well with good weight gain and no fussiness until 4 days ago (age 16 days of age). No apnea, no vomiting, no fever, no constipation, no seizure activity, no trauma or history of shaking or abuse. He has been acting normally between daily episodes of fussiness.

Exam: VS T 37.0, P 130, RR 32, BP 80/55, oxygen saturation 100% in room air. Height, weight and head circumference are at the 50th percentile. He is a healthy appearing infant who is not crying at this time. He is alert and active. HEENT: Soft fontanelle, good eye contact. No evidence of corneal abrasion or watery eyes. Vigorously feeding during exam. No signs of closed head injury. Neck, heart and lung exams are normal. His abdomen is soft and non-distended. There is no definite tenderness. Bowel sounds are active. He has no inguinal hernias. His testes are normal. No tourniquets are noted over his penis and digits. He is moving all extremities well and his muscle tone is normal. He has no pain on movement. Color and perfusion good. No pallor or mottling of his skin is present.

Diagnostic impression by the physician: Unexplained recurrent crying with normal physical examination. Unclear etiology.

Colic is one of the most commonly made diagnoses during the first 4 months of life with a reported incidence of 10% to 35% of all infants. The word "colic" is derived from the Greek word "kolikos", which refers to the large intestine. Colic has also been called the three month colic, infant colic syndrome, or paroxysmal fussing in infants. The classic definition of infantile colic was described by Wessel (1) in 1954 as, crying lasting more than 3 hours per day, 3 days per week, and continuing more than 3 weeks in infants less than 3 months of age. During these paroxysms, the legs are often flexed, the infant may be described as gassy, and parents often think the infant has abdominal pain. In addition, crying is not relieved by normal parental interventions (feeding, burping, changing diapers, etc.).

How much crying is normal? In 1962, Brazelton (2) published characteristics of the median daily crying at various ages: At 2 weeks of age: 1 hour and 45 minutes. At 6 weeks of age: 2 hours and 45 minutes. At 12 weeks of age: less than 1 hour. The peak time for crying is 3:00 pm through 11:00 pm ("prime time"). Infants whose crying significantly exceeds these median values could be labeled as having "colic"; however, this is also dependent on the parents' ability to cope with crying and as to whether they label their infant's behavior as "normal crying" or "abnormal crying" (i.e., colic) (2).

The four clinical signs of colic are: 1) paroxysmal onset, 2) distinctive high-pitched pain cry, 3) physical signs of hypertonia and 4) inconsolability (3). Colic presents as intermittent and unexplained crying during the first three months of life by babies that are otherwise healthy. The "infant colic syndrome" (paroxysmal fussing) basically involves cyclic discrete periods of intractable crying, usually on a daily basis, with onset at 1-4 weeks of age (may be as early as the first week of age) and dramatic spontaneous improvement by 3-4 months of age. In addition to infant irritability, colic is characterized by recurrent episodes, excessive restlessness or activity, or diminished consolability. Colic is distinguished in that the crying is paroxysmal, intense and different in type from normal fussing and crying.

The defining elements of colic, according to Carey (4) are: full force crying for at least 3 hours per day, for 4 or more days per week, in infants who are less than 4 months old and are otherwise healthy. The infant begins a colic episode with a paroxysmal or sudden onset of crying. The cry reaches a screaming level, is often high pitched and coupled with facial grimacing indicating that the infant is in severe pain. There is increased motor activity, which may include flexion of the elbows, clenched fists, and generalized hypertonicity of the musculature, with the knees drawn up or legs stiff and extended. Milder cases of "colic" may exist, but defining this would be difficult.

There is no clear understanding of the etiology, pathophysiology and treatment of colic; however, proposed models for the etiology of colic fall into 3 broad categories: intrinsic or biological factors in the infant, extrinsic factors in the psychosocial environment and an interaction or systems approach.

The most important thing to remember about infants who present with intractable crying is this: ALL THAT CRIES IS NOT COLIC! Crying is a non-specific response in an infant, which may be a major symptom of an underlying pathologic process. The etiologies of intractable crying in infancy range from a benign phase of psychomotor development to a life threatening illness. The etiology is initially obscure and an accurate diagnosis is dependent on a knowledgeable and organized approach. A careful history and physical exam with selected laboratory studies usually establishes a diagnosis.

Since most of these patients initially present to the emergency department, the emphasis is on the evaluation of the infant or young child with intractable crying, and one must exclude serious underlying illness. In Poole's 1991 study (5) in afebrile infants, those who ceased crying before or during the initial assessment were unlikely to have a serious underlying illness, whereas the persistence of excessive crying after the initial examination was predictive of a serious underlying process. Therefore, do NOT discharge an infant or young child with persistent, excessive crying. Look for "red flags" in the history and physical, which suggest the possibility of significant underlying pathology (see Tables 1 and 2). The presence of any of these "red flags" should prompt a more extensive evaluation and aggressive management, often including specialty consultation and hospitalization (e.g., meningitis or sepsis).

Robert Bolte (6) has described "Red Flags" of non-colic causes of extreme fussiness, which may be signs or symptoms of life threatening illness, obtained by further history or physical examination. ANY OF THESE RED FLAGS SUGGEST NON-COLIC ETIOLOGIES OF FUSSINESS and must lead to extensive evaluation and aggressive management (Tables 1 and 2) (6). Do not make a diagnosis of colic on patients with any of these historical or physical examination "red flags" until other causes listed under "differential diagnosis" (Table 3) are ruled out.

Table 1 - Historical "Red Flags" Associated with Intractable Crying in Infancy (6)

1. Fever (>38 degrees C, 100.4 degrees F, rectal) in an infant less than twelve weeks of age.
2. Paradoxical irritability (infant doesn't want to be held).
3. Premature rupture of membranes (>24 hours), perinatal maternal fever/infection, neonatal jaundice.
4. Maternal drug use.
5. Poor feeding, poor weight gain.
6. Significant decrease in level of activity, cyanotic/apneic "spell", or seizure-like episode.
7. Bilious or projectile vomiting.
8. History not suggestive of classical "infant colic syndrome".
9. History suggestive of physical abuse (injury not consistent with reported history, inappropriate delay, non-maternal caretaker).
10. Antibiotic pre-treatment ("partially treated" sepsis/meningitis), particularly in the young infant.
11. History of recent head trauma.

Table 2 - Physical Examination "Red Flags" Associated with Intractable Crying in Infancy (6)

1. Fever (>38 degrees C, 100.4 degrees F, rectal) in the infant less than twelve weeks of age.
2. Hypothermia.
3. Heart rate >230.
4. Lethargy, poor eye contact.
5. Paradoxical irritability.
6. Pallor, mottling, poor perfusion, weak pulse.
7. Hypotonia, jitteriness, poor feeding.
8. Petechiae, ecchymoses.
9. Meningismus, full fontanel, head circumference >95%.
10. Retinal hemorrhages, signs of basilar fracture/closed head injury.
11. Tachypnea, retractions, nasal flaring, cyanosis.
12. Abnormal extremity movement (hip, etc.).
13. Abdominal tenderness/mass.
14. Bloody stool (not just external streaks).
15. Bilious or projectile vomiting.
16. Weight less than the fifth percentile for age.

Table 3 - Differential diagnosis of Infant Colic Syndrome(6):

I. Infectious
   1) otitis media
   2) meningitis/sepsis
   3) encephalitis
   4) urinary tract infection
   5) osteomyelitis, septic arthritis
   6) pneumonia
   7) gingivostomatitis, pharyngitis
   8) gastroenteritis
   9) Kawasaki Disease

II. Trauma
   1) child abuse - shaken baby
   2) corneal abrasion or foreign body in eye
   3) accidental fracture/musculoskeletal injury

III. Gastrointestinal/Genital
   1) intussusception
   2) reflux esophagitis (GERD)
   3) constipation/anal fissure
   4) midgut volvulus
   5) incarcerated inguinal hernia
   6) appendicitis
   7) milk protein intolerance
   8) testicular torsion
   9) penile tourniquet (from hair)

IV. Nutritional
   1) underfeeding

V. Respiratory
   1) hypoxemia/hypercapnia

VI. Metabolic
   1) hyponatremia, hypernatremia
   2) metabolic acidosis
   3) hypocalcemia/hypercalcemia, hypoglycemia, hyperglycemia
   4) inborn errors of metabolism

VII. Integument
1) diaper dermatitis
2) atopic eczema
3) burns (accidental and non-accidental)
4) foreign body (pin)
5) hair encirclement (strangulation of digit, penis, clitoris, uvula) diagnosed by a thorough physical exam
6) bites and stings

VIII. Drugs and Toxins
1) neonatal narcotic withdrawal
2) neonatal barbiturate, ethanol, hydantoin withdrawal
3) irritability related to smoking mothers who breastfeed
4) reaction to pertussis immunization
5) theophylline, antihistamine, decongestant, cyclic antidepressant, amphetamine, cocaine toxicity

A thorough history and a meticulous physical exam are the cornerstones of accurate diagnosis. Poole (5) described 56 afebrile infants who presented with unexplained excessive crying to the emergency department. The history provided clues to the final diagnosis in 20% of the cases, while the physical exam revealed the final diagnosis in 41% of the cases and provided clues to the final diagnosis in another 11%. Physical examination must start with a 2 or 3 minute period of observation from a distance with the child undressed, on the parent's lap. Assess the patient's appearance, distractibility, alertness, eye contact, ability to be comforted, respiratory rate and pattern, spontaneous extremity movement, etc. The extent of your work-up is usually determined from this observation period. Special emphasis should be given to the examination of the skin, palpation of the abdomen, eye examination (with funduscopic and eversion of the eyelids), evaluation of anterior fontanelle fullness, inspection of the tympanic membranes, oropharynx, and gums, palpation of extremities and clavicles, and performance of an anal rectal exam which may be done with a cotton tip swab.

If colic is determined to be the likely diagnosis, there have been a number of studies with varying results regarding treatment:

1. Taubman's (7,8) behavior-modification approach provides useful information for counseling parents (Table 4). His behavior-modification approach resulted in a 65-70% decrease of crying time (3.2 to 1.1 hours per day) in colicky infants in his 1984 and 1988 studies and a similar reduction in the crying time (3.8 to 1.1 hours per day) in a 1998 controlled study by Dihigo (9). This "good" approach assumes that colic results from inadvertent failure to respond to the infant's desires. The infant's crying is not a "cry of pain" but rather a way to communicate a need or desire. Taubman also described a "bad" approach (ignoring the baby) which assumes colic that results from over stimulation, therefore generally "ignoring" the baby (letting them cry) would be the logical treatment. The ignoring approach did not result in any decrease in the crying time in Taubman's 1984 study.

2. Simethicone (Mylicon, OTC) (10) (a non-toxic "defoaming" agent). The apparent effectiveness of simethicone (seen within 1-4 days in 54-67% of treated infants) probably represents a high-grade placebo effect. Simethicone converts gas foam into non-foam gas, but the gas remains in the bowel lumen.

3. Herbal tea (commercially available chamomile tea). Weizman, et al (11) showed that 57% of colicky babes improved (vs. 26% placebo), 5 oz. tea per dose with each colic episode not to exceed three times per day.

4. General counseling (6,7,12,13,14). Empathy and describing the natural history of colic to parents results in improvement by 3-4 months. Increased carrying time, automatic rocker swings, driving around the neighborhood (with baby in a car seat) and nap-time swaddling are benign measures that may be helpful.

Paregoric (tincture of opium), Bentyl (dicyclomine, possible association with SIDS) and Levsin (hyoscyamine sulfate, associated with anticholinergic toxicity) should NOT be used (6). Placing the infant in a car seat on the washing machine should NOT be used because of the possibility of falls and secondary head injury (6). Empiric formula changes are generally not useful, but this is a benign measure and it is often suggested. Mothers who are breast and bottle feeding should be encouraged to breast feed as much as possible and minimize formula feeding. Infants who are exclusively formula fed can be changed to a protein hydrolysate formula (Nutramigen, Pregestimil, Alimentum), as a trial to see if there is a beneficial response.

Table 4 - Good Colic Advice" for Parents: The underlying assumption of this advice is that continued crying in colicky infants results from the parents' inadvertent failure to respond to their infant's desires which the cries are signaling to the parents. The infant's crying is not a "cry of pain" but rather a way to communicate a need or desire.

1. Try to never let your baby cry.
2. In attempting to discover why your infant is crying consider these possibilities:
   a. The baby is hungry and wants to be fed.
   b. The baby wants to suck, although he/she is not hungry.
   c. The baby wants to be held.
   d. The baby is bored and wants stimulation.
   e. The baby is tired and wants to sleep.
   f. The baby needs his/her diaper changed.
3. If the crying continues for more than 5 minutes with one response, then try another.
4. Decide on your own in what order to explore the above possibilities.
5. Don't be too concerned about overfeeding your baby.
6. Don't be too concerned about spoiling your baby.

When infant crying continues despite all efforts to stop it, including feeding, do the following:

1. Put the baby in the crib and let him cry for up to one-half hour.
2. If still crying, pick the baby up for a minute or so to calm him/her then return him/her to the crib.
3. Repeat the above until the infant falls asleep or three hours have passed.
4. After three hours, feed the baby.
5. Do not shake the baby.

In summary, it is important to remember that crying is a non-specific response in an infant, which may be a major symptom of an underlying severe pathologic process and NOT necessarily just "colic." A careful history and examination combined with selected

laboratory studies usually establishes a diagnosis. Crying may simply be a normal response to stress such as hunger, discomfort, or over or under-stimulation, or may represent the "infant colic syndrome" (paradoxical fussiness). Close follow-up is crucial if the etiology of the irritability and excessive crying is still somewhat obscure at discharge. Do not discharge an irritable infant if "extreme fussiness" has not resolved, particularly if a "red flag" is present.

Questions

1. Which of these are NOT a feature of the infant colic syndrome?
    a. distinctive high-pitched pain cry
    b. inconsolability
    c. paroxysmal onset
    d. vomiting

2. Which of these is correct?
    a. colic usually occurs in infants greater than 3 months of age
    b. fever often accompanies colic
    c. colic is very rarely seen
    d. none of the above are correct

3. All of the following are correct regarding historical red flags, except:
    a. Red flags suggest that this intractable crying infant may not be due to the classic "infantile colic syndrome".
    b. Red flags include head trauma.
    c. Red flags exclude maternal illicit drug use.
    d. Red flags include paradoxical irritability.

4. Physical red flags include which of the following (check all that apply):
    a. fever
    b. lethargy
    c. poor feeding
    d. abdominal tenderness

5. True/False: Good advice for parents assumes their infant is trying to communicate a need or desire resulting from the parents inadvertent failure to respond to their infant's desires.

6. An acceptable approach(es) to infant colic include(s):
    a. Let the baby cry and ignore the baby.
    b. Put the baby in a car seat on the washing machine.
    c. Shake the baby to sleep.
    d. Try to discover why your infant is crying.

Chapter IX.2. Abdominal Pain
Walton K.T. Shim, MD

This is a 6 year old female presenting with a 2 day history of crampy abdominal pain. The pain is located in the upper mid-abdomen and is associated with anorexia, nausea and four episodes of green vomitus. She appears to be weak and her parents noticed a decrease in urination. There is no history of diarrhea, trauma, fever or coughing. She has not passed any stools for the two days that she has been ill.

Her past history is significant for an appendectomy one year ago. Her family history is negative for other family members with similar problems.

Exam: VS T 37.0, P110, R 12, BP 100/60. She is alert and subdued. She moves without difficulty but cries episodically because of crampy pain. Her mucous membrane are sticky. Her eyes are sunken. Her neck is supple. Her heart and lungs are normal. She has a RLQ (McBurney's point) scar. She has moderate abdominal distention with hyperactive bowel sounds, peristaltic rushes and borborygmi with generalized mild tenderness. She has no inguinal hernias and her external genitalia are normal. A rectal exam finds no stool or mass. Her back is non-tender. Her skin turgor is decreased, but her overall color and perfusion are good.

CBC: WBC 14.0, Hgb 16, Hct 48, Na 132, K 3.0, Cl 90, bicarb 30. Urinalysis: SG 1.030, no pyuria or hematuria. Abdominal series radiographs show distended ladderlike small bowel with large air/fluid levels and no large bowel gas. No calcifications. Lung bases are normal.

Impression: Small bowel obstruction secondary to adhesions; dehydration, metabolic alkalosis and hypovolemia.

Abdominal pain is a common symptom of childhood. Its importance lies in differentiating the vast majority self-limited causes of pain from those few conditions that may be life threatening. In the latter category are those conditions that lead to a diagnosis of an "acute abdomen," usually leading to surgical intervention. Examples of these in children are most commonly acute appendicitis followed by incarcerated inguinal hernias, bowel obstruction, traumatic injury, ovarian torsion, pancreatitis, and biliary disease. Further complicating the diagnosis is the young child's relative inability to communicate and his/her inability to evaluate the abstract concept of pain.

In general, it is helpful to classify abdominal pain into two large categories: 1) pain originating in a hollow viscus, and 2) pain originating in a solid organ or the peritoneum.

Hollow viscus pain such as that of an the obstructed ureter, intestine, and gallbladder is colicky or spasmodic in nature. It coincides with the peristaltic waves of the organ as it attempts to overcome the distal obstruction such as ureteral or cystic duct stone or a fecal bolus in constipation. These waves or cramps are exactly what we experience with early acute appendicitis and gastroenteritis and are somewhat ameliorated by writhing and massage.

On the other hand peritoneal and solid organ pain such as caused by infection or trauma is aggravated by motion caused by coughing, abdominal compression, and walking. It is usually unrelenting or steady.

The search for the cause of abdominal pain is a good example of both inductive and deductive reasoning. In gathering data, a complete history and physical examination should suggest a disease process, a hypothesis or diagnosis (induction) which in turn should suggest a search for confirmative or corroborative data to strengthen or disprove the diagnostic hypothesis (deduction).

In evaluating the case above using inductive reasoning, the symptoms of crampy mid-abdominal pain, bilious vomiting, and history of prior abdominal surgery, suggest a hypotheses of bowel obstruction. If it is intestinal obstruction, an abdominal series should show an obstructive pattern (deduction).

It could be ureteral colic but this is uncommon in children and there is no blood in the urine indicating that a ureteral stone is unlikely. It could be biliary colic but this is rare in children and the pain distribution is not that of biliary pain. It could be a gynecological problem but this girl is prepubertal, and ovarian torsion frequently presents in the lower quadrant and radiates to the anterior thigh.

With a bowel obstruction, there may be bowel infarction. If there is gangrene by deduction there should be an elevated WBC, absent bowel sounds, marked tenderness, and localization of pain. Since none of these findings is present, bowel compromise (infarction) is unlikely.

The following data suggest dehydration by induction: urine specific gravity of 1.030, history of infrequent urination, sticky (dry) mucous membranes, sunken eyes and weakness.

In addition to peritoneal and hollow viscus pain, there is pain of neural origin. Nerve root compression by spinal cord tumors are rare but must be suspected if no other cause for the discomfort can be found and if the pain distribution is that of a dermatome. There should be no tenderness to palpation, but there may be hypesthesia.

Inflammation of the pleura from a pneumonic process in the distribution of the lower thoracic nerves is not an infrequent cause for referred abdominal pain and should be a reason for auscultation of the chest in a search for pneumonia or pleurisy. The abdominal series includes the lung bases and should be noticed when evaluating abdominal films. Lower lobe pneumonia can frequently be seen in the lung portions of an abdominal series, and it is very frequently overlooked since the clinician is usually focusing on the abdominal structures.

Diabetic acidosis, lupus erythematosus, porphyria, and other systemic illnesses may cause pain and inflammation of the serous surfaces (serositis). Some non-surgical causes of abdominal pain are lactose intolerance, inflammatory bowel disease, intussusception (sometimes requires surgery), Henoch-Schonlein purpura, ascariasis and acute gastroenteritis. Of help in the diagnosis of many of the non-surgical diseases is their chronicity or recurrence. Of course, the first occurrence of the symptoms is always more difficult to sort out.

Constipation is a common cause of chronic, recurrent and acute abdominal pain of varying degrees of severity. Relief after an enema is characteristic, but some cases are associated with more serious GI pathology, since the presence of constipation does not rule out the presence of something else, such as appendicitis.

As with most rules of thumb or generalizations there are exceptions that the clinician should keep in mind. One of these is that appendiceal pain always occurs in the right lower quadrant since the appendix is located there. However, since it is 6-13 cm long, its inflamed tip may come to rest anywhere in a radius of 6-13 cm from its base. This means that tenderness may be produced in the right upper quadrant, the midline, or in the suprapubic region. Similarly, if it is retrocecal so that it has no contact with peritoneum, the child may not exhibit severe tenderness. In its retrocecal position however, it may rest on the right psoas muscle and cause pain with active right hip flexion. If it lies on the right ureter, hematuria and pyuria may be produced.

Malrotation of the cecum may lead to all sorts of additional presentations for acute appendicitis. However, the astute clinician should keep in mind that rare things occur rarely and that when you hear hoof beats they are most likely horses and not gazelles or camels (in North America anyway).

The examiner of children must realize that most children wish to please, so that a child brought in the middle of the night to the hospital may feel obligated (obliged) to its adult caregivers and nighttime physicians to show cause for such concern. Thus, when asked if their tummy hurts, they may be inclined to answer affirmatively to justify the trip and trouble.

Similarly, older teenage boys with a macho image to uphold, may hesitate to admit pain and/or tenderness. It is a useful ploy to engage the child/teen in conversation about his or her dog, siblings or other familiar childhood topics while depressing the abdominal wall. Any true tenderness will be confirmed or refuted by involuntary guarding or its absence. A useful technique is to ask the child to cough while asking what he or she feels. This ploy will direct attention away from the abdomen but almost always elicits peritoneal discomfort if present.

Persistence and constancy of a sign heightens its importance in diagnosis. Tenderness should be reproducible. Sensory innervation of the intestines is via the ninth through eleventh thoracic nerve roots. Consequently pain from the intestines due to stretching is appreciated as originating from the mid-abdomen until an inflammatory process localizes it in the dermatome of the parietal peritoneum. There are several areas of referred pain which, when present, may suggest a specific entity. Radiation of flank pain into the groin and ipsilateral scrotum or labium suggests ureteral colic. Lower quadrant pain radiating to the anterior thigh should suggest torsion of the ipsilateral ovary and tube. A point of pain in either shoulder indicates subdiaphragmatic irritation from blood or pus. Right upper abdominal pain radiating around to the back suggests biliary tract involvement but epigastric pain radiating through to the back suggests a pancreatic origin.

The use of specific diagnostic tests should be guided by the clinical examination and evaluation. They should not be a substitute for such evaluation and should not precede the clinical examination since the clinical appraisal may obviate the need for additional tests. Plain film radiographs, ultrasound, computerized axial tomography (CAT scan), magnetic resonance imaging (MRI), and contrast studies may aid in the evaluation of abdominal pain but should be used judiciously. The flat and upright plain film radiographs can be particularly useful in recognizing small bowel obstruction, ileus, abnormal calcifications and lower lung pathology.

In summary, acute abdominal pain is a common childhood complaint. In most instances it usually passes without much interruption of the events of daily living. However, abdominal pain can also signal severe illness leading to serious morbidity and death if not attended to. Thus, separating the chaff from the wheat is extremely important. Persistence of pain associated with vomiting, dehydration and signs of inflammation should not be ignored, but should stimulate a thorough evaluation. The use of both inductive reasoning to formulate a hypothesis for the cause of the pain followed by deductive reasoning to confirm the hypothesis is the basis for identifying the correct diagnosis.

Questions

1. True/False: Surgical causes of abdominal pain are much less common than non-surgical causes.

2. True/False: Predicting a finding from a hypothesis is called deductive reasoning.

3. What characteristics differentiate hollow viscus from solid viscus and peritoneal pain?

4. Pain from distended intestines is appreciated in what area?

5. Where is the pain of urogenital origin referred?

4. Mid-abdomen
5. Flank, groin and ipsilateral scrotum or labium

Chapter IX.3. Gastroenteritis and Dehydration
Sherloune Normil-Smith, MD

An 18 month old male is brought to the emergency department with a chief complaint of diarrhea and vomiting for 2 days. His mother describes stools as liquid and foul smelling, with no mucous, slime or blood. He reportedly is unable to keep anything down, vomiting after every feeding, even water. He has about 6 episodes of diarrhea and 4 episodes of vomiting per day. His mother reports that he is not feeding well and his activity level is decreased. He seems weak and tired. He has a decreased number of wet diapers. He attends daycare during the day when he is well. His last weight at his 15 month check up was 25 pounds (11.4 kg).

Exam: VS T 37.0, P 110, RR 25, BP 100/75, weight 11.3 kg (40th percentile). He is alert, in mother's arms, crying at times, and looks tired. HEENT: anterior fontanel closed, minimal tears, lips dry, mucous membranes tacky, no oral lesions or erythema, TMs normal. His neck is supple. Heart exam reveals mild tachycardia, no murmur. Lungs are clear. His abdomen is flat, soft, and non-tender with hyperactive bowel sounds. Testes are descended, non-swollen, non-tender. His diaper is dry. He moves all his extremities. No rashes are present. His capillary refill time is less than 3 seconds and his skin turgor is slightly diminished.

He is given 40 cc/kg of IV normal saline over two hours in the emergency department, but when given 30 cc of fluid to drink in the ED, he is unable to hold this down and he passes another large diarrheal stool. He is then hospitalized for further management.

Acute gastroenteritis is an ailment that is very common among children. During the first 3 years of life, a child will likely experience about 1 to 3 acute diarrheal illnesses. Diarrhea is defined as an increase in fluidity and volume of feces. Nearly all diarrheal infections are transmitted via the fecal-oral route. Many bacterial etiologies are also food borne.

When evaluating a child with diarrhea and/or vomiting, several important points and observations in the history and physical can help to assess severity and determine its etiology and pathogen involved. Information on the number, volume, and/or fluidity of stools and emesis should be obtained (1). However, this can be rather cumbersome if the number of episodes is large since recording the volume of each stool and emesis is unrealistic and not very helpful clinically, once the number of episodes exceeds 5 to 10. A history of fever, blood or mucus in the diarrhea, foul odor to the diarrhea, a large quantity of diarrhea or diarrhea for a prolonged duration are suggestive of a bacterial etiology. Diarrheal "mucus" is not something that is intuitive to most parents. The best question to ask is whether they have noticed any slimy, gooey, gelatinous, or mucous-like material in the diarrhea. The presence of mucus in the diarrhea is generally indicative of sheets of white blood cells in the diarrhea. The vomiting history should determine whether the vomitus is bilious or bloody (i.e., red or brown) and whether this is associated with abdominal pain. Parents will often convey that the vomitus contains mucus, but unlike the mucus in diarrhea, this is normal gastric mucus that is not helpful clinically. Other important historical items include: weight loss, dietary (intake) history, ill contacts and travel history. The physical exam should focus on signs of dehydration, conditions that may suggest an acute surgical condition and other systemic conditions which may cause these symptoms. The differential diagnosis of vomiting is extensive including systemic conditions such as meningitis, increased intracranial pressure, heart failure, pneumonia, urinary tract infection and many acute surgical conditions such as appendicitis, intussusception, midgut volvulus, etc. The differential diagnosis of diarrhea is more limited and is most often due to gastroenteritis.

Many organisms can cause acute infectious diarrhea and vomiting. These include bacteria, viruses, and parasites. Bacterial etiologies include: Campylobacter, E. coli, Staph aureus, Salmonella, Shigella, Vibrio, Yersinia and a few others. Viral gastroenteritis is by far more common. Amebic and parasitic etiologies are not very common in the United States, but such cases are treatable, making the identification of the pathogen essential.

Lab tests available include: CBC, stool Wright stain, stool culture, stool Rotazyme, serum electrolytes and glucose. In most instances, no laboratory studies are required. A CBC might raise the clinical suspicion of a bacterial etiology if a very high band count is present; however, this may also occur in viral etiologies, therefore it is not very helpful in most instances. A positive stool Wright stain identifies WBCs in the stool. This is suggestive of a bacterial etiology (similar to the history or observation of mucus in the stool), but since it is unable to determine the specific pathogen, it does not help clinicians in determining whether antibiotics are indicated. Thus, in most instances of gastroenteritis, a Wright stain is not helpful. A stool culture can be obtained by swabbing a diarrhea sample or by inserting a swab into the rectum, then rotating it to obtain organisms from the rectal mucosal surface. This latter method is called a rectal swab and it has a higher yield for identifying enteric pathogens, which are more likely to be found on the rectal mucosal surface than in the diarrhea itself. Thus, if a stool culture is to be obtained, it should be done via a rectal swab. A stool Rotazyme is a rapid test which identifies the presence of rotavirus in the diarrhea. A positive Rotazyme negates the need for a stool culture and antibiotic therapy. Serum electrolytes and glucose may be helpful in determining the degree of electrolyte imbalance, metabolic acidosis and hypoglycemia.

Campylobacter

Campylobacter is a major cause of diarrhea in the world. Many species have been identified as enteropathogens, but C. jejuni and C. coli are the two predominant species causing acute diarrhea in humans. C. jejuni is the most commonly documented bacterial cause of diarrhea. Transmission occurs by the fecal-oral route, through contaminated food and water or by direct contact from infected animals and people. The main source of C. jejuni and C. coli infection in humans is poultry, although dogs, cats, and hamsters are also potential sources. Outbreaks of diarrhea caused by C. jejuni and C. coli have been associated with consumption of undercooked poultry, red meat, unpasteurized milk and contaminated water. In industrialized nations, C. jejuni mainly affects children younger than 5 years of age, and individuals 15-29 years old. In temperate climates, infections occur mostly during the warm months, and in tropical climates, the incidence is greater during the rainy season. Prodromal symptoms begin after an incubation period of 1-7 days. These include fever, headache, chills and myalgia. Diarrhea accompanied by nausea, vomiting, and crampy abdominal pain occurs within 24 hours. Stools vary from loose and watery, to grossly bloody. Abdominal pain affects more than 90% of patients older than 2 years, and if severe enough, may mimic appendicitis. The clinical presentation may also mimic inflammatory bowel disease. Gradual resolution is to be expected, but in 20% of cases, diarrhea can last longer than 2 weeks. The variation in clinical presentation of Campylobacter diarrhea makes clinical diagnosis difficult. In order to differentiate it from other causes of colitis such as Salmonella, Shigella, E. coli 0157:H7, one has to rely on microbial diagnosis (2).

Rehydration and correction of electrolyte abnormalities are the mainstay of treatment. The use of antimicrobial therapy remains a controversial issue since resolution without antibiotics usually occurs, but early initiation of antibiotic therapy can shorten the duration of infectivity (i.e., the excretion of the organisms), and the duration of symptoms. Erythromycin is the antibiotic of choice for the treatment of C. jejuni enteritis. Since it is not possible to reliably identify Campylobacter as the etiology prior to a positive culture, erythromycin is

generally not prescribed until several days after a culture has been obtained. A notable exception might be when diarrhea develops in a contact of an individual who was known to have Campylobacter gastroenteritis.

C. jejuni has also been associated with septicemia, abortion and Guillain-Barre syndrome. C. pylori, now called Helicobacter pylori, does not cause diarrhea, but is associated with peptic ulcer disease. C. fetus rarely causes diarrhea, but is recognized as a cause of fever, bacteremia in immunocompromised hosts, and spontaneous abortion.

Escherichia coli

E. coli is one of the most common causes of bacterial diarrhea in humans worldwide. Normal bowel flora consists mostly of E. coli; however, some strains of E. coli are pathogenic. Several categories of E. coli cause diarrhea: EHEC (enterohemorrhagic), ETEC (enterotoxigenic), EIEC (enteroinvasive), EPEC (enteropathogenic), and EAEC (enteroaggregative).

EHEC causes a hemorrhagic colitis syndrome manifested by bloody diarrhea without fever. Illness is characterized by abdominal pain with diarrhea that is initially watery, but becomes blood streaked or grossly bloody. E. coli O157:H7 has most commonly been associated with this syndrome, which can also be caused by other strains of EHEC which produce large quantities of a potent cytotoxin. The cytotoxin produced by E. coli is called Verotoxin 1, and is virtually identical to the shigatoxin. Unlike shigellosis or EIEC disease, fever is uncommon in this diarrheal illness. The strains of E. coli producing this potent cytotoxin, are important because 5% to 8% of symptomatic patients go on to develop hemolytic uremic syndrome (HUS).

ETEC typically causes explosive diarrhea, accompanied by nausea, vomiting, abdominal pain, with little or no fever. Symptoms resolve in a matter of days, but these organisms can have a major effect on the hydration status of infants. ETEC is often responsible for the syndrome of "traveler's" diarrhea, since it is more common in non-industrialized countries (note the "T" in enteroToxigenic and Traveler's).

EIEC causes a dysentery-like illness or watery diarrhea caused by an enterotoxin called the EIEC enterotoxin. This illness is clinically indistinguishable from shigella dysentery, and is characterized by fever, abdominal pain, tenesmus, watery or bloody diarrhea.

EPEC rarely causes diarrhea in older children and adults, but has been incriminated in sporadic and epidemic diarrhea in infants and children in the first 2 years of life. This can be remembered as pediatric diarrhea (note the "P" in enteroPathogenic and Pediatric). The diarrhea is non-bloody, and contains mucus. These organisms can cause prolonged diarrhea, especially in the first year of life, a feature that in not shared by the ETEC, EIEC, or EHEC.

EAEC have been associated with acute and chronic diarrhea in developing countries. They can cause significant fluid losses. Like EPEC, these organisms can cause a prolonged diarrhea, and severe abdominal pain, lasting 2-4 weeks.

Management of fluid and electrolyte losses should be the focus of treatment. Early refeeding (within 8-12 hours or initiation of rehydration) should be encouraged, because a prolonged delay in feeding can lead to chronic diarrhea and dehydration. The decision to treat with antibiotics is difficult, because of the lack of a rapid diagnostic test. EPEC and ETEC respond well to treatment with trimethoprim-sulfamethoxazole, but antimicrobial treatment of EHEC organisms may increase the risk of hemolytic uremic syndrome (1). Thus, it is preferable to withhold antibiotics until a culture proven etiologic indication for antibiotics is determined.

Staphylococcus aureus

S. aureus is a major cause of food poisoning. Symptoms begin within 1-6 hours after ingestion contaminated with preformed S. aureus heat-stable enterotoxins. Symptoms include nausea, vomiting, abdominal pain, diarrhea without fever, and last less than 12 hours (1).

The term "food poisoning" describes a phenomenon in which bacterial contamination of food results in toxin production by the bacteria. This toxin ingestion is what causes the acute symptoms. Typically, the onset after exposure is rapid (i.e., no incubation period is required) and resolution is relatively rapid. Food poisoning should be distinguished from food borne infection, in which the latter is due to contamination of food which is ingested and symptoms develop several days later after a period of incubation.

Salmonella

Salmonella is one of the most frequently reported causes of food borne outbreaks in the United States. Three main species are identified: S. cholerae-suis, S. typhi (known as typhoid), and S. enteritidis. Salmonella gastroenteritis occurs throughout life, but is most common in the first year of life. Many outbreaks of S. enteritidis have been associated with ingestion of contaminated eggs. For clinical disease to occur, 10,000 to 100,000 viable organisms must be ingested. The incubation period for salmonella gastroenteritis is 6 to 72 hours. The major virulence trait of salmonella species, especially S. typhi, is their ability to invade the intestinal epithelium. Nontyphoidal salmonella can also display this trait, but most are associated with watery diarrhea. Salmonella causes several clinical syndromes: 1) acute gastroenteritis, 2) a subacute or prolonged carrier state, 3) enteric fever, bacteremia or both, and 4) dissemination with localized suppuration (i.e., abscesses), osteomyelitis, or meningitis (3).

The most common manifestation of disease caused by salmonella is gastroenteritis. The most prominent symptom is diarrhea, which is usually self-limited, lasting 3-7 days. However, the diarrhea can range from a few stools, to profuse bloody diarrhea to a cholera-like syndrome. Abdominal cramps and fever are usually present (3).

The diagnosis is made by stool culture. Antimicrobial agents such as ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole and some third generation cephalosporins can be used in patients with severe and progressing disease. Initiation of empiric antibiotic treatment is not indicated unless: 1) the infant is very young, 2) the patient is immunocompromised, or 3) sepsis or disseminated infection is suspected.

Shigella

Infection by shigella is rare in the first 6 months of life, but is common between 6 months and 10 years, and is most common in the 2nd and 3rd year of life. There are 4 major serogroups of Shigella: S. sonnei, S. flexneri, S. boydii, and S. dysenteriae. S. sonnei and S. flexneri are more common causes of diarrhea in the U.S. and Europe. Infection occurs mostly during the warm months in temperate climates, and during the rainy season in tropical climates. Transmission is mainly via person-to-person contact and by contamination of food and water. Only a small inoculum of shigella is required to cause illness (as few as 10 organisms). After ingestion, an incubation period of 12 hours to several days follows, before the development of symptoms. Shigella organisms invade the epithelial cells of the colon, causing colitis. Infected individuals may present with: 1) asymptomatic excretion, 2) enterotoxin-like diarrhea, 3) bacillary dysentery (bloody diarrhea), 4) arthritis similar to Reiter's, 5) HUS after infection with S. dysenteriae (1).

Diarrhea is initially watery and of large volume, and develops into frequent small volume, bloody and mucoid stools. Other clinical features include, vomiting, severe abdominal pain, high fever, and painful defecation. As many as 40% of children with bacillary dysentery will develop neurologic findings. Seizures, headache, confusion, lethargy, and/or nuchal rigidity may be present before or after the onset of diarrhea. In very young and malnourished patients, sepsis and disseminated intravascular coagulation can develop as complications. When sepsis occurs, the mortality rate is high. In those infected with S. dysenteriae serotype 1, hemolytic anemia and hemolytic uremic syndrome are common complications caused by shigatoxin. Post infectious arthritis occurs 2 to 5 weeks after dysenteric illness, and is seen characteristically in patients with HLA-B27 (1).

Stool culture (rectal swab) is the gold standard for diagnosis. The presence of fecal leukocytes, fecal blood, and a CBC leukocytosis with left shift can help support a presumptive diagnosis of bacterial gastroenteritis. Fluid and electrolyte correction and maintenance should be the initial focus of treatment. Drugs that delay intestinal motility (Lomotil, loperamide) should be avoided. Empiric antibiotic treatment of all children strongly suspected of having shigellosis is highly encouraged, and should be initiated as soon as possible. However, other bacterial etiologies may be worsened by antibiotic treatment, so it may be preferable to await culture results.

Vibrio cholera and parahaemolyticus

Vibrio species are common causes of diarrhea worldwide. V. cholera serogroups O1 and O139 have been responsible for cholera epidemics in many developing countries. These serogroups produce profuse watery diarrhea (known as rice water stools) after adhering to and multiplying on small intestinal mucosa. They cause diarrhea by producing several toxins. The most important toxin is the cholera toxin which is a heat stable enterotoxin. V. parahaemolyticus is a common marine organism found in water, shellfish, fish, and plankton. It is generally an uncommon cause of diarrhea, but people who consume raw shellfish and seafood are at higher risk. Infected individuals experience diarrhea, abdominal cramps, nausea, and less frequently, vomiting, headache, low grade fever and chills (1).

Yersinia enterolitica

Y. enterolitica is a gram negative bacillus that appears to be a common cause of gastroenteritis among children in Europe and Canada, but is uncommon in the United States. Outbreaks have been associated with ingestion of contaminated milk or food. The clinical manifestations vary depending on the age of the involved person. It usually causes acute gastroenteritis in younger children, and mesenteric adenitis in older children. Most infections occur in children 5 to 15 years of age, and incidence is greater during the winter months. Children younger than 5 years old usually have self-limited gastroenteritis, lasting from 2 to 3 weeks. Symptoms include diarrhea accompanied by fever, vomiting, and abdominal pain. The abdominal pain is colicky, diffuse, or localized to the right lower abdomen. Stools may be watery, containing blood or mucus, and fecal leukocytes are commonly present. Children older than 6 years often present with abdominal pain associated with mesenteric adenitis that mimics acute appendicitis. Intussusception secondary to Y. enterolitica has also been described in children.

While isolation of Y. enterolitica from stool specimens is difficult, it is readily isolated from blood or lymph nodes. Serologic diagnosis can be obtained with enzyme-linked immunosorbent assays. Antibodies are detectable from 8-10 days after the onset of clinical symptoms, which persist for several months.

Y. enterolitica gastroenteritis is usually self-limited, therefore antibiotic therapy is only indicated for complicated infections, and compromised patients. It is usually susceptible to trimethoprim-sulfamethoxazole, aminoglycosides, tetracycline, chloramphenicol, and third generation cephalosporins. It is resistant to penicillin, ampicillin, carbenicillin, erythromycin, and clindamycin (4).

Other bacteria

Other bacteria that cause an acute diarrheal illness include Bacillus cereus, Aeromonas hydrophila and Plesiomonas shigelloides. Clostridium difficile is associated with pseudomembranous colitis, and Clostridium perfringens can cause a short duration food poisoning syndrome.

Viral gastroenteritis

Diarrhea and vomiting caused by viruses are usually self-limited. It usually manifests as watery diarrhea, without blood or mucus. The most common accompanying symptom is vomiting. Other symptoms include abdominal cramps, nausea, headaches, myalgias and fever. Four viral groups are regarded as medically important causes of acute gastroenteritis (rotaviruses, astroviruses, enteric adenoviruses, and calciviruses). They are all spread largely via the fecal-oral route.

Rotavirus accounts for 82,000 hospitalizations and 150 deaths per year in the United States. It is a very common cause of acute gastroenteritis in infants and children, responsible for over 50% of cases of acute diarrhea in children. Rotavirus causes severe illness in children 6-24 months. Most children (more than 90%) have been exposed to rotavirus by their 3rd birthday. It is the most common cause of diarrhea in infants and children in the winter months in colder climates, and is responsible for 35-50% of hospitalization for infants and children with acute diarrhea. Clinical features range from asymptomatic infection, to diarrhea preceded by severe vomiting. The incubation period is 2-4 days, and viral shedding occurs from a few days before, to 10 days after the onset of illness. Newborns tend to have asymptomatic infections in the first few months of life, because transplacental antibodies and breastfeeding are protective. Clinical symptoms in infants and children usually consist of fever, abrupt onset of vomiting and watery diarrhea. One third of children will also have a concurrent respiratory infection. The diagnosis can be made by a number of enzyme immunoassays (Rotazyme) and latex agglutination tests with good specificity and sensitivity. Stools collected early in the course of the illness are more likely to contain virus, than those collected 8 or more days after the onset of illness. Treatment is directed toward correction of dehydration with oral fluid replacement. Breastfeeding is the most important and available preventive strategy, because human colostrum contains rotavirus antibodies (5).

Adenovirus commonly causes a wide range of human diseases, including conjunctivitis, pneumonia, and upper respiratory infections. A subgroup of adenovirus (enteric adenovirus) has been found to cause acute gastroenteritis, lasting 4 to 20 days. After rotavirus, enteric adenovirus is the next most common cause of viral gastroenteritis in infants and children, accounting for 5% to10% of hospitalizations for acute gastroenteritis in children. They have been linked to outbreaks in child care centers, and asymptomatic excretion can occur. Most episodes occur in children less than 2 years. Infection increases in the summer months. Symptoms are indistinguishable from those associated with rotavirus but are less severe. The diagnosis is a presumptive one. Research laboratory confirmation can be made by solid phase immunoassays, electron microscopy, and viral culture but these studies are not routinely available. As with rotavirus, treatment is aimed at replacing fluid losses, and at correcting electrolyte abnormalities (5).

Caliciviridae primarily infect infants and young children. Human caliciviruses (HuCVs) have been associated with outbreaks from contaminated food or water in restaurants, schools, hospitals, summer camps and cruise ships. They are divided into 4 genera: Norwalk-like calciviruses (which causes illness mostly in adults), Sapporo-like calcivirus (which primarily cause pediatric gastroenteritis), rabbit-like calcivirus, and swine-like calicivirus. Hepatitis E, which was previously classified as a calcivirus, is no longer classified in this family. The gastroenteritis is indistinguishable from that of rotavirus. The incubation period is 12 hours to 4 days. Excretion lasts 5-7 after the onset of symptoms, and can continue for 4 days after the resolution of symptoms (5). The diagnosis is presumptive, but epidemiologic and research confirmation of these etiologic agents can be made by electron microscopy.

Astrovirus infection is believed to occur very commonly, since 80% or more adults have antibodies against the virus. They cause watery diarrhea, especially in children younger than 4 years. Symptoms are mild, consisting of fever and malaise, followed by watery diarrhea. Vomiting is uncommon. The incubation period is 3 to 4 days, and excretion typically lasts for 5 days after onset of symptoms (5).

Protozoan and parasitic gastroenteritis

Several protozoans cause diarrhea: Giardia lamblia, Entamoeba histolytica, Cryptosporidium parvum, Isospora belli, Microsporidium species, and Cyclospora cayetanensis. Within the intestinal tract, 3 organisms, namely Giardia lamblia, Entamoeba histolytica, and Cryptosporidium parvum are the most important.

Infection with E. histolytica occurs more frequently in tropical countries, especially in areas with poor sanitation. The life cycle of E. histolytica has 2 stages: the trophozoite which is found in diarrheal stools, and the cyst, which is more predominant in formed stools. The cysts are transmitted primarily by the fecal-oral route in contaminated food and water. The minimum incubation period is 8 days, but ranges up to 95 days. The clinical symptoms that occur in patients with amebiasis consist of: 1) Intestinal amebiasis, with the gradual onset of colicky abdominal pain and frequent bowel movements, tenesmus, and flatulence. 2) Amebic dysentery, characterized by profuse diarrhea containing blood, mucus, and constitutional signs such as fever and dehydration. 3) Hepatic amebiasis, presenting with an amebic abscess within the liver often without diarrhea. 4) Asymptomatic infection. E. histolytica can usually be identified in stool samples, or acute infection can be confirmed by serology. Metronidazole is the treatment of choice.

Giardia lamblia is a flagellated protozoan that is a major cause of diarrhea, especially in patients who travel to endemic areas. It is the most common intestinal protozoan found in the United States. Children seem to be more susceptible to Giardia than adults. Like E. histolytica, the life cycle consists of 2 stages: the trophozoite (motile form), and the cyst. IgA deficiency and hypogammaglobulinemia predispose patients to symptomatic infection. The clinical manifestations are foul-smelling diarrhea, with nausea, anorexia, abdominal cramps, bloating, belching, flatulence, and weight loss. Abdominal distention and cramps can last for weeks to months. The illness is usually self-limited, lasting 2 to 6 weeks, but may become chronic. Chronic symptoms can include fatigue, nervousness, weight loss, steatorrhea, lactose intolerance, and growth retardation. The easiest way to diagnose Giardia is by identifying cysts in a stool specimen. However, these specimens are frequently falsely negative. The diagnosis can also be made by antigen detection tests, endoscopic examination of the upper small intestine, by mucosal biopsy or by collection of jejunal contents. The treatment of choice for both symptomatic and asymptomatic patients is furazolidone or metronidazole. An alternative drug is quinacrine (6).

Cryptosporidium organisms are small protozoans that are a common cause of enteric infection worldwide. The oocyst form of cryptosporidium is found in feces, and is the infective form. Cryptosporidium parvum is thought to be the cause of infection in humans. Cryptosporidium causes cryptosporidiosis mainly in immunocompromised patients, infecting approximately 3% to 4% of patients with AIDS in the United States. Another high risk group for acquiring infection with this organism, are children 6 to 24 months old. It is acquired by fecal-oral transmission, and has an incubation period of 2 to 14 days. Because the oocyst is highly stable in the environment, contaminated drinking water, swimming pools and apple cider are major sources of outbreaks. Several outbreaks of diarrhea in day care centers have been attributed to cryptosporidium. In the United States, 13% of children less than 5 years old, 38% of those 5 to 13 years of age, and 58% of adolescents 14 to 21 years old are seropositive for C. parvum. Symptoms are self-limited in immunocompetent patients, consisting of watery nonbloody diarrhea, accompanied by vomiting, flatulence, abdominal pain, myalgias, anorexia, weight loss, and low-grade fever. Symptoms last an average of 9 days in immunocompetent patients, but can last months in immunocompromised hosts, causing large fluid losses, profound malabsorption and weight loss. The diagnosis of cryptosporidiosis is made by demonstrating the presence of cryptosporidium oocysts in stool specimens. Patients with diarrhea who attend day care centers, those with AIDS or other immunodeficiencies are at higher risk. There is no specific antimicrobial therapy for cryptosporidiosis (7).

Dehydration

Fluid losses resulting from acute vomiting and diarrhea can lead to dehydration. Diarrhea is the most common cause of dehydration in infants and children, and is a leading cause of death worldwide in children less than 4 years of age. Quantifying the degree of fluid loss by history and the amount and type of fluid intake can help to determine dehydration severity and the risk of electrolyte imbalance. The amount of urine output and the presence or absence of tears as well as the presence of documented weight loss, can help determine the severity of dehydration present. Other important aspects of the history include the presence of fever, sweating and hyperventilation, which may cause insensible losses, contributing to the degree of dehydration.

The vital signs can offer clues on the degree of dehydration present. Tachycardia can indicate moderate dehydration, whereas hypotension is a late sign of severe dehydration. The absence of tachycardia cannot be used to rule out dehydration. An increase in the respiratory rate is associated with a higher degree of dehydration, whereas in mild dehydration, the respiratory rate is normal. Attention should be paid to the child's overall appearance and mental status (alert, irritable, tired-appearing, poorly responsive, unresponsive). Other pertinent exam findings include the fontanelle (sunken or not), the eyes (presence or absence of tears, sunken or not), the mouth (dry lips, tacky or sticky mucous membranes), the skin (cool or warm, skin turgor). Measurement of the capillary refill time is a variable and unreliable indicator of dehydration. It should be performed in a warm room. Light pressure is applied to the finger nailbed. And the time from blanching to restoration of color to the nailbed is measured. It may be preferable to assess capillary refill centrally (over the chest or forehead) and peripherally (fingers), so that the two can be compared. A delay of less than 2 seconds is normal. Delays of 2 to 3 seconds may indicate moderate dehydration, and more than 3 seconds in delay may indicate severe dehydration. Most children with clinically significant dehydration, will have 2 of the following 4 clinical findings: 1) capillary refill greater than 2 seconds, 2) tacky mucous membranes, 3) no tears, and 4) ill appearance (8).

Management

The decision to hospitalize or to attempt outpatient management will be based on the clinical findings, combined with a history of fluid intake, the frequency of urination, assessment of concurrent stool losses and the response to therapy.

Once a child is presumed to be dehydrated, the degree of dehydration needs to be determined. Acute weight loss can be used to determine the degree of dehydration, but accurate baseline weights in growing children are almost never known. Clinical criteria can be used to estimate degrees of dehydration. Mild dehydration is 5% or less, moderate is about 10%, and severe dehydration is about 15% or greater. This classification is relative and not well standardized. If severe dehydration or uncompensated shock is present, the patient should be immediately treated with an IV fluid infusion (20 cc/kg of normal saline or lactated Ringer's) to restore the intravascular volume. It is likely that more than one fluid bolus may be necessary to restore the patient's intravascular volume, since 20 cc/kg only corrects 2% of the body weight. Therefore, the patient should be reassessed after each fluid bolus (8).

Children with mild to moderate dehydration can be initially treated with oral rehydration. Contraindications to oral rehydration therapy (ORT) include severe dehydration, intractable vomiting, and severe gastric distention. Children who had initially received IV fluid infusions for severe dehydration who now feel well enough to take oral fluids should also be considered for oral rehydration. Oral rehydration therapy (ORT) can be as effective as IV therapy. It is noninvasive and inexpensive. The AAP recommends that rehydration solutions contain 70-90 mEq/L of sodium, 20 mEq/L of potassium, and 2.0-2.5 grams/dL glucose. Examples of rehydration solutions (ORS) are: Rehydralyte (70mEq/L Na, 20 mEq/L K, 2.5% glucose, and the WHO solution (90m Eq/L Na, 20 mEq/L K, 2% glucose). ORT should initially be given in small, frequent volumes, 5 to 20 cc every 5-10 minutes, and advanced slowly to approach 5 cc/min. The degree of dehydration and the presence of ongoing losses dictate the volume of fluids to be administered. If the degree of dehydration is mild (3-5%), the volume of ORS administered should be 50 cc/kg (i.e., 5% of the body weight) over 4 hrs. Those with significant dehydration (5-10%) should received 100 cc/kg (i.e., 10% of the body weight) of ORS over 4 hours. In either case, an additional 10 cc/kg should be given for each diarrheal stool seen. Once rehydration is complete, maintenance fluid is given. Examples of maintenance oral solutions are: Pedialyte and Infalyte, containing 45-50 mEq/L Na, 2-2.5 mEq/L K, 1.5-2.5% glucose (9).

Patients with mild dehydration can potentially be managed without laboratory analysis. However, in moderate or severe dehydration, laboratory studies should be obtained to look for electrolyte abnormalities of to measure the degree of metabolic acidosis.

Children who are severely dehydrated and those who cannot retain oral fluids because of intractable vomiting should be hospitalized and treated with IV fluid. Once the initial resuscitation phase is completed, replacement IV therapy should be instituted, taking into account fluid and electrolyte deficits as well as ongoing losses. Usually, half of the replacement therapy in addition to the maintenance fluid requirement is given over the first 8 hours, and the second half is given over the next 16 hours. However, patients with hypernatremic dehydration (serum sodium >150mEq/L) require special intervention. After initial management with normal saline or lactated Ringer's, the replacement fluid is given more slowly, over 48 hours or more. This is done because rapid correction of hypernatremia can result in acute brain swelling, brain herniation, and death. Therefore, care should be taken to avoid dropping the serum sodium by more than 15mEq/L per 24 hours.

Once a child is adequately rehydrated, the question of when to start feedings arises. It was previously perceived that a period of "gut rest" should follow rehydration of patients with acute gastroenteritis. However, numerous trials have shown no advantage to this strategy. The concept of early refeeding is replacing the old concept of "gut rest". Numerous trials have shown that early feeding of age-appropriate foods results in faster recovery. Breast fed infants should continue nursing despite diarrhea. Following rehydration, children with mild diarrhea who drink milk or formula can tolerate full strength feedings. The traditional BRAT diet (bananas, rice, applesauce, toast), although acceptable, should be considered to be a concept representative of a bland diet rather than a specific diet. Controlled clinical trials have shown that starches, complex carbohydrates (rice, wheat, bread, potatoes, cereals), soups, fresh fruits and vegetables, yogurt, and lean meats are better choices, and well tolerated (9). Fatty foods, juices, teas, sweetened cereals, soft drinks, are poor choices, and should be avoided. Some patients may benefit from lactose-free or low-lactose formulas.

Most pediatricians and experts recommend against using anti-diarrheal agents such as Imodium (loperamide), Pepto-Bismol (bismuth subsalicylate), and Kaopectate. This is more of a precaution since many studies do show some beneficial effects from these medications in patients with mild diarrhea. However, patients with mild diarrhea will get better on their own so these medications are usually not necessary. For young children with severe gastroenteritis, there is insufficient data to confirm the benefit and safety of these medications, which is why they cannot be recommended routinely at this time.

Questions

1. Which diarrhea causing organism may be also cause neurologic symptoms?
2. What is the most common viral cause of acute gastroenteritis, and what are its associated symptoms?
3. How is Giardia lamblia most easily diagnosed and how is it treated?
4. List 4 physical signs of dehydration in children?
5. How are children with mild dehydration initially treated?
6. How are children with severe dehydration initially treated?

Answers to questions

1. Shigella.
2. Rotavirus. It causes fever, vomiting, and watery diarrhea.
3. The diagnosis can be made by antigen detection, identifying cysts in the stool, endoscopy or examination of jejunal contents. It is treated with metronidazole or furazolidone.
4. Sunken fontanelle, absence of tears, sunken eyes, sticky/tacky oral mucosa, delayed capillary refill, reduced skin turgor, inactivity/lethargy, tachycardia, hypotension.
5. With oral rehydration, small frequent volumes 5-20cc every 5-10 minutes, advanced slowly.
6. With IV fluid infusion of normal saline or lactated Ringer's at 20cc/kg. Oral rehydration with ORS is commonly employed in other countries.

Chapter IX.4. Biliary Atresia
Jason T. Nomura, MD

This is a 4 week old female who presents to the office with parental reports of increasing jaundice over the last week. Her parents report that 2 weeks ago, she began to have yellowing of her eyes with subsequent yellowing of her skin when she was diagnosed with physiologic jaundice. After persistent jaundice for 5 days, her parents changed her from breast-feeding to a commercial formula. Since the jaundice appears to be worsening, her parents decided to bring her in for re-evaluation. Her stools have been pale in color for the past 10 days along with darker urine.

She was born by spontaneous vaginal delivery to a G2P1 A+ mother at 39 weeks with Apgar scores of 9 and 9 and 1 and 5 minutes. There were no complications noted at birth, the nursery, or at discharge home. The patient was not jaundiced at discharge or when seen at initial office visits. Her highest bilirubin previously was 12.0 and her blood type is A+.

Exam: VS Normal. Weight and height are at the 60th percentile. She is awake, alert, in no acute distress and is easily comforted by her mother during the exam. Her skin is jaundiced, most notably in the cephalic and truncal areas, with scleral icterus. Her liver is slightly enlarged without nodularity. No splenomegaly is noted. The remainder of her exam is normal.

Laboratory examinations reveal a total bilirubin of 15 mg/dL, direct bilirubin of 12.3 mg/dL, ALT 45 U/L, AST 52 U/L, and an alkaline phosphatase of 2007 U/L. The patient undergoes a DISIDA scan after 5 days of phenobarbital therapy. The scan showed normal uptake by the liver but no excretion of the isotope (i.e., no bile flow) into the bowel even after 24 hours. She is referred to the surgical service for evaluation. She is then scheduled for a laparotomy with intraoperative cholangiogram, wedge liver biopsy and possible Kasai procedure.

Biliary atresia (BA) is a serious cause of infantile cholestasis and the most common cause of orthotopic liver transplantation in children. BA was originally thought of as the progressive fibrosis and obliteration of the extrahepatic biliary system. However, it is now known that the intrahepatic bile ducts are also affected by the disease process (1,2). The incidence of BA is not well known with individual studies reporting an incidence ranging from 1 in 8,000 live births to 1 in 25,000 (1-5).

There are 2 types of BA that are currently recognized and described: a fetal or embryonic type and a perinatal type. The fetal type occurs in 15-35% of cases and is characterized by an earlier onset of cholestasis (1). There is an association between the fetal type and other congenital anomalies such as situs inversus, polysplenia, cardiac malformations, and other manifestations (1,2). There also tends to be a lack of bile duct remnants at the porta hepatis with the fetal form of BA. The more common form of BA is the perinatal form which occurs in 65-85% of cases and is not associated with congenital anomalies (1).

As the names imply, the initiating event of the two types are theorized to occur at different times in development with probably very different etiologies. Research has focused on the possible etiology of the perinatal form with causes including viral infections, auto-immune disease, and immune mediated damage (1,4). The viruses that are under question include CMV, reovirus, rotavirus, HPV, and retroviruses (4). Theories of the etiology of the fetal type of BA center around a possible morphogenesis defect, known as the ductal plate malformation, due to defective gene expression leading to the associated congenital anomalies (1,4). While there are possible candidates for the defective gene there has been no definitive identification. Therefore the etiology of both forms of BA remains unknown at this point.

The signs and symptoms of biliary atresia will be dependent upon the time of presentation. Usually, the patient is born at term with a normal birth weight. Jaundice can be present at birth or it can present as late as 3 to 5 weeks of life. Other than jaundice, another common complaint is acholic stools, which are highly suggestive of cholestasis. There can be some pigment in the stool due to sloughing of cells that contain pigments. However, this pigment is only present superficially with the core of the stool remaining pale (3). Since the bile pigments are no longer released into the stool, they will be deposited in the urine leading to darker urine.

On physical exam the patient will usually have an enlarged firm liver (normal averaging 4.5-5 cm at 1 week and 6-7 cm during early adolescence) (3). The presence of splenomegaly is variable and more common with later presentations as part of the constellation of portal

hypertension. Patients may also present with the findings associated with the fetal form of BA including polysplenia, situs inversus, and cardiac malformations (1).

The undiagnosed infant with BA will present with a much different picture. This is due to the progressive nature of the disease. Later presentations are associated with the progression of the disease to biliary cirrhosis and the development of portal hypertension with failure to thrive (2). The clinical picture at this point will be dominated with findings suggestive of cirrhosis and portal hypertension such as jaundice, hepatosplenomegaly, a nodular liver, varices, ascites, and hepatic vascular bruits (1,3).

Laboratory examination will show an elevated total bilirubin with an increased direct (conjugated) portion. The serum aminotransferases levels will tend to be normal or mildly elevated. Alkaline phosphatase will be highly elevated reaching levels higher then 5 times normal (2). Early in the disease process there are usually no changes in coagulation studies.

There are many conditions that can cause cholestasis in the neonate and lead to jaundice. These include hepatitis (viral and other causes), sepsis, endocrinopathies, metabolic derangements, and nutritional hepatotoxicities (6). The most common disorders in decreasing incidence are idiopathic neonatal hepatitis, BA, alpha-1-antitrypsin deficiency, and persistent intrahepatic cholestasis disorders (2). The greatest challenge is the differentiation of BA from idiopathic neonatal hepatitis and the intrahepatic cholestasis disorders.

Idiopathic neonatal hepatitis is not the same entity as neonatal viral hepatitis. As its name implies, the cause is unknown. There have been diseases that are now described that were once under the heading of idiopathic neonatal hepatitis such as alpha-1-antitrypsin deficiency. These patients tend to present with low birth weight, early onset of jaundice, and usually have pigmented stools (2). Associated malformations are usually not found with this disease and if present should prompt the search for an alternate diagnosis. Laboratory findings include elevations in the serum aminotransferases and bilirubin. Alkaline phosphatase can be elevated but is not always. Coagulation studies may also be abnormal. A diagnosis of idiopathic neonatal hepatitis should only made when other causes of cholestasis (including BA and alpha-1-antitrypsin deficiency) are ruled out. Histologic findings include disruption of the lobular architecture with hepatocellular swelling, focal necrosis, and the presence of multi-nucleated giant cells (2,7). However, the presence of hepatocellular swelling giant cells can also be seen in BA (7). The largest portion of the workup for idiopathic neonatal hepatitis is to rule out any metabolic, infectious, genetic, or other described conditions.

Under the heading of persistent intrahepatic cholestasis disorders is intrahepatic bile duct paucity which includes both non-syndromic bile duct paucity and syndromic forms such as Alagille syndrome. These are characterized by the absence or marked decrease in the number of intrahepatic interlobular bile ducts, with normal sized arteries and portal veins in the triad. Intrahepatic bile duct paucity was previously referred to as "intrahepatic bile duct atresia" or "intrahepatic biliary atresia" (6, 8). This was a misleading term that is no longer used since by definition BA is the fibrosis and obliteration of the extrahepatic biliary system, not the intrahepatic system. These diseases are diagnosed by the presence of cholestasis and bile duct paucity on liver biopsy. The non-syndromic form describes a common pathology with various etiologies, which are still poorly understood. With the syndromic forms there are characteristic findings associated with the bile duct paucity (8). For example in Alagille syndrome, or arteriohepatic dysplasia, there are characteristic facies along with ocular, cardiovascular, vertebral, and kidney pathology.

Efforts must be made to diagnose BA early since the success of intervention is dependent upon the time frame. When a child presents with jaundice, the first step is to evaluate the total and fractionated bilirubin in each patient with jaundice. If the elevation is isolated to the unconjugated (indirect) fraction of bilirubin then significant liver pathology is unlikely (3). However, if the elevation is in the conjugated (direct) fraction or it is 20% or greater of an elevated total bilirubin then cholestasis more likely (6). If the presence of cholestasis is established, then the etiology must be found in a timely fashion. Panels of testing can quickly rule out or diagnose entities such as hypothyroidism, galactosemia, tyrosinemia, alpha-1-antitrypsin deficiency, and infectious diseases. Once these items are ruled out, the challenge is to differentiate between idiopathic neonatal hepatitis and BA.

Non-invasive testing for biliary atresia currently relies on the use of hepatobiliary scintigraphy with the use of 99mTc-iminodiacetic acid compounds or HIDA scans. The newer iminodiacetic compounds have greater concentrations in the bile then the original compounds. HIDA scans using older compounds will not visualize the biliary tract if the bilirubin is high, so the currently favored compound is 99m Tc-disofenin or DISIDA. Images consistent with BA will show normal uptake by the liver with no excretion into the bowel even after 24 hours. The specificity of the DISIDA scan can be increased by pretreatment with phenobarbital (5mg/kg/24h PO for 5 days prior to study) to increase the excretion of the disofenin (6,9). If the DISIDA scan demonstrates bile flow from the liver to the duodenum (i.e., the biliary tree is visualized), then BA is ruled out and the work-up can stop. Patients who demonstrate an obstructive pattern on DISIDA will have BA in 80-85% of cases (10); however, neonatal hepatitis is still possible since it can cause severe cholestasis. In patients with idiopathic neonatal hepatitis, there is slow uptake of the compound with excretion into the bowel; however, in some instances, the cholestasis is so sluggish, it cannot be reliably distinguished from BA. DISIDA scanning is less reliable with higher levels of serum bilirubin, however bowel activity is still observed with hyperbilirubinemia as high as 20-30 mg/dL. If there is poor uptake by the liver without bowel activity it is indicative of severe hepatocyte damage that could be caused by either BA or idiopathic neonatal hepatitis (9).

Another method for the diagnosis of BA is the use of ultrasound guided liver biopsy. While there are no pathognomonic histological changes, the biopsy is reported to provide a diagnosis of BA ranging from 70% to 97% (3,7). Findings include edema of the portal tracts, tortuous proliferation of bile ductules, fibrosis, along with intracellular and canalicular cholestasis. There is also a mixed infiltration of neutrophils and lymphocytes with a mild non-specific cholangitis (7). Of note is that there can also be ballooning of the hepatocytes and multinucleated giant cell formation. This can cause some overlap between the histological picture presented by BA and by idiopathic neonatal hepatitis (2,7). If the biopsy shows absence or reduction in the amount of interlobular bile ducts at the portal triad, with an intact biliary tree on scintigraphy, then a diagnosis of intrahepatic bile duct paucity (formerly known as intrahepatic biliary atresia) is established and true or extrahepatic BA is ruled out (6). Also of note is that there should be no dilation of the intrahepatic bile ducts in BA as can happen with some other forms of extrahepatic cholestasis (11).

The gold standard for the diagnosis of BA is the laparotomy with intraoperative cholangiography. If an intact extrahepatic biliary system is not visible, then extrahepatic biliary atresia is evident. If an intact biliary tree is visible, then an intraoperative cholangiogram is done, in which the surgeon cannulates the bile duct and injects contrast to determine if the biliary ducts are patent. Non-patency indicates sclerosed ducts and extrahepatic biliary atresia. A patent biliary system visualized on the intraoperative cholangiogram rules out extrahepatic biliary atresia. At this point, a wedge liver biopsy is obtained. This biopsy is examined for the presence of intrahepatic bile ducts. If the intrahepatic bile ducts are obliterated or reduced in number, then bile duct paucity (formerly called intrahepatic biliary atresia), is present. An intact and patent extrahepatic biliary tree rules out extrahepatic biliary atresia and the presence of normal intrahepatic bile ducts rules out bile duct paucity. This diagnostic algorithm is summarized below.

Diagnostic algorithm of biliary atresia:

1) Direct hyperbilirubinemia prompts evaluation and lab work-up.

2) Look for evidence of bile excretion (DISIDA scan, pigmented stools): Any evidence of bile excretion, rules out BA. If cholestasis is present (i.e., no bile excretion is demonstrated), then proceed to next the step.

3) Laparotomy:

a) Look for a visible biliary tree: If absent, then extrahepatic BA is present. If present, then proceed to next step.

b) Perform an intraoperative cholangiogram: If non-patent, then extrahepatic BA is present. If cholangiogram demonstrates patents ducts, then proceed to next step.

c) Perform a wedge liver biopsy: If intrahepatic bile ducts are obliterated or reduced in number, then bile duct paucity (formerly known as intrahepatic BA), is present. The biopsy can also be used to find an alternate diagnosis. If bile ducts are patent and present, then BA is not present, in which case the biopsy is likely to demonstrate an alternate diagnosis such as neonatal hepatitis.

Depending on the anatomic type of BA which is present, it can be classified as either a correctable lesion (20% of cases) or a non-correctable lesion (80% of cases) (2,10). A correctable lesion has fibrosis of the distal biliary tree with the proximal biliary tree and the intrahepatic bile ducts remaining patent. In these cases, excision of the fibrotic area and direct drainage into the bowel is possible.

In the non-correctable lesions, the biliary system is fibrotic to the level of the porta hepatis. These patients need to undergo the Kasai procedure to establish bile flow. The Kasai procedure is the Roux-en-Y hepatoportoenterostomy where the porta hepatis is attached to a loop of bowel after resection of the fibrotic biliary system. This procedure basically anastomoses the liver directly to the bowel so that in theory, bile can flow from the liver into the bowel. The reason that the procedure succeeds is that at the porta hepatis there are microscopic bile ductules that have proliferated which communicate with the intrahepatic system. Some groups use frozen section biopsy during the laparotomy to examine the tissue at the porta hepatis using the size of the vessels as a marker for the likelihood of successful re-establishment of bile flow. However, there have been variations in the size of vessels required and this theory is not universally accepted.

The success of the Kasai procedure depends largely on 2 factors: age at procedure and experience of the center it is performed at. To obtain maximum benefit from the Kasai procedure it should be performed before the patient is 3 months old, ideally less then 2 months. This is the major reason why the diagnostic determination of whether BA exists, must be done expeditiously. Establishment of bile flow is achieved in 80% of the patients who are less then 2 months, 50% between 2 and 3 months, and less then 10% if older then 3 months (12). The decrease in the success rate of the Kasai procedure with advancing age is due to progressive damage to the liver from untreated BA (i.e., further back-up of bile flow inflicts additional damage to the existing intrahepatic ducts). The other factor is the experience of the center performing the surgery. Outcomes of the procedure and post-procedure survival are improved when the hospital does more then 5 procedures a year (1,5,13).

If the child is diagnosed at an age greater then 3 months, the Kasai procedure has a low probability of success. Performing a Kasai procedure after this age is thus controversial, versus proceeding straight to liver transplantation, which is the treatment for a failed Kasai procedure. It is the general consensus that a patient should undergo the Kasai procedure even if they present at ages greater then 3 months if it is possible that bile flow can be established (12,14). While a post Kasai transplant is technically more difficult, there was no reported change in survival after transplantation in patients who underwent primary transplantation versus those who had a failed Kasai procedure prior to transplantation (11,13). The use of the Kasai procedure may not provide long term cure in the older BA patient but it may buy time for preparation for transplantation, finding a donor, and advancement of transplantation technology.

Ascending cholangitis is the most common complication, occurring in 40-60% of Kasai procedures (1). The etiology for this is anatomic and bacterial. Bowel bacteria have access to the existing bile ducts and hepatic tissue. The normal anatomy of an intact bile duct prevents bowel contents from refluxing up toward the liver. In the Kasai procedure, the bowel contents containing digestive enzymes have direct access to the existing bile ducts and hepatic tissue causing the cholangitis. An anti-refluxing valve can be surgically created within the duodenal segment anastomosed to the liver, but such alterations in the Kasai procedure and various medical regimens have not proven successful. There does appear to be an increased risk in the patients with established bile flow, probably due to an intact pathway for ascending bacteria. Prophylactic antibiotics with trimethoprim-sulfamethoxazole is designed to reduce bowel bacterial counts. Repeated episodes of cholangitis can lead to extensive liver damage and cirrhosis.

Another common complication of BA is portal hypertension, which occurs in 35-75% of patients (1). This occurs due to the progressive inflammation and fibrosis of the intrahepatic biliary system and/or repeated episodes of cholangitis leading to cirrhosis. The portal hypertension that develops will have the sequelae of other forms of portal hypertension such as varices, ascites, hypertensive gastropathy, hypersplenism, and encephalopathy (1). The most common presentation is esophageal variceal hemorrhage occurring in 30-60% of patients (1). Treatment relies on the same methods employed in adults for other forms of portal hypertension.

BA is a chronic cholestatic disease if untreated can lead to complications as a result of the cholestasis. The end result is biliary/hepatic cirrhosis if BA is not treated with a life expectancy of 2 years (2). Mortality is a result of liver failure or portal hypertension. As mentioned before the chance of establishing bile flow in BA patients with the Kasai procedure is dependent upon the age that the patient undergoes surgical intervention. However, it should be noted that the establishment of bile flow does not necessarily mean long term cure since BA also involves intrahepatic inflammation that can lead to cirrhosis.

After the Kasai procedure, the patient can be stratified into 1 of 3 prognostic groups at 4 to 6 weeks post operatively (10). The first group are the patients who produce adequate bile flow and are relieved of their jaundice. They will have long term survival and possibly not need liver transplantation. The second group has moderate bile flow but they remain jaundiced and will continue to survive post-Kasai, however they will eventually need liver transplantation later in life. The third group are those who do not establish bile flow. This is considered a failure of the Kasai procedure and they will need liver transplantation in order to survive.

While the Kasai procedure establishes bile flow, it does not necessarily halt the intrahepatic inflammation and fibrosis. Patients who undergo the Kasai procedure can survive with their native liver in 20-30% of cases, but the remainder will eventually need liver transplantation (2,10). Overall survival rates of patients with BA post intervention in recent studies range from 70 to 85% (5,13). Ten year survival ranges from 33% in older studies to 68% in more recent studies (2,13). Survival with one's native liver at 5 years has been reported to be as high as 32% in recent studies and 27% at 10 years (5,13).

Biliary atresia is no longer a fatal disease in all who are diagnosed with it. The early diagnosis and treatment of BA can lead to long term survival without the need for liver transplantation. However, the key is the early diagnosis of BA in order to ensure that surgery can be performed in a timely manner at a high level center to increase the likelihood of success. Despite this, there are still many children who are untreated at 3 months of age (as high as 14-19% in some studies) (1). Efforts to introduce screening methods for BA have been

attempted with poor results. The best method so far, is to maintain a high clinical suspicion in the jaundiced patient. Direct hyperbilirubinemia deserves a prompt and thorough evaluation.

Questions

1. True/False: A 2 week old infant presents with persistent jaundice to the office. No further work up is necessary since this is physiologic jaundice.
2. A DISIDA scan report, for a patient in whom biliary atresia is suspected, comes back stating that there was poor uptake into the liver and no visualization of the isotope into the bowel. Can you diagnose biliary atresia in this patient?
3. A liver biopsy shows hepatocellular ballooning and the presence of multinucleated giant cells. Is this consistent with biliary atresia?
4. A patient presents to you with lightly colored stool; however, when the stool is broken up it is noticed that the center is clay colored. What is this indicative of?
5. A 16 week old patient is diagnosed with biliary atresia, should he/she undergo a Kasai procedure if there are no contraindications or should the patient just wait for a liver transplant?

Answers to questions

1. False. Persistent jaundice needs to be worked up before permanent damage is done by any number of pathological conditions, such as BA. Since there is little risk involved, the threshold to obtain a serum fractionated bilirubin should be low. If there is an elevation of conjugated bilirubin at 14 days of age or earlier, it is by definition neonatal cholestasis.
2. No. With poor uptake into the liver you can only state that there is cholestasis. This may be transient cholestasis due to hepatitis, or it may be due to severe damage to the hepatocytes by several possible causes including biliary atresia. To make a diagnosis, there needs to be normal uptake in the liver with no movement into the bowel, even after 24 hours. Pretreatment with phenobarbital improves the yield on the DISIDA scan.
3. Yes, this histopathology is consistent with the histopathology seen with biliary atresia. However, it is also consistent with idiopathic neonatal hepatitis and therefore a definitive diagnosis can not be made on this biopsy result alone.
4. The presence of clay colored or acholic stools are indicative of cholestasis. The lack of bile flow into the bowel prevents the characteristic stool coloring. The superficial light coloring is due to the sloughing of pigmented cells during the transit in the bowel and does not affect the core of the stool.
5. While there is little chance of long-term survival with the patient's native liver in someone who undergoes the Kasai procedure after 3 months of age, there is some benefit. The Kasai procedure can lead to extended survival time with the native liver, allowing the patient to stabilize baseline health. There is also a benefit in that there will be longer period of time to find a donor and prepare the patient for transplantation. However, each patient is different and some may be better served by primary liver transplantation.

Chapter IX.5. Hepatitis
Vince K. Yamashiroya, MD

This is a 14 year old Caucasian patient who comes to your office with a chief complaint of nausea, poor appetite, and fever for one week. Her fever has been between 101 and 102 degrees, and occurs every day. She had two non-bloody, non-bilious episodes of emesis in the last two days and also has abdominal pain on her right side below the ribs, which has been getting worse. Her urine color is darker than normal, although she has not been drinking much fluid. She denies any coughing, URI symptoms, diarrhea, and dysuria. She is not sexually active and denies drug or alcohol use. She is not taking any medications other than ibuprofen for her fever.

Exam: T38.4, P85, R16, BP 100/70. She has a 2.3 kg (5 pound) weight loss since her last visit 6 months ago. She appears tired and ill-appearing, but is cooperative with her examination. Her skin is jaundiced and there is scleral icterus. Her liver edge is palpable 5 cm below the right costal margin, and is moderately tender. There is no splenomegaly. The rest of her examination, including ophthalmologic, cardiac, pulmonary, and neurological systems, is normal. She has no lymphadenopathy.

Laboratory data: Normal CBC and reticulocyte count. Electrolytes, BUN, and creatinine normal. AST 500, ALT 550, alkaline phosphatase 500, GGT 50, total bilirubin 13.5 (direct fraction 5.0). Prothrombin time is 14.0 seconds (prolonged).

In light of her presentation, additional blood work is sent for anti-HAV IgM, HBsAg, anti-HBc, and HCV. On further questioning, it is discovered she ate at a restaurant one month ago where a worker was found to have hepatitis A. Her blood work later returns positive for hepatitis A.

The liver performs many essential functions. It is the first to receive blood from the intestines through the portal vein. It stores vitamins B12, A, D, E, and K. It also stores glucose in the form of glycogen, or converts it into fatty acids. It deaminizes amino acids into ammonia, which is then converted into urea. It manufactures proteins such as albumin, prothrombin, fibrinogen, transferrin, and glycoprotein from amino acids. The cytochrome P-450 system is responsible for the detoxification of many different compounds (e.g., drugs), and is important in the metabolism of steroid hormones and fatty acids. It also synthesizes bile and plays an important role in lipid metabolism. It excretes bilirubin and biliverdin formed from heme in red blood cells from the reticuloendothelial system in different parts of the body (1). Therefore, diseases that damage the liver can have a very detrimental effect on the body. This chapter will discuss some of the diseases that affect the liver, focusing on viral hepatitis.

Hepatitis is an inflammation of the liver and can be due to many different causes. Although viral hepatitis is well known, other diseases include autoimmune causes such as systemic lupus erythematosus, drug-induced causes such as isoniazid, and metabolic disorders such as Wilson disease, alpha-1-antitrypsin deficiency, tyrosinemia, Niemann-Pick disease type 2, glycogen storage disease type IV, cystic fibrosis, galactosemia, and bile acid biosynthetic abnormalities (2). The anatomy and physiology of the liver is complex and outside the scope of this chapter, although its basic concepts are important to understand the pathophysiology of liver disease. The common theme is that there is injury or death to the hepatocytes. When this occurs, enzymes in these cells are released, which include the aminotransferases (aspartate aminotransferase and alanine aminotransferase), alkaline phosphatase, and gamma-glutamyl transpeptidase (GGT). It should be noted that these aminotransferases are also located in heart and skeletal muscle tissues, although alanine aminotransferase (ALT) is more specific to the liver than aspartate aminotransferase (AST) and has a longer plasma half-life (which makes an elevation of AST indicative of early hepatic damage). Alkaline phosphatase, besides being found in the liver, is also present in kidney, bone, placenta, and intestine. GGT is found in biliary epithelia and hepatocytes, and is therefore a more specific marker for liver disease (3). A misnomer is that liver function tests (LFT's) consists of measuring the levels of aminotransferases, alkaline phosphatase, and GGT. However, these intracellular liver enzymes are not indicative of liver function, but rather damage to the liver. As was mentioned earlier, the liver has many functions, such as the production of proteins from amino acids, gluconeogenesis and glycogenolysis, and the excretion of bilirubin. Therefore, damage to the hepatocytes will result in decreased production of proteins, notably albumin, prothrombin, fibrinogen, glycoproteins, lipoproteins, and enzymes. Low albumin can result in ascites, and low prothrombin, fibrinogen, and other clotting factors can lead to a hypocoagulable state. Hypoglycemia can result from failure of the damaged hepatocytes in maintaining glucose homeostasis (4). A major function of the hepatocyte is the conjugation of bilirubin and its excretion into the bile canaliculi. A sign of hepatic injury is not elevated unconjugated bilirubin, but rather conjugated hyperbilirubinemia, which may be due to the decreased excretion of conjugated bilirubin (cholestasis) due to inflammation around the canaliculi. The build up of bilirubin in the bloodstream leads to jaundice or icterus, which is a yellow coloring of the skin and sclera (of note, scleral icterus can be seen when the bilirubin level exceeds 2.5 mg/dl) (5). Note that only some patients with hepatitis are jaundiced because only some patients develop cholestasis. Ammonia is a normal byproduct of protein degradation by intestinal bacteria, of deamination processes in the liver, and glutamine hydrolysis in the kidneys. The liver metabolizes this toxic ammonia into urea by the Krebs-Henseleit cycle. With hepatic injury, however, the ammonia may accumulate which can lead to encephalopathy and coma (6).

With this short explanation on the pathophysiology of hepatic parenchymal injury, the diseases that cause hepatitis can be more readily understood. This next section will focus primarily on viral hepatitis, in addition to two major causes of metabolic diseases of the liver: Wilson disease and alpha-1-antitrypsin deficiency.

The viral causes of hepatitis can be divided into hepatotropic and non-hepatotropic viruses. The non-hepatotropic viruses include measles, rubella, enteroviruses (coxsackie and echo), flaviviruses (yellow fever, Dengue fever), filoviruses (Marburg and Ebola), arenaviruses (Lassa fever), parvovirus B19, adenovirus, and herpesviruses (herpes simplex types 1 and 2, varicella-zoster virus, cytomegalovirus, Epstein-Barr virus, and human herpes virus type 6) (7). The hepatotropic viruses are fewer in number and consist of hepatitis A, B, C, D, E, and G. The hepatitis viruses important in clinical medicine are hepatitis A, B, C, and delta.

Hepatitis A (HAV) is a picornavirus (single-stranded RNA virus) and is transmitted via the fecal-oral route. After it is ingested, it replicates in the small intestine, and then travels to the liver via the portal vein, where it attaches to hepatocytes via a receptor on the hepatocyte membrane. The replicated HAV is then excreted in the bile and passed on in the feces. Liver injury is thought to be due to a T-cell mediated destruction of hepatocytes, rather than to a direct cytotoxic effect. Important risk factors for acquiring HAV infection are close contact (including sexual), fecal-oral (i.e., poor hand washing, etc.), travel to developing countries, and intravenous drug abuse. Therefore, parenteral transmission of HAV is possible, although uncommon. The incubation period of HAV is 15 to 40 days, with a mean of 28 days, after which the patient can develop clinical manifestations of hepatitis. In older children and adults, symptoms can include fever, anorexia, nausea and vomiting, right upper quadrant abdominal pain, dark urine, and jaundice. Less common symptoms include headache, myalgias, arthralgias, pruritus, and rash. Signs can include hepatosplenomegaly, leukopenia, cervical lymphadenopathy, hyperbilirubinemia, and elevation of serum aminotransferase levels. Fulminant hepatic failure is rare. In infants and younger children,

HAV can be asymptomatic or present with "stomach-flu symptoms" of nausea, vomiting, and diarrhea without icterus; therefore suspicion of hepatitis in these patients is often low. Diagnosis is made by measuring anti-IgG and anti-IgM HAV titers. Anti-IgM is present in the acute period, peaking at 1 week and disappearing 3 to 6 months later. Anti-IgG appears later and is highest at 1 to 2 months and lasts for years, and therefore signifies convalescence or immunity. The treatment for HAV is mainly supportive, and the prognosis is good in that it is acute and self-limiting. It does not lead to chronic hepatitis or chronic carriage. In a small percentage of patients, HAV infection can be relapsing or protracted. Prevention consists of good hygiene, the administration of immunoglobulin prophylaxis to contacts, and active vaccination (8,9). Intramuscular immunoglobulin when given as postexposure prophylaxis has >85% effectiveness in preventing symptomatic infection if given in the first 2 weeks of exposure; however, its immunity is short-lived. Active HAV vaccination is recommended for preexposure prophylaxis to people traveling to foreign countries with a high rate of HAV (excludes Australia, Canada, Japan, New Zealand, Western Europe, and Scandinavia). Other recommendations for vaccination are children living in areas of the United States with an incidence rate twice the national average (which includes Arizona, Alaska, Oregon, New Mexico, Utah, Washington, Oklahoma, South Dakota, Idaho, Nevada, and California), people with chronic liver disease, homosexual and bisexual men, IV drug users, patients with clotting-factor disorders, and those who are at risk for occupational exposure) (10).

Hepatitis B (HBV) is a DNA virus in the family hepadnaviridae and has a unique structure. It consists of two shells, of which the outer shell contains the hepatitis B surface antigen (HBsAg) and the inner shell contains the hepatitis B core antigen (HBcAg). In the core are the viral DNA and the hepatitis B e antigen (HBeAg) which is a derivative of the precore DNA region of the HBcAg gene. Like the hepatitis A virus, it has a high affinity for hepatocytes and causes destruction through T-cell mediated cell destruction. HBV is transmitted parenterally and is found in all bodily fluids, but is not found in feces. Although it is found in saliva, the chances of acquiring HBV through sharing of toys by young children are small. Sexual intercourse and vertical transmission (from mother to infant) are other important routes of transmission. Vertical transmission, which is a major cause of acquiring HBV in endemic countries, can occur through the infant swallowing maternal blood during birth or transplacentally. In addition, infants who acquire HBV perinatally have a high risk for chronic hepatitis infection, cirrhosis, and hepatocellular carcinoma. The incubation period is from 50 to 180 days. The clinical course has three stages: prodromal (incubation) stage, symptomatic (icteric) stage, and convalescent stage. The prodromal stage lasts for 2 to 3 weeks and although in most cases the patient is asymptomatic, it can rarely present with membranous nephropathy and vasculitic syndromes. This is followed by the symptomatic (icteric) stage that consists of fatigue, fever, myalgias, anorexia, pruritus, nausea, vomiting, and abdominal pain. This stage can last for 4 to 6 weeks. An interesting dermatologic phenomenon that can occur is papular acrodermatitis of childhood (Gianotti-Crosti syndrome), which presents as nonpruritic symmetrical lichenoid papules on the face, buttocks, and extremities that last for 2 to 3 weeks and often preceded by lymphadenopathy, hepatomegaly, and occasionally splenomegaly (11). The extrahepatic manifestations are possibly due to immune complexes of HBsAg and anti-HBs. After this stage is the convalescent stage (8).

The diagnosis of HBV is made by interpretation of serological markers of HBsAg, HBeAg, anti-HBe, anti-HBc, and anti-HBs, (note the absence of HBcAg which can only be assayed on a liver biopsy, since it does not circulate in the blood in appreciable quantities) and the patient's clinical state. It would be helpful to look at a graph of these markers and course of disease for a visual depiction. However, these graphs are confusing to most students so it would be better to understand where these markers are from and their immunologic/clinical consequence. After inoculation, viral replication occurs. So during incubation and replication of the virus, one would find viral antigens in the serum, namely HBsAg and HBeAg. In fact, these antigens are not found in the blood until 1 to 3 months after the person becomes infected. Patients with these circulating antigens are potentially contagious. A positive HBsAg together with a positive HBeAg is associated with a higher degree of contagiousness than a positive HBsAg alone. While the patient has these antigens then, he is infected and is either in the incubation or symptomatic stage of the disease (acute or chronic). In the meantime, the immune system is fighting off this infection with the production of antibodies against these antigens. For example, Anti-HBs is made in response to HBsAg. The antibody and antigen should not be detectable in the blood stream simultaneously. Basically, the presence of HBsAg indicates infection and contagiousness, while the presence of anti-HBs indicates the presence of immunity. However, there is a brief period after the HBsAg declines and before the anti-HBs rises, when both of them are non-detectable (negative), which is called the "window phase". Anti-HBc is always positive during this window phase.

In acute HBV infection, HBsAg and HBeAg are present. If recovery and immunity are to follow, both antigen levels decline as anti-HBc and anti-HBe levels rise. Ultimately, the presence of anti-HBs signifies immunity. In chronic HBV infection, HBsAg persists and anti-HBs fails to develop. Once anti-HBs and/or anti-HBc are present, these can be fractionated to IgM and IgG. IgM signifies an early immune response, while IgG signifies a later or booster response. It may be best to understand these antigens and antibodies in relation to specific clinical questions.

Is the patient immune or contagious? If the HBsAg is positive, the patient is contagious. If the HBsAb is positive, the patient is immune.

Is a pregnant mother at risk for passing HBV to her child at birth? If mother's HBsAg is positive, then perinatal transmission of HBV is possible and the newborn must receive HBV prophylaxis. If the HBsAg is negative, there is no risk.

The patient is contagious (i.e., the HBsAg is positive), but how contagious is he? If the HBeAg is positive, he is very contagious. If the anti-HBe is positive, then he is less contagious.

Has the patient been exposed to HBV in the past? Check the HBsAg, anti-HBc and anti-HBs. If all of these are negative, the patient has never been exposed to HBV. If one or more are positive, then the patient has been exposed to HBV.

A hepatitis B vaccine recipient wants to confirm immunity. If the anti-HBs is positive, he is immune. If not, immunity has not yet developed.

The prognosis of HBV infection is variable and depends on immune and genetic factors, the age of the patient, and serologic stage of infection. The risk for chronicity increases when primary infection is acquired in the neonatal period compared to adults. For instance, 95% of neonates become chronic carriers, compared to 20% of children, and less than 10% of adults. Chronic states can range from chronic active hepatitis to a chronic non-symptomatic carrier state. Also, the risk for hepatocellular carcinoma (HCC) increases with chronicity; therefore, patients who develop HBV in the neonatal period have the highest risk of developing liver cancer compared to other age groups. It has been shown that men who develop HBV at birth have a 50% lifetime risk for developing HCC compared to women who have a 20% lifetime risk. Patients who develop HCC have a poor prognosis, which has a less than 5% 5-year survival rate (8).

Fortunately, the risk of HBV has declined with universal immunization and diligent prenatal screening. Infants who are born to HBsAg-negative women are given the routine 3-dose hepatitis B immunization, with preterm infants given the first dose after they reach 2 kg. However, newborns from HBsAg-positive women are given both the hepatitis B vaccine and hepatitis B immunoglobulin (HBIG) as postexposure prophylaxis within 12 hours of birth regardless of their birth weight. For infants less than 2 kg, the initial dose should not be

counted in the 3-dose schedule (i.e., they are given 4 doses). After completion of the HBV vaccine series, these infants born to HBsAg positive mothers should be tested serologically for anti-HBs and HBsAg 1-3 months after the last dose. For infants who have low anti-HBs (<10 mIU/ml) and negative HBsAg, they should receive 3 additional doses of vaccine at a 0, 1, and 6-month schedule, with anti-HBs testing done 1 month later to determine immunity. If the HBsAg status of the mother is unknown, serologic testing on the mother should be performed as soon as possible. Term infants should receive the hepatitis B vaccine within 12 hours of birth. HBIG does not need to be given unless the mother's serology returns as being HBsAg positive, in which case HBIG is given soon after. Two hepatitis B vaccines are currently available (Recombivax and Engerix). The schedule consists of 3 doses, with the first dose being given soon after birth, a second dose at least 1 month later, and the third dose when the infant is at least 6 months old or at least 2 months after the second dose and at least 4 months after the first dose (12,13). HBV vaccine is also available in a combination vaccine with diphtheria-tetanus-pertussis (DTaP) and inactivated polio vaccine (IPV).

Hepatitis C was a major cause of post-transfusion hepatitis in the past and was known as non-A, non-B hepatitis prior to the late 1980's. It belongs to the family flaviviridae, which are enveloped RNA viruses. It is spread parentally with highest risk factors being illicit intravenous drug use and unprotected sexual intercourse. Although it is an important cause of posttransfusion hepatitis, only 5 to 10% of HCV infections are due to transfusions. Another risk factor is needlestick injuries in hospital workers. Vertical (perinatal) transmission is probably the most common cause of HCV in children, although overall, it is uncommon for an infant to acquire HCV compared to HBV. HCV is thought to have a direct cytotoxic effect, which is in contrast to HAV and HBV. Clinical manifestations are the same for the other forms of hepatitis B, with most cases being anicteric. However, unique features are fluctuating or polyphasic levels of aminotransferases during the course of disease and slow resolution. In 50% of individuals, chronic HCV infection can occur. Out of this 50%, half become chronic carriers and the other half progress to chronic active infection or chronic persistent infection. For those who are chronic carriers, they are asymptomatic although test positive for HCV. For those who develop chronic infection, 20% will develop cirrhosis and are at high risk for hepatocellular carcinoma. There is no vaccine available against HCV due to its high rates of mutation in its viral envelope, although children who do develop HCV infection have been treated successfully with interferon alpha (8,14).

Hepatitis D virus (HDV) or delta agent is a satellite virus, meaning that it can only cause disease, not by itself, but in conjunction with another virus, which in this case is hepatitis B virus. HDV is a very small RNA virus and is thought to damage hepatocytes by a direct cytotoxic effect. Like HBV, it is spread parenterally. Unfortunately, those patients with HBV who are co-infected with HDV have severe forms of hepatitis. Mortality is higher at 2% to 20% compared to less than 1% for those with only HBV infection. Most patients (about three-quarters) with chronic HDV infection develop cirrhosis and portal hypertension (8).

Two forms of metabolic liver diseases will be discussed next: Wilson disease and alpha-1-antitrypsin deficiency. Wilson disease or hepatolenticular degeneration is a disease of copper metabolism. It is autosomal recessive with the affected gene, ATP7B, being on the long arm of chromosome 13. It occurs worldwide, with a prevalence of about 1 in 30,000, with higher rates in consanguineous families. Mutations in this gene cause impaired copper excretion from the hepatocyte to bile, and decreased incorporation of copper into ceruloplasmin in the hepatocyte leading to high serum copper levels and deposition of copper in many organs. The clinical manifestations of Wilson disease rarely appear until 5 years of age, at which time the gradual build up of copper in various organs becomes symptomatic. Dangerous levels of copper become present in the liver, nervous system, cornea, kidneys, and other organs leading to hepatitis, neuropsychiatric symptoms (some of which are tremor, clumsiness, ataxia, headaches, seizures, and dementia), and Kayser-Fleischer rings around the corneas (a greenish-brown ring in Descemet's membrane at the periphery of the cornea). The diagnosis is made on the basis of several tests and clinical data. Serum ceruloplasmin is low (<20 mg/dl), hepatic copper concentration is high (>250 mcg/gm of dry wt.), 24-hour urine copper excretion is high (>100 mcg/24 hours), Kayser-Fleischer rings are present, and incorporation of 64Cu into ceruloplasmin is low. Without treatment, Wilson disease is fatal; therefore, the basis of therapy targets the reduction of stored copper and preventing reaccumulation of copper. This is done by using copper-chelating agents (e.g., D-penicillamine, trientine, zinc acetate, ammonium tetrathiomolybdate, and vitamin D), a low copper diet, oral zinc therapy, and possibly antioxidants (15).

Alpha-1-antitrypsin deficiency (A1AT deficiency) is another important metabolic liver disease that is autosomal recessive and occurs in 1 in 1,600 to 2,000 live births. Alpha-1-antitrypsin is a glycoprotein that inhibits neutrophil proteases such as neutrophil elastase, cathepsin G, and proteinase 3. The absence of alpha-1-antitrypsin allows these dangerous enzymes to cause damage to organs. The two organs that are affected are the liver and lung. Hepatic manifestations include prolonged jaundice in infants; neonatal hepatitis syndrome, and mild elevations of aminotransferases in toddlers; portal hypertension and severe liver dysfunction in older children; chronic hepatitis, cryptogenic cirrhosis, and hepatocellular carcinoma in adults. The pulmonary manifestation is emphysema, although this commonly occurs in adult cigarette smokers and rarely in children. A1AT deficiency is suspected in infants with neonatal jaundice or older children and adults with unexplained chronic liver disease. The diagnosis is made by determining the phenotype of serum alpha-1-antitrypsin by electrophoresis or isoelectric focusing, and confirmation by liver biopsy. The phenotype associated with liver disease is an individual homozygous for PiZZ (ZZ phenotype of the protease inhibitor system). The treatment of liver disease is by liver transplantation, and emphysema with lung transplantation and cessation of cigarette smoking. Gene therapy may be possible in the future (16, 17).

Lastly, the work-up of hepatitis should be done in a systematic and stepwise fashion. Initially, a complete blood count, total and fractionated serum bilirubins, aspartate aminotransferase (AST), alanine aminotransferase (ALT), gamma-glutamyl transferase (GGT), and prothrombin time (PT) should be performed. AST, ALT, and GGT assess for hepatocellular damage (one could argue that only one of these is necessary) and PT is the most useful test to determine if liver dysfunction is present. If these tests are abnormal and the etiology is unknown, viral hepatitis titers consisting of anti-HAV IgM, HBsAg, anti-HBc, and anti-HCV should be performed. If these tests are negative, other viruses such as Epstein-Barr virus and cytomegalovirus should be considered. If these tests are still negative, other etiologies should be sought after. These etiologies include biliary atresia in neonates (refer to the chapter on biliary atresia), Wilson disease by ceruloplasmin and 24-hour urinary copper excretion, cystic fibrosis by sweat chloride, tyrosinemia by urinary succinyl acetone, alpha-1-antitrypsin deficiency by serum alpha-1-antitrypsin and protease inhibitor phenotyping, and autoimmune hepatitis by presence of autoantibodies and hypergammaglobulinemia (18).

In summary, although viral hepatitis can be self-limited, hepatitis B, C, and delta can cause cirrhosis, death, and liver cancer. Despite the nature of these infections, excellent vaccines can prevent the most common one, hepatitis B. In fact, the hepatitis B vaccine is unique in that it is the only vaccine that can prevent cancer. With the advent of new technologies and gene therapies on the horizon, the outlook for liver disease is favorable.

Questions

1. Why are aminotransferases, alkaline phosphatase, and GGT not considered liver function tests? What is the most useful test for liver function?
2. True/False: Most infants and young children with hepatitis A present with jaundice.
3. A family is planning a vacation in China that is known to have a high rate of hepatitis A. How would you give preexposure prophylaxis to this family who has a 15 month old and a 5 year old child?
4. A labor and delivery nurse informs you that a term infant was just born whose mother is HBsAg negative and anti-HBs positive. How would you approach this infant for prophylaxis?
5. A 1600 gm infant is born to a mother who is HBsAg positive, anti-HBc positive, and anti-HBs negative. The NICU nurse is asking what your order is for this patient. Out of these three HepB tests, which one is the most useful in your decision making process.
6. Name three organ systems involved in Wilson disease and its manifestations.
7. What element is implicated in Wilson disease?
8. What organ systems are involved in alpha-1-antitrypsin deficiency and what are their manifestations?

Answers to questions

1. These enzymes are found within the hepatocyte, and therefore are indicative of hepatocellular damage, and not actual function of the liver. The most useful test for liver function is prothrombin time.
2. False. They are usually anicteric.
3. The 15 month old should receive immunoglobulin (too young to receive Hep A vaccine). The 5 year old can receive the Hep A vaccine since she is over 2 years of age. The vaccine is given as two doses 6 months apart.
4. The mother is actually immune to hepatitis B, perhaps from receiving hepatitis B vaccinations in the past or from a previous exposure to hepatitis B. She does not have infection, she is not contagious and in fact, she is immune. This infant does not need HBIG prophylaxis, but should be vaccinated against hepatitis B in the usual fashion.
5. The mother has a positive HBsAg, which means that she is contagious. Therefore, this infant needs HBIG and hepatitis B vaccine prior to 12 hours of age. Because this premie is less than 2 kg, a 3-dose vaccine schedule should be instituted after this infant is over 2 kg, and not counting the initial dose because he was less than 2 kg. After completion of the 3-dose schedule, he should be tested serologically for anti-HBs and HBsAg 1-3 months after completion of the series. If his anti-HBs (<10 mIU/ml) is low and HBsAg is negative, then he should receive 3 additional doses of vaccine at a 0, 1, and 6-month schedule, with anti-HBs testing done 1 month later to determine immunity. The mother's status could be consistent with acute hepatitis B, chronic hepatitis B, or a hepatitis B carrier state. The most important serologic test out of the three listed is the HBsAg, since this test tells us whether the mother is contagious and the newborn requires HBIG prophylaxis.
6. Brain (or nervous system), liver, and eye. Manifestations are neuropsychiatric symptoms, hepatitis, and Kayser-Fleischer rings.
7. Copper.
8. Lung and liver. The pulmonary manifestation is emphysema and hepatic manifestations include prolonged jaundice in infants, neonatal hepatitis syndrome, mild elevations of aminotransferases in toddlers, portal hypertension and severe liver dysfunction in older children, and chronic hepatitis, cryptogenic cirrhosis, and hepatocellular carcinoma in adults.

Chapter IX.6. Gastroesophageal Reflux
Ken Nagamori, MD

A one month old male is brought to your office by his first time parents with a complaint of constant irritability and spitting up. The 2.8 kg (6 pounds, 3 ounce) product of an uneventful full term pregnancy and delivery, he was discharged on the second day of life. He always seems to be hungry, and since his mother is certain that she is not producing enough milk, she has been following the breast feedings with formula for the last 2 weeks. He currently will feed at the breast for 10 minutes, then consume another 4 ounces by bottle. When left with his grandparents, he will finish an entire 8 ounce bottle in 5-10 minutes and they report he will cry if they try to cut him off at the recommended 4-5 ounces. The vomiting generally occurs immediately after feedings. It is not forceful, nor is it blood or bile-tinged. He fills 10 diapers with urine daily, and lately he has been having watery stools, which have further worried his grandparents. Despite all this, he weighed 3.5 kg (7 pounds, 11 ounces) at the two week checkup and he now weighs 4.3 kg (9 pounds, 8 ounces).

Exam: VS are unremarkable. His physical examination is notable only for fussiness when laid supine on the table, with resolution when held upright or in the prone position. You witness effortless regurgitation of 2-5 ml of curdled formula every few minutes during the history and exam since his parents "topped him off" with formula in your waiting room before the appointment as he was beginning to fuss.

Gastroesophageal (GE) reflux is defined by the North American Society for Pediatric Gastroenterology and Nutrition (NASPGN) as the "passage of gastric contents into the esophagus" (1). This is a normal physiologic process including regurgitation (the generally low pressure passage of gastric contents up to the mouth) as opposed to vomiting (the forceful expulsion of gastric contents via the mouth) as the latter is more often associated with obstruction or other significant abnormal alteration of gastric motility involving reversal of the usual gastric emptying phenomenon. Likewise, it is to be differentiated from rumination, which is the purposeful return of gastric contents to the mouth as a response to behavioral issues, most typically beginning in the second half of the first year of life and occurring in neglected infants and children in part as self-stimulatory behavior or as a means of getting attention from an otherwise markedly non-interactive (and usually clinically depressed) caretaker.

GE reflux occurs at all ages, and its consideration is best divided between infantile reflux and reflux in the older toddler/child, as the presentations will differ due to responses available due to developmental stage. It can be a chronic and a recurrent problem.

In infants, the more typical presentation is as above, which the NASPGN label "the happy spitter" (1) who freely regurgitates, but more commonly than not, has no sign of respiratory compromise. With the relatively low acid secretory capability and the constant feeding of early infancy, there is less tendency to irritability suggestive of dyspepsia, though many (like the child in the example) will show some sign, and some will become markedly colicky. The attribution of the colicky behavior to reflux is supported by an increase in fussiness in positions where reflux would be promoted; such as supine or slumped in a mal-positioned baby seat, or at times when reflux can be expected; such as following an overfeeding as in our example.

In toddlers and older children, overt regurgitation is less common as they spend more time upright and typically will have learned eating behaviors favoring solids and minimizing liquids which further help retain most of the feedings in the stomach. The retention is not complete, however, and they more typically present with symptoms or signs suggestive of distal esophageal irritation. Aside from complaints of epigastric pain (in the pre-verbal toddler often indicated as holding the epigastrium or refusing to eat further), they can include drooling (caused by reflex hypersalivation triggered by the acid sensors of the distal esophagus acting via the brainstem on the salivary glands), or pronounced eructation (i.e., belching, representing regurgitation of air co-swallowed with the saliva). The latter two are manifestations of the esophageal protective mechanisms, and can be seen in early infancy presentations, just as many toddlers will still regurgitate freely. In the older child and adolescent, hypersalivation is more commonly manifest as a sleeping behavior (as not all the saliva produced while recumbent is swallowed) and often is accompanied by sleep in specific positions of comfort, the most common of which are prone and left decubitus as these offer some positional advantage to mitigate reflux. These options are not available to the infant (particularly in the face of the American Academy of Pediatrics' "Back to Sleep" campaign against SIDS), often resulting in worsening colicky behavior, as noted in our example.

Occasional patients will present with respiratory symptoms as their primary complaint with reflux laryngitis and the contribution of microaspiration of either regurgitated acid or oral secretions (from the hypersalivation) in the exacerbation of chronic asthma is gaining increasing recognition. Though more common as a presenting complaint among older children, it will occur in younger children as well, but is not the more common presentation for any age. A more worrisome presentation is frank aspiration or choking, resulting in pneumonia for the former and symptoms ranging from gagging and sleep interruption to apparent life threatening events (ALTE) for the latter. These more serious conditions require full regurgitation, and are also far less common than the non-respiratory symptoms which require reflux only part-way up the esophagus. The NASPGN have acquiesced to the AAP in dissuading prone sleeping position before 12 months of age, though proning may be used while "awake, particularly in the postprandial period" (1).

GE reflux, and more specifically secondary esophageal irritation (if not frank esophagitis), can result in voluntary reduction in intake in all ages, resulting in classic failure to thrive or frank weight loss. It can result in overt feeding refusal, though it more commonly is manifested as a selective intake, avoiding items which cause pain including acidic and spicy foods, and surprisingly commonly, items with adverse effect on the distal esophagus, including caffeine and chocolate if the examiner questions specifically.

GE reflux must be differentiated from vomiting, as the latter hints at obstruction, and can also arise from metabolic processes (urea cycle defects and Reye syndrome) as well as disease in other organ systems (increased intracranial pressure, pancreatitis, urinary tract infection, or distention of any hollow viscus such as the gallbladder or renal pelvis/ureters). It should also be differentiated from extra-abdominal causes such as post-tussive vomiting, or altered motility due to allergic enteritis or eosinophilic gastroenteritis. In the case above, a one month old with projectile vomiting would suggest pyloric stenosis, but in our case the vomitus is not forceful and has been present from the neonatal period. Projectile vomiting requires an intact lower esophageal sphincter (LES) function to develop adequate intragastric pressure. Since GE reflux is common at this age (>50%), projectile vomiting may not be present in infants with coexisting pyloric stenosis with GE reflux, which may delay the diagnosis of pyloric stenosis.

Three mechanisms produce the majority of GE reflux: 1) Chronically decreased lower esophageal sphincter tone is most common at all ages and can be expected to improve over the first year of life. It is characterized by symptoms which occur more commonly immediately after feedings and further reflect effects of posture or intra-abdominal pressure. 2) Delayed gastric emptying is common among adults due to progressive gastroparesis, particularly with diabetes mellitus, but is less common in children. Characteristically it will produce symptoms which continue for hours after feedings, reflecting the persistently full stomach. 3) Inappropriate LES relaxation is

least common of the three, and typically produces more irregular timing of the symptoms, which tend to be more fleeting as the esophageal protective mechanisms are typically more effective in these youngsters than with the other two.

The diagnosis of GE reflux is typically made by a detailed history and physical examination alone. Regurgitation reliably reported or observed with appropriate adjunct symptoms and signs is suggestive of uncomplicated GE reflux. A careful elucidation of a consistent constellation of symptoms can suggest reflux which is not visible (which is also sufficient to trigger the first lines of intervention). It is in situations where significant secondary disease is present (such as recurrent aspiration, stridor suggesting laryngeal irritation, or failure to thrive with or without frank feeding refusal), that subspecialist assistance should be sought at an early stage, even if overt regurgitation makes the diagnosis fairly certain. Efforts should be made to exclude the other items in the differential diagnosis above, but many can be excluded on the basis of a good history and physical examination of the relevant organ systems.

Radiographic studies are not part of the usual initial workup since the absence of reflux on a short radiographic study cannot rule out GE reflux, and the manipulation inherent in the exam can itself trigger regurgitation. The main utility of the upper gastrointestinal contrast study is to search for structural anomalies such as malrotation as well as the much rarer webs and secondary strictures. These are often accompanied by signs of obstruction (though bilious vomiting may be absent if the obstruction is proximal to the mid-duodenum). The exception is the younger patient with signs of tracheomalacia, as the rare vascular ring, trapping both the esophagus and trachea in its grasp during in utero growth, deserves early intervention. Another exception is pyloric stenosis, for which ultrasound provides less invasive evaluation, permitting earlier access to surgery.

The radionuclide gastric emptying study, likewise is not commonly part of an initial workup, as its prime utility is in assessing delayed gastric emptying. Unfortunately, age appropriate standards are not well established, prompting the use of this test in the more severe cases where surgery is already being contemplated (typically fundoplication). Scintigraphic imaging during the hour-long study can also identify reflux visually (but again cannot rule it out due to the short duration of the study) and 24 hour delayed imaging is cited as being of utility in searching for evidence of aspiration.

pH probes offer a means of assessing the frequency and duration of acid reflux, and with the double-sensor probes, the differentiation between regurgitation and reflux only part-way up the esophagus can be made. Twenty-four hour studies are more reliable than those of shorter duration, since reflux varies with activity and sleep state. Their prime utility is in the patient with symptoms which are clear and disruptive who does not have a clear association with visible regurgitation. The classic example is the infant with repeated ALTEs who is found with curdled feedings. The main issue in such patients in establishing causality is determining whether the reflux came first, then the obstruction, then the apnea. It is more common that the apnea came first, then the agonal relaxation of the LES and regurgitation. In such situations, simultaneous multichannel recordings are essential, since the transition from one stage to the next may be only seconds apart, and on such studies many infants with obstructive apneic episodes and known GE reflux have the two occur at completely different times.

Manometric studies have fallen on disfavor, as they do not address the issues of delayed gastric emptying or inappropriate relaxation of the LES.

For the average healthy infant with no threatening complications, the GE reflux can be approached first with basic mechanical measures:

1) Regulate feedings: As in our illustration, overfilling of the stomach is to be discouraged, and in such a patient, I would recommend the bottle feedings be halted if there is ample evidence of sufficiency of breast feedings. This can be reinforced by following the urine output, with most parents being reassured when told that the fluid urinated had to have been absorbed, and the nutrients associated with that fluid can be expected to be absorbed as well. In the bottle-fed infant, the volume can be calculated, but I have found it easier to give the caretakers a means of identifying the volume that would fit in a minimally distended stomach as being roughly a quarter of the abdominal volume as measured between the ribs and the pelvic brim. This forestalls repeated questions of "how much can we feed now?" as the child grows. The feedings also need to be regularly spaced, to avoid overfilling with too closely spaced feedings. This is less of a problem in the exclusively breast-fed infant, but is not eliminated. For the demanding infant, use of suitable pacification (particularly a parental digit) can be helpful. The feedings also need to be evenly paced, to allow enough time for the infant to feel full and cut off the feeding before overfilling occurs. With the bottle-fed infant, thickening of the feedings is possible; in exclusive breast-feeding, the parental digit will again have to be used.

2) Positioning: Maximizing the vertical distance between the mouth (or more particularly the larynx) and the stomach helps minimize reflux and secondary esophageal irritation (i.e., colic). The literature does support prone positioning in this regard, but the cautions noted above regarding SIDS apply. It is worth mentioning to parents, however that infants choose their own sleeping positions once they are able to roll from supine to prone around 4 months of age to avoid many sleepless nights repeatedly rolling their infant back into the supine position only to flip back as soon as he or she is free to do so. Decubitus positioning provides some relief, as can positioning in a recliner (as long as the angle chosen does not cause slumping). There will be times when carrying the infant upright may offer the only relief (particularly after overfeeding).

3) Thickening the feedings may be a consideration in the formula fed infant, and is far less practical in the breast-fed one. In many cases the greater utility of the thickening is in slowing the feeding rate than in any retention within the stomach. Rice cereal is preferred over the recently introduced formulas that thicken when exposed to acid (recall many young infants may not produce much acid). Typical recipes call for one-half to one tablespoon of rice cereal per ounce of formula, which also adds substantially to the overall caloric intake. Thickening to encourage retention in the stomach is of most use in those with evidence of chronic low LES tone (spitting which occurs predominantly shortly after the meal) and can be less than useful in those who have delayed gastric emptying (with spitting which continues for hours after a meal) as it may cause further delay in emptying. In such infants who are formula fed, one of the cheaper partially hydrolyzed formulas may provide the better option, as fluids empty from the stomach faster than curd. In that respect, breast feeding, with its thinner curd, tends to empty faster than most formulas.

In older toddlers and children:

1) Regulate the feedings: Many with secondary esophageal irritation (if not frank esophagitis) will tend to complain of nausea and anorexia in the morning, and skip or minimize breakfast intake. They may or may not eat much lunch, particularly if the school is providing a spicy menu. They often eat more of their daily caloric intake throughout the afternoon and evening. Redistributing the intake to be more evenly spaced during the day will result in less nocturnal acid reflux and is of most utility in those complaining of symptoms after supper or nocturnal waking or morning nausea. Avoidance of after supper snacking can also help.

2) Positioning is less of a problem once infants pass 6 months of age and can choose to be upright. For older children, the option of elevation of the head of the bed for sleep is often declined as more seem to prefer prone positioning.

3) Avoid agents prone to adversely altering LES tone and functioning such as caffeine and nicotine.

In all age groups, a therapeutic trial to address acid can be of significant diagnostic utility. My personal preference is to use antacids, since this provides immediate pain relief (good reinforcement). Typical therapeutic courses with histamine-2 receptor blockers or proton pump inhibitors run 6-8 weeks with only partial resolution. In infants, the aluminum containing antacids should be avoided since aluminum absorption may cause osteodystrophy. A typical therapeutic trial yields suggestive results within 2 weeks, and can be helpful in determining whether an atypical (but non-threatening) symptom is acid-related.

Beyond these basic steps, the evaluation and therapy diverge based on the dominant symptoms. If delayed gastric emptying is the issue, therapy centers on properistaltic agents and may include a more thorough evaluation of structure and gastric emptying. If pain or other inflammatory signs are dominant (i.e., reflux laryngitis), acid secretion suppression or blockade are the mainstay, and endoscopy (with biopsy) offers the best diagnostic discrimination. These measures typically prompt subspecialist assistance.

Infantile reflux typically presents with overt regurgitation and dyspepsia (colic). These can be expected to improve markedly over the first year of life with the transition to a diet based more on solids than liquids and attainment of a more upright posture. Conversely, GE reflux in the older child tends to present as chronic or recurrent pain, with only secondary signs or symptoms of reflux and no overt regurgitation. It represents a chronic problem, the symptoms of which may run life-long, and if mechanical measures and intermittent acid neutralization do not provide adequate symptomatic relief, long-term medical therapy may be warranted. In either case, in the absence of life-threatening complications, surgical options are not a routine consideration, and generally are considered only in the face of failure of extended and aggressive medical management of significant levels of disease.

Questions

1. True/False: Gastroesophageal Reflux is a rare phenomenon in childhood.

2. For the vomiting infant:
   a. The parents can be reassured it is a process the child will outgrow as they get older.
   b. Thickening the feedings sometimes works.
   c. Proper positioning may be helpful.
   d. Deserves further evaluation.

3. A one month old second born female presents with worsening of her GE reflux. The regurgitation remains effortless, but is increasing in volume and seems more prominent an hour or so after meals. She has been more demanding of feedings and has had fewer wet diapers over the last few days and is losing weight. Her parents have felt "something moving" in her stomach in the hour after feedings over the last week. What is happening?

4. True/False: A 4 year old with complaints of abdominal pain that disrupt school attendance warrants a two week trial of a proton pump inhibitor.

5. True/False: A diagnosis of pain due to gastroesophageal reflux is likely to lead to a lifetime of expensive medication.

References

1. Rudolph CD, Mazur LJ, Liptak GS, et al. Pediatric GE Reflux Clinical Practice Guidelines. J Pediatr Gastroenterol Nutrition 2001;32(suppl 2):S1-S31.

Answers to questions

1. False. Though most episodes are asymptomatic, reflux is a routine physiologic phenomenon in everyone, at every age. It is gastroesophageal reflux DISEASE that is uncommon in most of childhood.

2. d. Remember regurgitation is effortless, vomiting is forceful and is atypical for uncomplicated GE reflux. It can indicate obstruction or metabolic derangement, and represents a problem that requires an answer in as short a period of time as possible (even if the answer is a diagnosis of routine gastroenteritis).

3. Consider pyloric stenosis, even if only a few of the classic symptoms and signs are present. Waiting for the diagnosis to become more obvious further delays surgical intervention and increases the risk of complications such as hypochloremic alkalosis and dehydration. See differential diagnosis above.

4. This one is arguable, but my personal preference is to start treatment with antacids since it offers a means of immediate relief of any truly peptic pain episode, and younger children are better reinforced by immediacy of the response. Of course a good history and physical should come first to verify the pain does fit a "peptic" pattern, as constipation is more likely at this age.

5. False. The vast majority of uncomplicated pain seems to respond to mechanical measures, avoidance of caffeine, nicotine, and the like, and intermittent antacid use. It is only when the pain episodes remain disruptive more than once weekly that it is generally warranted to proceed to chronic medical therapy, and then only at the minimal doses necessary unless other complications (e.g., Barrett's esophagus) occur.

Chapter IX.7. Gastrointestinal Foreign Bodies

Lu'ukia Ruidas, MD

A 2 year old previously healthy male is brought to the emergency department by his mother with a chief complaint of gagging. The patient was playing alone when his mother found him gagging and coughing. There were no apneic or cyanotic episodes and the child denied any pain. The gagging ceased after a minute and he was breathing normally. Later that evening, he was watching TV with his mother and again had a gagging episode lasting a minute. His past medical history and family history are unremarkable.

Exam: VS T 37, P 110, R 30, BP 95/60, oxygen saturation 98% on room air. He is alert, cooperative, non-toxic, and in no acute distress. The oral cavity is without lesions or erythema. Lung exam reveals clear lung fields and normal breath sounds. The remainder of the exam is unremarkable.

AP and lateral chest radiographs, obtained 3 hours after his mother noted the first episode of gagging, reveals a coin lodged in the proximal esophagus. A gastroenterologist is consulted and the child is taken to the operating room for endoscopic removal of the coin.

Eighty percent of all foreign body ingestions occur among children (1). Children aged 6 months to 3 years are especially prone to foreign body ingestions since they taste and swallow nearly everything while exploring their surroundings (2). In the United States, about 1500 ingestion cases end in death annually (3). Many of these deaths occur in children with preexisting gastrointestinal (GI) abnormalities, such as fistulas, diverticula, webs, or rings, since these abnormalities put them in danger for foreign body impaction and its complications.

While any small object is an ingestion hazard, coins, food, toy parts, disc batteries, paper clips, needles, earrings, bottle caps, and marbles are among the most common objects ingested by the pediatric population. Nearly all objects that reach the stomach will pass spontaneously over a period of 4-7 days (1,4). Three points in the esophagus represent the most narrow regions of the GI tract. These are the cricopharyngeus muscle in the proximal esophagus (where the cricoid ring impinges on the esophagus), the aortic arch crossover in the midesophagus, and the lower esophageal sphincter. The cricoid region is the most common place to find a foreign body. If the foreign body manages to pass into the stomach, it has already passed the three narrow points in the GI tract so it is very likely to pass spontaneously. However it is possible, though unlikely that the foreign body may have difficulty passing through other narrow points such as the pylorus, duodenal sweep, ligament of Treitz, and the ileocecal valve. Therefore, the clinical approach to GI foreign bodies depends on the type of object ingested and its location along the tract. Dividing the GI tract into three distinct areas, the oropharynx and esophagus, stomach, and intestines, aids in organizing the clinical approach to foreign body ingestions.

A child with a foreign body in the oropharynx or esophagus may present with a foreign body sensation in the throat, airway compromise due to impingement of the easily compressed pediatric trachea, drooling, dysphagia, coughing, gagging, vomiting, or throat or chest pain. A foreign body in the stomach or intestines will not usually cause symptoms. If symptoms are present, they commonly result from complications in these areas such as perforation or obstruction. Symptoms include abdominal pain, hematochezia, nausea, vomiting, hematemesis, or fever. Still, up to 40% of patients with foreign bodies are asymptomatic, regardless of location (1).

On physical exam, inspection of the oropharynx may reveal the foreign body, abrasions, blood, or erythema. Physical findings are unusual with esophageal foreign bodies unless there is tracheal compression, in which case stridor or wheezing may be present. Similarly, the examination of a patient with a gastric or intestinal foreign body is unlikely to reveal any specific findings. Signs indicating perforation or obstruction of the lower GI tract should be sought.

Because the symptoms of foreign body ingestion are often nonspecific, the list of differential diagnoses encompasses a wide variety of conditions. These include pharyngitis, esophagitis, reactive airway disease, pneumonia, pneumothorax, gastroenteritis, and appendicitis. Fortunately, there is often a history consistent with foreign body ingestion from the caregiver, who witnessed the ingestion or from the child, who reported the ingestion to a caregiver. Nonetheless, the possibility of foreign body ingestion should always be considered when caring for children.

Radiographic imaging from mouth to anus should be obtained in any child suspected of ingesting a foreign body, as it is often difficult to determine the exact location of the object from the history and physical. If an oropharyngeal foreign body is visualized on the physical exam of a cooperative, stable patient, attempts can be made to remove it with forceps. Otherwise, indirect laryngoscopy, fiberoptic nasopharyngoscopy, or plain films may help localize the object, most commonly a fish or chicken bone. If the object is visualized but attempts to remove it are unsuccessful, arrangements should be made for endoscopic removal. In the case where the object is not visualized by any of these techniques, endoscopic evaluation should, likewise, be obtained (3). Although an endoscopically confirmed object is found in only 17-25% of patients complaining of a foreign body sensation in the throat, endoscopy may reveal esophageal abrasions or mucosal tears that may be causing the sensation (3). Patients with potential airway compromise or evidence of perforation should first receive airway protection and then referred for immediate endoscopy.

Radiopaque objects in the esophagus are consistently visualized on the mouth to anus screening radiographs obtained for suspected foreign body ingestion. The objects will frequently be seen in one of three locations along the length of the esophagus. In the pediatric population 60- 80% of objects get caught at the level of the cricopharyngeus muscle in the proximal esophagus, 10-20% become trapped at the level of the aortic crossover, and 5-20% are found at the level of the lower esophageal sphincter (3). Coins account for the majority of esophageal foreign bodies in children. Radiographically, a coin in the esophagus is seen as a disk in the anteroposterior projection and from the side on lateral films as it is lodged in the easily compressed esophagus, which lies posterior to the trachea. Conversely, a coin in the trachea is seen from the side on anteroposterior films and as a disk on lateral films as its orientation conforms to that of the vocal cords en route to the trachea (however, most coins cannot fit in a pediatric trachea). Although AP films are sufficient to determine whether the coin is in the esophagus or trachea, based on its orientation, lateral films should also be obtained to ascertain whether there is more than one coin lodged in the esophagus, not easily seen in the AP projection. Radiolucent objects in the esophagus, such as plastic, wood, or aluminum can tabs, are difficult to detect on plain films. In this case, CT, contrast radiography or endoscopic examination should be obtained.

Management of an esophageal foreign body depends on the type and location of the object. Any sharp, rigid, or long (>5-6 cm) object should be removed endoscopically since these objects are associated with a high incidence of esophageal and lower GI tract perforation (1,2). Objects in the proximal and mid esophagus should also be removed endoscopically since they usually do not pass spontaneously into the stomach (5). A single blunt object located in the distal esophagus for less than 24 hours in an asymptomatic, otherwise healthy patient may be allowed to pass spontaneously into the stomach if close follow up can be assured. However, if passage is not seen on radiographs obtained 24 hours after ingestion, the object should be removed endoscopically since objects allowed to remain in

the esophagus for more than 24 hours are associated with mucosal inflammation (6). Patients with respiratory difficulties or those showing signs of esophageal perforation should be immediately referred for endoscopy.

Several other removal techniques have been described for blunt esophageal foreign bodies in an asymptomatic or minimally symptomatic patient. The Foley catheter method, done by experienced personnel, involves inserting the deflated catheter orally, past the object. The balloon is then inflated and the catheter is slowly withdrawn, pulling the foreign body ahead of it. The use of glucagon to relax the smooth muscle of the lower esophageal sphincter and allow passage of the object into the stomach has also been described. Success rates using glucagon in children range from 30-50% (2). Frequent side effects of glucagon are nausea and vomiting. While these techniques may be cost effective, compared to endoscopy, they do not offer airway protection or allow visual evaluation of the GI tract (1).

Asymptomatic patients with foreign bodies in the stomach may be observed for spontaneous passage of the object. If movement from the stomach is not detected on follow up radiographs in 7 days or if the patient becomes symptomatic, referral for endoscopic removal is required (4). Sharp gastric or duodenal foreign bodies should be removed by endoscopy immediately since 15-35% of sharp objects will perforate the lower GI tract (3). As mentioned previously, long objects should also be removed endoscopically since these might not be able to navigate through the duodenal sweep.

Once the foreign body reaches the intestines, it will likely pass through the rest of the GI tract successfully. If the object remains in any region of the lower GI tract for more than 7 days or if the patient develops signs or symptoms of perforation or obstruction, the foreign body should be removed surgically (2). If a sharp object passes beyond the pylorus, endoscopic removal is more difficult so the patient should be followed with daily radiographs and observed for signs of perforation and bleeding. If complications do develop, the patient should be referred for surgical removal of the object. By the time a sharp object reaches the colon, it becomes surrounded by fecal material and is able to pass though the rest of the lower GI tract safely.

Complications of foreign body ingestion can occur throughout the GI tract. These include airway compromise, abrasions, perforation with resultant abscess formation, obstruction, ulceration, fistula formation, or vascular injuries. With the advent of endoscopy, more foreign bodies are successfully removed resulting in less complications.

Disk or button batteries are small, coin-shaped batteries used in hearing aids, watches, and calculators. Prior to 1982, only a few cases of disk battery ingestion were described (4). As the use of these small electronic gadgets have increased, the problem of disk battery ingestion has become more common. Seventy percent of disk battery ingestions occur in children aged 6 to 12 years (1). The danger of disk batteries is that they contain mercury, silver, zinc, manganese, cadmium, lithium, sulfur oxide, copper, and sodium or potassium hydroxide. If the battery becomes lodged in the GI tract it may cause pressure necrosis, low-voltage burns, or ulceration due to liquefaction necrosis stimulated by leakage of the battery's alkaline solution (2). As little as one hour of contact between the battery and esophageal mucosa may result in injury (4). Because of the damage that can occur in the esophagus, endoscopic removal should be done immediately after localization by radiographic imaging. On the anteroposterior projection, disk batteries can be distinguished from coins by the double-density shadow of its bilaminar structure (4).

If the battery is located in the stomach, there is a 90% chance that it will pass through the GI tract spontaneously (3). As the battery is allowed to pass, patients should be monitored for signs of perforation or bleeding. If these complications become evident or if the battery has not moved beyond the stomach in 3-4 days, endoscopic removal should be performed. Endoscopy will also allow for visualization of the upper GI tract for evidence of ulceration or necrosis caused by the battery. Batteries that pass into the intestine are generally eliminated without consequence. Though there may be concern about mercury toxicity should the contents of the battery leak out into the GI tract, mercury oxide, is not readily absorbed by the GI tract (1). Therefore, the risk of toxicity is low.

Bezoars are accumulations of exogenous material in the stomach and small intestine. They are classified according to their composition. Trichobezoars are accumulations of hair, often the patient's own. Ninety percent of patients with trichobezoars are females aged 10-19 years with trichotillomania and trichophagia (4). Phytobezoars are composed of plant and vegetable matter. Persimmons, celery, pumpkin, grapes, leeks, and grass have all been known to form phytobezoars if they are ingested in great amounts. Lactobezoars are formed by milk components. Though the reasoning is not clear, the majority of lactobezoars are found in premature, low birth weight infants (7). Factors associated with lactobezoar formation may include rapid advancement in feedings, high calcium and protein content of specialized formulas, or the unique gastric physiology of premature infants. Antacid bezoars are accretions of dehydrated antacids, commonly seen in patients with poor gastric motility or patients receiving high dose antacid therapy.

Bezoars, regardless of composition, often present with symptoms of abdominal pain, anorexia, nausea, and vomiting. The physical exam may reveal abdominal distention or a palpable abdominal mass. Bezoars may be visible on plain films but computed tomography with contrast is the imaging technique of choice since it allows for estimation of the size of the bezoar, which often directs management. Endoscopy allows direct visualization of the bezoar and also provides information on its content. Most trichobezoars are managed surgically. Small trichobezoars may be removed in fragments by endoscopy. However, the density of the bezoars often presents a challenge. Phytobezoars are frequently dissolved using a clear liquid lavage and metoclopramide or endoscopic fragmentation. Otherwise, surgical removal is required. Feeding withdrawal for 48 hours with maintenance IV hydration is usually all that is required for resolution of lactobezoars.

Questions

1. At what three areas of the esophagus are foreign bodies commonly located?
2. If a coin is seen as a disk on the anteroposterior film, is it in the esophagus or trachea?
3. True/False: A sharp object in the distal esophagus may be observed for 7 days if the patient is asymptomatic.
4. True/False: There is a high risk for mercury toxicity if the contents of a disk battery leak into the GI tract.
5. What are phytobezoars?
6. If an 12 month old swallows a penny, is there any possibility that it is in the trachea?
7. What accounts for the increased incidence of ingested disc batteries?

Answers to questions

1. The level of the cricopharyngeus muscle in the proximal esophagus, the aortic arch crossover in the midesophagus, and the lower esophageal sphincter.
2. The esophagus because of its orientation.
3. False. A sharp object in the esophagus should be endoscopically removed immediately to prevent perforation.
4. False. The mercuric oxide in disk batteries is not readily absorbed by the GI tract.
5. Accumulations of plant and vegetable matter.
6. A penny cannot fit in an infant's trachea.
7. More gadgets which use disc batteries increases the likelihood that these batteries will be left around the house for young children to put into their mouths.

Chapter IX.8. Constipation
Ken Nagamori, MD

Case #1: At her one month well child visit, worried parents ask about their child's protuberant abdomen. She had been breast-feeding well during the first week, but her intake has been declining and she has begun spitting up. Physical examination finds lethargy, pallor with diaphoresis, tachycardia, distended loops of bowel, and rectal examination finds a narrow anus, and further insertion gives the impression of putting on a glove two sizes too small. The narrow canal extends for two centimeters, then widens into a pool of loose stool. When the examining digit is withdrawn, it is followed by a sudden spurt of particularly foul-smelling stool laden with mucus and streaked with blood, accompanied by a moderate amount of flatus. Questioning the parents identifies the failure to pass stool or flatus without stimulation with a rectal thermometer, having received instruction to do so from her aunt who is a nurse.

An abdominal series is obtained which demonstrates dilated bowel loops and a pattern resembling an acute bowel obstruction. Hirschsprung's disease with acute enterocolitis is suspected.

Constipation is a commonly used term, but its definition is somewhat ambiguous. It could refer to conditions such as: a) the stools are hard, b) the stool is difficult or painful to pass, 3) no stools for a period of time, 4) a bloated feeling, 5) painful cramps associated with a segment of stool that is not moving well, 6) a chronic condition in which a patient's stooling frequency is less than average. All of these definitions are used in medical and/or everyday communication, but it is preferable to use specific terms to describe the symptoms of the patient. The specific findings and their clinical significance will be described in this chapter.

Enterocolitis (as seen in case #1) is the extreme sequel of fecal retention, and is almost unique to Hirschsprung's disease, itself a uniquely pediatric version of the broader definition of chronic constipation: "a delay or difficulty in defecation, present for two or more weeks, sufficient to cause significant distress to the patient" adopted by the guidelines of the North American Society for Pediatric Gastroenterology and Nutrition (NASPGN) (1). The subject is best broken into two broad categories: infants and children.

Infantile constipation: Per the guidelines, this does not include neonatal delays in defecation since the structural anomalies (imperforate anus, cloacal exstrophy, and other perineal anomalies, as well as intestinal atresia, stricture or web, volvulus, duplication, or perforation) and genetic diseases (e.g., meconium ileus of cystic fibrosis) often present in the first few days. Newborns should pass their first meconium stool within 24 hours. Those who don't have a higher risk of GI conditions associated with constipation. However, this criterion should not be relied on in isolation since pathologic conditions will not necessarily present this way. The algorithm proposed by the NASPGN constipation subcommittee emphasizes early suspicion of serious disease, by rapidly sorting out newborns with delayed passage of meconium for rectal biopsy and directing infants with "fever, vomiting, bloody diarrhea, failure to thrive, anal stenosis, tight empty rectum, impaction and distention" (1) to immediate further evaluation, including subspecialty consultation as needed.

The workup begins with a thorough history and physical examination. The above alarm indicators are searched for, as are signs of other structural anomalies. The rectal examination is key, with careful assessment of the anal location, anal neurologic function (the anal wink, which assesses both the sensory afferent and motor efferent pathways), anal structure (looking for distention of the internal anal sphincter), anal tone (looking for spasticity or patulousness), function of the muscles of the pelvic floor (which provide additional help with control of defecation), and rectal diameter and tone (looking for signs of chronic distention even if no stool is present on the day of exam). The anal location should be halfway between the posterior border of the scrotum or posterior fourchette and the tip of the coccyx. Anything outside of the middle third of this region should raise the suspicion for a "perforate imperforate anus" (a structure resembling an

anus is visible externally, but it is not contiguous with the rectum). If benign constipation is found, treatment is stratified based on age and developmental state.

Exclusively breast fed infants are permitted a longer interval between stools if they show no signs of distress or distention and if they are not prone to becoming impacted.

In exclusively formula-fed infants, my favorite strategy is the substitution of a commercially available partially hydrolyzed formula, which may produce suitable loosening of the stools. Malt soup extract (a dehydrated powder derived from an effusion of malted barley used in the brewing industry) has been advocated by the committee, as have corn syrup, lactulose or sorbitol, while the use of mineral oil was cautioned against due to the risk of aspiration posed by the frequency of gastroesophageal reflux and swallowing incoordination in this age group.

Impaction is most commonly dislodged by glycerin (non-stimulant) suppositories for which the commercially pre-softened versions sold in soft plastic applicators (glycerin gel) have been my personal favorite, as they provide more immediate relief (the traditional refrigerated suppositories require a wait while they melt in situ). Stimulant enemas are to be avoided in young infants.

Older infants who are of an age where pureed foods would be appropriate should have the fiber content of their diet optimized (i.e., push fruits and vegetables and reduce the other starches). Another personal favorite in the older formula fed infant is the use of undiluted apple juice (not apple drink) for its sorbitol content, titrating the amount administered to the stool texture while making certain that formula intake remains adequate. Pear and prune juice can also be used as they are high in sorbitol, but the cost of the former and the TASTE of the latter are often limiting factors.

Case #2: This 6 year old male presents with fecal soiling on a daily basis, which began in late October. He claims he "can't tell when" he is about to soil. His parents report multiple bouts daily of fecal urgency where he rushes to the toilet, only to pass small amounts of diarrheal stool. His toilet sitting behavior is peculiar in that he sits far back on the toilet seat with his knees extended and his toes pointed, straining at defecation. Once or twice weekly he will pass a very large caliber formed stool, which has on occasion plugged the plumbing. This pattern was not thought to be a problem by his parents as it began shortly after they began potty training him at two years old so that he could enter preschool earlier than rest of the neighborhood children. The dietary history finds that he eats the school breakfast and lunch, and will often not touch his vegetables at supper. Closer questioning indicates he does not pick fruit or vegetables from the salad bar at school, and the school typically offers only sweet buns or a burrito for breakfast. Physical examination finds a midline mass in the lower abdomen, with a rectal examination that shows a normally placed anus with an intact anal wink and a perineum coated with stool. The anus is shortened with the internal anal sphincter dilated by a massive boule (little football) of formed stool. You are unable to accurately assess the diameter of the rectum as the stool appears to fill the pelvic bowl. The stool tests negative for occult blood.

Unlike the child with Hirschsprung's disease in the first illustration, the retention of stool in the older child who does not have a structural or neurogenic anomaly (as seen in case #2) will NOT cause secondary inflammation and enterocolitis, regardless of the duration of the problem. This lack of inflammation is an important differentiating factor that permits immediate identification of the older child with chronic constipation. The primary cause is voluntary fecal withholding, usually due to fear of pain on defecation, giving rise to the term "Psychogenic Constipation". The often accompanying overflow diarrhea or involuntary soiling arising from passage of looser chyme above and around the impaction is termed Encopresis in verbal analogy to enuresis. In simpler terms, the child has a football shaped mass of hard stool in the rectum which reduces the sphincter's ability to hold in liquified stool (chyme) coming from above, which results in soiling. The withholding behavior most often arises from a pattern of passage of large caliber stool as was the case with our illustration, but it can arise in response to a single traumatic event, such as a particularly large stool resulting in a traumatic fissure, a too-rapid transition from diarrhea with a raw perineum to fully formed stools, perianal cellulitis (more properly erysipelas, an intensely painful superficial infection of the anus and surrounding structures with Group A streptococcus identifiable by culture of the affected area), or least frequently but most insidious: overt trauma of physical or sexual abuse.

As in infantile constipation, the history and physical exam are key. The above historical markers are useful in establishing an understanding of the process by the patient and his or her caregivers. Dietary issues must also be explored, as well as the pattern of toileting (it is amazing how little time and opportunity school age children seem to have for sitting on the toilet, with some schools having policies of allowing only two minutes per bathroom break).

The issues on the physical examination of the older child are the same as those of the infant, particularly those regarding the rectal examination. Indicators of failure to thrive are more important beyond the first year, since celiac disease and cystic fibrosis occasionally present with constipation instead of diarrhea, and Crohn's disease can leave the rectum fully capable of extracting fluid from the reduced flow of chyme arising from the reduced appetite, if the inflammation is confined to the small bowel or proximal colon. Hypothyroidism is a particularly rare (but often cited) cause of constipation. A particular caution regarding Hirschsprung's disease bears noting as a significant fraction of the cases present beyond the second year of life in children who require stimulation to trigger defecation: repeated suppositories and enemas will often dilate the spastic segment making it impossible by digital examination alone to identify what should otherwise have been a microcolon. If suspicion is high (inability to spontaneously pass flatus or a strict requirement of stimulation to pass stool which when triggered tends to be foul, loose, and voluminous), an unprepped barium radiographic colon examination is indicated. This study should specifically look for a transition zone, to and fro peristalsis in the unobstructed segments, or uniform mixing of the contrast material throughout the colon (rather than concentration of the remaining barium in the rectum) on the 24 hour delayed film (hence the stipulation for barium rather than water soluble contrast which would tend to be absorbed by the next morning). If the radiographic study is equivocal, anorectal manometry may be of benefit. If either are indicative of Hirschsprung's disease, the diagnosis is confirmed by biopsy of the rectum deep enough to include the myenteric plexuses, as their absence indicates the disease.

If simple constipation without impaction or soiling is identified, therapy begins with education regarding the need for a more regular defecation pattern to prevent progression of the problem.

Dietary intervention is advocated, emphasizing fiber and fluid in accordance with proper nutritional guidelines. Here I find a concrete set of recommendations is most helpful in facilitating compliance, and I have abridged the USDA's food pyramid (2) to a set goal of 6 servings of fruit or vegetables daily with a like number of servings of fluid, which is even further simplifiable to 2 servings of fruit or veggies at each meal which is easily understood by preschool AND adolescent patients.

More importantly, the need for regular toileting in the already potty-trained is emphasized, and I ask that they sit on the commode twice daily after meals to take advantage of the gastrocolic reflex to promote more regular rectal emptying. As in our illustration above, there must be an immediately preceding meal for the process to be most effective, and I have found that eating two fruits before toileting to

be helpful. Suppers eaten out should be followed by a trip to the restaurant toilet to avoid missing the increased post-prandial peristaltic activity. A five minute time limit is set for commode sitting to avoid any sense of a punitive nature to the requirement and in some cases I will advocate using a kitchen timer in a "beat the clock" game if appropriate for the patient's personality.

Encopresis on the other hand is an indicator of repeated impaction, and usually is accompanied by enough dilatation as to render the rectal musculature patulous. Here again, education is key, and to simplify the biophysics (the wall tension is proportional to the fourth power function of the bowel lumen diameter), a quick analogy to a balloon that has been repeatedly inflated to the point of flaccidity is readily within the experience of most 4 or 5 year olds. Likewise an analogy to repeatedly compacting the trash over a 3-4 day period rather than dumping it daily will usually trap a kindergartner into admitting such behavior is likely to lead to a heavier, harder and bigger trash bag (and stool). Most importantly, education and discussion is important which should center on the cycle of pain at defecation leading to withholding which results in larger, firmer stools which in turn leads to more pain at defecation, perpetuating the cycle. This helps create understanding in the patient and the parent as to the origin of the process and its ultimate eradication. A thorough discussion of the mechanics of impaction and overflow passage of the as-yet unformed stool around the obstruction helps explain why distention of the rectum and internal anal sphincter and distortion of the levator structures of the pelvic floor result in inadvertent passage of loose stool whenever voluntary control of the external anal sphincter is relaxed. A thorough understanding is important in defusing the animosity that often arises between the patient and caregivers (parents, school, babysitters, etc.) over misunderstanding of what causes and perpetuates the soiling.

Treatment in the impacted, encopretic patient starts with disimpaction. High dose mineral oil and polyethylene glycol bowel preparation solutions have demonstrated efficacy and magnesium citrate, lactulose, sorbitol, senna and bisacodyl having been used anecdotally (1). Though the NASPGN subcommittee found that the oral route can be effective, typically this route is messy and more time-consuming. I strongly prefer a series of hypertonic phosphate soda enemas that are administered at 12 hour intervals (3). Typically only 3 are required, but the importance of removal of all formed elements is emphasized to prevent worsening the overflow diarrhea in the face of the fecal softening to follow. Caution is advised in using too much or too many enemas as each leaches a substantial bolus of calcium. In the case of particularly large and firm impaction, pre-softening by application of a mineral oil enema an interval before the stimulant one can be helpful. Saline enemas were also advocated by the committee as safe and effective, but soap suds, tap water and magnesium enemas are discouraged due to toxicity (1).

The next step is fecal softening, the issues being two-fold: produce a stool loose enough to be eliminated by the patulous rectum, AND eliminating any association of pain with defecation. Again, while the committee found lactulose, sorbitol, magnesium hydroxide, magnesium citrate, and mineral oil to be effective (1), I strongly prefer mineral oil (3) starting at 2-3 ml/kg/day but specifically titrating the dose to achieve the desired stool texture which I specify as "pancake batter", which has enough form to be routinely retained by the internal anal sphincter yet which is loose enough to empty out of the rectum with little more force than that of gravity alone whenever the levator structures of the pelvic floor are lowered and the anal sphincters are opened. In most cases, a patient whose rectum is dilated enough to allow soiling will have trouble expelling stool even the texture of toothpaste, which is the softest that can routinely be expected from fiber and fluid alone. A looser stool is needed to start the process, and mineral oil provides the cheapest and least flatulent method of attaining that goal. While the committee also made provisions for short-term addition of laxatives to this regimen (1), I feel anyone whose rectum is patulous enough to require such additional assistance, should have subspecialist evaluation, as this is by far the exception rather than the rule.

The third step is effective toileting: the already potty-trained patient should be seated on the commode with good foot support (to obviate any tendency to use the musculature of the buttocks and legs to assist in further withholding activity) on the commode twice daily after meals under the same guidelines and for the same reasons as outlined in the simple constipation as above. The sitting is made "non-negotiable" simply to ensure its application as it will become the most enduring and important part of the regimen as the weaning process progresses. Those who are not yet potty-trained are excused from formal sitting but are encouraged to crouch in diapers after meals in an analogous fashion.

Once a better than daily bowel habit is established and withholding is clearly extinguished, weaning off the mineral oil can begin. It is taken VERY slowly, in part to avoid recurrence of pain and resumption of withholding, but more to allow time for the patulous rectum to regain motor tone. I illustrate the importance of this to the patient and family by referring back to the balloon illustration, pointing out the difference between inanimate latex and living muscle, which can regain tone and function. I specifically warn that the process will take months to improve, and that prolonged use of mineral oil has been proven benign (4). This helps improve adherence to the long-term nature of the measures involved, and weaning typically occurs at monthly intervals, and then ONLY if the rectum is indeed shrinking in diameter (and improving in function) and if the withholding remains extinguished. Failure with either issue should result in either maintenance at the current step or return to the next higher one.

Adherence to the mechanical measures involved typically results in an immediate return to continence with the completion of disimpaction, as the nondistended internal anal sphincter is able to retain the loose stool. Continued adherence to the slow weaning typically results in return to long term function (and confidence) through the months of steady increase in stool texture. Permanent adherence to a daily defecation pattern results in long-term avoidance of reimpaction, and is the ultimate goal of the process. Each step along the way involves the physician acting as coach, cajoling and encouraging patients and caregivers, solving problems in techniques, and refereeing any residual conflicts. It must be kept in mind that control in this issue lies with the patient. There is nothing we can (or should) do that will force regular toileting, and there are times when I have to call a "time out" from the process to enable the patient to proceed on his or her merry way until THEY are ready to work on the problem. I often remind parents that the only thing one will die of with routine encopresis is embarrassment, remembering that children are often beaten to death by caregivers for soiling behavior. As can be seen above, the initial visit to address the issue of encopresis can be particularly time-consuming, not with regard to the history or physical examination, but because of the need to impart the understanding of the process of the disease that will encourage an apprehensive child to undertake the measures needed to clear it. The hour rapidly fills with illustrations and instruction, and does not readily fit into a routine sick-child office visit. Time must be set aside for proper handling of the process, and I know most consultations for encopresis arise from the inability to carve out such time in the primary care practice setting.

Questions

1. The nurse points out a two day old healthy term infant who is otherwise ready for discharge who still has not passed meconium. Your next step is:
   a. Order a suppository prior to discharge.
   b. Careful physical examination, including digital rectal examination.
   c. Give a normal saline enema to prep for a barium enema.
   d. Call radiologist to discuss an unprepped barium enema
   e. Rectal biopsy.

2. The exam of a 3 year old with recurrent impaction is normal except for the impaction and the absence of an anal wink. Which of the following are true.
   a. An anal wink is not commonly found in this age group.
   b. The anus may be so traumatized by the impaction that the wink cannot be reliably elicited.
   c. There may be a neurogenic component to the problem in addition to the psychogenic one.

3. Your examination of a chronically soiling 13 year old female finds a normal sized rectum containing soft stool. Is this routine encopresis?

4. A 6 month old infant has been getting suppositories and enemas every 3-4 days because she does not otherwise defecate. The stools were passed without apparent trouble on breast feeding. Rectal examination finds a normal sized rectum as far as you can reach. Does this rule out Hirschsprung's disease?

5. The barium enema performed yesterday was read as normal, but the remaining barium did not pass overnight. You obtain a followup film this morning, and find dilute barium evenly distributed from the cecum to the rectum. What is the likely diagnosis and why?

Answers to questions

1. Answer d is correct, and the radiologist will appreciate the warning as to why the exam is being requested without prior bowel cleanout (which may otherwise be performed as part of the radiology routine, rendering the same end result as answer c). Answer a will not only miss the diagnosis but may also render diagnosis more difficult later if the pattern is set for stimulation for defecation. Answer b may give the diagnosis if a microcolon can be identified on exam, but can make interpretation of a barium enema difficult. Answer c is wrong for the same reasons as a and b. Answer e is doing too much too soon.

2. Correct answers are both b and c. Anal winks can be expected at any age unless the anus has indeed been badly traumatized. Its absence usually indicates a neurogenic component, and the examiner is prompted to carefully assess the tone of the sphincter and retrospectively look for other signs of aberrant function of the longer neuron sensory and motor tracts or signs of sacral anomalies. If the issue is still in doubt, it can be deferred by one visit. The process can still be addressed by full fecal softening and re-establishment of regular bowel habits since the therapies diverge at a later stage where a timing suppository needs to be added to maintain regular defecation as the weaning progresses and the stool becomes firmer. Full fecal softening is needed initially for both causes to address the flaccidity of the rectum.

3. No, the absence of impaction is worrisome, and the behavioral and social history are likely incomplete. The above pattern suggests voluntary soiling, in which a socially uncomfortable behavior is expressed to avoid an even more uncomfortable behavior, such as sexual abuse.

4. NO! The enemas may have dilated the rectum beyond the reach of the examining digit, and it is common for patients with short segment Hirschsprung's disease to pass the softer stools of breast feeding but have trouble with formula and pureed food. Expert radiographic evaluation is necessary, and the assistance of a pediatric surgeon or gastroenterologist may be helpful.

5. This is the typical appearance of the delayed view in a patient with Hirschsprung's disease. The obstruction is of high enough a grade that the portion of the colon with normal ganglion innervation has set up a "to and fro" pattern of peristalsis, evenly mixing the remaining barium with the increased fluids present in the lumen, rather than transporting the barium to the rectum where the excess fluid is removed (which is the appearance of the normal colon).

Chapter IX.9. Hirschsprung's Disease
Walton K.T. Shim, MD

An infant male presents in the second day of life with a large bilious emesis. He had been "spitty" for a day and had yielded 15 ml of greenish gastric aspirate at birth. He had not passed meconium for the first 36 hours of life. He was born at term weighing 3.5 kg.

Exam: VS T 37.2 (rectal), P 125, R 30, BP 75/55, weight 3.4 kg. He is an active hungry infant with a moderately distended abdomen. Bowel sounds are very active but not obstructive in nature. No organs or abdominal masses are appreciated and no herniae are present. His anus is patent.

An abdominal series reveals large dilated loops of bowel but no air in the rectum. A hand injected contrast enema on the third day of life shows no distinct transition zone. A 24-hour delayed film shows retained contrast and a rectal mucosal suction biopsy reveals an absence of ganglion cells and the presence of hypertrophied nerve fibers consistent with a diagnosis of Hirschsprung's disease.

Rectal irrigations are not successful in decompressing the colon leading to the establishment of a descending colonic ostomy, placed under biopsy guidance. When the infant achieves a weight of 7 kg (15 pounds) a definitive resection will be performed.

Hirschsprung's disease (also known as congenital megacolon or congenital intestinal aganglionosis) is a disease condition most commonly affecting the rectosigmoid portion of the colon. It presents with constipation in older infants and children, but mainly by distention and vomiting in newborn infants. The affected segment lacks ganglion cells which aid in normal peristalsis. Without these ganglion cells, normal peristalsis is lacking, resulting in a functional obstruction. This produces a proximal dilated colon and a distal normal appearing segment. Classically, there is an obvious transition zone where the dilated colon (with normal ganglion cells and peristalsis) meets the non-dilated colon (which is abnormal and aganglionic). The appearance is paradoxical, and in the past, has led surgeons to remove the grossly dilated (normal) portion rather than the normal appearing aganglionic segment of the colon. This of course resulted in recurrence of the obstruction and dilatation. The severity of Hirschsprung's disease varies with the length of the involved segment and may be very difficult to diagnose especially in the ultra short segment disease because of the variability of the constipation. Total aganglionosis of the colon is quite uncommon but aganglionosis involving the small bowel is rare.

The earliest description of a case of congenital megacolon was by Fredrick Ruysch in 1691, almost two centuries prior to the classic description of the Danish physician Harald Hirschsprung who reported two cases of young boys dying with a hugely dilated proximal colon and a narrowed distal colon and rectum in 1886.

Early in the history of the disease attention focused on the hugely dilated proximal colon as the abnormal portion so that resection of this area was attempted. Of course this failed soon after operation with resumption of a megacolon.

A pediatric surgeon, Orvar Swenson, was the first to devise a procedure based on observations that a colostomy established in the dilated segment functioned normally but again became obstructed when reconnected to the distal narrow portion. He concluded that functional obstruction occurred in the narrower but normally appearing distal segment. Swenson followed up these observations with pressure measurements through colostomies in patients both with and without Hirschsprung's disease and showed normal peristaltic activity in the proximal dilated colon but no peristalsis in the distal narrowed segment (1). His contribution was to resect the distally narrowed area and connect the dilated segment to two or three centimeters of distal rectum. The procedure was successful and described in 1948 (2).

This was followed a few years later by Duhamel who incorporated a portion of the anteriorly placed aganglionic rectum with a posteriorly placed, normally innervated colon to produce a new rectum composed of half aganglionic and half ganglionic musculature.

A still later modification was proposed and used by Soave who stripped the mucosa from the distal aganglionic rectum and passed the normally innervated colon through the sleeve of dysfunctional rectum (an endorectal pull-through) relying on the normal portion to propel through the abnormal cuff.

Each of these procedures has been successful in overcoming the functional obstruction in the great majority of cases, but each has its own complications.

Common to each procedure is post-operative enterocolitis characterized by abdominal distention, loose foul smelling stools, and vomiting. It occurs in a quarter to a third of cases and should be treated early and aggressively with rectal irrigations, anal dilatations and intravenous support as death may occur if it is neglected (3). Although fever and signs of infection may be present, stool cultures are often not helpful. The author routinely has parents or caregivers dilate the anus or irrigate the rectum postoperatively for several months to prevent enterocolitis. Most patients continue to improve bowel control for several years postoperatively (4).

About five percent of Swenson procedures experience anastomotic leaks. Incomplete emptying of the aganglionic portion of the pouch plagues some Duhamel patients. Patients with endorectal Soave procedures suffer from cuff abscesses and may require continued dilatations.

Recently with the introduction of minimally invasive procedures involving laparoscopic dissection and various stapling devices, techniques have changed but the basic concepts for overcoming the non-relaxing, functionally obstructive distal colon are unchanged.

The diagnosis is suggested in a term newborn who has emesis and abdominal distention early in the newborn period. Since a newborn usually passes his/her first meconium on the first day, the most suggestive symptom is the lack of meconium passage during the first day of life. Ninety-nine percent of normal newborn infants pass stool within the first 48 hours of life (5). A digital rectal examination is not helpful and may prevent an accurate contrast enema study, although a temperature probe may be gently inserted to prove anal patency.

In the face of delayed meconium passage, vomiting and abdominal distention, an abdominal series should be obtained. In congenital megacolon, intestinal dilatation is usually present with a gasless rectum. A hand injected contrast enema should be obtained to outline the rectum and sigmoid colon. Particular attention should be directed at not overfilling the intestines, thus obscuring the transition zone.

Infants with Hirschsprung's disease frequently retain contrast material longer than 24 hours and this delayed passage strongly suggests the diagnosis despite the absence of a definite transition area. Absence of ganglion cells as the cause for uncoordinated peristalsis was correctly identified as the cause for Hirschsprung's disease in infancy in1938 by Robertson and Kernahan.

Although the gold standard of diagnosis is the histological absence of ganglion cells and hypertrophied autonomic nerves, the typical radiographic transition zone between the proximal dilated and distally narrowed colon is sufficient evidence for the diagnosis in the face of supportive presence of delayed meconium passage, vomiting, and distention. Histochemical patterns with special staining techniques have also been correlated with ganglion cell absence.

Occasionally an older child presents with a history of long standing constipation requiring enemas and other attentive measures directed at producing defecation. In such cases the diagnosis is made by contrast enema as the transition zone is usually easily demonstrated. Contrast enemas in infants less than two months old may be non-diagnostic in over 20% of cases (6). In these instances when clinical and radiographic findings are unable to make a definitive diagnosis, a rectal biopsy becomes necessary. A full thickness biopsy should have an absence of ganglion cells in Auerbach's plexus located between the circular and longitudinal muscle layers. Although ganglion cells are more plentiful in this area, the full thickness biopsy complicates later surgical dissection so a rectal mucosal suction biopsy of Meissner's plexus located in the muscularis propria (i.e., performed more superficially and less invasively) is the preferred biopsy technique. Although ganglion cells are more sparse, the associated presence of hypertrophied nerve fibers is diagnostic.

Ganglion cells are absent in the most distal two centimeters of the normal rectum which is of importance when performing the biopsy and in the determination of an ultra short segment Hirschsprung's (i.e., the rectal biopsy should ideally be obtained proximal to this region).

The normal physiologic pressure in the anal canal during defecation involves a decrease in internal sphincter pressure (relaxation) with rectal distention, thus allowing passage of the fecal bolus. In a baby with Hirschsprung's disease this relaxation of the involuntary internal sphincter does not occur, thus providing another means of making the diagnosis by ano-rectal manometry.

The most frequently involved areas of aganglionosis are the rectum and sigmoid, with decreasing incidence progressing cephalad. Total aganglionosis of the colon is a rarity, and small bowel involvement is even less common.

The incidence of Hirschsprung's disease is about 1 in 5000 births with a 4:1 predominance in males. There is a familial inheritance factor greatest among siblings but less common among children of parents with the disease. It is one of the most common causes of infant intestinal obstruction and is exceeded only by intestinal atresia, malrotation and meconium ileus (in Caucasians). Hirschsprung's disease mutations have been mapped to RET protooncogenes at 10Q11.2, the recessive EDNRB gene at 13Q22, its ligand endothelin 3 (EDN3) and glial cell line-derived neurotrophic factor (GDNF) in humans. Although the majority of cases are multigenic or multifactorial, there are some conditions associated with Hirschsprung's disease such as Down's syndrome, Waardenburg syndrome, neurofibromatosis, neuroblastoma, pheochromocytoma, the MEN2B syndrome and others. The trypanosome causing Chagas' disease is responsible for an acquired form of aganglionosis which may affect not only the colon but the esophagus and heart as well.

There have been described a limited number of Hirschsprung's patients with neuronal intestinal dysplasia that may explain continued post-operative morbidity. The diagnosis of neuronal intestinal dysplasia is not easily made but is associated with abnormal neural elements and their distribution in both the submucosal (Meissner's) and intermuscular (Auerbach's) plexus. This may explain some cases of continued post-operative constipation. Since ganglion cells are of neural crest origin, other conditions affecting the physiology, distribution and migration of these cells may be related to Hirschsprung's disease (7).

Questions

1. True/False: A digital rectal examination carefully performed is most important in the diagnosis of Hirschsprung's disease in a newborn infant.
2. True/False: Post operative diarrhea from enterocolitis is a common occurrence.
3. In a newborn infant with abdominal distention and/or vomiting, what is the most significant clinical finding to raise the suspicion of Hirschsprung's disease?
4. True/False: In a child over a year of age with a radiographic transition zone, a rectal biopsy is required for a definitive diagnosis?
5. What cell line differentiates into Auerbach's and Meissner's plexus and may be responsible for other associated neurological defects?

Answers to questions

1. false
2. true
3. No meconium for the first day of life.
4. false
5. neural crest cells

Chapter IX.10. Gastrointestinal Bleeding and Peptic Ulcer Disease
Ken Nagamori, MD

Upper GI Bleeding

Case 1: The parents of a 3 year old who you have been following since birth for biliary atresia, call to report a "nosebleed" (epistaxis) overnight. Closer questioning discloses that what they are calling a nosebleed is simply a puddle of blood found on the pillow. Having anticipated this potential complication, you ask them to meet you in the Emergency Department. There you find him to be in no distress, with no tachycardia or diaphoresis. You can find no site of bleeding in the nose or pharynx, and you also note his ascites has disappeared and his spleen seems smaller than when you saw him last week. What's going on?

Case #1 described above illustrates the one exception to the rule in large volume bleeding. In children with varices and ascites (both arising from portal hypertension) the acute volume loss from the bleeding can be repleted by 'auto-infusion' of the ascites. Portal hypertension triggers ascites at relatively low pressures (10-12 mm Hg), and the volume depletion from bleeding results in enough reduction in the portal pressure to coax the fluid back into the circulation. The hypovolemic state accounts for the loss of the previously existing splenomegaly. These patients also illustrate that all blood loss is whole blood and that the hemoglobin and hematocrit will not fall until they are volume repleted with crystalloid or plasma. Cirrhotic patients with ascites are the only ones where the acute CBC may be a better indicator of the volume lost than vital signs at presentation.

His hemoglobin is 7 (hct 21). His INR is 1.2. He continues to be in no acute distress and he is able to go directly to endoscopy, having requested 2 units of packed RBCs to be available in the OR for emergency transfusion if needed, with more packed RBC and fresh frozen plasma standing by. A small ulcer is found in the distal esophagus, with an associated gastric varix. There are two other fully distended esophageal varices which are band ligated, and while sclerotherapy is considered for the gastric varix (the banding is impossible to accurately apply in this location) you elect to watch as it appears to be thrombosed and plans are made to return for a repeat endoscopic inspection and treatment as needed in a week or two. He tolerates the procedure well with no complications, and after talking with his parents, you call his transplant specialists to update them on his situation.

Gastrointestinal bleeding covers a wide topic, and is best managed by subdividing it into smaller and smaller entities. But even before making the first obvious decision as to whether it's "upper" or "lower" GI bleeding, the first step is to make a rough assessment as to how MUCH bleeding is going on. In pediatrics, the best single vital sign for assessing acute volume depletion is the heart rate rather than the blood pressure, since infants, children and adolescents have a huge reserve capacity for increasing cardiac output by increasing the heart rate. Thus, the blood pressure begins to fall only in late shock. Orthostatic change in the heart rate is a useful sign (only occasionally unreliable), since a difference of 10% or more may indicate substantial acute volume depletion. Another sign to look for are cool extremities, often with a relatively sharp demarcation between cool and normal skin temperature, as an indication of peripheral vasoconstriction. These signs are applicable to acute volume depletion from any cause (such as vomiting and diarrhea) and not just to acute bleeding. As with any pediatric life support issue, the first steps in assessment and management are to verify airway, breathing, and circulation (ABC). Acute volume depletion requires rapid volume replacement and determination of the source of loss.

When there is a significant difference between the degree of volume loss from either end and the apparent normal state of the intravascular volume, the next step is to verify the material as blood and that it is indeed coming from the patient. Here are some anecdotal examples: 1) A child whose bright red diarrheal stools are closer in color to the red-orange of the food dye of the fruit punch that he has been guzzling during his acute gastroenteritis than to any blood color you've ever seen (i.e., the "bloody" diarrhea is really fruit punch). 2) The robust, demanding, overfed infant whose mother has mastitis and whose hematemesis is actually coming from his mother's blood loss (i.e., swallowing mother's blood from a bleeding nipple) rather than his own. 3) The newborn whose mother had placenta previa and a particularly bloody delivery whose hematemesis again is ingested maternal blood and not his own. The first example often is resolvable during the initial phone conversation. The third can be identified reliably by performance of an Apt test for fetal vs adult hemoglobin, but the second often requires careful history taking and examination to exclude intrinsic GI bleeding.

Converse consideration must also be given to those who present with signs of acute intravascular volume depletion (especially impending shock) and NO signs of bleeding discernible externally. The GI tract can easily hide a loss of blood amounting to a substantial portion of the total intravascular volume. Processes with high rates of bleeding, particularly if beyond the stomach (making them less prone to hematemesis) must be considered. Such lesions include (but are not limited to) duodenal ulceration with arterial bleeding, duodenal varices or varices at small bowel anastomotic sites (in the case of children with surgical hepatoportoenterostomies), small bowel vasculitides, hemobilia (bleeding in the biliary tract), and enteric duplications (including Meckel's diverticula) with secretory mucosa and secretory products that lead to ulceration.

The next step is to verify that the bleeding is indeed coming from the GI tract, in part to determine whether the following algorithms will be applied, but also as reassurance that the volume of any recurrent bleeding is not likely to be high or is likely to be easily managed. Epistaxis is a common cause for moderate volume bleeding (some epistaxis blood is swallowed and then vomited as hematemesis) and is more common than peptic ulceration as a cause of hematemesis and melena. Always check the anterior portion of the nasal septum for evidence of blood and ulceration indicative of bleeding. Application of direct pressure for 5 minutes (by the clock) to allow for good clot adherence and retraction (no peeking or the clot will lift off and the bleeding will resume) during any recurrent bleeding episode, is usually all that is necessary. Cautery typically causes more problems than it solves. Topical antibiotics can be used to treat nasal impetigo if that is the cause of the epistaxis. Dental and oral bleeding typically is smaller in volume and is usually identifiable on close inspection. Anal fissuring is technically a "GI" lesion, but the risk of rebleeding is low and its generally benign nature differentiates it from the lesions below. Here, the bleeding is typically bright red, and can be painless (though more often associated with pruritus at the anus or cramping prior to the passage of a larger caliber formed stool). Passage of clots is possible if the fissure extends internal to the internal anal sphincter. But the differentiating hallmark is any continued dripping of blood into the toilet after the formed stool has passed (and the internal anal sphincter has closed) or the persistence of bright red blood on the toilet paper for more than 2-3 wipes. Either of these indicates the presence of the lesion outside the internal (but potentially proximal to the external) anal sphincter. Good inspection requires gentle separation of the buttocks, best attained in the decubitus position with the knees up against the chest. The goal is to open the external anal sphincter, often attainable by having the patient take a slow deep inhalation. The fissure is identifiable as the red or white-based linear ulcer, usually anteriorly or posteriorly positioned. Specific attention should be paid to whether the margins appear undermined (traumatic fissures have simple vertical margins, while the anal lesions of Crohn's disease and the vasculitides are caused by the undermining of the subcutaneous supportive structures).

Once it is verified the patient is indeed losing blood from their GI tract, but is stable, attention turns to specific diagnosis. Here again subdividing the possibilities is helpful, with the next step being the semi-artificial conceptual one of "upper" vs "lower" tract bleeding. With the provisos of the preceding paragraphs accounted for, hematemesis is a reasonable indicator of an UGI source. Conversion to "coffee grounds" is not necessarily indicative of a gastric source since any blood placed in acid for even a few seconds converts to acid hematin (brown color), and conversely if the acid is neutralized or is otherwise not present for any reason, the blood will not convert (and will be red). On the other hand, melena is only an indicator of bleeding in an area bathed in acid, and while this usually indicates the upper GI tract, other sites of acid production such as a Meckel's diverticulum (with acid secreting ectopic gastric mucosa) or occasionally acid fermentation in the right colon can trigger the same chemical conversion. And conversely, the absence of melena in the bleeding does not preclude an UGI site, since brisk bleeding from an arterial source in the duodenum, plus the rapid transit times of infants and younger children, and their lower acid secretion rates can result in passage of blood per anus that is still nearly bright red.

Quantification of the bleeding seen is of some help diagnostically, as is the presence or absence of associated symptoms and signs. Further stratification by age helps establish probabilities:

Newborns are not old enough (not enough time) to develop full peptic ulceration. Coagulopathy due to liver cirrhosis is possible, but rare. Neonates under the intense physiologic stresses that would place them in an NICU setting typically develop gastric erosions rather than deeper gastric ulceration or they can hemorrhage from DIC. Even vitamin K deficiency of infancy takes time to develop.

Infants have had time to develop some, but not all of the ills that befall older children. Again mechanical trauma to (or other lesions of) oral structures will result in small to medium amounts of hematemesis and are far more common than the erosions of severe reflux esophagitis or frank ulceration of the stomach or duodenum. The latter lesions are usually suspected by signs of dyspepsia, including (but not limited to) crying, irritability centering around feedings, colic, drooling, eructation (belching), and vomiting. The preverbal infant and young child often will not be able to adequately indicate the associated pain, and peptic disease is therefore more often not identified until there is significant vomiting or even frank hematemesis. Allergic gastroenteritis more commonly first appears in the first few months of infancy though eosinophilic gastritis can be identified at any age. Though more commonly presenting as failure to thrive, allergic gastroenteritis can occasionally present with hematemesis or other evidence of upper (and lower) GI tract bleeding.

In toddlers most of the above processes continue, but their added mobility increases the possibilities for mechanical issues, including ingested caustic agents (lye, tile cleaner, electric dishwasher detergent) or acids, and foreign bodies. A toddler presenting with signs of partial esophageal obstruction (inability or unwillingness to swallow solids) and intermittent hematemesis warrants a radiographic evaluation to establish the absence of a lodged foreign body and if no clear history is obtainable regarding of the duration of the lodgment, caution is to be exercised in its removal, since penetration of or even embedding in the wall of the esophagus or adjacent structures (e.g., vena cava or aorta) is not uncommon. Ingestion of button batteries is another special consideration in the case of foreign bodies since the lithium ones can retain sufficient charge as to cause significant mucosal burn even when they appear to be dead, while the mercury, silver, and alkaline button batteries usually do not.

In older children, a Mallory-Weiss tear (esophageal tear) or an erosion caused by prolapse of a portion of the gastric cardia (typically along the lesser curvature) is far more common than nonspecific gastritis, erosion (esophageal or gastric), or frank ulceration as a cause of UGI bleeding. Such bleeding usually follows a period of protracted and usually forceful vomiting, and is usually relatively limited in volume (a few teaspoons), but it can be profuse. A rectal examination with stool which is negative for occult blood helps verify the observed short duration of the process. Esophageal erosion typically is preceded by complaints identifiable as peptic in origin in pediatrics and is rarely present in a pain free setting, which requires an extensive burn. In the case of the older child or adolescent with this presentation, consideration needs to be given to NSAID-induced gastropathy arising from self-medication. The lesions are typically erosions arising from the disruption of mucosal cytoprotection due to the broader inhibition of prostaglandin synthetase. The incidence is low compared to the widespread use of these medications and the increase in the absolute rate of this complication reflects the increasing use of these medications in the over-the-counter setting.

Upper GI bleeding etiologies by age:

Age	Small volume	Medium volume	Large volume
Newborn		Gastric erosion (in NICU setting)	Ingested maternal blood, vitamin K deficiency, DIC.
Infant	Mechanical trauma, allergic or other gastritis, reflux esophagitis, ulcer.	Same as infant, plus oral lesions and ulcerations (rare).	
Child	Dental/oral source, hemoptysis, gastritis (non-allergic), reflux/chemical esophagitis, (beware of foreign body).	Same as infant, plus epistaxis, Mallory-Weiss tear/erosion, peptic ulcer.	Varices, arterial bleeding from ulcer, DIC.

Frank peptic ulceration remains uncommon as a source of bleeding during most of childhood and adolescence. Helicobacter pylori can play a role, and by itself, can cause bleeding from gastritis, though far more commonly it presents as a non-bleeding distinctive nodular gastropathy with preference for the antrum. While breath testing using labeled urea is identified as showing promise in establishing the diagnosis, the North American Society of Pediatric Gastroenterology and Nutrition's position is that endoscopy remains the only reliable means of establishing and refuting its presence, and that blood testing, due to poor specificity, is of little utility (1). In that regard, the low probability of Helicobacter gastritis in this age group even in the face of proven duodenal ulceration means that for each child appropriately identified by serologic testing, there will be several falsely labeled, and extension of this testing into evaluation of those who simply present with hematemesis or even just pain raises the likelihood of identifying false positives.

However, in true hemorrhage from the upper GI tract (defined as bleeding sufficient to require volume repletion with blood), peptic ulceration, variceal bleeding, and DIC are the most common causes. Of these, variceal bleeding is the most frightening, since blood loss rates can approach total blood volume within an hour or less. Varices arise from portal hypertension, which in turn arises most commonly

from cirrhosis (e.g., biliary atresia as in case #1), but can also arise from extrahepatic obstruction of the portal vein. They most commonly present in the distal esophagus but may also be found in the gastric cardia or in the duodenum, where they can be far more difficult to treat. They represent an enlargement of the submucosal venules as a means of rerouting the blood flow from the portal to systemic venous circulation (a porto-systemic shunt) and the degree of portal hypertension required to establish the shunt is only minimally higher than that which would produce splenomegaly or ascites, making these physical findings important in the evaluation of the hemorrhaging patient. Identifying patients at risk for this prior to hemorrhage is far preferable, and a routine search for these findings should be undertaken at every office visit of any patient being followed for a process that can lead to cirrhosis (such as biliary atresia in the case presented). The bleeding is typically painless, as the vessels are superficial to the muscular layers and the erosion that starts the bleeding is therefore particularly shallow. The initial (or "herald") bleed may be surprisingly small as the vein rapidly collapses and clots, but the dislodgement of that clot can be followed by particularly voluminous bleeding. Endoscopic examination for diagnosis and treatment either by banding or injection of sclerosing agents is the preferred acute management once volume repletion has made sedation or anesthesia possible, and while a trans-jugular intrahepatic portovenous shunt placement (TIPS procedure) may be palliative, the only "cure" is resolution of the underlying cirrhosis (by transplantation) for those with intrahepatic disease conditions. Those with cavernous transformation of the portal vein typically will create other intraabdominal shunts in locations which do not bleed so profusely if they can be carried into the second half of the first decade.

The myriad causes of upper GI bleeding prompt usage of a layered strategy to the diagnostic process. With the above history parameters and physical findings indicating that: 1) the patient is (at least temporarily) hemodynamically stable, 2) no clear site of bleeding external to the GI tract as an alternate source to explain the bleeding, 3) no known lodged esophageal foreign body, 4) medium to moderate bleeding in whom the presumed risk of later hemorrhage is worth giving serious consideration; the next step is placement of a naso-gastric catheter to assess the volume of blood that has not been regurgitated, and more importantly, to identify (or refute) any ongoing bleeding. A large-bore tube is recommended, as clots may need to be removed, and the orogastric (rather than nasogastric) route may facilitate evacuation. Gastric lavage with normal saline at body or room temperature is more comfortable. Icing of the saline is not required and in smaller patients, may produce significant hypothermia. Gastric sampling and lavage may be omitted if variceal bleeding is suspected and endoscopy is already planned, but the hemorrhaging patient typically otherwise deserves both procedures. The gastric sampling and lavage serves to identify the patient who has indeed bled briskly from the upper GI tract or who may still be bleeding, and who will need to go on to immediate endoscopic examination. In contrast, the patient whose bleeding is suspected as coming from a non-intrinsic or otherwise low-risk source does not require immediate endoscopy. A negative gastric aspirate in a patient who is otherwise only suspected of an upper GI bleeding site because of passage of melena and who has no hematemesis would prompt a search for alternate sites of acid-associated bleeding such as a Meckel's diverticulum.

Gastric aspiration will only rarely be falsely negative. This would typically occur in patients who are bleeding from a deep ulcer in the duodenal bulb with sufficient pylorospasm to prevent any regurgitation of blood into the stomach. These patients can easily be mistaken to have a Meckel's diverticulum with acid-secreting ectopic gastric mucosa and secondary ulceration as they too may present with volume depletion and melena but no hematemesis, and if suspicion is otherwise high (primarily due to tenderness to epigastric palpation) and/or larger volumes of bleeding, endoscopy is warranted anyway.

Endoscopy offers both diagnostic and therapeutic advantages, and typically is much more sensitive than radiographic evaluation of the upper GI tract as most hemorrhaging lesions are still superficial. Radiographic contrast studies are dependent on identification of a moderate-sized ulcer crater, and lack sensitivity in identifying risks for rebleeding such as a visible vessel or adherent clot. Even varices are difficult to identify radiographically, and endoscopy offers the ability to intervene to reduce the risk of rebleeding via variceal band ligation or intravascular injection of a sclerosing agent. Likewise, ulcers and other lesions at significant risk for resumption of hemorrhage may be addressed thermally or chemically through the endoscope.

Peptic ulcer disease is most accurately diagnosed by endoscopy. Referral to an endoscopist (usually a gastroenterologist) facilitates diagnosis and treatment since treatment regimens which consist of a□
cimetidine, ranitidine, etc.), proton pump inhibitors (e.g., omeprazole) and antibiotics for H. pylori create numerous therapeutic option combinations. Optimal therapeutic decision making for pediatric patients with peptic ulcer disease is best left to gastroenterologists who are most familiar with the most recent studies and recommendations.

If endoscopy fails to identify the bleeding lesion, further investigation of the hemorrhaging patient includes radionuclide scanning and angiography. Radiographic intervention can include selective intraarterial embolization as well as the TIPS (trans-jugular intrahepatic portovenous shunt) procedure, but a full discussion of this is beyond the scope of this chapter in basic diagnosis, as the choices are typically guided by the pediatric gastroenterologist involved in the endoscopic procedure above (2,3,4,5).

Lower GI bleeding

Case 2: The parents of an otherwise robust 3 year old boy call with a frantic report of bright red bleeding per anus. Pain is denied, as are fever, malaise, or rash. The toilet bowl seems filled with blood and clots, but the anus wipes clean with one swipe and no further blood is seen. You are able to convince them to come to the office instead of heading for the ER. In the office, the child is in no distress and wonders what all the fuss is about. His vital signs are normal for age, and physical examination shows no abnormalities, including external inspection of the anus with the child in the knee-chest position on his left side to enable full exposure of the anus down to the internal anal sphincter. What do you do next?

The patient who presents with bleeding only from the anus produces a separate (but overlapping) diagnostic tree. The presence of melena hints at an upper GI tract origin, but is simply indicative of passage of the blood through acid, which can arise in the presence of acid secreting ectopic gastric mucosa in any enteric duplication, of which the most common is a Meckel's diverticulum, or occasionally if the cecum is particularly acidic due to fermentation. Conversely the absence of melena does not exclude an upper GI tract origin if the transit time is sufficiently short or the acid is otherwise neutralized or not present and the bleeding is brisk enough.

As discussed in the patient who presents with hematemesis, the initial evaluation centers around rapid estimation of the volume of blood lost and the risk of ongoing or recurrent bleeding. Again the problem is best stratified into ages and rates of loss.

As with upper GI bleeding, the neonate has fewer diagnostic possibilities since most problems take a while to develop fully. While any infection (bacterial or viral) can lead to sufficient mucosal inflammation ranging from punctate bleeding to gross hemorrhage and DIC, necrotizing enterocolitis is almost unique to the neonatal period. In other respects, resembling ischemic injury in the older child or adult, the process in the neonate does more commonly include submucosal pneumatosis, implying compromise of the mucosal barrier. It usually presents with other signs of intestinal obstruction, partial or complete, and bleeding is typically one of the lesser findings, and is most

commonly occult. It presents more commonly in the severely premature, but can afflict term infants who have a preceding clinical problem that predisposes them to bowel ischemia (such as polycythemia or birth asphyxia). Refer to the chapter on necrotizing enterocolitis.

Allergic enteropathy is more typically a problem of the young infant, as the inflammatory process is acquired and requires time to set up. It typically presents before 2 months of age with either occult or gross bleeding, and typically is accompanied by failure to thrive and/or a moderate degree of mucus in the stool to suggest widespread mucosal irritation. Involvement of the proximal GI tract (the stomach and small bowel) more commonly results in slow weight gain, signs of poor enteric motility (vomiting) and other signs of gastric stasis and protein losing enteropathy. Involvement of the colon is associated with mucusy stools laced with blood. In the latter, a Wright stain may be helpful only if it shows sheets of eosinophils, but a firm diagnosis rests on mucosal biopsy showing widespread nests of eosinophils in the submucosa rather than the scattered eosinophilia seen in more nonspecific inflammation. A clinical diagnosis may be made by rapid and complete resolution of the symptoms by elimination of the offending protein either by a return to exclusive breast feeding or substitution of a properly hydrolyzed formula (e.g., Nutramigen, Pregestimil, Alimentum). A switch to an alternate allergenic protein source (soy, goat's milk, etc.) during a period of sensitization may result in further reactivity and only true hypoallergenic feedings are to be allowed. Widespread reports, laboratory research, and personal experience indicate that while generally hypoallergenic, maternal breast milk may contain identifiable fragments of cow's milk protein from the maternal diet in quantities sufficient to trigger a reaction. Personal experience suggests the quantity needed in the maternal diet is substantial, and typically lies outside routine dietary parameters, however maternal exclusion of dairy products may be undertaken in the case of stubbornly persistent (and typically low-grade) inflammation. If allergic enteropathy (gastroenteropathy or colitis) is encountered, firm exclusion of the offending protein is to be undertaken for the entire first year of life in hopes of eliminating the clone of sensitized lymphocytes. This involves reading the ingredient panel of every item the child will eat, looking for "non-fat dairy solids" or "non-dairy" creamers (which contain powdered milk protein). If a soy allergy is present, the prohibition shifts to soy, including soy sauce and tofu. Typically the exclusion is not complete, and if (repeated) inadvertent exposure shows no sign of reaction, the restrictions can be lifted. But recurrent reactions can be severe if of the acute hypersensitivity (type I) variety. This can result in sufficient vomiting and diarrhea to cause significant volume depletion, and if uncertain as to the residual reactivity, a formal staged dietary challenge with nursing support (i.e., this may need to be done as an inpatient or in an observation unit) may be needed at one year of age before the offending food may be safely reintroduced in quantity.

Another cause for minor bleeding per anus that is unique to infancy is nodular lymphoid hyperplasia. It typically presents with punctate bleeding best characterized as streaks of blood with small streaks of mucus in otherwise normal stool in an otherwise thriving infant. The number of streaks and the amount of blood do not vary with fecal texture. This compares to infection, allergy or other more generalized inflammatory processes of the distal bowel where loose stool indicates inflammation, and therefore goes hand in hand with more mucus and blood. The only time the bleeding disappears in nodular lymphoid hyperplasia is in the face of liquid stools, in which case the streaks of mucus and blood are dissolved in the diarrhea but can be found by occult blood testing. Nodular lymphoid hyperplasia can readily be identified by proctoscopic examination which typically demonstrates a rectum that is studded with submucosal nodes measuring 2 mm across with central ulceration. The bleeding comes from the ulceration and the intervening mucosa is completely normal in appearance, explaining the disparity between the texture of the stool, the amount of bleeding and the normal growth of most of these infants. This permits exclusion of allergy and infection as possible causes since these typically cause more widespread inflammation, visible in the rectum of infants presenting with visible blood and mucus in the stool. Nodular lymphoid hyperplasia is a benign, self-limited process associated with the age-appropriate hypertrophy of the lymphatic tissue of the enteric submucosa. In some infants, the central portion of the overlying mucosa undergoes punctate ulceration. The cause of the process remains unknown. What is known is that the process normally becomes dormant during the latter half of the first year as the nodes regress in size (and activity), and though there may be occult blood found in the stool for the remainder of the first year, there is little likelihood of anemia and no association of any later enteric disease process. As such, my usual recommendation is to continue with routine feedings, introducing solid foods at the usual times as the process is not allergic in origin. The hemoglobin may be checked slightly more frequently than your usual schedule for age, and iron supplementation should be started only if it drops significantly. Inability to keep up with iron loss is atypical enough to warrant reassessment of the original diagnosis.

Toddlers in turn have a cause for chronic occult bleeding and often times severe anemia which is unique to their age range in overconsumption of milk. The lactoferrin of cow's milk has an extremely high affinity for iron, higher than anything in the human iron transport system, and it typically is not saturated in milk as routinely sold (but it is saturated in infant formula). Lack of an alternate iron source and excessive intake of milk can result in severe iron depletion, and as iron is also required for maintenance of gut mucosal integrity, the process accelerates as the iron stores fall. Hemoglobins of 4.0 gm/dl are not uncommon in this setting, and if tested, the stools may be positive for occult blood. The diagnosis is made by a detailed diet history, and verification of the extremely low iron stores. The cure is effected by a return to a truly regular diet for age with reasonable milk intake and a sufficient source of iron, though an occasional patient will require transfusion.

Processes that can cause small but visible quantities of bleeding at any age are dominated by infection, though anal fissures are even more common, as described previously. The most common worrisome organisms include Campylobacter, Salmonella, Shigella, and enterotoxigenic E coli, but other routine pathogenic bacteria and protozoans can be acquired from contaminated food and standing water sources. The first 4 are routinely included in culture screens for enteric pathogens (the rest are not). Campylobacter can cause a severe colitis which is identified more often now that CT scanning is the preferred method for identification of appendicitis in the patient presenting with crampy abdominal pain. The degree of thickening of the submucosa and muscular layers can be mistaken for transmural thickening indicative of Crohn's disease, with the pain and bloody diarrhea adding to this diagnostic possibility. But a normal ESR in the proper clinical picture suggests a pause in the rush to colonoscopy and therapy until the culture results are available, since the process clears rapidly with erythromycin treatment. Shigella also warrants antibiotic therapy if found, and while treatment of Salmonella may raise the risk of producing a chronic carrier state, since most carriers arise from colonization of the gallbladder, cautious treatment with an agent concentrated in bile (such as trimethoprim/sulfamethoxazole) if the organism is sensitive may be warranted in the patient with ongoing or severe symptoms. The one organism whose treatment with antibiotics or antispasmodics is to be avoided is enterotoxigenic E. coli (such as E. coli O157). Use of these agents can produce enough enterotoxin release as to trigger Hemolytic Uremic Syndrome. Antibiotics should be held until the offending bacteria is positively identified, and even over the counter antispasmodic agents are to be avoided.

The immune suppressed patient presents a particular challenge, for in addition to the above agents one needs to consider atypical organisms such as cytomegalovirus and Mycobacterium avium intracellulare (MAI), which can produce severe bleeding with transmural lesions scattered throughout the bowel and colon. Epstein-Barr virus can cause lymphoproliferative disease with chronic low-grade blood

loss and more of a protein losing enteropathy picture. Typhlitis also occurs in the patient recovering from neutropenia as the new granulocytes are preferentially directed toward the inflamed cecum. These processes are rare in the immune competent patient.

Enterocolitis due to Hirschsprung's disease can occur both prior to and after surgical repair. The latter instance is indicative of stricture at the anastomotic site and recurrence of functional obstruction. As a stasis phenomenon it can also be seen in those with ileorectal pouches and other anastomosis, and while it can cause bleeding, it usually presents with explosive, foul diarrhea. For evaluation of the infant presenting with enterocolitis as the first manifestation of Hirschsprung's disease, see the chapter on constipation. Hirschsprung's disease itself is covered in a separate chapter.

Other processes that can cause moderate bleeding volumes, usually as part of a broader clinical picture include general obstructive processes such as intussusception, volvulus, and other mechanical issues that can cause focal bowel ischemia. They usually present with other signs of obstruction, typically with an acute onset of crampy abdominal pain that cycles every 10 to 60 minutes as the major migrating motor complex passes through the obstructed segment. Waiting for the passage of currant jelly stool (bloody stool) before considering intussusception in the differential diagnosis is to be discouraged since this is a late finding. Early radiographic evaluation with plain films is to be encouraged. In fact, the possibility of intussusception should be considered when any type of blood in the stool is encountered.

In patients presenting similar to the above, but with lesser signs of obstruction, consideration should be given to vasculitis, far more commonly due to anaphylactoid (or Henoch-Schonlein) purpura than to Systemic Lupus Erythematosus. The typical presentation is dominated by crampy pain with a usually minor bleeding component. In the case of anaphylactoid purpura, the platelet count may be high, but the ESR is typically in the normal range, in contrast to the elevation seen in SLE or to EBV-induced lymphoproliferative disease, both of which can mimic the radiologic picture of HSP. Treatment with corticosteroids is discouraged until these entities and lymphoma or leukemia are more definitively ruled out.

Inflammatory bowel disease (IBD) typically presents with a history of chronic but nonspecific signs. Poor weight gain and especially linear growth can be noted as much as 6 months before onset of cramping and bleeding, though there are hyper-acute variants of ulcerative colitis. These entities are covered in detail in a separate IBD chapter but for the purposes of this discussion, IBD can produce anything from occult bleeding to florid bloody diarrhea. In ulcerative colitis, the blood and stool texture are inversely related, with both mucusy diarrhea and bleeding being indicators of inflammation. Crohn's disease, more commonly affecting portions of the GI tract other than the rectum, can present with unremarkable stools, but will also produce mucusy diarrhea if the distal colon is involved. A quick check of the oral mucosa and anus for the undermined vasculitic lesions seen in either site can be diagnostic of Crohn's disease. A detailed family history searching for other versions of autoimmune disease can be supportive diagnostically, for while it is rare to have another with IBD in the family, there is often a strong family history of other autoimmune manifestations.

And finally, among the (relatively) common causes of colonic bleeding, polyps are to be considered whenever there is a report of painless bleeding of apparently moderate volume. Solitary juvenile polyps are the most common, and typically do not become large enough to cause bleeding before the end of the second year. As hamartomas, they are extremely vascular but have no sensory tissue and bear essentially no neoplastic risk as long as they are indeed solitary. The familial polyposis syndromes produce diffuse adenomatous polyposis, resulting in studding of the mucosa with often nearly confluent polyps, all of roughly the same size. These carry a significant neoplastic risk, and were until recently, an indication for early colonic resection, but experience with NSAIDs (particularly sulindac) in adults has been extended to children in causing regression of the visible lesions. It remains to be seen if this significantly reduces the long-term neoplastic risk, but it seems to permit a reduction from the every-other-year colonoscopy surveillance often undertaken in the second decade. The diagnosis of polyps (single or multiple) starts with the history of painless bright red bleeding, generally without anemia despite a protracted history, and no anal fissure on inspection. Digital rectal examination is usually diagnostic as most solitary polyps arise within the last 2 inches of the rectum, and the familial adenomatous polyposis syndromes result in many small polyps within reach. Gardner's syndrome is associated with unusual retinal pigmentation in affected individuals and may also present with osteomas, though these usually are more prominent in the second decade while the small but visible bleeding usually appears by the middle of the first decade. Peutz-Jeghers syndrome is associated with pigmentation in unusual sites (buccal mucosa, the webbing between fingers and toes) but like the other multiple hamartomatous polyp syndromes, PJ typically does not present with bleeding. Therapy for isolated polyps is endoscopic removal and for multiple polyps is endoscopic sampling to establish a diagnosis. Waiting for a polyp to autoinfarct will not permit specific identification as to type, and the presence of more than 3 polyps, even with a "juvenile" type histology, is still associated with a higher risk of eventual colon cancer. Recent advances in genetic screening in the diagnosis and management planning of the familial adenomatous polyposis syndromes in pediatrics was recently discussed in detail in reference #6.

Lower GI bleeding etiologies by age

Age	Small volume	Medium volume	Large volume
Newborn	Infection, necrotizing enterocolitis		Ingested maternal blood, sepsis, DIC
Infant	Fissure, allergy, infection, nodular lymphoid hyperplasia	Same as infant plus volvulus intussusception, other bowel obstruction and/or ischemia	DIC, peptic or other ulceration, Meckel's diverticulum, CMV, MAI (esp. with HIV)
Child	As above plus IBD (Crohn's disease), cow's milk protein sensitivity (with severe iron deficiency), EBV (esp. immunosuppressed)	As above plus HSP and other vasculitides, typhlitis (immunosuppressed)	All of above plus polyp(s), IBD (ulcerative colitis)

In summary, identification of "lower" GI bleeding is even more dependent on the history and characterization of the bleeding than that from the upper GI tract, and can be confounded by "upper" GI sources. Even with hemorrhage, patients rarely become significantly

volume depleted on an acute basis and in most instances there is enough time to perform appropriate testing, including culture, in a sequential manner. Many times, the workup of the crampy patient with modest bleeding in loose mucusy stools involves a quick survey of inflammatory markers and a 2 to 3 day wait for the culture results from the rectal swab. A rectal swab has a superior yield over culture of stool material because the center of the lumen (i.e., stool material) typically contains dead or less viable organisms, while the viable enteric pathogens are closer to the mucosa and are more readily sampled by brushing the rectal wall. If the ESR is low in the face of thrombocytosis and a history of crampy pain, particularly in a patient with any dermal lesions, a small bowel series may demonstrate the characteristic "thumb-printing" of localized mucosal edema typical of HSP and enable early administration of corticosteroids. Otherwise, if the ESR is high and the growth parameters are low, once the culture results are found to be negative, the next step is colonoscopy to look for lesions indicative of IBD. On the other hand, finding a solitary polyp on initial examination permits a relaxed scheduling on a more elective basis both for the physician and the family.

For case #2, our patient's presentation with painless bleeding of apparent moderate volume yet without signs of significant volume depletion is indicative of a polyp. Rectal examination finds a single 1 cm pedunculated polyp 2 cm from the anal verge. Colonoscopy is scheduled, as the prep for even proctoscopy for polypectomy requires stringent removal of all stool to prevent a short-circuit current and an unintended burn, and a search is to be made for further polyps. The gastroenterologist reports no others are seen and the polyp in question has been easily removed by an electrocautery snare. Histologic analysis verifies a juvenile polyp, and no followup is planned.

Questions

1. You are called to the nursery where you are shown a burp cloth with loose clots of regurgitated blood. The newborn in question is sleeping quietly, with completely normal vital signs and no sign of tenderness or other bleeding when examined. You recall his mother presented with placenta previa. What do you do next?
2. At a two month well baby visit, his parents bring in a diaper double-bagged because of the foul odor. The stool is tarry and tests positive for occult blood, but the child appears particularly robust, having gone from a birth weight of 7 pounds 1 ounce to his current weight of 12 pounds 10 ounces. He is somewhat fussy and demanding of feedings, and his mother complains of getting no rest as she has to feed him hourly. Recently, her left breast has become quite sore and there is intense pain when he nipples. On examination, the infant is colicky, but there is no abdominal tenderness and his vital signs are also within normal limits with no adjunct signs of intravascular volume depletion. What is going on?
3. 3 year old presents with melena but no hematemesis, and no abdominal pain. How do you evaluate him?
4. Melena is usually indicative of upper GI bleeding. Indicate how this can sometimes be due to lower GI bleeding.
5. Red blood per rectum is usually indicative of lower GI bleeding. Indicate how this can sometimes be due to upper GI bleeding.
6. A 14 year old female has yet to show secondary sexual development which you have always attributed to excessive involvement with the school track team. However in the last 6 months her finishing times on the mile (her favorite event) have steadily lengthened from second best in the state to this week's race where she could not finish. She presents today complaining of loose stools, streaked with blood. How do you work up her illness?
7. A 3 year old boy presents to the emergency department passing bright red blood per anus. He is diaphoretic and tachycardic (120 supine, 140 upright) and complains of generalized abdominal pain. You are unable to localize tenderness but are comfortable that there is no rebound tenderness and he is not at risk of perforation. Placement of an NG tube to lavage his stomach is negative. By the time you have given enough crystalloid to replete his blood volume, his hemoglobin has dropped to 7 grams. Since his summer physical 2 months ago had included a hemoglobin of 12, you realize he has indeed lost a substantial portion of his blood volume over a short period of time. He is admitted to the hospital, where over the next two days as you wait for the stool culture results. He requires 250 cc transfusions daily to maintain his hemoglobin and you realize that the brisk bleeding continues. The stools remain bright red. What do you do next?

Answers to questions

1. A modified Apt test can be done. Take the loose clots and suspend them in a minimal amount of tap water (you need a visibly pink supernatant composed of free hemoglobin, hence the tap water to lyse the cells). Centrifuge the cells and to 5 cc of pink supernatant add 1 cc of 1% sodium hydroxide. Read in two minutes: adult hemoglobin turns yellow or brown, fetal hemoglobin remains pink. If the supernatant turns yellow, the blood is mother's, and every one can relax.
2. This infant has no sign that the bleeding originates with him, as bleeding sufficient to produce melena should leave him quite shocky. The history gives every sign that he has induced a mastitis (and nipple bleeding) in his mother, and she is able to compensate for the several ounces of blood loss that produced the melanotic stool. You counsel her on proper feeding and handling techniques to keep the infant satisfied without having to overfeed, and have his mother avoid feeding on the affected side until the inflammation subsides. At followup in a week, all are smiling.
3. ABC's first. He shows no sign of acute intravascular volume depletion, but looks a little pale and turns out to be mildly anemic, indicating a longer standing problem. Next, place an NG tube to look for upper GI bleeding but you find no evidence of this. Now what? There is evidence of bleeding in an area bathed in acid, but it is not the stomach (or the duodenum). If he is hemodynamically stable, you have time to pretreat with a histamine-2 receptor blocker to improve the yield of a Meckel's scan looking for ectopic gastric mucosa. This finds a hot spot in the lower mid-abdomen which the technician assures you is not tracer in the bladder. You contact your pediatric surgeon for minimally invasive removal of a presumptive Meckel's diverticulum with acid-secreting ectopic gastric mucosa.

4. The black color is due to blood exposure to acid. Acid fermentation can take place in the cecum. If this occurs and the transit time is relatively slow, bleeding in this area can present as melena. Bleeding from a Meckel's can also result in acid exposure in the lower GI tract.

5. The acid level in the stomach is low (possibly due to antacids and H2 blockers) and/or the bowel transit time is very rapid. Also, the bleeding may originate from the duodenum which does not expose the blood to acid if the pylorus is tight or the level of stomach acid is low.

6. The history has all the hallmarks of inflammatory bowel disease, but still the common things are more common. The physical examination shows no weight loss (but little net gain over the year), and she has a mild temperature elevation (100.5 degrees) and tachycardia (105) but no specific findings in the abdomen other than a mild increase in the amount of fluid and gas palpable in the small bowel and colon. Along with the CBC and ESR, you obtain a rectal swab for stool culture. There is no anemia, but the WBC count is slightly elevated and the ESR is 6. You are puzzled until the stool culture results return 2 days later, positive for Campylobacter. You call to discuss the results and find her new puppy had been ill the week before (dogs can both harbor and become ill from this organism), and the poor race performance actually arose because she was getting fed up with her coach (her father) and had been wanting to quit. Since she is still out of school with the cramping and diarrhea, you start her on erythromycin, offer to act as a go-between on the issue of changing sports, and annotate her chart to remind yourself to monitor for other signs of depression in the future.

7. As the negative gastric aspirates over the last 2 days indicate no UGI source, you prep him for colonoscopy to look for a lower GI bleeding site. GoLYTELY is used in hopes of diluting the bleeding as blood rapidly absorbs all light even in a thin film, and you anticipate much suctioning and lavage which will markedly extend the time for the procedure. As he will be under anesthesia anyway, you also obtain consent for EGD for completeness' sake. At endoscopy, the EGD study finds the pylorus is tightly shut as there is a large duodenal ulcer (not a simple erosion) with a visible vessel (an indicator of high risk of recurrent bleeding). With this you joyfully cancel the colonoscopy as being unnecessary, and chalk up the experience as a reminder that rapid transit times and the low acid production of early childhood can sometimes prevent the blood from encountering enough acid to turn to acid hematin or melena. Indeed, the higher the volume lost, the more acid is needed and the less likely the reaction. Unfortunately, as the finding was a therapeutic surprise, you are unprepared to address the ulcer in any invasive manner (sclerotherapy, heater probe, etc.) and have to return the patient to intensive care on an IV histamine receptor blocker and carafate and sufficient antacid to keep the pH of the gastric contents, measured every hour, above 6.5 (and well above the 4.5 activation level of pepsin). Preparations are made to return with the proper equipment the next day if he continues bleeding, only to find the bleeding stops with the procedure (and the drop in splanchnic pressures encountered under anesthesia), the current measures are more than sufficient, and no further transfusions are required. The patient makes a rapid and full recovery, with no recurrence in over 5 years (based on actual personal experience).

Chapter IX.11. Inflammatory Bowel Disease
Alan K. Ikeda, MD

This is a 16 year old female who presents with fever and diarrhea. Further questioning finds that she has had similar episodes in the past few years, but none as severe as the current episode. She does not weigh herself regularly so weight loss could not be confirmed. However, she does admit that her clothes feel somewhat looser than last year. Her menstrual periods are regular. Her last menstrual period began two weeks ago.

Exam: VS T 37.0, P 85, RR 18, BP 100/65, oxygen saturation 100% in room air. Height is at the 50th percentile. Weight is at the 5th percentile. She is a thin appearing female in no acute distress. HEENT exam is significant for slightly tacky oral mucous membranes. Her eyes are not sunken. Neck is supple without lymphadenopathy. Her heart has a regular rhythm, but slight tachycardia with no murmurs. Her lungs are clear with good aeration. Her abdomen appears scaphoid. There are mildly hyperactive bowel sounds with diffuse vague abdominal pain without any point tenderness. No masses or organomegaly are noted. Her extremities are cool to at the distal limbs, but warm and dry otherwise. Her pulses are good with brisk capillary refill. No rashes are noted. Her breasts and genitalia are Tanner stage 3-4. Rectal exam demonstrates non-specific discomfort without masses or severe tenderness. Her anus is normal externally. Her stool is guaiac positive.

A CBC shows mild microcytic, hypochromic anemia and thrombocytopenia. Wright's stain of the stool for fecal leukocytes is positive for WBCs, but no eosinophils. Stool, blood and urine cultures are obtained.

Inflammatory bowel disease (IBD) is a term that is used to describe chronic inflammatory diseases of the gut. It usually refers to Crohn's disease and ulcerative colitis.

Crohn's disease (CD) is also known as regional enteritis. The disease is described as discontinuous (regional) areas of transmural inflammation that affect any part of the GI tract (mouth to anus). Ulcerative colitis (UC) is described as a process that results in diffuse superficial colonic ulceration.

Although there are some discrepancies over previous misdiagnoses of IBD as infectious gastroenteritis, most experts agree that the incidence of UC has increased over the first half of the 1900s. Since then, the prevalence of UC has plateaued, while Crohn's disease has increased during the 1950s-1980s. The incidence of UC, as compared to CD is similar worldwide. Both have an increased prevalence in the Northern regions of the world. The two diseases are prevalent in North America, northwestern Europe, and in the United Kingdom. This is in comparison to the decreased rates in Southern Europe, South Africa, and Australia. IBD is rare in Asia, Africa, and South America.

UC and CD are both diseases of late adolescence and early adulthood. However, there have been documented cases of IBD diagnosed in infancy and childhood. The incidence of UC is equal in the male and female gender. Crohn's disease is more common in females than males by 20-30%, but in the younger pediatric age groups, males have a greater incidence. Caucasians, especially Ashkenazi Jewish, have a greater risk than other ethnicities.

Although the precise mechanism of IBD is still unknown, there is a general consensus that it is multifactorial. There is currently no known infectious agent that has been identified/isolated, which reproducibly causes IBD. Still, infection may be a "triggering event" for an acute episode of IBD. Viruses and Mycobacterium paratuberculosis are some of the organisms that have been studied.

Genetics is a likely contributor in the pathogenesis of IBD. In CD, monozygotic twins have a concordance rate of 44%, while just 4% in dizygotic twins. UC has less of a genetic preponderance as monozygotic twins have a concordance rate of 6% to 25%. There are multiple studies attempting to isolate the gene(s) involved in this disease that are beyond the scope of this chapter.

Dietary components have also been studied. No toxin or antigen has been isolated. In a retrospective study, CD has been associated with "westernization" of the diet or an increased of intake of animal proteins, total fat and animal fat.

Some interesting modulating factors are the protective effects of breastfeeding against CD and appendectomy against UC. Cigarette smoking increases the risk for CD while it decreases the risk for UC.

The big picture is that multiple events have an additive effect that results in an abnormal mucosal immune response, which leads to intestinal inflammation. If this inflammatory response is not well regulated, then chronic IBD develops.

Common Comparative Aspects of CD and UC:

Description	Crohn's Disease	Ulcerative Colitis
Location	Mouth to anus 60% ileocolic 30% small intestine 10% colonic	Colon only
Abdominal mass	common	rare
Perianal disease	common	rare
Strictures	common	unusual
Fistula	common	unusual
Risk of cancer	increased slightly	increased greatly
Histology	Transmural inflammation Skip areas Aphthoid lesions Fissuring ulceration Granuloma Fibrosis	Mucosal inflammation Diffuse involvement Crypt abscesses Crypt distortion
Microscopic	Edema, increase in mononuclear cells in the lamina propria. Again, the hallmark is transmural extension into the bowel wall and adventitia.	Active UC: Neutrophils in the mucosa, goblet cell mucus depletion, and clumps of neutrophils in crypt lumens.
Clinical Presentation	Abdominal pain Anemia Weight loss Falling off growth curve Delayed puberty Perianal lesions Finger clubbing	Bloody, mucusy diarrhea Lower abdominal cramps (less common) Abdominal tenderness Vomiting Fever Weight loss

Crohn's Disease commonly presents with crampy abdominal pain, recurrent fever, weight loss, and diarrhea. Abdominal pain is diffuse and more severe than in UC and often worse in the lower right quadrant. Rectal bleeding is seen in about a third of the cases. Weight loss, poor weight gain, anorexia, and delayed growth occur in 40% of cases. This growth abnormality may present as short stature and/or delay in sexual maturation. Perianal disease may be the presenting complaint. Further examination may show a fistula, skin tags, or recurrent abscesses.

Ulcerative colitis presents with bloody stools, abdominal pain, and tenesmus. 100% of cases present with bloody mucinous stool. Mild disease is defined as less than 6 stools per day, no fever, no anemia, and no hypoalbuminemia. Moderate disease is described as more than 6 stools per day, fever, anemia, and hypoalbuminemia. 90% of cases present with mild to moderate disease. Severe disease exhibits high fever, abdominal tenderness, distention, tachycardia, leukocytosis, hemorrhage, severe anemia, and more than eight stools per day. Rare complications that may arise include toxic megacolon and intestinal perforation.

Extraintestinal complications of IBD may involve the joints (arthralgias are more common than arthritis), integument (erythema nodosum and pyoderma gangrenosum), eyes (episcleritis, uveitis, and rarely, orbital myositis), hepatobiliary system (sclerosing cholangitis, chronic active hepatitis), pancreas (pancreatitis), renal system (nephrolithiasis, hydronephrosis), coagulation system (hypercoagulability), and bone (decreased bone density).

The diagnosis is based on clinical presentation, radiologic findings, endoscopy with mucosal biopsy, and exclusion of other causes. Since corticosteroids will likely be used for treatment, stool cultures are done to rule out infectious causes. The stool may need to be evaluated for tuberculosis and schistosomiasis. Double-contrast barium enema may show diminished colonic haustrations in UC. In CD, it may identify nodularity, skip areas, a string sign, and fistula formation. Colonoscopy is superior to evaluate the large bowel because of its increased sensitivity and biopsy capability for histologic assessment.

Hematologic findings may exhibit anemia and thrombocytopenia. Further studies may show specific nutritional deficiencies including iron deficiency, hypoalbuminemia, and elevated transaminases. There have been recent advances in serologic testing, which in addition to screening for IBD, can differentiate between CD and UC. Anti-neutrophil cytoplasmic antibodies (ANCA) and anti-Saccharomyces cerevisiae antibody (ASCA) are laboratory tests that are used to serve this purpose. ANCAs are immunoglobulin IgG antibodies that are directed against neutrophil cytoplasmic components. Initially ANCAs had been studied in Wegener's granulomatosis

and necrotizing vasculitis. By utilizing immunofluorescence studies, UC can be identified as it demonstrates perinuclear staining (pANCA). The test is specific in separating IBD from infectious colitis and other GI disorders. Unfortunately, the sensitivity is only 50-65%. ASCAs are IgG and IgA antibodies that bind to mannose sequences in the cell wall of S. cerevisiae strain Sul. The specificity and sensitivity of this test is also suboptimal. It is positive in 55-60% of people with CD and 5-10% of those with other GI disorders. Its low sensitivity and specificity have kept these studies from replacing definitive radiologic and endoscopic studies. The tests are also limited in the cases where they are most needed. In CD limited to the colon, the pANCA may also be positive. ASCA is also less likely to be positive in CD limited to the colon. Thus, the dilemma remains in which the clinician attempts to distinguish UC from CD involving the colon only.

Sulfasalazine is the usual treatment for mild to moderate UC and Crohn's disease of the colon. Sulfasalazine is not effective in small bowel CD. In moderate to severe UC and Crohn's disease of the small bowel, corticosteroids are used. Care must be taken to rule out bacterial causes of diarrhea prior to starting systemic corticosteroid therapy. Severe UC is treated with hyperalimentation, high dose corticosteroids, sulfasalazine, and cyclosporine. Corticosteroids may result in growth retardation. Metronidazole is used to treat perirectal fistulae in patients with CD. Metronidazole is used for both active disease, as well as prevention of recurrence. Azathioprine and 6-mercaptopurine are immunomodulating drugs which are used to reduce inflammation of the intestines, so that the corticosteroid doses can be reduced. Cyclosporine and tacrolimus inhibit cell-mediated immunity. Anti-TNF-alpha is a newer intervention that may be beneficial.

Surgical resection is indicated when there are intractable symptoms despite medical therapy, intestinal complications, intra-abdominal abscesses, bowel-bladder fistula, perforation, and/or hemorrhage. Surgical resection does not necessarily result in a cure. In some patients, elective colectomy is performed to reduce or eliminate the risk of colon cancer.

Crohn's disease may be subdivided into 3 categories: 1) The fistulizing type may form fistulas that are entero-enteric (between bowel segments), bowel-bladder, enterocutaneous (bowel to skin), perianal fistulas, and/or intra-abdominal abscess. 2) Patients with fibrostenosing disease have persistent abdominal pain and radiologic findings consistent with stenoses of the small or large intestine. 3) The inflammatory category includes patients who do not fit either of the two diseases or had been in one category and now fit in another. As listed above, growth impairment may occur either secondary to the illness or to therapy.

Death in CD is rare in children. Adults with Crohn's colitis may have the same risk for cancer as do patients with UC. The overall risk for colorectal cancer is 8% after twenty years of disease. This risk is increased in those affected by perianal disease. Most patients undergo resection of the affected segment within 20 years, which decreases the overall incidence of carcinoma.

Ulcerative colitis is also divided into 3 categories, which include mild, moderate and severe disease. One large study noted 70% of children entering remission by three months despite their initial severity level. The greater the severity of the disease, the greater was the likelihood of undergoing a colectomy. Nine percent and 25% those with moderate to severe disease underwent colectomy by 1 and 5 years, respectively.

After 10 years of disease, the risk for colorectal cancer increases. About 12% of those with disease for 10 to 25 years will have colorectal cancer. Since there is such a high risk, regular colonoscopic surveillance is recommended, which identifies colorectal cancer at a potentially curable stage 65% of the time. However, these biannual examinations that start at 7-10 years of disease were not found to be cost effective. A more sensitive, specific and reliable screening test is currently being sought.

Questions

1. What portion(s) of the GI tract are affected by CD versus UC?
2. Which IBD has a greater association with cancer?
3. What are the common histologic findings in CD and UC?
4. Name three extraintestinal findings in IBD?
5. Describe the three types of CD and UC.

Answers to questions

1. CD affects the gut anywhere between the mouth to the anus, while UC affects the colon.
2. UC has a greater risk for cancer. CD only slightly increases the risk for cancer.
3. CD: Transmural inflammation, skip areas, aphthoid lesions, fissuring ulceration, granuloma, fibrosis. UC: Mucosal inflammation, diffuse involvement, crypt abscesses, crypt distortion.
4. Joints: arthralgias are more common than arthritis. Integument: erythema nodosum and pyoderma gangrenosum. Eyes: episcleritis, uveitis, and rarely, orbital myositis. Hepatobiliary system: sclerosing cholangitis, chronic active hepatitis. Pancreas: pancreatitis. Renal system: nephrolithiasis, hydronephrosis. Coagulation system: hypercoagulability. Bone: decreased bone density.
5. Crohn's disease may be subdivided into 3 categories: 1) The fistulizing type, 2) Patients with fibrostenosing disease, and 3) The inflammatory category. Ulcerative colitis is divided into three categories: mild, moderate, severe.

Chapter IX.12. Malabsorption Conditions
Max C. Miranda

A 15 year old girl presents to the physician's office with a three year history of intermittent diarrhea. Further history reveals a past history of anemia, anorexia, and minor abdominal pain. Her weight has been the same for 3 years now. Her mother has attributed this to her having a "rough time in school". Her mother also questions whether the symptoms could be related to a recent move from their home state of Minnesota. She has not yet reached menarche. A diet history suggests a normal diet with adequate iron intake. Her family history is negative for malabsorption and inflammatory bowel disease.

Exam: VS T 37.5, P98, R 18, BP 110/70. Ht 145 cm (57 inches), wt 35 kg (78 pounds), both less than the 5% percentile. She is alert, active and cooperative. She is thin and small for age but not cachectic. HEENT: Her conjunctivae are pale. Her teeth are pitted and discolored. Her neck is supple without adenopathy. Her heart and lungs are normal. Her abdomen is slightly protuberant and hyperresonant. Bowel sounds are slightly hyperactive. Tanner stage 4 for both breasts and pubic hair. Examination of both hands reveal mild pallor and flat fingernails. She is able to ambulate and no neurologic deficits are noted.

Because of her small size and amenorrhea, a bone age reveals a 3 year delay and suggests osteopenia. A stool examination is negative for blood and reducing sugars. The 72-hour fecal fat study shows a moderate increase in fat content. A CBC shows a mild anemia. Her reticulocyte count is low and her iron studies indicate the presence of iron deficiency. An ESR is normal, making the possibility of inflammatory bowel disease less likely. Her small size, the steatorrhea and the iron deficiency all suggest the possibility of some type of GI malabsorption condition. An upper GI study with small bowel follow-through is normal. A chloride sweat test for cystic fibrosis is normal. A lactose breath hydrogen test showed an elevation in hydrogen of 40 ppm, suggesting carbohydrate malabsorption. An upper GI endoscopy shows no visible abnormalities; specifically, no ulcers or hemorrhage. Biopsies from the duodenal and proximal jejunal area reveal severe villus atrophy consisting of a flat mucosa with deep crypts and no evidence of Giardia lamblia. A serologic human anti-tissue transglutaminase ELISA test came back positive for autoantibodies suggesting the diagnosis of celiac disease.

She is started on a strict gluten-free diet. She responds dramatically and upon follow-up is now reporting an increased appetite and improved mood. She has remained symptom free for about a year now. She has also noticed a resurgence in her growth and has reported menarche that started about a month ago.

Gluten-sensitive enteropathy, also known as sprue, celiac sprue and celiac disease, is one of the many causes of malabsorption. Malabsorption is a clinical term for the entire spectrum of conditions occurring during digestion and absorption of ingested nutrients by the gastrointestinal tract. Perturbations in the digestion and absorption of food nutrients can occur either in the luminal phase, the mucosal phase, or the transport phase of the ingested food. Classifying the many entities of malabsorption in this manner makes it easier to understand their exact mechanisms. Causes of malabsorption can be explained by the way the disease process interferes with the normal digestive and absorptive mechanisms.

Malabsorption encompasses conditions that go from a single nutrient malabsorption (e.g., lactose intolerance) to pan malabsorption (e.g., cystic fibrosis and celiac sprue). Celiac sprue is a disease that predominantly affects people of European descent (rare in people of African and Asian ethnicity), and currently has a frequency of 1 in 5000 in the US (although this frequency is debated and some feel that this frequency may be much higher). Celiac disease is manifested variably by malabsorption to different types of nutrients. While presenting symptoms such as diarrhea and weight loss are common, the specific cause of malabsorption should be established using physiological evaluations. In celiac sprue, suggestive screening investigations include steatorrhea that denotes fat malabsorption, decreased d-xylose absorption found in carbohydrate malabsorption, and serological markers such as antigliadin antibodies or the new ELISA test for anti-tissue transglutaminase. The treatment of the underlying disease is often dependent on the establishment of definitive cause for the malabsorption. In the case described, gluten-sensitivity is the underlying cause. Were it not for the logical steps followed by the clinician, the quite dramatic resolution of symptoms brought about by denying the patient food devoid of gluten would not have happened if the exact etiology was missed.

As emphasized before, the causes of malabsorption can be best appreciated if they are classified into the specific phase of digestion and absorption that is disturbed.

1. The luminal phase is where dietary fats, proteins, and carbohydrates are hydrolyzed and stabilized by digestive enzymes and bile. Diseases often associated with this phase include:

- Enterokinase and trypsinogen deficiencies that can lead to protein malabsorption.
- Impaired micelle formation that can cause problems in fat stabilization and the resulting fat malabsorption due to deconjugation of bile salts in bacterial overgrowth.
- Stasis of intestinal content due to a variety of factors (motor and anatomic abnormalities, small bowel contamination from enterocolonic fistulas) can cause bacterial overgrowth.
- Bacterial overgrowth can also cause decreased luminal availability of substrates (carbohydrates, protein, vitamins).

2. The mucosal phase relies on the integrity of the brush border membrane of intestinal epithelial cells to transport digested products from the lumen into the cells.

- Impaired brush border enzyme activity may lead to lactose intolerance and sucrase-isomaltase deficiency.
- Impaired nutrient absorption can be inherited or acquired deficits. Inherited defects include glucose-galactose malabsorption, a-betalipoproteinemia, and Hartnup disease.
- Acquired defects which are more common may be caused by decreased absorptive surface area (intestinal resection), damaged mucosa (celiac sprue, tropical sprue, giardiasis, Crohn's), or an infiltrating disease of the intestinal wall (lymphoma, amyloidosis).
- Tropical sprue and Giardiasis are two mucosal phase abnormalities due to damaged intestinal mucosa. Tropical sprue, a syndrome characterized by diarrhea, weight loss, and malabsorption, occurs in residents or visitors to the tropics and the subtropics, usually in connection with certain geographical areas such as Southeast Asia and the Caribbean. The pathophysiology is poorly understood but is theorized to be caused by an acute intestinal infection that leads to jejunal mucosal injury. The disease is primarily a disease of adults but it is also described in children.
- Giardiasis like celiac sprue has symptoms characteristic of panmalabsorption. The organism, Giardia lamblia is a protozoan that appears to alter intestinal epithelial structure and function leading to malabsorption. Giardiasis usually begins with ingestion of the cyst

that eventually leads to trophozoites in the stomach and duodenum. High-risk groups include travelers, homosexual men, individuals with immunoglobulin deficiency states, and children, especially those who attend day care centers.

3. Transport (removal) phase malabsorption abnormalities may be caused by lymphatic obstruction or vascular insufficiency.

The signs and symptoms of malabsorption depend on the specific cause or etiology, and the specific nutrient deficiency that ensues. Age also plays a big factor. Malabsorption causes a far more acute and wide-ranging symptomatology in younger children than in the older child. Diarrhea is the most common symptomatic complaint which might lead to dehydration, especially in younger patients. In older children, weight loss and fatigue might be more pronounced. Some patients may try to compensate by increasing caloric consumption, making the diagnosis more difficult. Children in the pubertal ages may display disturbance in anthropometric growth (weight, height, weight by height) and pubertal development. Other symptomatology that follows from specific components of disturbed digestion and absorption include:

Steatorrhea: Most often due to fat malabsorption.
Flatulence and abdominal distention: Release of gas by bacterial fermentation of undigested or unabsorbed food particles.
Edema: Commonly from chronic protein malabsorption or loss of protein into the lumen.
Anemia: Depending on the cause, can be micro or macrocystic, such as Fe deficiency anemia secondary to celiac disease.
Bleeding disorders and ecchymosis: Usually a result of vitamin K malabsorption.
Bone defects: Can be due to vitamin D deficiency or calcium malabsorption.
Neurological manifestations: Electrolyte disturbance or specific vitamin malabsorption such as B12 neuropathy.

A malabsorption condition usually contains a specific physical manifestation (e.g., growth, weight, and pubertal disturbance). Growth and developmental charts are extremely helpful in diagnosis. A physical examination should look into the possibility of finding specific signs of individual nutrient malabsorption to aid in the organization of symptoms.

General: Orthostatic hypotension, weight loss, muscle wasting, loss of subcutaneous fat, pallor, ecchymosis.
HEENT: Alopecia or thinning hair, pale conjunctiva, aphthous ulcers, cheilosis, glossitis, dental hypoplasia, abdominal distention, tympanic abdomen, hyperactive bowel sounds, ascites.
Hands: Koilonychias (flattened or spoon shaped nails), pale skin.
Neurologic: Motor weakness, peripheral neuropathy, ataxia, Chvostek or Trousseau's sign due to hypocalcemia or hypomagnesemia, numbness, paresthesias.
Musculoskeletal: Mono or polyarthropathy, back pain, muscle weakness.

After the initial examination, a physician may have a reasonable idea of a diagnosis. Often, laboratory investigations are needed to confirm the cause.

Stool analysis: Quantitative stool fat analysis for 72 hours, consistency, pH (due to acidic stools in the presence of fermented sugars and reducing sugars in carbohydrate malabsorption), stool bile acids (increased in bacterial overgrowth syndromes), presence of large serum proteins (such as alpha-1-antitrypsin, may indicate a protein-losing enteropathy, ova and parasites (for Giardia), testing for chronic intestinal infections (such as C. difficile or Cryptosporidium), consistency, fecal leukocytes (such as in inflammatory bowel disease), and occult blood.

Screening Lab Tests: CBC (for anemia), blood smear (for abnormal blood morphologies that may indicate vitamin B-12 deficiency, amyloid, or a-betalipoproteinemia), urinalysis (urine may reveal unusually high concentration of malabsorbed substance since, in many cases, the kidney and the gut use the same transporter such as in glucose transporter deficiencies where urinary glucose will be elevated while the serum level is normal), total protein (decreased in protein malabsorption), albumin (decrease may indicate severe malnutrition or pancreatic insufficiency), liver function tests (in liver and biliary diseases), calcium and phosphorus levels (to determine vitamin D deficiency which might be present in gross steatorrhea), serum immunoglobulins (for autoimmune enteropathies), sweat test (for cystic fibrosis), and radiographic bone age (especially in pediatric patients).

Other lab studies to be considered include: Schilling test (for B12 deficiency), urinary 4-hydroxy phenylacetic acid (shown to be elevated in the urine of children with bacterial overgrowth syndrome; enteric bacteria that posses L-amino acid decarboxylase produce 4-hydroxyphenylacetic acid from dietary tyrosine), fat-soluble vitamin assays for fat malabsorption, LDL cholesterol (may be lower than normal with bile and malabsorption), ESR and C-reactive protein (may be elevated in inflammatory bowel disease), serum bile acids (congenital deficiency in the sodium-bile cotransporter results in primary bile acid malabsorption, which may appear as diminished reabsorption of bile acids in the kidney), GI motility studies (can be as simple as an upper GI contrast study or as complex as the performance of antroduodenal motility studies, depending on the need, which can recognize damage or abnormalities present in the gut due to inflammatory and infective processes), breath hydrogen analysis and, d-xylose absorption study (to specify carbohydrate malabsorptions), carbohydrate oral tolerance test (for specific carbohydrate digestion and absorption dysfunctions). IgG and IgA antigliadin and IgA antiendomysial antibodies are present in gluten-sensitive enteropathy. The presence human antitissue transglutaminase ELISA has a reported sensitivity of 96-100% and specificity of 99-100% and now appears to be the new criterion standard for screening of sprue.

Barium radiographic studies (upper GI series) can be useful in assessing anatomy and function. Endoscopy performed by a gastroenterologist permits direct visualization of the mucosal surface. During the endoscopy procedure, mucosal biopsies can provide histological information, identification of infective organisms and functional assays of the biopsied tissue for specific enzymes.

Medical management of underlines two basic principles: 1) Treatment of the etiology of malabsorption. 2) Correction of nutritional deficiencies.

Treatment of malabsorption is as varied as the etiologies that cause them. The intestine appear to repair itself slowly, thus treatment may require a longer course. Since many of the conditions that are caused by malabsorption, respond well to specific remedies, the need to make an accurate diagnosis becomes even more important. Most treatments highlight the dramatic effect of correcting the underlying defects of digestion and absorption. An example would be the gluten-free diet instituted in patients with gluten sensitivity. The effects of strict adherence to this diet include the full reversal of the disease process. Treatment of diarrhea with oral gentamicin or an appropriate broad-spectrum antibiotics that includes anaerobic coverage (e.g., metronidazole) reverses bacterial overgrowth and chronic infections, resulting in a rapid improvement in the patient's function. Specific malabsorption syndromes that include enzyme deficiency or imbalance

can be successfully managed with oral supplements. The use of lactase supplements or non-lactose containing milk substitutes is beneficial in lactose intolerance. Pancreatic lipase can be replaced with oral supplements to improve fat digestion.

Efficient absorption of essential nutrients will not occur if the diarrhea is still present. Usually, the complete withdrawal of the offending substance can correct diarrhea. Care should be taken to avoid the iatrogenic elimination of necessary nutrients. For example, in celiac disease, gluten withdrawal is often enough to correct the symptoms. Carbohydrates and other foodstuff not continuing gluten can continue to be consumed.

Correction of nutritional deficiencies is the other important treatment goal. Dietary modifications and supplementation are especially useful if one considers the slow self-repair process of the severely damaged intestines. Dietary changes should be individually tailored to the individual and the underlying cause of malabsorption, but in general, a high protein, low fat diet is recommended. Decreased fat intake also reduces steatorrhea. The dietary modifications closely parallel the essence of withdrawing certain offending food products in the diet and promoting adequate calorie intake. Vitamin, mineral, and trace element deficiencies should be sought and corrected. Supplementation of nutrients whose absorption and digestion mechanisms were disturbed is essential. Anemia should be treated with appropriate supplements and specific deficiencies corrected by oral (or parenteral) supplementation. Fat-soluble vitamins may be required for a patient with severe steatorrhea.

Questions

1. What are the three phases of digestion and absorption discussed in this chapter?
2. Dietary fats, proteins, and carbohydrates are hydrolyzed and stabilized by digestive enzymes and bile in which phase?
3. Identify the phase in which digested food is moved from the lumen into the cells.
4. True/False: The symptoms of malabsorption are worse in older children compared to younger children.
5. True/False: Diarrhea is the most common presenting symptom of malabsorption in younger children.
6. True/False: Withdrawal of gluten-containing food from a patient with celiac disease is often enough to reverse the symptoms of malabsorption.

Answers to questions

1. Luminal phase, mucosal phase, and transport (removal) phase.
2. Luminal phase.
3. Mucosal phase.
4. False. Younger patients often display a more acute and wider-ranging symptomatology than older children.
5. True.
6. True.

Chapter IX.13. Meckel's Diverticulum
Gareth K. Nakasone

An 18 month old male is brought to the ED by his parents with a chief complaint of passing large amounts of dark red blood from his rectum, and black jelly-like stools of two days duration. The child does not appear to be in acute distress at rest, although his parents say that he seems to sleep more and looks paler than normal over the past 24 hours. Two days ago they were alarmed by maroon-colored blood on the child's bedding and oozing out the side of his diaper. He has not cried, complained, or shown any signs of focal pain or discomfort thus far. He has not vomited and continues to feed regularly. Prior to the onset of symptoms, he is reported as having a good appetite and is a generally "healthy and active baby" with no significant PMH.

Exam: VS T 37.4 (rectal), P150, RR 40, BP 90/50, oxygen saturation 100% in room air. His weight, height and head circumference are at the 50th percentile. He is pale and quiet, lying supine on the exam table. HEENT exam is significant for pale conjunctiva and lips. His neck is supple, non-tender, no bruits, no lymphadenopathy. His heart is slightly tachycardic, regular rhythm, no murmurs, no rubs, no gallops. His lungs are clear to auscultation. His abdomen is mildly distended with possible generalized tenderness upon palpation. No inguinal hernias are noted. Testes and penis are normal. A small amount of dark red blood is present in the diaper which is guaiac positive.

Labs: WBC 7,000, hemoglobin 9.6 g/dl, hematocrit 31%, MCV 67. Bleeding from a Meckel's diverticulum is suspected. A Tc-99m pertechnetate scintigraphy scan (a "Meckel's scan") is ordered, which demonstrates an area of focal uptake in the right lower quadrant of the abdomen. This focus appears at the same time as gastric activity, and its intensity increases in parallel with gastric activity. These findings are consistent with ectopic gastric tissue in a Meckel's diverticulum.

He is given an IV normal saline infusion. A transfusion is contemplated, but held off for the time being. A surgeon is consulted, and an emergent laparotomy is performed in which a portion of the patient's ileum is resected containing a 6 cm x 1.5 cm ulcerated appendage (a Meckel's diverticulum). He recovers well postoperatively.

Meckel's diverticulum is the most common congenital anomaly of the gastrointestinal tract, affecting about 2% of the population. Meckel's diverticulum affects the distal ileum and represents the remnants of the proximal end of the embryologic yolk stalk (i.e., the omphalomesenteric or vitelline duct) which normally obliterates completely by the 8th week of gestation. While most cases of Meckel's diverticulum are asymptomatic, complications such as perforation, hemorrhage from peptic ulceration, intussusception, volvulus or intestinal obstruction are associated life-threatening disease states.

During early embryonic development, the omphalomesenteric duct connects the midgut to the yolk sac, allowing free communication between the compartments. Starting from the 7th gestational week, this duct undergoes progressive narrowing, becomes occluded, and ultimately disappears completely by the 8th week (1). For reasons not well understood, the normal obliteration of the duct fails to occur in 1-3% of the population. When this happens, possible outcomes include (2):

1. Persistence and patency of the entire tract leading to a congenital umbilico-ileal fistula (presenting as a draining fistula at the umbilicus).
2. An outpouching diverticulum secondary to persistence of the proximal part of the vitelline duct (Meckel's diverticulum) with or without a fibrous band connecting the ileum to the inner surface of the umbilicus.
3. Persistence of the duct deep to the umbilicus, forming an umbilical sinus.
4. Fluid-filled cysts (enterocystomas) either intra-abdominal or just below the umbilical skin because of persistence of the middle portion of the duct.
5. Obliteration of the lumen of the duct but persistence of the duct tissue, forming a fibrous omphalomesenteric ligament.

Meckel's diverticulum is the most common omphalomesenteric duct anomaly, accounting for 97% of reported cases (2). The prevalence of Meckel's diverticulum based on autopsy records is estimated to be 2-4% of the general population. The male:female ratio of patients with asymptomatic Meckel's diverticula is 1:1, however, males with the anomaly are 3 times more likely to develop complications at some point during their lives. Four to six percent of all Meckel's diverticula cases result in complications and classically present in infants 2 years old or younger (3).

There are a few studies suggesting familial inheritance of Meckel's diverticula, however no other evidence currently exists to support a genetic predisposition as a risk factor (4). Other congenital anomalies, such as cleft palate, bicornate uterus, and annular pancreas, have been noted in association with Meckel's diverticulum, and Meckel's diverticulum may be found more frequently in patients with Crohn's disease compared to the general population (5).

A Meckel's diverticulum is a finger-like projection located in the distal ileum, usually within 100 cm of the ileocecal valve, about 1-10 cm long, and 2 cm wide. In contrast to intestinal duplications and mesenteric cysts, a Meckel's diverticulum arises from the antimesenteric border of the bowel, has its own mesentery, and derives its blood supply from a terminal branch of the superior mesenteric artery (the embryonic right vitelline artery). It is also considered a true diverticulum as it contains all layers of the intestinal wall (2).

The mucosa of the Meckel's diverticulum is heterotopic in over 50% of all cases, with 80% gastric in origin. Although pancreatic acinar tissue, duodenal Brunner's glands, colonic mucosa, hepatobiliary, jejunal, rectal, and endometrial tissues, or a combination of these tissues is noted on occasion, heterotopic gastric mucosa is by far the most common tissue seen (6). Consequently, the ectopic gastric mucosa found in the diverticulum may form a chronic ulcer and may damage the adjacent ileal mucosa via increased acid secretion. Such peptic ulceration can lead to pain, bleeding, and/or perforation.

Meckel's is the most common cause of gastrointestinal bleeding in children. Painless melena or bright red blood per rectum is a classic presentation, but there are other presentations as well.

A few cases of large diverticula measuring up to 3.5 cm in diameter and 9 cm in length have been reported in newborns presenting with a palpable mass and intestinal obstruction (2).

The Meckel's rule of 2's (8):

1. Occurs in 2% of the population.
2. Only 2% of those with a Meckel's diverticulum will manifest clinical problems.
3. Usually located 2 feet proximal to the ileocecal valve and the diverticulum is approximately 2 inches long.
4. Symptoms commonly manifest at age 2 years.

Most Meckel's diverticula are asymptomatic and are found either during autopsy or incidentally on laparotomy, laparoscopy, or barium study for other abdominal conditions. It is controversial whether to attempt surgical correction of an asymptomatic Meckel's diverticulum found incidentally as the risk of developing postoperative complications may be as high as 8% in such cases (3).

When patients with a Meckel's diverticulum develop symptoms, a complication is almost always present. The principal complications of Meckel's diverticulum include ulceration, hemorrhage, small bowel obstruction, diverticulitis, and perforation (9).

Ulceration with subsequent hemorrhage (often hemodynamically significant, but usually not life threatening) is the most common complication, with an incidence of about 20-30% of all complications. It is more common in children younger than 2 years and in males. The most common presentation is painless hematochezia due to ulceration within the diverticulum or adjacent intestinal mucosa as a consequence of acid secretion from ectopic gastric mucosa contained in the diverticulum (6). This represents the most common cause of painless hematochezia in patients less than 2 years old. Consequently, severe anemia or hemodynamic shock affects many of these children. Gastric mucosa with peptic ulceration is found in the vast majority of these cases (10).

Intestinal obstruction is another frequent complication and is observed in 20-25% of all symptomatic Meckel's diverticula and is attributable to intussusception, volvulus (often twisting around a persisting umbilical remnant), herniation, or entrapment of a loop of bowel through a defect in the diverticular mesentery (11). Patients with intestinal obstruction due to Meckel's diverticulum are usually older and present with abdominal pain, and vomiting. In cases of intussusception, patients may also present with a palpable mass in the lower abdomen and bloody (currant jelly) stools. Radiography of the abdomen may indicate an ileus or frank stepladder air fluid levels as observed in a bowel obstruction (8).

Diverticulitis occurs in approximately 10-20% of patients with symptomatic Meckel's diverticulum and occurs more often in the elderly population. Patients may present with symptoms of intermittent, crampy abdominal pain and tenderness in the periumbilical area, indistinguishable from appendicitis. Perforation of the inflamed diverticulum leads to peritonitis while stasis in the diverticulum causes inflammation and secondary infection leading to diverticulitis. Diverticular inflammation can lead to adhesions, which can cause intestinal obstruction (2).

Umbilical anomalies occur in up to 10% of patients with a symptomatic Meckel's diverticulum. The anomalies consist of fistulas, sinuses, cysts, and fibrous bands between the diverticulum and umbilicus. A patient may present with a chronic discharging umbilical sinus, superimposed by infection or excoriation of periumbilical skin. There may be a history of recurrent infection, sinus healing, or abdominal wall abscess formation. When a fistula is present, intestinal mucosa may be identified on the skin. A discharging sinus should be approached surgically with a view toward correction. Exploratory laparotomy may be required. When found at laparotomy, a fibrous band, should be excised because of the risk of internal herniation and volvulus (12).

Neoplasm is the least commonly associated pathology and is reported in approximately 4-5% of complicated Meckel's diverticulum. Of the various types of tumors reported, leiomyoma is the most frequent tumor, followed by leiomyosarcoma, carcinoid, fibroma, sarcomas, benign mesenchymal tumors, and adenocarcinomas (2).

Plain film radiographs are rarely useful in detecting a Meckel's diverticulum, although these may be useful at identifying an intussusception or bowel obstruction. An upper GI series and barium enema are also unreliable detection modalities. In addition, barium absorbs pertechnetate and its use should never precede a 99mTc scan since this may give rise to false negative results (7).

Preoperative diagnosis of a bleeding Meckel's diverticulum is best established by a technetium-99m pertechnetate scintiscan (Meckel's scan). The isotope, administered intravenously, identifies ectopic gastric mucosa as it is readily taken up by parietal cells (13). In a positive scan, the patient develops immediate tracer localization in the stomach and in the right lower quadrant. This test has a sensitivity of about 75%, with 15% false-positive and 25% false-negative rates. Reportedly, a size of 1.8 square cm of ectopic gastric mucosa in a Meckel's diverticulum is required for a positive result. The accuracy of the Meckel's scan may be improved with the use of pentagastrin or cimetidine, which increase the uptake of pertechnetate by parietal cells (7).

False negative scans are seen in Meckel's diverticulum that do not contain ectopic gastric mucosa or those with rapid bleeding that prevents the accumulation of tracer in the diverticulum. False positive Meckel scans can also be caused by appendicitis, peptic ulcer, hemangioma, abscess, intussusception, Crohn's disease, small bowel lymphoma, dilated or ectopic renal collecting structures, abdominal aneurysm, Peutz-Jeghers syndrome, and intestinal duplications (2).

Depending on the presentation pattern, the differential diagnosis can include appendicitis, Crohn's disease, acute porphyria, intussusception, volvulus, small bowel obstruction, bezoar, juvenile colonic polyp, incarcerated hernia, Hirschsprung's disease, necrotizing enterocolitis, perforated viscus, gastroenteritis, Henoch-Schonlein purpura, peptic ulcer, constipation, urinary tract infection, sickle cell crisis, urolithiasis, ovarian torsion, etc. The differential diagnosis of abdominal pain alone, is extensive.

Preoperatively, hemodynamic stabilization and control over diverticular infection should be addressed when Meckel's diverticulum complications are present. Cimetidine has been used successfully to stop bleeding before diverticulectomy is performed and empiric antibiotic administration is also often indicated (7). NG tube placement can be useful in patients presenting with intestinal obstruction requiring nasogastric decompression, and it can also help rule out upper GI hemorrhage proximal to the ligament of Treitz (2).

Surgical resection is the standard treatment of choice for all patients with a symptomatic Meckel's diverticulum (7). As mentioned earlier, the morbidity associated with a Meckel's diverticulectomy precludes routine surgical resection if found incidentally. However, if the diverticulum is suspected to contain ectopic gastric mucosa, if fibrous bands extend to the umbilicus, if mesodiverticular bands are present, or if there is surrounding inflammation, surgical resection of the Meckel's diverticulum is indicated (3).

The reported surgical mortality rate for symptomatic Meckel's diverticulum patients is 2-5%. Symptomatic patients have a 10-12% incidence of early postoperative complications such as ileus, suture line or intestinal anastomotic leak, intra-abdominal abscess, and pulmonary embolism. Late postoperative complications occur in 6-8% of patients and consist of small bowel obstruction due to intestinal adhesions (12).

Questions

1. What is the most common congenital gastrointestinal anomaly?
2. What embryologic structure composes a Meckel's diverticulum?
3. Are Meckel's diverticula more likely to be found in males rather than females?
4. What kind of ectopic mucosa is commonly found inside of a Meckel's diverticulum?
5. How do Meckel's diverticula usually present?
6. How do young children with symptomatic Meckel's diverticula usually present?
7. What are the principal complications of Meckel's diverticula?

8. What is the most useful imaging modality used to diagnose a Meckel's diverticulum?
9. A false negative Meckel's scan could be due to what?
10. What is the Meckel's rule of 2's (four elements)?

Answers to questions

1. Meckel's diverticulum is the most common congenital anomaly of the gastrointestinal tract, affecting about 2% of the population.
2. The embryologic yolk-stalk or omphalomesenteric or vitelline duct
3. Meckel's diverticula appear in males and females at equal frequencies, however, males are 3 times more likely to develop symptomatic or complicated Meckel's diverticula.
4. Gastric mucosa is present in 80% of all heterotopic cases.
5. Most cases of Meckel's diverticula are asymptomatic, are detected at autopsy, or incidentally during unrelated abdominal surgery.
6. The infant or young child who has a massive, painless bout of dark red rectal bleeding most likely has Meckel's diverticulum.
7. The principal complications of Meckel's diverticulum include ulceration, hemorrhage, small bowel obstruction (may be due to volvulus or intussusception), diverticulitis, and perforation.
8. A Meckel's scan (technetium-99m pertechnetate scintigraphy).
9. False negative scans are seen in Meckel's diverticulum that do not contain ectopic gastric mucosa and in Meckel's diverticulum with rapid bleeding that prevents the accumulation of tracer in the diverticulum.
10. Meckel's rule of four 2's: a) Occurs in 2% of the population, b) Only 2% of those with a Meckel's manifest clinical problems, c) Usually located 2 feet proximal to the ileocecal valve and the diverticulum is approximately 2 inches long, d) Symptoms commonly manifest at age 2 years.

Chapter X.1. Wound Management
Jeffrey J. Wong, MD

A 7 year old male presents to the emergency department 30 minutes after sustaining a right lower leg laceration. He fell off his bicycle, causing his right lower extremity to collide with the edge of a cement park bench. This resulted in a 2 cm laceration lateral to his right shin, which started to bleed. The patient's mother firmly applied a towel to the wound to control the bleeding, and drove him to the emergency room for treatment. He denies pain in any other areas besides his wound. He denies difficulty walking or increased pain while bearing weight.

PMH is unremarkable. Immunizations are up to date.

Exam: VS are normal. He is alert and comfortable. There are no signs of trauma elsewhere. His exam is unremarkable except for his lower extremity, where he has a 2 cm vertical laceration lateral to his tibia, 6 cm inferior to the patella. The depth of the laceration is approximately 5 mm. The laceration is not actively bleeding at this time. His perfusion, sensation and motor function are intact distally. No bony tenderness or deformity is present.

The wound is infiltrated with buffered 1% lidocaine. The wound is then irrigated and explored. The laceration is closed in two layers with a 4-0 absorbable suture closure of the subcutaneous layer, followed by a 5-0 skin closure with black nylon. The nylon sutures are removed 9 days later.

Traumatic wounds are a common reason for presentation to the emergency department. A wound is defined as a physical disruption of tissue from trauma. They can be accidental as a result of trauma or intentional from surgery. Generally, wounds include abrasions, punctures, lacerations, burns and larger wounds. This chapter will focus mainly on minor abrasions and lacerations. Larger wounds, such as those requiring extensive debridement or grafts, are beyond the scope of this chapter. Burns are covered in a separate chapter.

Effective management of wounds requires a basic understanding of the physiologic process of wound healing. Wound healing can be divided into three phases: the inflammation (exudative or substrate) phase, the proliferative phase, and the remodeling (maturation) phase. The inflammation phase involves vasodilatation of capillaries in wound edges and migration of plasma, polymorphonuclear leukocytes and macrophages into the wound space. The macrophages are particularly important in removing debris and bacteria, stimulating fibroblasts, and promoting angiogenesis. The proliferative phase involves the development of granulation tissue (a new vascular and cellular tissue comprised of new capillaries, inflammatory cells, collagen, fibronectin and proteoglycans). This phase does not occur until the surface has completely epithelialized. Finally in the remodeling phase, the collagen structure becomes more organized through cross-linking and forms the appearance of a flatter, stronger scar. However, at 3 weeks, the wound has only about 40% the strength of normal tissue. At 6 to 8 weeks, the wound achieves close to 70% of its strength. Although remodeling will increase the strength of the wound for at least 2 years, the scar will never reach the strength of its original, undivided tissue.

While all wounds go through the above three phases, they do not all close in the same way. There are three distinct methods in which wounds heal and close: by primary intention, secondary intention, and tertiary intention.

In healing by primary intention, the edges of the wound are well approximated (e.g., via suturing) and allow for more rapid healing and less granulation tissue and scarring.

In secondary intention, the wound is left open with the wound edges far apart from each other. Thus, there is a greater production of granulation tissue which then must undergo contraction and epithelialization. Myofibroblasts are the cells responsible for helping the wound to contract. Epithelial cells grow from the wound edges until the wound surface is totally covered. This is a slow process; epithelialization takes place at a rate of about 1 mm/day. A clinician may intentionally allow a wound to heal by secondary intention to prevent infection in wounds in which there is significant bacterial contamination, foreign bodies, or extensive tissue trauma. By leaving the wound open, there is less chance that bacterial colonization will occur (i.e., the risk of wound infection is reduced).

Healing by tertiary intention (delayed primary closure) is intentional closure after a delay of days to weeks. Similar to secondary intention, the wound is allowed to heal open for a period of time. However, the wound is then closed once the risk of infection has decreased significantly.

Urgent problems such as active bleeding should be addressed first. Then a history should be obtained and the patient should be screened for systemic conditions that put them at risk for infection or delayed healing and wound closure. Other risk factors for infection include wounds that have been open for longer than 1 hour and contaminated wounds. Also, the history of the mechanism of injury is essential to identify wound contaminants and foreign bodies that can lead to infection or delayed closure. Depending on the degree of contamination of the wound and the patient's immunization status; cultures, antibiotics, and tetanus prophylaxis should be considered. Then, utilizing universal precautions, the wound should be examined and assessed for location, length and depth, and extent of injury. One should also look for foreign bodies, damage to nerves or tendons, and the need for debridement. A neurovascular examination is important to document before anesthesia is applied. If a fracture or foreign body is suspected, radiographs should be obtained.

The mechanism of injury is important in several specific examples. If a sharp object such as a knife or glass is responsible for a laceration over the path of a tendon, then a severed tendon or a nick in the tendon should be suspected even if the tendon function appears to be intact. Similarly, such injuries over the path of digital nerves should lead one to suspect that the digital nerve may be severed. If broken glass is responsible for a laceration, then x-rays of the wound should be strongly considered to look for glass fragment foreign bodies which are difficult to identify on wound exploration. Most glass fragments are radiopaque. Stepping on a nail which pokes through a tennis shoe puts the patient at risk of a foreign body consisting of foam rubber from the insole of the shoe once the nail is removed. Such injuries have caused wound infections and osteomyelitis due to a retained foam rubber foreign body.

Abrasions are common. An abrasion occurs when a physical force scrapes and damages superficial layers of epithelium, usually with little damage to the underlying dermis. Abrasions tend to be very simple to manage and often only require thorough cleansing of the wound. Afterwards, the wound should be dressed with ointment and a sterile bandage and kept fairly moist to prevent desiccation to allow rapid and effective epithelialization. Healed abrasions often leave the skin hyperpigmented when exposed to the sun, thus sunscreen for 6 months post-injury may be helpful to prevent hyperpigmentation.

Puncture wounds are usually caused by a sharp and pointed object and may have variable depth of penetration through the tissues. Thus, one must consider possible damage to underlying structures. Also, these wounds may contain foreign material and are ideal sites for bacteria to flourish, making infection very common. Most uncomplicated, clean puncture wounds presenting less than 6 hours after injury will only require irrigation and cleansing to remove debris and aid in visualization of the wound. These wounds can usually be dressed

with a light bandage. Irrigation under pressure is controversial since it may push foreign material and bacteria deeper into the wound. Some have recommended excision of the puncture wound (core out) for puncture wounds at high contamination risk; however, this is aggressive and unnecessary in most instances.

Antibiotic therapy in wound management is greatly dependent on the timing of administration, the mechanism of injury, the severity of the wound, and the degree of bacterial contamination. In heavily contaminated wounds, it has been shown that infection usually results despite antibiotic therapy. Thus, irrigation and debridement are more important to prevent infection by reducing the bacteria count within the wound. Also, the effect of antibiotics depends on the length of time the wound has been open. The longer the wound is exposed, the less effective antibiotics become.

For lacerations, the wound must also be cleansed. If local anesthesia is planned, then cleansing is more effectively done after local anesthesia. Several local anesthesia and wound closure options are available. Ideally, these options should be discussed with the family and a decision should be made based the medical considerations while considering patient and family preferences.

Local anesthesia will be required for most wound closures. Lidocaine is commonly used to infiltrate wounds which has a rapid onset and a duration of about 1-2 hours. Some techniques to reduce the pain associated with infiltration include buffering the lidocaine (by adding sodium bicarbonate), warming the anesthetic solution, using fine gauge needles (e.g., 30 gauge), injecting through (i.e., from inside) the wound rather than through the skin (2), and slowing the speed of injection (3). Lidocaine with epinephrine may be used under some circumstances instead of plain lidocaine. Epinephrine is a vasoconstrictor which slows the rate of lidocaine entering the general circulation, allowing a higher total dose to be given (important for large wounds), extending the duration of action, and reducing the amount of bleeding. However, vasoconstriction agents should not be used in areas with end arterioles (such as the fingers, toes, ear, penis, and the tip of the nose) to prevent ischemia and tissue necrosis (5). Flap type lacerations may also be adversely affected by epinephrine if the perfusion to this flap is marginal. Optionally, longer acting local anesthetics such as bupivacaine can be used, but many consider this drug to be more expensive with a higher risk of toxicity.

Topical anesthesia can also be used alone or as a premedication preparation for subsequent infiltrated local anesthesia. Topical anesthesia does not utilize needles and administration is relatively painless. Tetracaine-adrenaline-cocaine (TAC) gel is no longer used because the cocaine component can be absorbed by mucous membranes potentially causing seizures and death (4). Lidocaine-adrenaline-tetracaine (LAT) gel is just as effective with fewer adverse effects. LAT's major disadvantage is that it requires 30 minutes for its local anesthesia effect to take place. EMLA cream (eutectic mixture of local anesthetics) is another topical local anesthetic (6) but its onset time is similarly slow.

After local anesthesia, the wound is cleansed to help prevent bacterial infection by removing foreign bodies and reducing the bacterial count within the wound. Direct inspection and exploration of the wound is necessary to remove visible foreign bodies. Irrigation is used to reduce surface bacterial counts and to rinse microdebris from the wound. Although many irrigation fluids have been studied, sterile normal saline is inexpensive and effective. Concentrated povidone-iodine, hydrogen peroxide, and detergents can cause significant tissue toxicity and are not recommended for internal wound irrigation (7). These agents are more effective on intact skin and possibly abrasions. Thus, povidone-iodine can be used to sterilize the skin as a skin prep for suture closure, but the wound should be irrigated with saline and not with povidone-iodine.

Sutures are the most common method of wound closure for lacerations. They have the greatest tensile strength and the lowest rate of dehiscence. However, one must consider the requirement of local anesthesia and sometimes sedation, cost issues (sutures are inexpensive, but they require a set of instruments and often, suture removal at a follow up visit), and more time and skill to apply.

Non-absorbable sutures made of nylon or polypropylene are commonly used for closing the skin layer of a laceration. Advantages include their ability to retain tensile strength for more than 60 days, and their relatively low tissue reactivity. These sutures require a follow-up visit for suture removal. In contrast, absorbable sutures such as chromic gut and polyglactin do not need to be removed. They are typically used for deeper layers or for subcuticular tissues. Deep sutures are beneficial in reducing the skin tension required for the skin sutures and the prevention of hematomas, dead space, and scarring. Some physicians prefer to use special fast absorbing sutures in the outer skin layers to avoid the pain and anxiety associated with suture removal (5) (popular products include fast absorbing gut and Vicryl Rapide). Otherwise, sutures should be removed after about 3-14 days depending on their location: face (3-5 days), scalp (5-7 days), trunk (7-10 days), extremities (10-14 days). Facial sutures should be removed earlier to prevent the formation of sinus tracts. After suture removal, wound closure tape is usually applied to reinforce the wound and prevent dehiscence.

The advantages of wound closure tape are that there is almost no tissue reactivity and they can be applied very rapidly. However, they are not able to evert the wound edges or close deep tissue. Tape should not be used alone in areas of high tension since they have low tensile strength and a high rate of dehiscence. Wound closure tape would be acceptable for smaller lacerations which are under little or no tension.

Tissue adhesives, which are cyanoacrylates, have been found to have negligible tissue toxicity, bacteriostatic properties, and good tensile strength (7). Histoacryl Blue (HAB or N-butyl-2-cyanoacrylate) has been in use for the past 20 years in Europe and Canada, but it is not approved for use in the U.S. (9). 2-octylcyanoacrylate (2-OCA, Dermabond trade name) was approved for use in the U.S. in 1998. After holding the two edges together, it is applied to the surface of the skin, requiring about 30 seconds for polymerization, forming a strong bond to the uppermost layer of the skin (10). This polymer holds the edges of the laceration together, allowing for good wound approximation and healing. The adhesive should never be placed inside the wound, since this results in a foreign body effect and impedes the wound edges from approximating. Aside from increased flexibility, 2-OCA has been found to be 3 to 4 times stronger than HAB, allowing it to be used on larger lacerations and incisions (11). 2-OCA can be used on almost any size laceration with an intact epidermis, although subcutaneous sutures are recommended on lacerations to extremities (7). This is due to the high tissue tension in these areas. For deeper lacerations to the epidermis, absorbable sutures can be used in the deep tissues in conjunction with tissue adhesive applied to the surface edges of the wound. After about 7-10 days, 2-OCA peels off, avoiding the need for the patient to return for suture removal. However, water can disrupt the 2-OCA bonds and cause premature peeling off of the adhesive. Thus, children should be encouraged to keep the affected area dry. Some of the other advantages of 2-OCA over sutures include ease of application, quicker application time (less than half the time needed for sutures), and fewer cases requiring local anesthesia (10). Tissue adhesives have been found to have comparable cosmetic results when compared with sutures (3,4,12). Some disadvantages include less tensile strength compared to sutures, and increased wound dehiscence over joints and high-tension areas. Tissue adhesives are seemingly simple, but they should be used by experienced personnel since they have many adverse effects described which are preventable if used in the correct manner, and if their use is avoided in wound conditions which are unsuitable for tissue adhesives (e.g., highly mobile areas and on the feet).

Questions

1. What is the purpose of using epinephrine in local infiltration and topical anesthesia?
2. Name the drawbacks of tissue adhesives in laceration repair.
3. What has the best cosmetic result in the repair of lacerations: sutures or tissue adhesives?
4. How long does it take for the tissue adhesive 2-OCA to fall off after application?
5. What are the adverse effects of using tetracaine adrenaline cocaine (TAC) gel?
6. What is the major clinical reason for preferring healing by secondary or tertiary intention (as opposed to primary closure)?
7. True/False: Antibiotics have only a modest effect on reducing the rate of wound infections in contaminated wounds.

Answers to questions

1. Since epinephrine is a vasoconstrictor, it slows the rate of local anesthetic release into the general circulation permitting a higher total dose of local anesthetic that can be given (useful if the wound is large), it extends the duration of action, and decreases bleeding.
2. Lower tensile strength compared to sutures and thus it can't be used in areas of high tension such as wounds over joints. If it gets wet, the adhesive may fall off prematurely.
3. The research done on the comparisons between sutures and tissue adhesives have shown that they have comparable cosmetic results.
4. Approximately 7 to 10 days
5. Cocaine component: arrhythmia, urticaria, drowsiness, excitation, seizure, vomiting, flushing, and death. TAC should be avoided near mucous membranes. TAC is no longer available in most centers.
6. Significantly contaminated wounds, are at greater risk of infection if closed by primary intention.
7. True. Heavily contaminated wounds will develop infection despite antibiotic treatment.

Chapter X.2. Inguinal Hernias and Hydroceles
Leticia P. Borja, MD

A 2 week old male infant, born at 38 weeks gestational age, presents for his first visit to a pediatric clinic. According to his parents, he has been doing well since birth. Their only concern is the persistence of a bulge in his right scrotum. On review of birth records, a moderate-sized scrotal mass had been appreciated on newborn examination with no other abnormalities noted. According to his parents, the bulge has not changed in size since birth and there has been no noticeable discomfort.

On exam, a moderate sized right scrotal mass is palpated. It is firm, smooth, non-fluctuant and non-tender. It brilliantly transilluminates. There is no reduction with compression of the mass. Both testes are descended. No inguinal or abdominal masses are appreciated on palpation. A diagnosis of non-communicating hydrocele is made. His parents are reassured and counseled on the possibility of a communicating hydrocele/complete inguinal hernia and to proceed to an emergency room if signs or symptoms of incarceration and strangulation occur. On subsequent well child visits, the right scrotal mass is noted to minimally decrease in size. His parents continue to report no fluctuation in size during activity, crying or defecation. At his 12 month well child visit, the right scrotal mass is noted to be unchanged since his last visit 3 months prior. He is referred to a pediatric general surgeon for evaluation. Elective surgical correction is performed.

Inguinal-scrotal swelling is a common finding in the pediatric population. Of the possible causes, the most common diagnoses are hernias and hydroceles. Approximately 1-2% of male newborns have a hydrocele. Most are non-communicating hydroceles (1). The estimated incidence of inguinal hernias in children is 5-50/1,000 live births. It is seen more frequently in males than females with a ratio of about 5:1 with a definite familial tendency. About 50% of cases present before 12 months of age with most occurring in the first 6 months of life. Approximately 99% of all inguinal hernias in children are indirect inguinal hernias. Direct hernias are rare. Most inguinal hernias are unilateral with about 60% occurring on the right side and 30% on the left side. Ten percent are bilateral (i.e., clinically apparent at initial presentation). Of note, inguinal hernias are more common in premature infants with an incidence of 5-30%. Most cases are bilateral, occurring in about 62% of affected premature infants (2-5).

Normally, in the male fetus, the testes descend to the vicinity of the internal ring of the inguinal canal by approximately 28 weeks gestational age. Then, by about 29 weeks gestation, the testes descend into the scrotum. With testicular descent, the lining of the peritoneal cavity extends into the inguinal canal and scrotum. This peritoneal canal is referred to as the processus vaginalis. Each testis descends through the inguinal canal external to the processus vaginalis. In the female fetus, a similar mechanism with descent of the ovaries into the pelvis occurs. The processus vaginalis in females extends through the inguinal canal into the labia majoris and is referred to as the canal of Nuck (2). In males, a hydrocele is formed when there is patency of the processus vaginalis between the scrotum and the peritoneal cavity resulting in an accumulation of fluid between the layers of the tunica vaginalis surrounding the testis. In the weeks prior to birth or shortly after, the processus vaginalis closes spontaneously in the area of the internal ring, obliterating the entrance to the inguinal canal. The scrotal fluid collection that remains within the tunica vaginalis is referred to as a scrotal hydrocele, or a non-communicating hydrocele. If the processus vaginalis fuses proximally and distally but remains open in between, the isolated fluid collection is referred to as a hydrocele of the cord. This type of hydrocele, although not in communication with the peritoneal cavity or the scrotum, is often associated with a hernia and/or a scrotal hydrocele (6). In some older boys, a scrotal hydrocele may result from inflammation within the scrotum caused by various conditions including testicular torsion, torsion of the appendages, epididymitis, and testicular cancer (1,4). When the processus vaginalis fuses distally but remains patent proximally, abdominal contents can enter the inguinal canal resulting in an inguinal hernia. However, if the processus vaginalis fails to fuse completely, there will be communication between the scrotum and the peritoneal cavity through the patent processus vaginalis resulting in an inguinal-scrotal hydrocele, or communicating hydrocele. Of note, there is a rare but important type of communicating hydrocele called an abdominal-scrotal hydrocele. With this type of hydrocele, the communication is between the scrotum and a cystic loculation of fluid within the lower abdomen. This may result in recurrent communicating hydroceles or unusually large hydroceles. If a communicating hydrocele is large enough, abdominal contents may extend through the patent processus vaginalis to the scrotum resulting in an inguinal-scrotal hernia (complete inguinal hernia). A similar mechanism may result in hernias in girls. The hernia sac in males and females may contain intestine or omentum, with the ileum being the most common intestinal component. However, other possible intestinal components include colon, appendix, and Meckel's diverticulum (hernia of Littre). In males with undescended testes, a testis may be contained within a hernia sac. In females, a hernia sac may contain an ovary, fallopian tube, or both (6). Of note, it is possible for a testis to be found in the hernia sac of a female infant if testicular feminization (complete androgen insensitivity) is present. More than half of patients with testicular feminization have an inguinal hernia (4).

In differentiating a hydrocele from a hernia, history and physical examination can be diagnostic. The most important information elicited from parents is a history of fluctuation in the volume of the mass that would be consistent with a hernia or communicating hydrocele. Parents may report an increase in size that is particularly noticeable at times of increased intra-abdominal pressure (activity, crying or straining). At rest, the bulge will be noted to spontaneously decrease in size. Parents may also report previous reduction of the mass by either themselves or another physician. A history of fussiness, obvious discomfort, poor feeding, vomiting, and abdominal distention would suggest incarceration. The physical examination starts with the child supine. The child should be positioned with legs extended and arms raised over the head. This usually results in crying, thereby causing an increase in intra-abdominal pressure. The mass is palpated and evaluated for tenderness, tenseness, and associated skin discoloration that, if present, would suggest incarceration and possible strangulation. This would be an indication for immediate referral to a pediatric surgeon. If the mass is non-tender, smooth, firm and located in the scrotum, a hydrocele is likely to be present. Of note, a hydrocele may also be found in the spermatic cord. A scrotal hydrocele should be moved away from the inguinal canal and palpation of normal cord structures superiorly should be performed to exclude the presence of a hernia. The testes may not be palpable. If a patient presents with a large hydrocele or a history of recurrent communicating hydroceles with or without a palpable ipsilateral lower abdominal mass, an abdominal-scrotal hydrocele should be suspected. If compression of the fluid-filled mass completely reduces the size of the hydrocele, a communicating hydrocele or hernia is the likely diagnosis. An inguinal hernia is non-tender, soft, reducible and can be located in the inguinal canal or may extend into the scrotum (inguinal-scrotal hernia). Of note, retractile testes, a common finding in infants and young children, can resemble an inguinal hernia. To avoid misdiagnosis, palpation of the testes should be done prior to palpation of an inguinal mass. The physical examination continues with the child erect. This raises the intra-abdominal pressure. Any fluctuation in the size of the mass should be noted. If the

child can cooperate, cough and Valsalva maneuvers (e.g., attempts to blow into an obstructed straw or a balloon) should be encouraged. An increase in size of the mass would be consistent with a hernia or communicating hydrocele.

Transillumination of the mass can be attempted. A hydrocele will brilliantly transilluminate. However, in children, inguinal-scrotal hernias and incarcerated bowel may also brilliantly transilluminate. Thus, transillumination in the pediatric setting may be unreliable. The internal ring of the uninvolved side should be examined before proceeding to the internal ring of the affected side. If an inguinal hernia is present, abdominal contents may be palpated extending through the internal ring (2,3,6).

If there is a history suspicious for a hernia but no mass can be demonstrated on examination, it may be helpful to empty the bladder which, when full, can block the internal inguinal ring and mask an inguinal hernia. Otherwise, a classic history of intermittent inguinal, scrotal or labial swelling that spontaneously reduces may be all that is necessary for diagnosis. However, another physical examination finding that can be present with inguinal hernias is a thickened spermatic cord with an associated "silk" sign. The spermatic cord is palpated over the pubic tubercle and a "silky sensation" is appreciated when the two layers of peritoneum are rubbed together. This finding, along with a history of a hernia, is highly suggestive of an inguinal hernia (2).

A scrotal hydrocele that is sufficiently large and tense may cause ischemic injury to the testis. A communicating hydrocele may enlarge and lead to development of an inguinal-scrotal hernia (6). Nine to twenty percent of inguinal hernias in children become incarcerated with more than half of those cases occurring in children less than 12 months of age. The incidence of incarceration increases in premature infants and in term female infants (2,5). When incarcerated, complete manual reduction of the hernia may not be possible. Strangulation of the hernia can occur and ischemic injury to intestine and testis/ovary may result (3,6). Intestinal obstruction, intestinal gangrene, and gonadal infarction occur more commonly in the first 6 months of life (4). Thus, because the risk of incarceration is high, particularly in infants, with a risk of strangulation, prompt surgical intervention is recommended as soon as the diagnosis is made.

The differential diagnosis of inguinal-scrotal swelling in children (6,7) can be classified based on acuteness of presentation, tenderness, location (intratesticular versus extratesticular), and transillumination. All hydroceles are non-acute, non-tender and they transilluminate. They are extratesticular, but scrotal hydroceles may be difficult to distinguish from an enlarged testicle on palpation. Communicating hydroceles are compressible (that is, they decrease in size with pressure), while non-communicating hydroceles will not change in size.

Inguinals hernias are usually non-acute and non-tender. They usually do not transilluminate. Incarcerated inguinal hernias are usually acute and tender. Vomiting may be present. Non-communicating hydroceles are frequently mistaken for incarcerated hernias, because they do not change in size with compression (seemingly non-reducible). However, scrotal hydroceles are spherical or oval in shape, while an incarcerated inguinal hernia is usually tubular in shape (often shaped like a small banana with a slightly tapered point at the end). Additionally, hydroceles are usually softer in consistency, while incarcerated hernias are the consistency of a refrigerated hot dog and sometimes harder than this. A hydrocele of the cord can be very difficult to distinguish from an incarcerated hernia, but this should be suspected if the onset is non-acute, it is non-tender, and the child's behavior appears to be normal.

Other diagnoses in the differential include lymph nodes, undescended or retracted testis (smaller in size), varicocele (soft spaghetti or bag of worms consistency), and spermatocele. Other considerations include epididymal cyst, testicular cancer, peritesticular rhabdomyosarcoma, benign soft tissue tumors, meconium sequestration, testicular torsion (tender), torsion of appendages, epididymitis, trauma, idiopathic scrotal edema, and Henoch-Schonlein purpura.

If there is uncertainty in the diagnosis, an ultrasound examination may aid in differentiating a hydrocele from a hernia, may confirm the presence of an abdominal-scrotal hydrocele, or may rule out other causes of inguinal-scrotal swelling. In a female, ultrasound examination can be used as part of the evaluation for testicular feminization (4). It can also be used to examine both ovaries when an incarcerated ovary is suspected (6). Abdominal x-rays are unnecessary for diagnosis of an incarcerated hernia, although they may be helpful in confirming an intestinal obstruction. If an incarcerated or strangulated hernia is associated with bowel obstruction or shock, laboratory studies and vascular access are indicated (5).

Treatment is usually not required for uncomplicated, simple hydroceles (non-communicating) because they tend to decrease in size with complete resolution in the first 2 years of life. Significant hydroceles persisting beyond 12-24 months are likely to be communicating and are generally surgically corrected at that time (1). However, early surgical repair is recommended for large, tense hydroceles because they rarely disappear spontaneously, they can cause ischemic injury to the testis, and they may be difficult to distinguish from hernias. Communicating hydroceles also require early surgical repair due to the fact that they may progress to symptomatic inguinal-scrotal hernias (6). All inguinal hernias will eventually require surgery. In fact, inguinal hernia repair is the most common surgical procedure in children (4). However, the urgency of surgical correction varies. In an outpatient setting, if a child presents with an inguinal hernia but is otherwise well (no obstruction or shock), manual reduction should be attempted. About 95% of inguinal hernias can be reduced by applying gentle but steady upward pressure on the hernia sac. If the hernia is easily reducible, referral to a pediatric surgeon should be done for elective surgical repair. While awaiting repair, parents should be counseled to seek immediate evaluation and treatment in an emergency department if signs and symptoms of incarceration and strangulation occur. Inguinal hernias that cannot be easily reduced are incarcerated and require immediate referral to an emergency department. In an emergency department, manual reduction can be attempted with sedation. Once the child is sedated, firm steady upward pressure can be applied to the hernia sac using one hand while the other hand gently guides the neck of the hernia sac into the distal ring of the inguinal canal. A Trendelenburg position may be helpful. If reduction is successful, a pediatric surgeon should be consulted for outpatient follow-up. However, children with difficult to reduce hernias or a history of incarceration in the past are at high risk for future incarceration and strangulation and should be managed more urgently. Some cases require inpatient observation. If reduction is unsuccessful, then a pediatric surgeon must be consulted immediately. If, however, a child presents with an incarcerated inguinal hernia and symptoms of intestinal obstruction or shock, a pediatric surgeon must be consulted emergently while resuscitation begins with intravenous fluids and nasogastric tube decompression of the stomach (5).

In young females, an ovary may incarcerate in the hernia sac. This has a spherical shape and the child is often asymptomatic with the exception of the inguinal mass. While incarcerated bowel is at risk for ischemia and must be surgically corrected immediately, the vascular supply to the incarcerated ovary is usually not compromised, thus, this is often less emergent.

Elective surgical repair can be safely done as an outpatient. Hospitalization may be necessary for children at high risk for post-operative/post-anesthesia complications (e.g., premature infants <60 weeks of post-conception age and infants with chronic medical conditions including heart disease, respiratory disease and seizure disorder) (2). Surgical correction is done through an inguinal incision. The spermatic cord is identified and, if present, a hydrocele is excised. If a hernia is present, reduction is performed. In the case of an incarcerated hernia, careful inspection of the incarcerated bowel is done to assess viability. After inspection and reduction, a high ligation of the processus vaginalis is performed (1,4). Of note, females undergoing surgical correction of a hernia should be evaluated for the possibility of testicular feminization. A rectal examination should be done to palpate the uterus. If a uterus is not palpable beneath the

symphysis pubis in the midline, a pelvic ultrasound examination should be done to evaluate for normal female anatomy. If the results are inconclusive, the hernia sac must be explored during surgery and the presence of a fallopian tube verified. If present, testicular feminization can be ruled out. Conversely, the presence of testes confirms the diagnosis. If neither fallopian tube nor testis is found, an endoscopic examination of the vagina after surgery should be performed to evaluate for a cervix. If a cervix is present, testicular feminization can be ruled out. However, if it is absent, chromosomal analysis will need to be done (2,6).

There is controversy surrounding the topic of contralateral surgical exploration at the time of herniorrhaphy. Studies have shown that development of a contralateral inguinal hernia after unilateral herniorrhaphy occurs with an incidence of 12-30% (>10% since the contralateral hernia often develops later). Bilaterality is more frequent in females, children less than 12 months of age, and children with left-sided inguinal hernias. For this reason, it is recommended that bilateral surgical exploration be done in males less than 12 months of age, females less than 24 months of age, and children at high risk for development of inguinal hernias. Bilateral surgical exploration should also be strongly considered in children less than 24 months of age with left-sided inguinal hernias. Of note, contralateral exploration can be avoided with laparoscopic herniorrhaphy. This technique allows for visualization of the contralateral side during repair of the affected side. However, the surgeon must be experienced in laparoscopic technique. In general, the decision to undergo bilateral surgical exploration should be based on surgical expertise and a child's pre-operative medical condition (2).

Premature infants will often develop a symptomatic hernia while remaining hospitalized for prematurity. These infants should have surgical correction of the hernia prior to discharge from the hospital. Other significant risk factors for development of an inguinal hernia include presence of a ventriculoperitoneal shunt or peritoneal dialysis catheter. These devices cause increased intra-abdominal pressure resulting in a high incidence of inguinal hernias in affected infants. They are also associated with greater risk for surgical complications. It is recommended that prophylactic antibiotic therapy with ampicillin and gentamicin be given perioperatively to children with ventriculoperitoneal shunts. This is also the recommendation for children with congenital heart disease. Other conditions associated with an increased incidence of inguinal hernias include congenital dislocation of the hip, ascites, congenital abdominal wall defects, meconium peritonitis, connective tissue disorders (Ehlers-Danlos syndrome), mucopolysaccharidosis (Hunter-Hurler syndrome), ambiguous genitalia, hypospadias/epispadias, cryptorchid testes, and cystic fibrosis. Cystic fibrosis is also associated with agenesis of the vas deferens. Thus, if bilateral absence of the vas deferens is noted incidentally during herniorrhaphy in a child without a prior diagnosis of cystic fibrosis, an evaluation for cystic fibrosis should be done including a sweat chloride test and/or DNA testing. However, agenesis of the vas deferens can also be an isolated finding. If a child has cryptorchid testes and an inguinal hernia, elective orchiopexy should be done along with herniorrhaphy to reduce the risk for ischemia and infarction or the testis (2,4).

Most hydroceles resolve by 12-24 months of age following reabsorption of the hydrocele fluid. However, if the hydrocele persists beyond this time frame, if it is large and tense, or if the hydrocele is communicating, it is unlikely to resolve spontaneously and can be difficult to distinguish from a hernia. In these cases, as with hernias, surgery can be curative. However, there can be complications of surgery including damage to intestine, testis and vas deferens or to ovary and fallopian tube. Rarely, the bladder may be damaged with resultant urinary ascites. A surgeon should be able to recognize and appropriately manage such injuries (6). Post-operative complications including wound infection and hernia recurrence are uncommon. In fact, the hernia recurrence rate is less than 1% (2). More commonly, a recurrent swelling is due to reaccumulation within the tunica vaginalis and/or enlargement of retained tunica vaginalis tissue due to edema. These will often resolve spontaneously without the need for reoperation (6). However, there is an increased risk for hernia recurrence after repair of incarcerated or strangulated hernias as compared to elective surgical repair (4). Children with connective tissue disorders, chronic respiratory disease, and chronic illnesses associated with increased intra-abdominal pressure are also at higher risk for hernia recurrence (2).

Questions

1. True/False: Bilateral inguinal hernias are common in premature infants.

2. Which of the following statements is false?
    a. Each testis descends through the inguinal canal into the scrotum within the processus vaginalis.
    b. A hydrocele can result from incomplete fusion of the processus vaginalis.
    c. A scrotal hydrocele, or simple hydrocele, is a type of non-communicating hydrocele.
    d. A communicating hydrocele can develop into an inguinal-scrotal hernia. Some use the terms interchangeably.
    e. A hernia sac can contain intestine, omentum, testis/ovary or fallopian tube.

3. What is the classic clinical presentation of an inguinal hernia?

4. True/False: The risk of incarceration and strangulation of an inguinal hernia is highest in the first 12 months of life.

5. Which of the following is not part of the differential diagnosis of an inguinal-scrotal swelling in children?
    a. Varicocele
    b. Undescended or retracted testis
    c. Volvulus
    d. Testicular torsion
    e. Testicular cancer

6. True/False: All inguinal hernias will eventually require surgery.

7. Which of the following is not a risk factor for development of an inguinal hernia?
    a. Presence of a ventriculoperitoneal shunt
    b. Congenital heart disease
    c. Prematurity
    d. Cystic fibrosis
    e. Family history of inguinal hernias

8. True/False: After herniorrhaphy, hernia recurrence is rare.

Chapter X.3. Appendicitis
Walton K.T. Shim, MD

A 7 year old girl presents to the emergency department with a chief complaint of abdominal pain for one day. Mid-abdominal pain started after lunch yesterday. This was followed by vomiting her lunch and a bowel movement, which did not relieve the pain. She did not feel like eating dinner and went to bed but slept fitfully. By morning the pain had increased and she vomited again. The pain has moved to the right lower quadrant and is increased by walking and coughing.

ROS: Non-contributory. No dysuria, cough or URI. No similar GI problem in the family. Pain remained constant in RLQ without radiation.

Exam: T 37.1, R 16, P 100, BP 150/70. She is alert, but subdued. HEENT Negative. Neck is supple. Chest is clear. Heart regular without murmur. Abdomen: Bowel sounds hypoactive with right lower quadrant tenderness and guarding. No organs or masses are felt. Right lower quadrant rebound tenderness is present. Genitalia: Normal; no hernias. Rectal: No masses or tenderness. She walks slowly and slightly hunched.

Lab: CBC WBC 14.0, 60% Segs, 15% Bands. UA 10-15 WBC, 15-20 RBC, no bacteria. Abdominal radiographs: Non-specific, no fecalith is seen.

Impression: Acute appendicitis

Surgery: Acute appendicitis; appendectomy performed

Pathology of appendix: Acute appendicitis

The recorded history of appendicitis demonstrates the evolution of our understanding and treatment of a disease process. It starts in the early 18th century and is summarized by Dr. Mark Ravitch in the chapter titled "Appendicitis" of the text Pediatric Surgery. It is recommended to all students of medicine (1). The Pathologist Reginald Fitz of Boston first described the condition of appendicitis in 1886 and in 1887, the Philadelphia surgeon T.G. Morton performed the first successful removal of an appendix which had been perforated. Charles McBurney immortalized "McBurney's point" when he described it in 1889 as the point of greatest tenderness located 1.5 to 2 inches (4 to 5 cm) from the anterior spine of the ileum on a line drawn between that point and the umbilicus.

It is estimated that 60,000 - 80,000 children are diagnosed with appendicitis annually (2), making it the most frequently performed emergency medical procedure in childhood. About 100 will die from complications (0.2%).

Obstruction of the lumen by impacted fecal material is the prime cause of appendicitis. This creates an increase in intraluminal pressure, edema and ultimately mucosal ulceration leading to infection and perforation. Obstruction from bacterial infections such as Yersinia, Shigella and Salmonella, from systemic viral infections, and from parasitic ascaris are rare causes. The earliest cases recorded were caused by ingested foreign bodies.

The diagnosis of acute appendicitis is a good example of critical thinking in medicine. It involves both inductive and deductive reasoning. It starts with a chief complaint, or the reason the patient comes to see the physician, followed by a probing evaluation and expansion of the chief complaint into what amounts to a history of symptoms surrounding the chief complaint or the present illness. We apply the recent mnemonic of S.O.A.P. (Subjective, Objective, Assessment, Plan) to the diagnosis and treatment of appendicitis.

S (subjective or symptoms): We find the subjective symptom of abdominal pain to be epigastric or mid-abdominal in location associated with anorexia and vomiting in most cases. This corresponds to the period of early obstruction and edema of the appendiceal lumen. This colic of the appendix, as with obstructive colicky pain of the entire intestinal tract is appreciated in the mid-abdomen or epigastrium. As the process of obstruction proceeds to edema and inflammation of the appendiceal wall and serosa, pain starts to localize in the dermatome overlying the infected appendix which is usually in the right lower quadrant. With a knowledge of pathophysiologic progression of the disease the physician/diagnostician/sleuth can round out the symptomatology with probative questions to elicit

predictable symptoms associated with bowel inflammation such as the presence of an urge to defecate during the obstructive phase caused by the attempt of the intestine/appendix to expel the offending impacted material, anorexia and/or vomiting, pain with walking, and sudden pain relief with rupture only to have more intense symptoms recur as peritonitis becomes established.

At this point with the knowledge that abdominal pain can also be caused by genitourinary, respiratory, gynecological, lymphatic and neurological diseases, application of deductive reasoning should lead the diagnostician to ask whether or not the child has a respiratory infection with cough, sore throat or chest pain; whether or not there is radiation around the right flank or dysuria and groin pain indicating a urological cause; or in a girl, whether or not the pain radiates to the anterior right thigh indicating pain of ovarian origin. In post menarchal females, low abdominal pain occurring in mid-cycle may be caused by a ruptured ovarian follicle which is called mittelschmerz (literally, middle pain). Infected lesions of the right lower extremity may cause acute femoral and/or iliac adenitis and tenderness. Neurological causes such as nerve root pain should also be considered. Having eliminated these, concentrates the symptoms in the gastrointestinal tract. To rule out small bowel pathology, such as acute gastroenteritis, flu syndrome, Henoch-Schonlein purpura, chronic GI problems, the investigator must question the chronicity of the symptoms (regional ileitis), the involvement of family members (acute gastroenteritis), the presence of blood in the stools (intussusception and intestinal infection), etc. Once these are eliminated and the general health of the child has been established, the diagnostician can move on to the next phase which is observation.

O (objective or observations): It is of interest that colicky pain caused by obstruction of a hollow viscus is somewhat ameliorated by movement on writhing, whereas peritoneal pain is aggravated by movement. So we see that children with appendiceal inflammation causing peritoneal irritation tend to lie motionless and often say that the pain is aggravated by walking.

The next step in physical diagnosis and slightly more intrusive is auscultation with a stethoscope. As appendiceal inflammation progresses, the protective mechanism of the bowel causes it to become less active and bowel sounds are diminished until the belly becomes quiet with frank peritonitis. Normal or hyperactive bowel sounds should cast doubt on a diagnosis of appendicitis. While the examiner is evaluating bowel sounds, he or she should listen to the lower lobes of the chest as pneumonia of the lower lobes can cause inflammation of the lower thoracic dermatomes and be interpreted as abdominal pain.

Peritoneal pain can and should be elicited by palpation which should start in the LLQ and progress counterclockwise ending in the RLQ. If the examiner starts in the area of pain first, the child will start crying and make further evaluation difficult. The stiffening of the abdominal muscles to restrict deeper palpation is called voluntary guarding and is an important observation when limited to the RLQ. Further inflammation of the serosal surface leads to involuntary guarding or spasm indicating peritonitis.

Finally the physical examination portion of observation should conclude with an evaluation of groin tenderness to rule out a hernia or iliac adenitis as the cause for abdominal pain. A rectal examination may also be indicated in appendiceal perforation when a pelvic abscess is suspected.

A (assessment): Acute appendicitis is the most likely explanation for the findings since the patient's temperature is usually not elevated but the WBC is frequently slightly increased. There may be a left shift of the white count with bands being elevated even though the WBC is normal. The microscopic blood and white cells in the urine can be explained by an inflamed appendix overlying the right ureter causing transmural inflammation with blood and white cells in the urinalysis. This assessment is strengthened by the absence of dysuria and pain distribution in the area usually manifested in renal colic (right flank and groin).

The single most important observation which places acute appendicitis at the head of a list of differential diagnoses is RIGHT LOWER QUADRANT tenderness. Tenderness should be <u>persistent</u> and <u>constant</u>. Inconsistent tenderness casts doubt on the diagnosis of appendicitis. In addition to the laboratory tests of CBC with differential and a urinalysis I usually obtain an abdominal series looking especially for a RLQ fecalith, air/fluid levels, abnormal quantities of stool and signs of bowel obstruction and/or masses.

The CT scan should be used judiciously in cases when a diagnosis of appendicitis cannot definitely be made or ruled out. It is probably the single most important recent addition to the physician's armamentarium of diagnostic tools, but should not be used in place of a thorough history of symptoms and a good physical examination.

A repeat abdominal examination following an enema when much stool is present on rectal examination or abdominal radiographs may clarify the diagnostic dilemma. It is important to remember that initial symptoms frequently ameliorate with time.

P (plan): When the assessment leads to a diagnosis of acute appendicitis, immediate appendectomy should be scheduled. If perforation is suspected because of the severity of symptoms and the presence of peritonitis or evidence of perforation on CT scan, preoperative antibiotics should be administered and continued post-operatively.

Since these children have not eaten for a day or so and probably have vomited, dehydration and contraction of the extracellular space is an important consideration. Proper and adequate intravenous fluid administration should be given. If dehydration is severe and peritonitis is present, the bladder must be catheterized to monitor urine output as a reflection of adequacy of fluid administration. It is not unusual that three or four times the maintenance rate of electrolyte rich fluid is required for extracellular repletion and adequate blood volume support. Those patients with peritonitis should have particular encouragement to cough and deep breathe to prevent atelectasis and pneumonia as abdominal pain and distention cause elevation and splinting of the diaphragm leading to inadequate lung expansion and retention of secretions.

Questions

1. What is the difference between colicky and peritoneal pain?
2. Where is McBurney's point?
3. What two characteristics of the tenderness at McBurney's point make the diagnosis of appendicitis?
4. In cases of right lower quadrant pain and tenderness what is the second most frequent system implicated as its cause?
5. What is mittelschmerz?

Answers to questions
1. Movement alleviates colicky pain but exacerbates peritoneal pain.
2. 4 to 5 cm (1.5 to 2 inches) cephalad on a line drawn between the anterior-superior iliac spine and the umbilicus.
3. Persistent and constant in nature.
4. Genitourinary.
5. Literally "middle pain" caused by a ruptured ovarian follicle which occurs approximately in mid-menstrual cycle.

Chapter X.4. Intussusception
Lynette L. Young, MD

An 18 month old male presents to the emergency department with six hours of stomach pain. He awoke at 0400 crying. His mother carried him and he settled down after a few minutes and then fell back asleep. Over the next few hours, he woke up intermittently crying. His appetite has been poor since the onset of these symptoms. He is able to walk but prefers to be carried by his mom this morning. He is less playful than usual. He would sometimes bend down crying. There is no vomiting or diarrhea. His last stool yesterday was normal. There is no fever, cough, or runny nose. There is no history of abdominal trauma.

Exam: VS T37.6, P 118, R 24, BP 85/55, weight 11kg. He is awake, alert, and being carried by mom. His skin is pink with good perfusion and brisk capillary refill. His oral mucosa is pink and moist. There are no ulcers in the posterior pharynx. His tympanic membranes are normal. Heart regular rhythm and normal rate. Lungs are clear with good aeration. His abdomen is soft and not distended, with normoactive bowel sounds, and no masses noted. It is difficult to determine if any abdominal tenderness is present. His genitalia are normal (no scrotal/testicular swelling or tenderness). His distal extremities are warm and the distal pulses are strong. He is responding to mom appropriately.

An abdominal series reveals a soft tissue density in the right lower quadrant. Intussusception is suspected. A water-soluble contrast enema is performed. An intussusception is identified at the hepatic flexure. The ileocolic intussusception is successfully reduced. There was reflux of the contrast into the ileum. Admission to the hospital is discussed with the mother, but she refuses. He is observed in the emergency department. After a short nap, he is able to tolerate oral fluids and his behavior normalizes. The risk of recurrence is discussed with his mother. His pediatrician is contacted and the patient is then discharged home.

Intussusception is a common abdominal emergency in children. Intussusception is best described as a portion of the intestine which telescopes into a more distal intestinal segment. It is one of the most common causes of abdominal obstruction in infants. Intussusception occurs most often in patients between 3 to 12 months of age. There is a male to female predominance of 2:1. It is often difficult to diagnose because of the variable presentation of symptoms in a young infant.

The most common type of intussusception is ileocolic (also known as ileocecal) (90%). A portion of terminal ileum intussuscepts through the ileocecal valve into the colon. The intussusception may sometimes extend all the way to the rectum. Other types of intussusception that are rarer include ileoileal, colocolic, and ileoileocolic. The majority of intussusceptions are idiopathic. An anatomic lead point (a piece of intestinal tissue which protrudes into the bowel lumen such as a polyp) occurs in approximately 10% of intussusceptions. This is most often found in children older than 2 years. Possible lead points include Meckel's diverticulum (most common), polyps, an inflamed appendix, neoplasm (lymphoma), and ileal duplications. Intussusceptions with lead points are more common in patients with Henoch-Schonlein purpura (intestinal wall hematoma) and cystic fibrosis (hypertrophied mucosal glands). In infants it is hypothesized that hypertrophied Peyer's patches, following a respiratory infection or gastroenteritis, may serve as the lead point.

The mesentery is pulled along with the intussusceptum (leading invaginating segment) into the intussuscipiens (receiving segment). The intussusceptum is propelled distally through peristalsis. The mesenteric vessels are compressed leading to venous obstruction. The intussusceptum becomes engorged causing bleeding from the mucosa (bloody mucusy stools, sometimes known as currant jelly stool since extreme amounts of blood in the stool will loosely resemble the red jelly of currant berries). However, it should be noted that any blood in the stool may be caused by an intussusception. With a prolonged intussusception, perfusion to the intestine may be compromised, which can then lead to bowel necrosis, perforation, and shock.

The classic triad of intussusception include crampy (intermittent, also known as colicky) abdominal pain, vomiting, and bloody stools. The classic triad was found in only 21% of cases and two symptoms were found in 70% of cases in one series of patients with intussusception (1). The colicky abdominal pain usually appears first and is the most common symptom. The pain is intermittent lasting for 4 to 5 minutes. It may return in 5 to 30 minute intervals. The patient may pull up his knees with crying. In between the episodes the patient may be asymptomatic. The patient may develop vomiting (90% of cases). The emesis may become bilious because of the obstruction. Bloody stools, found in 50% of cases, can be a late sign of intussusception. The absence of blood (even occult blood) does not rule-out intussusception. Patients with an intussusception may also present with lethargy/altered level of consciousness and pallor. The etiology of this lethargic presentation is not known, but it tends to occur in younger infants. Some hypothesize that this is due to release of endogenous opioids or endotoxins released from ischemic bowel. Intussusception in a child presenting with lethargy is often difficult to diagnose since other causes of lethargy such as dehydration, hypoglycemia, sepsis, toxic ingestion, post-ictal state, etc., must also be considered.

The physical examination of a patient with an intussusception may be unremarkable. If the patient is between attacks of the crampy abdominal pain, he may appear normal and the abdominal examination may be unrevealing. Also, examining the abdomen of an active or

crying child can often be difficult. Lethargic or tired infants with very soft abdomens are the easiest to examine. In some patients, a mass may be palpable in the right upper quadrant. It is often described as sausage-shaped. A sausage-like mass in the right upper quadrant and emptiness (the absence of bowel) in the right lower quadrant is clinically indicative of an intussusception. Blood may be found on rectal examination. If the intussusception has been present for a longer period of time, the abdomen may be distended and there may be findings of peritonitis.

There are several findings described on plain film abdominal radiographs of patients with intussusception. There may be evidence of a soft tissue mass or signs of bowel obstruction (air fluid levels and distended loops of bowel). The absence of gas in the right lower quadrant or flank may be seen with an intussusception. A target sign, crescent sign or indistinct liver margin sign may be present. A target sign is viewing the intussusception on cross-section which appears as two concentric circles (created by bowel fat density differences) usually in the right upper quadrant. The crescent sign is formed by the leading edge of the intussusception outlined by gas in the colon forming a crescent (intussusceptum protruding into a gas filled pocket). The absent liver margin sign can be seen if the soft tissue mass of the intussusception is resting at the hepatic flexure of the colon or there is absence of gas in the right upper quadrant making the lower edge of the liver indistinct. Free air may be visible on the radiograph if there has been intestinal perforation. An abdominal series may be normal especially early on. More recently, ultrasound has been advocated as it is highly specific (100%) and sensitive (98%) in making the diagnosis of intussusception, but only when interpreted by highly skilled radiologists. It may be helpful with confirming the diagnosis if an enema is contraindicated. The major problem with utilizing ultrasound is that it must be able to definitively rule out intussusception, since if diagnostic uncertainty still exists following the ultrasound, a contrast enema must still be performed. Additionally, if the ultrasound does identify an intussusception, a contrast enema must still be performed to reduce the intussusception. Thus, before considering an ultrasound, the diagnostic ultrasonography skills of the available radiologist must be determined. The high specificity and sensitivity percentages are published from studies done in ultrasound pediatric super centers and thus, these numbers are not necessarily applicable to general radiologists.

A barium enema has been the gold standard in the past for confirming the diagnosis and nonsurgical reduction of an intussusception. Water-soluble contrast has been used and more recently air enema reduction has been introduced. There are several reasons why radiologists have different preferences for which type of contrast they choose to use for the procedure. After the radiologist reduces the intussusception, they look for the contrast to reflux into the ileum. This is necessary to eliminate the possibility of an ileoileal intussusception. This is more difficult to see with an air contrast enema compared to a barium or water-soluble contrast enema. Air leaking into the peritoneal cavity because of intestinal perforation may also be difficult to see. Those in favor of using the air contrast enema technique argue that with perforation, the sudden loss of pressure would signal to the radiologist to stop the procedure. If a tension pneumoperitoneum results, this should be decompressed immediately with an 18-gauge needle. Barium leaking into the peritoneal cavity may cause a chemical peritonitis. Using a water-soluble contrast may decrease this complication. An air contrast enema is advocated as the preferred method by many pediatric radiologists (2), but since there is no clear consensus among radiologists of the best contrast enema option, this decision is best left to the radiologist performing the contrast enema procedure. The success rate of nonsurgical reduction is about 60% to 80%. Several factors are associated with a contrast enema being unsuccessful in reducing the intussusception. These include ileo-ileocolic intussusception, longer duration of symptoms (>12 hours), dehydration, small bowel obstruction, and age greater than 2 years or less than 3 months. The intussusception being present for 24 hours or more, is no longer a contraindication for attempting contrast enema reduction. The rate of intestinal perforation with nonsurgical reduction of an intussusception is 1% to 3%. A contrast enema is contraindicated in patients who have a bowel perforation, shock, or peritonitis. Ultrasound has also been used to monitor reduction of the intussusception using saline rather than contrast under fluoroscopy. The advantage of using ultrasound is that there is no radiation exposure. This is not commonly used in the United States. Computed tomography can also identify an intussusception. This usually occurs incidentally when the patient is having a CT scan for the evaluation of abdominal pain and intussusception was not initially suspected. If the intussusception is not reduced by an enema, or if there is intestinal perforation, shock, or peritonitis present, the patient is sent for surgical reduction. An intravenous line, a nasogastric tube, and consultation with a surgeon should be considered. If the patient is dehydrated, a fluid bolus with NS or LR should be given.

If the intussusception is reduced successfully by enema, some may discharge the patient home from the emergency department after observing the patient. However, most feel that the patient should be observed in the hospital for 24 hours. The risk of recurrence is about 4%. Intussusception recurs in up to 5% to 10% of the cases reduced by contrast enema and about 1 to 5% of those reduced by surgery, though most recurrences are late recurrences (after the patient has been discharged).

Questions

1. The most common type of intussusception is:
    a. ileoileal
    b. colocolic
    c. ileocolic
    d. ileo-ileocolic

2. Contraindications for non-surgical reduction of an intussusception include all of the following except:
    a. symptoms for longer than 24 hours
    b. shock
    c. intestinal perforation
    d. peritonitis

3. Which is the most common pathological lead point found with intussusception?
    a. neoplasm
    b. appendicitis
    c. polyps
    d. intestinal duplication
    e. Meckel's diverticulum

4. A pathologic lead point can be identified in approximately what percentage of patients with intussusception?
   a. 1%
   b. 5%
   c. 10%
   d. 15%
   e. 25%

5. The "classical triad" of symptoms of intussusception include:
   a. diarrhea
   b. vomiting
   c. fever
   d. bloody stools
   e. abdominal pain

6. Which element of the "classical triad" usually appears first?
   a. diarrhea
   b. vomiting
   c. fever
   d. bloody stools
   e. abdominal pain

7. All three of the "classical triad" of symptoms is found in what percentage of patients with intussusception?
   a. 9%
   b. 21%
   c. 50%
   d. 70%
   e. 90%

8. True/False: A normal abdominal series rules-out intussusception.

9. If a mass is palpable on physical examination, it is most often found in the:
   a. right upper quadrant
   b. right lower quadrant
   c. left upper quadrant
   d. left lower quadrant

Chapter X.5. Malrotation and Volvulus
Loren G. Yamamoto, MD, MPH, MBA

A 6 year old male is brought to the ED with a chief complaint of abdominal pain and vomiting. He has vomited 15 times since the onset of illness 30 hours ago. He is complaining of diffuse abdominal pain. His mother was attempting to give him small amounts of juice at a time, but this was not succeeding. He feels weak and he looks pale. His urine output is diminished. He was completely normal prior to the onset of vomiting. He has no fever, diarrhea, dysuria or coughing. His past history is significant for two previous episodes of severe abdominal pain associated with about 3 episodes of vomiting which resolved on its own. The first episode occurred at age 3 and the second episode occurred at age 5.

Exam VS T37, HR 100, RR 30, BP 110/70. He is moderately ill appearing; pale and somewhat weak. His eyes are sunken. His oral mucosa is moist. Neck supple. Heart regular. Lungs are clear. Abdomen is soft and mildly tender all over. Bowel sounds are diminished. He has no inguinal hernias and his testes are normal. His back is non-tender. His skin turgor is diminished.

An abdominal series is obtained which shows an obvious bowel obstruction. A surgeon is consulted and at laparotomy, his entire small bowel is found to be necrotic due to a midgut volvulus. The necrotic small bowel requires resection. He is admitted to the ICU post operatively. He develops shock requiring aggressive fluid resuscitation, pressors and inotropes. He eventually survives, but he will require parenteral nutrition for the rest of his life, since he does not have enough small bowel to survive with enteral nutrition.

Malrotation of the intestine refers to an intestinal malformation in which the intestines are suspended by a stalk rather than a broad fan of peritoneum. The term "malrotation" emphasizes the embryology of the malformation. From a clinician's standpoint, it is probably best to forget this since it is merely confusing trivia of little clinical importance.

In malrotation, the intestines function normally, so the patient is entirely asymptomatic until a complication of the malrotation occurs. Malrotation should really be renamed to "guts on a stalk syndrome" because this is the clinical feature that causes the major complication of malrotation in which the peritoneal attachments suspend the intestines like a stalk rather than a broad fan. If the attachment of the intestine to the peritoneum and abdominal wall is normal, it is broad extending from the right lower quadrant, across the back of the abdominal wall toward the left upper portion of the abdomen. This broad attachment (like a rectangular flag) makes it difficult or impossible for the intestinal loops to twist and cause an obstruction. However, in malrotation, the intestines are suspended from a narrow attachment to the back of the abdominal wall, which makes the intestines highly susceptible to twisting about this stalk (guts hanging on a stalk). This is called a midgut volvulus. Once the stalk twists, there is a fair likelihood that it will untwist on its own, relieving the volvulus. However, if this fails to occur, or if it twists the wrong way to make the twist tighter, blood flow to the intestines is interrupted, and this midgut volvulus eventually results in a catastrophic bowel infarction. This is why, this syndrome should be renamed "guts on a stalk syndrome".

Note that the patient in our case example had two previous episodes of vomiting with abdominal pain which resolved on its own. These could have been episodes of "intermittent volvulus" which occurs when the volvulus just happens to twist, then untwist on its own. If the clinician is really smart, it may be possible to diagnose a malrotation just from a history or clinical pattern consistent with an intermittent volvulus. How can a malrotation be diagnosed if the patient does not have a midgut volvulus at the time? An upper GI series will show that the junction of the duodenum and jejunum are misplaced. A barium enema may identify that the cecum is not in the right lower quadrant where it should be, which is indicative of a malrotation; however, this finding is not as reliable as the upper GI series findings. An ultrasound may be able to identify a misplacement of the superior and inferior mesenteric axes coming off the descending aorta which is indicative of a malrotation, but again, this sign is not 100% diagnostic.

Malrotation may also present with a less severe form of a bowel obstruction in which the stalk of the peritoneum known as Ladd's bands, may overlie and compress the underlying bowel causing a bowel obstruction. This does not necessarily occur with a midgut volvulus which is much more serious.

Otherwise, the presentation of a malrotation is with an acute bowel obstruction caused by a midgut volvulus. This diagnosis must be made IMMEDIATELY because only prompt surgical intervention can relieve the volvulus which restores perfusion to the bowel, to prevent a catastrophic bowel infarction. The anatomy of a midgut volvulus is such that the bowel infarction that results is truly catastrophic since it often involves the entire small bowel. This results in substantial tissue necrosis and complications such as shock and sepsis. If the patient is able to survive this, parenteral nutrition is required for the remainder of his/her life since there is not enough bowel remaining for enteral nutrition.

Midgut volvulus should not be confused with sigmoid volvulus which generally occurs in adults. Sigmoid volvulus involves the large bowel and can often be decompressed by barium enema or other non-surgical procedures. In a sigmoid volvulus, the sigmoid is excessively lengthy. It has a tendency to twist upon itself resulting in a sigmoid obstruction. Abdominal radiographs demonstrate a gas distended sigmoid colon. Non-surgical reduction measures are usually successful.

This is opposed to a midgut volvulus, which occurs mostly in children with a malrotation. Approximately half the cases of malrotation will present during the neonatal period with an acute bowel obstruction. However, the other cases can present with an acute bowel obstruction at any time.

Questions

1. What are the two mechanisms of a bowel obstruction associated with malrotation?
2. Does the term "malrotation" refer to any patient condition, symptom or malformation description that is relevant for clinicians?
3. What is the most reliable imaging procedure to identify or rule out a malrotation in the absence of a midgut volvulus?
4. Name two different types of intestinal volvulus and describe how they are different.
5. Is it likely that one could have a malrotation and never have a volvulus throughout life?

Answers to questions

1. a) Ladd's bands compressing and obstructing the proximal small bowel. b) Midgut volvulus.

2. The term "malformation" originates from the embryological formation of the malrotation which is of little or no value for clinicians.

3. Upper GI series. Barium enema and ultrasound are less reliable.

4. Midgut volvulus and sigmoid volvulus. Midgut volvulus is a true surgical emergency involving nearly the entire small bowel which will infarct unless the volvulus is relieved surgically. Sigmoid volvulus, which occurs in the elderly, involves the sigmoid colon and can usually be relieved without surgical means.

5. It is unlikely, but it can happen. About half the patients with a malrotation will present in the neonatal period, with the other half presenting at any other age.

Chapter X.6. Gastroschisis and Omphalocele

Rodney B. Boychuk, MD

A newborn male infant is born to a 21 year old G2P1 mother at 36 weeks gestation via cesarean section. Appropriate antenatal care and monitoring occurred throughout the pregnancy. Prenatal ultrasonography was done at 32 weeks gestation revealing what appeared to be free intestine floating in the amniotic fluid, coming from the anterior abdominal wall. The mother elected for a cesarean section delivery after fetal lung maturation was assured (at 36 week gestation in this case scenario). The baby looks normal at birth except for matted intestinal loops coming through an anterior abdominal wall defect just to the right of the umbilical cord. The loops are very edematous and do not resemble normal intestines. Treatment in the delivery room includes evaluation of the ABCs, then the intestines are wrapped with saline soaked sterile gauze (well padded with no pressure), followed by dry sterile dressings to minimize heat loss. Placement of a nasogastric tube to decompress the stomach and warming for maintenance of a normal temperature are done next. No attempt is made to force the exteriorized intestines back into the abdominal cavity. The patient is transported to NICU where the neonatologists first take care of his medical needs, and a pediatric surgeon is consulted.

Omphalocele (OC) and gastroschisis (GS) are congenital defects of the anterior abdominal wall. They are usually associated with gut abnormalities, including abnormal rotation and fixation. Although the midgut is usually nonrotated, complications secondary to this including volvulus are infrequent, and duodenal obstruction from Ladd's bands is rare. Both these conditions (OC and GS) are obvious at birth.

An omphalocele arises at the umbilical ring as a central defect secondary to developmental arrest of layers of the abdominal wall. Embryologically different, a gastroschisis involves the base of the umbilical stalk, with the defect in the abdominal wall always occurring lateral to the base of the umbilicus, through which a portion of the intestine has escaped (usually the right side). Originally confused as a type of omphalocele, gastroschisis is now recognized as a separate entity. This defect may represent an isolated congenital defect in the abdominal wall, or be the result of closure of the celomic cavity while a portion of the intestinal tract remained trapped outside the abdomen, at the base of the umbilical cord. The intestines float freely in the amniotic fluid.

The diagnosis of both types of anterior abdominal wall defects are frequently made antenatally by ultrasound, as early as 12 weeks gestation. Diagnosis is made entirely by inspection and is readily apparent after delivery. Striking differences between the two are obvious. An omphalocele is usually covered by a translucent membrane overlying the bowel and solid viscera. Size varies from a small hernia of the cord (1 to 2 cm in diameter), to a huge mass containing essentially all the abdominal viscera. Usually, the sac remains intact, but it occasionally ruptures during delivery. The defect is always within the umbilical ring. The sac may contain bowel, stomach, and

liver. Omphaloceles are often associated with other congenital malformations and with abnormal karyotypes. Occasionally, the bowel is attached to the sac.

Alternatively, the defect of gastroschisis is lateral to the umbilicus. This has allowed the escape of the intestine into the amniotic cavity at different times in fetal development. Therefore, the appearance of the intestines are variable. Some appear edematous and matted that have been exposed to the amniotic fluid for many weeks, while other intestines are glistening and normal looking, as they "escaped" just before birth. There is no sac, and the liver does not protrude.

The immediate treatment in the delivery room is similar for both conditions. The abdomen (omphalocele) or exteriorized intestine (gastroschisis) is wrapped with saline soaked sterile gauze (well padded with no pressure), followed by dry sterile dressings to minimize heat loss. Placement of a nasogastric tube to decompress the stomach and maintenance of a normal temperature are essential. No pressure is placed on the omphalocele and there should be no attempt to reduce it. This maneuver may rupture the sac, interfere with venous return, and/or impede the infant's respiratory effort. Similarly, no attempt should be made to force the exteriorized gastroschisis intestine back into the abdominal cavity.

Although the definite treatment is surgical, delay in closure has no adverse outcome. Therefore, it is essential that optimal resuscitation occur prior to surgery. The general consensus on operative management of abdominal wall defect is to provide primary closure, if it can be achieved without hemodynamic or respiratory compromise. Patients with primary closure have better survival rates, reduced risk of sepsis and overall, a shorter hospital stay.

Although smaller omphaloceles usually undergo primary closure, giant omphalocele in the neonate is a challenging surgical emergency that requires individualized approaches to operative repair. In general, omphaloceles greater than 6 cm in diameter require silo reduction with silastic interwoven with Marlex. A silo is first created, by placing the intestines into what looks like a plastic bag turned upside down, with the edges of the bag sewn to the edges of the opening in the abdomen. This essentially creates an "artificial abdomen". The contents of the bag are squeezed daily from the top down, slowly forcing the intestines back into the abdomen. Over days to weeks the intestines are pushed back into the abdomen, and the abdominal wall is finally closed.

Interesting methods have recently been described utilizing continuous controlled pressure to achieve smooth, rapid, and safe silo reduction of an anterior abdominal wall defect. One example includes a metal tube with larger wheels at each end that is suspended by runners and counterweights, to slowly roll the silo and squeeze the contents into the abdominal cavity.

More recently a silastic spring-loaded silo (SLS) has been used routinely (in one center) for infants with gastroschisis. These surgeons found that SLS, followed by elective repair, permitted gentle, gradual reduction in the viscera. SLS was associated with lower airway pressures, earlier extubation, fewer complications, and decreased length of stay and hospital charges.

Regardless of the methods, the principles of the silo technique rely on steady pressure on the prosthesis, and a reduction in size over several days, to bring about gradual reduction of the intestines. Finally, once reduced, surgical closure can be accomplished. Irrigation with povidone-iodine (Betadine) solution or coverage with a layer of silver sulfadiazine cream (Silvadene) is effective in reducing surface contamination throughout the time for which the prosthesis is required.

Although the survival rate of patients with abdominal wall defects has gradually improved with the advances in the diagnostic and treatment modalities, the outcome is largely dependent on coexisting anomalies. Omphaloceles are often associated with abnormal karyotypes (trisomy 13, 18, and 21) or congenital malformations. In a recent review, 10 of 31 cases of omphalocele (OC) and 4 of 11 cases of gastroschisis (GS) cases, multiple congenital anomalies were diagnosed. The birth weight was below the 10th percentile in 23% of OC and 36% of GS cases. An abnormal prenatal karyotype was established in 5 of 25 OC cases versus none in the GS group. In 36 cases, an expectant obstetric management was followed, and in six OC cases, the pregnancies were terminated because of severe multiple anomalies (3 cases) or an abnormal prenatal karyotype (3 cases). The preterm delivery rate (excluding terminations) was 12 of 25 in the OC group versus 8 of 11 in the GS group. The cesarean section rate was almost identical (19% versus 18%) in both subgroups, the majority of which were performed to protect the abdominal wall defect. The overall survival rate was 39 per cent in the OC group compared to 72% in the GS group.

The surgeon must be aware of other associated defects. Congenital malrotation of the colon usually occurs in patients born with an omphalocele. Although not a serious defect, the anomaly can lead to midgut volvulus and intestinal obstruction in a baby who has previously recovered from treatment of an omphalocele, and therefore must be corrected at the time of initial surgery.

A different defect, intestinal atresia, occurs in about 10% of patients with GS. In these infants, the clinical course is one of early complete obstruction, which requires abdominal exploration if the lesion has been inadvertently overlooked at the time of initial repair of the gastroschisis. Rarely, there is a short gut from an antenatal volvulus.

Even after successful reduction of the bowel and closure of the defect, normal motor function of the gut may be delayed for weeks to months in cases of gastroschisis. Although long term outcome of these patients is generally good, they have high incidence of gastroesophageal reflux (GER) (40-50%) for which they should be closely monitored. Parenteral nutrition and intensive care have markedly improved survival.

A recent follow-up study was done involving patients post-operatively, from 1-28 years prior. Primary closure was possible in 25 omphalocele (OC) and 20 gastroschisis (GS). Eighteen children with OC and 8 with GS suffered from additional abnormalities, which were treated simultaneously. Twenty percent of the babies with OC died mostly because of severe congenital anomalies and 12.9% of GS because of infectious complications in combination with other diseases. There were fewer neonatal deaths in the last decade, attributed to better operative and perioperative treatment, as well as abortions following improved ultrasound diagnosis (as early as 12 weeks gestation).

Long-term follow-up revealed normal growth and development, except for those with severe congenital anomalies. Late surgical problems have also recently been studied. A questionnaire concerning late surgical problems was distributed to the parents of 47 surviving children. The mean follow up time was 5.4 years. There was no mention of remaining problems regarding 16 of the 28 omphalocele patients and 10 of the 16 gastroschisis patients. Postoperative abdominal wall hernia was reported in 7 OC cases and in 6 GS cases. Postoperative intestinal obstruction occurred in 4 OC cases and 1 GS case. The other complications were related to abdominal pain, cryptorchidism, constipation and difficulties with care of the intestinal stoma. All the remaining problems could be corrected and the long-term results in both conditions were good.

In summary, an omphalocele or gastroschisis are congenital defects of the anterior abdominal wall. An omphalocele arises within the umbilical ring as a central defect, while a gastroschisis involves the base of the umbilical stalk, with the defect in the abdominal wall always occurring lateral to the umbilicus. Although the diagnosis of both types are frequently made antenatally by ultrasound, if missed, they are readily apparent after delivery in the delivery room, where striking differences between the two are obvious. Although the survival rate of patients with abdominal wall defects has gradually improved, the outcome is largely dependent on coexisting anomalies.

Although surviving children without severe congenital anomalies have a good quality of life, late surgical problems are seen, and close follow-up is essential to good outcome.

Questions

1. The earliest way to diagnose an anterior abdominal wall defect is:
    a. by physical exam
    b. by history
    c. by fetal ultrasound
    d. by fetal CT scan

2. The following are correct regarding omphaloceles except:
    a. is usually covered by a translucent membrane
    b. is frequently associated with other congenital malformations
    c. is lateral to the umbilical stump
    d. is within the umbilical ring

3. The following are true about gastroschisis:
    a. occurs lateral to the umbilical stump
    b. can be diagnosed antenatally
    c. at birth often have edematous matted intestinal loops
    d. all of the above

4. Treatment of abdominal wall defects includes:
    a. immediate surgical repair
    b. pushing the intestines back into the abdominal cavity while still in the delivery room
    c. provide immediate optimal resuscitation and stabilization first, and then surgery
    d. always do primary closure in both lesions

5. The true statement below is:
    a. The surgeon does not need to worry about other associated defects as the neonatologist will already have treated them.
    b. There are essentially no late surgical problems after repair.
    c. Improved ultrasound diagnosis has resulted in some women seeking termination of pregnancy as early as 12 weeks gestation.
    d. The long term outcome of survivors reveal poor growth and development.

Chapter X.7. Diaphragmatic Hernia
Rodney B. Boychuk, MD

A newborn male infant is born to a 23 year old G2P1 mother at 39 weeks gestation via NSVD (normal spontaneous vaginal delivery). Appropriate antenatal care and monitoring occurred throughout the pregnancy. As there were no significant antenatal problems, no prenatal ultrasonography was done. Immediately following delivery, the baby looks "normal". He cries immediately, however, at 1 minute of age, he remains very cyanotic. The neonatal resuscitation team is called to the delivery room. At 5 minutes of age, the baby remains very cyanotic, tachypneic and dyspneic, despite 100% oxygen via mask. The resuscitation team starts bag-mask positive pressure ventilation with 100% oxygen, but the baby becomes bradycardic, therefore he is intubated and ventilated. Auscultation of the lungs reveal good breath sounds in the right chest, but no breath sounds in the left. The heart sounds seemed loudest in the right chest, and the abdomen appears scaphoid. Ventilation is continued through the endotracheal tube, while an NG tube is inserted and suction is applied. A STAT chest x-ray is done, which reveals bowel (and the NG tube tip) in the left chest cavity. The baby is transferred to the NICU. This is a case of congenital diaphragmatic hernia presenting in the delivery room.

Although congenital diaphragmatic hernia (CDH) is rare (approximately 1 in 3000 births) it is associated with high mortality, morbidity, cost and suffering. Embryologically, by the end of the 12th week of gestation, fetal bowel has returned to the abdominal cavity and the formation of the diaphragm is complete, separating the intrathoracic from the intra-abdominal contents. Failure of this to occur results in a persistent pleuroperitoneal canal (foramen of Bochdalek), which allows the intra-abdominal viscera to occupy the chest cavity. This in turn prevents the lungs from developing, resulting in lung hypoplasia, worse on the side of the hernia. Although in the case above the diagnosis was not made until after delivery, with increasing use of fetal sonography, the diagnosis is commonly made prenatally, often as early as 15 weeks gestation. Unfortunately, more than 40% have associated anomalies of their brain, heart or other regions resulting in a poorer prognosis.

Classically, if undiagnosed prenatally, these infants present as a "neonatal emergency" in the delivery room. They do not respond to the typical steps of neonatal resuscitation, and usually get worse with bag-mask ventilation (BMV). With left sided CDH, breath sounds are diminished or absent in the left chest and because the mediastinum is displaced to the opposite side, the heart sounds are heard louder in the right chest. As the stomach and bowel fill with gas, (made worse by BMV), respiration and cardiac action are further compromised, and hypoxia and respiratory acidosis worsens. The neonate exhibits progressive respiratory distress, cyanosis and ultimately bradycardia. Because the abdominal contents are displaced into the chest, the abdomen often is scaphoid. Cases have been reported in which the infants remain relatively asymptomatic in the early hours and days of life. Rarely, a diaphragmatic hernia presents in an older child, as an incidental finding on physical exam or chest x-ray, or may be "acquired" as a result of traumatic rupture of the diaphragm secondary to a severe blow to the abdomen.

From the practical standpoint, 90% of congenital diaphragmatic hernias (CDH) occur on the left side. If the diagnosis is suspected clinically (but not yet confirmed), never bag-ventilate the infant. Rather, intubate, and apply "gentle" positive pressure ventilation. Secondly, pass a nasogastric catheter and apply intermittent suction to decompress the stomach (occupying the thorax and acting similar to a tension pneumothorax). These two measures alone may result in considerable clinical improvement. An emergency chest x-ray is mandatory to confirm the diagnosis. On x-ray, the air-filled bowel is seen occupying the left hemithorax, with resultant displacement of the mediastinum to the right. However, CDH has been misdiagnosed as a left tension pneumothorax, with acute respiratory distress temporarily relieved by needle aspiration. This x-ray finding of a "hyperlucent hemithorax" due to intrathoracic gastric dilatation alone is a unusual presentation of CDH in neonatal period, but can lead to a delayed diagnosis. Always look at the abdomen on x-ray, as absence of the stomach bubble in the left upper quadrant of the abdomen is an important radiologic clue to make the diagnosis.

The differential diagnosis must also include any neonatal emergency that presents with respiratory failure within minutes of birth. The clinical and radiological presentations are variable, making the diagnosis of a right-sided diaphragmatic hernia even more difficult. Careful evaluation of the clinical presentation, ultrasonography and chest films are mandatory for precise diagnosis. The liver partially blocks the pleuroperitoneal canal and limits the amount of bowel that can herniate into the chest. Symptoms in infants with right-sided hernias may be less severe, but the management is the same.

As with any form of ventilation, positive pressure can result in a pneumothorax on the contralateral side, which must be carefully observed for. If unrecognized, this can be a disastrous complication, resulting in death.

The infant born with congenital diaphragmatic hernia (CDH) remains one of the most complex patients to manage. Pulmonary hypoplasia and immaturity of the lungs remain the leading cause of death, from pulmonary hypertension (right-to-left shunting) with resultant hypoxemia. Over the last decade, there has been a constant improvement in the understanding of the pathophysiology of CDH and its management. Based on the knowledge that CDH is more of a physiological disease than a surgical disease, management strategy has shifted from immediate repair to delayed repair preceded by stabilization. However, the ideal treatment remains elusive. The old management strategy of immediate surgery is now replaced by the principle of physiologic stabilization and delayed surgery. Conventional ventilatory techniques, with high pressures and hyperventilation used to reverse ductal shunting and cause alkalinization, are now being replaced with ventilatory techniques utilizing the concepts of permissive hypercapnia and high frequency oscillation ventilation. The complications of ventilation including air leaks, barotrauma and consequent bronchopulmonary dysplasia are at least in part circumvented because of these newer techniques. Regardless of the treatment, the goal is to reverse the persistent pulmonary hypertension causing right to left shunting through the ductus arteriosus and foramen ovale.

Another recent development is the use of inhaled nitric oxide. Endogenous nitric oxide is an important modulator of vascular tone in the pulmonary circulation. Initial studies indicated that inhalation of nitric oxide results in a reduction in pulmonary hypertension, with improvement in oxygenation but no change in the systemic vascular resistance. However, no such beneficial effect has as yet been consistently reported in infants with congenital diaphragmatic hernia. Inhaled nitric oxide has side effects, although those due to nitrogen dioxide and methemoglobin formation can be minimized by using the smallest effective nitric oxide dose, continuous nitric oxide and nitrogen dioxide monitoring and frequent methemoglobin analyses. Longer term follow-up studies are needed to determine the true risk:benefit ratio of inhaled nitric oxide treatment in newborns with CDH.

Extracorporeal membrane oxygenation (ECMO) has been shown to salvage some of the most severely affected neonates. As some infants do not improve despite aggressive therapy, some centers use ECMO before hernia repair to stabilize these critically ill infants. Venovenous or venoarterial bypass is used, depending on the infant's hemodynamic stability. Bypass is continued until the pulmonary hypertension is reversed and lung function is improved, usually between 7 and 10 days of age. Approximately 60% of infants with CDH

who are supported by ECMO survive. Despite this aggressive therapy, there are newborns with such severe pulmonary hypoplasia that all forms of life support are futile.

Other advanced and experimental respiratory therapies merit investigation. Further insights into the pathophysiology of CDH and the introduction of less invasive therapeutic techniques such as high frequency oscillation ventilation, inhalation nitric oxide, surfactant, and perfluorocarbon liquid ventilation may make the need for ECMO redundant.

Once medically stable, the definite treatment is surgical. The surgeon reduces the hernia gently by withdrawing the viscera from the chest. There may be enough diaphragmatic tissue to complete a direct suture repair. However, if a large portion of the diaphragm is missing, prosthetic material must be used to repair the defect. A chest tube is usually placed in the left hemithorax and brought out through an intercostal space. As the abdominal contents have been in the thorax for most of fetal development, the abdomen often does not have enough room for the "missing" contents. Forcing the contents into the abdomen will compress the vena cava and compromise respirations by pushing up on the diaphragm. The surgeon may be forced to omit total anatomic closure of the abdominal wall, and utilize skin flaps with only the skin being closed. An alternative is to create a silastic silo like those used for gastroschisis or a large omphalocele (see Gastroschisis and Omphalocele chapter). The pouch created accommodates the intra-abdominal organs, and diaphragmatic action and venous return are unimpeded. The final repair is completed after the infant has been weaned off the ventilator and is clinically stable.

Fetal surgery for congenital diaphragmatic hernia and other fetal conditions has been considered. However, at this time, open fetal surgery has proven too invasive to be justified for the treatment of diaphragmatic hernia, and progress in postnatal therapy (including ECMO) has dramatically improved the neonatal outcome in all but the most severely affected infants.

The outcome of congenital diaphragmatic hernia differs depending on the stage of the fetus or infant's life (i.e., antenatal, immediate postnatal, and postoperative). A review of the available literature on the outcome of CDH from 1985 to March 1998 (35 studies) revealed the median overall mortality was 58% for babies diagnosed in utero, 48% if born alive, and 33% postoperatively (lower mortality in this group that was stable enough to reach surgery). Although one may expect a poorer outcome with earlier intrauterine diagnosis, ultrasound, diagnosis before 25 weeks of gestation was not found to be a uniformly bad prognostic indicator (median mortality, 60%). However, outcome was worse for those fetuses with other congenital anomalies (median mortality, 93%). ECMO appears to improve survival. The median percentage mortality for all infants born alive and treated in ECMO centers was 34%, while the median percentage mortality for all ECMO-treated infants was 44%.

Unfortunately, surviving the initial repair doesn't assure future well being. Survivors of CDH usually have persistent pulmonary and nonpulmonary problems to deal with. Many of these patients require bronchodilators, oxygen, diuretics, and corticosteroids for obstructive airway disease and bronchopulmonary dysplasia. They are at high risk from respiratory syncytial virus (RSV) and should receive RSV immunoprophylaxis. Pulmonary problems continue to be the major source of morbidity for survivors of CDH long after discharge. Although the need for ECMO and the presence of a patch repair are both predictive of more significant morbidity, non-ECMO CDH survivors also require frequent attention to pulmonary issues beyond the neonatal period. There is a need for long-term follow-up of CDH patients preferably with a multidisciplinary team approach. Hopefully, future developments in medical therapy will continue to decrease the mortality and morbidity of patients with CDH.

In summary, if not diagnosed antenatally by sonography, CDH presents as a neonatal emergency in the delivery room, with a normal appearing infant not responding to resuscitation. Endotracheal intubation with gentle ventilation, followed by nasogastric suctioning is immediately indicated. Pulmonary hypoplasia and pulmonary hypertension with right-to-left shunting are common with resultant hypoxemia. The old management strategy of immediate surgery is now replaced by the principle of physiologic stabilization and delayed surgery. Other advanced and experimental respiratory therapies merit investigation. Further insights into the pathophysiology of CDH and the introduction of less invasive therapeutic techniques such as high frequency oscillation ventilation, inhalation nitric oxide, surfactant, and perfluorocarbon liquid ventilation may replace the need for ECMO. However, the ideal treatment remains elusive

Questions

1. The earliest way to diagnose a diaphragmatic hernia is:
    a. by physical exam
    b. by history
    c. by fetal ultrasound
    d. by fetal CT scan

2. The following are correct regarding diaphragmatic hernia except:
    a. is usually on the left side
    b. is frequently associated with hypoplastic lungs
    c. can present similar to a tension pneumothorax
    d. is frequently asymptomatic at birth

3. The following are true about diaphragmatic hernias:
    a. often have scaphoid abdomen on exam
    b. can be diagnosed antenatally by ultrasound
    c. at birth often have persistent cyanosis and respiratory distress
    d. all of the above

4. Treatment of diaphragmatic hernia includes:
    a. immediate surgical repair
    b. pulling the intestines back into the abdominal cavity while still in the delivery room
    c. provide immediate optimal resuscitation and stabilization first, and then surgery
    d. always do primary closure of the diaphragm

5. The true statement below is:
   a. The surgeon does not need to worry about medical problems as the neonatologist will already have treated them.
   b. There are essentially no medical problems after surgical repair.
   c. Improved ultrasound diagnosis has resulted in some women seeking termination of pregnancy.
   d. The long term outcome of survivors reveals no significant chronic pulmonary problems.

Chapter X.8. Pyloric Stenosis
Kevin H. Higashigawa, MD

This is a 3 week old male infant who presents to the emergency department with a chief complaint of vomiting x 3-4 days. His mother states that the vomiting has gotten progressively worse and now seems to "shoot out of his mouth." The emesis always occurs after feeding, sometimes vomiting the entire volume of his feed. The vomitus is non-bilious and non-bloody. After vomiting, the infant remains hungry and is still eager to feed. He is exclusively bottle fed with formula. There is no history of fever, URI symptoms, or diarrhea. He is less active than normal. He is making fewer wet diapers and less stool than usual. There is no history of trauma or recent travel. There are no ill contacts.

Exam: VS T 37.0, P 170, R 50, BP 80/50, O2 saturation 99% on RA. Length is 54 cm (50th percentile) and weight is 3.6 kg (25th percentile; previously 50th) and head circumference is 37 cm (50th). He is a well-developed, well-nourished male in no distress. His skin is normal. HEENT exam is normal. His neck is supple. Heart auscultation reveals tachycardia and a regular rhythm. Lungs are clear. His abdomen is slightly distended with active bowel sounds. No hepatosplenomegaly is noted. Attempting to palpate an olive mass is inconclusive. He has no inguinal hernias. Genitalia are normal. Extremities are normal. Color, perfusion, and capillary refill are good. Neurologic examination is normal.

CBC is unremarkable. Electrolytes: Na 131, K 3.2, Cl 95, bicarb 30. An IV fluid infusion is started. An abdominal series shows no obstruction, but the stomach is dilated. An ultrasound study confirms the diagnosis of pyloric stenosis. The patient undergoes a pyloromyotomy and recovers without complications.

Hypertrophic pyloric stenosis (HPS) is a common cause of GI obstruction in the young infant. HPS occurs in approximately 3 of every 1000 live births in the United States (1). Males are four times more likely to develop HPS than females. A familial pattern exists, although HPS does not follow classic Mendelian genetics. The risk for developing HPS is about 7% if the father was previously affected and about 10-20% if the mother was affected (1,2).

The manifestations of GI obstruction do not typically occur until about the 2nd to the 6th week of life (1). HPS presents after several weeks of life because the pylorus is normal at birth and hypertrophies as time progresses (2). The hallmark of gastric outlet obstruction is non-bilious vomiting. The vomiting occurs immediately after feeding and varies in intensity, depending upon the degree of stenosis present. Eventually, the vomiting increases in severity to become projectile and will typically involve the entire volume of the feed. Asking parents if the emesis is "projectile" is not very useful since, in the eyes of parents, ALL vomit "projects". Thus, a more discriminating question to ask, is to stand an arm's length from a wall and ask them if the emesis will hit the wall from that distance. If the answer is "yes", then it is projectile vomiting. After regurgitation, the infant will remain hungry and want to feed again. Approximately 8% of patients will have some degree of hematemesis related to gastritis or esophagitis (3).

The exact etiology of HPS is unclear. One theory proposes the lack of pyloric inhibitory innervation leading to reduced levels of nitric oxide, a smooth muscle relaxant. As a result, the pylorus experiences unopposed contraction following muscarinic stimulation (4). Elevated levels of prostaglandins have also been implicated owing to the increased incidence of pyloric stenosis in infants who have received PGE to maintain a patent ductus arteriosus. HPS has also been associated with other GI anomalies, such as tracheoesophageal fistula, pyloric atresia, antral webs, gastric duplications, and gastric volvulus. Furthermore, HPS has been linked to other disease states, such as eosinophilic gastroenteritis, epidermolysis bullosa, trisomy 18, and Turner Syndrome (1).

On physical exam, the infant may exhibit poor weight gain or even weight loss. Marasmus, however, or severe protein-calorie malnutrition, is rarely seen today. Jaundice may be seen in approximately 5% of infants (1). After feeding, a wave of gastric peristalsis may be seen traversing the abdomen from left to right, representing intense contractions against an obstruction. Abdominal distention may be a late finding, as is usually the case with proximal GI obstructions. The hypertrophied pylorus may be palpable. The pylorus is firm, mobile, and olive-shaped. It is located in the right upper quadrant of the abdomen, beneath the liver edge (1). It is best palpated from the left side while the infant is feeding since the abdominal muscles are relaxed. A palpable "olive" is pathognomonic of HPS (2), but it is very hard to feel in practice (requires experience to appreciate this accurately).

The diagnostic test of choice is the ultrasound, which has approximately 90% sensitivity (1). Criteria for diagnosis include an elongated pyloric channel (longer than 16 mm), an enlarged pyloric diameter (greater than 14 mm), and a thickened muscle wall (greater than 3.5 mm) (3). If an ultrasound is non-diagnostic but clinical suspicion remains high, an upper GI series may be helpful. Characteristic signs of HPS include an elongated pyloric channel with a "shoulder sign" (representing the hypertrophied pylorus bulging into the antrum) and streaks of barium flowing through the stenosed channel, producing either a single "string sign" or a "double track sign" (if there are parallel streaks) (1).

The "classic" laboratory finding in HPS is a hypochloremic, hypokalemic metabolic alkalosis. Repeated vomiting results in a loss of HCl, causing the hypochloremic metabolic alkalosis. The patient is likely dehydrated from repeated GI loss and poor oral intake. A metabolic acidosis (lactic acidosis) may result with severe dehydration. Due to more expedient diagnosis and treatment, however, more than 90% of patients with HPS do not typically present with any metabolic disturbance (5). Levels of glucuronyltransferase can be decreased in a small percentage of infants, as the liver is deprived of substrate from poor caloric intake, leading to an indirect hyperbilirubinemia (2).

The differential diagnosis of HPS is extensive. Vomiting in infants under 1 month of age is more likely due to a serious cause (often one requiring surgical intervention). Vomiting in older infants is more often secondary to gastroenteritis, but serious etiologies occur which may be difficult to diagnose.

Management of HPS initially consists of fluid replacement and management of electrolyte abnormalities to stabilize the patient. In the 1960s, HPS was treated medically with oral atropine, and surgery was reserved for sicker infants (4). However, due to the improvements in surgical technique and associated lower mortality and morbidity rates, as well as the rapidity of the resolution of symptoms, pyloromyotomy is now the treatment of choice. Currently, the mortality rate for pyloromyotomy is between 0 and 0.5% and can now be performed laparoscopically (1). HPS is not a surgical emergency. The infant should be fluid resuscitated prior to surgery and the patient's alkalosis should be resolved (bicarbonate level < 30 mEq/dL) to minimize anesthetic risk (3). Post-operative vomiting may occur secondary to edema of the pylorus at the incision site. In cases of incomplete pyloromyotomy, endoscopic balloon dilation has been successful. Of interest is that other countries may not treat HPS routinely with surgery, but rather IV fluid maintenance until the condition resolves with time in most instances. Pyloromyotomy is reserved for those infants who fail to improve.

Questions

1. What is the "classic" presentation of HPS?

2. How is HPS diagnosed?

3. What is the "classic" laboratory finding in HPS?

4. What is the initial step in management?

5. Which of the following sets of electrolytes could be seen with HPS (Na, K, Cl, bicarb):
   a. 130, 2.7, 90, 28
   b. 130, 5.8, 94, 22
   c. 130, 3.9, 98, 17
   d. 148, 4.1, 108, 13

Answers to questions

1. A 3 to 4 week old male infant who presents with progressively severe, non-bilious vomiting, which may be projectile. The vomiting occurs immediately after feeding, after which the infant is still hungry and wants to feed again. On physical exam, the infant may display signs of dehydration. Visible waves of peristalsis may be seen and an "olive" may be palpable.

2. A palpable "olive" is pathognomonic but is very difficult to determine with certainty. If the pylorus cannot be palpated, ultrasound is diagnostic with 90% sensitivity.

3. The "classic" laboratory finding is a hypochloremic, hypokalemic metabolic alkalosis. However, due to more expedient diagnosis, this metabolic abnormality is seen in less than 10% of patients.

4. The initial step in management involves fluid resuscitation and correction of any metabolic abnormalities. HPS is not a surgical emergency, and any fluid deficits or alkalosis should be corrected prior to surgery to decrease surgical/anesthetic risks.

5. Electrolyte patterns are not pathognomonic for pyloric stenosis. The correct answers are a and c. Pattern "a" is a classic early vomiting picture, often seen with HPS. Pattern "c" is a picture of vomiting resulting in dehydration and lactic acidosis. This can also be seen later in the clinical course of HPS as dehydration worsens. Pattern "b" is typical of adrenal crisis (low Na, high K). Pattern "d" is typical of hypernatremic dehydration.

Chapter X.9. Intestinal Atresias, Duplications and Microcolon
Timur M. Roytman

This is a newborn infant male born to a 25 year old G1P1A0 mother at 36 weeks gestation via vaginal delivery. Mother received appropriate antenatal care throughout her pregnancy. The pregnancy was remarkable for polyhydramnios. The baby looked normal at birth, however, at 1 day of age (day 2 of life), the infant begins to vomit bilious material and appears jaundiced. Physical exam of the infant is remarkable only for jaundice. A pertinent negative finding is the absence of a distended abdomen.

A plain abdominal radiograph reveals a "double-bubble sign." His symptoms along with the radiographic findings are suggestive of duodenal atresia. Initial treatment consists of insertion of a nasogastric tube along with IV fluid replacement. An echocardiogram and radiographic studies of the spine are performed to evaluate for other congenital abnormalities. No other abnormalities are found and the patient is referred to surgery for surgical evaluation and treatment.

Atresia, by definition, is the absence of an opening of a hollow visceral organ, resulting in a complete obstruction (1). There are several types of atresias: esophageal atresia with and without tracheoesophageal fistula, duodenal atresia, jejunal atresia and ileal atresia.

Esophageal Atresia

Esophageal atresia (EA) occurs in 1/3,000-4,500 live births. Approximately one third of infants with esophageal atresia are born prematurely (2). EA occurs as a result of the failure of the primitive foregut to recanalize (3). An overwhelming majority of EAs are accompanied by a fistula between the trachea and the distal esophagus. These tracheoesophageal fistulas (TEF) occur due to the failure of the lung bud to separate from the foregut (3). An EA with a TEF can be distinguished from an EA without a TEF by the presence of a gas in bowel. EA without TEF does not permit any passage of gas into the bowel, but a TEF permits a pathway from the trachea to the distal esophagus and the stomach.

In rare instances, infants have a tracheoesophageal fistula without an esophageal atresia. This is known as an H-type TEF (the connection between the esophagus and trachea looks like an H). It usually presents with recurrent coughing along with aspiration pneumonia. H-type TEF is commonly diagnosed in childhood or sometimes adulthood by esophageal instillation of methylene blue followed by bronchoscopy to look for dye entering the trachea. Once identified, H-type TEFs require surgical correction.

Esophageal atresias should be suspected if any one of the following is present: maternal polyhydramnios (from inability of the fetus to swallow and absorb amniotic fluid); excessive oral secretions in the newborn; cyanosis, choking, regurgitation or coughing occurring with the first feeding. If suspected, the diagnosis of an esophageal atresia can be confirmed by inability to pass the nasogastric tube into the stomach and by a chest radiograph, which shows the coiling of the tube in the proximal esophageal pouch. Injection of 1mL of contrast into the obstructed esophageal segment can also assist with the diagnosis (3).

One half of infants with esophageal atresia have other associated abnormalities. For example, the VACTER association includes vertebral defects, anal atresia, cardiac anomalies, tracheoesophageal fistula with esophageal atresia, radial upper limb hypoplasia and renal defects (2).

Newborns with EA are at risk for pulmonary aspiration, so nasogastric (actually nasoesophageal) suctioning of the esophageal pouch should be implemented once the diagnosis is confirmed. Also, patients should be placed in the prone position to minimize the flow of gastric contents into the lungs (stomach to distal esophagus through the TEF into the lungs). Postoperatively, an esophagogram should be performed before feeding is resumed to determine the integrity of the anastomosis of the two ends of the esophagus. Prognosis is determined by the extent of pulmonary aspiration. Patients with EA commonly have structural malformations of the trachea such as degeneration of elastic, cartilage and connective tissue of the trachea (tracheomalacia). However, tracheal development is normal if the EA presents in the absence of a fistula. Other complications of the disease are failure to thrive, slow feeding, esophageal stenosis, recurrent aspiration pneumonia, reactive airway disease, severe gastroesophageal reflux, coughing and choking (2).

Intestinal Atresias

Intestinal atresias (duodenal, jejunal and ileal) are common and account for approximately one third of all cases of neonatal intestinal obstruction, but colonic atresias are rare. Distribution of atresias within the small intestine is as follows: 50% in the duodenum, 36% in the jejunum and 14% in the ileum. Other congenital abnormalities are more common with duodenal and jejunal atresias as compared to ileal atresia. Atresias affect males and females equally (3).

Duodenal atresia is similar to esophageal atresia in that it also results from a failure of recanalization. In the case of duodenal atresia, the failure occurs after the solid phase of intestinal development during week 4 and 5 of gestation. It may also be caused by local ischemia and may have a genetic component. Duodenal atresia occurs in 1/10,000 live births. Approximately 50% of infants with duodenal atresia are born prematurely (4). Duodenal atresias occur most frequently distal to the ampulla of Vater (3). There are three types of duodenal atresia: Type I is a mucosal web with normal muscular wall. Type II describes a short, fibrous cord that connects two ends of the atretic duodenum. Type III represents complete separation of the atretic ends. Type I is the most common and type III is the least common (5). Other conditions are associated with duodenal atresia: Down syndrome, malrotation, esophageal atresia, annular pancreas, renal anomalies, congenital heart disease and imperforate anus. Bilious vomiting without abdominal distention on the first day of life is the hallmark of duodenal atresia. Other manifestations include polyhydramnios which is present in 50% of cases, jaundice and intolerance to feeding. Radiographically, duodenal atresia is suggested by the presence of the "double-bubble sign" which results from accumulation of gas in the stomach and proximal duodenum. Because of the atresia, bowel gas does not enter the remainder of the bowel until after the first day of life. Duodenal atresia can be diagnosed prenatally by fetal ultrasonography. Initial treatment consists of nasogastric or orogastric decompression in conjunction with IV fluid replacement to correct fluid and electrolyte derangements. Prior to surgical correction of duodenal atresia, an evaluation for associated life-threatening congenital abnormalities should be performed. Duodenal atresia is usually repaired by duodenoduodenostomy which bypasses the obstruction. Long term prognosis is determined by the patient's associated congenital abnormalities (5).

Unlike esophageal and duodenal atresias, jejunal and ileal atresias are not caused by failure to recanalize the intestinal lumen. Instead it is thought that their etiology is an intrauterine ischemic event of the bowel such as intussusception, volvulus, malrotation, arterial occlusion, internal hernia or strangulation due to an abdominal wall defect such as an omphalocele or in gastroschisis (5). This may result in a focal infarction resulting in an atretic portion of bowel. These atresias are also associated with meconium ileus which occurs in

newborns with cystic fibrosis. Similarly to other atresias, a quarter of patients with jejunoileal atresia have a history of polyhydramnios (4).

Jejunal atresias are more common than ileal atresias (5). Isolated jejunal atresia has a higher prevalence in twins and infants with low birth weight. Also, patients with isolated jejunal atresia are more likely to have other unrelated congenital abnormalities (3). There are four different types of jejunal and ileal atresias. Type I is mucosal obstruction that is caused by an epithelial intraluminal membrane, but the proximal and distal ends of the bowel are intact. In type I, which accounts for 20% of jejunal and ileal atresias, the bowel wall and the mesentery of the intraluminal membrane are both intact. Type II is characterized by the connection of the blind ends of the bowel by a fibrous cord and constitutes 35% of intestinal atresias. Type III is subdivided into Type IIIa and IIIb. In type IIIa, the blind ends of the bowel are completely separated by a mesenteric defect that is V-shaped. It accounts for 35% of all atresias. Type IIIb, also known as "apple peel" or "Christmas tree" deformity, describes a loss of the normal blood supply to the distal bowel and is associated with a significant mesenteric defect. It appears that there is a genetic predisposition to Type IIIb (3,5). Type IV comprises 5% of all bowel atresias and is characterized by multiple bowel atresias which resemble a string of sausages (4,5).

Jejunoileal atresia can be diagnosed by prenatal ultrasound. The majority of newborns with jejunoileal atresia exhibit clinical symptoms during the first day of life. Symptoms are characterized by abdominal distention, bilious emesis or bilious gastric aspirate. Other symptoms include jaundice and failure to pass meconium. However, the passage of meconium does not rule out intestinal atresia because a third of infants with jejunoileal atresia will pass meconium prior to development of obstructive symptoms (3). Air-fluid levels or peritoneal calcifications may be seen on plain abdominal radiographs. In the differential of jejunoileal atresia are: Hirschsprung's disease, meconium ileus and meconium plug. These diseases can be distinguished from jejunoileal atresia by contrast studies of the upper and lower bowel which will pinpoint the level of obstruction (4). Definitive treatment requires resection of the atretic portion of the bowel with an end-to-end anastomosis. Postoperatively, nutritional support is provided by parenteral hyperalimentation until bowel function is restored (5). Prognosis is determined by the length and function of the remaining bowel. Long-term complications include malabsorption, feeding intolerance and bacterial overgrowth (3). Multiple atretic segments may result in a short gut syndrome with insufficient or marginal total bowel nutrition absorptive capacity.

Intestinal Duplications

Intestinal duplications are rare congenital abnormalities that consist of tubular or spherical structures with gastrointestinal epithelium. These structures are attached to the intestine and are located on the mesenteric border. The lumen of the normal intestine usually is not continuous with that of the duplication. Usually the duplication and the normal intestine share vascular supply and a fraction of the muscular layer. There are three categories of intestinal duplications. The first category is localized duplications. These duplications are most common in the jejunum and the ileum, although they may occur in other areas of the GI tract. Localized duplications are usually tubular or cystic. Their exact etiology is unknown, although it is thought that defects in the recanalization of the intestinal lumen after the solid stage of embryologic development, may contribute to the development of these duplications. The second category is duplications that are associated with spinal cord or vertebral abnormalities such as hemivertebra or anterior spina bifida. A possible cause of these duplications may be the separation of the notochord during embryologic development. The last category is duplication of the colon. This duplication is commonly associated with abnormalities of the genitals or the urinary tract. In general, duplications tend to be symptomatic and present during the first year of life as a palpable mass or they may cause intestinal obstruction, volvulus or intussusception. Other symptoms include vomiting, abdominal pain, constipation, diarrhea and acute GI hemorrhage. Duplications may be diagnosed with ultrasound, MRI or CT of the abdomen. Undiagnosed intestinal duplications may undergo malignant transformation. Definitive treatment includes complete resection of the duplication with an end-to-end anastomosis (3,7).

Microcolon

Microcolon is a rare congenital cause of intestinal obstruction. The microcolon generally results from intrauterine underutilization of the colon, which would include conditions in which intestinal contents are not passed into the colon during gestation. This would include ileal atresia, but this would not include duodenal atresia, because duodenal atresia is in the proximal small bowel, such that the middle and distal small bowel continue to shed epithelial tissue (meconium precursors) distally into the colon during gestation. Microcolon is also part of a megacystis-microcolon-intestinal hypoperistalsis syndrome (MMIHS). MMIHS is a genetic disorder with an autosomal recessive pattern of inheritance. This syndrome affects primarily female infants. Infants with MMIHS present with bilious vomiting, delayed passage of meconium and abdominal distention. Dilation of the bladder and the small bowel causes abdominal distention. Physical exam reveals thin musculature of the anterior abdominal wall. Diagnosis is confirmed by ultrasound, upper GI contrast study and an enema which shows a nonobstructed microcolon (7,8). This syndrome is usually lethal within the first year of life (9).

Questions

1. The double-bubble sign on plain abdominal radiograph is diagnostic of what kind of atresia?
2. How could you distinguish between an esophageal atresia with tracheoesophageal fistula (TE) from an esophageal atresia without TE fistula?
3. What other abnormalities are associated with an esophageal atresia?
4. How does an esophageal or duodenal atresia differ etiologically from a jejunal or an ileal atresia?
5. What makes undiagnosed intestinal duplication potentially life threatening?

Answers to questions

1. Duodenal atresia.
2. Esophageal atresia with tracheoesophageal fistula results in a gas within the bowel, esophageal atresia without tracheoesophageal fistula does not.
3. VACTER association; includes vertebral defects, anal atresia, congenital cardiac anomalies, tracheoesophageal fistula with esophageal atresia, radial upper limb hypoplasia and renal defects.
4. Esophageal or duodenal atresias result from failure of the lumen to recanalize. A jejunal or ileal atresia results from an intrauterine ischemic event.
5. Undiagnosed intestinal duplications may cause a bowel obstruction or may undergo malignant transformations in adults.

Chapter X.10. Craniofacial Malformations

Robert L. Peterson, MD

This is a newborn infant male born to a 29 year old G6 P4 A1 mother at 38 weeks gestational age via vaginal delivery with Apgar scores of 8 and 9 at 1 and 5 minutes, who is noted to have complete left cleft lip and palate.

Exam: He is alert and active in no distress. His head shape is normal with a flat anterior fontanelle. There is clefting of the left upper lip, extending across the alveolar ridge and all the way back into the palate. The uvula is cleft (bifid). His eyes and ears are normal. His neck, heart, lungs, abdomen and extremities are normal.

This infant has some difficulties in feeding initially, which resolve upon use of a cleft palate nipple. Weight gain is a bit slow over the first few weeks of life, but it then improves, following the growth chart.

Clefting of the lip and palate is caused by incomplete fusion of the lateral elements in utero. Normally, during embryogenesis, there is migration of the elements from the side to join in the midline. When this process is interrupted, a cleft results. Pressure from the tongue pushes the palatal shelves up into the nose, moving them away from each other, making the palatal cleft wider. Loss of the muscle activity from the lip (because it does not form a complete band) allows the anterior portion of the palate to drift sideways and open the lip cleft. The cleft in the lip can vary in width from a small notch to a complete division all the way into the nose. In a complete cleft, the lip is completely split into two parts, with a resulting division under the nasal opening on one or both sides. In an incomplete cleft, there will still be some lip tissue under the nasal opening; this is known as the nostril sill. Clefts can be unilateral or bilateral. Isolated clefting of the lip does not cause much functional problem, but makes social adaptation of the baby more difficult.

Clefting of the palate also varies in degree. The most mild form involves clefting of the uvula. This can be associated with "submucous" clefting of the soft palate, where there is failure of fusion of the palatal musculature in the midline. Most infants with this aberrant muscle anatomy learn to compensate. Speech develops normally and the clefting goes undetected. When speech is abnormal, the diagnosis is made by observing a lack of fullness in the central soft palate. It looks thinner and paler in the anterior-posterior direction (the "translucent midline raphe"), and gentle pressure with a cotton tipped applicator will confirm that there is only thin mucosal tissue.

Cleft lip and palate is a relatively straightforward diagnosis to make. Usually it is an isolated condition, but, like all congenital defects, it may be associated with other abnormalities due to environmental factors, intrauterine events or genetic syndromes. The most important of these is Pierre Robin sequence (the new name is "sequence" instead of syndrome because all of the associated anomalies can be explained as consequences of the initial event which is a hypoplastic mandible), where poor development of the mandible (micrognathia) leads to a lack of room for the tongue to fit in the mouth. The tongue, then pushes up the palate, and prevents fusion of the two palatal shelves. The child has trouble breathing due to the small oropharynx, and treatment requires early intervention to keep the tongue from obstructing the airway. Other syndromes associated with cleft lip/palate include Treacher-Collins syndrome, and other syndromes of genetic inheritance of the cleft. These are important for genetic counseling of the child and family.

The goals of management are to achieve normal appearance and normal function. The most important functional goal is to achieve normal speech. Timing here is very important, because there is a window for speech development from about 6 months to about 30 months of age. Normal speech cannot develop if the cleft palate is not repaired, because air from the mouth escapes through the nose and prevents normal sound development. Earlier repair of the cleft palate permits better development of normal speech. If repair is delayed, the child will develop speech habits (compensatory articulations) that will have to be "unlearned" later.

The goals of cleft lip repair are: to get a normal looking lip and to restore the continuity of the lip musculature. This is especially important when the cleft is bilateral. In bilateral clefts, the central portion of the lip (prolabium or premaxillary segment) is not attached to the lateral portion of the lip on either side. Thus, it tends to grow outward and away from the lateral segments, which then tend to collapse medially. Attachment of the lip to close the cleft then creates a band of lip tissue which restrains this forward growth of the central portion. In addition, clefting of the lip is almost always associated with abnormal shape and location of the nasal cartilages. This can be

addressed at the time of initial repair, but growth of the cartilage is usually disturbed and final correction will have to be done as a teenager.

Thus, a typical sequence for cleft lip/palate repair is as follows: a) First repair of cleft lip at about 3-6 months of age (when the child is 5 kg or so). b) First stage of cleft palate repair at about 12 months. Additional repair of cleft lip and or palate at 18 months or so. c) If speech is abnormal, possible procedure to correct velo-pharyngeal incompetence. d) Repair of alveolus to permit normal development of adult dentition at the time when adult incisors are beginning to erupt ("mixed dentition") at age 8-10 years. e) Repair of cleft nose deformity as a teenager.

The prognosis for a child with unilateral cleft lip and palate is generally good. They usually learn to take bottle feedings easily with a cleft palate nipple, and learn to control the escape of fluids through the nose. Speech development can sometimes be problematic, requiring speech therapy. Poor function of the muscles of the soft palate can cause blockage of the Eustachian tubes, and frequent ear aches and otitis media.

There are several other, less common syndromes associated with growth abnormalities. There can be failures of growth and union of other facial bones, leading to a variety of rare facial clefting syndromes. Malformation of the branchial arches can also cause malformation patterns, the most common of which is Treacher-Collins syndrome, an autosomal dominant mandibulofacial dysostosis with zygomatic and mandibular hypoplasia and associated orbital anomalies. Down's syndrome is also associated with characteristic facial malformations, although these are mild and of secondary concern.

In addition, there can be problems of growth of the cranial bones, leading to funny shaped skulls. If the suture lines of the skull fuse prematurely (synostosis), then the bones cannot grow at this suture line, and the skull cannot grow in this direction. If the sagittal suture is involved (the most common), the skull cannot grow and separate across this line, so instead the skull becomes long rather than wide (scaphocephaly) in order to accommodate the growing brain. If the metopic (anterior forehead) suture is involved, this leads to trigonocephaly, with narrowing of the distance between the eyes. If both coronal sutures are involved, the head cannot grow in an anterior-posterior direction, and there is compensatory sideways growth leading to a skull that is shallow and broad (brachycephaly). Fusion of the lambdoid sutures causes flattening of the back of the head for similar reasons. Imbalanced or combined suture problems can result in a variety of other plagiocephalies - literally meaning "funny shaped skull". Reshaping of the skull can be accomplished by surgically opening the involved suture.

The brain is usually able to grow normally if only one suture is involved, compensating by increased growth along the other sutures without increase in intracranial pressure. This is more difficult when more than one suture is involved, causing more pressure on the growing brain. In Crouzon's Disease, a cranial synostosis is combined with exorbitism and midface retrusion ("froglike facies") in an autosomal dominant disorder. A similar disorder with hand syndactyly is called Apert's syndrome. Both require extensive surgery for repair.

Questions

1. In the newborn nursery, the mother of a child with a cleft lip and palate typically has a lot of concerns and will ask about the following. What do you tell her?

a. What caused the cleft lip?

b. Was there anything that she did or took in her early pregnancy that could have caused this, before she knew that she was pregnant?

c. What about feeding the baby and can she breast feed?

d. What surgeries the baby will need, and when?

e. If they have another baby, what are the chances that the next baby will have a cleft lip? What about the babies' children?

2. Why do cleft palate children develop more ear aches?

3. Why do cleft palate children have trouble with speech development, and what can be done to minimize this?

Answers to questions

1a. The clefting is caused by improper migration of the lateral lip segments in utero. This is a complex process, and sometimes it malfunctions.

1b. Probably not, and reassurance is the best treatment as the parents will inevitably feel some guilt. For future pregnancies, good nutrition (especially folic acid) and avoidance of toxins (alcohol, cigarettes, drugs, medications, environmental) are helpful. For further discussion, see http://www.cleft.net/reduce.

1c. The parents will probably need help in learning how to feed their baby, since the baby has less ability to create suction. Making a larger opening in the nipple, and using a broad nipple can help - the baby can get milk by compressing the nipple with the tongue rather than sucking. Breast feeding is possible, but more difficult. For a nice discussion of this, see http://www.samizdat.com/pp2.html

1d. The surgeries involve repair of the lip in the first year, repair of the cleft palate at about age 1, repair of the alveolar cleft at 6-10 years, and repair of the cleft nasal deformity as a teenager, after growth is complete. Each of these may involve one major operation, and perhaps one or more refinement operations if desired.

1e. The incidence of cleft lip in the general population is about 1:750. This approximately doubles for each affected family member, so the next baby would have about a 1:375 chance of having a cleft. For more precise evaluation, consultation with a genetic counselor is recommended.

2. In cleft palate, the muscles of the soft palate (levator palatini) are incorrectly aligned: they cannot cross the midline as they normally do. Thus, contraction of these muscles does not pull on the Eustachian tube to open it up, and the ears remained "plugged", causing serous otitis which then can get infected and cause otitis media.

3. Because of the clefting of the palate, the children cannot build up air pressure in the mouth (the air escapes into the nose). Thus, they cannot properly form the sounds which require increased air pressure (b, p, t, k, g, v, and s). As they try to learn to speak, they substitute other sounds for the ones that they cannot make ("compensatory articulations"). As they get older, it becomes increasingly difficult for them to unlearn these habits, so repair of the cleft palate should be done prior to speech development if possible. In addition, hearing is often slightly impaired, as noted above.

Chapter X.11. Abscesses
Myrna I. Kuo

This is a 4 year old boy who presents to the hospital with a chief complaint of a painful lump in his neck. He has been complaining of progressively worse pain in his ear for the past few days, but now comes to the office because of the development of the neck mass. He has been given acetaminophen for pain relief. He has otherwise been a healthy child and attends pre-school.

Exam: VS T 37.0, P 100, RR 25, BP 100/60, oxygen saturation 99% in room air. He is alert and active, in no distress. He is not toxic and not irritable. Head and eye exam are normal. His right tympanic membrane is bulging and purulent. His left tympanic membrane is normal. His neck exam demonstrates a fluctuant mass on the right side with overlying cellulitis (redness). His mouth exam shows a normal pharynx, mucosa and good dentition. Heart, lung and abdomen exams are normal. He ambulates normally and no neurological deficits are noted. His color and perfusion are good.

A CBC is obtained which shows WBC 12.0, 60% segs, 15% bands. The neck mass is aspirated with an 18 gauge needle for 3 cc's of thick pus. A gram stain of this shows many gram positive cocci. Clindamycin is prescribed and he is seen in follow-up the next day. The culture is positive for Staph aureus. The neck mass continues to enlarge, so he is hospitalized for further management. A surgeon is consulted who performs an incision and drainage. Entry of the abscess cavity reveals thick pus with loculations which does not drain easily so the incision is enlarged and a gauze drain is placed within the cavity. The staph aureus is determined to be methicillin resistant, but sensitive to clindamycin and vancomycin. He is continued on IV clindamycin and he is discharged from the hospital two days later to continue oral clindamycin as an outpatient. The gauze drain is removed three days after the initial incision. The abscess cavity gradually closes and shrinks.

Abscesses are focal collections of purulent material, usually due to bacterial infection, that are contained within a tissue, organ or confined space. Organisms may reach the tissue through various pathways including direct implantation by a foreign object, contiguous spread from an adjacent locus of infection, dissemination via lymphatics or hematogenous routes, and contamination of sterile tissue by normal flora (e.g., perforation of viscera into the abdomen) (1). As an abscess forms, there is an accumulation of necrotic white cells and tissue cells in the center of the abscess surrounded by a layer of preserved neutrophils and a second layer of dilated vessels and fibroblasts. Without spontaneous or surgical drainage, an abscess occasionally resolves slowly after proteolytic digestion of the pus producing a thin, sterile fluid that is resorbed into the bloodstream. Incomplete resorption leaves a cystic loculation within a fibrous wall, where calcium salts sometimes precipitate to form a calcified mass (2). More often, the abscess remains and becomes walled off by a capsule of connective tissue. Risk factors for abscess formation are immunosuppression, the presence of foreign bodies, obstruction to normal drainage of a visceral tract (e.g., respiratory, biliary, or a sweat gland as in acne), areas of low oxygen tension and stasis (e.g., ischemic tissue or hematomas), and trauma (1).

The symptoms associated with abscess formation vary depending on what organ is affected. For superficial or cutaneous and subcutaneous abscesses there is heat, swelling, tenderness, erythema over the affected site, and sometimes fever. Chronic or subacute deep abscesses present more often with local pain, tenderness, and systemic symptoms such as fever, anorexia, weight loss, and fatigue (1). Abscesses can lead to serious complications such as bacteremia, rupture into neighboring tissue, bleeding by erosion into nearby vessels, impaired function of the affected organ or systemic effects. Prompt treatment is generally preferable, but most abscesses are subacute, in that they have often formed over several days or longer. In general, treatment for abscesses is similar regardless of location. For superficial abscesses, incision and drainage with or without antibiotics is indicated. Treatment of a deep-seated abscess consists of drainage and antibiotics active against the responsible bacteria. Without sufficient drainage, antibiotics are ineffective, because the necrotic center of abscesses are not vascularized (i.e., no antibiotic is delivered to organisms within the abscess). Adequate drainage consists of thoroughly removing pus, necrotic tissue, and debris. To prevent reformation of the abscess, loculations (fibrous strands) must be broken and drainage must be permitted to continue. A gauze wick can be used to maintain the patency of the incision site so that fluid within the abscess can continue to drain out of the cavity. Without a wick or drain to keep the cavity open, the incision site will close and fluid will collect within the cavity causing a recurrence of the abscess. Dead space within the cavity can be eliminated by packing with gauze. The leading end of the gauze packing wick is advanced daily to reduce the size of the abscess cavity as it closes. Predisposing conditions, such as obstruction of a duct or the presence of a foreign body, should be corrected or eliminated if possible. Gram stains and cultures followed by susceptibility studies of isolates obtained from the abscess provide a guide to antimicrobial therapy (1).

Each organ is associated with common microbes, with slight differences in pathogenesis and treatment. Some of the more common locations such as brain, lung, liver, neck, pilonidal, and perirectal will be touched upon in this chapter. Additional areas of abscess formation include abdominal, retropharyngeal, peritonsillar, tubo-ovarian, and osteomyelitis Brodie abscesses. These have been covered in other chapters.

NECK

Cervical lymphadenopathy, which is defined as enlargement of the cervical lymph nodes due to viral infection or bacterial infections that drain to lymph nodes, is the most common reason for neck masses in children. Up to 90% of children between the ages of 4 and 8 years can have cervical adenopathy without obvious associated infection or systemic illness. Cervical lymphadenopathy should resolve as the primary infection resolves.

Cervical lymphadenitis, on the other hand, occurs when acute infection is present within the lymph node. Acute bilateral cervical lymphadenitis is often due to viral infection, while acute unilateral cervical lymphadenitis is usually due to bacteria. Cervical lymphadenitis and abscess formation commonly occur in children under 5 years old (3). It often follows an upper respiratory illness, pharyngitis, tonsillitis, or otitis media. The bacteria spread from their initial sites of infection to the lymph nodes in the neck. If not contained by the child's immune system, they multiply within the node and evoke an inflammatory response (3). Up to 80% of cervical lymphadenitis is caused by S. aureus and group A streptococci. Less common organisms include anaerobic bacteria (from periodontal disease), H. influenzae, Yersinia pestis, gram-negative bacilli, Francisella tularensis, Actinomyces, and Mycobacterium (3,4). S. aureus is more likely to form an abscess, whereas group A streptococci usually form a general cellulitis or more commonly, a simple reactive lymphadenitis. Bacterial cervical lymphadenitis presents with firm, tender, and warm lymph nodes. Fever may or may not occur. Treatment includes antibiotics and warm soaks. If left untreated, these nodes may become fluctuant with regional cellulitis (3). Needle aspiration should be done on fluctuant masses, and antibiotic treatment should empirically cover Staph aureus, with subsequent therapy based on culture and sensitivity results. If resolution does not occur after needle aspiration and antibiotics, incision and drainage should be done (3). Some would argue that needle aspiration is merely used as a diagnostic test to determine if an abscess is present. Once an abscess is identified by needle aspiration, then incision and drainage should immediately follow.

SOFT TISSUE

Cutaneous abscesses primarily form as a result of minor trauma to the skin. The bacterium most frequently involved is S. aureus. Normal skin flora is also commonly involved. The presenting signs are a painful, fluctuant mass that is erythematous and indurated with overlying cellulitis. High fevers may indicate systemic infection and should prompt a more in-depth evaluation. Treatment consists of application of local anesthetic, followed by incision and drainage with probing to remove loculations, irrigating the cavity with saline and sometimes packing with gauze. Because abscess drainage is often very painful and local anesthetics do not penetrate necrotic tissue well, general and regional anesthesia may sometimes be preferable. Elliptical incisions are preferred because they keep the wound from prematurely closing. Applying warm compresses twice a day after drainage is usually recommended. Antibiotic treatment is often used, but it is usually unnecessary (1).

Pyomyositis with subsequent skeletal muscle abscess formation is due to S. aureus in greater than 80% of cases. The accumulation of pus is always intramuscular initially and is not secondary to infection of adjacent skin, soft tissue, or bone. It often occurs after a penetrating wound, prolonged vascular insufficiency in an extremity, or a contiguous infection (5). Often termed tropical myositis due to its geographic distribution, pyomyositis can also be found, though less commonly, in temperate climates. Patients present with fever, chills, malaise, and pain and swelling in the muscle involved (usually large skeletal muscles such as the thigh, psoas and buttocks) (6). The pathogenesis of muscle abscess formation is not clear. One hypothesis is that migrating helminth larvae damage tissue, making it susceptible to bacteria of hematogenous origin or carried by the worm. Treatment of the abscess requires surgical drainage and appropriate antibiotic coverage (usually vancomycin, clindamycin or an anti-staphylococcal penicillin). If group A streptococcus is cultured from a smear of the pus, treatment should be switched to penicillin. Continued fever after drainage and antibiotics may indicate other untreated foci of abscess. A complication of pyomyositis is compartment syndrome (especially when in the anterior tibial compartment), which may require additional treatment including additional surgical drainage, fasciotomy, and debridement (5).

BRAIN

Brain abscesses result from direct extension of cranial infections (e.g., osteomyelitis, sinusitis), from penetrating head wounds, or from hematogenous spread (e.g., bacterial endocarditis, bronchiectasis, congenital heart disease with right-to-left shunt, or IV drug abuse) (7). An abscess in the frontal lobe is often caused by extension from sinusitis or orbital cellulitis, whereas abscesses located in the temporal lobe or cerebellum are frequently associated with chronic otitis media and mastoiditis. Abscesses resulting from penetrating injuries tend to be singular and caused by S. aureus, whereas those resulting from septic emboli, congenital heart disease, or meningitis often have several organisms (8). Bacteria frequently involved include: S. aureus, streptococci (viridans, pneumococci, microaerophilic), anaerobic organisms (gram-positive cocci, Bacteroides, Fusobacterium, Prevotella, Actinomyces, Clostridium) and gram-negative aerobic bacilli (enteric rod, Proteus, Pseudomonas, Citrobacter diversus, and Haemophilus). One organism is cultured from the majority of abscesses (70%), two from 20%, and three or more in 10% of cases. Abscesses due to sinusitis often involve anaerobic bacteria. Once the infection extends into the brain parenchyma, it is encapsulated by glial cells and fibroblasts, forming an abscess (7). The abscess results in increased intracranial pressure, causing symptoms similar to tumors such as headache, vomiting, papilledema, seizures, personality changes, focal neurological deficits, and hemiplegia. Brain abscesses are often fatal unless treated. Treatment consists of prompt administration of appropriate antibiotics: penicillin (for streptococci and anaerobes), metronidazole (for bacteroides), a 3rd generation cephalosporin (for Enterobacteriaceae), vancomycin (for S. aureus infection due to cranial trauma or endocarditis) (7). Clindamycin may also be used for anaerobes and synergistic efficacy with other antibiotics. In many cases, aspiration and drainage of brain abscesses are necessary. Response to antibiotics should be followed by serial CT or MRI scans for a minimum of 4 to 8 weeks. The duration of antibiotic treatment is often about 4 to 6 weeks.

LIVER

Hepatic abscesses can be divided into two broad categories, pyogenic and amebic. Pyogenic hepatic abscesses are uncommon in immunocompetent individuals, but can occur in immunocompromised persons (9). Biliary tract disease and obstruction, abdominal infections via the portal vein or contiguous spread, and generalized sepsis are usually responsible. However, in up to one half of cases, no definite cause can be found (10). The right lobe is most often infected. Many bacteria are involved in liver abscesses, most commonly S. aureus, E. coli, Salmonella, Klebsiella, Proteus, Pseudomonas, enterococcus and anaerobic organisms (11). Patients may have either an acute or subacute presentation. Acutely, they may experience high fever and chills, RUQ pain, nausea and vomiting (9). Less commonly, once the abscess is encapsulated, the patient may only manifest dull pain over an enlarged liver which is tender to percussion (9). Jaundice is uncommon. Treatment consists of adequate antibiotic coverage and percutaneous drainage. Triple antibiotic coverage with an

aminoglycoside or third-generation cephalosporin (gram-negative coverage) plus metronidazole or clindamycin for anaerobes and ampicillin (for streptococcal species) should be used (9).

Amebic abscess occurs by fecal-oral transmission of Entamoeba histolytica, usually involving ingestion of contaminated food or water. Amebae reach the liver after invasion of the intestinal mucosa and enter the liver via the portal vein. The acute presentation is similar to pyogenic hepatic abscess (9). Treatment consists of one week of metronidazole. Most patients will recover with metronidazole alone and percutaneous catheter drainage is only required in complicated cases.

LUNG

Lung abscesses are usually due to aspiration (e.g., during coma, obtunded from alcohol or other drugs, CNS disease, general anesthesia), bronchial obstruction, periodontal disease, infection secondary to lung infarction or complications of pneumonia. Many different bacteria are responsible for lung abscess. Lung abscess due to aspiration are typically normal flora of the GI tract (anaerobes) (12). Virulent organisms (e.g., S. aureus), cystic fibrosis, or endotracheal intubation may cause failure of microbial clearance mechanisms resulting in bronchial obstruction and abscess formation (13). Lung abscess caused by periodontal disease contain normal anaerobic nasopharyngeal flora. Pneumonia due to Klebsiella, S. aureus, Actinomyces, beta-hemolytic streptococcus, Streptococcus milleri (and other aerobic or microaerophilic streptococci), Legionella, or Haemophilus influenzae can sometimes be complicated by abscess formation. In immunocompromised hosts, Nocardia, Cryptococcus, Aspergillus, phycomycetes, atypical mycobacteria or gram-negative bacilli should also be considered. Blastomycosis, histoplasmosis, and coccidioidomycosis can cause acute or chronic nonputrid lung abscesses in visitors or residents of endemic areas. Finally, pseudomonas should be considered in hospitalized patients and individuals with cystic fibrosis. Cavitary TB is not considered a lung abscess but should be included in the differential diagnosis (12).

Symptoms of a lung abscess may range from minimal fever, anorexia, and weakness, to symptoms of pneumonia, i.e., malaise, sputum-producing cough, sweats, severe prostration and temperatures of 39 to 40 degrees (102 to 104 degrees F) (12). Unless the abscess is completely encapsulated, about 50% of patients will cough up sputum that is purulent and sometimes blood-streaked. In fact, an abscess may not be suspected until it perforates into a bronchus, causing copious purulent sputum to be expectorated over the next few hours or several days. Putrid sputum is indicative of anaerobic bacteria. Chest pain suggests involvement of the pleura. Signs of a subacute or chronic abscess are months of low-grade fever, cough, weight loss and anemia (12,13). Treatment usually consists of 1 to 3 months of the following antibiotic treatments: a) clindamycin, b) penicillin with oral metronidazole, or c) antibiotics determined by sensitivity testing. Vancomycin should be added if S. aureus is suspected. Drainage by aspiration or surgery is usually not required for a lung abscess. Postural drainage may be helpful, but should be done with caution. The risk of perforation and spilling of abscess contents is potentially disastrous and unnecessary, as antibiotic treatment will usually suffice. If, however, the abscess is resistant to drugs, segmental resection or lobectomy is indicated.

PILONIDAL

Pilonidal abscesses usually occur in hirsute, adolescents. Pilonidal sinuses are common malformations in the sacrococcygeal area that may occur during embryogenesis. They are lined by stratified squamous epithelium and often asymptomatic; however, hair obstructing the sinus can lead to pilonidal cyst formation. Recurrent infection of a cyst, due to foreign body (ingrown hair) granuloma formation, often leads to pilonidal abscess. Due to its location, cultures of pilonidal abscess predominantly contain anaerobic GI flora. Common symptoms include back pain with local tenderness and induration. The abscess, however, may not be superficially obvious. Smaller abscesses only require incision and drainage, which may be done on an outpatient basis under local anesthesia. All hair and pus should be removed, and the lesion should be packed. The area should be repacked every 2 to 4 days and may take weeks to heal. The abscess cavity, however, is often large and recurrence is common. Therefore definitive treatment is removal of the cyst, sinus, and all sinus arborizations once the inflammation has passed. Antibiotics are rarely necessary (14).

PERIRECTAL

There are several common locations for perirectal abscess: >45% perianal, 20% ischiorectal, 12% intersphincteric, and 7% pelvirectal (14). Perianal abscesses occur in healthy infants and adults during the fourth decade of life and more frequently in males (>2:1 ratio). Because they are commonly deep lesions, there is considerable morbidity associated with inadequate treatment of perirectal abscesses. An understanding of anal canal anatomy helps clarify the pathophysiology of perirectal abscesses. The mucosa of the anal canal is loosely attached to the muscle wall. At the dentate line, columnar epithelium transitions into squamous epithelium, and there are vertical folds of tissue called the rectal columns of Morgagni. The columns are connected at their distal end by small semilunar folds (anal valves), and under the valves are invaginations called anal crypts. The crypts contain collections of ducts from anal glands, which are mucus-secreting structures that terminate in the area between the internal and external sphincters. Most perirectal infections begin as a result of blockage and subsequent infection of the anal glands. This causes normal host defense mechanisms to break down resulting in invasion and overgrowth by bowel flora. A mixed infection of GI flora usually occurs, with E. coli, Proteus, streptococci, staphylococci, and bacteroides predominating (14). GI fistulas, inflammatory bowel diseases (Crohn's Disease), episiotomies, or any local trauma that contributes to anal gland infection, predisposes an individual to perirectal abscesses (14). Fistula formation is common in infants, resulting in recurrence of the abscess unless the fistula tract is excised surgically.

Signs and symptoms of superficial perirectal abscesses include: throbbing pain (aggravated by sitting, coughing, sneezing, and straining), swelling, induration, tenderness, and a small area of cellulitis in the perianal region. Deeper abscesses may cause systemic, toxic symptoms, but localized pain may be less severe (14,15). Small, well-defined perianal abscesses are the only perirectal infections that should be treated on an outpatient basis. Incision and drainage result in almost immediate relief of pain and resolution of the infection. However, many perianal abscesses are large and deep resulting in greater morbidity.

ABDOMINAL

Intraabdominal abscesses most frequently occur as a result of GI tract perforation or inflammation (i.e., ruptured appendicitis). Therefore mostly GI flora, a combination of aerobic gram-negative bacilli (E. coli and Klebsiella) and anaerobes (Bacteroides fragilis) are involved. Symptoms of abdominal abscess include fever and minimal to severe discomfort in the area of the abscess. Anorexia, nausea, vomiting, diarrhea, constipation, and paralytic ileus may also occur. Treatment involves: 1) drainage by surgery or percutaneous catheters, and 2) antibiotics which cover all relevant organisms. Treatment regimens include: a) an aminoglycoside (gentamicin) and clindamycin, b) 3rd-generation cephalosporin and metronidazole, or c) single agent cefoxitin or cefotetan. Hospital acquired infections should also cover Pseudomonas (1).

Questions

1. True/False: Some abscesses can resolve spontaneously.
2. What is the most common organism involved in abscess formation?
3. True/False: All abscesses are treated by incision and drainage.
4. What is the rationale behind multi-drug antibiotic treatment?
5. Does a person have to be immunocompromised to develop an abscess?
6. What are the complications of untreated abscesses?

Answers to questions

1. True
2. Staph aureus
3. False, lung abscesses are not.
4. Abscesses are often mixed infections, therefore antibiotic treatment needs to provide adequate coverage of the common bacteria associated with that type of abscess. Some antibiotics (notably clindamycin) may provide synergistic efficacy as well.
5. No
6. Bacteremia, rupture into neighboring tissue, bleeding by erosion into nearby vessels, impaired function of the affected organ or systemic effects such as cachexia and anorexia.

Chapter X.12. Lymphangiomas
John J. Chung, MS, MPH

This newborn male infant was born to a 30 year old G1P1 mother at 40 weeks gestation via cesarean section. Prenatal ultrasonography performed at 32 weeks gestation revealed a 1 cm x 1 cm x 1 cm hypoechoic but nonseptated mass in the posterior neck. An encephalocele or meningocele were deemed unlikely and the infant was suspected of having a cystic hygroma (a type of lymphatic malformation). No evidence of fetal hydrops or other congenital anomalies were noted. The pregnancy is closely monitored with detailed serial ultrasounds for the duration of the pregnancy. At term, the hypoechoic lesion is 2 cm x 1 cm x 2 cm. While there is still no indication of hydrops fetalis by ultrasonography, a cervical cystic mass could obstruct a vaginal delivery and the mother is advised to undergo a cesarean section.

Upon delivery, Apgar scores are 8 and 9 at 1 and 5 minutes. VS T 37.5, HR 110, R 60, BP 51/25, weight 3.3 kg (50th %ile), length 51cm (50th %ile). His head is normocephalic with no evidence of additional cystic masses. Eyes, ears, nose and mouth are all normal. A 2 cm wide mass is noted in the posterior neck. Heart, lung, abdomen, extremity, skin and neurologic examinations are normal.

He begins to breast feed normally. Imaging studies fail to demonstrate any other cysts. Because nuchal cysts can grow to obstruct the trachea or esophagus, most of the cyst is surgically excised. Histology of the cyst shows only lymphatic tissue, confirming the diagnosis of a cystic hygroma. Because of its proximity to nerves, the cystic hygroma tissue could not be completely removed. By 12 months of age, local recurrence of the cystic hygroma is evident. Options for recurrent and unresectable lymphangiomas, such as drug sclerotherapy, were discussed with his parents. They are also informed of the possibilities of infection, hemorrhage, and continual recurrence despite treatment.

Lymphangiomas or lymphatic malformations (LM) are defined as isolated regions of lymphatic tissue which are thought to occur after the 6th week of gestation, when developing lymphatic tissue fails to properly anastomose (1,2,3). Lymphatic tissue can also improperly anastomose with capillaries, veins, and arteries (4). These isolated regions of lymphatic tissue function to absorb interstitial fluid and enlarge as lymph fluid continues to accumulate with time (3). Depending on their location and size, lymphatic malformations can be benign and asymptomatic or they can press against nerves, organs, or obstruct circulation (4). For example, lymphangiomas in the head and neck can cause airway obstruction, and alter speech and/or mastication (3).

The true incidence rate for lymphatic malformations is uncertain, since small ones may not be very evident. The most common lymphatic malformation, cystic hygromas, have an estimated incidence of 1:875 among miscarriages (3). By comparison, hemangiomas are much more common and occur in as many as 10% of 1 year olds (5). Lymphatic malformations are found equally in boys and girls (5). Lymphatic malformations are commonly diagnosed in infancy with more than half of the cases identified prenatally or postpartum and more than 90% diagnosed by the 2nd or 3rd year of life (4,6). Lymphatic malformations rarely regress after birth but can remain asymptomatic until later in life when trauma or infections can cause lymphatic malformations to rapidly grow and interfere with other structures (7).

Seventy-five percent of lymphatic malformations are found in the head and neck but lymphatic malformations can occur anywhere (1). Generally, the most common sites are in the head and neck, mediastinum, axilla, and abdomen (1). Lymphangiomas that are microcystic superficial lesions of the skin or mucous membranes have many names: lymphangioma simplex, lymphangioma circumscriptum, capillary lymphangioma and angiokeratoma circumscriptum (4,9). Deeper lymphangiomas can be either microcystic (cavernous lymphangiomas), macrocystic (lymphangioma cystoides, cystic hygromas, or cystic lymphangiomas), or mixed microcystic-macrocystic (4,9).

The etiology of lymphangiomas is unknown (10). However, cystic hygromas have been found to be associated with chromosomal abnormalities such as Turner syndrome and Down syndrome (2,3). Chromosomal abnormalities are usually associated with other congenital findings such as mental or developmental retardation, heart defects, or alterations in the development of sexual characteristics at puberty.

Diagnosis is principally made on the basis of clinical appearance and imaging. For example, capillary lymphangiomas or lymphangioma simplex are superficial white, purple, or red papules that appear wart-like (9). Such superficial lymphangiomas are usually asymptomatic but can become infected. They can occasionally bleed when the superficial lymphangioma is in communication with ruptured blood vessels. Lymphangioma circumscriptum are superficial clusters of papules that are said to look like frog eggs (9). Lymphangioma circumscriptum is also found in skin or mucous membrane but extend deeper into the dermis than lymphangioma simplex (9). Cavernous lymphangiomas usually involve the skin or mucous membranes but they extend deeper into muscle where they form small, thin-walled, lymph fluid filled spaces referred to as microcysts (9).

Cystic lymphangiomas or cystic hygromas are large, well-circumscribed, loculated, lymph fluid-filled spaces (macrocysts) (3,9). Large loculated cysts tend to occur in areas where expansion is possible such as the deep lymph vessels in the neck and head or near other organs. These deep lymphangiomas can be asymptomatic or they can present with signs and symptoms associated with serious complications. Cystic hygromas, usually identified prenatally or antenatally, are especially serious. Considerable lymphedema can accompany growing cystic hygromas which can sometimes lead to hydrops fetalis and intrauterine fetal demise (IUFD) or early perinatal neonatal death (early PND) due to circulatory failure (3). Additionally, the size and position of the cyst may complicate vaginal delivery (3).

When aspirated, the cystic space fluid includes proteinaceous fluid with few lymphocytes (1). MRI findings are important in distinguishing between lymphangiomas and other vascular malformations (1). Arterial or venous vascular malformations enhance with contrast during MRI contrast studies, while lymphatic malformations do not. CT scans can also help differentiate venous malformations from lymphangiomas as well as help identify hemorrhages. Plain film radiographs can identify associated skeletal deformities. Ultrasound imaging is particularly useful during the perinatal/neonatal period (4).

Specimen biopsies of superficial lesions show typical lymphatic vessels lined by well differentiated, flat, endothelial cells (3,8). Deeper lesions show dilated and interconnected lymph vessels that can form loculations (3).

The differential diagnosis includes lymphadenitis, other congenital vascular malformations (hemangiomas, branchial cleft cyst, cellulitis, dermoid cyst), and tumors. Bloody lymphangiomas are often easily confused with hemangiomas or Kaposi's sarcoma (4). Because of the variable location of lymphangiomas, the differential diagnosis should also include site-specific pathologies. For example, the differential diagnosis of a nuchal cystic hygroma should include encephalocele or meningocele, and tumors of the head and neck (3).

Small superficial lymphangiomas are generally left untreated if asymptomatic (1). Cystic hygromas identified in a fetus are especially concerning. The fetus is assessed for additional abnormalities that would increase the risk of fetal death or poor postpartum prognosis such as chromosomal abnormalities, hydrops fetalis, and large cyst volumes (2). These factors are important in whether or not the fetus is aborted or delivered vaginally or by cesarean section. In the U.S., deep lymphangiomas such as cystic hygromas and larger superficial lymphangiomas are surgically excised (1,3,6). However, surgical excision is difficult because of the delicate nature of thin-walled lymphatic tissue and the close proximity of lymphatic malformations to nerves, organs, and blood vessels (3,6). As a consequence, complete excision is possible in less than a third of the cases (6). Incomplete excision does eliminate the space occupying effects of the lesion but are complicated by a high risk of recurrence and infection (3).

In sclerotherapy, drugs including bleomycin, OK-432 (derivative of low virulence Group A streptococcus pyogenes), and fibrin adhesives are used to stimulate sclerosis and regression (6). In the U.S,. sclerotherapy is generally reserved for recurrent or unresectable lymphangiomas but, in some small studies, sclerotherapy agents have been used in place of surgical excision with good results (3,6). Sclerotherapy complications include ulcers, scarring, and recurrence of lymphangiomas (3,7). Other treatment options include interferon-alpha treatment (7), laser ablation or radiation treatment. Radiation treatment carries a number of complications and is usually reserved as a treatment of last resort (7).

Questions

1. Which of the following is NOT a kind of lymphangioma?
    a. lymphangioma simplex or circumscriptum
    b. capillary lymphangioma
    c. cavernous lymphangioma
    d. cystic hygroma
    e. subdural hygroma

2. Which two of the following choices are NOT characteristic of cystic hygromas?
    a. bluish color
    b. increases in size with dependent position
    c. if superficial, transilluminates brightly
    d. does not enhance with contrast in MRI
    e. large neck mass presenting at birth

3. True/False: The differential for a lymphatic malformation depends on its location.

4. In the U.S., primary treatment of lymphatic malformations can include all of the following EXCEPT:
    a. surgical excision
    b. no treatment if benign
    c. pharmacological sclerotherapy
    d. radiation therapy

5. Complications of cystic hygromas in the head and neck include all of the following EXCEPT:
    a. airway obstruction
    b. esophageal obstruction
    c. infection
    d. hydrops fetalis
    e. hemorrhage
    f. no exceptions (all above are correct)

Answers to questions

1.e. A subdural hygroma is liquefaction of a subdural hematoma.
2.a & b. These are indicative of venous malformations.
3.true
4.d. Radiation is reserved as a last resort.
5.f

Chapter XI.1. Anemia
Darryl W. Glaser, MD

A 22 month old boy presents to your office with a chief complaint of pallor. A visiting relative who has not seen the child for 5 months told his mother that the boy appears pale. The mother brings him in for a checkup even though she notices no change in his coloring (he has always been fair skinned). On review of symptoms you find that he is an active toddler, with no recent fatigue, exercise intolerance, or increase in sleeping. He has had no blood in his diapers and no black or tarry stools. He is a picky eater, taking small amounts of chicken, pork and some vegetables, but loves milk and drinks six to eight bottles of whole milk per day.

Family history reveals a distant aunt who had anemia when she was pregnant but which subsequently resolved. There is no history of splenectomy, gall stones at an early age, or other anemia in the family.

Exam: VS: T 37.5, BP 90/52, P 145, RR 16, Height 85.5 cm (50th %ile), Weight 13.2 kg (75th %ile). General appearance: He is a pale appearing, active toddler, holding a bottle, tearing and eating paper from your exam table. Eyes: No scleral icterus. Pale conjunctiva. Mouth: Dental caries. Chest: Clear. Heart: Mild tachycardia as above, grade II/VI systolic ejection murmur heard best over the upper left sternal border. Abdomen: No hepatosplenomegaly. Rectal: Dark brown, soft stool, negative for occult blood.

CBC: WBC 6,100, Hgb 6.2 g/dl, Hct 19.8%, Plt 589,000, MCV 54 fL, RDW 17%. Reticulocyte count is 1.8%. The lab reports microcytosis, hypochromia, mild anisocytosis and polychromasia. There is no basophilic stippling.

You correctly diagnose iron deficiency anemia, start oral iron and limit his milk intake. You see him in 3 days to assure compliance and his RDW is 27% and his reticulocyte count 17%. When you see him back in two weeks his mother is amazed at his new interest in table foods. His Hgb is now 8.5 g/dl, and his MCV 64 fL. Two months later his hemoglobin has completely normalized, and you continue iron therapy for three more months.

Anemia occurs when the red blood cell mass or hemoglobin content is too low to meet a person's physiologic demands. In children, "normal" levels vary with age, gender, and geographic location (height above sea level). A summary of normal values is listed below (1):

Table 1. Lower limit (3rd %ile) of normal hemoglobin (Hgb column) and lower (3rd %ile) and upper (97th %ile) limit of normal MCV by age and sex (1) (M=males, F=females).

Age	Hgb (g/dl)	Lower MCV limit	Upper MCV limit
1 - 4	11.2	72	85
5 - 7	11.5	75	87
8 - 10	11.8	76	89
12 - 14	12	76	89
15 - 17	12 (F), 13 (M)	78	92
Over 18	12 (F), 14 (M)	80	95

Signs of anemia include pallor of the skin, conjunctiva, and mucus membranes, tachycardia, orthostatic hypotension, heart murmur and edema. Symptoms may include fatigue, headache, dizziness and dyspnea. Other signs and symptoms depend on the cause for anemia, such as jaundice, dark urine, or splenomegaly in hemolytic anemias (2).

When the diagnosis of anemia is suspected based on signs and symptoms, it can quickly be confirmed by laboratory evaluation. The more difficult task is determining the etiology, which can appear daunting due to the myriad of causes of anemia in children. Testing for all these causes at once would be inefficient, time consuming, and expensive. It is, in fact, unnecessary because the differential diagnosis can be narrowed significantly by careful history, thorough examination, and use of various classification schemes.

History

1) Has there been a sudden onset of pallor, fatigue, or exercise intolerance? Rapid onset of symptoms suggests a more acute anemia, while anemia without symptoms may indicate a more chronic process, allowing the body more time to compensate for the low hemoglobin levels. Note that the presence of symptoms does not necessarily reflect the level of anemia. A child whose Hgb drops from 14 to 10 over one week may be quite symptomatic, while the child in our case presentation was virtually asymptomatic dropping to a Hgb of 6.2 over a period of months. Pallor unrecognized by the patient's day to day caretaker also suggests a gradual process.

2) Any history of blood loss? Obtain a menstrual history. Prolonged, heavy periods are a source for acute blood loss. Over time chronic loss can lead to iron deficiency, especially when superimposed on poor dietary iron intake.

3) Did the child have jaundice in the newborn period or episodes of jaundice in the past? Glucose-6-phosphate dehydrogenase deficiency (G6PD) and hereditary spherocytosis will cause recurrent episodes of jaundice and anemia, especially following illness or stress.

4) Describe the child's diet. When did he start whole milk? How much milk does he drink now? Excessive milk intake with inadequate dietary iron is a common cause of iron deficiency anemia in toddlers. Does he eat anything unusual (paper, dirt) or chew on ice? Pica suggests iron deficiency and can predispose to lead poisoning.

5) Has anyone in the family ever had anemia or low blood counts, or ever been on iron? This may suggest a hereditable cause of anemia, but is not diagnostic. A positive response may simply reflect dietary patterns in siblings. It is quite common for families to recall at least one relative who was anemic at some time, especially during pregnancy. Ask if they are still receiving treatment or if the condition resolved. Also remember that a negative family history does not exclude an inherited anemia.

6) Has anyone in the family ever had their spleen taken out or had gallstones at an early age? Surprisingly, not all patients know the reasons for past procedures, or may have been too young when they occurred. A positive response suggests a family history of a hemolytic anemia (such as hereditary spherocytosis). A negative response does not rule out these causes.

7) What is the child's ethnic origin? Hemoglobinopathies (e.g., sickle cell anemia), thalassemias, and G6PD deficiency are more common in certain ethnic groups.

Physical Examination

Compare the child's color to his siblings or both parents. Is he active and playful or fatigued? Tachycardia and heart murmur are common in children with anemia, but look for signs of heart failure including tachypnea, rales, hepatomegaly or edema. Splenomegaly may indicate immune hemolytic anemia or hereditary spherocytosis. Look for any skeletal abnormalities as can be seen with the congenital bone marrow failure syndromes.

Two classification schemes are frequently employed to narrow down the differential diagnosis in anemia. The first uses the MCV to classify the size of the red blood cell as microcytic, normocytic, or macrocytic. Although it can be quite helpful, the system is imperfect. Since MCV values in children vary with age, the age specific MCV values must be used (See Table 1). Even so, certain conditions do not fit neatly into one category. The anemia of inflammation/chronic disease and of lead poisoning can be microcytic or normocytic, and the anemia seen with liver failure can be normocytic or macrocytic.

Microcytic anemias include iron deficiency, thalassemia, chronic inflammation, lead poisoning, and sideroblastic anemia.

Normocytic anemias include acute blood loss, immune hemolytic anemia, hereditary spherocytosis, G6PD deficiency, sickle cell anemia, renal disease, and transient erythroblastopenia of childhood (TEC).

Macrocytic anemias include folate deficiency, B12 deficiency, liver disease, hypothyroidism, neoplasms and bone marrow failure syndromes such as aplastic anemia, Diamond-Blackfan anemia (DBA) and congenital dyserythropoietic anemia (CDEA)

The second classification scheme categorizes anemia by its mechanism. If a patient's hemoglobin is low, it is due to one of three basic reasons: he/she is either not making adequate amounts (decreased production), destroying it (increased destruction), or losing it from somewhere (blood loss). This system is more intuitive and more reliable, but is more difficult to categorize in some cases. A high reticulocyte count indicates that the patient is able to adequately make red cells and is trying to compensate for the anemia, suggesting the cause to be blood loss or destruction. A low reticulocyte count suggests decreased production. Signs of destruction include jaundice, elevated bilirubin, dark urine, splenomegaly, schistocytes and microspherocytes on peripheral smear, and low serum haptoglobin.

Decreased production results from iron, folate, or B-12 deficiency, lead toxicity, thalassemia, aplastic anemia, chronic inflammation, neoplasms, TEC, DBA, renal disease, hypothyroidism, CDEA (congenital dyserythropoietic anemia), and sideroblastic anemia.

Blood loss results from acute hemorrhage, dysfunctional uterine bleeding (heavy and/or prolonged menstrual periods), pulmonary hemosiderosis (pulmonary hemorrhage), Goodpasture's disease, and gastrointestinal blood loss (peptic ulcer disease, other GI conditions).

Increased destruction results from immune hemolytic disease, hereditary spherocytosis, G6PD deficiency, sickle cell disease, thalassemia, DIC (disseminated intravascular coagulation), mechanical heart valves, burns, PNH (paroxysmal nocturnal hemoglobinuria), and hypersplenism.

Iron deficiency is the most common cause of anemia in childhood (2). Prevalence of iron deficiency ranges from 5% to 29% of the population, with higher numbers seen in inner city and socioeconomically deprived populations (3,4). It is most common in toddlers and in the adolescent age groups (periods of rapid growth and higher potential for inadequate dietary iron) (5).

In infants, early introduction (at age 6 or 8 months) of whole cow's milk into the diet is clearly associated with iron deficiency anemia, and patients consuming larger amounts of milk are at higher risk of anemia (3). This is due to three factors: 1) Cow's milk exerts a direct toxic effect on the intestinal mucosa of infants, leading to prolonged microscopic blood loss in the stools. 2) The caloric value of whole cow's milk is high due to fat content, decreasing the appetite and leading to less intake of potential iron-rich foods. 3) The bioavailability of iron in cow's milk is low (6). Accordingly, the American Academy of Pediatrics recommends that cow's milk not be used in the first year of life. Infants should receive breast milk or iron fortified formulas for the first year of life, and iron-fortified cereal should be added at the age of four to six months (6). Infants with appropriate diets and older children and adolescents with iron deficiency anemia must be evaluated for a source of chronic blood loss. Abnormal uterine bleeding and blood loss from the GI tract are common. Blood loss in the urine is rare, and from the lungs (idiopathic pulmonary hemosiderosis) is exceedingly rare. Hemolytic anemias generally do not lead to iron deficiency because the body reuses the freed iron. Iron deficiency has conclusively been linked to behavioral changes (6) and to lower cognitive achievement in school aged children and adolescents (7). Thus it should be recognized early and treated adequately.

Presenting signs and symptoms may be mild because of the gradual onset and the body's ability to compensate for low hemoglobin concentration. Pallor, fatigue, exercise intolerance, headache, or dizziness may be present. Physical exam may reveal pale mucus membranes and skin, especially of the palms, tachycardia with or without heart murmur, and orthostatic hypotension. Laboratory evaluation reveals a low MCV, low hemoglobin and hematocrit, low reticulocyte count, and often an elevated platelet count. The red cell distribution width (RDW), a measure of the difference in size between the smallest and largest RBCs in circulation, may be elevated, denoting a dual population of cells: small (microcytic) iron deficient cells and some normocytic cells with adequate iron. Evaluation of the blood smear reveals microcytosis and hypochromia. Serum iron is low, and total iron binding capacity (TIBC) is elevated with low % saturation. Erythrocyte protoporphyrin is increased. Low serum ferritin is diagnostic of iron deficiency, but normal levels can be misleading because ferritin is an acute phase reactant and can be falsely elevated in inflammation (5). Low-normal ferritin values must be interpreted in light of clues from the history, physical, and other laboratory studies. A bone marrow sample stained for iron shows no iron stores. This test is most definitive, but generally unnecessary and invasive.

Treatment with multivitamins containing iron is inadequate once the child is anemic. Oral ferrous sulfate, available in liquid or pill form, at a dose of 3 mg/kg of elemental iron for mild anemia or 6 mg/kg for severe anemia should be instituted. It should be continued for two to three months after normalization of blood counts to replete the total body iron stores. The liquid can stain the teeth so it should be given in juice rather than dropped directly into the mouth. Avoid giving it with milk as milk interferes with its absorption.

Lead poisoning is less common today with the federally mandated removal of lead from gasoline, canned food sealants, and paint intended for household use in 1977. Since then, there has been a 90% decrease in the number of children defined as "lead intoxicated" (8). Nationwide, 4.4% of children aged one to five meet this criteria with blood levels above 10 mcg/dL (9). The primary source of lead in children's blood today is from lead based paint in older households. Most is ingested as household dust, with only a minor contribution from paint chips (8). Children under 2 years of age are at highest risk due to exploring behavior and the practice of bringing paint dust-coated fingers and toys to the mouth. Not surprisingly, the age and state of disrepair of the home is an important risk factor. Children in an older but well-maintained home have less exposure than those in an old home with cracked and peeling paint (10).

Most lead poisoning is now found through lead screening. The American Academy of Pediatrics recommends that a risk assessment survey be given at health maintenance visits, and if any questions are answered "yes" or "not sure", blood lead levels should be drawn. The survey should be adapted for known lead risks in each community, but should include at least the following three questions (10):

1) Does your child live in or regularly visit a house or childcare facility built before 1950?

2) Does your child live in or regularly visit a house or childcare facility built before 1978 that is being or recently has been renovated or remodeled?

3) Does your child have a sibling or playmate who has or did have lead poisoning?

In communities where more than 27% of housing was built before 1950 or where more than 12% of 1 and 2 year olds have elevated blood lead levels, all children should have lead levels drawn at age 9-12 months and age 2 years (10).

Acute signs and symptoms of lead intoxication are now rarely seen. Vomiting, abdominal pain, and constipation are nonspecific and common in this age group. Because of prevention, screening, and the use of chelating agents as treatment, encephalopathy, seizure, and coma associated with extremely high lead levels are almost unheard of today. Chronic effects of lead poisoning are more ominous, and include possibly permanent behavioral and cognitive deficits, including decrease in IQ points (11,12). Complete blood counts are often normal in children with low to moderately elevated lead levels. Basophilic stippling, seen as fine blue specks in the RBC membrane under light microscopy, can be prominent. Erythrocyte protoporphyrin is elevated (13). Anemia results from lead's inhibition of enzymes required for hemoglobin synthesis (4), but the microcytic anemia of lead poisoning reported in the past is most likely due to concomitant iron deficiency. Iron deficiency leads to pica which increases risk of lead ingestion, and iron deficiency leads to increased absorption and retention of lead from the GI tract.

Treatment depends on the blood lead level (BLL) in mcg/dL (10):

I. BLL <10 requires no action.

II. Levels of 10-20 require education and action to decrease lead exposure, including frequent hand washing, frequent dusting and mopping, and ideally repair or repainting, followed by repeat BLL in 2-3 months.

III. Levels of 20-44 require a detailed history to identify sources of lead exposure, including hobbies (ceramics), vocations (repair of bridges or boats, plumbing, home building/renovating), and contact (car batteries, contaminated soil). Corrective action must be taken to decrease exposure. Consider a home visit or a referral to the local health department for a detailed environmental investigation and referrals for support services.

IV. Levels of 45-69 require all of the above plus initiation of chelation therapy.

V. Levels of 70 or higher require hospital admission for close observation of mental status and immediate IV chelation.

The anemia of inflammation, also called anemia of chronic disease, is the second most common cause of anemia in children after iron deficiency (14). Initially recognized in patients with chronic inflammatory conditions, it has now been shown to occur in the acute setting, accompanying mild self-limiting illnesses such as otitis media or upper respiratory infections (15). The mechanism of anemia is multifactorial, primarily from decreased RBC production (impaired iron utilization and decreased erythropoietin production and response) but also from decreased RBC survival (16). The degree of anemia is usually mild, with hemoglobin concentrations of 10 to 11 g/dl, but can be moderate with hemoglobins of 8 to 9 g/dl. The red blood cells are usually normocytic but can be microcytic (15). Reticulocyte counts are low. Iron studies, if done, show low serum iron, high serum ferritin, and low TIBC. Bone marrow evaluation would show abundant iron stores. Anemia associated with acute inflammation is usually benign and self-limited, resolving 1-2 months after the infection resolves (15). Children with chronic diseases such as rheumatoid arthritis have a more protracted course; even so, the anemia is rarely significant enough to require treatment. High doses of erythropoietin can correct the anemia in those rare cases (14).

Folate and vitamin B12 deficiency are rarely seen in children. They cause a macrocytic anemia which may be accompanied by granulocytopenia and thrombocytopenia. Hypersegmented neutrophils may be seen on peripheral smear of patients with B12 deficiency. The diagnosis is confirmed by low serum concentration of the vitamins (4). B12 deficiency requires a Schilling test to determine the cause of the B12 deficiency (intrinsic factor deficiency, malabsorption due to inflammatory bowel disease, etc.). B12 deficiency is also associated with neuropathic symptoms.

The thalassemias are a group of inherited disorders of hemoglobin synthesis that cause a microcytic anemia. Aberrant hemoglobins have shortened lifespans, so the anemia may be caused by both decreased RBC production and increased destruction. Thalassemia is fully discussed in a separate chapter.

Anemia from bone marrow failure is usually macrocytic. Causes can be congenital (Diamond-Blackfan anemia, congenital dyserythropoietic anemia) or acquired (aplastic anemia, transient erythroblastopenia of childhood). These are discussed in detail in a separate chapter. Replacement of normal bone marrow by malignancy (leukemia or metastatic tumor) can lead to failure of normal red blood cell production, as can restriction of the marrow space by bone in osteopetrosis.

Destruction of red blood cells, or hemolysis, causes release of intracellular contents into the plasma. Consequently, indirect (unconjugated) bilirubin, LDH, and AST (SGOT) may be elevated. The urine may be dark due to excreted hemoglobin or bilirubin. The reticulocyte count is elevated (18). Haptoglobin, a protein that binds free hemoglobin, decreases. A low serum haptoglobin is diagnostic of hemolysis. If the red cells are destroyed in the spleen (extravascular hemolysis) red cell fragments are not seen, and the peripheral smear shows polychromasia and microspherocytes.

Hereditary Spherocytosis (HS) is the most common cause of hemolytic anemia in children. It is inherited in an autosomal dominant pattern in 75% of cases, but family history is not always positive because of variations in severity even among family members. Abnormal membrane proteins cause a loss of portions of the cell membrane, resulting in a rigid red blood cell with a spherical shape. These cells are trapped in the spleen and destroyed, resulting in hemolytic anemia (17). Patients present with jaundice, anemia, and splenomegaly. The reticulocyte count is elevated, and the MCV is normal. An elevated MCHC strongly suggests HS, as it is rarely elevated in any other condition but is high in 50% of those with HS (18). The peripheral smear usually shows spherocytes, but the degree is variable and depends on smear quality. One cannot rule out HS by a lack of spherocytes reported on a peripheral blood smear. The definitive diagnostic test is the incubated osmotic fragility assay, which shows increased hemolysis to osmotic stress.

Patients with HS can have a "hyperhemolytic crisis", which is an acceleration of the rate of hemolysis brought on by infections. They typically present with increased jaundice, pallor, and hemoglobins in the 5-8 g/dl range during or just after a nonspecific viral illness. Blood transfusions may be required. An "aplastic crisis" can occur following infection with human parvovirus B19, the cause of Fifth disease (erythema infectiosum) (18). This virus stops all red cell production in the marrow. The reticulocyte count falls to 0, and in the

face of continued RBC destruction without RBC production, the hemoglobin falls precipitously to levels of 3-6 g/dl. Timely blood transfusions can get these patients through this one time complication. HS patients whose siblings contract Fifth disease must be followed closely. Treatment consists of educating the family about the disease and instructing them to come in for examination and blood work at the first signs of pallor, increased jaundice, or fatigue. Splenectomy is curative but because of the risk of post-splenectomy sepsis, especially in those under age five, the surgery is reserved for those with more severe disease. Indications include frequent hyperhemolytic episodes, symptomatic anemia leading to limitation of lifestyle, gallstones, or growth retardation.

G6PD deficiency is the most common of the RBC enzyme defects. The enzyme deficiency causes the red blood cells to be more sensitive to oxidative stress (17). Hemolysis ensues, resulting in jaundice and anemia. It is an X-linked disorder and so it mostly affects males, but females can be variably affected due to random inactivation of one X chromosome or they can be homozygous (mother is a carrier and father has G6PD deficiency). The clinical course is marked by episodic jaundice. Prolonged neonatal jaundice is sometimes seen. Older patients may have a history of jaundice, pallor and anemia that accompanies infections or certain drugs or foods. Different individuals and different ethnic groups (Asian, African, Mediterranean) may have different mutations which result in differing G6PD deficiency severities, so the patients may have different susceptibilities to severe neonatal jaundice, kernicterus and acute hemolytic reactions. Laboratory evaluation reveals a normocytic anemia with variable evidence of hemolysis such as increased bilirubin, decreased haptoglobin, and hemoglobinuria. The blood smear shows fragmented cells, schistocytes, and may show characteristic "bite" cells or "ghost" cells. Special stains for Heinz bodies, denatured hemoglobin, may be positive. A specific G6PD assay is available, and if low, is diagnostic. The test may be falsely elevated to normal levels during or just after acute hemolysis due to a high reticulocyte count, so it should be repeated several weeks after the hemolytic event if the diagnosis appears likely (18).

Patients can make auto-antibodies against red blood cell antigens due to autoimmune syndromes, medications, infections (EBV, mycoplasma, or nonspecific viruses), or unknown reasons. The presentation is variable, but characteristic findings of hemolytic anemia are the norm. Blood smears show microspherocytes but schistocytes are not seen. The direct Coombs test is positive. Treatment with corticosteroids usually results in resolution of the hemolytic anemia (4,17). Intravenous immune globulin (IVIg) and splenectomy have been used with success in cases refractory to corticosteroids.

Maternal antibodies against infant red blood cell groups can cross the placenta and cause varying degrees of hemolysis (alloimmune hemolytic disease of the newborn). The clinical picture ranges from mild hyperbilirubinemia to hydrops and death, but is most often benign and self-limited. Observation alone or treatment with phototherapy is usually adequate. This topic is covered fully in the newborn hematology chapter.

With intravascular hemolysis, as seen in disseminated intravascular coagulation (DIC), hemolytic-uremic syndrome and burns, mechanical injury to red blood cells causes hemolysis within the blood vessel rather than in the spleen. Red blood cell fragments (schistocytes) are therefore commonly seen on peripheral blood smears (4). Treatment involves correction of the underlying condition. Because the defect is extrinsic to the red cell, transfused blood is hemolyzed as quickly as is the patient's, and so transfusion is only a temporizing measure.

Sickle cell anemia is a hemoglobinopathy common in African, Caribbean, Middle Eastern, and Mediterranean peoples. A mutation in the hemoglobin molecule causes red cells to take on a rigid sickled shape, causing obstruction of flow through the microvasculature. Complications due to tissue hypoxia and hemolytic anemia can be profound. Sickle cell anemia is discussed fully in a separate chapter.

Questions

1. What two classification schemes can be used to narrow down the differential diagnosis of anemia in children?

2. What laboratory finding suggests that an anemia is due to a decreased production of red blood cells?

3. What elements of the history, physical, and laboratory evaluation suggest increased red cell destruction as the cause of anemia?

4. What is the best test to rule in or rule out iron deficiency? Justify your answer.

5. True/False: A child raised in a lead based paint containing home that is well maintained has a significantly lower chance of lead poisoning than if that home is in disrepair.

6. True/False: Cow's milk exerts a direct toxic effect on the intestinal mucosa of some infants, leading to microscopic blood loss and iron deficiency anemia.

7. True/False: Children with iron deficiency anemia caused by excessive cow's milk intake often have a history of black or tarry stools.

8. True/False: The iron content of cow's milk is zero or very close to zero.

9. The lab reports a patient's hemoglobin as 7 g/dl, and the reticulocyte count as 1%. The published normal value for the reticulocyte count is 0.7% to 2.0%, so the reticulocyte count is within the laboratory's normal range. How would you interpret this reticulocyte count?

a. This reticulocyte count is normal, so the patient's bone marrow is making RBCs adequately.

b. This reticulocyte count is low. The laboratory's normal values are incorrect.

c. This reticulocyte count value is normal for a patient with a normal hemoglobin, but for a severely anemic patient, the reticulocyte count should be high. Thus, in view of this patient's severe anemia, this patient's reticulocyte count is actually low and indicative of a condition in which RBCs are not being produced.

d. This reticulocyte count is too high for a low hemoglobin. Thus, this is indicative of a hemolytic etiology.

Answers to questions

1. Classification by red blood cell size (microcytic, normocytic, and macrocytic anemias) and classification by mechanism (decreased production, increased destruction, and blood loss).
2. Low reticulocyte count.
3. History: dark urine. Physical exam: jaundice, scleral icterus, splenomegaly. Lab: elevated LDH, AST, indirect bilirubin; decreased serum haptoglobin; positive direct antibody test (DAT, also known as Coombs test), high reticulocyte count.
4. Bone marrow stain for iron has the highest positive predictive value and specificity, but it is too invasive in most instances. Low serum ferritin is diagnostic of iron deficiency, but its wide range of normal values and its fluctuation with acute inflammation may make interpretation difficult. Serum iron coupled with TIBC and % iron saturation are satisfactory, but this test is subject to some laboratory fluctuation as well. Response to a therapeutic trial of iron is also acceptable as proof of iron deficiency. No actual correct answer to this question.
5. True
6. True
7. False
8. False. Cow's milk contains a modest amount of iron, but little of it is bioavailable.
9. c

Chapter XI.2. Thalassemia
Kelley A. Woodruff, MD

A 12 month old female of Hawaiian, Chinese, Portuguese and Japanese ethnicity is noted to have a hemoglobin of 9.1 g/dl with an MCV of 58 on a routine CBC screen at her one year well child check up. She is otherwise healthy and has no complaints. PE is normal. On a review of this child's medical record, you note the presence of Hemoglobin Barts on her newborn screen.

Thalassemia is one of the most confusing of the hemoglobinopathies, mostly due to confusing nomenclature, lack of easy diagnostic tests, and its similarity to iron deficiency anemia. Whereas both thalassemia and iron deficiency anemia are characterized by microcytic hypochromic anemias, iron deficiency anemia is easily corrected with iron supplementation, but iron supplementation does not correct the anemia due to thalassemia. In any anemic state, there is increased gut absorption of iron. Even in non-transfused patients, iron overload is often noted in the more severe forms of thalassemia. Since thalassemia is not an iron deficiency problem, it is not be corrected by additional iron. In fact, in thalassemia over time, the body becomes iron overloaded, and iron is "stored" in the organs (liver, endocrine organs and heart), which can cause significant morbidity and mortality.

There are two basic types of thalassemia: alpha thalassemia and beta thalassemia. They have nothing to do with one another. Alpha thalassemia usually results from the deletion of any number of the 4 genes necessary to make alpha globin chains. Occasionally, an alpha globin gene is abnormal instead of being completely deleted. Beta thalassemia usually results from an abnormal gene in one or both of the genes necessary for beta globin chain production. Occasionally, the entire gene (on one allele) is actually deleted. The alpha and beta genes are located on different chromosomes and therefore, abnormalities of each are inherited separately.

Beta thalassemia usually occurs from abnormal beta genes, or less commonly, a deletion of a beta gene. In beta thalassemia, there is a large lack of normal beta chain production, thus causing a relative excess amount of alpha chains, which clump together. This abnormal hemoglobin is very unstable, and leads to erythrocyte death in the bone marrow.

Beta thalassemia minor occurs when only one gene is affected, causing a moderate, lifelong anemia. This typically requires no treatment other than recognition for the purposes of patient education, to avoid supplemental iron, and for genetic counseling.

Beta thalassemia major, historically called Cooley's Anemia, occurs when both genes necessary for beta globin production are affected. Since beta chains are not present in fetal hemoglobin, beta thalassemia does not manifest itself in newborns. Beta thalassemia presents at 6 months of age when adult hemoglobin has replaces fetal hemoglobin. Peripheral anemia, caused by the disease, sends signals to the bone marrow to increase production of erythrocytes (e.g., via erythropoietin), however, erythrocyte production is abnormal (ineffective). This process is called "ineffective erythropoiesis". With time, the marrow cavities (skull bones, facial bones, and ribs) expand, leading to the classical facial features and skull X-ray findings ("hair on end" in untreated patients due to excessive extramedullary hematopoiesis). Erythrocytes that do enter the circulation are noted to be abnormal by the reticuloendothelial system (spleen and liver), and are taken up by these organs with ensuing enormous hepatosplenomegaly. In untreated patients, death usually occurs by the end of the second decade of life from anemia and congestive heart failure.

Currently, part of the standard treatment for beta thalassemia major is lifelong transfusions given every 2-4 weeks. The intent of these transfusions is to keep their hemoglobin trough above 9 or 10 gm/dl. This will, in effect, shut off the patient's own erythropoiesis and stop the vicious cycle of anemia stimulating "ineffective erythropoiesis". With each milliliter of transfused packed red blood cells, the patient receives one milligram of elemental iron. Iron, in addition to being relatively difficult to absorb, is also not easily excreted. Thus, such transfused patients quickly become iron overloaded. Untreated, iron overload will be fatal. Regularly transfused patients need to be on lifelong chelation therapy to help their bodies excrete the excess iron. There are no effective oral iron chelation agents. Currently, most regularly transfused thalassemia patients receive their chelation as a subcutaneous infusion of deferoxamine over 10 hours each night (lifelong). With the combination of transfusion and chelation therapy, life expectancy can to be normal.

A form of alpha thalassemia occurs when any number of the four genes that control alpha globin production are missing, thereby causing an excess of non-alpha globin chains. The various forms of alpha thalassemia with their genetic correlate are listed below:

A. 4 normal alleles (normal)
B. 3 normal / 1 missing gene (silent carrier)
C. 2 normal / 2 missing genes (thal trait)
D. 1 normal / 3 missing genes ("Hemoglobin H disease")
E. 4 missing genes (results in hydrops fetalis)

Silent carriers are 1 missing alpha gene. They have no clinical abnormalities. Their hemoglobin, and hemoglobin electrophoresis are normal and their MCV is borderline normal.

Those with alpha thalassemia trait are clinically normal, but their hemoglobin is slightly low and their hemogram demonstrates microcytic indices. Their hemoglobin electrophoresis is normal unless it is done in the newborn period at which time Hemoglobin Barts is present (recall this finding in the case example at the beginning of the chapter).

Traditionally, people with alpha thalassemia trait are taught that they have a benign condition and no further education is provided. However, it should be emphasized that although the anemia is benign, supplemental iron must be AVOIDED to prevent harmful iron buildup. There is suspected sustained morbidity in persons with thalassemia trait, who are on repeated, or continued iron supplementation. Additionally, such iron supplementation is generally useless, even in menstruating females, as their stores are readily replenished by a greater degree of absorption of dietary iron from the gut. The extra iron is stored in the organs, leading to end organ dysfunction. Additionally, parents with this, so called, "benign" alpha thalassemia trait, can produce offspring with fatal hydrops fetalis if both parents pass on alleles with two defective alpha genes.

The name Hemoglobin H disease is a misnomer. In developed countries with otherwise good medical care, it is not a disease, but rather a condition. People with Hemoglobin H condition can live healthy, long lives. They are not transfusion dependent, as are those with beta thalassemia major. There are some rare variants, such as Hemoglobin H Constant Springs, (the Constant Springs is an abnormal gene, rather than a deletion, named after a U.S. city where it was first identified), that can be dependent on lifelong monthly transfusions. These people are missing 2 genes from one allele, and have the severely dysfunctional Constant Springs gene on the other allele. People with Hemoglobin H need to avoid all forms of supplemental iron, and pregnant women need very close prenatal care for their own health matters. Since the bone marrow of thalassemia patients requires excess folic acid (due to erythroid hyperplasia), most clinicians advise

lifelong supplementation of 1 milligram daily of folic acid to avoid relative folate deficiency. During times of severe illness, or in pregnancy, the hemoglobin may drop significantly below baseline in Hemoglobin H disease, and a transfusion may be recommended. Again, iron is generally not deficient and, thus iron supplementation is not helpful, nor is it appropriate.

When four beta chains clump together, Hemoglobin H is formed. In infants, gamma chains predominate over beta chains, and Hemoglobin Barts (four gamma chains) is formed. Hemoglobin H and Hemoglobin Barts are both useless, with no effective oxygen carrying capacity. There has been a lot of confusion between this abnormal Hemoglobin H (4 beta chains clumped together) and the clinical condition in which 3 alpha genes are missing, called "Hemoglobin H disease or condition". The abnormal Hemoglobin H exists (in varying amounts) in all 4 clinical alpha thalassemia categories. Similarly in newborns, Hemoglobin Barts exists in varying amounts in all alpha thalassemia categories.

Hemoglobin H and Hemoglobin Barts do not cause the degree of ineffective erythropoiesis seen in beta thalassemia. Therefore, the classical "thal facies", "hair on end" skull X-rays, and enormous hepatosplenomegaly, all typical of beta thalassemia, are not seen to such degree in severe alpha thalassemia.

Hemoglobin E results from a single amino acid substitution on the beta globin chains. It is very common in the golden triangle of Laos, Cambodia, and Thailand. In the heterozygous form, it affects one out of three persons in this region. Heterozygous Hemoglobin E by itself is not harmful and causes no anemia. However, when combined with beta thalassemia minor, significant anemia develops over time. Such people usually become transfusion dependent later in the first decade of life, and if treatment is not sought or maintained, early death is most likely. The effects of Hemoglobin E on Hemoglobin H are not clear. Homozygous Hemoglobin E usually causes mild microcytic hypochromic anemia, which resembles alpha thalassemia trait.

Questions

1. In reference to the case presentation at the beginning of the chapter, what is the best approach to an otherwise healthy, asymptomatic 12 month old female with the hemoglobin of 9.1 g/dl (MCV 58) on routine CBC screen and the presence of Hemoglobin Barts on her newborn screen?

a. explain to the parents that the baby may have thalassemia and obtain an electrophoresis.
b. start the baby on Fe supplements and order an electrophoresis.
c. start the baby on Fe supplements, recheck in a month, and if the hemoglobin is not improved then, assume the baby has thalassemia.
d. counsel the family that the baby has a form of alpha thalassemia, and that no immediate other tests or Fe supplements are needed.

2. A 15 year old Filipino female is noted to have a hemoglobin of 10.6 g/dl with an MCV of 65 on routine testing. She reports regular menses lasting 4-5 days each cycle. She has no specific complaints. She is unaware of a family history of anemia. By history, her diet appears to be nutritionally adequate. PE is normal; specifically there is no hepatosplenomegaly, jaundice, or scleral icterus. What is the most appropriate management?

a. start on oral contraceptives and recheck a CBC in two months
b. start on empiric Fe while awaiting results of a hemoglobin electrophoresis and iron studies. Recheck CBC in 2 months if iron was deficient.
c. check for Hemoglobin Barts; if not present start on Fe supplements and recheck CBC in 2 months
d. order a hemoglobin electrophoresis; if Hemoglobin H is not found start on Fe while Fe studies are pending, and recheck CBC in 2 months if iron deficiency anemia was present

3. A newborn Laotian boy is noted to have Hemoglobin E on his newborn screen. He is otherwise well. A family history is not available due to a language barrier. What is the least pertinent issue to be considered here?

a. presence of Hemoglobin Barts
b. hemoglobin at 6 months of age
c. hemoglobin level now
d. the order of the hemoglobins printed on the newborn screen

4. Indicate whether iron supplementation is indicated or contraindicated in each of the following clinical situations.

a. Menstruating female with a hemoglobin of 10.0 g/dl., with no known hemoglobinopathies.
b. Beta thalassemia patient who just lost a modest amount of blood from a scalp laceration. Hemoglobin is 9.5 g/dl.
c. Healthy alpha thalassemia trait male who wants to build up his hemoglobin to run a marathon.
d. Menstruating female with alpha thalassemia trait who has had heavy and prolonged periods for the past year. Her hemoglobin is 8.0 and her iron levels and ferritin demonstrate severe iron deficiency.

5. Some ethnic groups with alpha thalassemia trait have a small risk of hydrops fetalis, but other groups have no risk. How is this possible? (The answer to this question was not stated in the chapter, but it can be answered with exceptionally brilliant thinking.)

Answers to questions

1. Answer is d. Since the child had Hemoglobin Barts on the newborn screen, a form of alpha thalassemia is present. The hemoglobin of 9.1g/dl implies that it is likely Hemoglobin H thalassemia. There is no need to do a hemoglobin electrophoresis, since the type of thalassemia (alpha) is already known. Additionally, Hemoglobin H is so fast moving that it is typically missed on routine hemoglobin electrophoresis, thereby giving "normal" results. In general, therefore, hemoglobin electrophoresis is typically useless in evaluating for alpha thalassemia. This patient and her family should be provided with genetic counseling and education. She should be counseled to avoid supplemental iron, as a true iron deficiency is extremely rare in Hemoglobin H thalassemia. If iron deficiency is ever suspected, iron studies should be done to clearly document a true deficiency before iron supplementation is started.

2. Answer is b. The two most likely etiologies of the anemia in this young lady are iron deficiency or a form of thalassemia. She could most effectively be managed with a trial of iron (for one month). If a repeat CBC shows no change, then either alpha or beta thalassemia should be considered. A hemoglobin electrophoresis would be the next step if the iron trial fails. An increase in Hemoglobin A2 is very suggestive of beta thalassemia. In this case, the mild anemia would indicate a heterozygous beta thalassemia (beta thalassemia minor). Workup may stop there with proper genetic counseling and patient education. If the hemoglobin electrophoresis is normal, or near normal, then alpha thalassemia is the most likely cause.

3. Answer is C. The effects of Hemoglobin E are most significant when combined with beta thalassemia minor (see text), which is why the newborn's current hemoglobin (mostly fetal hemoglobin with no beta chains) is of the least concern. A CBC should be done at 9 or 12 months of age to screen for coexisting beta thalassemia.

4a. Fe is indicated as a therapeutic trial. But if no improvement in the hemoglobin results, then a thalassemia is possible.

4b. Fe is contraindicated since it will not improve the hemoglobin and it will add to the potential for iron toxicity.

4c. Fe is contraindicated, since it will not improve his hemoglobin and it will add to the potential for iron toxicity.

4d. Despite the presence of thalassemia, iron deficiency is documented by laboratory studies, so iron supplementation is indicated until iron deficiency resolves. Once iron deficiency is no longer present, iron supplements become contraindicated.

5. The four alpha genes are not inherited independently. They are inherited in pairs on each chromosome. Thus, a patient with alpha thal trait who has two defective alpha genes and two normal alpha genes could have this in one of two ways: 1) AX/AX, or 2) AA/XX, where "A" is a normal alpha gene and "X" is a defective alpha gene. Some ethnic groups have the genes arranged in the first form only, in which case, two parents with alpha thal trait would always pass AX to their child resulting in a child with AX/AX (alpha thal trait). Fetal hydrops (XX/XX) could never result from such a genetic arrangement. However, if both parents with alpha thal trait were AA/XX, then their children could either be: AA/AA, AA/XX, or XX/XX (fetal hydrops).

Chapter XI.3. Sickle Cell Disease
Kelley A. Woodruff, MD

A 6 year old girl with sickle cell anemia, who is well known to ED personnel, presents with URI symptoms for 2 days, and fever to 38.9 (102 F). The URI symptoms consist of a stuffy nose, no rhinorrhea, and a dry cough, which has not interrupted her sleep. Oral intake has been decreased, but adequate. She has been given acetaminophen and over the counter cold medications. She also takes daily prophylactic amoxicillin.

Exam: VS T37.7, P 100, R 30, BP 98/52. She is nontoxic appearing. She has anicteric sclera, clear conjunctiva, mild clear white nasal discharge, a non-injected pharynx and normal TMs. No cough is heard during the exam. Her lungs are clear to auscultation. Her heart is regular without murmurs. Her abdomen is soft and non-tender to palpation. Her spleen in not palpated below the left costal margin, and her liver is palpated 2 cm below the right coastal margin. There are no rashes or skin lesions, and she moves all extremities well.

A CBC and blood culture are drawn. She is given IV fluids and IV ceftriaxone. Her primary care physician is contacted to discuss the case and to determine whether she should be hospitalized.

There are over 100 known hemoglobinopathies, but sickle cell disease remains the best described and is the prototype for all hemoglobinopathies. Sickle cell disease is a clinically significant condition which involves the sickle cell gene. Several forms of sickle cell disease exist: sickle cell anemia (the homozygous state, also known as SS disease), Hemoglobin SC disease, sickle beta thalassemia, and other rare entities. The heterozygous sickle cell state results in sickle cell trait. Such individuals are asymptomatic and have no significant medical problems. However, it is important for these individuals to be aware of their trait status for purposes of genetic counseling.

Sickle cell disease carries lifelong health considerations. Historically, 10% of children with sickle cell diseases died before their 10th birthday, most often due to overwhelming infection. Survival and morbidity have been unpredictable, largely due to problems with disease recognition and availability of medical care. Therefore, sickle cell diseases are now identified on the newborn screen in almost all states. This permits a proactive approach to the health maintenance of these patients, resulting in less morbidity and mortality.

The gene mutations for both sickle cell and hemoglobin C disease result in a single amino acid substitution on the beta globin chain. The normal beta globin chain has a glutamic acid in the codon 6 position. A valine substitution here results in hemoglobin S, while a lysine substitution in the same position results in hemoglobin C. Both conditions are autosomal recessive. A single sickle cell gene is carried by about 10% of African Americans and the gene for Hemoglobin C is carried by about 2% of African Americans. Sickle cell disease can be easily detected on hemoglobin electrophoresis. The normal hemoglobin electrophoresis in a person greater than 6 months of age shows about 92.5% Hemoglobin A, which consists of 2 alpha globin chains and 2 beta globin chains, and about 2.5% hemoglobin A2 which consists of 2 alpha chains and 2 delta chains. Since the sickle cell gene produces an abnormal beta globin chain, hemoglobin S is comprised of 2 alpha globin chains and 2 abnormal beta globin chains. In the heterozygous state, the normal beta globin gene produces sufficient beta globin chains to produce enough normal hemoglobin A (asymptomatic heterozygous state). Likewise, hemoglobin C

consists of 2 alpha globin chains and 2 abnormal beta globin chains. Both hemoglobin S and hemoglobin C are also easily picked up on the newborn screen, which utilizes methods that separate out and identify various hemoglobins, abnormal and normal alike. Hemoglobin F (fetal hemoglobin) predominates in the normal newborn, and is completely replaced with hemoglobin A by 6 months of age. Hemoglobin F consists of 2 alpha globin chains and 2 gamma globin chains. Since hemoglobin F has no beta globin chains, it is not affected by the sickle cell gene. The normal adult or child produces less than 1% hemoglobin F. On the newborn screen, hemoglobin S is identified quantitatively at birth in its relation to hemoglobin F. If more hemoglobin S than F is present, the child most likely has sickle cell disease. If more hemoglobin F than S is identified, the child likely has sickle cell trait.

Sickle cell anemia occurs when both alleles of the beta globin gene on chromosome 11 are affected by a single amino acid substitution of valine for glutamic acid (resulting in hemoglobin S). Such children produce no normal hemoglobin A. Instead, they produce hemoglobin S. The presence of hemoglobin S within the red blood cells causes an unnatural stiff folding, or sickling of the red blood cell, especially under conditions of oxidative stress. These sickled cells have a tendency to stack up on one another, and thus causes intravascular clogging in the microvasculature. This in turn leads to a vascular occlusion crisis with infarction of local tissue, and severe pain (vaso-occlusive crisis). Hydration is the mainstay of treatment for such crises. The presence of sickle hemoglobin alone, decreases erythrocyte survival leading to chronic hemolytic anemia. It is always important to know a sickle cell patient's baseline hemoglobin when they are well (while not having an obvious vaso-occlusive crisis). The clinical syndromes as a result of this sickling vary depending on whether one is seeing a pediatric or adult patient.

Sickle cell anemia does not present clinically before 6 months of age because of the protective effect from the uninvolved Hemoglobin F. But after 6 months of age, the usual clinical manifestations include infection (usually respiratory), failure to thrive, unexplained fever, and irritability. Before routine newborn screening for sickle cell disease, young children often presented with dactylitis (hand-foot syndrome), which is a swelling of the dorsum of the hands or feet, associated with pallor and fever. Since appropriate and prompt attention is given to symptoms such as fevers, pain, and swelling without a delay in diagnosis, children presenting with dactylitis from sickle cell anemia has become mostly a thing of the past.

The pediatrician is most often confronted with infectious complications of sickle cell anemia. These children are especially prone to bacterial infections such as pneumococcus, Haemophilus influenzae B and Salmonella. Historically, infections have been the primary cause of death during early childhood. Since fevers alone can increase sickling, any febrile child with sickle cell anemia should be given IV hydration to prevent further sickling, and empiric antibiotic therapy should be strongly considered (after appropriate cultures are taken). One reason for the high rate of infections in children with sickle cell disease is that they are functionally asplenic. Because the spleen acts as a sponge for these abnormal sickled cells, subclinical intermittent episodes of intrasplenic vaso-occlusion occur causing local splenic infarcts. Therefore, by the age of 8 years, sickle cell patients are completely functionally asplenic (due to infarction). All sickle cell patients are given prophylactic penicillin, especially during childhood. Additionally, by now identifying children with sickle cell disease at birth, prophylactic pneumococcal vaccine, plus strict attention to the routine childhood vaccinations have been shown to dramatically decrease childhood morbidity and mortality from infection.

Rarely, infants have massive splenic congestion of red blood cells called the splenic sequestration crisis. When this occurs, it is frequently fatal, since it rapidly removes enormous amounts of red blood cells from the circulation, which can lead to circulatory collapse.

A pain crisis is one of the most common reasons for hospitalizing an older child with sickle cell anemia. In a pain crisis, a specific limb or other body part is affected by the vaso-occlusive effects of the sickling cells in the microvasculature. The biggest challenge to the treating clinician in managing this condition, is to administer sufficient analgesia to stop the pain. This is problematic for a variety of reasons: fear of narcotic addiction on either the family's part or the caregiver's part, belief that the pain cannot be controlled completely, belief that some patients exaggerate their pain, and lack of quick access to appropriate analgesics. Success in treating a painful crisis is reached when the analgesic is effective in stopping the pain. Standard doses of analgesics may not be sufficient. Many painful crises can be managed at home with oral analgesics and oral hydration. However, other such crises require IV hydration and IV narcotic analgesics. In these cases, a continuous infusion of a narcotic such as hydromorphone (Dilaudid) with a PCA (patient controlled analgesia) pump is far superior to a "Q 3 hour prn pain" regimen. Meperidine (Demerol) should never be used because patients receiving this have a higher incidence of seizures. There is presently no role for serial intramuscular analgesic injections for pain management.

Acute chest syndrome is another common reason for hospital admission in the older child. Clinically, this is an acute pneumonia-like illness characterized by fever, dyspnea, chest pain, and fatigue. It is usually caused by local pulmonary infarction from vaso-occlusive sickling. Often, acute chest syndrome is complicated by Mycoplasma pneumonia.

Another unique complication of sickle cell disease is aplastic crisis, especially erythroid aplasia. This is often the direct result of human parvovirus infection. Other complications of sickle cell disease include devastating cerebral strokes, leg ulcers, bone infarction, bone marrow hyperplasia, priapism, gallstones, biliary tract disease, or splenic sequestration crisis in the young child.

Hydration is the mainstay of treatment for vaso-occlusive crises, pain crises, strokes, and infections associated with sickle cell disease. Vigorous intravenous hydration should be given to the very young child (<5 years). Above this age, outpatient oral hydration can be considered for mild complaints only. Intravenous hydration with at least twice maintenance fluids, after deficits are corrected, is mandatory in treating dehydration, and strongly recommended in all other situations.

Prevention of the clinical symptoms associated with sickle cell anemia is not considered a universal goal because, unlike other hemoglobinopathies, the clinical course of each patient is unpredictable. An individual patient can go for years without any significant problems, and then have many crises for months or years. Allogenic bone marrow transplantation (from an unaffected donor) would cure the patient of sickle cell disease, but such a transplant is done most safely in infancy, before one knows what that individual's sickle cell course, and its morbidity, will be. Allogenic transplantation carries its own serious morbidity (graft versus host reaction, immunosuppression, etc.), thus it is impossible to predict the risk/benefit ratio for an individual patient. Bone marrow transplantation in an older child would only be considered in the presence of significant morbidity from sickle cell disease itself. However, at that point, end organ tissue damage has occurred, further increasing the morbidity of transplantation. Thus, allogenic bone marrow transplantation is not a good strategy for sickle cell disease.

It has been shown that patients with sickle cell anemia become clinically asymptomatic if the amount of Hemoglobin S in the circulating blood is less than 30%. One way to accomplish this is to transfuse children with normal red blood cells, thereby diluting down their amount of Hemoglobin S, and also shutting off their own hematopoiesis to a large degree. Thus, children with significant morbidity can be placed on a transfusion protocol, in which patients are transfused about every 2 to 4 weeks, indefinitely. The goal of transfusion therapy is to lower the percentage of hemoglobin S to <30% at all times, and to keep the hematocrit below 46%, reducing blood viscosity. With this, there is no further clinically significant sickling. The main hindrance to a transfusion protocol is iron overload. Without chelation, iron overload is eventually fatal (due to hemochromatosis). Currently, chelation involves nightly 10 hour subcutaneous

infusions of deferoxamine as long as the transfusions continue. Poor compliance is an issue, especially in the teen years. Additionally, alloimmunization to blood products can develop in some patients. This creates greater difficulty in obtaining compatible blood products causing a higher incidence of delayed hemolytic reactions.

Other methods to decrease the relative amount of hemoglobin S are currently under investigation. Such methods are met with only varied individual success. Hydroxyurea has been shown to increase the percentage of Hemoglobin F (which lacks abnormal beta globin and does not sickle), thereby creating a relative decrease of Hemoglobin S. This is an oral medication with few other side effects and would seem to be an attractive therapeutic option. Unfortunately, it has not been shown to be consistently effective in reducing either the frequency or severity of symptoms in these patients.

Children with hemoglobin SC disease have one beta-C mutation on one allele and one beta-S mutation on the other. Hemoglobin SC disease is typically associated with milder and less frequent vaso-occlusive events compared to sickle cell anemia. However, like sickle cell anemia, the clinical course can be quite variable. Typically, patients go for years between clinically significant events. They usually have a higher hematocrit than those with sickle cell disease, as they have a less chronic hemolysis. Children with SC disease should receive the same prophylactic care as those with sickle cell anemia.

Likewise, sickle beta thalassemia, in general, is associated with milder symptoms than sickle cell disease, although the clinical severity depends on the type of beta anomaly present. If the beta gene is deleted, the degree of morbidity is similar to patients with homozygous sickle cell disease. If the beta gene is present but abnormal, then the clinical severity tends to be milder, comparable to SC disease.

Questions

1. Of the following, what is the best approach for a febrile child with sickle cell disease?
   a. CBC, BC, oral hydration, IM or oral antibiotics if source of infection is noted on PE.
   b. CBC, BC, IM ceftriaxone, follow-up with PCP next day.
   c. CBC, BC, admit for IV hydration and IV antibiotics.
   d. CBC, BC, no oral antibiotics if no specific source of infection is noted on PE.

2. A 13 year old girl with sickle cell anemia is admitted to the hospital for treatment of a pain crisis. She states her right arm and shoulder started hurting yesterday evening. She has taken acetaminophen with codeine every 3 hours for the last 8 hours, but the pain has only escalated. She denies recent fevers, cough, or URI symptoms. She is on no routine pain medications at home, and was last admitted 5 months ago with a similar pain crisis. On PE, she is in obvious pain, and is crying. Her exam is remarkable for pallor, and slight scleral icterus. She has full range of motion of the right arm, and the rest of her joints. CBC shows a hemoglobin of 7.9 g/dl, WBC 17.8, and platelet count of 543 thousand. Appropriate initial management includes:
   a. IV hydration if oral intake is insufficient, IV or PO pain management as needed.
   b. IV hydration, hydromorphone PCA plus continuous infusion.
   c. IV hydration, IM meperidine prn.
   d. IV hydration, transfusion of PRBC, IV narcotic q 4 hours prn.

3. Explain why most states have adopted newborn screens that identify sickle cell disease at birth.

4. Explain why children with sickle cell disease do not develop symptoms until after 6 months of age?

5. Will a child with sickle beta thalassemia be identified as such on its newborn screen? Why or why not?

Answers to questions

1.c. This fever is significant, thus there will be an increase in sickling, and the patient is at risk for vaso-occlusive events. Therefore, IV hydration is necessary. It is also prudent to start empiric antibiotics after blood cultures are obtained.

2.b. Appropriate initial management should include vigorous IV hydration, plus IV pain management to include both a continuous infusion and a PCA. One would not transfuse initially, because a transfusion of packed red blood cells will only increase the viscosity of the blood, causing more sickling. Also, one does not know at this point, what the baseline hemoglobin is. The hemoglobin of 7.9 g/dl may not be very different than baseline. If there is further hemolysis, and a transfusion is indicated, it should be done carefully after several hours of IV hydration. Also, remember that meperidine increases seizure activity in children with sickle cell anemia, and is contraindicated.

3. It has been shown that a proactive approach to sickle cell disease decreases morbidity and mortality. Therefore, by identifying all children with sickle cell disease at birth, before symptoms start (usually after 1 year of age), quality of life can be improved.

4. Only after 6 months of age is gamma globin chain production decreased and beta globin chain production sufficient to cause sickling.

5. No. Both beta and sickle anomalies are on the beta globin gene. The newborn screen will identify the sickle hemoglobin, but will not identify the abnormal beta globin genes. The newborn screen will therefore appear as that for sickle cell trait with Hemoglobins F,A, S.

Chapter XI.4. Bone Marrow Failure
Desiree Medeiros, MD

This 2-1/2 year old male is referred to the pediatric hematologist with a chief complaint of easy bruising, nosebleeds and decreased activity for one week. He has no history of fever or appetite changes. His past medical history is unremarkable. There is no travel history, history of recent illnesses, or known exposure to toxins.

Exam: He is a well developed, well nourished, pale boy in no acute distress. His conjunctivae are pale. Sclera are anicteric. TMs are normal. His oral mucosa is moist and shows rare petechiae on the buccal mucosa. He has some small palpable posterior cervical lymph nodes. He has a sinus tachycardia with a grade I/VI systolic ejection murmur, without a gallop. His lungs are clear to auscultation. His abdomen is soft and nontender with normoactive bowel sounds. He has no palpable masses, hepatosplenomegaly, or inguinal hernias. His penis and testes are normal (no masses). He has no rashes, but he has ecchymoses present on his left shoulder, chin and both lower extremities. Petechiae are present on his extremities and groin.

Labs: Hemoglobin 7.9 g/dl, hematocrit 24%, platelet count 12,000, WBC 3,000 with 90% lymphocytes (absolute neutrophil count 210). Reticulocyte count 0.5%. A bone marrow aspirate and biopsy show a markedly hypocellular marrow (12% cellularity) with decreased megakaryocytes and erythroid and myeloid precursors. Bone marrow cytogenetics are normal. A diepoxybutane test shows no increase in chromosome breakage. Ham's acid serum test is normal. Serology for CMV, EBV, parvovirus, and hepatitis demonstrates no recent infection.

He is diagnosed with severe acquired aplastic anemia. One of his sisters is a perfect 6 out of 6 HLA match and he undergoes a matched related bone marrow transplant.

Bone marrow failure is a decreased production of one or more cell lines (erythrocytes, granulocytes, and/or platelets) in the bone marrow resulting in peripheral blood cytopenia. These disorders can either be inherited or acquired. The inherited cytopenias are due to a genetic abnormality and may be associated with congenital physical anomalies. The acquired cytopenias may be due to exposure to a toxin, infectious agent (however, a causal agent is usually not identified), or invasion of the bone marrow by a neoplastic process.

The most common type of bone marrow failure not due to neoplastic causes, is aplastic anemia. Acquired aplastic anemia results from an injury to the bone marrow by radiation, drugs (chemotherapy, antibiotics, such as chloramphenicol), insecticides, toxins (benzene, carbon tetrachloride), or infection (hepatitis, HIV, CMV, parvovirus) (1). However, most cases of acquired aplastic anemia are without an identifiable cause (idiopathic). The onset of symptoms is gradual. Signs and symptoms include pallor, fatigue, weakness, loss of appetite, easy bruising, petechiae, mucosal hemorrhage, and fever. Laboratory evaluation demonstrates a normocytic or macrocytic anemia, reticulocytopenia, leukopenia, and thrombocytopenia. A bone marrow biopsy is essential to make the diagnosis and typically shows depression or absence of hematopoietic elements with fatty infiltration of the marrow (2). Severe aplastic anemia is defined as pancytopenia with an absolute neutrophil count <500, platelet count <20,000, reticulocyte count <1%, and <25% bone marrow elements on bone marrow biopsy (2,3).

Without treatment, acquired severe aplastic anemia carries a high mortality rate, with deaths occurring within a year of diagnosis. These are usually due to fatal infection or hemorrhage (2). Supportive care (intravenous antibiotics and transfusion support) has improved outcomes. Early stem cell transplantation with an HLA matched donor is the treatment of choice for severe aplastic anemia (1,2). When transplantation is an option, blood product support should be used sparingly to reduce the risk of sensitization and graft rejection. When stem cell transplantation is not feasible, immunosuppressive therapy with high dose corticosteroids, anti-thymocyte globulin and cyclosporin A is an alternative (1,2).

Fanconi's anemia is inherited in an autosomal recessive pattern (4). Classically, patients have pancytopenia and characteristic congenital anomalies. These include hyperpigmentation and/or cafe-au-lait spots on the trunk, neck and intertriginous areas, short stature, upper limb abnormalities, hypogonadism, skeletal anomalies, eye or eyelid changes, renal malformations, and more rarely, deafness, gastrointestinal and cardiopulmonary malformations. Blood counts start to decrease between 4 and 12 years of age. This usually presents with thrombocytopenia followed by neutropenia then anemia. Severe aplastic anemia develops months to years after initial CBC changes. MCV is often >100 fl. Fetal hemoglobin and i-antigen (an antigen on immature red cells) are increased. Macrocytosis, fetal hemoglobin and the i-antigen are manifestations of a stressed bone marrow. Bone marrow shows patchy hypoplasia. The diagnostic test for Fanconi's anemia is a chromosome breakage analysis using clastogenic agents such as diepoxybutane or mitomycin C (1,4). A high proportion of cells will show chromosomal breaks. Children with Fanconi's anemia have a higher incidence of acute leukemia, squamous cell carcinoma, and hepatocellular carcinoma (4). Therapy consists of supportive care with transfusions and/or antibiotics for infection. Some patients respond to corticosteroid and androgen therapy (4). Stem cell transplantation from a matched sibling donor, or from an unrelated donor if a sibling donor is not available, is recommended in patients who are not responsive to corticosteroid and androgen therapy.

Diamond-Blackfan anemia (DBA) or congenital pure red cell aplasia is usually inherited in an autosomal dominant pattern (5). Infants present in the first 3 months of life with pallor and poor feeding. Associated physical anomalies are present in 25% of patients and include short stature, craniofacial abnormalities (hypertelorism, flat nasal bridge, and high or cleft palate), thumb abnormalities, skeletal anomalies, deafness, learning difficulties, and renal and cardiac abnormalities (1,5). CBC reveals a normocytic or macrocytic anemia with reticulocytopenia. White cell and platelet counts are normal. Fetal hemoglobin is elevated on hemoglobin electrophoresis and i-antigen is expressed on RBCs. Erythrocyte adenosine deaminase levels are high. Chromosome studies are normal. Bone marrow is cellular with isolated reduction of red cell precursors (1,5). Corticosteroids remain the mainstay of therapy for DBA. Up to 70% of patients have a good initial response to oral corticosteroids (5). The dose can be individualized according to response. However, about one-half of patient with DBA require chronic transfusions, either because they did not respond to corticosteroids or because they developed significant side effects. Rarely, spontaneous remission occurs. Other therapies, such as erythropoietin, interleukin-3, cyclosporin A, intravenous immune globulin, androgens, or splenectomy have been used but have not shown consistent benefit (5). Stem cell transplantation is potentially curative.

Transient erythroblastopenia of childhood (TEC) is an acquired red cell aplasia which occurs in healthy children between 6 months and 5 years old (5). The onset is usually at an older age than that seen in DBA. These children present with a gradual onset of symptoms of anemia, such as pallor and decreased activity. The physical examination is unremarkable except for pallor and tachycardia. A complete blood count (CBC) shows a normocytic normochromic anemia with hemoglobins ranging from 3 to 8 g/dL (5). The reticulocyte count is extremely low. White blood cell and platelet counts are usually normal. Bone marrow examination is not necessary but reveals erythroid hypoplasia (5). Chemistries, such as LDH, bilirubin, and haptoglobin, are normal. During recovery, the reticulocyte count and RDW rise.

RDW (measurement of the distribution width of red cells) rises when there is a spectrum of older (smaller) and younger (larger) red cells. Spontaneous recovery occurs within weeks to months. Recurrence of TEC is rare. Packed red blood cell transfusion may be necessary in patients who exhibit associated cardiac compromise, but is usually not necessary since the onset of the anemia is gradual (5).

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired disorder characterized by hemolytic anemia, thrombosis and progression to pancytopenia (6). It is rarely seen in the pediatric population but should be considered in any child with anemia and "dark urine". The classic presentation is paroxysmal episodes of hemolysis, hemoglobinuria and abdominal and back pain. Pain is due to intravascular hemolysis or small vessel thrombosis. Diagnosis is confirmed by laboratory testing designed to show RBC sensitivity to complement lysis. The Ham's (acid hemolysis) and sugar-water lysis tests show selective lysis of PNH RBCs (3,6). Therapy is controversial. Corticosteroids seem to decrease hemolysis in adult patients (6). Iron supplementation may be necessary because of significant daily iron losses. However, it is thought to exacerbate hemolysis (6). Long term anticoagulation to prevent thrombosis may be required. Stem cell transplantation may play a role in patients with markedly hypoplastic marrows.

Dyskeratosis congenita is a rare X-linked recessive disorder characterized by the triad of: 1) hyperpigmentation of the face, neck and shoulders, 2) mucous membrane leukoplakia, and 3) dystrophic nails (3). Approximately 50% of patients will develop refractory pancytopenia and severe bone marrow hypoplasia. They are also at risk of developing acute myeloid leukemia (3). Stem cell transplantation is an effective therapy.

Thrombocytopenia with absent radii (TAR) is usually diagnosed at birth because of the characteristic physical finding of bilateral absence of the radii and presence of thumbs. These infants also present with petechiae and bloody stools. Associated problems include additional bony deformities, facial hemangiomas, congenital heart disease, and cow's milk allergy (1,7). The platelet count is typically below 50,000 at diagnosis (1,7). Bone marrow studies demonstrate markedly decreased or absent megakaryocytes and normal erythroid and myeloid cell lines. TAR has an autosomal recessive inheritance pattern. The risk of hemorrhage is greatest in the first year of life with mortality being due to intracranial or gastrointestinal hemorrhage (1). Therapy includes platelet support for bleeding symptoms and as prophylaxis for infants with severe symptomatic thrombocytopenia. Dietary modifications are required for those with cow's milk allergy. The prognosis for patients with TAR is very good. After the first year of life, the platelet count rises to above 100,000 which is adequate for necessary orthopedic intervention (1).

Bone marrow infiltration due to leukemia or diseases metastatic to the bone marrow potentially results in pancytopenia by crowding out the normal bone marrow elements. Patients will often first present with symptoms related to the suppression of one or more of the cell lines (RBCs, WBCs, or platelets). Patients present with lethargy (from anemia), bruising and bleeding (from thrombocytopenia) and/or unexplained fever. They may also complain of bone pain or present with a limp. A CBC shows pancytopenia or anemia, thrombocytopenia and leukocytosis. Depending on the underlying malignancy, the physical examination, and laboratory or radiographic studies will demonstrate other abnormalities.

Questions

1. What is the treatment of choice for severe acquired aplastic anemia?
2. What laboratory study is diagnostic for Fanconi's anemia?
3. How can one differentiate between Diamond Blackfan anemia and transient erythroblastopenia of childhood?
4. What is the triad associated with dyskeratosis congenita?
5. Which two factors are associated with gastrointestinal hemorrhage in infants with TAR syndrome?
6. Name some viruses and drugs which cause aplastic anemia?
7. What is the i-antigen and what hematologic problems is it associated with?

Answers to questions

1. Stem cell transplantation from a matched sibling donor or other compatible stem cell source.
2. Diepoxybutane induced chromosome breakage (increased in patient with Fanconi's anemia).
3. Diamond Blackfan anemia presents at an earlier age (<1 year) and may have associated physical anomalies. At diagnosis, MCV, hemoglobin F and i-antigen are increased. TEC presents at an older age (>1 year). Since it is acquired, there are no associated anomalies. MCV, hemoglobin F and i-antigen should be normal.
4. Skin hyperpigmentation, mucous membrane leukoplakia, dystrophic nails.
5. Cow's milk allergy and thrombocytopenia.
6. Viruses: hepatitis, HIV and parvovirus. Drugs: Chemotherapy, chloramphenicol.
7. The i-antigen is a marker found on immature red cells. It, along with fetal hemoglobin and macrocytosis are manifestations of the fetal-like hematopoiesis seen in the stressed bone marrows of patients with acquired aplastic anemia, Fanconi's anemia, and Diamond Blackfan anemia.

Chapter XI.5. Newborn Hematology
Robert W. Wilkinson, MD

This is a newborn female born to a 17 year old gravida 1, para 0, B+, mother at 39 weeks gestation. Maternal risk factors include a kidney infection in the second trimester. All other risk factors are negative. After an uneventful vaginal delivery, the infant is discharged at two days of life breast feeding at home. On the third day of life, moderate jaundice is noted and a bilirubin in the primary care doctor's office is 18. Home phototherapy is started, but on day six, the bilirubin is 22.9 with the direct component of 0.4. She is hospitalized for inpatient phototherapy. Her hemoglobin was 15.7 earlier, and it has now dropped to 13.4. The bilirubin continues to rise to 25.6 in spite of phototherapy. A G6PD is normal and the reticulocyte count is 3.1. Stools are negative for occult blood. The blood smear shows moderate aniso and poikilocytosis.

She is transferred to a tertiary pediatric center where she is noted to be normal except for marked jaundice. Her mother is of German decent and her father is Caucasian and Puerto Rican. Her mother was treated for newborn jaundice due to presumed ABO incompatibility. Others in her family also had neonatal jaundice. The father's history is unremarkable. No other family member had neonatal jaundice or anemia or gallstones.

Upon admission, vital signs are normal. She is visibly jaundiced and a spleen tip is palpable. Labs show a bilirubin of 25, white count of 17.5, platelets of 230,000 and an unremarkable differential. The hemoglobin is now down to 10.7 in spite of a reticulocyte count of 4%. In addition, the smear now shows moderate schistocytes with burr cells and moderate spherocytes. Blood type is B+ and the Coombs is negative. She is transfused and phototherapy continues until the bilirubin falls to 12. The infant has an otherwise uneventful course in the hospital and the final diagnosis is hyperbilirubinemia and anemia due to hereditary spherocytosis. In addition, alpha thalassemia trait is found on her newborn screen. Incubated red cell osmotic fragility studies on the mother and other maternal family member are consistent with hereditary spherocytosis.

At the moment of birth, the physician can be confronted with complex hematologic problems seen at no other time in life. Newborn red cells are much different than in older children and white cell and platelet disorders can be quite unique. Coagulation factors are abnormal and hemostasis can be markedly altered. Normal values for most newborn blood tests are different compared to children and adults. Interpretation of results in term and premature newborns can be critical.

Significant red cell disorders in the newborn period may be associated with a family history of anemia, jaundice, falling hemoglobin and reticulocytosis in addition to abnormal RBC morphology. The presence of surface antibodies (e.g., anti-A and/or anti-B) may be helpful or the deficiency of intraerythrocytic enzymes (e.g., G6PD deficiency). Finally hemoglobinopathies and thalassemia may offer an almost infinite combination of symptoms and signs in the newborn. Virtually all red cell problems are isolated and the rest of the hemogram is normal. Marrow failure resulting in pancytopenia with associated infections and altered hemostasis is vary rare. Definitive studies on red cells can be delayed for three months when the infant is well and their blood volume is larger. As in the above case, studies of maternal family members subsequently confirmed the diagnosis of hereditary spherocytosis. It is important to remember that in the perinatal period (28 weeks gestation to 28 days after birth) there are normal physiologic changes occurring in red cells. Some of these changes include switching from fetal to adult hemoglobin production, a 30% drop in hemoglobin, a fall in mean red cell volume (MCV) as well as changes in membrane pliability and intracellular enzyme levels. RBC survival is further impacted by acquired infections, medications, and other high-risk conditions. Repeated monitoring of hemoglobin and reticulocyte counts is warranted in the sick and unstable newborn.

Hydrops fetalis results from severe intrauterine hemolysis and anemia necessitating emergency exchange transfusion. The cause is usually due to severe alpha thalassemia, red cell surface antibodies or congenital infections. Rh incompatibility usually presents with rapid hemolysis and varying degrees of anemia and jaundice (depending on the extent of maternal sensitization and antibody production).

White blood cell abnormalities may be asymptomatic and incidental or associated with fever, infection, and altered host resistance. Wide fluctuation in the WBC count can be noted depending on marrow production of granulocytes. Infection, antibodies, and medications call all affect the circulating neutrophil pool. This is the pool of granulocytes sampled with a venipuncture. Interpretation of a peripheral WBC count can be difficult when trying to determine the risk of infection or underlying pathophysiology. A bone marrow examination can be very helpful in assessing granulocyte production and the risk of infection. Most WBC aberrations are secondary or reactive to a disease process, but occasionally rare hereditary disorders can present in the neonate. These are usually associated with an increased risk of infection (e.g., chronic granulomatous disease) or as part of a recognizable syndrome (e.g., Jobs syndrome). Congenital leukemia is extremely rare but striking leukemoid reactions can occur. Of note is the transient myeloproliferative condition or pseudoleukemia that may be observed in neonates with Down syndrome. Of prime importance when evaluating infants with any white cell aberration is the real risk of infection and the need for antimicrobials.

Platelet problems in the newborn present almost exclusively with thrombocytopenia and bleeding. Thrombocytopenia can be isolated or associated with other cytopenias. A low platelet count results from either decreased production or peripheral consumption of platelets. By examining the bone marrow and/or the mean platelet volume (MPV usually higher in younger platelets seen in consumptive disorders), the underlying pathophysiology can usually be identified. Most thrombocytopenias are consumptive and due to maternal antiplatelet antibodies, congenital infections, or part of complex DIC seen in sick newborns. It is paramount to compare the amount of clinical bleeding to the degree of thrombocytopenia in order to quickly make the right diagnosis and determine the need for transfusion or other therapy.

Hemorrhagic disease of the newborn is usually seen from day 2 to 4 of life resulting from vitamin K deficiency and the subsequent failure to produce clotting factors II, VII, IX and X. The prothrombin time is markedly prolonged and serious life threatening hemorrhaging can occur in many organ systems. This transient deficiency of vitamin K is thought to result from poor placental transfer, marginal content in breast milk, inadequate intake of breast milk and a sterile gut (lack of vitamin K producing GI flora). Hemorrhaging can be prevented by the intramuscular administration of prophylactic vitamin K shortly after birth.

Questions

1. True/False: Newborns with Down syndrome and elevated white counts and immature forms frequently progress to leukemia.

2. True/False: Factor VIII deficiency is on the vitamin K dependent factors leading to Hemorrhagic disease of the newborn.

3. Rh antibodies in mothers can result from:
    a. previous mismatched transfusions
    b. prior miscarriages
    c. fetal maternal transfusion
    d. all of the above.

4. True/False: Red cell problems are usually seen with abnormalities of white cells and platelets.

5. True/False: Neonatal immune thrombocytopenia can result from maternal auto sensitization or fetal maternal transfusion.

6. True/False: Thalassemia and hemoglobinopathies can present in the neonatal period with severe anemia.

Chapter XI.6. Bleeding Disorders
Desiree Medeiros, MD

This 4 year old female is referred to the hematology department with a chief complaint of acute onset of easy bruising and "rash" for 3 days. She has not had epistaxis, oral bleeding, gross blood in urine or stools. She has never had palpable bruises, hemarthroses or deep muscle bleeds in the past. She has no history of fever or appetite changes. She had upper respiratory infection symptoms approximately 2 weeks ago. There is no travel history. She has 2 older brothers, neither of whom have had bleeding symptoms. Family history is negative for frequent nosebleeds, oral bleeding, menorrhagia or excessive bleeding with surgery or trauma. There is no history of malignancies, or autoimmune disorders.

Exam: VS are normal. Height and weight are at the 50th percentile. She is a healthy appearing, cooperative girl in no acute distress. HEENT exam demonstrates no signs of bleeding or bruising. Heart and lung exams are normal. Her abdomen demonstrates no hepatosplenomegaly. A diffuse petechial rash is noted on her neck, trunk, extremities and groin. Nonpalpable ecchymoses of varying ages are present on shins and arms. Her neurologic examination demonstrates no deficits.

CBC shows Hgb 12.8, Hct 38.5, WBC 6,000 with a normal differential. Platelet count is low at 5,000. PT and PTT 12.0 and 32 seconds, respectively. Review of the peripheral smear shows normal morphology of red and white blood cell lines. The platelets are reduced in number and the majority of them are increased in size. A bone marrow aspirate is not performed.

She is diagnosed with immune thrombocytopenic purpura. She is followed closely with weekly CBCs. Her bruises and petechiae fade by her next visit and her platelet count returns to 240,000 one month later.

Bleeding disorders can either be inherited or acquired and are due to defects in either primary or secondary hemostasis. While evaluating a child with a bleeding tendency, the history and physical examination should be directed at differentiating between these. An appropriate history can be more helpful in evaluating these children than any laboratory test. Bruising with or without preceding trauma can be due to a defect in either primary or secondary hemostasis although deep palpable bruises are usually due to a clotting factor defect. Petechiae are usually due to a platelet or blood vessel defect. One should ask about a history of mucosal bleeding (including epistaxis, oral bleeding, gastrointestinal, genitourinary and menstrual bleeding), bleeding from injury or following procedures such as circumcision and tonsillectomy, and deep tissue or musculoskeletal bleeding. Age of onset, frequency and severity of each bleeding complaint should be determined and an extensive family history and medication history should be obtained.

The child should be examined for signs of bleeding, such as petechiae, bruising, mucosal bleeding, and oozing from venipuncture sites. Differentiate between superficial bruises and deep palpable ecchymoses, making note of their location. Special attention should be made to the joints and large muscle areas, looking for deep tissue bleeding.

Laboratory studies assist in confirming suspicions raised from the history and physical. Routine screening laboratory studies should include complete blood count (CBC) with a platelet count, prothrombin time (PT) and activated partial thromboplastin time (PTT). Further specific testing should be performed based on the working diagnosis. These include a PTT mixing study (which helps differentiate a factor deficiency from an acquired inhibitor), bleeding time, factor assays, von Willebrand studies, and platelet aggregation tests. The bleeding time is an uncommonly ordered test during which a standardized small laceration is created on the patient's forearm and the time for the bleeding to stop is measured and compared to standard times. This test is prolonged in conditions of thrombocytopenia and platelet dysfunction. Platelet aggregation studies are special studies that can be done to test the aggregation of platelets in response to several known agents which induce platelet aggregation in vitro such as adenosine diphosphate (ADP), epinephrine and collagen.

The more commonly encountered bleeding disorders are discussed in further depth in this chapter.

I. Primary Hemostasis (platelets)
   A. Quantitative (thrombocytopenia)
      1. ITP
      2. Hemolytic uremic syndrome (HUS)
      3. Thrombotic thrombocytopenic purpura (TTP)
      4. Medications
      5. Marrow failure (leukemia, aplastic anemia)
      6. Platelet sequestration, consumption and dilution
   B. Qualitative (poor platelet function)
      1. Inherited platelet aggregation defect
      2. Drug effect
II. Secondary Hemostasis (coagulation)
   A. Congenital factor deficiency
      1. Hemophilia A and B
      2. von Willebrand disease
      3. Other factor deficiencies (rare)
   B. Acquired factor deficiency
      1. Vitamin K deficiency
      2. Liver failure
   C. Antiphospholipid antibody

Defects in Primary Hemostasis

Quantitative platelet disorders result in thrombocytopenia, either due to decreased bone marrow production or increased platelet destruction.

Immune Thrombocytopenic Purpura

Immune or idiopathic thrombocytopenic purpura (ITP) is one of the most common acquired bleeding disorders of childhood. Usually, it is a benign, self-limited disease that occurs in previously healthy children. The typical course in an untreated child is resolution of bleeding symptoms 3 to 10 days after diagnosis, regardless of the platelet count and an increase in the platelet count within 1 to 3 weeks. The platelet count returns to normal in 4 to 8 weeks in approximately half of patients and two thirds of children have resolution by 3 months after diagnosis. By 6 months, platelet counts have returned to normal (>150,000 per cubic mm) in 80% of patients. The remainder are defined as having chronic ITP (1,2). Most children follow a course consistent with acute ITP, in which the platelet counts are very low, but they recover as noted above. Adults more commonly follow a course consistent with chronic ITP, in which the platelet counts are usually moderately low, but the thrombocytopenia persists for long periods of time and often for life. If patients with chronic ITP sustain significant consequences from recurrent bleeding, a splenectomy is sometimes necessary to raise their platelet count.

ITP is an immune-mediated disorder in which circulating antiplatelet antibodies target epitopes on the platelet membrane (1). The antibody-coated platelets are subsequently destroyed by macrophages in the reticuloendothelial system. Children with ITP present with sudden onset of bruising, petechiae and occasionally epistaxis. There may be a history of a preceding viral infection or a recent live-virus immunization (1). There should be no evidence of other disorders causing thrombocytopenia, such as systemic lupus erythematosus or HIV infection. These children appear well except for bruises and petechiae. A minority of patients have mucous membrane hemorrhage, such as menorrhagia, gastrointestinal bleeding or oral blood blisters. They do not have jaundice, pallor, or hepatosplenomegaly.

The most important laboratory assessment in the evaluation of ITP is the CBC and peripheral blood smear. The platelet count is typically very low (<20,000 per cubic mm) and unless there is appreciable bleeding, the hemoglobin concentration is normal as is the leukocyte count. The peripheral smear shows normal morphology of all cell lines except the platelets are reduced in number and tend to be large. PT and PTT are normal and do not need to be performed. The bleeding time is predictably prolonged and unnecessary in the evaluation of a child with ITP. When indicated by the medical history and physical examination, evaluation for HIV, systemic lupus erythematosus, or Evan's syndrome should be considered. Bone marrow aspiration should be considered in patients with lymphadenopathy, hepatosplenomegaly, or other abnormalities on the CBC.

Management of ITP in a child includes education and reassurance of the child's parents. The child's activities should be limited, and aspirin and NSAID containing medications should not be used. Children without significant clinical bleeding may be closely observed with CBCs once or twice weekly. Once the platelet count begins to increase, it may be measured every 2 to 3 weeks until it returns to normal (>150,000). Once the platelet count has normalized, recurrence is rare and follow-up platelet counts are unnecessary (1,2). A few children with ITP have bleeding significant enough to warrant medical management. Standard therapy options include oral or IV corticosteroids (which block the reticuloendothelial system's destruction of antibody-coated platelets and reduce synthesis of antiplatelet antibodies), IVIG (IV gamma globulin which inhibits Fc receptors on phagocytes, allowing antibody-coated platelets to circulate and alters T-lymphocyte subsets and B-cell function and reduces autoantibody production), and Anti-D (which is the anti-serum against the Rh(D) antigen on erythrocytes and by coating Rh(D) positive erythrocytes, it decreases platelet destruction).

Hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP)

HUS and TTP are closely related disorders caused by microvascular occlusion of arterioles and capillaries producing ischemia of multiple organs. HUS is a combination of thrombocytopenia, microangiopathic hemolytic anemia, and acute renal failure (4). It occurs mostly in children and has a fairly good prognosis. TTP is characterized by a pentad of features which include: thrombocytopenia, microangiopathic hemolytic anemia, neurologic disturbances, renal dysfunction and fever (4). It occurs in young adults and teenagers and carries a high mortality if unrecognized and not treated. Table 1 compares both disorders.

Table 1: Comparison of HUS and TTP

Feature	HUS	TTP
Course	Age usually <3 yr M=F Prodrome: infection, diarrhea Recurrence rare	Age usually 3rd decade F>M Prodrome less common Recurrence common
Diagnosis	Triad Acute renal failure Thrombocytopenia Microangiopathic anemia	Pentad CNS disturbance Thrombocytopenia Microangiopathic anemia Renal dysfunction Fever
Etiologic factors	E. coli, Shigella gastroenteritis, pneumococcus	Pregnancy, autoimmune disease, malignancy, drugs
Treatment	Renal dialysis Corticosteroids - no help Transfuse only if necessary	Plasma exchange Corticosteroids AVOID transfusions
Prognosis	Good	Poor

A variety of drugs have been reported to cause thrombocytopenia either by drug-induced platelet destruction or bone marrow suppression. Heparin merits special emphasis because it is so commonly used. Heparin does not inhibit platelet function but it may sometimes cause thrombocytopenia. There are two types of heparin-induced thrombocytopenia (HIT). The first occurs 2 to 5 days after initiation of heparin. Platelet counts rarely fall below 100,000 per cubic mm and normalize within 1 to 5 days. This type is thought to result from platelet aggregation secondary to a direct heparin effect (4). The second type of HIT occurs 3 to 15 days after the initiation of heparin (4). Platelet counts fall below 40,000. Arterial thrombosis may occur. The mechanism is immune mediated. Treatment involves discontinuation of heparin.

Decreased numbers of platelets result from impaired platelet production due to leukemia, aplastic anemia or bone marrow suppression due to viral infection or drugs. These are discussed in separate chapters. May-Hegglin anomaly is characterized by mild to moderate thrombocytopenia and the presence of Dohle bodies in the leukocytes. Kasabach-Merritt (giant hemangioma) syndrome is due to localized intravascular coagulation from low blood flow through the abnormal vascular tissue and is associated with thrombocytopenia (4). Foreign bodies in the circulation (central venous catheters and prosthetic valves) are sites for platelet consumption. Platelet loss also results from extracorporeal circulation and exchange transfusions. Massive plasma and blood transfusions lead to a dilutional thrombocytopenia. Finally, platelet counts may be low as a result of sequestration when the spleen is enlarged.

Qualitative platelet disorders (defects in platelet aggregation) are very rare. Most are inherited as autosomal recessive traits. Patients present with bleeding similar to that seen with thrombocytopenia. They complain of skin and mucous membrane bleeding, recurrent epistaxis, gastrointestinal bleeding, menorrhagia, and prolonged bleeding with injury or surgery (5). Aspirin (ASA) and non-steroidal anti-inflammatory drugs (NSAIDs) are common causes of temporary platelet dysfunction. Laboratory evaluation usually demonstrates a normal platelet count, prolonged bleeding time and abnormal platelet aggregation studies. Coagulation studies (PT, PTT) are usually normal. The most common platelet aggregation defects are described in table 2 below.

Table 2: Platelet aggregation defects

Condition	Platelet aggregation studies	Platelet count	Other
Glanzmann thrombasthenia	Abnormal to all agonists	Normal	
Bernard-Soulier syndrome	Abnormal to ristocetin	Decreased	Giant platelets
Storage pool defect (Dense body deficiency, Gray platelet syndrome)	Abnormal 2nd phase of aggregation	Normal	Abnormal platelet granules on electron microscopy
ASA/NSAID	Abnormal to arachidonic acid and abnormal secondary aggregation to ADP and epinephrine.	Normal	Drug induced enzyme effect inhibiting platelet granule release This is the most common cause of platelet dysfunction

Defects in Secondary Hemostasis

Hemophilia

Hemophilia is an X-linked inherited bleeding disorder transmitted from female carriers to their male children. It is due to a deficiency of factor VIII (Hemophilia A or "Classic hemophilia") or factor IX (Hemophilia B or "Christmas disease"). Hemophilia A is more common, occurring in 1/5000 male births while hemophilia B occurs in 1/15,000 (6). Signs and symptoms vary depending on the severity of the hemophilia. Severity is defined by baseline factor levels: severe <1%, moderate 1-5%, mild >5% (6,7). Children with severe hemophilia usually present in the first year of life with a history of extensive deep palpable ecchymoses. There may be a history of bleeding from the circumcision. After the age of 2 years, they begin to develop spontaneous hemarthroses or deep muscle bleeds. They can have mucosal bleeds, such as oral bleeding with procedures and hematuria. The bleeding is usually not catastrophic. Instead, it is prolonged and continuous without therapy. A head injury is considered an emergency since it is potentially life threatening if not treated appropriately. Children with milder forms of hemophilia may present later in life with a history of easy bruising or prolonged bleeding following injury. They usually do not have spontaneous bleeding. Laboratory findings include a markedly prolonged PTT (>100 seconds) and a decreased factor VIII or IX activity. Other screening tests (PT, platelet count and bleeding time) should be normal.

The mainstay of therapy is replacing the deficient clotting factor with factor VIII or IX concentrate (6,7). Both human derived and recombinant factor concentrates are available. In the past, factor replacement carried a risk of transmission of viral infections, especially hepatitis B and C, and HIV. This risk has been reduced with current viral inactivation techniques and with the availability of recombinant factor. Each unit of factor VIII will increase the factor VIII level by 2% and has an 8 to 12 hour half-life. Each unit of factor IX will increase the factor IX level by 1% and has an 18 to 24 hour half-life (6,7). Dosing depends on the location and severity of the bleed. In addition to factor replacement, males with hemophilia benefit from supportive measures, physical therapy and often require orthopedic intervention. Aminocaproic acid is an oral antifibrinolytic and can be used adjunctively to treat mucous membrane bleeding. Mild factor VIII deficient patients may be treated with intravenous or highly concentrated intranasal desmopressin (DDAVP) which causes a release in endogenous factor VIII stores. These boys need to be cautioned to avoid contact sports such as tackle football, boxing or wrestling. It is nationally recognized that hemophilia treatment centers have improved the prognosis of patients with hemophilia. Patients and their families have a home supply of factor and infuse themselves promptly at the earliest sign of a bleed. Prophylaxis has been instituted in most severely affected individuals where they infuse themselves regularly two to three times a week and/or prior to a sports activity in order to prevent spontaneous bleeds. This has reduced much of the chronic arthropathy in this population. Today, young people with hemophilia can lead independent and nearly normal lives.

von Willebrand Disease

von Willebrand disease (vWD) is the most common inherited bleeding disorder. It affects 1% to 2% of the population. von Willebrand factor is a cofactor for platelet adhesion and a carrier protein for factor VIII (8,9). The most common form is transmitted as an autosomal dominant trait. Severity of bleeding symptoms depends on the type and subtype. Types 1 and 3 result in quantitative defects of the von Willebrand protein (i.e., deficiency) while Type 2 is due to a qualitative defect in the von Willebrand protein. The vWD types are listed in table 3.

Table 3 - von Willebrand disease subtypes

Type	Defect	Bleeding symptoms
Type 1 (common)	Quantitative: Decreased vWF	Mild
Type 2 (uncommon)	Qualitative: Normal vWF levels	
2A	vWF not "sticky" enough	Variable
2B	vWF too "sticky"	Potentially severe
2N	Lacking receptor for factor VIII binding	Similar to hemophilia
2M	Lacking receptor for platelet binding	Fairly mild
Type 3 (rare)	Quantitative absent vWF	Severe

Patients with vWD often have a positive family history of bleeding and easy bruisability in addition to the personal bleeding history. The bleeding symptoms can be similar to that seen with thrombocytopenia or platelet dysfunction and usually involve the mucous membranes and patients present with complaints of recurrent epistaxis, oral bleeding with dental care, and menorrhagia. In addition, they often have a history of easy or spontaneous bruising and post-operative bleeding. More rarely, one may elicit a history of gastrointestinal or genitourinary bleeding. Types 2N and 3 may also have deep tissue bleeding, similar to the bleeding seen in moderate or severe hemophiliacs.

The most useful screening tests in patients with suspected vWD are bleeding time, PTT and von Willebrand factor activity (ristocetin cofactor). Ristocetin cofactor is a functional assay of the von Willebrand protein. At least one of these screening tests will be abnormal in 97% of patients with vWD (10). Other useful studies include platelet count, von Willebrand factor (vWF) antigen and factor VIII activity. Once the diagnosis of vWD is made, the vWF multimeric assay and platelet aggregation studies will determine the type of vWD. With deficient or defective von Willebrand factor, there will be abnormal platelet aggregation to ristocetin. Other platelet aggregation studies should be normal.

It is important to keep in mind that vWF is an acute phase reactant and therefore, studies for vWD can be affected by cigarette smoking, stress, exercise, pregnancy, corticosteroids, birth control pills, etc. In addition, people who are blood group O have a lower normal range for vWF antigen and ristocetin cofactor activity. When there is a strong suspicion that a patient has vWD, the laboratory evaluation may need to be repeated up to 3 times.

In most cases of vWD the bleeding symptoms are quite mild, and therapy includes education and measures for local control of bleeding. Aminocaproic acid is useful in treating mucous membrane bleeding. Desmopressin (DDAVP) causes a release of factor VIII and vWF from storage sites and is useful in treating bleeding symptoms in patients with mild (type 1) vWD. Patient with severe forms of vWD (type 3) or a qualitative defect of the vWF (types 2A, 2B, 2N) may need replacement with Humate-P (a factor VIII product

containing vWF) (8,9). Once diagnosed and followed and treated in a comprehensive hemophilia treatment center, people with vWD can lead normal lives.

Other Factor Deficiencies

Deficiencies in other fluid factors are much more rare than deficiencies in factors VIII, IX or vWF. Factor XI deficiency presents with variable bleeding and a prolonged PTT. Bleeding symptoms do not correlate with the factor level (11). It is more common in the Ashkenazi Jewish population. Deficiencies of the contact factors (factor XII-Hageman factor, high molecular weight kininogen, and prekallikrein) are associated with a significantly prolonged PTT without bleeding symptoms (11). Deficiencies of factors II, V, VII, X and XIII are very rare. For most of these, bleeding symptoms occur in those whose factor levels are <5% to 10% (11). Factor VII deficiency should be considered with isolated prolongation of the PT. Factors II, V, and X are common pathway factors and present with prolongation of both PT and PTT. Factor XIII deficiency is associated with bleeding from the umbilical stump and intracranial hemorrhage with a normal PT and PTT. It is only symptomatic in patients whose level is <1%. Treatment consists of replacement of the deficient factor with fresh frozen plasma or, if available, specific factor concentrate (11).

Acquired Defects of Secondary Hemostasis

Vitamin K is needed for the synthesis of factors II, VII, IX and X. Vitamin K is vital to the carboxylation of glutamic acid residues which is needed for the calcium and phospholipid-dependent activation of these factors (1). The most common circumstance in which vitamin K deficiency leads to bleeding is hemorrhagic disease of the newborn. Without vitamin K supplementation, significant GI and cutaneous hemorrhage may develop within a few days (1). After the newborn period, vitamin K is absorbed from the GI tract. Deficiency may then result from nutritional deficits, malabsorption, or alteration in intestinal flora. Treatment must be directed at the underlying disorder and vitamin K supplementation.

Decreased synthesis of coagulation proteins occurs in severe liver disease. Abnormalities in the liver's capacity to synthesize one or more clotting factors may result in problems with hemostasis. Treatment involves replacement of the decreased factor(s) with fresh frozen plasma. Liver disease may also lead to portal hypertension and platelet sequestration in the spleen.

Disseminated intravascular coagulation (DIC) occurs in patients who are critically ill and therefore, rapid diagnosis is essential. Fever, hypotension, acidosis, oliguria, or hypoxia may be present. In addition, petechiae, purpura, and oozing from wounds and venipuncture sites may develop. Although not always clinically evident, microvascular and large vessel thrombosis may occur. The platelet count is typically decreased due to consumption and platelet destruction. The PT and PTT are prolonged from depletion of factors V, VIII, IX, and XI. Fibrinogen is decreased. Fibrin degradation products and the D-dimer assay are increased. The mainstay of therapy is to treat the underlying disease. However, this may not always be enough to correct serious bleeding or thrombosis. Additional therapy consists of replacing clotting factors and platelets and possibly the use of heparin and antifibrinolytic agents (1).

Circulating inhibitors such as heparin and the lupus anticoagulant (antiphospholipid antibody) often lead to abnormalities in screening coagulation laboratory values. These cause a prolonged PTT which is not corrected with 1:1 dilution with normal plasma (the PTT mixing study). If the patient has a factor deficiency such as hemophilia, adding normal plasma to the patient's plasma, will partially correct the factor deficiency and the PTT will normalize. If the PTT does not normalize by adding normal plasma, this implies that an anticoagulant is present in the patient's plasma. The term “lupus anticoagulant” is misleading because it can occur in many clinical settings other than in SLE and the anticoagulant effects are only observed in vitro with prolongation of the PTT, but not with excessive bleeding. Instead, when it occurs in adults, it may be associated with spontaneous abortion, and thromboembolism. In the pediatric population, it usually occurs in otherwise healthy children, often following a viral illness and is transient with rare clinical sequelae (1).

A summary of laboratory studies for bleeding disorders is listed below. Routine tests are commonly ordered by non-hematologists. Special tests are not ordered routinely and are only ordered (most commonly by hematologists and other subspecialists) when a bleeding disorder is highly suspected.

	Tests for:	Abnormal in:
Routine tests:		
Platelet count	Disorders of platelet quantity	ITP, HUS, TTP, thrombocytopenia due to bone marrow suppression, platelet consumption.
PT	Extrinsic and common coagulation Pathway (factors I, II, V, VII, X)	Factor deficiency (I, II, V, VII, X), liver failure, vitamin K deficiency, coumadin, warfarins.
PTT	Intrinsic and common pathway (factors I, II, V, X, VIII, IX, XI, XII)	Factor deficiency (I, II, V, X, VIII, IX, XI, XII), heparinization, circulating anticoagulants, vWD
Special tests:		
PTT mixing study	Circulating anticoagulants.	PTT corrects with factor deficiency, but it does not normalize with circulating antibodies/anticoagulants.
Bleeding time	Platelet function	ASA, NSAIDs, platelet function disorders (see table 2), vWD
Platelet aggregation	Platelet function	ASA, NSAIDs, platelet function disorders (see table 2), vWD
Ristocetin cofactor	vWF function	vWD
vWF antigen	vWF quantity	vWD
vWF multimeric assay	Defines type of vWD	vWD

Questions

1. What is the mechanism for the thrombocytopenia in ITP?
2. What is the classic triad associated with hemolytic uremic syndrome?
3. How is hemophilia inherited?
4. Describe some indications for factor VIII administration in a patient with hemophilia A.
5. What are the functions of von Willebrand factor?
6. What combination of laboratory tests are good screening studies for von Willebrand disease?
7. Why is it important to test for blood type in a person with suspected von Willebrand disease?
8. Name the vitamin K dependent factors.
9. Explain why the addition of normal plasma to a patient's PTT test, will help to identify a circulating anticoagulant such as the lupus anticoagulant.

Answers to questions

1. ITP is an immune-mediated disorder in which circulating antiplatelet antibodies target epitopes on the platelet membrane. The antibody-coated platelets are subsequently destroyed by macrophages in the reticuloendothelial system.
2. Thrombocytopenia, microangiopathic hemolytic anemia, and uremia.
3. X-linked recessive.
4. Following trauma or injury, especially head injury; to treat spontaneous bleeding, such as hemarthrosis or deep muscle bleeding, and prior to procedures, including dental work.
5. von Willebrand factor is a cofactor for platelet adhesion and carrier protein for factor VIII.
6. Bleeding time, PTT, and ristocetin cofactor.
7. Patients who have blood group O have a lower normal range for von Willebrand studies.
8. Factors II, VII, IX, and X.
9. If the prolonged PTT is due to a factor deficiency, then the addition of factors from the "normal plasma", will correct the PTT. However, if the PTT is due to a circulating anticoagulant such as heparin or a lupus anticoagulant, the circulating antibody will inhibit the "normal" factors and the PTT will remain prolonged. Failure to normalize the PTT after the addition of normal plasma, implies the presence of a circulating anticoagulant.

Chapter XI.7. Transfusion Medicine
Kelley A. Woodruff, MD

A 7 year old boy is being worked up for profound pancytopenia. He was well until one week ago when his grandparents noted pallor. He has had no recent history of fever, and is otherwise well. He was initially seen yesterday in the hematology clinic, where a CBC showed a hemoglobin of 5.3 g/dl, WBC 1.9 K/ml with 96% lymphocytes, and a platelet count of 4,000. He has a bone marrow aspirate scheduled for tomorrow. He is brought back in to the clinic today, because he has epistaxis, which has been ongoing for 1 hour now. He states he feels weak and dizzy.

Exam: He is afebrile, BP 110/40, HR is 186 with a mild gallop. Weight is 26 kg (75%ile). He is lying down, with a tissue to his nose, and bright red blood is dripping out. He is alert and oriented, nontoxic, and comfortable. He is pale appearing, conversing appropriately, and no other overt bleeding is noted. His abdomen is benign.

CBC today shows hemoglobin 5.1, WBC 1.3, and platelet count 5,000. After IV access is obtained, he is given a fluid bolus and a "type and hold" for blood status is ordered.

The start of transfusion medicine occurred during World War II when the major blood types A, B, AB and O, and Rh factor were identified. Type A persons have A antigen on the membrane of their red blood cells. They develop anti-B antibodies shortly after birth without any prior antigenic stimulation, thus these antibodies are called natural antibodies. Type B persons have B antigen on the membranes of their red blood cells, and such persons naturally have anti-A antibodies in their plasma. Type AB persons have both A and B antigens, and no anti-A or anti-B antibodies in their plasma. Type O persons, who lack these major red cell membrane antigens, have both anti-A and anti-B antibodies. When crossmatching a unit of blood for a transfusion, the biggest concern is to avoid giving the patient antigen that would react with their own antibodies. Thus, people with type O blood are considered to be universal donors, with regard to red blood transfusions, since there are no major (A or B) antigens on their red blood cells.

Most transfusions of red blood are given as packed red blood cells (PRBCs) that have most of the plasma removed. Each unit of PRBCs is about 250 ml, depending on the type of preservative used, and each ml provides 1 milligram of elemental iron. The fastest rate of transfusing a patient should be 5 ml/kg/hour. Generally, a transfusion is ordered as 10-15 ml/kg given over 2 to 3 hours.

The advent of platelet transfusions in the early 1970's changed the survival rate for many diseases. Today, single donor platelets are usually considered the optimal product for most platelet transfusion needs. A single donor unit of platelets is based on the adult dose and contains about 225 ml per unit. It is obtained via pheresis from one donor and takes about 4 hours to donate, compared to 30 minutes to donate one pint of whole blood. Platelets extracted from a unit of whole blood (called random platelets) contain about 50 ml per unit. Usually about 6-8 random units (i.e., 6-8 different donor exposures!) need to be pooled together to equal the volume of one unit of single donor platelets. Single donor platelet transfusions are usually given over 1 hour.

A hemolytic transfusion reaction results when an antibody-antigen reaction causes (donor) red cell lysis. It is most severe when a patient has circulating antibody that reacts with donor antigen (RBCs). Some antigens produce stronger hemolytic reactions than others. For example, transfusion reactions involving A and B antigens will cause a brisk, severe hemolysis, leading to fatalities from renal failure. The Duffy and Kell antigens also cause significant hemolysis. The Lewy antigen leads to a mild hemolysis that is not usually fatal (remembered by the mnemonic Duffy dies, Kell kills, and Lewy lives). There are many other less common antigens, natural and acquired, that are screened for in the direct antibody test (DAT) during crossmatching. A patient having a hemolytic transfusion reaction may present with lower back pain, and hemoglobinuria. The treatment consists of supportive care, especially intravenous hydration to help protect the kidneys from damage. Corticosteroids may also be beneficial.

Another type of transfusion reaction is associated with urticaria, or less commonly, fevers. These reactions are typically caused by extraneous donor proteins, which are foreign to the recipient. These proteins are usually carried in the plasma of the donor product. Therefore, such reactions are usually seen more often with platelet transfusions than with red cell transfusions, since the platelet products carry more plasma than the packed red cell units. Urticaria reactions are usually mild, and treated with diphenhydramine and sometimes IV corticosteroids. Epinephrine is only rarely required. Fevers are usually mild and self-limited, and can be managed with acetaminophen.

Irradiation of blood products will inhibit the replication of nucleated cells (e.g., WBCs) in the donor product, by damaging their DNA. This radiation dose will not kill common organisms known to contaminate blood products. All transfusion products have donor stray white blood cells, which, in theory, could replicate when transfused into an immunocompromised host. This would cause a graft versus host (GVH) situation, which, when arising from a blood transfusion, is often fatal. Therefore, all blood products given to infants, oncology patients, or other immunocompromised hosts should be irradiated. The exception, of course, is a stem cell product for a stem cell (bone marrow) transplant. If these stem cells were irradiated, the new graft would not grow, and there would be no transplant.

Infusion filters should be used for all transfusions of packed red blood cells and platelets. The only exception to this is the infusion of a stem cell product for any type of stem cell transplant. There are many types of filters. Their main purpose is to filter out either extraneous white blood cells or large foreign proteins. The use of a filter during a transplant of stem cells would filter out the very stem cells that are intended for the patient! Since filters will not dependably remove all white blood cells, filters cannot replace irradiation to prevent graft versus host disease.

Infections acquired from transfusions are rare due to improved screening methods by blood banks. Infectious agents that can be transmitted through transfusions include HIV, Hepatitis B, Hepatitis C, Parvovirus and malaria. Blood is actively screened for all these agents and discarded if contamination is even suspected. Cytomegalovirus (CMV) infection can also be transmitted through blood transfusions. It is harbored in a dormant state in the white blood cells of previously infected persons. Since 80% of most adult populations are positive for past CMV infection, most donated blood is CMV serology positive. CMV infection can be transmitted to severely immunocompromised persons with no prior infection. Such an incident might occur during a bone marrow transplant. Since newborns up to age 4 months are considered immunocompromised and have no previous CMV infection, all newborns receive CMV negative blood.

Clinicians should familiarize themselves with the options for ordering, holding, or preparing for a PRBC transfusion. A "draw and tag" should be ordered for a patient who might possibly need a transfusion during the hospital stay (but the probability of this is low). In this case, a blood sample is drawn from the patient and the patient is tagged with a special blood products identification bracelet which is matched to the specimen drawn and a set of labels which will be used on any blood products which might be ordered for the patient in the next few days. If blood products are required for this patient, they can be ordered from the blood bank. The blood bank will crossmatch the blood using the previously drawn and labeled specimen.

A "type and hold", also called a "type and screen", should be ordered for a patient who has a moderate likelihood of requiring a transfusion during the hospital stay. The patient is drawn and tagged as in the "draw and tag" procedure. Additionally, the patient's blood type and Rh are determined and a screening test is performed for unexpected antibodies and minor compatibility group profiling. Thus, the patient's blood type and Rh are known which saves some time in case a crossmatch is needed.

A "type and crossmatch" should be ordered when the patient will be getting a transfusion. The patient is drawn and tagged. The patient's blood type, Rh, and antibody screens are performed. A unit of blood is then selected for the patient and compatibility testing is performed with the patient's specimen and the donor unit's PRBCs. This unit is then held for the patient. This unit cannot be used for any other patient, so a "type and crossmatch" should only be ordered when a transfusion is highly likely.

In a true emergency with a rapidly hemorrhaging and hypovolemic patient, the time required for blood typing and crossmatching (20 to 30 minutes) may not be available. Transfusing with O negative PRBCs (if available) is the best emergency option. In the meantime, a type and crossmatch should be in progress. Type specific blood (the patient's type and Rh are known, but a crossmatch has not yet been performed) is sometimes useful until a crossmatch is completed.

There are many ethical issues which need to be considered when transfusing patients. Because of the rare possibility of morbidity and mortality from transfusions, written and informed consent must always be obtained before a transfusion is given. The patient (or patient's guardian) must be fully informed of the rare possibilities of infectious agents and transfusion reactions. Full consideration must be given to the necessity of a transfusion. In short, if spontaneous resolution of the problem (anemia, thrombocytopenia, or other morbidity in which a transfusion is thought to be beneficial) can be expected, or if alternative treatments exist, the transfusion should be avoided. When considering a transfusion, the actual morbidity and mortality from the underlying problem itself, without a transfusion, must be weighed against the rare problems that may result from the transfusion itself. Adult patients may refuse a transfusion for themselves, regardless of their reasons, even in the face of death (e.g., Jehovah's Witness patients). A parent may also refuse a transfusion for their child. However, if a physician strongly believes that a child has a life-threatening condition that can only be effectively treated with a transfusion of a blood product, the physician is obligated to take legal action.

Questions

1. In the case above, you decide to transfuse the 26 kg patient with both PRBCs and one unit of single donor platelets. Which is the best way to transfuse the PRBCs?
   a. Transfuse 2 units, each over 6 hours, with furosemide in between the units.
   b. Transfuse 1 unit over 3 hours
   c. Transfuse 390 ml over 4 hours
   d. Transfuse 260 ml over 2 hours

2. During the transfusion of platelets, this patient develops 3 small hives (urticarial lesions) on his back. Which is the correct response? No pre-medications were given.
   a. Continue the transfusion. Stop and medicate if more hives appears.
   b. Stop the transfusion. Give diphenhydramine and proceed when the hives clear.
   c. Stop the transfusion. Draw blood for type and cross to check the crossmatch for that unit. Give diphenhydramine, and proceed with the same unit when the hives clear, and if the repeated crossmatch is OK.
   d. Stop the transfusion. Give diphenhydramine and methylprednisolone, and proceed when the hives resolve.

3. During the transfusion of PRBC, the child starts to complain of lower back pain during the transfusion. What is most likely happening?
   a. A febrile reaction from donor white blood cells causing an inflammatory response.
   b. A hemolytic reaction involving donor antibodies to recipient red blood cells.
   c. A hemolytic reaction involving donor red blood cells and recipient antibodies.
   d. Recipient mast cell histamine release, stimulated by donor antigen presenting cells.

4. All of the following should be done with this complaint of lower back pain, EXCEPT:
   a. Consider IV corticosteroids.
   b. Hydrate with IV fluid bolus.
   c. Repeat crossmatch with unit of blood being transfused.
   d. Administer subcutaneous epinephrine.

5. Which of the following children should receive a transfusion of PRBC?
   a. A 2 year old with Hgb 2.8 g/dl (etiology unclear at the moment), HR 200, with gallop.
   b. A 2 year old Jehovah's Witness with Hgb 2.8 g/dl (etiology unclear at the moment), HR 200 with gallop.
   c. A 4 year old just diagnosed with Neuroblastoma, Hgb 6.8 g/dl, HR 134.
   d. A 13 year old girl, presents with butterfly rash on her face, has fevers, Hgb 6.8 g/dl, rales, splenomegaly, HR 156.
   e. All of the above

6. Irradiation of blood products:
   a. Will prevent donor white blood cells from proliferating in the recipient's body.
   b. Will kill many common infections that could be transmitted in extraneous donor WBC or plasma.
   c. Could, in theory, take the place of blood filters.
   d. Is very expensive and tedious, and therefore should be used in only selected cases.

7. An 11 month old boy weighs 7.5 kg, and has Fe deficiency anemia with a Hgb 2.2 g/dl. HR is 188. You decide to transfuse him. Which is the best way to transfuse him with PRBCs (checking the Hgb at appropriate intervals)?

a. Transfuse 150 ml over 12 hours.
b. Transfuse 2 half units, each over 4 hours.
c. Transfuse 15 cc/kg, i.e. about 112 ml slowly over 6 hours, then start oral Fe.
d. Transfuse slowly at <3ml/kg/hour, with subunits from a unit split in the blood bank, and discard the remainder of each subunit after 4 hours.

8. All are true of a neonatal unit (of red blood cells) EXCEPT:

a. Always CMV negative.
b. Always irradiated.
c. Intended only for babies <2 months of age.
d. Always O negative.

Answers to questions

1. b. Once a unit is spiked (IV infusion begun from unit bag), any uninfused blood must be discarded after 4 hours. Thus, the most time allowed for 1 unit to run is over 4 hours. Therefore, a unit may not be transfused over 6 hours. Giving 390 ml would give this patient 15 ml/kg, but giving this over 4 hours would be slightly too fast with such a low and fast falling hemoglobin. Additionally, it would expose the patient to a second donor, and half of the second unit would be discarded (wasted). Giving 262 ml means giving 1 unit (about 250 ml), and about 10 ml from a second unit (discarding the rest). Giving this over 2 hours would also be too fast as noted.

2. b. For just a few hives, it is not necessary to check the crossmatch of the blood, since this will detect antibodies causing hemolysis. Urticaria is not a hemolytic reaction. Usually diphenhydramine alone can resolve the hives, and the same unit can be continued with the diphenhydramine in effect.

3. c. See text

4. d. Epinephrine has no known beneficial effect on the hemolytic process.

5 e. All of these children should probably receive a transfusion.

6. a. See text

7. d. A unit of PRBCs can be split in the blood bank (like neonatal units) so that only one part of this is out of the blood bank and infusing into the patient at a given time (which can infuse up to 4 hours). Additionally, a child with such an extremely low hemoglobin needs to be transfused very slowly, at least initially, so as not to push his already compromised heart into further failure. With severe anemia, the patient is already in high output congestive heart failure. Blood is a potent volume expander which can suddenly worsen the CHF. Thus, the transfusion must proceed very slowly under close hemodynamic monitoring.

Chapter XI.8. Neutrophil Disorders
Wade T. Kyono, MD

Case 1

This is a 13 month old female who is referred to you for cold symptoms, fever (T 38.5 degrees) and a persistently low absolute neutrophil count (ANC = WBC x (segs% + bands%)) of 40 (WBC 4.0, 1% bands, 0% segs). Her ESR is 12. She was hospitalized three weeks ago for a pseudomonas external otitis media and neutropenia that was treated with two weeks of intravenous antibiotics. Three weeks ago, her ANC was 342, with a low of 54, and at discharge her ANC was 896 (one week ago). She had been doing well since discharge until her current illness.

Of note, a CBC at birth and at 10 months of age demonstrated normal absolute neutrophil counts. There is no history of increased bacterial or fungal infections. There is no family history of recurrent bacterial infection, neutropenia, immunodeficiency disease, autoimmune disease, or malignancy. There is no history of infant deaths in the family. There has been no history of recent medication use.

Exam: VS are normal. Height and weight are at the 75th percentile for age. Physical examination had no unusual findings. No oral thrush, lymphadenopathy, hepatosplenomegaly, or skin lesions are noted.

She is hospitalized for IV antibiotics (ceftazidime). Blood cultures return negative and she is discharged after 3 days. During this hospital stay she does well. Antineutrophil antibody testing is sent off to a specialized reference laboratory and it returns positive. A bone marrow examination is done (mostly because of parental concern) which shows a normal cellular marrow. During subsequent febrile illnesses, she does well clinically. Three months later, after she initially presented with neutropenia, her ANC improves to 2400. Two months later, it remains over 2000.

Diagnosis: Chronic benign neutropenia of infancy and childhood.

Case 2

This is a 2 year old male who presents with a chief complaint of recurrent skin and soft tissue infections. The infecting organisms were catalase producing bacteria. Three nitroblue tetrazolium (NBT) slide tests sent to a reference laboratory returned normal. Screening tests of humoral, cell mediated, and complement mediated immunity were normal. Referral is now being made to a hematologist during his current hospitalization for the treatment of cervical lymphadenitis and left lower lobe pneumonia with bilateral pleural effusions. The patient's blood samples were sent to a neutrophil research laboratory with results that demonstrated no reduction of NBT (an abnormal result in contradiction to the normal NBT slide test results) and negligible quantitative production of superoxide. His mother demonstrated an intermediate production of superoxide and a decreased number of neutrophils capable of reducing NBT.

Past Medical History: At 2 months of age, he developed a perianal furuncle that was incised and drained because of no response to oral antibiotics. At 5 months of age, he had surgical treatment for multiple perianal fistulas with abscesses. At 7 months of age, he had a left inguinal Klebsiella pneumoniae lymphadenitis that was treated with incision and drainage and oral amoxicillin/clavulanic acid. Two weeks later, a left subauricular lymph node abscess was incised and drained and a persistent perianal fistula received topical treatment with silver nitrate. Pseudomonas aeruginosa grew out of cultures of the neck abscess and the patient was hospitalized for intravenous antibiotic treatment and immunological evaluation. In addition to his subauricular lymphadenitis, he had a left calf cellulitis that grew Serratia marcescens and a left inguinal abscess that grew Staphylococcus epidermidis.

Clinical Course: He completes treatment with 6 weeks of intravenous antibiotics until his ESR decreases <30. However subsequently, he develops a slight limp at which time a large lytic bone lesion is found in the distal left tibia on plain x-rays. Culture of that lesion grows out Staphylococcus aureus after debridement and curettage. He receives 6 more weeks of intravenous antibiotics until his ESR is in the normal range. He is placed on subcutaneous injections of gamma interferon (three times a week) and twice daily doses of oral trimethoprim-sulfamethoxazole and has not required any further hospitalizations for bacterial infections for the last 3 years.

Diagnosis: Chronic granulomatous disease.

Neutrophils (polymorphonuclear leukocytes) represent the first line of active defense against bacterial and fungal invasion for the innate immune system. Though a critical component of the body's immune system, primary disorders of neutrophil function account for only about 18% of all primary immunodeficiencies, with T cell (20-30%) and B cell deficiencies (50%) comprising the majority of defects seen. Despite the relative rarity of primary neutrophil defects, clinical situations in which neutrophil function is decreased, such as prematurity, are commonly associated with increased rates of invasive bacterial infection. Primary deficiencies of neutrophil numbers or function are usually associated with an increased risk of serious, often life-threatening infections. Secondary deficiencies of neutrophil numbers or function are usually markers of systemic disease and tend to be clinically benign.

The most common problem seen by primary care physicians is neutropenia (decreased neutrophil count). Acute inflammatory processes are commonly associated with normal or reactive increases in neutrophil counts. When low neutrophil counts are associated with infection it must be decided whether neutropenia is secondary to the infection, or if an underlying neutropenia contributed to the risk of infection. A key point to remember is that the risk of infection with neutropenia is high when bone marrow production of neutrophils is decreased from either primary or secondary causes.

In general, common disorders are usually benign clinically and occur in children with no significant medical history of bacterial or fungal infections. Rare congenital disorders result in extremely high risks of infection and require specialized laboratory tests to correctly diagnose.

The most common presentation of neutropenia (low neutrophil counts) and neutrophilia (high neutrophil counts) is an acute febrile illness in an otherwise normal child. Serious primary neutropenia or primary disorders of neutrophil function are associated with "frequent" or "atypical" bacterial infections. These important points should be kept in mind: i) An overwhelming, sudden onset of sepsis, as observed in children receiving intensive multi-agent chemotherapy, is rare in most children with neutropenia or defects in neutrophil function. ii) An intact humoral and T-cell immune response and monocytosis compensates somewhat for a decreased neutrophil count or altered neutrophil function. iii) Little or no increased propensity to infection is associated with the most common form of severe neutropenia in children, so-called "chronic benign neutropenia". iv) Neutrophil defects commonly present with frequent, indolent bacterial or fungal infections that are difficult to detect and treat.

While there are subtle differences in the presentation of primary neutrophil disorders, the overlap in presentation is significant and determining the precise defect is impossible on clinical findings alone. With the passage of time it is generally easy to determine that a child's history of infections is abnormal, suggesting a more serious disorder.

DISORDERS OF NEUTROPHIL NUMBERS

Key to the understanding of quantitative abnormalities of neutrophil counts is an understanding of neutrophil distribution. The peripheral neutrophil count reflects the equilibrium between the circulating pool and the marginated pool of neutrophils adherent to vascular endothelium, and a tissue pool. The complete blood count (CBC) only monitors neutrophils in the circulating pool.

NEUTROPHILIA (increased neutrophils): Upon infection and activation of the immune response, neutrophils from the marrow storage pool are released resulting in up to three fold increases in neutrophil counts within four to five hours. More than half of the peripheral granulocytes are attached to the vascular endothelium at any given time point and represent a "marginated" pool that can be released almost immediately at times of stress. Epinephrine mediated "demargination" of neutrophils to the circulating pool is sometimes seen during phlebotomy in an anxious child and can result in spuriously elevated mature neutrophil counts. Among the other causes of neutrophilia are: reactive leukocytosis, ethnic neutrophilia, Pelger Huet, leukemoid reaction, leukoerthyroblastic response, chronic myeloid leukemia and leukocyte adhesion defect.

NEUTROPENIA (decreased neutrophils): Neutropenia is defined by an absolute neutrophil count (ANC) <1,500/cubic mm. ANC = (%bands + %mature neutrophils) X total WBC count. Decreased neutrophil production, storage, or release; redistribution from circulating to marginated pools; or increased destruction explains most cases of neutropenia. The key determinants of infection risk are the adequacy of the bone marrow storage or reserve pool and the general robustness of the immune response. These determinants affect the ability to deliver neutrophils to infected sites and the ability of the immune system to compensate for quantitative deficiencies in neutrophils. Neutropenia discovered during the evaluation of infection is generally a secondary finding and characterizes the general low risk of infection associated with a normal marrow reserve and immune system. Some of the causes of neutropenia are summarized below:

1. Kostman syndrome: primary decrease in bone marrow reserve; AR (autosomal recessive), AD (autosomal dominant), S (sex linked recessive); extremely rare; severe neutropenia in the newborn.
2. Shwachman-Diamond Syndrome: primary decrease in bone marrow reserve; AR, S; extremely rare; steatorrhea from exocrine pancreatic deficiency; metaphyseal dysplasia; 50% survival; 1/3 progress to myelodysplastic syndrome or acute myeloid leukemia; normal sweat chloride.
3. Cyclic neutropenia: primary cyclic (every 21 days) variations in bone marrow reserve; AD, S; 1-2 per million; regularly recurring fever every 21 days with oropharyngeal and skin infections; diagnose with CBCs 2-3 times per week for 8 weeks.
4. Chemotherapy: direct toxicity to neutrophil precursors results in a severe reduction in bone marrow reserve (severity dependent on the intensity of chemotherapy agents used); generally a high risk of infection with poor marrow reserve and generalized suppression of the immune system.
5. Nutritional: protein-calorie malnutrition, B12 deficiency, copper deficiency can result in ineffective myelopoiesis; treat by correcting deficiency.
6. Viral infection: bone marrow suppression from a direct effect of infecting virus or through an immune mechanism.
7. Chronic benign neutropenia of infancy and childhood: normal bone marrow reserve; generally thought to be mediated through an anti-neutrophil antibody; common; median age of detection 8 months, 90% detected before 14 months; most resolve spontaneously within months of diagnosis; no significant propensity to infection; treatment is supportive.
8. Autoimmune neutropenia: generally with normal bone marrow reserve but may be associated with a late maturational arrest; antibody mediated destruction of neutrophils; may have an associated primary autoimmune disorder.
9. Alloimmune neutropenia: normal bone marrow reserve; secondary to maternal anti-neutrophil antibody that has crossed the placenta; resolves by 3-4 months of age; generally supportive care.
10. Drug-induced neutropenia: normal bone marrow reserve but has been associated with a late maturational arrest; antibody or complement mediated neutrophil destruction; treatment consists of stopping unnecessary medications.
11. Infection related neutropenia: normal bone marrow reserve; virus induced anti-neutrophil antibody; parvovirus B19 and HIV can be screened; no treatment generally necessary.
12. Hypersplenism: normal bone marrow reserve; sequestration/possible destruction of neutrophils in the spleen; associated with malaria, TB, neoplasm, collagen-vascular diseases, hemolytic anemia; spherocytes and tailed RBC on blood smear; treat underlying disorder.
13. Pseudo-neutropenia (severe infection): normal bone marrow reserve; generally associated with increases in marginated and tissue pools; mild and spontaneously resolves.

In general, the risk of infection can be related to the bone marrow reserve and overall immune competence of patients with neutropenia. Careful consideration of the overall risk of infection needs to be utilized to determine the appropriate management of these children. Inadequate treatment or follow-up of children with neutropenia and a high risk of infection can be fatal, while over aggressive treatment of a child with a benign neutropenia may result in inappropriate medical care and unnecessary morbidity.

These guidelines can be used in the evaluation and management of the child with neutropenia:

1. Patients with ANCs <500 and fever require prompt evaluation and the rapid initiation of broad spectrum parenteral antibiotics.
2. Empiric parenteral antibiotic therapy (consider ceftazidime, vancomycin, or meropenem) to cover S. aureus, Pseudomonas aeruginosa, Escherichia coli, and Klebsiella species.
3. Consider outpatient management with a parenteral broad spectrum antibiotic (ceftriaxone) if the child is non-toxic, the family and follow up are reliable, and the child has none of the signs of more serious neutropenia syndromes. Followup in an outpatient setting to check the patient's clinical status, check culture results, and administer a second dose of ceftriaxone.
4. DANGER SIGNS: failure to thrive, inflammatory anemia, thrombocytopenia, splenomegaly, lymphadenopathy, joint swelling/bone pain, dysmorphia, recurrent serious infections, fever/infectious symptoms every 21 days, unusual or resistant infections, periodontal disease. If any of these danger signs are present, patients should have more extensive evaluations and a hematology consultation. If no danger signs present themselves, no further testing is needed and parents should be reassured. The most likely diagnosis in the young child is chronic benign neutropenia.

5. Routine use of granulocyte-colony stimulating factor to increase bone marrow production of neutrophils is not indicated for most acquired neutropenias and should be limited to specific disorders where the neutropenia is due to inadequacy of the marrow reserve pool.

DISORDERS OF NEUTROPHIL FUNCTION

Abnormalities in neutrophil numbers are often recognized on a CBC done for other reasons. Children with neutrophil dysfunction must be suspected on clinical grounds, keeping in mind that even the most common primary neutrophil dysfunction syndrome is extremely rare. Children with primary neutrophil function defects usually present with low-grade chronic bacterial or fungal infections. Skin and mucosal infections, lymphadenitis, and abscesses are among those infections commonly seen. These infections tend to be persistent and difficult to resolve with standard treatment. Bacterial sepsis is an unusual finding at presentation.

Children with suspected immunodeficiency should be screened for humoral, cellular, and complement mediated immunity prior to neutrophil function assays. Screening tests routinely available through reference laboratories include: Complete blood count (note that a decrease in neutrophils and platelets/or red blood cells should raise concerns of leukemia or metastatic tumor in the bone marrow), quantitative immunoglobulins (IgG, IgM, IgA, IgE), antibody titers after vaccination (diphtheria, tetanus, and pneumococcus), B-cell counts/phenotype, delayed-hypersensitivity skin tests (Candida, tetanus, or Trichophyton), T-cell counts/phenotype, and total hemolytic complement assay (CH50).

Once a neutrophil defect is suspected and other causes of primary immunodeficiency are ruled out, referral to a specialist familiar with the evaluation of primary neutrophil defects should be made. Anticoagulated samples (usually sodium heparin) should be freshly drawn and transported as quickly as possible to a neutrophil or immunology laboratory. Control samples and parental blood samples are often requested for comparison purposes. Neutrophil function tests generally need to be performed at research laboratories experienced with the assays. NBT testing for reactive oxygen species is sometimes available through reference clinical laboratories, though often times it is unreliable with high false negative rates when done in this setting. General tests of neutrophil function include tests such as modified Boyden chambers (chemotaxis), nitroblue tetrazolium (NBT) slide test (reactive oxygen species), dihydrorhodamine oxidation by flow cytometry (reactive oxygen species), neutrophil receptor quantitation, and phagocytosis/particle ingestion assays.

Characteristic disorders of neutrophil function include:

1. Chronic granulomatous disease: Pathophysiology is impaired respiratory burst (defective NADPH oxidase); inheritance usually X-linked, some autosomal recessive; 1 in 500,000 prevalence, 1 in 2,000,000 live births, two-thirds< 1 year old at diagnosis; most common infections include pneumonia and lymphadenitis; most common infecting organisms (generally catalase negative) S. aureus, S. marcescens, B. cepacia, and Aspergillus sp.; most common clinical findings are lymphadenopathy, hypergammaglobulinemia, hepatomegaly, splenomegaly, anemia of chronic disease, underweight, chronic diarrhea, short stature, gingivitis, and dermatitis; diagnosis made by NBT, flow cytometry, or cytochrome C reduction; treatment includes prevention of infection with daily trimethoprim-sulfamethoxazole and gamma-interferon three times a week; bone marrow transplantation is experimental but curative.
2. Chediak-Higashi syndrome: Pathophysiology is decreased degranulation, chemotaxis and granulopoiesis; inheritance autosomal recessive; rare with 200 cases reported; multisystem disorder with clinical characteristics that include mild coagulopathy, peripheral and cranial neuropathy, hepatosplenomegaly, pancytopenia, partial oculocutaneous albinism, frequent bacterial infections (usually S. aureus), progressive lymphoproliferative syndrome with death by age 20; diagnosis made by neutropenia, giant lysosomes in neutrophils; treatment includes prevention of infection with daily trimethoprim-sulfamethoxazole and daily ascorbic acid; bone marrow transplantation in accelerated phase.
3. Leukocyte adhesion defect I: Pathophysiology is the lack of an adhesion receptor resulting in impaired chemotaxis, adhesion, and phagocytosis; inheritance autosomal recessive; rare with 60 cases reported; clinically characterized by moderate to severe phenotypes with a lack of pus at sites of infection, delayed separation of the umbilical cord, severe periodontitis and/or gingivitis; diagnosis made by the presence of neutrophilia, decreased neutrophil integrin adhesion receptor (CD11b/CD18) by flow cytometry, and impaired chemotaxis; treatment includes prevention of infection with daily trimethoprim-sulfamethoxazole and bone marrow transplantation if severe.
4. Hyper-IgE (Job's) syndrome: Pathophysiology is a variable chemotactic defect; inheritance autosomal dominant; rare with 50 cases reported; clinically characterized S. aureus pneumonia with pneumatoceles, fungal superinfection of lung cysts, recurrent "cold" abscesses that don't respond to antibiotics, eczema, mucocutaneous candidiasis, coarse facial features, and short stature; diagnosis made by an IgE>2,500 and eosinophilia; treatment includes prevention of infection with daily trimethoprim-sulfamethoxazole and bone marrow transplantation if severe.

Children with neutrophil functional defects rarely present with overwhelming bacterial or fungal infections, but more commonly suffer from low grade, chronic infections that may become indolent and impossible to effectively treat. Chronic infection and inflammation associated with deep seated infections leads to a high rate of morbidity and shortened survival. Low grade infections that are neglected can evolve into serious disseminated infections without the appropriate, timely administration of antibiotics or antifungal agents. Adding to this difficulty in clinical monitoring, is an attenuated inflammatory response that often masks serious infection. Referral to subspecialists experienced in the management of children with immunodeficiencies or neutrophil disorders is critical to minimize morbidity and mortality for this population.

Questions

1. The risk of infection with neutropenia is highest when:
    a. Neutropenia onset is rapid
    b. Low bone marrow cellularity is present
    c. Peripheral destruction of neutrophils is occurring
    d. Anti-neutrophil antibody is present

2. The most common cause of neutropenia is:
    a. Anti-neutrophil antibody
    b. Drugs
    c. Infection
    d. Bone marrow failure
    e. Malignancy

3. Neutropenia associated with steatorrhea is most characteristic of:
    a. Cystic fibrosis
    b. Kostmann syndrome
    c. Evan's Syndrome
    d. Chediak-Higashi Syndrome
    e. Shwachman-Diamond Syndrome

4. Neutrophil defect associated with increased infections with catalase-negative organisms
    a. Hyper-IgE syndrome
    b. Leukocyte adhesion deficiency type I
    c. Leukocyte adhesion deficiency type II
    d. Chronic granulomatous disease
    e. Pseudo-neutropenia

5. Infections in children with defects in neutrophil function are characterized by:
    a. Decreased inflammation that may mask serious infection
    b. Indolent, chronic infections
    c. Bacterial and fungal organisms
    d. Elevated erythrocyte sedimentation rate
    e. All of the above

Chapter XII.1. Oncology Treatment Principles
Nu T. Lu

A nine year old boy was treated for pharyngitis one month ago. He is now brought in because his mother notes a decrease in energy, pallor, and easy bruising in his extremities. He complains of leg and arm pains over the last 2 weeks that seem to be aggravated by exercise. He has lost five pounds (2.4 kg) in the past month.

Exam: Vital signs are normal. His height is 130 cm and weight 27 kg (both 25th percentile). He is slightly pale and in no apparent distress. Some palpable nodes are present in the anterior triangle bilaterally. Heart and lungs are normal to auscultation and percussion. The tip of his spleen is 2 cm below the left costal margin and his liver is 3 cm below the right costal margin. His joints have full range of motion and no swelling. His skin shows bruises over the anterior tibial regions and five bruises over the left knee.

Labs: Hemoglobin 7.3. Platelet count 20,000. WBC 42,100 with 86% lymphocytes and 12% atypical lymphocytes. Bone marrow studies confirm B cell acute lymphoblastic leukemia (ALL).

He is treated with a four drug induction chemotherapy which achieves initial remission. Eighteen months later, he relapses requiring an allogeneic bone marrow transplant (BMT). After engraftment, he no longer needs medications or blood product transfusions. Eight months after the BMT, he develops shingles with vesicles on his face. This resolves with appropriate treatment.

Although only 1% of all cancers occur in children (<19 years of age), it is the second leading cause of childhood death. Early detection and prompt therapy have the potential to prolong survival and frequently cure the disease. Many factors are considered in determining the treatment goals for an individual patient: the type of cancer, its stage of growth, the patient's age, and family members' wishes. A team of experts (nurses, social workers, oncologists, surgeons, pathologists, psychologists) tries to meet the complexities of giving the children the most intense course of therapy possible, while not depriving them from having some level of normalcy (going to school, playing with friends).

A variety of modalities are currently employed to treat common malignancies. Surgery, the oldest treatment, provides the best chance of a cure for a localized tumor. It also plays a major role in other aspects of management, including diagnosis, staging, relieving symptoms, reconstruction, and prevention. Yet, its invasiveness physically challenges those undergoing the procedure.

Radiation therapy is used in 2/3 of cancer cases. It induces free radicals to target breaks in DNA, hence interfering with cell proliferation. It is used to treat the primary lesion, shrink a tumor prior to surgery, or palliatively relieve painful symptoms of bone metastasis. Radiation targets rapidly dividing cells, which includes cancer cells and normally dividing cells of the skin, hair, gastrointestinal mucosa, bone marrow, reproductive tissues, sweat glands, and lungs. These correlate with radiation's common side effects: alopecia, nausea, vomiting, pancytopenia, infertility, prostatitis or impotence in males, lung fibrosis and edema. Many of radiation's toxic effects can manifest many years after the treatment. Some examples are: asymmetry of the irradiated extremity, hypothyroidism, neurological dysfunction, growth retardation, and development of a secondary tumor.

Chemotherapy is one of the most common treatments for cancer. It was introduced in the 1940s when Goodman and Gilman first administered nitrogen mustard to patients with lymphoma. Nitrogen mustard, the first alkylating agent used, produced partial remission with considerable toxicity. The era of modern chemotherapy has since evolved to include several other classes of drugs: hormones (prednisone), antimetabolites (methotrexate, 5-fluorouracil), plant alkaloids (etoposide, vincristine, paclitaxel), and antibiotics (doxorubicin, bleomycin). Most of these work by inhibiting some metabolic pathway or DNA synthesis, which ultimately leads to cytotoxicity. Though chemotherapy has limited use for localized tumors, it is often the most effective agent for the management of disseminated or systemic cancer. These include the hematological malignancies (leukemias, lymphomas), metastasis of the primary solid tumor, and potential micro-metastasis after surgery or radiation.

Unfortunately, their utility is limited by the various acute and chronic complications involved with their use. Frequent side effects of chemotherapy include vomiting, diarrhea, cachexia, bone marrow suppression, and immunosuppression. Vomiting and diarrhea lead to fluid loss that often result in hyponatremia. Hyponatremia is also worsened by SIADH. Bone marrow suppression leads to anemia, thrombocytopenia, neutropenia, and hyper-leukocytosis (this is an abnormal increase of white blood cells while the others are an abnormal decrease of different blood precursor cells). Immunosuppression can increase the rate of tumor growth, promote graft versus host disease (GvHD), and predispose patients to opportunistic infections. In addition, the substantial break down of tumor cells by chemotherapy can lead to tumor lysis syndrome, in which a large amount of phosphate, potassium, and uric acids are released into the circulation, when large number of cancer cells are killed.

Supportive care is therefore essential with chemotherapy. Hyponatremia can be corrected by limiting fluid intake, diuresis, or demeclocycline, an ADH antagonist. Vomiting may be prevented by metoclopramide, some H1 antihistamines (diphenhydramine), 5-HT3 inhibitors (ondansetron, granisetron and dolasetron), phenothiazines, dronabinol (marijuana active ingredient), as well as corticosteroids (dexamethasone). Patients undergoing chemotherapy often have a decreased appetite and consequently are malnourished. Enteral tube feeding and parenteral hyperalimentation may become necessary when oral intake is severely inadequate.

Myelosuppression can be treated with transfusion of packed red blood cells, platelet infusions, leukapheresis, or granulocyte-colony stimulating factor (G-CSF). Graft versus host disease may be prevented by irradiating all blood products. Febrile neutropenia may require G-CSF as well as empiric broad spectrum IV antibiotics.

In situations of continual febrile illness for more than 1 week, fungal and viral infections must be considered. Common opportunistic infections include candidiasis, aspergillosis, and Pneumocystis carinii. Temporary prophylactic treatment with trimethoprim/sulfamethoxazole is often prescribed in anticipated bone marrow suppression. Children on chemotherapeutic protocols are prone to complications from disseminated viral infections. They should not be given live attenuated vaccines, since these attenuated organisms may still cause disseminated disease in immunocompromised hosts. Children who are exposed to chickenpox during their chemotherapy should be given IV varicella zoster immunoglobulin. If clinical symptoms develop, hospitalization and IV acyclovir should be instituted.

Although the acute complications of chemotherapy are relatively manageable, some of its long-term consequences are devastating and often cause significant morbidity and mortality. Irreversible complications include leukoencephalopathy following high-dose intrathecal methotrexate, infertility in male patients treated with cyclophosphamide, myocardial damage from anthracyclines, pulmonary fibrosis after bleomycin, pancreatitis after asparaginase, and hearing loss associated with cisplatin. Chemotherapy or radiation may also cause the development of a secondary tumor. There is a 0.5% risk after the first year, but it increases to 25% 12 years after treatment. It is strongly recommended that children be checked annually post chemotherapy to detect a secondary malignancy.

Most of the chemotherapeutic complications result from their nonspecific targeting of both malignant and normally dividing cells. Hence, the newer tumor specific-agents, antisense messenger RNA, anti-angiogenic agents (angiostatin and endostatin), anti-angiogenic monoclonals attempt to overcome some of the side effects of the older chemotherapeutic agents. One of the huge advantages of newer agents is their minimal degree of dose-limiting toxicities. Clinical trials of these agents are currently underway.

Stem cell transplantation has revolutionized the therapeutic options for primary bone marrow diseases and systemic neoplasms. Both autologous and allogeneic transplants have been employed successfully for a variety of hematological and oncological conditions in which chemotherapy and/or radiation have failed to induce remission. Examples include juvenile myelomonocytic leukemia, acute lymphoblastic leukemia (ALL), acute myeloid leukemia in first or second remission, chronic myelogenous leukemia, severe combined immunodeficiency, hemophagocytic lymphohistiocytosis, aplastic anemia, Diamond-Blackfan anemia, beta-thalassemia major, and some inborn errors of metabolism.

Perhaps, the most challenging aspect of peripheral blood stem cell transplantation (PBSC) is finding a donor with sufficiently matching HLA haplotypes (i.e., chromosome 6, which encodes HLA). To minimize rejection and GvHD, more rigorous conditions, with serological as well as molecular matches, are now required to ensure closer HLA match. Once donors are identified, they are treated with G-CSF or GM-CSF (colony stimulating factors) to increase the proliferation of precursor stem cells. Collection of stem cells is made at various sites in the body: bone marrow, peripheral blood, and sometimes even cord blood.

Despite great efforts to match HLA genotypes, stem cell transplant is currently not widely used. Its limitations still include the non-availability of the "right" donors, concern about the lack of randomized comparisons to less risky chemotherapy in certain diseases where chemotherapy alone may induce remission, and chronic graft versus host disease. Certain measures may be instituted to decrease the prevalence and severity of GvHD. The combination of cytotoxic drugs such as methotrexate with inhibitors of T cells activation such as cyclosporin and FK 506 has dramatically reduced the severity of both acute and chronic GvHD. In addition, depletion of donor T-cells essentially eliminates GvHD. However, donor immunosuppression inadvertently increases the risk of infections and decreases the graft versus leukemia response that may lead to the higher relapse rate in these cases. Hence, it is a fine balance between the absolute prevention of GvHD and the risk of relapse.

Pain management, an essential component of oncological therapy, has recently become a focus of attention. Children were once believed to not feel as much pain because of their underdeveloped nervous system. However, cancer causes tremendous pain in children. Prolonged pain saps spiritual energy and diminishes the body's ability to heal. Pain therefore should be managed in a stepwise fashion, and should be a top priority for any oncological patient, especially those needing palliative care.

The magic bullet is hard to come by. The major challenge in oncology treatment is to find the right combination of type and amount of chemotherapy, right amount of radiation, and the best timing of stem cell transplantation for each individual patient. Future therapeutic approaches include immunotherapy as well as gene therapy. Immunotherapy can be viewed as fine-tuning of the GvHD reaction in order to have it work towards the body's advantage to fight against cancer. In several animal models, it has been successfully proven that the immune system can be an important component in fighting off cancer. The immune system provides high precision in selectively targeting cancer cells. If there is some means to engraft a competent immune system to a leukemic patient, it hopefully will stimulate an immune response against leukemic cells. Several research groups have tested interleukins, notably IL-2 and IL-4, which stimulate both T and B-lymphocytes in ways that theoretically inhibit tumor growth. Other interleukins, IL-6 and IL-10, promote the development of B cell malignancies because they inhibit the synthesis of antiviral cytokines (interferons) and IL-2. Future drug development may consider inhibiting these tumor-promoting compounds.

Gene therapy is an exciting possibility for essentially curing cancer. The principle behind this approach is that cancer is inherently a genetic defect. Hence, if it is possible to use a vector to carry the good genes to target the malignant cells, the deposit of the good genes into cancerous cells may lead to tumor regression. Gene therapy is still in the study phase.

Questions

1. What are some common opportunistic infections associated with immunosuppression induced by chemotherapy? What is the appropriate prophylaxis for these patients?
2. Give an example of a drug from each of the five classes of current chemotherapy in use.
3. What is a serious side effect for methotrexate use especially intrathecally delivered?
4. What is the mechanism responsible for most chemotherapeutic complications?
5. Where are various places that stem cells may be harvested from in the body?

Answers to questions

1. Common infections include candidiasis, aspergillosis, and Pneumocystis carinii. Prophylactic treatment with trimethoprim/sulfamethoxazole is indicated.
2. Hormones (prednisone), antimetabolites (methotrexate, 5-fluorouracil), plant alkaloids (etoposide, vincristine, paclitaxel), antibiotics (doxorubicin, bleomycin), anti-angiogenesis drugs.
3. Leukoencephalopathy
4. Most of these work by inhibiting some metabolic pathway or DNA synthesis, which ultimately leads to cytotoxicity
5. Bone marrow, peripheral blood, and sometimes even cord blood.

Chapter XII.2. Leukemia and Lymphoma
Bruce T. Shiramizu, MD

This is a 10 year old boy who presents to the emergency department with a chief complaint of fever and increasing tiredness. He was well until 2 weeks ago when he had an upper respiratory illness (URI). He has been tired with decreased activity since the URI, and has missed school and sports practices for 2 days. He has a decreased appetite and has lost 2 pounds over the last 2 weeks. He has some shortness of breath when he climbs stairs, but his parents deny cough, fever, nausea, emesis, bruising, headache, or visual problems. His past medical health, including birth history, immunizations, and other medical problems is unremarkable. He lives with his two parents and 6 year old brother, all of whom are healthy. The sibling and parents had similar URI symptoms 2 weeks ago, but everyone else is back to normal activity levels. There is no family history of relevant medical problems.

Exam: VS T 38.5 degrees C, P 120, R 32, BP 110/56. Height & weight at the 80th percentile. He is alert, tired and slightly pale appearing, but in no apparent distress. His head is normocephalic without scalp lesions. His hair texture is normal. His ear canals and TMs are normal. Pupils are equal and reactive to light. Conjunctivae are pale. His fundi are normal. His nasal passages are clear. His mucous membranes are dry and pale. His posterior pharynx is erythematous without lesions and no tonsillar enlargement. His dentition and gums are normal. No nuchal rigidity is present. He has bilateral cervical nodes, posterior cervical nodes, axillary nodes, and inguinal nodes palpable (about 1-2 cm), mobile and nontender. His chest exam (breasts, lungs, heart) is normal except for some tachycardia. His abdomen is flat and non-tender with normal bowel sounds. His liver edge is palpable at the costal margin. His spleen is palpable 4 cm below the left costal margin. His back is normal. His skin shows no lesions, bruises or petechiae. Upper and lower extremities are normal. His neurological exam is normal.

Laboratory: CBC Hgb 7, Hct 24, MCV 100, WBC 56,000, Differential 14% lymphoblasts, 80% lymphocytes, 6% atypical lymphocytes. Platelets 23,000. Chest x-ray shows clear lung fields but a wide mediastinum.

He is admitted to the hospital and a diagnostic workup including a bone marrow aspirate and biopsy reveals acute lymphoblastic leukemia.

There are different types of leukemia but the most common leukemia that occurs in children is acute lymphoblastic leukemia (ALL). ALL is the most common cancer in children representing 23% of cancer diagnoses among children younger than 15 years of age and occurring at an annual rate of approximately 31 per million (1). Approximately 2,400 children and adolescents younger than 20 years of age are diagnosed with ALL each year in the USA. There is a sharp peak in ALL incidence among children ages 2 to 3 years. Lymphomas, in general, are divided into two broad categories, Hodgkin's disease (HD) and non-Hodgkin's lymphoma (NHL). As a group, it is the third most common childhood malignancy with HD and NHL accounting for approximately 10% of cancers in children less than 20 years of age (2). In the United States, there are about 800 new cases of NHL diagnosed each year. Incidence is approximately 10 per 1,000,000.

For both ALL and lymphoma (HD and NHL), the signs and symptoms may be similar but non-specific. The clinical manifestations may present insidiously or acutely, as an incidental finding on a routine complete blood count analysis or as a life-threatening infection or respiratory distress. Some characteristics which may present at the time of diagnosis are lethargy, fever, joint pain, bleeding, abdominal pain, CNS manifestations, and/or difficulty breathing secondary to a mediastinal mass. On physical examination, there may be pallor, hepatosplenomegaly, petechiae, and/or lymphadenopathy.

Because some rare cases may be difficult to diagnose even with proper diagnostic biopsies, other diagnoses should be entertained. These include viral infections such as Epstein-Barr virus, cytomegalovirus; other malignancies such as neuroblastoma; hematological disorders such as aplastic anemia, histiocytosis, idiopathic (immune) thrombocytopenic purpura (ITP); and juvenile rheumatoid arthritis. In general, the differential diagnosis between ALL and NHL has been debated for years, and the criteria utilized to distinguish between the two categories of diseases have been arbitrary. While both entities can be of B-cell or T-cell phenotype, the distinction between NHL and ALL is currently based on the degree of bone marrow involvement. Children who have more than 25% infiltration of their marrow with blast cells are considered to have ALL.

Treatment and management of ALL and NHL are based on proper diagnosis and staging to determine the extent of disease involvement. Diagnosis is made from either the bone marrow (ALL) or tissue (NHL), and includes immunophenotyping, cytogenetics, flow cytometry, and/or molecular studies such as gene rearrangements. Recommended staging studies include a careful physical examination, complete blood count, bone marrow aspirate or biopsy, lumbar puncture, and radiographic studies including possible nuclear medicine studies to assess the extent of disease.

Prior to instituting specific therapy, measures should be instituted to treat emergent problems, particularly in patients with advanced disease and who may have associated airway compression or superior vena cava obstruction. Measures should also be in place to be able to monitor and intervene for treatment related problems such as tumor lysis. Tumor lysis can occur spontaneously or as a result of chemotherapy leading to serious metabolic complications such as hyperuricemia, hyperkalemia, and hyperphosphatemia. This could ultimately lead to renal failure or cardiac arrest if left untreated.

Successful treatment of children with ALL and NHL requires the control of systemic disease (marrow, liver and spleen, lymph nodes, etc.) as well as the treatment (or prevention) of extramedullary disease particularly in the central nervous system (CNS) (1,3). The main goal of therapy is to begin induction treatment as soon as the diagnosis is made in order to obtain remission. After inducing remission, the next goal is to maintain remission. In general, therapy is based on cytotoxic drugs affecting the rapidly dividing cells during the cell cycle. Multiple drugs are used because each class of drugs acts on a different part of the cell cycle with the intent of interrupting cell division in the majority of malignant cells. The concept of inducing remission initially is to try and rapidly destroy the majority of malignant cells within the first 30 days of treatment. Ongoing and subsequent treatment strategies are based on the concept that malignant cells that "escaped" the induction phase will enter the cell cycle over a period of time and will then be affected by the drugs. Most of the drugs are administered orally, intravenously, or intramuscularly. CNS treatment and/or prophylaxis is administered via a lumbar puncture (intrathecal). Occasionally, emergency treatment has to be considered for life-threatening situations such as airway compression, spinal cord compression, etc. This can be accomplished with the use of radiation to the involved sites. The immune system is compromised throughout the duration of therapy. Therefore one must be attentive to any signs or symptoms of septicemia. Additionally, exposure to infectious agents including live vaccines should be avoided.

In general, there are clinical and laboratory findings present at the time of diagnosis which may correlate with prognosis. A high tumor burden, whether assessed by total white blood cell count for ALL or high stage disease in NHL (or elevated serum LDH) has been

consistently found to be an important prognostic factor. Other factors might include specific chromosome abnormalities, age, race, or gender. Recently, the rapidity of response to induction therapy or the presence of residual disease has been examined as a predictor of outcome.

Approximate 75-80% of children and adolescents with ALL and NHL will survive at least 5 years with modern chemotherapy although outcome is variable depending on a number of factors. Since nearly all children will achieve remission with proper treatment, one of the main obstacles today is how to effectively treat bone marrow or CNS relapses. Other challenges are the result of successful treatment and related to screening and treating long term complications from therapy. These include CNS sequelae affecting cognition and learning, growth failure, reproductive sequelae, cardiac sequelae, and secondary malignancies.

Questions

1. You are called to the ER to evaluate a 10 year old boy who has been tired for 2 weeks and his parents noticed that he becomes short of breath when he walks upstairs to go to his bedroom. Upon your physical exam, you note that he has some shortness of breath when he is placed in the supine position. Which of the following procedures might you consider initially ?

a. Arrange for a better examination of the lungs and possible diagnostic biopsy under general anesthesia.

b. PA and Lateral chest x-ray.

c. An MRI of the chest to rule out an enlarged heart.

d. Diagnostic fine needle aspirate without general anesthesia to find out why he is short of breath.

2. One of your patients (5 year old female) was diagnosed with ALL 6 months ago and is being treated by a pediatric hematologist/oncologist with chemotherapy. She now wants to start back to school and the school administration tells the parents that she needs to be up to date on her immunizations. They would like her MMR administered. What advice do you offer them?

a. Even though the child is on chemotherapy, there is evidence that her immune status is competent, therefore she can be given all of her scheduled immunizations.

b. Her immune system will only mount an immune response to live, attenuated vaccines, therefore she can receive the MMR vaccine as scheduled.

c. MMR vaccine is contraindicated in a child receiving chemotherapy for cancer.

d. The parents should wait until the child recovers from the side effects of the current cycle of chemotherapy and then make an appointment for the MMR vaccine.

3. As the pediatrician of a 7 year old boy who was diagnosed with NHL at 4 years of age and successfully completed chemotherapy, the parents made an appointment to have him see you because they were advised by the boy's teacher that he has not been keeping up academically. You review the boy's medical history, and other than the chemotherapy, you do not see anything that would account for the poor school performance. What is the best advice to the parents?

a. You remind the parents that because of the child's past medical situation, he has a feeling of neglect and abandonment therefore will need some remedial attention to overcome the psychological condition, which is causing his poor academic performance.

b. There is a high likelihood that the child has a secondary brain tumor, and may need at CT scan of the head.

c. Having received therapy which compromised the child's immune status, he most likely has meningitis, therefore should be admitted for therapy.

d. Children who have received chemotherapy and/or radiation may experience delays in growth and development, therefore further testing and gathering of information should be suggested.

4. You are the primary pediatric resident on the hematology/oncology team and covering the service over the weekend. A 6 year old was admitted on Thursday, with a history of being tired, shortness of breath, pallor and weight loss. A prompt and efficient workup revealed a diagnosis of T-cell NHL. Following the family conference and consent process to begin the child on a lymphoma protocol, treatment was started by the weekend. The chemotherapy is being administered properly, with attention to tumor lysis precautions, including vigorous hydration. As you make your midnight rounds, you notice that the documentation of fluid input and output shows a large discrepancy. The amount of fluid administered (orally and intravenously) is almost twice the volume as the urine output. You suspect that the patient is experiencing complications from the chemotherapy and think you should do which of the following:

a. Increase the hydration because the fluid balance is not equal, and the patient should be receiving more than twice maintenance fluid intake during induction chemotherapy.

b. Perform a thorough physical exam, have the patient weighed, repeat the serum electrolytes immediately to determine if the patient is fluid overloaded.

c. The patient is experiencing renal failure, and needs immediate consultation by a nephrologist to begin dialysis.

d. You decide that the oral fluid intake has not been taken into consideration, which it should be, and estimate the amount the patient has been taking in orally based on what was served on his meal trays. By your calculations, the total fluid intake and output is equal, therefore no further action is needed.

5. The parents of a 5 year old boy bring their son to see you because they are concerned that their son has leukemia. His 3 year old sister had a URI 2 weeks ago, but fully recovered and has been back in school and active. This 5 year old boy has URI symptoms now. They noticed bruising on his legs and arms over the last few days, and their neighbor's daughter had similar findings 2 years ago before she was diagnosed with acute lymphoblastic leukemia. The mother's grandfather died at the age of 80 from leukemia. Your physical exam is unremarkable except for the bruises noted on the anterior legs and on the forearms. He is playful and cooperative. What course of action or advice should you do next?

a. Because of the strong family history of ALL and the leukemia case in the neighborhood, you should pursue a presumed workup of ALL and notify the state Cancer Control Division.

b. Obtain a complete blood count.

c. The bruising strongly makes you suspicious of possible child neglect or abuse. Reassure the parents that you do not suspect them, but you should alert them of your concerns and find out who could possibly be the perpetrator.

d. Since the bruises are the only abnormal finding, you are less concerned about leukemia, therefore you alleviate the parents' concerns and tell them that the bruising is most likely related to the child's aggressive activities at school.

Answers to questions
1. b. The fact that the child is short of breath in the supine position could be related to a mediastinal mass, which can be identified on a chest x-ray. A mediastinal mass could be a potential emergency situation, therefore a chest x-ray should be considered shortly after the history and physical exam are completed.
2. c. Live vaccines are contraindicated throughout the treatment course due to the immunocompromised status of the patient.
3. d. Delays in growth and development may occur as a result of chemotherapy and/or radiation therapy.
4. b. The chemotherapy may have induced tumor lysis causing hyperuricemia, which in turn may be affecting the kidneys.
5. b. As part of the differential diagnosis, you should consider ITP.

Chapter XII.3. Solid Tumor Childhood Malignancies
Christina Keolanani Kleinschmidt

An 18 month old female presents to the office for her well-child examination. A third year medical student is allowed to take the history and perform the initial examination. On a routine ophthalmoscopy exam, the student notices that the child does not have a red reflex in the right eye. This is reported to the physician who confirms the exam finding. There is no history of weight loss, anorexia, crossed eyes, fever, or irritability.

Exam: VS T 37.0, P 110, R 26, BP 92/42. Height, weight, head circumference are all at the 40th percentile. She is alert and active. Leukocoria is present in the right eye. A normal red reflex observed in the left eye. Pupils are equal and reactive. The eyes are conjugate. Facial function is good. The remainder of the physical examination is negative.

Clinical Course: The child is referred to an ophthalmologist. An ophthalmoscopy exam performed under general anesthesia reveals a tumor in the posterior pole of the right eye. An orbital CT demonstrates that the tumor is confined to the globe (i.e., no spread outside the eye). Since the tumor is small it is treated with laser photoablation. Careful follow ups are scheduled to monitor for recurrences or development of secondary tumors.

This chapter will cover the four most common malignant solid tumors of childhood: retinoblastoma, osteosarcoma, neuroblastoma and Wilms' tumor.

Retinoblastoma

Retinoblastoma is a slow growing malignant tumor of the retina that may be confined to the eye for up to months or even years. In the United States it is the seventh most common pediatric malignancy (1). About 90% of cases occur before the age of 5. Bilateral tumors occur at an earlier age than unilateral tumors. The mean age of diagnosis in bilateral tumors is 12 months whereas unilateral tumors occur at a mean of 24 months of age (2).

The exact molecular pathogenesis has been elucidated for retinoblastoma, which results when there is a mutation in the retinoblastoma gene found on the long arm of chromosome 13 at band 14 (13q14). The gene is a tumor suppressor gene that is involved in regulating the cell cycle. In order for retinoblastoma to manifest, both Rb alleles must be mutated (the essence of the two hit hypothesis). In the hereditary form of retinoblastoma, the individual inherits a mutant Rb gene from the germ line. Another mutation must occur in a somatic retinal cell in order for retinoblastoma to manifest itself. In the nonhereditary form, both mutations must occur in the same somatic retinal cell. When both are mutated, defective intracellular transcription and unchecked cell proliferation leads to malignant transformation (3).

If it is not detected during the routine ophthalmoscopic exam or suspected due to family history, the first presenting sign may be a white pupillary reflex called leukocoria, which is frequently noted on flash photography as a white reflex instead of the usual flash photography "red eye". Parents will often notice this and bring this to the attention of the child's physician, usually after a significant delay. This sign is present in approximately 60% of the patients and is attributed to the formation of a central posterior pole tumor. Another 20% may present instead with strabismus due to tumor involvement of the macula. Retinal detachment may also be detected. The patient may also present with a red, painful eye, poor vision, unilateral pupil dilation, heterochromia (the iris color of each eye are not the same), or nystagmus. If the tumor is in an advanced stage, the patient may present with constitutional symptoms and signs as well as neurologic defects, orbital mass, proptosis, or blindness (1).

Leukocoria is difficult to detect during a routine exam. If it is not detected during the exam, yet the parent reports an abnormal pupil, a referral should still be made to an ophthalmologist. Ophthalmoscopy done by a specialist through dilated pupils is the most important test performed to diagnose retinoblastoma. If the child is young, this must be done under general anesthesia. Parents and siblings should also have a dilated ophthalmoscopic examination to rule out unsuspected or dormant tumors (2). A CT scan can also be used to detect intraocular calcification, optic nerve involvement, and extraocular extension of the tumor (4).

Careful examination is required to rule out any other disorders that resemble retinoblastoma. The differential for a mass should include astrocytic hamartomas and granulomas of Toxocara canis, Coat's disease, retinopathy of prematurity, and persistent hyperplastic primary vitreous should be suspected when there is retinal detachment (1).

Treatment options for retinoblastoma include enucleation, external beam radiation, plaque radiation, laser photoablation, thermotherapy, cryotherapy, and chemotherapy. The choice of treatment will ultimately depend on the size, location, and extent of the tumor, whether it is bilateral or unilateral, if there is visual potential, or if extraocular disease or metastasis is present.

Enucleation is performed on large unilateral tumors that have led to severe visual impairment. Individuals with optic nerve invasion, secondary glaucoma, and seeding into the pars planta have also undergone enucleation (5). In the past, enucleation was performed on the eye with the most advanced disease in bilateral tumors. However, chemotherapy and local therapy have successfully replaced this practice (2).

In the past, standard therapy for the least involved eye in bilateral tumors has been external beam radiation. However, long term consequences such as cataract formation, radiation retinopathy, optic neuropathy, and the development of secondary tumors has lead to the search for alternative treatments. Radioactive plaque therapy (or brachytherapy, in which radioactive seeds are implanted close to the tumor) has since been employed to restrict the area of the orbit exposed to radiation. This procedure has reduced the harsh consequences of radiation. Brachytherapy has also been used to treat unilateral tumors. Small tumors have also responded well to other types of local therapy, in particular cryotherapy and laser photoablation (5).

Chemotherapy is also a common therapy used in the treatment of retinoblastoma. In the past, it was used basically to treat advanced extraocular disease. Today, it is used when there is extraocular extension, metastasis, and positive cerebrospinal fluid findings. It is also used if accidental dissemination of tumor cells has occurred. For example if a previous intraocular procedure was done before the diagnosis of retinoblastoma was made, the patient may be treated prophylactically with chemotherapy (5).

The extent of optic nerve involvement, extension of the tumor, and choroidal involvement directly influences mortality. The outcome has been excellent in individuals suffering from unilateral intraocular tumors. Individuals with optic nerve extension beyond the lamina cribrosa have only a 40% 5 year survival rate (4). A cure rate of greater than 90% has been seen after enucleation of unilateral intraocular tumors. The use of local ablation with or without chemotherapy is also usually successful (3).

Patients with a germ line mutation of the Rb gene fare a worse outcome. These are individuals who were born with one mutant Rb gene and sustained a subsequent spontaneous mutation in a somatic Rb gene. They have poor survival rates and have a reduced likelihood of salvage of vision. If they survive retinoblastoma they are at an increased risk for developing a secondary cancer. More than 90% will develop a secondary cancer within 32 years after treatment (1). This is because the retinoblastoma gene is linked to nonocular tumors, most notably osteosarcoma (1).

Osteosarcoma

Osteosarcoma is a malignant mesenchymal tumor of bone with resultant osteoid formation. It is the third most common cancer in children and adolescents (6). It has a bimodal incidence with the first peak occurring in the second decade of life and the second peak occurring in the elderly. It is more common in boys than in girls. The common sites of involvement are the metaphyseal regions of the distal femur, proximal tibia, and proximal humerus (7).

The exact cause of osteosarcoma is unknown, but it has been linked to a variety of syndromes and genetic changes. Most notably, it has been strongly correlated with a germ line mutation of the Rb gene. Patients with retinoblastoma have a significantly increased risk for the development of osteosarcoma. If these individuals were treated with radiation, their susceptibility increases further (7). Alkylating agents and other antineoplastic drugs, have also been reported to increase the risk of developing this neoplasm. Individuals suffering from Li-Fraumeni syndrome, a familial cancer syndrome associated with a germ line mutation, are also predisposed (8).

Patients usually present with pain and swelling most commonly at the knee. The pain may be intermittent and most commonly occurs at night causing it to be often dismissed as growing pains. Since individuals afflicted with this disease are commonly going through their "growth spurt", this conclusion seems rational. It may further be mistaken by the patient as a sports injury. However, not all patients present with a history of trauma. Physicians must take care not to make the same assumptions. Additional clinical findings may help them distinguish this disease from benign growing pains. These findings include a palpable mass, limited range of motion, tenderness, and warmth (8). However, since none of these findings may be present initially, an imaging study is often necessary to diagnose osteosarcoma during its earliest stage.

The diagnosis of osteosarcoma can be made on: x-ray of the affected bone, MRI, CT scan, radionuclide bone scan, and biopsy. Radiographs may display a mixed lytic and blastic lesion. In more advanced cases, a sunburst pattern of new bone formation and lifting of the bony cortex may create what is called a Codman triangle (4). An MRI of the lesion and the entire bone is done to evaluate the tumor's proximity to nerves and blood vessels as well as its extension into a joint or soft tissue. CT of the chest, and bone scintigraphy detects sites of metastasis (6). After all of these procedures are done, a biopsy can be performed to make the definitive diagnosis. Together, these procedures should help to differentiate osteosarcoma from other bone disorders such as histiocytosis, Ewing's sarcoma, lymphoma, and osteomyelitis (8).

In the past, osteosarcoma was treated with surgery alone. However, the survival rate was poor even for nonmetastatic cases, since most patients have non-detectable micrometastases at presentation. Surgical treatment combined with chemotherapy has greatly improved the survival rate. Treatment options available today include chemotherapy, amputation, and limb salvage procedures (7).

Previously, surgical treatment meant amputation of the affected bone. The bone would be amputated 7 cm proximal to the proximal border of the tumor to minimize recurrence. The patient would then undergo chemotherapy. However, with the advent of even more effective chemotherapeutic agents, limb salvage treatment is the new therapeutic approach to osteosarcoma. The patient undergoes preoperative chemotherapy to induce primary tumor necrosis and treat micrometastatic disease (6). A block excision of the tumor and prosthetic replacement is then performed (7). Contraindications for limb salvage therapy include involvement of a neurovascular bundle by the tumor, immature skeletal age (especially for the lower limb), infection in the region of the tumor, and extensive muscle involvement that would result in poor functionality (4).

This multi-agent approach has greatly improved survival rates. Approximately 75% of patients with nonmetastatic osteosarcoma of the extremity are cured. Even individuals with lung metastases have shown a 20% to 30% cure rate when treated aggressively with chemotherapy and resection of lung nodules (8). This is an improvement because pulmonary metastasis has been the major obstacle in curing patients with osteosarcoma.

Neuroblastoma

Neuroblastoma is a neoplasm of childhood that arises from neural crest cells involved in the development of sympathetic nervous tissue. It is the most common extracranial solid tumor of childhood, occurring at a rate of 1 case per 10,000 persons. Young children are the primary targets, with the median age of diagnosis occurring at 2 years of age. It rarely occurs in children over 10 years of age and it has a slight predilection for boys (2).

The exact cause of neuroblastoma is unknown, but it has been associated with various disorders and mutations. It has been tied to disorders that involve neural crest development such as Hirschsprung's disease and neurofibromatosis type I. It has also been linked with

several different types of genetic changes. These changes include n-myc proto-oncogene amplification, chromosome 1p deletion and chromosome 17q gain (9). It is believed that the 1p deletion and 17q gain are the result of an unbalanced translocation between these two sites (10). The exact role of these changes in the pathogenesis of neuroblastoma has not been elucidated.

Neuroblastoma develops from sympathetic neuroblasts anywhere along the sympathetic chain ganglia or in the adrenal medulla. Spontaneous malignant transformation is believed to occur when sympathetic neuroblasts fail to differentiate. When there is complete failure of differentiation, a neuroblastoma forms.

Primary tumors occur 50% in the adrenal gland, 30% in retroperitoneal sympathetic ganglia, and 20% in cervical and thoracic ganglion (9). The patient's clinical presentation depends on the location of the primary tumor, the size of the tumor, and if it has metastasized. The typical constitutional symptoms of cancer, fever, general malaise, and pain, are present. Complicating the patient's clinical presentation is the fact that approximately 75% of patients will present with metastatic disease at the time of diagnosis. Common sites of metastasis are lymph nodes, bone marrow, liver, skin, orbit, or bone (especially facial bones, skull, and appendicular bone) (2).

Adrenal and retroperitoneal tumors present as an abdominal mass extending from the flank to the midline of the abdomen. The mass is usually firm, irregular, and nontender. If the mass begins to enlarge and extend further in the cavity, abdominal distention, anorexia and weight loss occur. The mass may also be a result of hepatomegaly due to tumor metastasis, so physicians must take care not to miss this diagnosis. Retroperitoneal tumors may extend into the paraspinal area and compress on the spinal cord. Thoracic tumors may compress the spinal cord and cause paraplegia. Lower lumbar tumors may cause cauda equina syndrome (10).

Thoracic and cervical ganglion may also compress on surrounding structures. Thoracic masses may be an incidental finding on a chest x-ray done to evaluate dyspnea or other upper respiratory problems. A cervical tumor presents as a hard, fixed mass associated with Horner's syndrome or tracheal compression (10). These patients may present with myosis, ptosis, anhydrosis, flushing, and apparent enophthalmos.

On the initial visit, the patient may also present with bone or ocular problems that indicate metastasis to these regions. The bone metastasis may manifest as bone pain with refusal to walk and reported tenderness, swelling, or the finding of a localized lump. If the tumor extends into the marrow, bone marrow suppression may occur. This manifests as anemia and weakness. Periorbital metastasis is associated with orbital ecchymosis and proptosis, also described as "raccoon eyes" (10).

Clinical manifestations may also be a result of substances released from the tumors. Release of vasoactive intestinal peptide (VIP) may cause intractable secretory diarrhea leading to hypokalemia and dehydration. Release of catecholamines from the tumors is rare and may cause hypertension, tachycardia, palpitations, profuse sweating, and flushing (9). Another mysterious syndrome associated with neuroblastoma is opsomyoclonus (also called opsoclonus). This syndrome consists of myoclonic jerks and random eye movements sometimes associated with cerebellar ataxia. It is sometimes called the dancing eyes and dancing feet syndrome because of its physical presentation. The exact mechanism is unknown but hypotheses implicate either a peptide produced by the tumor or immunologic cross reactivity between the tumor and cerebellar neurons (10).

Bone pain may resemble symptoms seen in rheumatoid arthritis, rheumatic fever, osteomyelitis, and acute leukemia. Abdominal masses are also present in Wilms' tumor, lymphoma, mesenteric cysts, hydronephrosis, and splenomegaly. Intractable diarrhea may be due to malabsorptive states (11).

If the historical and physical findings lead to the suspicion of neuroblastoma, a complete blood count, urinalysis, and imaging studies should be done. A CBC may show anemia and thrombocytopenia indicating extension into the bone marrow. Special urine chemistry may pick up catecholamine metabolites such as homovanillic acid (HVA) and vanillylmandelic acid (VMA), break down products of the catecholamines secreted by the tumor. The skeletal survey may discover bone metastases. MRI may also detect bone metastases as well as intraspinal tumors (11). At initial presentation, ultrasound is useful for diagnosing intra-abdominal tumors and can display calcifications (11), but ultrasound interpretation requires skilled expertise. Falsely negative studies are misleading for the clinician unless an alternate imaging study such as a CT scan is done to make the diagnosis.

The diagnosis must be confirmed by histologic examination. Neuroblastoma is known as one of the small, blue, round cell tumors of childhood. Histologically, it is characterized by undifferentiated neuroblast aggregates that are separated by fibrovascular septae. Neuroblastomas that mature into benign ganglioneuromas due to spontaneous regression or therapy-induced maturation may have a mixture of undifferentiated and differentiated cells (10). Some neuroblastomas (especially in infants) may undergo spontaneous regression, even if widely disseminated at initial presentation.

Treatment depends on the stage of the tumor and its histology. Surgical resection is the primary treatment for those who have a localized tumor that is resectable. This includes patients with tumors that are localized to one side of the midline or those which cross the midline without encasement of major blood vessels. Radiation is indicated in those with localized, unresectable tumors that have not responded to initial chemotherapy. Chemotherapy is used in patients with advanced stages of neuroblastoma (2).

The main prognostic factors for neuroblastoma are the age of the patient, the stage of the disease, presence of n-myc amplification, and chromosome 1p deletion. Children who are younger than 1 year old and have favorable histology have better survival rates for all stages than those older than 1 year. For example, a child older than 1 year with stage 2 disease has an 85% disease-free survival whereas a child younger than 1 year with stage 2 disease has nearly a 95% disease-free survival (10).

Wilms' Tumor

Wilms' tumor is a malignant embryonic neoplasm of the kidney most commonly seen in young children. It is the second most common abdominal tumor in children (neuroblastoma is more common). It peaks at ages 1 through 3 years with the median age of diagnosis occurring at 3.5 years in those with unilateral involvement (13). Bilateral involvement presents at an earlier age than unilateral involvement.

The exact cause of Wilms' tumor is unknown, but mutations in the short arm of chromosome 11 have been detected in approximately 30% of the patients (15). The Wilms' tumor suppressor gene (WT1) is located on locus 11p13 and acts to regulate transcription of other genes during normal renal development (16). Mutation of WT1 predisposes an individual to nephrogenic rests, benign clusters of blastemal and stromal cells, which may be subjected to further mutation leading to malignant transformation (2). Deletion of this locus has been linked to the WAGR (see below) and Denys-Drash syndromes. These are syndromes that consist of various congenital anomalies in conjunction with Wilms' tumor. Individuals with the WAGR syndrome present with Wilms' tumor, aniridia, genitourinary malformations, and mental retardation (15). Those who suffer from Denys-Drash syndrome have Wilms' tumor, nephropathy, and genital abnormalities (15).

A second locus has recently been discovered at the 11p15 locus. It is denoted as the WT2 gene, but its exact functions have not been elucidated. Some hypothesize that the gene is actually IGF2 (insulin growth factor 2), which encodes for a growth factor found in

abundance in Wilms' tumor (2). The Beckwith-Wiedemann syndrome has been linked to this locus. Patients with Beckwith-Wiedemann syndrome display organomegaly (liver, kidney, adrenal, and pancreas), macroglossia, omphalocele, and hemihypertrophy (15). Individuals with this syndrome have a 10-20% incidence of tumor development, including Wilms' tumor (16).

This neoplasm most commonly presents as an asymptomatic abdominal mass discovered by parents during bathing or by a doctor during a routine exam. The mass is usually smooth, firm and rarely crosses the midline. Individuals who are symptomatic may present with abdominal pain, fever, anemia, hematuria, and hypertension. The tumor may compress on the renal artery causing renal ischemia leading to renin secretion with resulting hypertension (2). Post-streptococcal glomerulonephritis may be mistakenly diagnosed in cases presenting with hematuria and hypertension. Individuals may also present with abnormalities that may link them with the syndromes associated with Wilms' tumor (WAGR, Denys-Drash, Beckwith-Wiedemann). Rarely, a paraneoplastic syndrome may arise in which erythropoietin is released causing polycythemia (15).

An abdominal mass is linked with a variety of diseases all of which needs to be included in the differential. Those that are of importance include neuroblastoma, rhabdomyosarcoma, leiomyosarcoma, renal cell sarcoma, fibrosarcoma, hydronephrosis, polycystic kidney, adrenal hemorrhage, and renal vein thrombosis (13).

Imaging studies (ultrasound or CT) are required to confirm the presence of a renal mass. Once a Wilms' tumor is suspected, a complete blood count, liver and kidney function tests, skeletal survey, and chest x-ray should also be done. Ultrasound or CT helps localize the mass, identifies associated genitourinary abnormalities, confirms function of the contralateral kidney, and indicates if there is extension to the inferior vena cava (16). CT scan is better at detecting subtle intra-abdominal abnormalities such as tumor spread, lymph node enlargement, vascularity, etc. Chest x-rays are done to look for evidence of lung metastasis. A definitive diagnosis is made based on biopsy results (13).

The National Wilms' Tumor Study Group Staging System is the most common criteria used to stage a tumor. This system stages tumors according to information gathered by clinicians, surgeons, and pathologists.

The first line of treatment is surgical resection whenever possible. During the procedure the surgeon should remove the tumor taking precautions to prevent tumor spillage. While the abdomen is open, the contralateral kidney should be inspected to detect involvement. The liver should also be inspected for evidence of metastasis. The renal vein should be checked to see if the tumor has extended to this area. Lastly, a retroperitoneal lymph node sample should be obtained for histopathology. If the tumor is inoperable either due to large size or the presence of invasion, a biopsy should be taken and other forms of therapy started (15). This tumor is sensitive to chemotherapy and radiation so either of these treatment options are possible therapeutic choices.

If there is bilateral Wilms' tumor, complete resection is not an option since dialysis or a renal transplant would be required to prevent uremia. Instead, renal sparing surgery is preferred. First, a biopsy must be done to confirm bilateral involvement and to get histologic data to grade the tumors. Next, preoperative chemotherapy, appropriate for the stage of the tumor, is begun which lasts for up to six weeks. An abdominal CT scan is then done to determine if resection is possible. If it looks good, surgical excision is done. If it does not appear to be resectable, a second-look procedure is done in which another biopsy is taken and a partial resection is attempted. If a partial resection is not possible, then chemotherapy is utilized with or without radiation (16).

The prognosis of the patient is based on the histology (grade) and stage of the tumor. A favorable histology is one in which blastemal, stromal, and epithelial elements may be seen. An unfavorable histology is an anaplastic one detectable by the presence of gigantic polypoid nuclei within the tumor sample (14). Four year Wilms' tumor survival (4): Stage I with favorable histology (96%), stage II with favorable histology (92%), stage III with favorable histology (87%), stage IV with favorable histology (83%), unfavorable histology (60%).

Questions

1. A 2 year old boy presents with a large right flank mass, fever, weight loss, proptosis of the right eye, and ecchymosis around the right eye. The most likely diagnosis is:
   a. Wilms' tumor
   b. Neuroblastoma
   c. Hydronephrosis
   d. Metastatic neuroblastoma

2. What is the most common secondary tumor that develops after survival of retinoblastoma?
   a. Neuroblastoma
   b. Soft tissue sarcoma
   c. Osteosarcoma
   d. Acute lymphocytic leukemia

3. Which one of the syndromes in the following list is not associated with Wilms' tumor?
   a. Beckwith-Wiedemann syndrome
   b. Li-Fraumeni syndrome
   c. WAGR syndrome
   d. Denys-Drash syndrome

4. If a teenager comes in complaining of night pain in his knee, which disorder should be at the top of your differential? Which would be the most likely, and which would be the most serious likely consideration?
   a. Juvenile Rheumatoid Arthritis
   b. Osteosarcoma
   c. Paget's Disease
   d. Stress fracture
   e. Growing pains

5. Retinoblastoma is often detected by:
   a. Primary care physicians performing routine ophthalmoscopy checks for a red reflex, but finding a white reflex instead.
   b. Flash photography of infants and children done by family members.
   c. Incidental finding on CT scans done for head trauma.
   d. Genetic counseling and risk analysis.
   e. Detection of an orbital bruit.

Answers to questions

1. d
2. c
3. b
4. Growing pains (e) are ill-defined, but are supposedly very common, so from a numerical standpoint, this diagnosis is probably the most common. However, since this age group is one of the peak ages for osteosarcoma (b) and since this is a serious condition that should be diagnosed as early as possible, osteosarcoma is the most serious likely consideration.
5. a, b, and d are correct.

Chapter XII.4. Palliative Care

Dianne Fochtman, RN, MN, CPNP, CPON

A 10 year old boy presents to the pediatric oncology ward with epistaxis for 2 hours and hematemesis. He complains of nausea, constipation, severe hip pain and headache. He has a history of recurrent Stage IV neuroblastoma, initially diagnosed 2 years ago, treated with chemotherapy and a bone marrow transplant. He received chemotherapy again when his cancer recurred six months ago. Initially his tumor responded, but eventually it progressed and includes bone marrow involvement. He has started experimental chemotherapy at the request of his parents, with his assent. He has multiple metastatic bone lesions, most pronounced on his head and right hip. He has required increasing doses of pain medications. He has been attending school a few hours a day, but this week he has been increasingly tired with increased pallor. This morning, he woke up with epistaxis that would not stop with pressure. About 1 hour later he started vomiting bright red blood. He is currently taking 8 mg of hydromorphone (Dilaudid) orally every 6 hours around the clock for pain. He rates his current pain level as a 6 on a scale of 10.

Exam: VS T 37, P 120, RR 18, BP 100/50. His skin is pale and dry with multiple bruises. He has multiple lumps on his scalp. Dried blood, blood clots and some oozing blood is noted in both nares. Subconjunctival hemorrhages and pallor are noted. His neck is supple with no lymphadenopathy. Heart regular rate without murmurs. Lungs are clear. A central venous catheter is present in his left anterior chest. His abdomen is soft with no hepatosplenomegaly. There is mild tenderness. Exam of his extremities is significant for bruising and pallor. He has moderate tenderness over his back, hips and pelvis.

Lab: WBC 2.4, 70% neutrophils, Hgb 6.2, Hct 19.6, platelet count 3,000.

Hospital Course: He receives packed RBC transfusions to correct his anemia (which may also improve his stamina) and platelet transfusions which stop his epistaxis. He is started on MS Contin (slow release morphine) 60 mg PO q12 hrs with morphine 15 mg PO for breakthrough pain as needed which controls his pain well. His physician discusses the future use of IV morphine on a patient controlled analgesia (PCA) pump. He is started on Senokot (senna) to prevent constipation. Since he seems to improve, or at least remain stable, with the experimental chemotherapy, this is continued.

Palliative care is a broad philosophy of total compassionate care for children when their disease no longer responds to curative treatment. The goal is to give the best quality of life by preventing and relieving suffering. Palliative care affirms life and recognizes death as a normal process. It does not hasten death, nor does it postpone it. The objectives are to prevent or relieve physical symptoms, maintain activity and independence for as long as comfortably possible, alleviate psychological distress, and support those who are bereaved.

Interventions are defined as "palliative" by their therapeutic intent (e.g., comfort) rather than the type of intervention (e.g., radiation, medication, surgery). So that unrealistic expectations are not encouraged, parents and staff must be clear that the purpose is to make the child more comfortable, not to cure the child. Many of the interventions in palliative care focus on symptom management.

To minimize fatigue, prioritize the child's activities, prevent sleep disruptions, and provide rest periods. If they are anemic, consider transfusion depending on their potential for improved quality of life.

For respiratory difficulty, an early objective should be to improve their respiratory effort, and later focus on alleviating anxiety due to respiratory changes and shortness of breath. Other measures include: 1) oral-pharyngeal suctioning as needed, 2) opioids for dyspnea or cough, 3) cough suppressants (dextromethorphan) for dry, nonproductive cough and expectorants (guaifenesin) for wet, productive cough secondary to infection, 4) supplemental oxygen may be needed, 5) anticholinergic medications for increased secretions or dyspnea related to congestion, 6) bronchodilators for dyspnea, wheezing or congestion, 7) diuretics for pulmonary edema, 8) anxiolytic medications for dyspnea with anxiety, 9) aerosolized morphine for dyspnea. A pleural effusion or pneumothorax may require invasive procedures to increase comfort, but this must be weighed against the discomfort of the procedure

For anorexia, treat the contributing factors (nausea, vomiting, pain, constipation). Consider medications to increase appetite, such as prednisone, Marinol (dronabinol) or Megace (megestrol). Benefits to quality of life must be weighed when considering aggressive nutritional support (TPN, enteral feedings).

Nausea and vomiting can be reduced by using antiemetics such as Zofran (ondansetron), Kytril (granisetron) or Anzemet (dolasetron). Consider changing the opioid medication to one which causes less nausea.

Start a laxative regimen to prevent constipation if opioid therapy is used. Treat constipation promptly when it occurs. Mineral oil eases passage of stool by decreasing water absorption, softens stool and lubricates the intestines. If no fecal impaction or bowel obstruction exist, use stimulant laxatives such as Senokot (senna). Avoid suppositories in neutropenic or thrombocytopenic patient. Add fruits, vegetables, and fiber to the diet, and encourage fluids and activity.

For diarrhea, stop all laxatives, avoid milk products, fats and protein. Anti-diarrheal medications such as Imodium (loperamide) and oral electrolyte solutions can be administered if tolerated.

For febrile patients, administer antibiotics for infection, and antipyretics such as acetaminophen, ibuprofen, other NSAIDS or indomethacin (use with caution if the patient is thrombocytopenic).

For insomnia, maintain normal sleeping and waking routines and discourage daytime naps if they are awake at night. Sedative/hypnotics such as Ativan (lorazepam) can be given as needed (watch for interaction with pain medications), but are seldom necessary in the pediatric oncology patient. Avoid corticosteroids at bedtime because of the stimulating effect. Initiate interventions to deal with fears, dreams or nightmares.

Pain control is often the greatest challenge in palliative care. Medication should be used as needed in adequate doses on an appropriate schedule to relieve the pain. Multiple agents are available, ranging from acetaminophen to opiates, which can be given by several different routes. A major challenge is to give sufficient medication to relieve the pain while maintaining as much alertness as the child and family wish. Concerns must be allayed about addiction and the amount of medication sometimes required to eliminate the pain. The amount of medication required is whatever it takes to eliminate the pain.

For optimal pain control, administer pain medications around the clock rather than on an as needed basis. Choose the least traumatic and simplest route of administration. Include co-analgesic medications (acetaminophen, antidepressants, anticonvulsants, NSAIDS) as needed. Establish an alternative plan to be used if the pain increases or if oral medications become less effective. With the start of opiate analgesics, initiate measures to prevent constipation (a common side effect). Use non-pharmacologic pain reduction measures (massage, distraction, music, relaxation) when appropriate

The decision to stop monitoring labs and to stop transfusing blood products when blood counts are low is a difficult one. Routine blood testing is usually not performed in palliative care and the use of transfusions is based on clinical symptoms. Treatment of bleeding is directly related to the child's comfort and the degree of unpleasantness witnessed by the family. Increased bruising and petechiae do not produce discomfort, but severely bleeding gums, uncontrolled epistaxis, or severe GI bleeding can cause discomfort and increase anxiety. Red blood cell transfusions may be given if the child is very tired from anemia and wants to remain active, or has headaches related to anemia, but anemia is not painful and transfusions may not improve the child's activity level. There may come a time when transfusions prolong the dying process and not the living.

Questions

1. True/False: There is no "ceiling" on the amount of pain medication that can be used in palliative care.
2. True/False: Transfusions are not appropriate for terminally ill patients.
3. True/False: NSAIDS and acetaminophen can potentiate the action of opioids
4. True/False: The amount of pain medication required is whatever it takes to eliminate the pain.
5. True/False: Although the physical suffering related to a child's dying may not be totally eliminated, there is no reason for the child to be in pain.

Answers to questions

1.True, 2.False, 3.True, 4.True, 5.True

Chapter XIII.1. Nephritic Syndrome
Teresa M. Bane-Terakubo, MD

A 7 year old male presents to his primary care physician with the chief complaint of dark "cola colored" urine, facial puffiness and abdominal pain for the past 2 days. He had been in his usual state of good health until 14 days ago when he had a sore throat and fever. His sore throat and fever resolved. He was not seen by a physician at that time. Over the past 2 days facial puffiness has been noted, but no swelling of his hands or feet. He has had some nonspecific abdominal pain that comes and goes which does not seem to be related to eating or bowel movements. There is no nausea or vomiting. His urine is dark brown and he has not been voiding as much as usual, only 2 times in the past 24 hrs. There is no urinary frequency, urgency, dysuria or foul smell to the urine. His appetite has been poor although he is still drinking fluids well. He is also complaining of some back pain in the flank area that he describes as a dull pain that comes and goes and does not seem to be related to activity. His energy level is down and he has not felt up to going to school for the past 2 days. He is also complaining of a dull generalized headache that has not been relieved with acetaminophen.

Review of systems is negative for recent skin infection, skin rash, cough, rhinorrhea, seizure activity, fever, arthralgia or weight loss. His past medical history, family history and social history are unremarkable.

Exam: VS T 37, P 100, RR 20, BP 120/75, oxygen saturation 100% in RA. Height and weight at 50th %tile. He is tired appearing but in no acute distress. Pupils are equal and reactive. Optic disc margins are sharp. Sclera are white and conjunctiva are clear. Mild periorbital is edema noted. TMs are normal. Throat, oral mucosa and nose are normal. His neck is supple without lymphadenopathy. Heart is regular without murmurs. Lungs are clear. Abdomen is diffusely tender (mild), without guarding or rebound. Bowel sounds are normal. No organomegaly is noted. Mild CVA tenderness is present. His extremities are warm, with strong pulses. Capillary refill is less than 2 seconds. No edema is noted in his legs, feet or hands. No skin rashes or impetigo scars are noted. His genitalia are normal. No scrotal edema is present. Neurologic exam is normal.

Lab: His urine is tea colored. UA shows an increased specific gravity. A dipstick is positive for a large amount of blood and moderate protein. RBCs are too numerous to count. 5-10 WBCs per HPF. RBC casts are present. CBC with diff is normal. Throat swab is sent for culture. ASO titer is elevated. Serum complement C3 level is low. Serum electrolytes are normal. BUN 23 and Cr 0.8.

Clinical Course: He is diagnosed with acute poststreptococcal glomerulonephritis. He is initially hospitalized for treatment of oliguria/volume overload with furosemide, and monitoring of his modest hypertension. He has a good urine output with the furosemide, however he later requires a calcium channel blocker to control worsening hypertension. He is placed on a fluid and sodium restricted diet. His throat culture later returns positive for group A beta hemolytic streptococci (GABHS), so he is given a course of penicillin. He is discharged after 3 days of hospitalization. His hypertension resolves over the next 2 weeks. He is followed closely by his primary physician and his proteinuria and gross hematuria resolve early. His C3 level normalizes two months after the onset of illness. Microscopic hematuria is expected to persist for months so this will be rechecked in 3 to 6 months. He does not develop any long term complications.

Acute glomerulonephritis (GN) presents with hematuria, oliguria, hypertension and volume overload (edema), which are the findings of the classic "nephritic syndrome". Acute GN (AGN) is associated with inflammation and proliferation of the glomerular tuft. Most AGN is immunologically mediated. In acute poststreptococcal glomerulonephritis (APSGN), immune complexes form with streptococcal antigens, localize on the glomerular wall, activate the complement system, and initiate a proliferative and inflammatory response. AGN may be rapidly progressive (RPGN). Chronic GN (CGN) implies that permanent damage has occurred.

Acute poststreptococcal glomerulonephritis (APSGN) is the most common form of glomerulonephritis in children. APSGN can occur in all ages but is most frequent in males between 5 and 15 years. APSGN can occur after either an upper respiratory tract or skin infection due to GABHS. It is more common after an infection of the throat. CGN occurs more often in teenagers and adults. There are genetic predispositions for familial GN (Alport, X-linked) and autoimmune etiologies (e.g., SLE-lupus nephritis). Goodpasture's disease (anti-basement membrane autoantibodies) also presents with a classic nephritic syndrome in conjunction with hemoptysis, but this condition is rare.

Important questions to ask the patient/caregiver include history of macroscopic (gross) hematuria (tea or cola colored urine, or red colored urine), sore throat, impetigo, prior URI at least 1 week previously or skin sores (impetigo) in the preceding 3-4 weeks (suggestive of APSGN), URI in the preceding few days (suggestive of IgA nephropathy), reduced urine output, dyspnea, fatigue, lethargy, headache or seizures (hypertensive encephalopathy). Also, symptoms of a systemic disease such as fever, vasculitic rash (especially on the buttocks and legs posteriorly), arthralgia and weight loss may be present. On physical exam, pay particular attention to hypertension, pallor, signs of volume overload (edema, jugular venous distention, hepatomegaly, crackles in the lung bases), impetigo and rash. For PSGN, edema (specifically, facial edema involving the periorbital area) is the most frequent presenting symptom. Dark colored or bloody urine is frequently not noticed by patients because the abnormal color is only visible when the urine is collected in a cup. The abnormal color is not noticeable in a urine stream unless the urine color is very dark.

Many patients with APSGN are asymptomatic and do not seek medical care. Mild hypertension is often asymptomatic. The classic dark urine is often not noticed. Screening urinalysis may often identify persistent microhematuria which eventually resolves months later. Many of these cases are felt to be resolving APSGN cases which never presented for medical attention during the acute nephritis phase.

Throat culture for GABHS will be positive in 15-20% of patients with APSGN. CBC is normal in AGN and with chronic renal insufficiency a normocytic normochromic or hypochromic microcytic anemia will usually be found. Serum chemistries will reflect the degree of renal failure (BUN, creatinine, potassium and phosphate are all elevated, while calcium is decreased), which is usually mild. The ASO titer will be positive in 60% of patients with APSGN. The complement C3 serum level will be low in APSGN and in other causes of GN described below. Urine microscopy shows RBC casts and crenated RBCs in AGN. EKG, CXR and renal ultrasound are other tests that should be considered. RBC casts indicate the presence of acute nephritis. WBC casts can also be seen in APSGN, interstitial nephritis and pyelonephritis.

During convalescence from APSGN, complement C3 levels return to normal within 6-8 weeks. Persistently low C3 levels indicate an etiology other than APSGN. Gross hematuria will generally resolve within 1 to 2 weeks. Microscopic hematuria may persist for a year or more.

The differential diagnosis for glomerulonephritis includes infectious etiologies such as GABHS, pneumococcus, mycoplasma, mumps and EBV. Glomerulonephritis may also be related to hepatitis B and C as well as syphilis infections. IgA nephropathy, membranoproliferative GN, autoimmune GN, familial GN, acute interstitial nephritis, hemolytic uremic syndrome and pyelonephritis

should all be on your differential diagnosis list. One way to sort out the etiology of the glomerulonephritis is to look at the complement level and whether evidence of systemic or renal disease is present. For a patient with low serum complement level and systemic disease consider vasculitis and autoimmune disease (SLE), subacute bacterial endocarditis, shunt nephritis and cryoglobulinemia. For a patient with low serum complement level and evidence of renal disease consider APSGN and membranoproliferative glomerulonephritis (types 1,2, and 3). In a patient with normal serum complement level and evidence of systemic disease consider polyarteritis nodosum, Wegener vasculitis, Henoch-Schonlein purpura and hypersensitivity vasculitis. In a patient with normal serum complement and evidence of renal disease consider IgA nephropathy, idiopathic RPGN and immune complex disease. A renal tumor (e.g., Wilms) will occasionally present with gross hematuria so an imaging study may be indicated to rule this out.

APSGN is a self-limiting disease. Treatment is symptomatic. Restricted fluid and sodium diets are initially beneficial. Potassium and phosphate may also need to be restricted. Medication may be required for management. Loop diuretics (e.g., furosemide) are the first choice for volume overload, hypertension and hyperkalemia control. Vasodilators such as calcium channel blockers are also used to manage hypertension. IV antihypertensives may also be required to treat severe refractory hypertension. In severe hyperkalemia serum potassium lowering agents and IV calcium may be needed. Immunosuppressive agents are used in the treatment of vasculitis associated GN, membranoproliferative GN and RPGN. Plasmapheresis may be used to treat RPGN.

Most patients with APSGN do not need hospitalization. Indications for hospitalization include: an uncertain diagnosis, significant hypertension, anticipated poor follow-up, cardiovascular or cerebrovascular compromise, etc. The diagnosis can usually be firmly established as an outpatient. An imaging study may be necessary to rule out a Wilms tumor. If the patient's blood pressure is normal or only mildly elevated, most parents can be taught to measure the child's blood pressure at home using an automated blood pressure measurement device which is easily available at most stores. Parents must notify the physician when the blood pressure exceeds the parameters given by the physician. If the parents are deemed to be unreliable, or are not capable of measuring the child's blood pressure, then hospitalization should be considered.

Prognosis is excellent for APSGN and variable for other causes of GN in children. Complications of AGN include acute renal failure, hyperkalemia, hypertension, volume overload (congestive heart failure, pulmonary edema, hypertension) and chronic renal failure.

Questions

1. When does the complement C3 level return to normal in APSGN?
2. What is the significance of finding red cell casts in the urine?
3. What is the significance of finding white cell casts in the urine?
4. How long does hematuria persist in APSGN?
5. Describe some indications for hospitalization of patients with APSGN.
6. What are the clinical elements of the nephritic syndrome?
7. What are classic causes of the nephritic syndrome?
8. A 5 year old boy has a screening urinalysis as part of a general physical exam. The UA shows microscopic hematuria. History suggests that he has impetigo periodically. What a likely cause for the microscopic hematuria?

Answers to questions

1. C3 levels return to normal within a 6-8 week period in APSGN. Persistently low C3 levels suggest a cause other than APSGN.
2. The presence of red cell casts on urinalysis almost always indicates the presence of glomerulonephritis. They can also be seen after strenuous exercise and renal trauma.
3. The presence of white cell casts on urinalysis can be seen in APSGN, interstitial nephritis and pyelonephritis.
4. Gross hematuria resolves within days to weeks. Microhematuria may persist for months.
5. An uncertain diagnosis, significant hypertension, anticipated poor follow-up, cardiovascular or cerebrovascular compromise, etc.
6. Gross hematuria, oliguria, hypertension, edema (usually mild).
7. APSGN and Goodpasture’s. Other causes of nephritis include SLE nephritis, MPGN, RPGN, Alport's, etc.
8. Convalescing APSGN.

Chapter XIII.2. Nephrotic Syndrome
Paul J. Eakin, MD

A previously well 5 year old male presents to your office with the chief complaint of facial puffiness. His mother noticed this a few days ago and it seems to be worsening. He has no other symptoms, but about two weeks ago had "a bad cold."

Exam: VS T 37, HR 90, RR 20, BP 92/55. He is alert and cooperative with the examination. His face shows moderate periorbital edema. His eyes are non-injected, his conjunctiva are not edematous and his throat is not red. His heart is regular without murmurs. Heart sounds are normal. His lung exam shows good aeration, with no crackles or rhonchi. Abdomen is soft, non-tender, non-distended and without masses or shifting dullness. No hepatosplenomegaly. He has normal male genitalia with no scrotal edema. The dorsal surfaces of his hands and feet have mild pitting edema. He has brisk capillary refill and 2+ pulses. No rashes are noted.

Urinalysis shows 4+ protein, and a specific gravity of 1.030. His chemistry panel is remarkable for protein of 2 g/dL, serum albumin of 1.4 g/dL and cholesterol of 350 mg/dL. BUN and creatinine are normal.

He is not ill enough to require hospitalization. He is started on oral prednisone BID. He is followed as an outpatient clinically and by daily urine dipsticks. His edema and proteinuria gradually resolve with treatment. His corticosteroids are tapered off and he remains stable.

Nephrotic syndrome describes the collection of clinical and laboratory findings secondary to glomerular dysfunction, resulting in proteinuria. The diagnostic criteria are marked proteinuria, generalized edema, hypoalbuminemia, and hyperlipidemia (with hypercholesterolemia). The proteinuria in nephrotic syndrome is severe, exceeding 50 mg of excreted protein for every kilogram of body weight over 24 hours. Primary nephrotic syndrome refers to diseases limited to the kidney, whereas secondary nephrotic syndrome indicates systemic diseases that include kidney involvement (e.g., diabetic nephropathy).

In healthy children (less than 18 years of age), the annual incidence of nephrotic syndrome is 2-7 new cases per 100,000. The prevalence is approximately 16 cases per 100,000 children, making nephrotic syndrome one of the most frequent reasons for referral to a pediatric nephrologist. Also, the most common type of nephrotic syndrome is recurrent to some degree, so cases will often manifest repeatedly over time. The peak age for the onset of nephrotic syndrome is 2-3 years of age. In early childhood, males outnumber females about 2:1 for new cases of nephrotic syndrome. In adolescence and adults, the gender distribution is more equal. Primary nephrotic syndrome is more common in children less than six years of age, while secondary nephrotic syndrome predominates for patients older than six. The disease inheritance is usually sporadic, although there is a congenital form of nephrotic syndrome, called Finnish type congenital nephrosis, which is inherited in an autosomal recessive manner. This abnormality has been mapped to a defect in the nephrin gene on chromosome 19q13.1 that codes for a protein in the glomerular basement membrane.

The main pathogenic abnormality in nephrotic syndrome is an increase in glomerular capillary wall permeability, resulting in pronounced proteinuria. The normal glomerular wall is remarkably selective for retaining protein in the serum. Once this selectivity is lost, the excretion of large amounts of protein will follow. This increase in permeability is related to the loss of negatively charged glycoproteins within the capillary wall that usually repel negatively charged proteins. The predominant protein lost is albumin, although immunoglobulins are also excreted. The pathophysiology for the formation of edema is incompletely understood. A simplification of the predominant theory is that after the plasma albumin concentration drops, secondary to protein excretion, the plasma oncotic pressure drops. With the decrease in oncotic pressure, fluid moves from the intravascular space to the interstitial space causing edema. The liver has a very large capacity to synthesize protein, so the persistent hypoalbuminemia is likely not due entirely to increased losses. Reduction of the intravascular volume results in activation of the renin-angiotensin-aldosterone system. Sodium and water are retained, which further increases the edema. There are likely other factors involved in the formation of edema, because some patients with nephrotic syndrome have normal or increased intravascular volume.

The hyperlipidemia in nephrotic syndrome is characterized by elevated triglycerides and cholesterol and is possibly secondary to two factors. The hypoproteinemia is thought to stimulate protein synthesis in the liver, including the overproduction of lipoproteins. Also lipid catabolism is decreased due to lower levels of lipoprotein lipase, the main enzyme involved in lipoprotein breakdown.

More than 90% of children with primary nephrotic syndrome have idiopathic nephrotic syndrome and this will be the focus of this chapter. The etiology of this condition remains largely unknown, but some have postulated an immunologic mechanism. Supporting evidence for this theory include the characteristic response to corticosteroids and cytotoxic agents, an observed increased incidence of concurrent allergic conditions, and spontaneous remissions with natural measles infections (known to induce suppression of cell-mediated immunity). Evidence against an immunologic etiology is a failure to identify immune reactants or inflammation in kidney biopsies.

There are three morphological patterns of idiopathic nephrotic syndrome, with minimal change disease (also called "nil disease") making up 80-85% of the cases. In this condition, the glomeruli appear normal or have a minimal increase in the mesangial cells or matrix. As well as being the most common form of primary nephrotic syndrome, minimal change disease also has the mildest clinical course. The rest of this chapter will focus on this disease entity after briefly describing the other forms of primary nephrotic syndrome as well as secondary nephrotic syndrome. The less commonly seen types of primary idiopathic nephrotic syndrome are focal segmental glomerular sclerosis, membranous glomerulonephritis and membranoproliferative glomerulonephritis.

Focal segmental glomerular sclerosis is found in about 7-15% of patients with nephrotic syndrome, making it the second most common primary renal lesion. It tends to have a more severe clinical course with persistent proteinuria, progressive decline in glomerular filtration rate and hypertension that can be unresponsive to therapy. Renal failure occurs, with dialysis or transplant being the only treatment options. Unfortunately, the recurrence rate of focal segmental glomerular sclerosis can be as high as 40% after renal transplant.

Membranoproliferative glomerulonephritis accounts for roughly 7% of primary idiopathic nephrotic syndrome. These patients often have hematuria, hypertension and mild azotemia. Another characteristic finding is persistently depressed C3 levels. The clinical course is variable with only a small percentage of patients going into remission.

Membranous glomerulopathy is rare in the pediatric age group, but becomes more common into adolescence and adulthood. It is often associated with infections, with hepatitis B being the most common. The clinical course is variable, but the overall prognosis is good, with spontaneous remission of proteinuria occurring in 50-60% of cases.

There are many different causes of secondary nephrotic syndrome in children. These include multisystemic diseases such as systemic lupus erythematosus and Henoch-Schonlein purpura, malignancies such as Hodgkin disease or leukemia, drug or toxin exposures such as mercury, gold, penicillamine or bee sting, and infectious etiologies such as Epstein-Barr virus, cytomegalovirus and tuberculosis.

Children with idiopathic nephrotic syndrome secondary to minimal change disease usually present with edema. Clinically apparent edema usually is not seen until albumin levels drop below 2 g/dL. The edema is initially noted around the eyes and in the lower extremities. Over the course of a day, the edema often distributes from the eyes to more dependent areas. After time, the edema becomes more pronounced, generalizes and there can be weight gain. Patients or parents may notice tighter fit of clothes, belts and shoes and scrotal or labial edema often occurs. As the edema accumulates, pleural effusions, ascites and decreased urine output may develop. In many cases, there is a history of preceding upper respiratory symptoms. Anorexia, abdominal pain and diarrhea may be seen, possibly secondary to the formation of ascites. Blood pressure and renal function are usually normal.

The hallmark of nephrotic syndrome is severe proteinuria, most reliably diagnosed using a 24-hour urine collection. Spot urinalysis is also informative and reveals +3 to +4 proteinuria (300 to 1000 mg/dL), with a specific gravity usually greater than 1.020. Gross hematuria is not common. Blood samples show decreased albumin levels usually less than 2.0 mg/dL and elevated triglyceride and cholesterol levels. Because of the hypoalbuminemia, hypocalcemia is often seen, with calcium levels less than 9.0 mg/dL. Usually the ionized calcium will be normal. Hyponatremia and hyperkalemia can be seen, with hyperkalemia developing in patients who are oliguric. Serum C3 levels are normal in cases of minimal change disease.

Renal biopsy is not necessary for the child with newly diagnosed nephrotic syndrome and the initial treatment will be the same, regardless of the cause. How the disease responds to corticosteroids may help dictate the need for biopsy. If the response is good and renal function is normal, the diagnosis of minimal change disease may be presumed. If relapses respond to corticosteroids and there is no proteinuria during disease free periods, this diagnosis is strengthened. Biopsy is generally obtained in cases where there is poor or no response to corticosteroids, the patient is less than 1 year old (high likelihood of congenital nephrotic syndrome) or over 10 years old, secondary nephrotic syndrome is suspected, there is corticosteroid toxicity, or the use of a cytotoxic agent is being considered. Patients with low serum complement levels or hypertension on presentation may require biopsy since these conditions are not characteristic of minimal change disease and may indicate other renal lesions.

The treatment of primary idiopathic nephrotic syndrome of childhood is corticosteroid therapy and supportive care. Steroid therapy will be discussed below. Many patients may be treated on an outpatient basis, although the newly diagnosed patient is sometimes admitted for diagnostic and educational purposes. Edema is managed with sodium restriction (the "no added salt diet") and diuretics such as hydrochlorothiazide. If hypokalemia develops, an oral potassium supplement or spironolactone may be added. Aggressive use of loop diuretics may be harmful since most patients initially presenting with nephrosis are hypovolemic. The use of diuretics necessitates close monitoring of patients. Patients need to monitor their weight closely and consume adequate amounts of protein.

Conditions that require immediate attention and hospitalization are severe scrotal edema, dehydration (more than 10% dehydrated), respiratory compromise due to pulmonary edema or pleural effusions, and peritonitis or suspected bacterial infection. Despite their edematous appearance, most patients have decreased intravascular volumes. Therapy is aimed at the restoration of intravascular volume and preventing volume overload. Intravenous fluids are used, sometimes with the infusion of albumin to increase the serum oncotic pressure. The albumin must be given slowly, over 8-12 hours, to prevent fluid overload from rapid intravascular volume expansion. There is some debate over the use of albumin, since the effect seems to be transient and it is presumably excreted rapidly (1). Electrolyte levels and renal function must be closely monitored. Once the intravascular volume is restored, diuretic therapy is used to mobilize the fluid and prevent volume overload. Paracentesis is performed if there is respiratory compromise secondary to severe ascites. Antibiotic therapy to cover for the most common pathogens should be started if there is evidence of bacterial infection (discussed below).

Minimal change disease is characteristically responsive to corticosteroid therapy and once the diagnosis is confirmed with laboratory testing, steroid therapy should be started. Prednisone is initiated with a dose of 60 mg/sq-meter/day or 2 mg/kg/day divided in 2-3 doses. The daily dose is continued until the proteinuria resolves, usually in 2-3 weeks. Some sources suggest continuing the daily dose for 4-6 weeks (1). Regardless, the corticosteroids are continued and then tapered over the course of 3-6 months. In patients with minimal change nephrotic syndrome, approximately 98% will eventually have satisfactory therapeutic responses. This disease is one of frequent relapse, with two thirds of patients having a single relapse and roughly one third experiencing repeated relapses over many years. Most patients with steroid-responsive nephrotic syndrome will continue to have relapses until they are in their late teens. Relapses are treated the same as the initial presentation. With repeated relapses or severe steroid toxicity (growth retardation, elevated blood pressure), cytotoxic agents such as cyclophosphamide are added to a lower corticosteroid dose. This agent has been shown to prevent relapses and to increase the duration of remission. Chlorambucil and less commonly cyclosporine have also been used for remission induction. Another regimen for patients refractory to corticosteroids is indomethacin and an angiotensin-converting enzyme (ACE) inhibitor.

The most common complications of nephrotic syndrome are bacterial infection and thromboembolism. There are also complications secondary to medications such as the gastric irritation and insulin resistance seen with corticosteroids or the hemorrhagic cystitis, sterility and leukopenia seen with cyclophosphamide. The tendency to develop infections, especially "primary peritonitis" (a type of pneumococcal sepsis), is thought to be due to IgG excretion, decreased complement function, and diminished splanchnic blood flow. The organisms causing peritonitis are most commonly Streptococcus pneumoniae and Escherichia coli. Peritonitis should always be considered in a patient who has nephrotic syndrome and abdominal pain or fever. Antibiotics such as ampicillin or vancomycin with a third generation cephalosporin or an aminoglycoside would provide good empiric coverage. Other infections such as sepsis, cellulitis, pneumonia and urinary tract infection are also seen. The signs of infection may be masked if the patient is currently on corticosteroid therapy. Any child with nephrotic syndrome and a fever must be thought of as having an infection until proven otherwise, since they are at high risk for sepsis, similar to splenectomy patients. Because of their predilection for S. pneumoniae infection, polyvalent pneumococcal vaccine should be administered to children over two years of age.

Another complication, thromboembolism is thought to be more common secondary to increased platelet aggregation, increased fibrinogen concentration, decreased antithrombin III concentrations, increased blood viscosity and decreased blood flow. Venous thrombosis is most common, especially in the renal vein, pulmonary artery, and deep vessels of the extremities. In patients with refractory nephrosis, low dose anticoagulants are sometimes used.

The prognosis for children with minimal change nephrotic syndrome is good, with most patients ultimately becoming disease free and living a normal life. Mortality is approximately 2% with the majority of deaths being secondary to complications such as peritonitis or thromboembolic disease.

Questions

1. The most common cause of primary idiopathic nephrotic syndrome is:
    a. Focal segmental glomerular sclerosis
    b. Membranoproliferative glomerulonephritis
    c. Membranous glomerulopathy
    d. Minimal change disease

2. Common causes of mortality in primary nephrotic syndrome is/are:
    a. Acute renal failure
    b. Thromboembolism
    c. Congestive heart failure
    d. Peritonitis
    e. Seizure

3. True/False: A renal biopsy is necessary to confirm the diagnosis of primary idiopathic nephrotic syndrome.

4. The inheritance pattern of primary idiopathic nephrotic syndrome is/are:
    a. Autosomal recessive
    b. X-linked recessive
    c. Autosomal dominant
    d. Sporadic

5. Reasons for biopsy in a patient with nephrotic syndrome include:
    a. Continued proteinuria after a week of prednisone therapy.
    b. Age at onset of 10 months.
    c. Relapse 1 year after initial course of therapy.
    d. Cholesterol level greater than 400 mg/dL.
    e. A patient who has a history of systemic lupus erythematosus

Answers to questions

1. d. Minimal change disease or "nil disease" accounts for 80-85% of cases of primary idiopathic nephrotic syndrome in childhood.
2. b and d. Infection, especially peritonitis and thrombosis account for the majority to nephrotic syndrome mortality.
3. false. The decision to perform a renal biopsy is usually deferred until the initial course of corticosteroid is initiated, unless there are specific risk factors such as age below one or above 10, hypertension on presentation or decreased complement on presentation.
4. d. Primary nephrotic syndrome is sporadic in nature. Congenital nephrotic syndrome is passed in an autosomal recessive manner.
5. b and e. Nephrotic syndrome in a child less than 1 year old may indicate congenital nephrotic syndrome and renal biopsy is often performed. In a patient with SLE, the nephrotic syndrome is likely secondary and a renal biopsy is indicated.

Chapter XIII.3. Cystic Kidneys
Miki E. Shirakawa

A one month old female is brought to her pediatrician with a chief complaint of an abdominal mass. Her mother noticed the mass earlier in the week and immediately made an appointment to see the pediatrician. The mother also notes that the infant has been frequently wetting her diapers, although there is no history of fever, vomiting or diarrhea. The infant's perinatal and birth history are unremarkable (spontaneous vaginal delivery at term with a birth weight of 2750 grams). There is a family history of cystic kidneys in the infant's 14 year old brother. The infant's four other brothers and sisters do not have any renal disease and both parents do not have a history of renal disease.

Exam: VS T 37.5, P 110, R 26, BP 115/85, Weight 3.32 kg (10th percentile). She is alert and active, in no distress. Her physical exam is unremarkable except for a nontender 7 cm by 8 cm left-sided abdominal mass.

Urinalysis reveals cloudy urine, positive for leukocyte esterase and nitrites. A renal ultrasound is ordered and reveals bilateral enlargement of her kidneys with diffuse echogenicity and microcysts. A hepatic ultrasound reveals periportal fibrosis. The infant is diagnosed with autosomal-recessive polycystic kidney disease and a possible urinary tract infection. She is hospitalized for antibiotic treatment and further evaluation. She improves and is discharged from the hospital. Her renal function is sufficient, but it is anticipated that it will worsen as she grows.

Cystic kidneys in children and adolescents present in various forms and can range from a single cyst to multiple bilateral cysts. In this chapter, a few of the more common disease conditions will be discussed: multicystic dysplastic kidneys, autosomal recessive polycystic kidney disease and autosomal dominant polycystic kidney disease. Other cystic kidney diseases that will not be discussed include nephronophthisis (a common genetic cause of chronic renal insufficiency in children which presents with polyuria and polydipsia, anemia and growth retardation), medullary cystic disease (autosomal dominant disease in which young adults develop renal failure), medullary sponge kidney (dilated intrapapillary collecting ducts and multiple small cysts that usually presents in adulthood), glomerulocystic kidney disease (seen in a variety of inherited syndromes), simple renal cysts (incidental findings that generally do not impair renal function), multilocular cysts (unilateral benign tumor), acquired cystic kidney disease (occurs in patients with renal failure), and syndromes with cystic kidneys (such as tuberous sclerosis, Meckel syndrome, and von Hippel-Lindau disease).

Multicystic dysplastic kidney (MCDK) is usually a benign unilateral disorder of small to large renal cysts separated by dysplastic parenchyma. The shape of the kidney is irregular and normal renal architecture is lost. There are two types of MCDK: the classic type and the hydronephrotic type (1). The classic type contains multiple cysts of various size, with an abnormal renal shape and an atretic proximal ureter. The hydronephrotic type is rarer and consists of peripheral cysts that communicate with a large central cyst with a dilated pelvis and calyces (1).

MCDK is the most common type of renal cystic disease, comprising 10% of fetal uropathies (1). The most recent studies estimate that the incidence is 1 in 2400 livebirths, and it is more common in males (1,2). The disease usually occurs unilaterally, but can be seen bilaterally in as many as 20% of cases (2). MCDK is generally considered to be nonhereditary and sporadic, although rare cases have shown an autosomal dominant inheritance (2,3). Two theories stand out as the most probable causes of MCDK. The first proposes that abnormal induction of the metanephric blastema leads to dysplasia of the renal parenchyma that is non-uniform, resulting in cysts that increase in size and eventually compress normal renal tissue (1). The second theory suggests that MCDK is due to obstruction of the ureter that results in cyst formation (1,3). This theory was exhibited in Beck's experiments of fetal lamb ureter ligations, which resulted in cyst formation in the lambs (1). Urine is usually present in the cysts and causes the cysts to enlarge. In unilateral cases, there is a compensatory hypertrophy in the contralateral kidney.

The most common presentation of MCDK is on prenatal ultrasonography (71% of cases), viewed as early as 16 weeks gestation (1). MCDK usually presents in newborns as a unilateral flank mass, but can occasionally cause vomiting, anorexia and failure to thrive secondary to compressive effects (2). Other possible but rare presentations include urinary tract infection, abdominal pain, hematuria, hypertension, and compromised respiratory function (1,2). MCDK is associated with other anomalies of the urinary tract in half of cases and 15-28% show vesicoureteral reflux in the contralateral kidney (1). There is also an association with contralateral ureteropelvic junction obstruction (1). Other major anomalies can be seen in the cardiac, respiratory and gastrointestinal systems (1). Bilateral cystic kidneys are usually not compatible with life due to oligohydramnios and result in either stillborn babies or newborns requiring dialysis at birth (2). MCDK is diagnosed with ultrasonography but also requires radionuclide imaging to determine functioning of the kidney after 1 month of age (1).

The differential diagnosis for MCDK includes hydronephrosis as well as the other cystic kidney diseases, and may be distinguishable by ultrasound. Hydronephrosis usually retains a reniform shape and shows apparent renal parenchyma around a central cyst (1). Hydronephrosis also retains communication of the cysts with the collecting systems (2). A radionuclide study may need to be performed when distinguishing hydronephrosis from the hydronephrotic type of MCDK. Autosomal dominant polycystic kidneys are usually bilaterally enlarged while autosomal recessive polycystic kidneys are generally small with a hyperechoic pattern.

The management of MCDK is controversial because it is not clear that nephrectomy results in a better outcome. It is recommended to obtain sonography and perform a voiding cystourethrogram within the first 48 hours of life. Radionuclide studies are also performed after 1 month of age to determine renal functioning. Since most cases are asymptomatic, nephrectomy is not always performed and instead close follow-up is maintained. Ultrasound is performed every 3 months up to 1 year of age and then every 6 months up to 5 years of age. Blood pressure is also monitored. Nephrectomy is usually performed only if the child is symptomatic or the parents choose surgery after understanding the benefits and risks.

Unilateral MCDK has an excellent prognosis, especially if there is an absence of other anomalies. In 73% of cases, the cysts decrease in size, with a 40% complete resolution rate (1). However, in 13% of cases, the cysts increase in size and may cause symptoms (1). Uncommonly, children may have pain, infection, or hypertension and even rarer is the possibility of malignant degeneration into a Wilms tumor (1). In the 5% to 17% of cases that are bilateral, newborns generally do not survive and if they do, they require dialysis immediately (1).

Autosomal-recessive polycystic kidney disease (ARPKD) is a recessively inherited disorder that results in bilateral cystic dilation of renal collecting ducts and hepatic fibrosis. The kidneys are enlarged, while retaining their normal shape and have a spongy appearance.

The incidence of ARPKD is believed to be 1 in 6000 to 1 in 55,000 livebirths (4). A single defective gene on chromosome 6p causes ARPKD and is inherited as a typical autosomal recessive disorder (5). Heterozygotes are unaffected. There is a 25% chance of recurrence with subsequent pregnancies. Males and females are equally affected.

Three factors have been shown to contribute to the formation of renal cysts and their subsequent enlargement. The first factor is that tubular hyperplasia is present in all cystic diseases and contributes to cystic expansion (5). Second, secretion of tubular fluid leads to the accumulation of intratubular fluid and progressive enlargement (5). Third, abnormalities in extracellular matrix interactions appear to have an effect on cell growth and can lead to abnormal epithelial hyperplasia and secretion (5).

ARPKD may present with various features but is usually seen within the first year of life (4). Many cases are seen prenatally on ultrasound with oligohydramnios and large renal masses (5). Other presentations include enlarging abdominal masses, respiratory problems due to limited diaphragm mobility (or pulmonary hypoplasia), failure to thrive due to enlarged kidneys, proteinuria, pyuria, hypertension due to fluid overload, and urinary tract infections due to vesicoureteral reflux (4). Children eventually develop chronic renal failure and end-stage renal disease with associated electrolyte imbalances of hyperkalemia and hyperphosphatemia (4). Liver abnormalities may present as signs of portal hypertension such as esophageal varies, hepatomegaly, and spider nevi.

The diagnosis of ARPKD is suspected in children with bilaterally enlarged kidneys and is highly suspected if siblings also have a history of ARPKD. Ultrasound is the diagnostic test of choice, although an intravenous pyelogram will also show enlarged kidneys (4). On renal ultrasound, there is increased echogenicity with a possible hypoechoic rim (4). It is important to rule out autosomal-dominant polycystic kidney disease (ADPKD), nephroblastomatosis and bilateral Wilms' tumor (4). ADPKD usually does not have associated liver abnormalities and the inheritance pattern is dominant instead of recessive (4).

Management of ARPKD involves ventilatory support for respiratory problems due to pulmonary hypoplasia and diaphragmatic compression. Hypertension should be treated with medications, although it may be difficult to control. Urinary tract infections should be properly diagnosed and treated with antibiotics. Chronic renal failure and end-stage renal disease are treated by managing electrolyte abnormalities, anemia, and renal osteodystrophy, with eventual dialysis and transplantation (4). Nephrectomy may be an option if there are respiratory problems and/or feeding problems due to compression (4).

Improvements in technology continue to increase the survival rates of ARPKD. Studies show that about 46% are alive at 15 years of age and those that survive through the first year of life have an even higher survival rate (79% alive at 15 years) (5). Renal failure is the most common cause of death and ARPKD continues to have significant long-term morbidity (4).

Autosomal-dominant polycystic kidney disease (ADPKD) rarely presents in children but occasionally exhibits a severe course in childhood. It is characterized by renal cysts in various locations and extrarenal manifestations in the gastrointestinal and cardiovascular systems. As the disease progresses, renal fibrosis and glomerulosclerosis increase (4). ADPKD is the most common inherited renal disease, occurring between 1 in 500 to 1 in 1000 livebirths (4). Mutations in any one of three genetic loci (PKD1, PKD2, PKD3) result in ADPKD. PKD1 is located on chromosome 16p and encodes the protein polycystin, a transmembrane protein (4). PKD2 is found on chromosome 4q and encodes for polycystin-2, another transmembrane protein that interacts with polycystin (4). There is not much known about PKD3 (4). The variability in cyst formation and disease severity depends on the locus affected and how much protein is being made.

The clinical presentation of ADPKD depends on the age of presentation. Most often, children are asymptomatic and are only diagnosed because of a positive family history and subsequent CT or sonogram. Symptomatic children typically present in late childhood or adolescence with any of the following: hematuria, hypertension, abdominal or flank pain, abdominal mass, urinary tract infection, or proteinuria (4). Symptoms in childhood usually correlate with greater than 10 cysts present (4). The third pediatric presentation is severe neonatal disease that is frequently fatal. These neonates usually die from respiratory failure but they may also die of renal failure during the first year of life (4). Extrarenal manifestations are not common in children but are common in adults. These extrarenal problems include mitral valve prolapse, hypertension, extrarenal cysts, aortic aneurysms, intracranial aneurysms, hernias, colonic diverticula, cholangiocarcinoma, and congenital hepatic fibrosis (4). Intracranial aneurysms are a significant cause of mortality when they rupture (4).

ADPKD is diagnosed with sonogram or CT scan as macroscopic renal cysts. As children age, the number and size of cysts increases and therefore, the sensitivity and specificity of diagnosis by ultrasound increases as children become older (4). ADPKD can often be distinguished from other cystic kidney diseases through family history. Ultrasound can also be used to distinguish ARPKD from ADPKD. ARPKD shows bilaterally enlarged kidneys with microcysts as well as hepatic periportal fibrosis, while ADPKD will show enlarged kidneys with macrocysts as well as extrarenal cysts (4,5).

Management of ADPKD includes physical examination, urinalysis and blood pressure monitoring every 6-12 months (4). Ultrasound should also be performed every 2-3 years (4). Presenting problems of ADPKD should be treated with standard therapy. Chronic renal insufficiency is monitored carefully, especially with respect to its effects on nutrition and growth (4). Hypertension is treated with antihypertensives and urinary tract infections are treated appropriately. Screening for intracranial aneurysms should be performed in teenagers with a family history of intracranial aneurysms due to the serious consequences of rupture (4,5).

Since most children with ADPKD are asymptomatic, the prognosis throughout childhood is generally good. One study showed that 80% of children diagnosed maintained normal renal function throughout childhood (5). As adults, disease progression is variable and unpredictable.

Potter syndrome is variably defined as including congenital renal failure or cystic kidneys associated with oligohydramnios, abnormal facies and hypoplastic lungs. If the fetal kidneys are non-functional or minimally functional, oligohydramnios results since the source of amniotic fluid is fetal urine. Oligohydramnios results in the abnormal facies due to the compression of the developing face against the inner uterine wall. Pulmonary hypoplasia results from large kidneys (due to one of the cystic kidney conditions) compressing the diaphragms, preventing fetal lung development. Congenital bilateral renal agenesis is also included in Potter syndrome. Potter syndrome is generally incompatible with life due to congenital renal failure and pulmonary hypoplasia.

Questions

1. Which renal cystic diseases are inherited? What is the most common inherited renal disease?
2. How can you differentiate between ARPKD and ADPKD?
3. Compare the outcomes of MCDK and ARPKD?
4. What abnormalities besides renal manifestations should a clinician look for on physical examination of a patient with ARPKD?
5. Do extrarenal manifestations of ADPKD usually present in children?

Answers to questions

1. ARPKD and ADPKD are inherited. MCDK is usually non-heritable. ADPKD is the most common inherited renal disease.
2. ARPKD: bilateral enlargement and microcysts on ultrasound. Hepatic fibrosis is also present in ARPKD. ADPKD: macrocysts and usually involve extrarenal cysts in the liver, pancreas, ovary, and/or spleen. ADPKD will also have a positive family history in a parent and the aunts/uncles on the affected parent's side of the family.
3. Unilateral MCDK has an excellent prognosis with most cases decreasing in size. ARPKD, since it is bilateral, eventually leads to end-stage renal disease.
4. Signs of portal hypertension: spider nevi, esophageal varices, hepatomegaly. There can also be signs of respiratory distress or abnormal feeding due to the compressive effects of enlarged kidneys.
5. No, extrarenal manifestations of ADPKD such as intracranial aneurysms and extrarenal cysts usually present in adulthood.

Chapter XIII.4. Dialysis

James H.E. Ireland, MD
Julie Won Ireland, MD

A 16 year old girl with a past medical history of systemic lupus erythematosus (SLE) presents with intractable nausea and vomiting, increasing edema and no urine output for two days. She had been diagnosed with SLE at age 14. A biopsy of her kidney at that time revealed a diffuse proliferative glomerulonephritis with prominent crescents and minimal fibrosis. Her creatinine at that time was 1.5, and she was started on cyclophosphamide, prednisone and furosemide.

Exam: VS T 36.5, P 110, RR 18, BP 180/110, weight 75 kilograms. She is very nauseated and actively vomiting. She responds to verbal commands and is slightly somnolent, but oriented. She has pale conjunctiva and no oral lesions or thrush. Her lungs are clear. She is tachycardic and has a rub. Her abdomen is soft and nontender and her upper and lower extremities have 1-2+ edema.

Her CBC is significant for a low hemoglobin of 7.5 g/dl with an MCV of 92. Her chemistries show an elevated potassium at 5.7; a low bicarbonate at 13 and a markedly elevated BUN at 119 and a creatinine of 14. Her ANA is elevated at 160 and her TSH is normal. A renal ultrasound shows small echogenic kidneys with no hydronephrosis, masses or stones. A chest x-ray shows engorged pulmonary vessels (fluid overload) and an enlarged heart. An echocardiogram reveals a moderate pericardial effusion, but is otherwise normal. Emergent vascular access is obtained, and she is taken to hemodialysis. She receives dialysis daily and within a week, her symptoms resolve. A follow-up echocardiogram demonstrates a reduction in the pericardial effusion.

The above case illustrates the use of acute hemodialysis for a patient with uremia secondary to chronic renal failure in the setting of SLE. There are a number of indications for acute hemodialysis (HD). One is renal failure (creatinine clearance less than 10) as manifested by a urea nitrogen over 150 mg/dL or a serum creatinine elevated 10-fold over normal, or signs and symptoms of uremia. This may include nausea and vomiting, altered mental status, seizures, pericarditis or bleeding diathesis (platelets become progressively dysfunctional in the setting of uremia). Other indications for HD include uncontrolled hyperkalemia, refractory fluid overload, severe metabolic acidosis, tumor lysis syndrome, certain inborn errors of metabolism, and certain acute poisonings/overdoses.

When a teenager needs HD, vascular access must be obtained prior to initiating therapy. In the acute or emergent setting, a double-lumen catheter (such as a Vas-Cath) can be placed in a large vein. The internal jugular or femoral vein is preferred, but sometimes the subclavian vein is used. This vascular access device has large lumens to permit optimal blood flow. As with any central venous line, there is a risk of pneumothorax if the internal jugular or subclavian sites are used; a risk of bleeding (especially in the uremic patient) and a risk of infection. Although placed with sterile technique, the risk of infection increases the longer the line is kept in place. If kept in for an extended period, infection is one of the drawbacks to having this type of vascular access; however, it can be used immediately and is ideal when dialysis needs to be done quickly.

If chronic, "maintenance" dialysis is planned for some future time (as with chronic renal failure), more permanent vascular access should be established. One method involves connecting a vein to an artery to create an AV fistula. It is usually done in the non-dominant arm, in case ischemia or other complications occur. Once it is decided that permanent vascular access is needed, the patient and nurses should be instructed to make that limb "off-limits" for blood draws, intravenous lines or arterial punctures. This is done to minimize any potential trauma to the blood vessels prior to fistula surgery. As a reminder, a large sign is usually placed above the patient's hospital bed stating "No Draws: Left Arm." A number of artery-vein anastomoses are possible, but the two most common are the wrist radiocephalic and the elbow brachiocephalic. After surgery, the fistula needs about 6 weeks to mature and cannot be used during this time. Maturation is the histologic process of venous thickening and dilating, essentially taking on some of the characteristics of the attached artery. These changes enable the venous portion of the graft to accept the repeated insertion of the dialysis needle. If the patient is already requiring dialysis, a temporary percutaneous double lumen catheter can be used until the fistula is mature and usable. After surgery, the fistula should have a palpable thrill and audible bruit. This should be checked at least daily as an assessment of patency.

If an AV fistula is not anatomically possible, another type of permanent access is an arterial-venous (AV) graft. This involves the use of a synthetic tube to connect the artery and the vein. Common sites for AV grafts include the radial artery to the basilic vein, the brachial artery to the basilic vein and the brachial artery to the axillary vein. Maturity is faster than the fistula, usually occurring in 2-3 weeks. The major drawback of the AV graft is it is much more likely to clot and occlude than the native fistula, due to intimal hyperplasia in the native vein to which the graft is attached. If this should occur, medical therapy (thrombolysis) or a surgical procedure can be done to salvage the graft (interventional procedures or thrombectomy). Both AV fistulas and AV grafts have a number of long-term complications. This includes edema or ischemia of the hand, pseudoaneurysm at the graft or fistula site, infection, thrombosis and congestive heart failure. If a hemodialysis patient has a fever or positive blood cultures and fistula or graft infection is suspected, a nuclear WBC scan can be done to help confirm the diagnosis. Staphylococcus is a frequent infecting organism, but gram negative rods and enterococcus infections can also occur. Empiric therapy should be directed at these organisms, and may require vancomycin coverage for methicillin-resistant Staphylococcus aureus (MRSA). Species of Candida can also infect these sites.

Vascular access in infants and small children is more complicated than in older children and teenagers. In neonates, an umbilical vein may be used. Some hemodialysis machines permit a single lumen or needle to be used. For permanent access, AV grafts may be necessary if native blood vessels are too small to create a fistula.

Once vascular access is established, blood leaves the body via tubing into the dialysis unit. It passes along a semipermeable membrane with a dialysis solution (dialysate) flowing along the other side of the membrane. Solute particles from the blood then pass down their concentration gradient into the dialysate for removal. The mechanism of dialysis can be simplified based on standard diffusion: where particles (solutes) of high concentration (in the blood) move down their concentration gradient to an area of low concentration (the dialysate). The movement is across a semipermeable membrane, so larger particles will cross more slowly or not at all. Thus the smallest particles will be removed the fastest. Also, the steeper the concentration gradient, the quicker the removal. Blood and dialysate run through a filter in opposite directions, with the membrane separating them. This countercurrent flow maximizes the concentration gradients for solute removal. The blood is then returned to the body. Other aspects of the dialysis prescription include the type of membrane, flow rate of blood and dialysate, temperature, length of time on dialysis, and composition of the dialysate. Modern machines can monitor these functions and monitor for potential air emboli and blood leaks in the dialyzer as well.

The dialysate is purified water with precise amounts of various ions and glucose. For example, a typical solution would contain: Na+ 145 mEq/L; K+ 3.5 mEq/L; Ca++ 3.5 mEq/L; Mg++ 0.75 mEq/L; and dextrose 200 mg/L. Different ionic concentrations can be used for different clinical situations. For example, if a stable patient needs routine dialysis, and her pre-dialysis potassium is usually 5.0, a dialysate with 3.0 mEq/L of potassium would be used. If the same patient had a viral gastroenteritis and her pre-dialysis potassium was 3.0 then a dialysate with 4.0 mEq/L of potassium would be used. If that same person was feeling fine and ate some high potassium foods such as fruit the day before dialysis and her pre-HD potassium was 7.0, a dialysate with zero potassium would be used.

Besides normalizing ionic concentrations and removing waste, another function of dialysis is to remove accumulated water. Water moves across the membrane under hydrostatic forces and this is known as ultrafiltration. The degree of that force determines the amount of net water movement. Small particles within the water are also removed during this process, which is called convection. Particles larger than the dialysis membrane pore size will be left behind in the blood.

Major complications of hemodialysis are unusual. These can include: seizures, hypotension and hypothermia. The seizures are a severe manifestation of the dysequilibrium syndrome. The syndrome has a characteristic EEG tracing and in mild cases can be associated with headaches, nausea and vomiting. More severe manifestations include seizures and coma. The cause of the syndrome is unknown, but it may have to do with osmotic shifts in the brain. It can occur during or after hemodialysis. Preventative measures include limiting the flow and the total time on hemodialysis for the first few sessions to prevent large fluxes.

Hypotension is another common complication during hemodialysis. If significant, it can be treated with volume replacement. If fluid removal is necessary, however, more frequent dialysis sessions with smaller volumes removed per session may be required. Additionally, some patients tolerate fluid removal better if dialysate sodium concentrations are increased, something known as sodium modeling. If large changes in fluid status are avoided, hypotension during the session is minimized. Finally, hypothermia can be a problem, as removed blood can be cooled in the tubing and machinery. This is prevented by heating units in the dialysis machine to keep the temperature constant.

As mentioned, hemodialysis can be associated with large fluid shifts that can result in hypotension. When patients are unable to tolerate such a drop in blood pressure or are already on vasopressor support (for example, in septic shock) another form of dialysis may be required. This typically is known as continuous renal replacement therapy (CRRT) or slow continuous therapies. When done via a Vas-Cath, it may also be called continuous veno-venous hemofiltration (CVV-H). This form of dialysis is done continuously (compared to three times a week for 4-5 hours in standard hemodialysis). It is used almost exclusively in the intensive care unit for critically ill patients. This type of therapy is also better than standard hemodialysis for clearing elevated phosphorus seen in tumor lysis syndrome in leukemia or lymphoma, in part because a different and more porous membrane is used.

Another method of dialysis is peritoneal dialysis (PD). In this method, an indwelling catheter is placed in the abdomen, usually under general anesthesia in children, and the PD solution (another form of dialysate) is circulated through the peritoneal cavity. This is the most common method of chronic dialysis for pediatric patients. PD can also be used in the acute setting, but it is not efficient in correcting hyperkalemia, hyperphosphatemia or hyperammonemia and if these values are critical, another dialysis modality should be used. The advantages are that vascular access is not needed; no complicated machinery is required; it does not cause large volume shifts; and it can be performed at home after fairly brief training. In PD, the peritoneum acts as a biological dialysis membrane and solutes cross this from the blood to the dialysate. Fluid can be changed manually every six hours or changed through an automated cycling machine (such as during sleep.) The major complication of this method is peritonitis. Other drawbacks include the presence of an external catheter from the abdomen, which may make children self-conscious.

Long term complications of chronic renal failure in children include growth failure, anemia, hypertension, acidosis and renal osteodystrophy. The etiology of the growth failure is multifactorial. Children may respond to exogenous recombinant human growth hormone. Erythropoietin deficiency accompanies renal failure and results in anemia. Folic acid is usually added as a supplement and ferrous sulfate can be started if iron stores are low. If anemia persists, exogenous erythropoietin can be initiated. Hypertension may be due to dietary indiscretion, inadequate fluid removal during dialysis, or the renin-angiotensin axis. If these cannot be remedied, anti-hypertensive medications are used. Acidosis can interfere with growth hormone function and should be treated with exogenous alkali (calcium carbonate, sodium bicarbonate) to maintain a serum bicarbonate levels of 22 mEq/L or higher.

Renal osteodystrophy can be minimized with careful control of calcium and phosphate metabolism. As the kidney fails, phosphate excretion is impaired and the serum levels rise and a concurrent fall in serum calcium. The lower serum calcium levels stimulate

parathyroid hormone production which acts on bone to release calcium. This can cause bone pain, deformities and growth retardation. Radiographically, osteopenia, epiphyseal slipping and subperiosteal resorption may be present. Laboratory findings can include elevated PTH and alkaline phosphatase with low levels of active vitamin D (1,25-dihydroxy-vitamin-D3). Vitamin D undergoes final hydroxylation and activation in the kidney, which is hampered in chronic renal failure. The reduction in active metabolites of vitamin D results in calcium malabsorption in the intestines and further exacerbates osteodystrophy, and in children with open epiphyses can lead to what is known as "renal rickets". Therapy should reduce excess phosphate by limiting dietary phosphorus to 1 gram per day, and if levels remain high, treatment with binders (calcium carbonate, calcium acetate, or sevelamer) should be initiated. These are given with meals to bind dietary phosphate and prevent absorption. Additionally, calcium and active vitamin D replacement should be optimized and PTH levels should be monitored for hyperparathyroidism.

In summary, dialysis can be a life-saving therapy for acute renal failure, certain poisonings and in severe electrolyte disturbances seen in the tumor lysis syndrome. It can also substitute for native kidneys in patients with end stage renal disease, although children do not thrive as well as they do with a functioning renal transplant. Ideally, dialysis can act as bridge until normal renal function returns or the patient is able to receive a kidney transplant.

Questions

1. What are the indications for dialysis in pediatric patients?
2. What situation is CVV-HD preferred over HD or PD?
3. What are the advantages of PD?
4. What are three complications that may occur in patients undergoing hemodialysis?
5. What are some long term complications of renal failure?

Answers to questions

1. Renal failure with uremia; BUN over 150 mg/dl; creatinine over 10 mg/dL; severe hyperkalemia; severe acidosis; refractory fluid overload (CHF); certain inborn errors of metabolism; certain acute poisonings; tumor lysis syndrome.
2. In hemodynamically unstable patients.
3. Can be done at home; no complex machinery; no vascular access.
4. Hypotension, seizures, hypothermia.
5. Anemia; acidosis; hypertension; growth retardation, renal osteodystrophy, platelet dysfunction.

Chapter XIII.5. Hemolytic Uremic Syndrome

Jonathan K. Marr, MD

This is a 3 year old male who is brought to the ED by his mother when she noted bloody diarrhea earlier in the day. There is no fever, ill contacts, or recent exposures to children with diarrhea. He is noted to be pale. His family had attended a birthday party 7 days prior where the child had consumed hot dogs and hamburgers.

Exam: VS T 37.7, P 150, R 28, BP 100/45, oxygen saturation 100% in RA. Weight 17 kg (75%ile). He is alert but fussy, pale, and non-toxic appearing. His conjunctiva are pale. His TMs are normal. He has no nasal flaring or palatal petechiae. His oral mucosa is moist and his tongue is pale. His neck is supple without adenopathy. His heart has a regular rhythm with tachycardia and a grade III/VI vibratory systolic ejection murmur at the left sternal border without radiation. No heaves, lifts, thrills, rubs, or gallops are present. His lungs are clear with good aeration. His abdomen is flat, soft, and non-tender, with the liver edge palpable 3cm below the RCM. The spleen is non-palpable. His genitalia and anus are normal (no rectal prolapse). His pulses and perfusion are good. There are is no edema, rash, or petechiae.

Labs: CBC: WBC 16,000 with 56% segs, 12% bands, 27% lymphs, 3% eos, 2% basos, hemoglobin 8 mg/dL, hematocrit 24.6, platelet count 75,000; peripheral smear shows schistocytes, helmet cells, and polychromasia. Na 133, K 5.9, Cl 96, bicarbonate 16, BUN 45, creatinine 1.3, glucose 145 mg/dL, Ca 7.8, PO4 7.1, uric acid 7.3, and LDH 300. Coagulation studies are normal.

Hemolytic uremic syndrome (HUS) is a heterogeneous group of similar entities that has been recognized for over 45 years and has been reported from most parts of the world. It is one of the most common causes of acute renal failure in childhood and is defined by a combination of microangiopathic hemolytic anemia, variable degrees of thrombocytopenia, and renal failure (1). Other systems, such as the CNS may be involved.

HUS can be classified in a number of ways, but the most common is the diarrhea-associated (D+ HUS) versus atypical (D- HUS) HUS without diarrhea. The D+ HUS is characterized by a sudden onset of hemolytic anemia, thrombocytopenia, and acute renal failure after prodromal gastrointestinal enteritis. The atypical (D- HUS) is rare in childhood, portends a worse prognosis, is more likely to relapse, and may be associated with a family history of HUS disease. It appears to be associated with certain chemotherapy drugs (cyclosporin and tacrolimus), oral contraceptives, cancer, bone marrow transplantation, Streptococcus pneumoniae infections, and vasculitic diseases (1).

Another common classification used is Shiga-like toxin-associated HUS (Stx HUS), since D+ HUS has been strongly associated with a toxin-producing strain of Escherichia coli O157:H7 (1,2). Historically, Shigatoxin (Stx) is an exotoxin produced by Shigella dysenteriae type I and the term verotoxin is derived from the use of vero (monkey) cells as a cytotoxic assay for the Shigatoxins produced by E. coli O157:H7 (1). Human verotoxin producing E. coli (VTEC) strains produce one or both of the toxins Stx-1 and Stx-2 and are established causes of HUS associated with bloody diarrhea. Other strains of E. coli besides O157:H7 produce shiga toxins; they include E.

coli O111, O26:H11, and O103:H2, although they are less commonly found in HUS cases, since their assays are not routinely commercially available (1,2).

Epidemiologically, the most common form of the HUS syndrome (D+ HUS) occurs predominantly in healthy children 6 months to 5 years of age, and has seasonal variation with peaks in the summer and fall (1). Most cases of D+ HUS occurring during epidemics are due to ingestion of contaminated, usually undercooked, ground beef. Approximately 1% of beef cattle in the United States harbor intestinal E. coli O157:H7. The organisms become incorporated during the processing of ground beef that mixes meat from multiple cattle such that one infected animal can contaminate large quantities of ground beef. E. coli O157:H7 can also be acquired by consuming fruits or vegetables contaminated by manure, drinking unpasteurized milk, swimming in contaminated lakes, and person-to-person contact (1).

Stx produced by VTEC is most specifically toxic to cells containing a specialized glycolipid receptor called glycosphingolipid globotriosyl ceramide (Gb3) (2). Glomerular epithelial cells in the renal cortex contain large quantities of Gb3. This explains the predilection for renal cortex lesions and acute renal failure (1). Other areas that contain Gb3 include the CNS and the pancreas.

VTEC also releases lipopolysaccharide (LPS), stimulating WBCs to release inflammatory mediators (TNF-alpha, IL-1, and elastase) that cause endothelial cell detachment, increased procoagulant activity, and release of free radicals causing oxidative cell membrane injury (1). The injury to endothelial cells in renal microvessels results in local intravascular coagulation and a microangiopathic hemolytic anemia with mechanical destruction of erythrocytes and platelets by fibrin strands in narrow vessels (1). Platelet adherence contributes to microthrombi and platelets are consumed when platelet-fibrin thrombi are formed in these injured areas. The capillary lumina are narrowed by endothelial swelling and occlusive thrombi, effectively decreasing blood flow to the glomeruli leading to renal insufficiency and eventually progressing to renal failure.

Clinically, HUS presents with abdominal pain, vomiting, and bloody, mucoid diarrhea. The prodromal phase of the illness varies from 1-15 days before the onset of HUS. Pallor and petechiae occurs within 5-7 days after the onset of the bloody diarrhea. Other signs that may be noted include oliguria, personality changes, and drowsiness. The oliguria found in 60% of patients lasts an average of one week; however 50% of patients, are anuric for an average of 3 days. Most patients are irritable and somnolent. Other findings include behavioral changes, ataxia, dizziness, tremors, and twitching. With progression of the disease, anuria, coma, hemiparesis, cranial nerve dysfunction, cerebral infarcts, seizures, and death can occur. Seizures are reported in 3-5% of cases (2). Active bleeding other than the bloody diarrhea is rare. Hypertension is a common feature of HUS and occurs in 50% of all affected individuals. Possible etiologies for this include fluid overload and increased renin activity (1). Pancreatic insufficiency manifested as transient diabetes mellitus occurs in 4-15% of patients (1,2). Mortality has declined and is between 5-10% during the acute phase. Predictive features associated with poorer long-term outcomes include: severe gastrointestinal prodrome (colitis with rectal prolapse), prolonged duration of anuria, extended duration of dialysis, coma on admission, and high leukocyte count (1). Generalized seizures during the acute phase of the disease are not predictive of death or poor neurological sequelae (1). Age and gender have no consistent correlations on outcome.

The differential diagnosis of early HUS includes: ulcerative colitis, Crohn's disease, appendicitis, intussusception, idiopathic rectal prolapse, gastroenteritis, or acute bacterial endocarditis.

Thrombotic thrombocytopenic purpura (TTP), also known as Moschcowitz's syndrome is similar to HUS with the features of: microangiopathic hemolytic anemia, thrombocytopenia, renal dysfunction, fever, and neurological disturbances (4). It is probable that TTP and HUS represent a similar pathological process, except that TTP is the more serious multisystem disorder with a higher mortality (30-40% within 3 months). The pathophysiologic events involved with TTP are not fully understood but probably involve abnormalities in endothelial composition and unusually large von Willebrand Factor (vWF) multimers in the circulation causing platelet activation with resultant platelet thrombi formation.

Laboratory findings in HUS include a negative Coombs test, normochromic, normocytic anemia with helmet cells, schistocytes, and polychromatophilia on blood smear indicative of hemolysis. Other evidence for hemolysis is an elevated LDH and low serum haptoglobin. An unconjugated hyperbilirubinemia is usually present. The mean hemoglobin is 8 mg/dL. The platelet count is moderately depressed to 50,000, but can be as low as 5,000. Neither the severity nor the duration of the thrombocytopenia correlates with the overall severity of disease. The duration of the thrombocytopenia lasts from 2-3 weeks and there are usually no signs of active bleeding other than the bloody diarrhea. The half-life of infused platelets are shorter, as they are likely taken up by the liver and spleen; furthermore, circulating platelets are dysfunctional. Leukocytosis is present and is nonspecific diagnostically; a recent study, however, found the risk of developing HUS proportional to the initial WBC count (3). Coagulation tests are normal and fibrin split products may be positive.

Signs of renal dysfunction include elevated serum levels of creatinine, potassium, phosphorus, and uric acid which result from decreased glomerular filtration, hemolysis, and transcellular cation shifts (1). Elevations in BUN and creatinine may initially reflect volume depletion because of the diarrhea, but may later be the result of renal failure. Sodium, calcium, and albumin may be low from initial diarrhea losses and later from volume overload because of renal failure. Pancreatic insufficiency is manifested by elevations in amylase and lipase or glucose intolerance.

Histopathology on renal biopsy (not always done unless clinically indicated) demonstrates glomerular lesions of endothelial cell swelling and a widened subendothelial space filled with fibrin-like substances and lipids (1). This results in a thickened capillary wall and reduced capillary lumen. The glomerular basement membrane is intact. Occasionally there may be crescents and signs of necrosis and the glomeruli may be lobulated and resemble membranoproliferative glomerulonephritis (1). Thrombi may occlude arteriolar lumens and there may be tubulointerstitial disease. Fibrin, fibronectin, IgM, and C3 are found by immunofluorescent microscopy along capillary walls, mesangium, and in the subendothelial spaces of capillaries and arterioles (1).

Treatment for HUS is supportive. Dehydration should be corrected, but over hydration should be avoided if oliguric renal failure occurs. Fluids must be limited to insensible losses plus the volume of urine output. Hyperkalemia, hyperphosphatemia, and severe metabolic acidosis may be managed medically. Dialysis is indicated if this fails. Packed red blood cells should be transfused if the hemoglobin falls below 6g/dL or for symptomatic anemia. Platelet transfusions are rarely administered since generalized bleeding is not common; however, they may be indicated before surgical procedures (i.e. catheter placement for hemodialysis or peritoneal dialysis) or active bleeding. Hypertension should be treated to prevent encephalopathy or congestive heart failure. Calcium-channel blockers (nifedipine) or nitroprusside are the medications often recommended to control hypertension.

Peritoneal or hemodialysis should be considered when fluid and electrolyte imbalances cannot be corrected by medical management, or when fluid overload compromises cardiac or pulmonary function. In general, when the BUN exceeds 100 mg/dL, dialysis should be considered even in the absence of fluid and electrolyte imbalances (2). Non-oliguric patients generally do not need dialysis.

Antiplatelet drugs, intravenous immune globulin, anticoagulants, thrombolytic agents, prostacyclin, and corticosteroids have not been found to be beneficial (1,2). Plasma infusion or exchange therapy found to be beneficial in patients with TTP, has not been found to be advantageous in patients with HUS. Plasmapheresis has been of benefit in atypical HUS (D-) when neurological involvement is present

(1). Fresh frozen plasma administration may be harmful in patients with HUS (1). Antibiotic therapy during D+ HUS is controversial, after a recent report suggested that the risk of developing HUS may be increased after antibiotic therapy (sulfa-containing and beta-lactam) for E. coli O157:H7 (3). Currently, a chemically synthesized trisaccharide (Synsorb-Pk), was found to bind with high affinity to Stx-1 and Stx-2, and is undergoing human trials in Canada in assessing its value in preventing D+ HUS (1).

Prevention of D+ HUS is most effective by cooking ground beef until the inside is no longer pink. The Food and Drug Administration recommends a minimum internal temperature of 155 degrees F for cooked hamburger. The most effective means of preventing person-to-person spread is supervised handwashing. Infected children must be excluded from day care centers, until they have documented negative stool cultures for E. coli O157:H7.

Prognosis for HUS has improved with the introduction of dialysis. Previously, children with HUS died from fluid overload, metabolic derangements, and uremia. The acute fatality rate ranges from 4-12% and another 5% develop acute renal failure and anuria. End-stage renal disease or chronic renal failure develops in 10-15% of HUS patients (2). 65-85% recover completely, however, a significant number of patients develop renal sequelae (proteinuria, hypertension, and low creatinine clearance) during long-term follow up studies (1).

Questions

1. What is the likely etiology of D+ HUS?

2. What defines HUS?

3. What types of blood cells would be most consistent with a diagnosis of HUS in a 3 year old child with bloody diarrhea?
   a. Atypical lymphocytes
   b. Elliptocytes
   c. Myeloblasts
   d. Schistocytes
   e. Spherocytes

4. What is the strongest indication for dialysis?
   a. Serum sodium of 120
   b. Initial bicarbonate of 14
   c. Serum BUN 120 mg/dL
   d. Initial K of 5.2
   e. Anuria for 3 days

5. True/False: The severity of hemolysis correlates with degree of renal failure?

6. A 3 year old girl presents with signs and symptoms of intussusception which include crampy intermittent abdominal pain, crying with puffy eyes, currant jelly diarrhea, pallor, dehydration and oliguria. Could this patient have HUS? Explain how all of the findings above could be due to HUS instead.

Answers to questions

1. E. coli O157:H7
2. Microangiopathic hemolytic anemia, thrombocytopenia, and renal failure.
3. d. schistocytes
4. c. serum BUN >100
5. False
6. Crampy abdominal pain (due to colitis), crying with puffy eyes (due to abdominal cramps, fluid retention due to renal failure causing puffy eyes), currant jelly diarrhea (actually bloody diarrhea due to E. coli O157:H7), pallor (due to hemolytic anemia), dehydration (due to diarrhea), oliguria (due to renal failure).

Chapter XIII.6. Urinary Tract Infection
Janet M. Berreman, MD

This is a 4 month old female who presents to the office with a chief complaint of fever, vomiting, and loose stools. She has had tactile fever for 3 days, and had 5-6 episodes of emesis on the first day of illness. Stools were liquid on the first and second days of illness. She was seen at an emergency room 2 days ago, where the impression was gastroenteritis. No labs or x-rays were done in the emergency department. She returns to the office now because of persistent fever. Vomiting and diarrhea have resolved, but she is breast-feeding less well than usual. Her mother notes that her urine seems "strong" and that she is not as playful as usual. She has had no known ill contacts. She has no cough, URI symptoms, or rash. Past history is unremarkable and she is on no medications.

Exam: VS T 38.9, P164, R40, Wt. 5.3kg (15%ile, and 150gm below her pre-illness weight). She is alert, smiling, active, not toxic, and in no distress. Her anterior fontanelle is soft and flat. Her eyes and ENT exams are normal. Her oral mucosa is moist. Her neck is supple. Heart rate is regular without murmurs. Lungs are clear and her respirations are non-labored. Her abdomen is flat, soft, non-tender, without hepatosplenomegaly or masses. Her external genitalia are normal. Her skin is warm and well perfused, with no rash. Her back exam reveals no deformities or cutaneous defects. Her neurologic exam shows normal tone, strength, and activity.

A urine specimen obtained by transurethral catheterization yields a small amount of cloudy urine, which is positive for leukocyte esterase and nitrite tests. This is sent for culture. Her CBC shows a WBC 9.4, H/H 9.3/27.5, platelets 389,000, 51% neutrophils, 44% lymphocytes, 3% monocytes, 2% eosinophils. She is given 250mg of ceftriaxone intramuscularly and is scheduled for recheck in the office the next morning.

At follow-up the next day, she is smiling and non-irritable, and shows a 250 gm weight gain. She fed well overnight and continued to have a low grade fever. Urine culture is positive for greater than 100,000 colonies/ml of a non-lactose fermenting organism, with identification and sensitivities pending. Ceftriaxone is repeated at the same dose. The following day, she is afebrile and her parents feel that she is entirely back to normal. Urine culture result identifies E. coli, sensitive to all antibiotics tested. She is started on oral trimethoprim-sulfamethoxazole (TMP-SMZ) to complete 10 days of antibiotic therapy. She remains well on oral antibiotics. Following 10 days of therapy, she is changed to a prophylactic dose of TMP-SMZ and a renal ultrasound and voiding cystourethrogram (VCUG) are scheduled. Both studies are normal. Repeat urine cultures on day 3 of antibiotics, and again at the time of VCUG are negative. Antibiotics are discontinued. She has done well without recurrent episodes of UTI.

Urinary tract infections (UTIs) are a common, potentially serious, and (especially in young children) often occult bacterial infection of childhood. During childhood, UTI occurs in approximately 3-5% of girls and 1% of boys. Most of the UTIs in boys occur in the first year of life, whereas the age of the first diagnosed UTI in girls is highly variable. After 2 years of age, UTI in females exceeds that in males by a factor of 10:1 (1). Uncircumcised males less than one year old are more likely to be affected than circumcised males (2,3). The prevalence of UTI in a febrile child 2-24 months of age, without other source of infection, is 5% (4). After 6 years of age, and before the onset of sexual activity, incidence of UTI falls dramatically in both sexes.

Many factors may predispose a child to UTI, including abnormalities of the urinary tract such as vesicoureteral reflux (VUR), renal anomalies with hydronephrosis or obstruction, neurogenic bladder, or nephrolithiasis; functional abnormalities such as constipation, fecal incontinence, or incomplete bladder emptying; and environmental factors such as bubble baths, poor perineal hygiene, pinworms, or sexual activity, including sexual abuse. Labial adhesions in girls and phimosis in boys also contribute to an increased risk of UTI.

UTI causes acute morbidity as well as long term sequelae including hypertension and impaired renal function. Accurate diagnosis of UTI is important both to facilitate appropriate management of the acute illness, and to insure appropriate evaluation and follow-up. Equally important is accurately ruling out a UTI to avoid unnecessary, costly, and potentially harmful treatment and evaluation.

The clinical presentation of UTI varies greatly, primarily with the age of the child. In general, the older the child, the more clearly signs and symptoms point to the urinary tract. Thus older children (over 6 years) and adolescents are likely to present with dysuria, urgency, or frequency, and may have associated fever, chills, flank pain, enuresis, or hematuria. Younger children (2-6 years) can have any of these same signs and symptoms, but they may show more nonspecific signs such as abdominal pain, altered voiding pattern, decreased appetite, or general malaise (5).

From infancy to 2 years of age, fever alone is the most common presentation of UTI (6). There may be associated vomiting, diarrhea, constipation, poor feeding, irritability, or late-onset jaundice, but these features do not aid in distinguishing UTI from other causes of fever. Vomiting and diarrhea are frequently attributed to gastroenteritis, when in fact it is a UTI. A history of malodorous urine or crying with urination is helpful when present, but absence of these complaints does not rule out UTI. In this age group, UTI should also be considered in the differential diagnosis of failure to thrive. The possibility of UTI should be considered in any febrile (temp greater than 39 degrees C, 102.2 degrees F) child under 24 months of age, keeping in mind that girls under 24 months of age, and boys under 6 months of age are at highest risk.

The diagnosis of UTI depends upon: first, maintaining a high index of suspicion for the condition, especially in young children and infants; and second, performing appropriate diagnostic studies.

Physical examination of the child with suspected UTI focuses first on assessing the overall degree of illness severity (relatively stable or possibly toxic and septic) of the child, including hydration status, level of alertness and comfort or discomfort, and perfusion state. Vital signs must be evaluated, especially for fever, hypertension (as a sign of renal impairment), signs of shock, and weight (for chronic failure to thrive or acute weight loss suggestive of dehydration). The abdomen should be carefully examined for any masses or tenderness, including costovertebral angle (CVA) tenderness. Genitalia should be examined for signs of trauma, urethral or vaginal discharge, labial adhesion, or phimosis. Rectal examination may provide further assessment of any intra-abdominal masses or tenderness, and assessment of rectal tone may aid in ruling out a neurologic abnormality which could contribute to UTI susceptibility. Visual inspection of the sacral spine for skin dimples or other cutaneous abnormalities may similarly lead the clinician to further evaluate the child for spinal cord abnormalities associated with a neurogenic bladder.

The diagnosis of UTI requires culture of a properly collected urine specimen (7). In children less than 2 years of age, a properly collected urine specimen requires an invasive procedure: either suprapubic aspiration or transurethral catheterization. As children advance in age and toileting abilities, it becomes possible to obtain a clean catch mid-stream voided urine specimen and thus avoid invasive collection techniques. A clean catch mid-stream urine sample means that the urethral meatus and surrounding area should be clean, and that the urine collected should be from the middle of the stream: i.e., the first few drops of urine should not be collected. For girls, cleaning involves separating the labia and cleaning the area (usually with a series of 3 pre-moistened antiseptic towelettes). For

circumcised boys, the glans of the penis should be similarly cleansed. For uncircumcised boys the foreskin is gently retracted prior to cleaning. After cleaning, the child voids over the toilet, with the parent "catching" the urine in a clean specimen cup after the first few drops are passed. In girls this is often more easily accomplished by having the child sit facing backwards on the toilet, so the parent can easily catch the urine stream from behind the child.

Urinalysis (UA) is helpful in evaluating the likelihood of UTI, but cannot definitively rule it in or out. The most readily available and useful components of the UA in this context are the leukocyte esterase test, nitrite test, and microscopy. Sensitivity is markedly improved when all three are used, although specificity is lower. A positive leukocyte esterase or positive nitrite test is suggestive of UTI, as are more than 5 WBC per HPF (high power field) of a spun urine specimen, or bacteria present on a gram stain of an unspun urine (a test not done by most labs unless specifically requested).

Urine culture results are expressed quantitatively, indicating the colony-forming units (CFU or colony count) of bacterial growth. The significance of a positive culture depends upon the method of specimen collection and the number of colonies of a single organism (8). In general, a colony count of greater than or equal to 100,000 is considered positive on any properly obtained urine specimen. Colony counts of greater than or equal to 10,000 on a catheterized specimen are also considered positive. Colony counts of 1,000 to 10,000 on a catheterized specimen are suspicious and should be repeated. A specimen obtained by suprapubic aspiration should be sterile, so any growth of gram negative bacilli or any more than a few thousand gram positive cocci is considered a positive culture.

Urine specimens obtained from young children by means of a bag applied to the perineum have a high rate of contamination. A negative culture of a bag-collected urine does rule out a UTI; however, a positive culture obtained in this way is not a definitive diagnostic test. In fact, positive culture results from such a specimen are estimated to be falsely positives as much as 85% of the time (7).

The most common causative agents of UTI are gram negative colonic bacteria, with Escherichia coli being the cause of most acute UTIs (1,8). Klebsiella, Proteus, and Enterobacter species are other common gram negative causes of UTI. Gram positive organisms include Staphylococcus species and Enterococcus species. Cystitis may be viral, usually caused by adenovirus (1,9).

UTIs are divided into two major classifications: those that involve the lower urinary tract (cystitis) and those that involve the upper urinary tract (pyelonephritis). Lower tract disease typically does not cause fever, and does not result in renal damage. Upper tract disease classically causes fever, abdominal or flank pain, and in younger children and infants the nonspecific signs of irritability, poor feeding, malaise, failure to thrive, or vomiting and diarrhea. The differentiation of upper tract disease from lower tract is primarily a clinical one, with supporting evidence provided by technetium (Tc 99m) dimercaptosuccinic acid (DMSA) scanning (10) and by elevated C-reactive protein (CRP) values (9).

The differential diagnosis of UTI varies with the age and presenting complaints of the patient. The nonspecific signs associated with UTI in infancy and toddlerhood may be associated with bacterial sepsis originating in any site, as well as with gastroenteritis, hepatitis, or viral infection. Signs of cystitis in older children or adolescents raise the possibility of chlamydial or gonorrheal urethritis. The presenting complaints of pyelonephritis must be differentiated from acute appendicitis, hepatitis, gall bladder disease, pelvic inflammatory disease, and other causes of acute abdominal pain.

Treatment of UTI depends upon assessment of the likelihood of the diagnosis of UTI and the clinical severity of the illness. These assessments will guide the clinician to: await culture results before initiating antibiotic therapy; initiate empiric oral antibiotic therapy; initiate empiric parenteral outpatient therapy; or hospitalize for empiric parenteral therapy. Initial treatment decisions are made before culture results are available, and are therefore empiric. The goals of prompt treatment are eradication of the acute infection, symptom resolution, prevention of progression of disease (e.g., to pyelonephritis, abscess, or sepsis), and reduction of the risk of renal scarring and its long term sequelae (7,11).

When therapy is initiated empirically, the clinical condition of the child is the primary factor considered. In every case, an adequate urine specimen for culture must be obtained prior to initiating therapy. The younger and/or more clinically ill the child with probable UTI is, the more aggressive initial therapy needs to be. In the non-toxic appearing, usually older child, in whom there is a relatively low suspicion of UTI, and no concern of upper tract disease, treatment may be deferred until urine culture results are available. A non-toxic child, who is feeding well, is well-hydrated, and for whom compliance and follow-up are not problematic, is appropriately managed with oral antibiotics and close outpatient follow-up.

At any age, a child with signs of urosepsis, severe clinical illness, or significant dehydration should be hospitalized for parenteral antibiotic therapy and close clinical monitoring and supportive care. High risk children, such as those with immunologic impairment or known urologic abnormalities, may also need hospitalization. Inpatient therapy traditionally has been recommended for all children with suspected pyelonephritis as well as for infants less than 1 year of age with UTI. Some of these children may be managed with outpatient parenteral antibiotics, or even with oral antibiotics (7,11,12), if compliance and close daily follow-up can be assured. Children who are vomiting, or otherwise unable to reliably take oral medications, or for whom compliance is a concern, should be treated parenterally (either as inpatients or outpatients) until these issues are resolved (7,13).

The initial choice of antimicrobials is guided by the chosen route of administration, known uropathogens, and any compromise of renal function of the patient. It is adjusted based on clinical response and results of culture and sensitivity testing. Initial oral therapy may be with a sulfonamide (TMP-SMZ or sulfisoxazole) or with a cephalosporin (cephalexin or cefixime are commonly used). Parenteral therapy may be with a cephalosporin (ceftriaxone, cefotaxime) or ampicillin and/or an aminoglycoside (used with caution in the setting of impaired renal function). The oral drug nitrofurantoin is excreted in the urine, but it does not reach therapeutic concentrations in blood or tissues. It therefore should not be used to treat febrile UTIs in infants, or to treat pyelonephritis.

The choice of initial oral empiric therapy involves consideration of spectrum, side effects, allergies, palatability, dosage schedule, and price. TMP-SMZ is often considered the drug of choice. It is, however, associated with some risk of Stevens-Johnson syndrome, and can precipitate hemolysis in patients with undiagnosed G6PD deficiency. Cephalexin is the most palatable of the three, and the least expensive, but usually dosed QID. Cefixime is the most expensive, but offers the advantage of once a day dosage. TMP-SMZ is intermediate in price, and dosed BID. All three have excellent coverage for the usual pathogens. Any of these drugs is an acceptable first choice. Amoxicillin should no longer be considered a first line drug for empiric therapy, due to increasing resistance of E. coli to amoxicillin/ampicillin.

Clinical response to therapy is generally prompt, with improvement evident within 24-48 hours of initiating antimicrobial therapy. If clinical improvement is seen, and culture results indicate that the uropathogen involved is sensitive to the antimicrobial being used, routine repeat culturing of the urine after two days of therapy is not necessary. However, if sensitivities are unavailable, are intermediate or resistant, or the expected clinical improvement is lacking, repeat culture should be obtained.

Children started on parenteral antibiotics may be changed to an oral antibiotic when they are clinically well enough to do so. That is, when they are non-toxic, well-hydrated, afebrile, and tolerating oral intake. Again, oral antibiotic choice is guided by the results of initial culture and sensitivity testing of the urine.

Duration of therapy varies somewhat, again based on age and degree of illness of the child. Any child or infant with a febrile UTI needs a total of 7-14 days of antibiotic therapy, with 10-14 days preferred for those with clinical evidence of pyelonephritis (7). Short course therapy (3 days or less) is reserved for adolescent females with uncomplicated cystitis (11).

The management of UTI does not end with the successful treatment of the acute infection. Rather, it continues with the evaluation for renal anomalies or VUR, monitoring for recurrence of UTI, short or long term antibiotic prophylaxis to prevent recurrence, and medical or surgical management of any underlying predisposing conditions.

Children with VUR are at increased risk of renal damage from UTIs, as are children with other anomalies of the urinary tract. Therefore, all children (with the exception of adolescent females with uncomplicated cystitis) with a documented UTI should be investigated with a renal ultrasound and VCUG (14,15). These studies may be performed as soon after the diagnosis of UTI as is convenient. Delaying studies for 3-6 weeks after the acute infection (as previously recommended) does not alter the detection of VUR, but does substantially decrease the likelihood that the studies will be completed (16).

If studies are delayed until after completion of 7-14 days of antimicrobial therapy, the child should remain on antimicrobial prophylaxis until the studies are completed. Drugs of choice include TMP-SMZ, sulfisoxazole, and nitrofurantoin, in doses adjusted for prophylaxis rather than therapy (7,17).

The child with VUR needs long term follow-up with antibiotic prophylaxis, periodic monitoring of urine cultures, repeat imaging of the urinary tract, and possible surgical consultation (for persistent VUR, high grade VUR, or recurrent UTIs despite prophylaxis) (14,18). DMSA scanning is helpful in determining the presence of renal scarring in children with VUR and thus can assist in management decisions.

Prognosis after UTI in childhood depends on: 1) whether the infection was limited to the lower tract (cystitis) or involved the upper tract (pyelonephritis), 2) the presence or absence of VUR, and 3) the presence or absence of other urinary tract anomalies, especially those with obstructive uropathy.

Uncomplicated infections without associated VUR or obstruction respond well to antimicrobial therapy. However, as many as one third of these patients may experience recurrence of UTI within the first year after acute infection (19). Follow-up urine cultures (generally monthly for 3 months, then at 3 month intervals X 3, and then at 6 month intervals X 2) are therefore recommended.

VUR is present in 30-50% of children with UTI (20). Its severity is graded on a scale of I, II, III, IV, V (14). While pyelonephritis and renal scarring can occur in the absence of VUR, the severity of renal scarring correlates with the degree of reflux (20). The natural history of low grade reflux is toward spontaneous resolution, whereas high grade reflux is less likely to resolve without surgical intervention. The combination of renal parenchymal infection (especially repeated infections) and VUR or obstructive nephropathy puts children at risk for renal scarring which may progress to chronic renal insufficiency, hypertension, reflux nephropathy, and end stage renal disease (9,14,20). Early diagnosis and treatment of UTI and VUR or obstruction may diminish the incidence of these long term complications (21).

In summary, appropriate management of UTI hinges on three essential factors, all of which are the responsibility of the clinician: 1) Maintaining a high index of suspicion for the diagnosis, especially in infants and toddlers who rarely have specific symptoms, 2) Properly obtaining an adequate urine specimen for culture before initiating antimicrobial therapy, 3) Following through on the patient's clinical response, culture and sensitivity results, and the results of imaging studies and follow-up cultures. Careful attention to all of these points will optimize the diagnosis, treatment, management, and outcome of the child with UTI.

Questions

1. When is it appropriate to treat empirically for UTI without first properly obtaining an adequate urine specimen for culture?
2. What factors affect the decision of how to obtain a urine specimen when UTI is being considered? How will the method of collection affect the interpretation of culture results? When is a urine specimen obtained by bag collection a definitive test for UTI?
3. What are some host and pathogen factors contributing to the development of UTI?
4. How is pyelonephritis distinguished from lower tract UTI? What is the importance of making the distinction?
5. What is the commonest clinical presentation of UTI in the child under 2 years of age? What are some associated signs and symptoms which may be present?
6. Which clinical features of UTI are reason to consider parenteral therapy and/or hospitalization?
7. How would you explain to parent and child the technique of obtaining a clean catch mid-stream urine sample: in girls and in circumcised and uncircumcised boys?
8. Familiarize yourself with the technique of transurethral bladder catheterization (22) in male and female infants and toddlers, including: a) Prevention of specimen contamination, b) Selection of appropriate equipment, c) Relevant anatomic landmarks, and d) Possible complications.

Answers to questions

1. Empiric treatment for UTI should not be initiated without first obtaining an adequate specimen for culture. The only pediatric exception would be a child so severely ill (in septic shock and/or anuric) that waiting to obtain a urine sample could be life threatening. One might consider empiric treatment without culture in an uncomplicated older teen, however, such patients are rarely "uncomplicated" when considering issues such as recurrence, sexually transmitted diseases, etc.

2. The method of obtaining a urine specimen is affected by the patient's age, severity of illness, state of cooperation, toileting abilities, and whether or not antibiotics are to be started empirically. The colony count considered positive varies with the collection method: any growth with suprapubic aspiration; greater than or equal to 10,000 CFU for a catheterized specimen; and greater than or equal to 100,000 CFU for a clean catch specimen. Bag specimens are only definitive when culture result is negative (and therefore should not be used if empiric therapy is to be initiated).

3. Host factors contributing to development of UTI include uncircumcised male, labial adhesions, poor hygiene, constipation, urinary tract obstruction, dysfunctional voiding patterns, and neurogenic bladder. Pathogens are those commonly found in the vicinity of the urethra: skin and GI organisms, as well as blood-born organisms in the neonate. The strains of E. coli which commonly cause UTI show increased adherence to uroepithelial cells.

4. Classical signs of pyelonephritis include CVA tenderness, fever, and signs of systemic illness, while lower tract disease is milder and may present with only urinary urgency, frequency, or dysuria. Abnormal DMSA scan or elevated CRP results support the diagnosis of pyelonephritis.

5. The commonest presentation of UTI in the child under two years of age is fever. Associated signs and symptoms may include vomiting, diarrhea, irritability, poor feeding, malodorous urine, oliguria, constipation, or jaundice.

6. Empiric parenteral therapy and/or hospitalization should be considered when suspected UTI is associated with signs of urosepsis, severe clinical illness, dehydration, immunologic compromise, or urologic abnormality. Vomiting, poor oral intake, or concerns for poor compliance are also reasons to use parenteral therapy.

7. "Clean catch mid-stream" urine sample means that the urethral meatus and surrounding area should be clean, and that the urine collected should be from the middle of the stream: i.e., the first few drops of urine should not be collected. For girls, cleaning involves separating the labia and cleaning the area (usually with a series of 3 pre-moistened antiseptic towelettes). For circumcised boys, the glans of the penis should be similarly cleansed. For uncircumcised boys the foreskin is gently retracted prior to cleaning. After cleaning, the child voids over the toilet, with the parent "catching" the urine in a clean specimen cup after the first few drops are passed. In girls this is often more easily accomplished by having the child sit facing backwards on the toilet, so the parent can easily catch the urine stream from behind the child.

8a. Transurethral catheterization is an invasive procedure and is performed using standard sterile technique, including povidone/iodine wash of the periurethral and perineal areas, sterile field, sterile gloves, and sterile catheter and specimen cup.

8b. Infant feeding tubes in #5 or #8 french size are adequate for most infants and toddlers. It is not necessary or advisable to use a Foley catheter, as there is no need for a balloon. The catheter is removed as soon as the sample is obtained.

8c. The catheter is introduced into the urethral meatus, and advanced gently until there is return of urine. This is done with the infant in the supine, "frog-leg" position. The catheter tip may be lubricated with sterile lubricant or sterile water. In circumcised boys the urethral meatus is easily seen. In uncircumcised boys it is usually revealed by gentle retraction of the foreskin (if not, the foreskin is retracted as far as is easily possible and the catheter introduced with gentle probing until the meatus is located). The urethral meatus may be less easy to see in infant girls. It is helpful to remember that it lies anterior to the vaginal introitus, and to be familiar with the often fleshy appearance of the infant hymen. Separation of the labia, adequate light, and familiarity with the appearance of the genitalia facilitate locating the urethral meatus. A frequent error is introduction of the catheter into the vagina (recognized by the absence of urine return and by resistance to gentle advancement of the catheter beyond a couple of centimeters). Some practitioners opt in this situation to leave the misdirected catheter in place while a second catheter is introduced into the urethra (using the first catheter to "block" or mark the vaginal introitus). Whether or not the first catheter is left in place, a new sterile catheter must be used for the second attempt, to avoid contamination with vaginal flora.

8d. Complications of urethral catheterization include doubling back of the catheter (either in the urethra or in the vagina), trauma to the urethral meatus or mucosa, and possible introduction of infection. There can be subsequent stricture formation. Familiarity with the anatomy and avoidance of any forceful catheter advancement can minimize the risk of complications. A lubricated catheter of appropriate size should advance easily through the urethra. Any resistance should be taken as a sign to retract the catheter rather than to advance it more forcefully. The risk of introduction of infection is minimized by careful adherence to sterile technique.

Chapter XIII.7. Hydronephrosis and Reflux
Robert G. Carlile, MD

Case 1

A term newborn male infant is noted to have unilateral hydronephrosis on prenatal ultrasound. At 3 days of age, a renal and bladder ultrasound shows a normal right kidney, and a moderately severe left renal hydronephrosis, with no dilation of the ureter. The bladder is normal. A voiding cystourethrogram is obtained at 6 weeks of age which shows no evidence of vesicoureteral reflux, and no posterior urethral valves. Urinalysis, complete blood count, electrolytes, BUN, and creatinine are normal. At 4 weeks of age, a Mag3 renal scan with furosemide (Lasix) washout shows equal split function (right kidney 50%, left kidney 50%). The t-1/2 (washout half time) shows normal washout on the right, and prolonged washout on the left.

The patient is placed on surveillance with serial renal ultrasounds and renal scans for the next 2 years. At 2 years of age, he develops left sided abdominal pain, nausea and vomiting, without fever or chills. A renal ultrasound shows worsening left hydronephrosis and a renal scan shows diminished left renal split function to 35% (the right split function is now 65%), and markedly prolonged left renal half-time. The right renal half-time is normal.

He undergoes a left pyeloplasty at 2 years of age, and does well post operatively. A Mag3 renal scan is done 3 months postoperatively, which shows the left renal split function to have returned to 45% (right 55%), with the washout half time to have normalized. A renal ultrasound postoperatively shows only minimal residual hydronephrosis.

Case 2

A 3 year old female infant presents with fever (T 39.6), nausea, vomiting, and left flank and abdominal pain, as well as dysuria. A CBC shows a WBC of 20,000, with a left shift. Urinalysis shows 50 to 100 WBCs per high power field. Intravenous fluids and IV antibiotics are administered with clinical improvement. Urine culture later grows out greater than 100,000 colonies of E. coli. A renal ultrasound shows normal kidneys (no hydronephrosis). She is discharged home on a full course of oral antibiotics for 2 weeks, which is then changed to once daily trimethoprim/sulfamethoxazole (TMP/SMX) prophylaxis thereafter.

A VCUG (voiding cystourethrogram) shows left Grade II vesicoureteral reflux. She is continued on suppressive TMP/SMX daily with no further UTIs. A nuclear cystogram 1 year later shows persistence of the reflux, and the suppressive antibiotics are continued. A subsequent nuclear cystogram one year later shows resolution of the reflux. The antibiotic prophylaxis is stopped, and the patient has no further problems with febrile UTIs/pyelonephritis.

For the pediatrician, hydronephrosis has become a finding to be encountered even before the child enters their care, with many children being diagnosed antenatally with prenatal ultrasonography. Hydronephrosis is the most common congenital condition that is detected by prenatal ultrasound and represents 50% of all abnormalities (1). The incidence of detectable urinary dilation in utero can be as high as 1 per 100 pregnancies but only 20% of these may be clinically significant postnatally. 50% of antenatal cases detected after 28 weeks gestation have postnatal imaging that is normal (2). The majority of cases detected prenatally will resolve either before the end of pregnancy or within year 1 of life (1).

Hydronephrosis in the older child is often found incidentally during the work-up for nonspecific abdominal complaints (3). Historically, prior to the extensive use of ultrasound, neonates with hydronephrosis presented with a palpable abdominal mass, urinary tract infections, urinary retention, hematuria, feeding difficulties, or failure to thrive (4,9).

With regards to ureteral development, in week 5 of gestation, the ureteral bud develops as a posterior diverticulum of the mesonephric duct. This ureteral bud penetrates the adjacent metanephric blastema inducing the formation of the metanephric kidney, and forms the urinary collecting system (ureter, renal pelvis, calices, and collecting ducts). As the ureters develop, they become temporarily obstructed, then undergo a physiologic recanalization along their middle portion. Acquisition of smooth muscle begins at the ureterovesical junction (UVJ) and proceeds cephalad. Recanalization is completed by day 41 of gestation. Urine formation begins at 10 weeks of gestation. It is believed that many of the dilations observed in the neonatal period represent ureteral distention in response to transient obstruction that occurred in utero. The levels at which these are suspected are the ureterovesical junction, the mid ureter, and at the ureteropelvic junction (1,3).

Failure of the ureteral bud to stimulate development of the metanephric blastema may result in multicystic, dysplastic kidneys, which may be confused with a hydronephrotic kidney. Unilateral multicystic, dysplastic kidney is the most common cystic disease of the newborn and the second most common infant abdominal mass after hydronephrosis. The left kidney is more commonly involved. There is no sex predilection or familial tendency (5).

Vesicoureteral reflux refers to the retrograde flow of urine from the bladder into the upper urinary tract. It occurs at a rate of 1 per 1000 in the general population, but is 8 to 40 times more frequent in families with a history of reflux in a sibling. It will be found in 50% of infants and 30% of children with a UTI (5). Of those diagnosed with neonatal reflux, there is a male predominance, whereas females predominate when diagnosed after the newborn period. The average age for diagnosis of reflux is 2 to 3 years (7).

Vesicoureteral reflux may occur because the ureteral bud arises ectopically, leading to a laterally placed ureteral orifice and short submucosal bladder tunnel, which allows reflux. Reflux may also occur if there is incomplete or delayed development of the intrinsic smooth muscle of the distal ureteral segment (5,6). Vesicoureteral reflux predisposes an individual to pyelonephritis by facilitating the transport of bacteria from the bladder to the upper urinary tract. The immunologic and inflammatory reaction caused by a pyelonephrotic

infection may result in renal injury or scarring. Extensive renal scarring causes reduced renal function and may result in permanent renal damage or renal failure (7).

Vesicoureteral reflux is graded as follows: Grade I results in urine reflux into the distal ureter only. Grade II results in urine reflux into the ureter and the renal pelvis, without ureteral dilation and no distension of the renal pelvis (i.e., normal calices). Grade III results in urine reflux into the ureter and the renal pelvis, causing mild hydronephrosis (defined as mild dilation of the renal pelvis and blunting/dilation of the calices) and mild hydroureter (dilation of the ureter). Grade IV results in moderate hydronephrosis and hydroureter. Grade V results in severe hydronephrosis and severe hydroureter.

An ectopic ureter is defined as a ureter that drains into any location other than the bladder trigone. Embryologically, the delayed entry of the ureteral bud into the bladder results in a more distal and medially positioned ureteral orifice. In some instances, the ureter may not even incorporate itself into the bladder but may enter other structures. In females, this may include the urethra, introitus, vagina, uterus, and fallopian tube. In males, the ectopic ureter may enter the bladder neck, prostatic urethra, epididymis, seminal vesicles, or vas deferens. 70% of ectopic ureters are associated with duplicated collecting systems, with 30% found in non-duplicated systems. Ureteral ectopia in a duplicated system is 6 times more common in females than males. Ureteral ectopia in a non-duplicated collecting system is more common in boys (8).

Ureteroceles are a cystic dilation of the distal ureter at the level of the ureteral orifice (intravesical ureter). It results from a failure of normal distal ureteral development. Ureteroceles are more common in females than males by a ratio of 4:1. 80% of ureteroceles are associated with a duplex system and arise from the upper pole moiety. These upper pole segments usually demonstrate varying degrees of renal dysplasia (8).

Posterior urethral valves (a congenital membrane that obstructs or partially obstructs the posterior urethra) occur in boys (1 per 5000 to 8000), with greater than 50% diagnosed in the first year of life. It is felt that the etiology is failure of regression of the terminal segment of the mesonephric duct, which is normally represented by the plicae colliculi, which results in a congenital membrane that obstructs or partially obstructs the posterior urethra (5,6,9).

The Eagle-Barrett Syndrome (Prune Belly Syndrome, Triad Syndrome) is characterized by a dilated, non-obstructed urinary tract, deficiency of abdominal wall musculature (a visibly obvious deficiency of abdominal wall musculature with a distinct flabby abdomen), and bilateral cryptorchidism (undescended testes). The incidence is 1 per 35,000 to 50,000 live births with 95% of the cases occurring in boys. The syndrome is a result of in utero urinary tract obstruction and a specific mesodermal injury between the 4th and 10th week of gestation. GU anomalies that most commonly occur are renal dysplasia or agenesis, vesicoureteral reflux, and a large capacity poorly contractile bladder. Cardiac, pulmonary, and orthopedic anomalies are common in these patients (6).

Older children and adults who present with calculi, flank pain, nausea and vomiting, hematuria, non-specific abdominal complaints, especially if intermittent in nature, during periods of high urine flow, may have ureteropelvic junction obstruction (3). Daytime incontinence, infrequent voiding, poor urinary stream, chronic severe urinary frequency, and complicated enuresis may suggest bladder outlet obstruction (from urethral obstruction or posterior urethral valves) (9).

Many patients with vesicoureteral reflux (VUR) have been discovered prenatally by detection of fetal hydronephrosis, although the diagnosis of VUR is not made until postnatal studies are performed. 80% of these neonates are boys, and most have more severe reflux than do females with VUR discovered after UTI. 80% of reflux diagnosed after UTI occurs in females (7). Children may present with clinical pyelonephritis, fever, abdominal/flank pain, malaise, nausea, vomiting, cystitis with dysuria, frequency, urgency, and urge incontinence.

Patients with ureteral ectopy and/or ureteroceles may be picked up initially with prenatal ultrasound. They may also present at an older age with febrile UTIs, incontinence, hematuria, failure to thrive, abdominal pain, or pelvic pain. Ureteroceles may also present with a palpable abdominal mass or cystic intralabial mass (the result of a large ureterocele that has prolapsed through the urethral lumen) (8).

For the infant noted to have hydronephrosis on prenatal ultrasound, an ultrasound on day 2 of life should be performed. Ultrasound is the mainstay of screening and can provide excellent morphological evaluation in experienced hands. The degree of hydronephrosis and caliectasis can be seen, together with the renal size, parenchymal thickness, and some subjective assessment of the renal cortical texture. Cortical cysts, calcifications, and corticomedullary junction can be noted. The presence and morphology of the contralateral kidney, and the distal ureter should be evaluated. A careful evaluation can rule out distal ureteral dilation, eliminating the necessity of an IVP or retrograde contrast study of the ureter (1). Renal and ureteral duplication may be noted on ultrasound, as well as the presence of a ureterocele in the bladder. If there is no dilation, then a repeat ultrasound is done at one month. If no hydronephrosis is present at one month of age, the evaluation can then stop.

A voiding cystourethrogram (VCUG) is done if hydronephrosis persists after birth. If the patient is a male, has hydroureteronephrosis, a thick walled bladder, and/or posterior urethral valves are suspected, then a VCUG should be obtained immediately (1). The presence of a bladder outlet obstruction is readily established on VCUG. Posterior urethral valves show a characteristic appearance of a prominent bladder neck, dilated posterior urethra, and a bulging membrane at the distal aspect of the verumontanum. The bladder is usually thickened, with trabeculation and diverticula (9). Vesicoureteral reflux may also be present. Ureteroceles may be evident. If valves are present, cystoscopy should be done and the valves resected.

If posterior urethral valves are not suspected, then antibiotic prophylaxis is begun, and a VCUG, and diuretic renography obtained at 4 to 6 weeks.

The VCUG may show vesicoureteral reflux. Reflux grade is important because more severe reflux is associated with higher rates of renal injury, and treatment success varies with reflux grade (7). Follow-up cystography is done using radionuclide cystography because radiation exposure is less than with standard contrast cystography.

Diuretic renography (Mag3 or DTPA radioisotopes) provides information on renal function, with the early uptake of tracer by a kidney indicative of separate renal function ("the split function"). It can also show obstruction by demonstrating the washout from the kidney, augmented by the administration of a diuretic 20 minutes after administration of the initial tracer (1,3). The initial transit of the tracer through the kidney reflects renal perfusion and the amount of tracer accumulated in each kidney 1 to 3 minutes after injection is proportion to its GFR. The differential function (i.e., split function) of each kidney can be calculated. A diuretic is administered IV once the collecting systems are full with the radioisotope. Sequential images, computer generated time-activity curves, and calculated half-times will determine the degree of washout of the tracer in the area of interest. Prolonged washout times (called washout half-times) are often associated with true urinary tract obstruction.

Diminished renal function is definitely present when the split function is less than 35% to 40% (10), while good renal function is demonstrated by split function values of 45% to 50%. A poor washout half-time is greater than 20 minutes, and a good washout half-time is less than 10 to 12 minutes.

A DMSA (another renal isotope) renal scan is useful for the evaluation of cortical renal scarring and patients with VUR. Following an episode of pyelonephritis, renal scarring is usually apparent in DMSA scans within 3 months, but may not be apparent in IVP or ultrasound until 1 to 2 years later (7).

Excretory urography (IVP-intravenous pyelography) is especially performed in the older infant and child. It defines the collecting systems anatomy well, and can be very useful with ectopic kidneys, duplicated kidneys, and ureters, as well as with megaureter. A CT scan is also useful for imaging the renal and ureteral anatomy, and CT angiography can be used to image crossing vessels at the ureteropelvic junction (UPJ). Urodynamics (bladder function studies) are indicated when a functional obstruction is suspected (neurogenic, or non-neurogenic). Patients with spinal dysraphism should be evaluated with urodynamics.

Serum blood chemistries, especially creatinine, are also useful in these patients, and should at least be obtained early on to help establish baseline renal function.

It is important to emphasize that imaging studies cannot be taken and evaluated in isolation, but must be evaluated in conjunction with the other imaging, laboratory, and clinical findings over time, especially with a period of observation (with serial studies), before definitive surgery is considered.

Ureteropelvic junction obstruction is the most common cause of congenital hydronephrosis. US or IVP will show a dilated renal pelvis, and calyces without ureteral dilation. Diuretic renography/renal scan will show an obstructive pattern (prolonged washout half time). Vesicoureteral reflux may be present in some children with UPJ obstruction (11). In the older child presenting with vague abdominal complaints, renal ultrasound, IVP, and/or CT scan will show a dilated renal pelvis and calyces, without ureteral dilation.

Ureterovesical junction obstruction is the second most common cause of congenital hydronephrosis. Hydronephrosis is noted, along with associated ureteral dilation on renal US and/or IVP. Renal scan may show an obstructive pattern. Dilated ureters (megaureters) are divided into three primary categories: refluxing megaureters, obstructed megaureters, and non-obstructed, non-refluxing megaureters. An uncommon fourth primary variety is the refluxing, obstructed megaureter. Secondary megaureter may occur because of extrinsic processes such as tumors, retroperitoneal fibrosis, and vascular malformation. Another cause is functional ureteral obstruction such as with neuropathic bladder disease in those with spinal dysraphism (12). VCUG is helpful in the differentiation of the above categories.

Posterior urethral valves are the most common cause of lower urinary tract obstruction and occurs in males. The prenatal US may show hydroureteronephrosis, bladder thickening, and oligohydramnios. The newborn physical exam may reveal a palpable distended bladder, a palpable prostate on rectal exam, poor urinary stream, and signs and symptoms of renal and pulmonary insufficiency. Renal US shows hydronephrosis and a thickened bladder. VCUG is diagnostic for posterior urethral valves. There is associated reflux in 30% of patients (6).

In females, the most common cause of anatomic bladder outlet obstruction is a ureterocele that has prolapsed into the urethra (urethral prolapse may resemble a large doughnut shaped mass in the perineum). 90% of cases are associated with the upper pole of a complete duplicated collecting system (7). This condition has also been observed in males. Renal ultrasound may show findings similar to those found with posterior urethral valves, as will VCUG and renal scan. The renal US and/or VCUG will also clearly show the ureterocele.

Primary vesicoureteral reflux may present initially as hydronephrosis in the newborn. VCUG is diagnostic, and renal scan shows a non obstructive pattern. It tends to be of higher grade and with a male predominance when presenting in the newborn period (11).

Other causes of hydronephrosis or apparent hydronephrosis, are the multicystic, dysplastic kidney, ectopic ureter, megacalycosis, simple renal cyst, urachal cyst, ovarian cyst, hydrocolpos, sacrococcygeal teratoma, bowel duplication, duodenal atresia, anterior meningocele, and the prune belly syndrome (1).

Ureteropelvic junction obstruction repair (open pyeloplasty) is recommended when there is the morphological appearance of UPJ obstruction on US or IVP, no evidence of distal ureteral distension, and renal function depressed to less than 35% of total renal function. Neonates with better than 35% renal function are followed with repeat scans at 3 to 6 months, then at 12 months of age, and surgery is indicated only when there is clear deterioration in renal function (1). 75 to 85% of infants followed in this manner with observation did not require surgery (1,10). Most patients being followed with observation received antibiotic prophylaxis (1).

Older children, and adults, who present with a symptomatic UPJ obstruction will need repair, and can be considered for laparoscopic and endoscopic treatment of their UPJ obstruction, in lieu of an open pyeloplasty (3). The success rates of open pyeloplasties are greater than 95%.

Ureterovesical junction obstruction/megaureters in the newborn can be managed with observation (with serial US and renal scans) and antibiotic prophylaxis, in those whose renal function is greater than 35% (1). Indications for surgical repair (open ureteral reimplant, sometimes with tapering), include deterioration of renal function, breakthrough pyelonephritis, pain, or calculus formation (12). When a ureterocele is present, the best initial management is endoscopic incision of the ureterocele (1,8).

Posterior urethral valves should be treated in the neonatal period. Treatment is centered on securing adequate drainage of the urinary tract, initially by placement of a urinary catheter and later, by primary cystoscopic ablation of the valves, vesicostomy, or upper urinary tract diversion. The long-term outcome is dependent upon the degree of renal dysplasia present. Associated vesicoureteral reflux should be treated with antibiotic prophylaxis. Persistent bladder dysfunction should be treated with anticholinergics, alpha blockers, and clean intermittent catheterization, as indicated (6,8).

Primary vesicoureteral reflux is managed with antibiotic prophylaxis. Penicillin in the neonate, and TMP/SMX or nitrofurantoin in the older infant and child, is generally administered once daily at a dose calculated to be 1/4th to 1/3rd of the dose necessary to treat an acute infection. Reflux tends to resolve over time as the intravesical segment of the ureter elongates, with the greatest rate of spontaneous resolution occurring in the lowest grades of reflux (approximately 15% per year) (6,7,11). Follow-up cystography is generally performed every 12 to 18 months. The radionuclide cystogram is performed by many because the radiation done to the gonads is lower than with a standard cystogram. In addition, periodic upper tract imaging studies (US, IVP, renal scan) are often performed to detect renal scarring and growth. Many clinicians treating children with reflux obtain urine specimens, periodically for UA and/or culture (7,11).

Medical management with antibiotic prophylaxis is considered successful if the child remains free of infection, develops no new renal scarring, and the reflux resolves spontaneously. Failure of medical management is indicated by breakthrough UTIs, the development

of new renal scars, or the failure of the reflux to resolve. Noncompliance and allergic reactions to the prescribed medications may also lead to failure of medical management (7).

Failure of medical management/antibiotic prophylaxis is an indication for surgical repair of the refluxing ureter. Open surgical management (ureteral reimplant) involves modifying the abnormal ureterovesical attachment to create a 4:1 to 5:1 ratio of length of the intravesical ureter to ureteral diameter. This corrects the reflux in 98% of patients who undergo ureteral reimplantation for Grades I to IV reflux, and in 80% of those who undergo reimplantation for Grade V reflux (7).

Ectopic ureters are treated surgically based upon whether the patient presents with single or duplex systems, how well each moiety functions, and whether there is ipsilateral lower pole reflux. Partial nephrectomy and ureterectomy are indicated for upper pole moieties that are nonfunctioning or very poorly functioning (less than 10% of total function). In those with upper pole function and no evidence of lower pole reflux, ureteropyelostomy or high ureteroureterostomy are reasonable approaches. Ureteral reimplant (ureteroneocystostomy) is a good option for patients with upper pole function and lower pole reflux (8).

The management of ureteroceles is similar to ectopic ureteral management in that the approach taken is dependent upon many variables (single or duplex systems, ipsilateral or contralateral reflux, obstruction, and degree of function present). The goals of surgery are to preserve renal function, correct obstruction and reflux, eliminate urinary stasis and infections, and preserve urinary continence with minimal morbidity and mortality (8). Management options include observation, transurethral incision of the ureterocele, upper pole nephrectomy with partial ureterectomy, ureteroneocystostomy with ureterocele excision, high ureteroureterostomy, and transvesical ureterocele repair.

Prune Belly Syndrome (Eagle-Barrett Syndrome) treatment involves optimization of urinary tract drainage, management of renal insufficiency, and antibiotic prophylaxis. Surgical repair of reflux, orchiopexy, and abdominal wall reconstruction is performed later in childhood (6).

Multicystic, dysplastic kidneys are followed by serial ultrasounds. They do not benefit from antibiotic prophylaxis (1). They involute over time. Most urologists observe the multicystic, dysplastic kidney. There are proponents of excision of these kidneys due to a risk (albeit a very small risk) of malignant transformation.

Fetuses with mild to moderate hydronephrosis are generally observed prenatally. Although there are some centers that treat severe hydronephrosis prenatally related to obstructive uropathy, this is very controversial. The consensus is that intrauterine intervention should be considered only if persistent or progressive oligohydramnios develops in a fetus with a normal karyotype, there are no other life threatening anomalies, and fetal immaturity that precludes delivery (2,6). These procedures should only be performed at tertiary referral centers with extensive experience with fetal surgery.

The widespread use of obstetrical ultrasound has resulted in the detection of antenatal hydronephrosis as a common presentation of congenital renal, ureteral, bladder, and urethral anomalies. Neonatal evaluation and treatment of these congenital urinary anomalies allows the preservation of renal function, the relief of obstruction and reflux, the elimination of infection, and the preservation of urinary continence, to a much greater degree than was possible prior to the advent of prenatal US. Patients with hydronephrosis and/or reflux have an excellent prognosis today.

Questions

1. What is the most common congenital condition detected by prenatal US?
2. What is the initial imaging study that should be done to evaluate a newborn with a history of antenatal hydronephrosis?
3. What further studies should be obtained in a 2 day old male with US findings of hydroureteronephrosis, and a thick walled bladder? What diagnosis is suspected and what is the appropriate treatment?
4. What are the two most common causes of newborn hydronephrosis and how are they distinguished one from another?
5. What further tests should be ordered for the infant, with a history of prenatal hydronephrosis which persists on US on day 2 of life?
6. What are the options for treatment of UPJ and/or UVJ obstructions?
7. What is a ureterocele?
8. What is the cause of primary vesicoureteral reflux?
9. How does antibiotic prophylaxis for the management of vesicoureteral reflux prevent renal scarring?
10. What are the indications for surgical treatment of primary vesicoureteral reflux?

Answers to questions

1. Hydronephrosis represents 50% of all abnormalities detected with prenatal US.

2. A renal and bladder US should be obtained on day 2 of life. US done earlier may yield a false negative (no hydronephrosis) due to low urine output not distending the collecting systems. If it is normal, then the US should be repeated at 1 month of age, and be normal before considering the hydronephrosis to have resolved.

3. A VCUG should be obtained to evaluate for posterior urethral valves. If PUV are present, the VCUG will show a prominent bladder neck, a dilated posterior urethra, with a bulging membrane at the distal aspect of the verumontanum. The bladder may be thickened. Reflux may be present. The treatment is centered on securing adequate drainage of the urinary tract; initially by placement of a urinary catheter, and later by transurethral ablation of the valves. A vesicostomy (surgical formation of a cutaneous bladder stoma) may be done as a temporizing measure if the infant cannot undergo transurethral ablation of the valves.

4. Ureteropelvic junction (UPJ) obstruction is the most common cause, with ureterovesical junction (UVJ) obstruction being the second most common cause of congenital hydronephrosis. They are distinguished by the fact that with UPJ obstruction, the ureter is not dilated, whereas the ureter is dilated with UVJ obstruction.

5. The infant should be placed on antibiotic prophylaxis (with penicillin) and a VCUG and diuretic renal scan done at 4 to 6 weeks of age.

6. In infants noted to have good (35 to 40% or greater) split function on the renal scan, then serial ultrasound and diuretic renal scans (at 3 to 6 months of age, then at 12 month of age) may be used to follow the patient nonsurgically, on antibiotic prophylaxis. If there is renal function deterioration, breakthrough UTIs, or symptoms of renal colic, then surgery (pyeloplasty in UPJ obstruction, and ureteral reimplant in UVJ obstructions) is indicated. Only 25% of children with UPJ obstructions will require conversion to surgical management.

7. A ureterocele is a cystic dilation of the distal ureter at the level of the ureteral orifice. A ureterocele which has prolapsed into the urethra is the most common cause of congenital bladder outlet obstruction in females. Transurethral incision of the ureterocele is a minimally invasive treatment for symptomatic ureteroceles.

8. The ectopic insertion of the ureter into the bladder wall laterally results in a short intravesical ureter (a short submucosal bladder tunnel), which acts as an incompetent valve during urination, allowing urine to reflux back up into the ureter.

9. The antibiotic prophylaxis sterilizes the urine, and thus prevents bacteria ascending up the refluxing ureters, from causing pyelonephritis and renal scarring/damage. This allows time for normal growth and development of the ureter and bladder to occur. With growth, lengthening of the submucosal bladder tunnel/intravesical ureter results in the resolution of reflux over time, particularly in those with lower grades of reflux. Observation includes serial cystograms (usually nuclear scintography) every 12 to 18 months.

10. The failure of medical management (and thus the need for ureteroneocystostomy) is indicated by breakthrough UTIs, the development of new renal scars, or the failure of reflux to resolve over time. Non compliance or allergic reactions to the prescribed antibiotics may also lead to the failure of medical management.

Chapter XIII.8. Circumcision
Robert G. Carlile, MD

A mother gives birth to a term male infant with a normal penis (no evidence of hypospadias or penile chordee). Testes are descended bilaterally and normal to palpation. The parents are do not want their child to be circumcised. This is not a problem until he is 12 years old, in 7th grade. Since the majority of his male friends are circumcised, he desires circumcision. This is performed by a urologist, under anesthesia, in the operating room. He recovers without any complications. However, the parents are distraught when they learn their medical insurance will not pay the $3,000 bill for this "cosmetic" procedure.

Circumcision is the most common operation performed on males in the United States. It is estimated that 1.2 million newborn males are circumcised in the United States at an annual cost of between $150 and $270 million (1). Sixty percent of boys in the United States undergo circumcision. In Scandinavia and Great Britain, it is rarely performed in newborns (2). Ritual circumcision has been part of Jewish and Muslim faiths.

The prepuce develops in the 10th week of fetal development as a small epithelial tag at the penile tip. At 12 weeks this tag becomes a pronounced fold and grows inward and vertically, surrounding the glans at birth. This fold's inner epithelial layer is fused with the glans' epithelium. The urethra must close before the prepuce (the foreskin covering the glans) completely develops (3). With incomplete urethral closure (hypospadias), the ventral development of the prepuce is incomplete and one will find a thinned or absent ventral foreskin in hypospadias. At birth, the preputial aperture (opening or meatus of the foreskin) is adequate for voiding.

At birth, the prepuce (foreskin) is retractable in only 4% of boys. By 3 years, 90% of the boys' foreskin can be completely retracted (4). At age 17, 99% of the boys can retract their foreskin (3). This progressive separation of the foreskin epithelium from the glans epithelium is caused, in part, by an enlarging accumulation of trapped desquamated cells called smegma (3). This smegma is not to be confused with infection. The prepuce should not be forcibly retracted as spontaneous separation will occur physiologically.

The decision on whether to circumcise a newborn male is controversial. The Task Force on Circumcision of the American Academy of Pediatrics stated that newborn circumcision is not recommended and that the procedure is not essential to the child's current well-being (1). However, there is compelling evidence that newborn circumcision protects against penile cancer, local infection, phimosis, urinary tract infection, and human immunodeficiency virus (HIV) infection (5).

Pediatricians, obstetricians, and family practitioners perform the vast majority of newborn circumcisions in the United States. Circumcision is contraindicated if any penile anomaly is found such as; hypospadias, epispadias, chordee, or micropenis (stretched penile length <2.5 cm). Also, neonatal circumcision is contraindicated with significant prematurity, illness, blood dyscrasia, or family history of a bleeding disorder.

The three methods most commonly used involve the Gomco clamp, the Bronstein (Mogen) clamp, or the Plastibell. In all, the penis is first examined and the preputial adhesions to the glans are lysed with a probe or clamp (2).

The Gomco clamp uses a metal bell placed over the glans with the redundant foreskin pulled over the bell and through the clamp. The clamp is screwed down tightly onto the bell and the foreskin excised. The Bronstein clamp is used in ritual Jewish circumcision and involves pulling the prepuce (foreskin) forward causing the glans to retract slightly. The clasp is locked across the redundant foreskin, and the foreskin is excised. Both the Bronstein and Gomco clamps achieve hemostasis by clamping, crushing, and sealing the skin edges that are left after the foreskin is excised. Electrocautery should never be used with these clamps, as the current could be transmitted to the entire penis, via the metal clamp, and result in penile necrosis.

The Plastibell is a plastic ring that is placed over the glans (inside the foreskin) to the coronal sulcus, and the foreskin is pulled over it, usually after a dorsal slit is made. A large silk suture is tied over tightly onto a groove in the ring. The foreskin is excised, and the ring is left in place (after the handle is broken off). This ring minimizes blood loss, and it falls off in 3 to 7 days.

Local anesthesia with lidocaine (plain) is generally recommended as a dorsal penile nerve block or a ring block in the performance of newborn circumcision (2,6).

The post operative complication rate of circumcision is between 0.2 and 0.6%. These complications include bleeding, infection, phimosis, concealed penis, skin bridge formation, ring retention, meatitis, urethral stenosis, chordee, inclusion cysts, penile lymphedema, urethrocutaneous fistula, hypospadias and epispadias formation, penile amputation, and penile necrosis (3,4). The two most common are bleeding and infection.

Minor bleeding and infection can be managed by primary care physicians, but a low threshold for obtaining a urologic consultation should be maintained for complication management.

Questions

1. What does neonatal circumcision protect against?
2. What are the 3 most common methods used to perform neonatal circumcision?
3. What are the 2 most common complications of neonatal circumcision?
4. What are the contraindications to performing a newborn circumcision?
5. Will you perform newborn circumcision? Why or why not?

Answers to questions

1. Penile cancer, balanitis, phimosis, urinary tract infection, reduced risk of HIV.
2. Gomco clamp, the Bronstein (Mogen) clamp, and the Plastibell.
3. Bleeding and infection.
4. Hypospadias, chordee, epispadias, penile torsion, micropenis, significant prematurity, blood dyscrasia, or family history a bleeding disorder.
5. Yes or no; see reasons associated with each answer. Yes, because it protects against penile cancer, etc., (see #1). No, because of the risks of complications of infection, bleeding, concealed penis, penile adhesions, meatitis, fistula formation, penile amputation and penile necrosis.

Chapter XIII.9. Enuresis
Potenciano Reynoso Paredes, MD

This is a 4.5 year old male who presents to the office with his mother with a chief complaint of bed-wetting twice a week. Essentially he is healthy except for an occasional cough and fever that the mother attributes to exposure to other children with colds. Urinary discharge occurs at night only and he therefore has to wear diapers to bed. His mother is worried since his brothers and sisters were all toilet trained by this age. There is no history of dysuria, intermittent daytime wetness, polyuria, or polydipsia.

His past medical history is unremarkable. Family history is significant for his father being a bed-wetter. His child development is normal.

Exam: VS T 37, P 110, R 20, BP 107/64, Ht 102 cm (25th percentile), Wt 16.2 kg (25th percentile). He is alert and active, in no distress. His appearance is non-toxic. HEENT and neck exams are negative. His lungs are clear bilaterally. His heart has a normal rate and rhythm, normal S1and S2, and no murmurs or rubs. No masses, organomegaly, or tenderness are appreciated on exam of his abdomen. Bowel sounds are present. He has no inguinal hernias. He has a circumcised penis of normal size. The meatus is normally placed, without discharge. No phimosis is present. His testes are descended bilaterally and are of normal size (Tanner stage 1). His back is straight with normal posture with no scoliosis or tenderness, or midline defects. His extremities and muscle tone are normal. His gait is normal. He is able to hop, skip, and stand on each foot for 5 seconds, copy a square and get dressed without help. His speech and behavior are age appropriate.

You reassure his mother that bladder control is usually attained between the ages of 1 and 5 years and bed-wetting becomes less frequent with each passing year. You recommend that she be supportive of her son's dry nights and avoid criticism of wet nights. You also recommend avoiding excessive fluid intake two hours before bedtime and emptying his bladder at bedtime. He returns to your office after 6 months and his mother feels that the bed-wetting problem has improved significantly. On his next appointment (4 months later) his mother reports the resolution of his bed-wetting problems.

Enuresis, commonly known as bed-wetting, is the most common childhood urologic complaint encountered by pediatricians. Nocturnal enuresis (NE) is defined as involuntary passage of urine during sleep beyond the age of expected continence which is approximately 5 years of age. There are two types of NE. Primary is when a child never stopped wetting for any lengthy period, whereas secondary is acquired enuresis after being dry for at least 6 months. Primary enuresis affects the large majority of children with enuresis.

Since urinary continence is reached earlier in girls than in boys, NE is 2-3 times more frequent in boys. At age 5, 20% have NE at least once a month, with 5% of boys nightly and less than 1% of the girls nightly. Since most NE is due to maturational delay, there is a significant resolution or improvement as the child gets older. Approximately 15% resolve each year. Interestingly, family studies show a strong genetic predisposition for enuresis. More recently studies suggest a genetic linkage of primary nocturnal enuresis to the short arm of chromosome 13.

Organic causes of bed-wetting account for less than 5% of all cases; with most being urinary tract infections. Other organic problems include: diabetes mellitus, diabetes insipidus, nocturnal seizures, genitourinary anomalies, nocturnal ADH deficiency, hyposthenuria (constant secretion of dilute urine) associated with sickle cell disease, medications, or emotional stress. These children need to be recognized and treated. Some children with severe constipation may compress the bladder and present with bed-wetting. Other theories suggest reduced bladder capacity or sleep disturbance.

The office evaluation of NE must exclude any organic causes. A careful history is taken which should include pattern of wetting, developmental milestones, fevers, polydipsia, polyuria, and prior urinary infections. Questioning about sickle cell disease, food allergy, and constipation is occasionally helpful. Attention should also be paid to family dynamics and stresses that may uncover psychological factors.

Physical examination should focus on the neurological, genital, bladder and bowel exams. Back examination should include a search for neurological involvement such as a midline defect or suggestions of an occult spinal dysraphism. A neurological examination that includes gait, muscle tone, strength, and perineal sensation should be done. Examination of external genitalia for abnormalities such as labial adhesions, meatitis, epispadias, and hypospadias should also be done. If possible, and the urine stream sounds abnormal by history, physicians should watch children void. The abdomen should be assessed for evidence of fecal impaction, organomegaly, or bladder distention.

The purpose of initial laboratory tests is usually limited to ruling out infection as the source of the problem. A specific gravity of 1.015 or greater rules out diabetes insipidus and the absence of glycosuria rules out diabetes mellitus. In cases in which urinary tract obstruction or neurogenic bladder are suspected, a voiding cystourethrogram may be warranted.

At present there is no treatment modality that is 100% successful. Again, parents need to be reminded that a majority of bed-wetting is due to maturational delay and not under conscious control. Therefore, the most important aspects of treatment are reassurance and protection of the child's self esteem. It is important that bed-wetting not be perceived as a bad behavior since punishment not only lowers the child self esteem, but also does nothing to improving symptoms. Early education of the parents in regards to maturational delay, role of genetics and the importance of a supportive toilet training practice may ease the difficult period. Remember that there is a 15% spontaneous remission every year so many advocate an approach of reassurance and watchful waiting. Some simple life adjustments such as improving access to the toilet, avoiding excessive fluid just before bedtime and emptying the bladder at bedtime may be tried initially.

To some families, this conservative approach (which requires patience) can lead to suffering and frustration. Instead, a comprehensive method of treatment that includes bladder training, pharmacologic therapy and behavior modification with an alarm system can be implemented.

Treatment can begin with positive reinforcement such as keeping a calendar and rewarding dry nights. Another treatment is bladder training consisting of different methods such as holding urine as long as possible then when the child does urinate he/she is suppose to stop and start the urine flow frequently. Another method is going to the bathroom several times a night, or having the parents wake the child several times during the night and subsequently lengthening the time interval between waking. The objective is to increase the muscle strength of the urethra as well as give the child confidence that he or she can control urine flow and link the feeling of a full bladder with the need to go to the bathroom. Average bladder capacity in children can be approximated by the formula: volume in ounces (30 ml per ounce) = 2 + age in years. Adult bladder capacity is about 250 to 400 ml.

Pharmacologic therapy consists of tricyclic antidepressants (imipramine) or desmopressin acetate (DDAVP). Each has advantages and disadvantages. Imipramine has anticholinergic effects on bladder capacity and noradrenergic effects which decrease bladder detrusor excitability. 10-60% respond favorably to imipramine treatment, but more than 90% relapse. Imipramine is also potentially lethal with acute overdose (especially cardiac toxicity). DDAVP is a synthetic analog of vasopressin stimulating water retention and urine concentration, thereby reducing urine volume. DDAVP is available in two forms, tablets and nasal spray. The oral form is often used on children with nasal congestion such as colds and allergies. The drawback is the cost and rare mild side effects of DDAVP. DDAVP is useful in certain situations such as a child going to overnight camp. There is a 25-50% success rate with DDAVP, but a relapse rate of 94%.

In recent years, enuresis alarms have been shown to be the most effective treatment for bed-wetting. Urination acts as a stimulus for the alarm and wakes the patient from sleep. The cure rate is 60-80% and it has the lowest relapse rate of 10-40% when compared to other treatments. The only drawback is that the child and family must be highly motivated to stay committed to these conditioning methods.

Questions

1. At what age do parents usually become concerned about bed-wetting?
2. True/False: Most nocturnal enuresis is due to organic causes.
3. Which drug for nocturnal enuresis is cardiotoxic?
4. What laboratory test should be done to evaluate a child with enuresis?
5. What is the bladder capacity of children?
6. In evaluating a chronic bed-wetting child, what should you look for in an abdominal exam?
7. True/False: Enuresis alarms produce excellent results if the child wakes up spontaneously when the alarm goes off.

Answers to questions

1. Typically at age 5 or 6 years.
2. False.
3. Imipramine.
4. Urinalysis with specific gravity, glucose, protein, blood and white cells.
5. Most adults have a bladder capacity between 250-400 ml, but the average bladder capacity in children can be approximated by the formula: volume (oz.) = 2 + age in years.
6. The abdominal exam should asses for masses secondary to enlarged urinary organs (bladder, kidney) and for evidence of palpable stool in the colon suggesting fecal impaction.
7. True.

Chapter XIII.10. Acute Scrotum
Robert G. Carlile, MD

A 10 year old male presents with a chief complaint of acute onset of left scrotal pain 3 hours earlier, which awoke him from sleep. The pain is constant and does not change with position. There is no history of trauma. He has no dysuria, fever, chills, nausea or vomiting.

Exam: He is afebrile in moderate distress secondary to left scrotal pain. The left hemiscrotum is edematous and erythematous. The left testicle has a transverse lie, with marked tenderness to palpation. The cremasteric reflex is absent on the left. The right hemiscrotum and testicle are normal on exam. The circumcised penis is normal, with no urethral discharge present.

A CBC and urinalysis are normal (this results in an unnecessary delay of one hour). Color Doppler ultrasound scanning of the scrotum demonstrates the absence of blood flow to the left testicle and epididymis. Normal blood flow to the right testicle is present. No testicular masses are noted.

An emergent urological consultation is obtained. Scrotal exploration, under anesthesia, reveals a 720 degree torsion of the left spermatic cord, an ischemic testicle, and a "bell-clapper" deformity. With detorsion, the left testicle's normal color returns. The left testicle is then "fixed" to the scrotal wall to prevent retorsion. The right testicle is also fixed to the scrotal wall. Post-operatively, his pain was markedly relieved with the detorsion of the left testicle, and the remainder of his recovery is unremarkable.

The acute scrotum is a true urologic emergency. The window of opportunity to salvage a torsed, ischemic testicle is only 6 hours (1). Acute scrotal swelling should be considered testicular torsion until proven otherwise.

Puberty is the most common age at which testicular torsion occurs, with the newborn period being the second most common. The incidence is 1 in 4000 males younger than 25 years (2).

Testicular torsion can be classified into two types, relative to the tunica vaginalis' relationship to the area of the spermatic cord that twists: extravaginal and intravaginal. Extravaginal torsions occur perinatally, during testicular descent and prior to testicular fixation in the scrotum (2). This incomplete fixation of the gubernaculum (the fibrous cord extending from the fetal testis to the fetal scrotum which occupies the potential inguinal canal and guides the testis in its descent) to the scrotal wall allows the entire testes and tunica free rotation within the scrotum (3). The rotation of the cord is "extravaginal" because the rotation of the cord is proximal to the attachment of the tunica vaginalis that encloses the testes. These comprise 5% of all testicular torsions (4).

Intravaginal torsion occurs in the remaining 95% of all testicular torsions (4). A congenital high attachment of the tunica vaginalis on the spermatic cord allows the testes to rotate on the cord, within the tunica vaginalis. This is the "bell-clapper" deformity which is a horizontal lie of the testicle instead of the normal vertical lie. It is called a bell clapper deformity because the testicle resembles a horizontal oval hanging from a cord at its midpoint (like the clapper in a bell) as opposed to the normal testicle which resembles the letter "b" or "d" with the testicle positioned vertically attached to the cord on its side. This deformity is commonly bilateral, which places the contralateral testicle at risk for torsion also (3). As viewed from below, the testes rotate inward or medially during a torsion; the right clockwise and the left counter clockwise.

The acute onset of severe testicular pain with associated nausea and vomiting is very suggestive of testicular torsion, especially in the adolescent. Fever and dysuria are not common in testicular torsion. Intermittent testicular torsion is suspected when brief episodes of acute testicular pain occur recurrently. Torsion of a testicular or epididymal appendage (appendix testis or appendix epididymis) usually presents in mid childhood with mild discomfort of a few days duration (2).

Epididymitis and/or orchitis, on the other hand, may be associated with fever, dysuria, and a more gradual onset of scrotal pain, usually over several days. A history of urethral strictures, posterior urethral valves, myelodysplasia with neurogenic bladder, and severe hypospadias with utricular enlargement may predispose to urinary tract infection, with secondary reflux into the ejaculatory ducts causing epididymitis (2). A history of scrotal pain and swelling associated with fever and parotid gland swelling suggest mumps orchitis.

Inguinal hernia and/or hydroceles may present with similar symptoms to acute testicular torsion. A history of constipation or upper respiratory infection, both causing increases in intraabdominal pressure may be present.

Henoch-Schonlein purpura, an uncommon cause of acute scrotal swelling (usually bilateral), is associated with a history of vasculitis and associated onset of a cutaneous purpuric scrotal rash (2).

Trauma, even minor, may be a cause of testicular pain and should be sought in the history (straddle injury, wrestling, sports). A history of trauma may suggest a traumatic etiology of pain and swelling, but this does not necessarily rule out the presence of testicular torsion.

The physical exam should be begun in conjunction with the history taking. The level of distress is noted along with vital signs and examination of the abdomen. There should be a specific notation of the presence or absence of inguinal and scrotal swelling, urethral discharge, scrotal or perineal ecchymoses or rashes, and lastly the appearance of the testes and area of pain and/or tenderness. The absence of a cremasteric reflex, in conjunction with testicular tenderness, is commonly associated with testicular torsion (5). This reflex is usually present in epididymitis. It is elicited by gently stroking the skin of the inner thigh: the presence of the cremasteric muscle results in movement of the testicle in the ipsilateral hemiscrotum.

Acute testicular torsion should be considered the leading diagnosis until it is ruled out. The acute onset of severe unilateral unrelenting pain, tenderness, high riding testicle, with absent cremasteric reflex and no change in pain in response to testicular elevation (Prehn's sign), highly suggest testicular torsion. In testicular torsion, the affected testicle may be more cephalad than normal and it may lie transversely (horizontally). A change in position is not seen in epididymitis or orchitis.

If one is able to palpate the testicle separate from the epididymis, one can distinguish between testicular torsion, epididymitis, and testicular appendage torsion. The affected testicle is exquisitely tender in testicular torsion, and the epididymis may not be palpable, but is also tender if palpable. In epididymitis/orchitis, the testicle itself is not tender, but the epididymis is palpable and tender. Epididymitis has a more gradual onset, with tenderness being present. A cremasteric reflex is usually present, and the pain may be relieved with testicular elevation. Fever, pyuria, and dysuria may be present.

A torsion of a testicular appendage may present in a fashion similar to that of acute testicular torsion. The tenderness may be well localized to the upper part of the testes and a characteristic "blue dot" sign in the skin of the scrotum may be applicable. This blue dot is due to venous congestion of the appendix testis of the torsed appendage.

Color Doppler ultrasound scanning has great utility in differentiating between the above diagnoses and ruling out testicular torsion (6). Absence of blood flow to the affected testicle is noted in testicular torsion, whereas increased blood flow is noted in

epididymitis/orchitis. Flow to the testicle will be present in appendage torsion. Of course, these findings should be combined with the signs and symptoms, and not taken in isolation. Testicular anatomy is also appreciated with ultrasound, helping to evaluate for testicular rupture, hematomas, and tumors.

Nuclear scintigraphy is not commonly used today in the evaluation of the acute scrotum. CBC and urinalysis are helpful in evaluating infectious etiologies, but waiting for these results should not delay a Doppler ultrasound study. A hernia or hydrocele or varicocele can be distinguished on exam.

Acute testicular torsion requires emergent scrotal exploration, detorsion of the affected testicle, with orchiectomy if testicular ischemia and necrosis persists, or testicular fixation if blood flow and testicular viability is restored with detorsion. In either case, the contralateral testicle should be explored and testicular fixation performed with permanent suture.

Epididymitis/orchitis can be treated with antibiotic and anti-inflammatory drugs. Occasionally "sepsis" may result from severe cases, requiring hospitalization with intravenous antibiotics. The majority can be treated with outpatient antibiotics. Activity should be limited.

Acute testicular appendage torsion may be observed, with analgesics/anti-inflammatories if the diagnosis is firm. No testicular fixation is necessary as these are not commonly associated with abnormalities of the attachments. If the diagnosis is in doubt, emergent scrotal exploration is indicated.

Trauma with rupture of the tunica albuginea of the testes requires exploration emergently, with debridement and repair. An isolated hematoma may be observed. Henoch-Schonlein purpuric scrotal swelling may be managed medically. Neonatal torsion may require exploration, if the diagnosis is made early enough, but unfortunately, the majority are diagnosed too late for testicle viability. Hernias and hydroceles should be repaired, emergently if incarcerated, electively if not.

The salvageability of a testicle within 6 hours of torsion is very good. Greater than 6 hours is more worrisome, but exploration should be performed to remove a necrotic testicle, even with a late presentation, as diminished fertility may result from leaving in an infarcted testicle (2). Epididymitis responds well to rest and antibiotic therapy. Any predisposing factors should be corrected.

Questions

1. What are the signs and symptoms that help to differentiate acute testicular torsion from epididymitis?
2. How is color Doppler ultrasound helpful in the differential diagnosis of acute scrotum?
3. What is the cremasteric Reflex? Prehn's sign? The blue dot sign? The bell clapper deformity?
4. What is the time frame most advantageous to restoring viability of a torsed testicle?
5. How is acute testicular torsion managed?
6. How is acute epididymitis managed?

Answers to questions

1.	Acute testicular torsion	Epididymitis
Onset	Acute	More gradual
Fever	Absent	May be present
Cremasteric reflex	Absent	Usually present
Scrotal lie of testicle	Cephalad/transverse	Lower in scrotum
Prehn's sign	No change in pain	Decrease in pain
Pyuria	Absent	May be present
Dysuria	Absent	May be present

2. Blood flow to the testicles can be evaluated rapidly and the testicular anatomy can be assessed. Normal or increased blood flow is seen in epididymitis, while absent blood flow is indicative of torsion. Testicular rupture as in trauma, can also be identified.

3. Cremasteric reflex: Gently stroking the medial thigh elicits spermatic cord cremasteric muscle contraction and testicular movement. Prehn's sign: elevation of the affected testicle may improve the pain in epididymitis. Blue dot sign: a torsed ischemic testicular appendage may appear as a blue dot through the scrotal skin. Bell clapper deformity: incomplete investment of the tunica vaginalis onto the testicle and epididymis, with the testicle being predisposed to rotate, and torse, more easily than if the tunica vaginalis were present.

4. Detorsion within 6 hours of the onset of the torsion.
5. Acute scrotal exploration and testicular detorsion with bilateral testicular fixation (if the testicle was detorsed and salvageable).
6. Antibiotics for acute epididymitis.

Chapter XIII.11. Ambiguous Genitalia
Robert G. Carlile, MD

This is a term infant noted to have atypical genitalia with perineoscrotal hypospadias and a marked ventral chordee. This could be a penis or an enlarged clitoris. Gonads are nonpalpable bilaterally on examination of the labioscrotal folds. The parents aren't sure whether their child is male or female and this constitutes a neonatal (social) emergency. Further evaluation is commenced immediately. An ultrasound reveals a normal uterus and ovaries, as well as normal kidneys and bladder. Chromosomal analysis shows a 46XX karyotype. A genitogram reveals a short distal common urethrovaginal confluence, a vagina with a normal cervical impression, and a normal urethra.

At two weeks of age, this infant is admitted to the ICU with hypovolemic shock, and found to have hyponatremia and hyperkalemia. Plasma 17-hydroxy-progesterone levels are markedly elevated and plasma cortisol levels are low. Hydrocortisone and mineralocorticoid replacement are administered, along with intravenous fluids and electrolyte replacements, with a good response. She is diagnosed with congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency.

A feminizing genitoplasty is performed at one year of age. This includes clitoral reduction and a flap vaginoplasty. In her mid-teens, the patient undergoes a vaginoplasty revision for introital stenosis.

Ambiguous genitalia are uncommon in a primary care pediatrician's practice, but their diagnosis and prompt treatment require urgent medical attention. Any delay may result in death in early infancy from an uncorrected metabolic disorder, if present. Quickly establishing a definitive diagnosis and appropriate treatment plan will minimize medical, social and psychological complications.

It is important to understand normal sexual differentiation in order to understand the development of intersex (ambiguous genitalia and sex determination) disorders. Up until six weeks of gestational age, the internal and external genitalia of the male and female fetuses are indistinguishable. The indifferent gonad is located on the urogenital ridge, with the Wolffian and Mullerian ducts nearby, which are destined to form the male and female internal ducts, respectively. The external genitalia in both sexes are represented by the genital tubercle, the urethral folds, and the labioscrotal swellings that surround the cloacal membrane (1). These primordial structures have the potential to produce either male or female genitalia.

The SRY gene, on the short arm of the Y chromosome, initiates male sexual differentiation (2). The SRY influences the undifferentiated gonad to form a testes, which produces the hormonal milieu that results in male sexual differentiation. Testosterone stimulates the Wolffian structures (epididymis, vas deferens, and seminal vesicles), and anti-Mullerian hormone suppresses the development of the Mullerian structures (fallopian tubes, uterus, and upper vagina). Testosterone converts to dihydrotestosterone in the skin of the external genitalia and masculinizes the external genital structures. By 12 weeks most of this male differentiation has occurred, after which the penis grows and the testes descend into the scrotum (3).

In the absence of these genetic (SRY gene) and hormonal influences (testosterone, anti-Mullerian hormone), the fetus will develop as a female. Intersex conditions arise because of an error along the male pathway that interferes with complete masculinization, or, in the case of a genetic female, some virilizing influence that acts on the developing embryo (3).

Infants whose genitalia are obviously indeterminate and ambiguous are investigated so that sex of rearing can be assigned. However, appearance can be deceptive. An apparent male may be a severely virilized female with congenital adrenal hyperplasia (CAH). An apparent female infant with only mild clitoral hypertrophy may be a male with severe androgen insensitivity.

Clinical findings in a newborn infant that raise the possibility of intersexuality (1,3) in an apparent male:

Bilateral nonpalpable testes in a full-term infant.

Hypospadias associated with clefting of the scrotal sacs.

Undescended testes with hypospadias.

Clinical findings in a newborn infant that raise the possibility of intersexuality (1,3) in an apparent female:

Clitoral hypertrophy.

Foreshortened vagina with single opening (instead of a urethral meatus and vaginal introitus noted separate from one another, there is just a single opening at the introitus and no separate urethral meatus visible).

Inguinal hernia containing a gonad.

Also, as noted above, those in whom the external genitalia are clearly ambiguous so that the sex cannot be immediately decided should be investigated.

A small number of children will only come to light in adolescence because of amenorrhea, inappropriate breast development, virilization, or the onset of cyclic "hematuria" (gross hematuria that occurs every 28 days, as a menstrual cycle would).

A careful history should be taken. An obstetric history should include any evidence of endocrine disturbance during pregnancy (mother with a Cushingoid or virilized appearance), and any medications taken during pregnancy (particularly any treatment for recurrent abortion or the use of hormonal contraceptives). As many intersex states are recessively inherited familial disorders, a family history may reveal genital anomalies, unexplained neonatal deaths, abnormal pubertal development, or infertility.

The physical exam starts with a search for evidence of a malformation syndrome. The genitalia are examined with the size of the phallus noted (a normal newborn stretched penile length should be greater than 2 cm and a normal clitoris is less than 7mm), and the position of the urethral meatus noted. Any penile chordee should be noted. The labioscrotal folds are evaluated for fullness, symmetry, rugosity and the presence or absence of a gonad (If a gonad is palpable in a female infant, then congenital adrenal hyperplasia is not present, as the CAH infant would have normal ovaries in the abdominal cavity). The position of the urethral meatus helps to determine the extent to which the urogenital sinus has closed (a separate urethral meatus and vaginal opening shows complete closure of the urogenital sinus while a single orifice suggests the persistence of a common urogenital sinus with the vagina and urethra connected distally). Areolar and labioscrotal hyperpigmentation associated with high levels of ACTH suggest congenital adrenal hyperplasia. The palpation of a uterus or cervix may be noted on rectal exam.

Since the appearances of the external genitalia vary so widely among patients who have the same condition, it is unwise to attempt a definitive diagnosis from the physical findings alone (1,3).

A chromosomal karyotype should be done in all patients. Since congenital adrenal hyperplasia is the most common cause of ambiguous genitalia in the newborn, serum 17-hydroxy-progesterone and deoxycorticosterone levels should be checked along with serum electrolytes and glucose in the infant with symmetrical masculinization and nonpalpable gonads (3,4).

A pelvic ultrasound will delineate the uterine anatomy, if present. It should normally be located posterior to the bladder. The kidneys and ureters should also be imaged. A genitogram will delineate the anatomy of the vagina, the uterine canal, one or two fallopian tubes, and/or the vasa deferentia, as well as the level at which the vagina enters into the urogenital sinus, if present (1,3). It is performed by injecting contrast retrograde through the common urogenital sinus (or the urethra and vagina if the urogenital sinus has closed), under fluoroscopy.

Further biochemical profiles may be necessary to identify a block in testosterone biosynthesis, decreased 5-alpha-reductase activity or androgen insensitivity (3).

Gonadal inspection and biopsy are necessary and can be done laparoscopically in many cases by an experienced pediatric urologist or pediatric surgeon. This will not be necessary in established cases of congenital adrenal hyperplasia and Turner syndrome. Cystovaginoscopy provides valuable information because it augments the genitogram's findings and aids in treatment planning.

The classification of intersex disorders are most conveniently divided into four main groups based on gonadal histology: 1) Female pseudohermaphrodites (two normal ovaries present). 2) Male pseudohermaphrodites (two normal testes present). 3) True hermaphrodites (both ovarian and testicular tissue are is found in the same patient). 4) Gonadal dysgenesis conditions (the gonads are histologically disordered; e.g., streak gonads) (1,3,5).

Female pseudohermaphrodism is a disorder in which a chromosomal female (46XX), with normal ovaries and mullerian derivatives and normal fertility potential, has virilized external genitalia (enlargement of the phallus and labioscrotal fusion are present to varying degrees). This virilization of the female fetus is secondary to androgens from either the maternal circulation or the fetal adrenal gland.

Congenital adrenal hyperplasia (CAH) is the most common cause of female pseudohermaphrodism, as well as the most common intersex disorder. The adrenal glands, in CAH, overproduce testosterone because an enzyme defect in intermediate metabolism results in decreased cortisol synthesis, which leads to an increase in circulating adrenocorticotropic hormone (ACTH), and thus to hyperstimulation of the adrenals (5). Because some forms of CAH are associated with salt-wasting, prompt monitoring and correction of electrolytes and corticosteroid/mineralocorticoid replacement are crucial. CAH is an autosomal recessive disorder that occurs in 1 of 15,000 births in the United States (6).

21-hydroxylase deficiency is the most common (95% of the cases) enzyme defect that causes CAH, with salt-losing a feature of a complete deficiency. 11-beta-hydroxylase deficiency is a rare form of CAH, which results in an accumulation of deoxycorticosterone, a potent mineralocorticoid. This results in salt retention and hypertension.

21-hydroxylase deficiency is suspected in a masculinized infant without palpable gonads and with Mullerian derivatives (female internal pelvic organs) evident on pelvic ultrasound. A 50 to 100 fold increase in serum 17-hydroxyprogesterone and a 46XX karyotype confirms the diagnosis. Salt wasting occurs in 75 percent of patients with classical disease, and is evident within the first two weeks of life, with resultant hyponatremia, hypokalemia, and inappropriate sodium wasting (high urine sodium despite hyponatremia) due to low serum aldosterone and elevated plasma renin activity (7). It is crucial to recognize this potentially life-threatening condition in the newborn period and institute replacement of cortisol and mineralocorticoid as necessary.

Other causes of female pseudohermaphrodism are maternal progesterone ingestion (with androgenic side effects) administered during pregnancy to prevent abortion, a virilizing ovarian or adrenal tumor in the mother, or idiopathic causes.

Male pseudohermaphrodism results from inadequate virilization of the male embryo. Chromosomal males (46XY) possess testes, but the male anatomic genital development is abnormal. Cellular testosterone sensitivity is abnormal in 80 percent of cases, and testosterone production is deficient in the remaining 20 percent. The causes include androgen insensitivity, gonadotropic failure, Leydig cell agenesis, bilateral vanishing testes syndrome, persistent mullerian duct syndrome, testosterone biosynthesis defects and 5-alpha-reductase deficiency (5).

Patients may have abnormal male genitalia, ambiguous genitalia, or female genitalia with palpable or nonpalpable testes, depending on the completeness and nature of the defect and the extent of gonadotropin oversecretion.

Androgen insensitivity is the most common (1 in 20,000 male births) cause of male pseudohermaphrodism and results from dysfunction or reduction of the androgen receptor. For complete testicular feminization, the androgen receptor is absent or completely nonfunctional. The pituitary and hypothalamus are insensitive to testosterone and thus secrete large amounts of gonadotropins, which results in the oversecretion of testosterone and estrogen (5). Breast development, general body habitus, and distribution of body fat are female in character. The clitoris is normal or small, and the vagina is short with a blind ending, but the external genitalia are female in appearance. All internal genitalia are absent (no uterus or ovaries) except for the gonads, which have the histologic appearance of undescended testes (6). Because of increased tumor risk in the undescended testes (5% to 10%), gonadectomy is recommended after puberty.

Patients with complete androgen insensitivity syndromes (testicular feminization) are normal phenotypic females who present during childhood with one or both testes palpable in an inguinal hernia, or with amenorrhea at puberty. A few are diagnosed based on discrepancy between prenatal karyotype and phenotype at birth (i.e., a 46XY karyotype with female external genitalia at birth). The diagnosis is based on clinical and family history, endocrine studies and, if indicated, androgen binding analysis in genital skin fibroblasts (5).

In the 17-beta-hydroxysteroid dehydrogenase deficiency (the most common biochemical defect causing deficient testosterone biosynthesis without CAH, which causes male pseudohermaphrodism), males have feminine external genitalia with mild to moderate degrees of clitoral hypertrophy, but with a separate urethra and blind ending vaginal pouch. Testes are usually inguinal. The diagnosis is often made at puberty, when progressive virilization associated with penile growth, attainment of male secondary sex characteristics, testicular descent, and a change in gender identity may occur (5).

5-alpha-reductase deficiency (pseudovaginal perineoscrotal hypospadias) is an autosomal recessive disorder associated with failure of dihydrotestosterone (DHT) formation, resulting in normal male internal Wolffian duct derivatives, but the external genitalia fail to virilize in utero (DHT is necessary for the external genitalia to masculinize while the internal genitalia masculinize in the presence of testosterone). The internal male genitalia are normal, and the testes are located in the labioscrotal pouch. The external genitalia typically show severe perineoscrotal hypospadias and a blind vaginal pouch opening into the urogenital sinus or urethra. At puberty, normal levels of luteinizing hormone and testosterone result in masculinization of the external genitalia, and breasts do not develop (5,6).

True hermaphrodism is a rare condition in which ovarian and testicular tissue exist in the same individual. 70 percent are 46XX (but they possess the SRY gene), 10% are 46XY, and the remainder show either mosaicism or chimerism (evidence of development from

two zygotes). Patients most commonly have ambiguous genitalia, but near-normal female and male genitalia may be present. A unicornuate or bicornuate uterus is usually present, and the differentiation of the genital ducts is determined by the ipsilateral gonad, with the ovary usually located on the left side (5). The most common gonad found is the ovotestes (50%), followed by ovary (30%) and testes (20%). Combinations are ovotestes/ovary (34%), bilateral ovotestes (27%), ovary and testes (27%) and ovotestes/testes (12%). The ovarian tissue is potentially fertile, but the testes are not (5).

A well masculinized patient may rarely present after puberty with gynecomastia, cyclical hematuria, or scrotal pain secondary to ruptured ovarian follicles.

In most patients, the external genitalia are masculinized to some extent, and two thirds of true hermaphrodites are raised as males. Of those raised as males, 80 percent have hypospadias and over 50 percent have labioscrotal fusion. Of those raised as females, two thirds will have clitoromegaly. All patients have a urogenital sinus, and in most cases, a uterus is present. The ovary is found in a normal location, but the testes or ovotestes may be at any point along the path of testicular descent (5). In addition to imaging studies, a gonadal biopsy is necessary to prove the existence of both ovarian and testicular tissue.

Dysgenetic gonads (histologically disordered gonads) are noted primarily in mixed gonadal dysgenesis, pure gonadal dysgenesis, and gonadal dysgenesis (Turner Syndrome). Mixed gonadal dysgenesis is the second most common intersex disorder. Karyotype is usually a mosaic 45XO/46XY. A testis is usually found intraabdominally opposite a streak gonad (resembling ovarian stroma histologically). A unicornuate (only one side of the uterus is present) uterus, fallopian tubes and vagina are present. The genitalia are ambiguous with severe hypospadias, a urogenital sinus, and labioscrotal fusion, with an undescended testicle. One third exhibit Turner stigmata (short stature, shield like chest, webbed neck, multiple pigmented nevi, and cubitus valgus) as well as cardiovascular and renal anomalies (5,6).

The incidence of gonadal tumors is 25 percent in patients with mixed gonadal dysgenesis and may arise in the streak gonad or the undescended testes. A gonadal tumor has not been described in a scrotal testes (8). Early bilateral gonadectomy with female rearing is appropriate in phenotypic females. In phenotypic males with a scrotal testes, male rearing is appropriate, but the streak gonads must be removed.

Pure gonadal dysgenesis is an abnormal differentiation of the gonads without a chromosomal abnormality. A 46XX female has normal immature female external genitalia, intact Mullerian duct structures and bilateral streak gonads. They have no stigmata of Turner syndrome. They usually present as adolescent females who fail to mature and reach menarche (5).

Patients with 46XY "pure gonadal dysgenesis" also have bilateral streak gonads, intact Mullerian structures, a female phenotype, and the absence of Turner stigmata. Some may present in the newborn period with clitoromegaly. These patients with the Y chromosome are at high risk for the development of gonadal tumors, so prophylactic gonadectomy is indicated (6,8).

Gonadal Dysgenesis (Turner Syndrome) is due to the loss of the second X chromosome (45XO), with resultant bilateral streak gonads, normal Mullerian duct development, and phenotypically female external genitalia. Mosaicism (45XO/46XX) lessens the severity of the gonadal abnormality. As neonates do not have ambiguous genitalia, the syndrome is usually diagnosed from investigations for other neonatal anomalies, which include: intrauterine growth retardation, head and facial anomalies, lymphatic anomalies, cardiovascular or urinary tract malformations or skeletal anomalies) (8). All should be raised as females, with gonadectomy indicated only in those with virilization or with clear evidence of a Y cell-line (6,8).

A child born with ambiguous genitalia constitutes a social and medical emergency. In the delivery room, no attempt should be made to suggest a diagnosis or assign a gender. The parents should be told that development is incomplete and further tests will reveal the appropriate gender. The infant should be referred to as "your baby" not "it", "he", or "she". Examination of the child in the presence of the parents to demonstrate the precise abnormalities of genital development is helpful, noting that the genitalia of both sexes develop from the same primordial structures, that both incomplete development or overdevelopment of the external genitalia can occur, and that the abnormal appearance can be corrected and the child raised as a boy or girl, as appropriate (3). A family should never be told that their child is male, but will be made female, or vice versa. Parents should be encouraged not to name the child or register the birth, if possible, until the sex of rearing is established. The parents need to be included in the discussions regarding sex of rearing decisions.

Transfer of the child to a tertiary care facility is usually necessary for optimal assessment and treatment. A multidisciplinary medical team, with representation from neonatology, endocrinology, urology, psychiatry and genetics services is useful. Pediatricians have a key role in coordinating the diagnostic evaluation, helping families understand their child's medical condition, and maintaining open communication between the family and other health care team members. The presence of the nursing staff is also critical at meetings, for it is they who will be spending the most time with the family and neonate.

The decision as to the appropriate sex of rearing of an infant, born with ambiguous genitalia, is based on the fertility potential, capacity for normal sexual function, endocrine function, potential for malignant change in a gonad, and psychosexual factors (testosterone imprinting) (3).

In female infants with CAH, exposure to maternal androgens, and rarely true hermaphrodites, can be expected to be potentially fertile and should be raised as females. The potential for fertility in most other intersex conditions is either reduced or absent.

Phallic size and its potential to develop at puberty into a sexually functional organ, are very important when male sex of rearing is considered. Testosterone injections may need to be given in equivocal cases, and the infant raised as male only when there is a very good response (especially in those with partial androgen insensitivity). The severity of the hypospadias should not be a deciding factor in the sex of rearing, as the results of hypospadias repair, using current techniques, are satisfactory, both functionally and cosmetically.

It is advantageous to retain a gonad appropriate to the assigned sex if it is likely to function adequately. The ovaries of virilized genetic females can be assumed to be normal. The ovaries of true hermaphrodites may also produce estrogen adequately. The testes of true hermaphrodites and those of infants with mixed gonadal dysgenesis may initially show good function, that later declines, so that testosterone supplements may be necessary from puberty onward (3).

There is potential for malignant degeneration in streak gonads, especially those with a Y-chromosome-bearing cell line. Testes that show dysgenetic features on biopsy should also be excised. Histologically, normal undescended testes have an increased incidence of tumor development, but can be preserved in a sex assigned male, with an orchiopexy, and the patient kept under long-term observation. Gonadectomy is considered when the risk of malignancy exists, or when gonadal tissue inappropriate to the assigned gender has been identified.

In the past, it was assumed that sexual identity was largely a result of rearing. However, in the past decade it has become apparent that testosterone imprinting of the fetal brain may play a role in determining male sexual orientation. Some girls with CAH engage in more typically male-like behavior patterns than their unaffected peers. Despite these findings, extreme caution should be exercised when a recommendation is made that the sex of the rearing should be different than the chromosomal sex (3).

Genital reconstruction is necessary in the majority of patients with ambiguous genitalia and intersex disorders once the multidisciplinary team, in conjunction with the family, have decided on the appropriate gender assignment.

Male reconstruction may require hypospadias repair (usually done between 6 months and 1 year of age), orchiopexy, and removal of inappropriate gonads as well as internal Mullerian structures.

Female reconstruction, also known as a feminizing genitoplasty, may involve a clitoral reduction and a vaginoplasty. Clitoral reduction can be done in a nerve sparing fashion, so as to preserve sensation and allow for orgasm, and is carried out as early in life as possible. Minor clitoromegaly can be left alone, as clitoral involution will take place once the source of androgen is shut down.

Vaginoplasty in a low lying vagina (flap-vaginoplasty) can be usually done at the time of clitoral reduction. This primarily widens the introitus. A major vaginal reconstruction for creation of a vagina de novo (substitution vaginoplasty) is best deferred until at least one year of age, or even until puberty.

Psychological and metabolic supports are also essential over time. Most individuals are able to function in the normal range and are well adjusted after treatment of intersex disorders. Certain affected individuals will have conflicts between their psychosexual orientation and their genital appearance and function. Thus, ongoing counseling of the parents and the affected child is advisable. Problems can be minimized when evaluation and treatment is done promptly by an appropriately constituted intersex team.

Questions

1. What clinical findings in an apparent newborn male raise the possibility of intersexuality?
2. What clinical findings in an apparent newborn female raise the possibility of intersexuality?
3. What findings in an apparent adolescent suggest the possibility of intersexuality?
4. What are the two most common causes of ambiguous genitalia in the newborn?
5. What laboratory and imaging studies should be done to investigate the infant with ambiguous genitalia?
6. What factors need to be weighed in deciding the appropriate sex of rearing for a newborn with ambiguous genitalia?
7. What genital reconstruction may be necessary in an infant with ambiguous genitalia and an assigned male sex of rearing? An assigned female sex of rearing?

Answers to questions

1. Bilateral non-palpable testes in a full term infant. Hypospadias associated with separation of the scrotal sacs. Undescended testes with hypospadias.
2. Clitoral hypertrophy. Foreshortened vagina with single opening. Inguinal hernia containing a gonad.
3. Amenorrhea, inappropriate breast development, virilization, or the onset of "cyclic hematuria".
4. Congenital adrenal hyperplasia and mixed gonadal dysgenesis.
5. Chromosomal karyotype, pelvic ultrasound, genitogram, cystovaginoscopy, gonadal inspection and biopsy, and biochemical studies as necessary (i.e., in an infant with symmetrical masculinization and non-palpable gonads, serum 17-hydroxyprogesterone, deoxycorticosterone, electrolytes, and glucose would be checked because of suspected congenital adrenal hyperplasia).
6. Fertility potential, capacity for normal sexual function, endocrine function, potential for malignant change in a gonad, and psychosexual factors.
7. Male reconstruction may require hypospadias repair, orchiopexy, and removal of inappropriate gonads and internal Mullerian structures. Female reconstruction may require a feminizing genitoplasty (clitoral reduction and vaginoplasty), as well as the removal of inappropriate gonadal tissue.

Chapter XIII.12. Hypospadias
Robert G. Carlile, MD

This is a term male infant who is noted to have a ventral penile chordee with mid-penile shaft hypospadias. His testes are descended bilaterally. No circumcision is performed. He voids normally, and at 6 months of age undergoes repair of the hypospadias and chordee using the foreskin as a vascularized graft. Postoperatively he develops a urethrocutaneous fistula along the suture line. This is repaired 6 months later, and he subsequently has no problems.

Hypospadias occurs in 1 of 300 males in the United States, and is the most common congenital anomaly of the penis (1). "Hypospadias" refers to an abnormal penile configuration in which the urethral meatus is located on the ventral surface of the penis, proximal to the end of the glans, and anywhere from the ventral gland to the perineum. Epispadias refers to the condition in which the meatus is located on the dorsal surface of the penis.

Penile chordee (ventral bending of the penile shaft) is often associated with hypospadias, and may be due to tethering or dysplasia of the ventral penile shaft skin (2). A dorsal hood of incomplete prepuce may also be present.

There is no single known cause of hypospadias. Genetic factors exist, most likely based on a multifactorial mode of inheritance (3). Hypospadias is more common in first degree male relatives. Fathers of affected boys have an 8 percent incidence of hypospadias; and male siblings, 14 percent. Undescended testes and inguinal hernia occur in about 9 percent of children with hypospadias (1,3). Other anomalies do not occur with any significance in isolated hypospadias. This is related to the fact that both are under androgenic hormonal control during development. There is a significantly increased incidence of intersexuality when both conditions coexist (4), and a karyotype should be considered (5).

Since urethral development occurs under the influence of dihydrotestosterone (which is converted in peripheral tissue from testosterone by 5-alpha-reductase), the development of hypospadias can be related either to a reduction in 5-alpha-reductase activity, to a lack of testosterone production, or to failure of the local receptors to recognize the hormone (2).

Hypospadias should be classified based on the anatomical location of the urethral meatus after the chordee has been released: glanular (meatus is located on the glans), coronal, distal shaft, midshaft, penoscrotal, scrotal, or perineal. Associated chordee should be described in terms of severity (mild, moderate, or severe). This provides the most practical classification of hypospadias.

Anterior hypospadias (glanular and coronal types) account for 50% of all hypospadias. Middle hypospadias (distal, midshaft, and proximal penile types) account for 30% of hypospadias cases. Posterior hypospadias (penoscrotal, scrotal, and perineal types) account for 20% of cases (1).

An older classification system, not used by urologists anymore, but which you may encounter, describes hypospadias by degrees. First degree with the meatus between the glans and the distal shaft; second degree with the meatus between the midshaft and the proximal shaft; and the third degree with the meatus being penoscrotal, scrotal or perineal. The severity of chordee is not considered in this system (2).

The pediatrician will be the first physician to exam the genitalia after birth. The foreskin should be examined for completeness circumferentially. Thinned ventral foreskin (a "hooded" penis) is associated commonly with hypospadias. The meatal position should be noted if abnormal (glanular, penile, penoscrotal, scrotal, or perineal), as well as the presence or absence of penile chordee (mild, moderate or severe). The stretched penile length in the newborn is 3.5 cm normally (range 2.8 cm to 4.2 cm) (3), and should be noted if abnormal.

The gonads should be palpated and any cryptorchidism (undescended testes) noted. Any scrotal abnormalities should also be noted, such as a bifid scrotum (a deep cleft between the scrotal sacs) or penoscrotal transposition (the penis lying in or beneath the scrotum). There is an increased incidence of an intersex state (the expression of male and female physical and sexual characteristics within the same individual) in unilateral and bilateral cases of cryptorchidism with hypospadias, especially if the hypospadias is severe (4). Any inguinal hernia should be noted.

If hypospadias is present, a family history of hypospadias should be noted. Any history of maternal ingestion of hormonal medication during pregnancy should be noted. Other congenital anomalies should also be noted (e.g., anorectal anomalies), if present.

Upper urinary tract abnormalities have been reported to be more frequent in boys with hypospadias (3,5). However, routine screening with ultrasound, IVP, or cystograms is not justified because the incidence of defective upper tract anomalies is low. If other associated anomalies are present, with a known higher incidence of upper urinary tract abnormalities (e.g., anorectal malformation), then imaging screening studies are justified (5).

No circumcision should be done in the newborn with hypospadias or any other penile anomaly, as the foreskin may be necessary to create a neourethra, and/or provide penile shaft skin coverage.

If the gonads are nonpalpable and the hypospadias is proximal (penoscrotal or scrotal), then the risk of having an intersex state is high, and emergent urologic consultation is indicated, as well as observation for salt wasting congenital adrenal hyperplasia conditions (the most common cause of intersex states). For hypospadias, urological consultation or referral should be obtained during or shortly after the neonatal period.

The goals of corrective surgery for hypospadias are to provide the child with a normally appearing circumcised penis with the urethral meatus well placed at the tip of the glans. The child should be able to stand to void and have a straight penis when erect (2). This will allow both normal voiding as well as reproductive functionality of the penis after repair.

The hypospadias repair is best performed when the patient is between 6 and 18 months of age. At this age, babies are amnestic of the procedure, post operative management while the patients are still in diapers is easier and allows the procedure to be performed as outpatient surgery (1). The child's anesthetic risk is lower after 6 months of age if a good pediatric anesthesiologist is used.

There are over 200 named surgical procedures to correct hypospadias (1), but there are general concepts in the approach to hypospadias repair common to all. Ventral penile chordee must be corrected first, as the urethral meatus may move proximally as the penis is straightened. Next, the urethroplasty (urethral advancement) is performed to allow the placement of the neourethra well into the glans (to the glans tip). The neourethra is formed from either local skin flaps, or from foreskin flaps (the reason circumcision is not performed). A glanuloplasty to create a normal appearing rounded glans penis may also be performed, if necessary. Penile shaft skin coverage is then accomplished by bringing penile shaft skin, or foreskin flaps ventrally. A short, small caliber silastic urethral catheter that drains directly into the diaper may be used to direct the urine away from the repair, which is removed 7 to 14 days later.

Most hypospadias repairs can be done with a single stage repair. Sometimes a 2-stage repair is necessary, especially for very long urethral defects. The chordee is corrected first, and the prepuce spread along the ventral shaft. Six months later, the neourethra is completed in a second stage repair.

The most common complication seen after hypospadias surgery are fistulae, strictures and recurrent chordee, occurring approximately 10 percent of the time (1,2,5). A wait of at least 6 months is necessary to allow complete healing of the tissue, before the secondary surgery is performed.

Although parents are usually quite distraught when their child is born with hypospadias, the technique for hypospadias repair used by pediatric urologists today are very successful in transforming the hypospadiac penis to a normally appearing and functioning penis, and can be done while the child is still in infancy.

Questions

1. What is the incidence of hypospadias in newborn males in the United States?
2. Why is the presence of non-palpable gonads and hypospadias worrisome?
3. What are the anomalies most commonly associated with hypospadias?
4. What are the goals of hypospadias repair?
5. What are some common complications of hypospadias repairs?
6. Describe the possible locations for the hypospadiac urethral meatus.
7. How should chordee be described?

Answers to questions

1. 1 in 300 newborn males.
2. Nonpalpable gonads and hypospadias (especially severe proximal hypospadias) is associated with an increased risk of the presence of an intersex state (about 27%) (4).
3. Cryptorchidism and inguinal hernias.
4. A normal appearing circumcised penis with the meatus at the glans tip. The erect penis should be straight.
5. Urethral fistula, urethral stricture and recurrent penile chordee.
6. Glanular, coronal, distal penile shaft, midshaft, penoscrotal, scrotal, perineal.
7. Mild, moderate, severe.

Chapter XIV.1. Pulmocardiac Resuscitation

Rodney B. Boychuk, MD
Alson S. Inaba, MD

Paramedics are transporting a 5 month old male infant with respiratory distress, when he tires and stops breathing. The patient is bag mask ventilated with CPR in progress. On arrival in the emergency department, the patient is apneic, asystolic, and pulseless. The infant has no IV access. After brief bag mask ventilation, the patient is intubated with a tracheal tube. A colorimetric carbon dioxide capnometer detector device confirms proper tracheal tube placement. Findings now include:

1) Airway/breathing: Breath sounds are equal bilaterally, and there is good chest movement with ventilation.

2) Circulation: No pulse is palpable without chest compressions, and no heart sounds are heard. ECG shows asystole. Oxygen saturation is not obtainable.

3) Vital signs: Heart rate 0, respiratory rate 0, blood pressure unobtainable.

4) Attempts at IV access are unsuccessful.

Ventilations and chest compressions are continued. Epinephrine 0.5 mg of the 1:1,000 solution is given down the tracheal tube, and an intraosseous line (IO) is inserted into the proximal left tibia. Blood is obtained from the IO needle and is sent for a number of studies including a rapid glucose check. The airway is reassessed, ventilation and chest compressions are continued, and a second dose of epinephrine is given. The patient converts to a sinus bradycardia with a fair blood pressure. After several more minutes of further stabilization, the infant's heart rate is 120 and he is beginning to move and cough against the tracheal tube. The resuscitation is a success.

Although the etiology of pulmocardiac resuscitation (PCR) in children is different than adults, the immediate goal is the same, to immediately reestablish effective cardiac output and tissue delivery of oxygen through the use of artificial ventilation, external chest compressions, and the administration of pharmacologic agents.

The pathophysiology of PCA (pulmocardiac arrest) in children is different from that in adults. The most common etiology of PCA in infants and children is respiratory failure with subsequent cardiac arrest; hence the term pulmocardiac arrest instead of cardiopulmonary arrest and PCR (pulmocardiac resuscitation) instead of CPR (cardiopulmonary resuscitation) as in adults. Furthermore, PCA in children generally is the end result of preceding progressive deterioration and rarely occurs as a sudden event. Thus it is vital to be able to identify and manage respiratory distress in children, and thus prevent the deterioration into respiratory failure and subsequent PCA.

There are many causes of PCA in children but most fit into the classifications of respiratory (pneumonia, apnea, bronchiolitis, asthma, submersion, aspiration, epiglottitis, smoke inhalation, suffocation, anaphylaxis), infectious (septic shock, meningitis), cardiovascular (congenital heart disease, arrhythmia, myocarditis, congestive heart failure, pericarditis, shock), traumatic, or central nervous system diseases (hemorrhage/edema, shaken baby syndrome, seizures, meningitis, hydrocephalus with shunt malfunction, tumor). Respiratory diseases and SIDS account for one-third to two-thirds of all pediatric PCA. Helpful history and physical exam items include: age, recent illness, previous medical problems, current medications, recent trauma, time of day, location of patient during PCA, access to toxins, medicines, poisons, access to potential foreign bodies, length of downtime, overall appearance (congenital defects, "special needs"), vital signs, tracheal deviation, subcutaneous air, pupillary response, evidence of trauma (including retinal hemorrhages), surgical scars (especially sternal, scalp which suggest surgical heart disease and brain surgery respectively). Findings which suggest prolonged time since death include rigor mortis, dependent lividity and corneal clouding.

The age distribution of childhood PCA is skewed toward infancy, with about 50% of patients younger than one year, about 25% between one and four years of age, and about 20% older than four years of age. Equipment and skills preparedness for this young age range by all EMS (emergency medical services) responders and those caring for pediatric emergencies is crucial for achieving best outcomes.

The outcome of PCA in children is dependent upon: 1) site of occurrence (i.e., in-hospital or out-of-hospital, and 2) cause of PCA. In eight reviews published since 1983, only 96/542 (17.7%) of children experiencing out-of-hospital PCAs survived versus 137/342 (40%) of those experiencing in-hospital PCA. The survival rates for children experiencing isolated respiratory arrests ranges from 75 to 97%, while survival rates for children experiencing full cardiopulmonary arrests range from 4 to 16%. The latter statistic reflects the terminal nature of asystole in children which is usually preceded by prolonged respiratory insufficiency with long-standing tissue hypoxemia and acidosis. Therefore directing initial management toward improvement of oxygenation and ventilation is imperative to a successfully resuscitation.

The initial approach to resuscitation is the same as it is for adults: A (airway), B (breathing), C (circulation), D (drugs). Attention to proper positioning, oxygenation and ventilation come first, with drug therapy last. Physiologically the ABC's can better be described as VOP (ventilation, oxygenation, and perfusion). In order to best accomplish this, an organized approach is necessary, with priorities established as follows:

1) Determine the level of responsiveness (or unresponsiveness).

2) Position the patient properly on a firm surface, maintaining cervical spine immobilization (in children with suspected head or cervical spine injury).

3) Establish a patent airway.

4) Assure oxygenation.

5) Assure or establish ventilation (breathing) while protecting the cervical spine.

6) Assure adequate circulation.

7) Reassess.

8) Utilize appropriate drug therapy if required.

The Broselow tape is a pediatric resuscitation tool which uses the length of the patient as a resuscitation guide providing intubation and drug dosing recommendations for each length along the tape corresponding to the patient's length. This eliminates the need to estimate the patient's age and weight.

The most common cause of upper airway obstruction in the unconscious child is posterior displacement of the tongue. This obstruction can be relieved by either a head tilt/chin lift or jaw-thrust maneuver, by pulling the jaw forward into a sniffing position. Do not perform the head tilt/chin lift maneuver in children with potential cervical spine trauma. Foreign material or vomitus can also obstruct the airway. Therefore open the mouth, inspect and suction early and repeatedly. Consider the use of nasopharyngeal or oropharyngeal

airways in selected patients. These type of airways should only be used in unconscious patients, because insertion of either a nasopharyngeal or oropharyngeal airway into a conscious patient will induce gagging and potential aspiration.

Assure oxygenation by administering supplemental oxygen. Although supplemental oxygen can be delivered to patients by a variety of different means, for the sickest patients, 100% oxygen should be administered, utilizing non-rebreather face masks at a flow rate of 10 liters per minute.

Children without adequate spontaneous breathing effort require positive pressure ventilatory support. Initially this is accomplished by bag mask ventilation. The American Heart Association Emergency Cardiac Care 2000 guidelines (1) refer to these the two bag mask ventilation devices as manual resuscitators which are: 1) the self-inflating bag and 2) the closed circuit anesthesia type bag (also called Rusch bag). The definitive airway, however, involves endotracheal intubation, which offers the most effective and secure means to deliver 100% oxygen and protect the airway. Tracheal tube (formerly called endotracheal tube) size should be determined according to one of the methods described in the intubation chapter, which also includes a description of the tracheal intubation procedure, placement and confirmation. The AHA ECC 2000 guidelines recommend secondary confirmation of proper tracheal tube placement by monitoring exhaled carbon dioxide using an end-tidal CO2 monitor or a colorimetric capnometer device (1). Adequate ventilation is determined by auscultation and chest movement (rise and fall).

Assuring adequate circulation does not mean just the blood pressure, but includes the evaluation of the overall appearance, heart rate, presence and strength of proximal vs. distal pulses, skin temperature and color, mucous membrane color, capillary refill time, alertness/responsiveness (brain perfusion) and blood pressure. With acute blood loss or any hypovolemic state, the protective/compensatory mechanisms of increasing the heart rate and increasing the systemic vascular resistance (poor perfusion with cool extremities) will maintain a child's SYSTOLIC blood pressure within a normal range in spite of losses as high as 30% of the child's circulating blood volume. Once these protective homeostatic mechanisms are no longer able to compensate for the hypovolemic state, the child's systolic blood pressure will then abruptly decompensate to a pressure that is now hypotensive for age.

If circulation is inadequate (i.e., absent or ineffectual pulses), then external cardiac chest compressions should be started. Optimally, these should be administered in a compression to ventilation ratio of 5:1. Current recommendations are that in infants, compressions be applied evenly over the midsternum (i.e., directly over the heart ventricles), utilizing the two thumbs on the chest with the hands encircling the chest technique. To avoid any liver trauma, compressions should not be applied over the lower third of the infant's sternum. For children (1-8 years of age), use the heel of one hand to compress the lower half of the sternum (with a compression to ventilation rate also equal to 5:1). For children over 8 years of age, the adult method of chest compressions should be utilized (heel of one hand over the lower half of the sternum with the other hand laid over the back of the first hand. The compression ventilation ratio is 15 compressions followed by 2 breaths) (1).

Vascular access must be established early. Even a small gauge IV can be used for resuscitation, which is better than no IV at all. Intraosseous (IO) infusion should be considered early, especially in the case of cardiac arrest, or decompensated shock. Although IO lines were previously recommended for children <6 years of age, there is no current age limit on the use of intraosseous infusion. The preferred site of IO placement is the proximal medial aspect of the tibia. Any intravenous preparation (medication or fluid) can be given intraosseously, and blood (if available) from the IO needle can be used for many laboratory tests.

After every step, reassess the patient. Pay attention to the VOP, physical exam (i.e., chest excursion, heart rate, skin color, perfusion, etc.) and to results of pulse oximetry or ancillary tests.

Drug therapy during resuscitation is reserved for those who do not respond adequately to the ABC's, and is the last line of therapy, NOT the first. While supplemental oxygen is typically utilized in all resuscitation scenarios, the majority of these resuscitations will not usually require a large number of medications. Drug doses are usually based on the patient's weight. The Broselow tape is an excellent tool to assist with this task. Some of the drugs utilized in pediatric resuscitation are noted here, but the entire list of resuscitation drugs is beyond the scope of this chapter. Epinephrine increases HR, contractility, and BP. Atropine increases HR in cases associated with increased vagal tone. Amiodarone and lidocaine (anti-arrhythmia agents) are used to convert ventricular fibrillation, pulseless ventricular tachycardia or ventricular tachycardia with a pulse. Amiodarone can also be used for certain atrial tachydysrhythmias. Dextrose reverses symptomatic hypoglycemia (which is an easily reversible cause lethargy, seizures and a potential element in shock and cardiac arrest). Sodium bicarbonate reverses the metabolic acidosis associated with most arrest situations; however, optimizing ventilation to reverse the respiratory component of an acidosis takes priority. Sodium bicarbonate is the treatment of choice for arrests due to cyclic antidepressant overdose (potentially lifesaving). Naloxone reverses cardiorespiratory and CNS opiate narcotic depression. Adenosine converts paroxysmal supraventricular tachycardia (PSVT). Dopamine improves BP. Dobutamine increases contractility.

There are also a number of drugs that can be given down the tracheal tube (TT) if vascular access cannot be established. The 4 medications which can be given via the TT can be remembered by the mnemonic "LANE" or "LEAN" which include lidocaine, atropine, naloxone and epinephrine. Epinephrine given down the TT is always given as "high dose" (i.e., 0.1mg/kg of the 1:1,000 solution).

The more common dysrhythmias that one may be confronted with during a pediatric resuscitation include bradycardia, asystole and pulseless electrical activity (PEA, formerly known as electromechanical dissociation or EMD). Ventricular fibrillation and ventricular tachycardia are not very common in children, but may be the presenting dysrhythmia in adolescent patients secondary to various drug overdoses. The key point in the treatment of PEA and asystole is to hunt for reversible causes. The mnemonic used to recall the reversible etiologies of asystole and PEA is "PATH", which stands for pneumothorax (tension), acidosis (severe), toxic ingestion, tamponade (cardiac), hypovolemia, hypoxia (severe), hyper/hypokalemia and hypothermia (so the mnemonic is actually PAT2H4). Although most of these can be ruled out by the history and clinical examination, the possibilities of hyper/hypokalemia and severe metabolic acidosis should also be quickly ruled out with a rapid bedside lab testing device which is much faster then sending a specimen to the lab. The most common cause of PEA in children is hypovolemia. Therefore a rapid fluid bolus (20 ml/kg of IV normal saline) should always be considered as a therapeutic option in a child with PEA who is not responding to epinephrine, CPR and adequate ventilation/oxygenation.

Although a complete discussion of all of the pediatric dysrhythmia algorithms is well beyond the scope of this textbook, a synopsis of the key treatment points for the various pediatric dysrhythmias is listed below:

Asystole and PEA: CPR, intubation, epinephrine and hunt for the cause.

Bradycardia: Assure adequate oxygenation and ventilation first then consider epinephrine, atropine and transcutaneous pacing.

Paroxysmal supraventricular tachycardia (hemodynamically stable): May attempt vagal maneuvers first, then consider adenosine.

Ventricular tachycardia (hemodynamically stable): Consider amiodarone or lidocaine or procainamide.

Any hemodynamically unstable tachydysrhythmia: Immediate synchronized cardioversion is the treatment of choice (unless vascular access is immediately available in the case of PSVT, in which case IV adenosine may be attempted first before cardioversion).

Ventricular fibrillation or pulseless ventricular tachycardia: Immediate defibrillation, epinephrine, intubation then consider antidysrhythmics such as amiodarone, lidocaine or magnesium sulfate (if torsades or hypomagnesemia).

Post resuscitation interventions include maintenance of normal ventilation (rather than hyperventilation), maintenance of normal temperature, glucose control, and management of post-ischemic myocardial dysfunction. Lastly, post arrest cardiogenic shock and septic shock must be treated aggressively with fluid, inotropes and pressors.

In summary, most seriously ill children experience respiratory distress followed by respiratory failure, or shock, before developing other organ system (i.e., cardiac) failure. Therefore a systematic approach to the early recognition and treatment of respiratory distress and compensated shock is the key to the prevention of pulmocardiac arrest. Oxygenation and ventilation must be established first. Without this, drugs, medication and resuscitation will be ineffective. The principles of ABC's (or VOP: ventilation, oxygenation and perfusion) must be followed by a trained skilled resuscitation team with proper equipment in a skilled facility.

Questions

1. The most common cause of pulmocardiac arrest in children is:
    a. Acute myocardial infarction
    b. Hemorrhagic shock
    c. Nonaccidental trauma
    d. Ventricular fibrillation
    e. Hypoxia and respiratory failure

2. Endotracheal intubation is not indicated for which of the following:
    a. Control and protection of the airway.
    b. Prolonged mechanical ventilation.
    c. Tension pneumothorax.
    d. Hyperventilation of the patient with a head injury.
    e. Improved oxygen delivery and ventilation.

3. The drug/treatment of choice for asystole in children is:
    a. Atropine
    b. Calcium chloride
    c. Adenosine
    d. Defibrillation
    e. Epinephrine

4. A 12 year old child comes to the ED pulseless. ECG reveals a wide complex tachycardia. Initial management should be:
    a. Immediate defibrillation.
    b. Immediate synchronized cardioversion.
    c. Adenosine
    d. Epinephrine

5. The most common cause of PEA in children is:
    a. Tension pneumothorax
    b. Metabolic acidosis
    c. Toxic ingestions
    d. Profound hypovolemia
    e. Hyperkalemia

6. The most common cause of bradycardia in children is:
    a. Hypokalemia
    b. Heart block
    c. Hypoxemia
    d. Toxic ingestions
    e. Myocarditis

Chapter XIV.2. Shock
Rodney B. Boychuk, MD

This 2 month old male infant with a 4 day history of vomiting and diarrhea is brought to the emergency department by his mother. Initial findings in the emergency department include:

Airway: Breath sounds are normal. Airway is patent.

Breathing: Breathing is regular at 45 breaths per minute, unlabored.

Circulation: Proximal pulses are poor, distal pulses are absent, and extremities are cool. Feeling from the 5th toe upwards, the legs are cool up to the knee. Capillary refill is 8 seconds. Heart rate is 209 beats per minute, and blood pressure is 70mmHg systolic.

ECG: There are narrow QRS complexes with sinus tachycardia on the monitor.

The infant does not recognize his parents, is extremely lethargic, and responds to pain only, with a minimal grimace.

You are unable to start an IV line, 100% oxygen is started. The mucous membranes of the mouth are pink. An intraosseous (IO) is placed in the left tibia and 20cc/kg of normal saline is infused as rapidly as possible. The infant is reassessed. Airway and breathing remain stable. The heart rate is now 195. A repeat bolus of 20cc/kg is given and the patient is reassessed. After the 3rd fluid bolus is given, the patient becomes more alert, distal pulses return, and the patient improves throughout resuscitation. The heart rate has come down to 160. However, a rapid bedside glucose analysis reveals a blood sugar of only 32, which is quickly treated. This case represents a patient in compensated hypovolemic shock (and hypoglycemia) secondary to vomiting and diarrhea.

Shock is a clinical syndrome of circulatory dysfunction resulting in inadequate oxygen and nutrient delivery, with inability to meet the metabolic demands of the tissues (cells). This results in a cascade of events resulting in altered cellular metabolism, function, structure, and ultimately death. Shock is NOT necessarily hypotension. It begins with a normal blood pressure and progresses over time.

Normal circulatory function depends on 3 components: 1) adequate cardiac function (the pump), 2) appropriate vascular tone (the pipes) and 3) adequate blood volume (the fuel). When one of more of these circulatory components fail, shock results. Adequate delivery of oxygen and nutrients is dependent on adequate cardiac output (CO). Cardiac output in turn is dependent on two cardiac factors: 1) heart rate (HR) and 2) stroke volume (SV). As children are "heart rate dependent", the heart rate is the single most important vital sign when determining shock. The heart rate itself is regulated by two factors: 1) vagal tone and 2) catecholamines. Catecholamines are released in response to stress and have two major circulatory effects in children: 1) increase in heart rate (i.e., tachycardia), and 2) increase in peripheral vascular tone (resistance) (i.e., vasoconstriction, resulting in cool, clamped down extremities).

Stroke volume is the second determinant of cardiac output, and is dependent on three factors: 1) preload (intravascular volume/blood often called "venous return"), (the fuel), 2) myocardial contractility (heart muscle function), (the pump), and 3) afterload (systemic vascular resistance) (the pipes). Children are particularly dependent upon adequate intravascular volume, and when volume depleted, they peripherally vasoconstrict to maintain stroke volume. The myocardium in infants is "stiff" and plays little role in increasing cardiac output. Therefore, the heart rate must increase in order to maintain adequate circulatory function. Remember C.O.=H.R. x S.V.

Shock is a dynamic process that if untreated, progresses through three phases: 1) compensated, then 2) uncompensated, and finally 3) irreversible. Compensated shock, by definition, occurs in a body, which has successfully compensated to a circulatory disruption and is maintaining adequate vital organ perfusion and oxygenation. This may be difficult to differentiate from the patient's normal status. Blood pressure is normal. Tachycardia is usually present, and as catecholamine release increases, the heart rate increases and peripheral vasoconstriction with prolonged (delayed) capillary refill occurs. Utilizing my exam technique, "The pediatrician's handshake", I first feel the 5th toe. If the 5th toe is cold with a prolonged capillary refill, I progress to the other toes, up the foot, then the leg. The further up the leg the capillary refill is prolonged and the leg(s) is cool, the more vasoconstricted the body is, and when counted, the faster the heart rate will be. Normal capillary refill is 2 seconds or less, about the time I take to say "pepperoni pizza". If I need to add "more toppings" to my pizza, then I know the capillary refill is prolonged and the body is "in shock". There are pitfalls when interpreting capillary refill; if the body is developing a fever, or in a cold environment, vasoconstriction results and capillary refill is not a reliable sign of shock. Like any other single sign, this must be taken in context with all other findings.

As shock progresses (hopefully by now you will have intervened and are reversing and treating the cause and it will not progress), the compensatory mechanisms (i.e., increasing heart rate and vasoconstriction) reach their maximum ability and cannot increase further, then suddenly the body decompensates. Metabolic demands are not met, and cellular ischemia results in the release of vasoactive mediators which affect the microcirculation resulting in end-organ compromise and acidosis, with signs including hypotension, altered mentation, oliguria, acidosis, mottled pale skin with cool extremities, tachypnea and dyspnea, tachycardia and the obvious appearance of an "sick body". At this point irreversible damage of key organs (heart, brain, kidneys) may have occurred, but aggressive therapy is still indicated in chance that cardiovascular measurements can still be normalized. Unfortunately, despite aggressive therapy, death may occur regardless of therapy.

The main point to reemphasize is: the early recognition and treatment of compensated shock (better prognosis) is essential to prevent decompensated and irreversible shock (poor prognosis, high risk of death). Remember, hypotension is a late sign of shock and should not be allowed to occur.

Important historical information and physical exam findings must be included when considering the clinical manifestations and differential diagnosis of shock. Historical information asked must include: 1) age, 2) preexisting conditions/illness, 3) fever, 4) vomiting/diarrhea, 5) poor feeding, 6) urine output, 7) lethargy, 8) trauma, 9) toxic ingestion. The physical exam must include: 1) general appearance/alertness/eye contact/activity, 2) heart rate, 3) skin perfusion, a) capillary refill, b) color, c) skin temperature, 4) oliguria (if an observation period is permitted), 5) altered mental status, 6) tachypnea, 7) fever, 8) blood pressure, to name a few.

Utilizing history and physical exam information, it is important to classify the shock syndrome into one of 3 major etiologies: 1) hypovolemic shock, a) absolute, b) relative, 2) septic shock, or 3) cardiogenic shock. Hypovolemic shock is the most common cause of shock in children. A loss of circulating blood volume results in decreased preload (the fuel) with resultant decreased cardiac output. Absolute hypovolemia has three major causes; 1) dehydration secondary to a) diarrhea and vomiting or b) poor intake; 2) hemorrhage or 3) renal losses of fluid from a) diabetes mellitus or b) diabetes insipidus.

"Relative" hypovolemic shock is also called "distributive shock" where the problem is not related to absolute volume but to loss of vessel tone resulting in vasodilation and therefore a larger intravascular space (secondary to vasodilation) with a "normal blood volume", which results in a "relative" hypovolemia. There are four major causes of this: 1) sepsis, 2) anaphylaxis, 3) spinal cord injury or 4) drug reactions secondary to drugs such as barbiturates, phenothiazines, and antihypertensives.

Septic shock is a microcirculatory dysfunction that results from activation of a systemic inflammatory response from age-group specific bacterial pathogens. Those at risk for septic shock include: oncology patients, those with central venous (oncology) catheters, on chronic high dose steroids, or with a congenital or acquired immunodeficiency. Gram negative bacterial endotoxin-mediated septic shock results in activation of numerous mediators of circulatory failure. The end result is impaired myocardial contractility, alteration in vascular tone, and capillary leak.

Lastly, cardiogenic shock (the pump) may be the primary cause of shock or a late manifestation of other forms of shock. Here, there is an abnormality in cardiac function due to depressed myocardial contractility. Etiologies include 1) congenital heart disease, 2) myocardial infarction (e.g., Kawasaki's), 3) myocarditis or pericarditis, 4) congestive heart failure, 5) cardiac trauma, 6) dysrhythmia, or 7) drugs affecting myocardial contractility.

The table below compares the cardiac output (CO), systemic vascular resistance (SVR) and central venous pressure (CVP) in the three shock syndromes. An increase in CVP will clinically be seen as distended neck veins and an enlarged liver. An increase in SVR will be seen as cold, clamped down extremities with weak pulses and prolonged capillary refill.

	CO	SVR	CVP
Hypovolemic	decreased	increased	decreased
Cardiogenic	decreased	increased	increased
Distributive	increased	decreased	decreased

Common Etiologies of Shock Syndromes

1) Hypovolemic Shock

a) Absolute Hypovolemia: water and electrolyte losses (diarrhea, vomiting, diabetes insipidus, renal losses, heat stroke, intestinal obstruction, burns), hemorrhage (trauma, surgery, GI bleeding), plasma losses (burns, nephrotic syndrome, sepsis, intestinal obstruction, peritonitis).

b) Relative Hypovolemia (distributive shock): anaphylaxis (antibiotics, blood products, insects, vaccines, local anesthetics, foods, etc.), neurologic injury (head injury, spinal shock), drug intoxication (barbiturates, phenothiazines, tranquilizers, antihypertensives), sepsis., toxic shock

2) Septic Shock

a) Bacterial: Group A streptococcus, Haemophilus influenzae type b, Neisseria meningitidis, Streptococcus pneumoniae, Group B Streptococcus, Gram negative bacilli (predominantly E. coli), Staphylococcus aureus.

b) Other: viral, fungal, rickettsial

3) Cardiogenic Shock:

Congenital heart disease (ductal-dependent systemic blood flow, post-operative complications), dysrhythmias, drug intoxication, myocarditis (viral, other inflammatory), hypoxic-ischemic injury (Kawasaki syndrome, perinatal asphyxia, near-drowning, near-SIDS), primary cardiomyopathy, metabolic derangement (hypoglycemia, acidosis), hypothermia, late sepsis, toxic shock.

4) Miscellaneous Shock Syndromes

a) Obstructive Shock: pericardial tamponade, tension pneumothorax, pulmonary embolus

b) Dissociative Shock: carbon monoxide poisoning, methemoglobinemia

Regardless of etiology, initial therapy is universal. All patients should receive 100% supplemental oxygen by face mask, followed by the correction of the mismatch between metabolic supply and demand. Early recognition and aggressive treatment is the key. Anticipation of the effects of shock as a dynamic, clinical syndrome with multi-system consequences, which can be reversed, with optimization of cardiac output is essential to prevent decompensation and irreversible shock.

Treatment can be classified broadly into: 1) oxygenation, 2) vascular access, 3) fluid administration, and 4) drug therapy. Oxygenation includes providing 100% oxygen and also assuring adequate hemoglobin, stopping hemorrhage, and replacing blood if the hematocrit is less than 30%. Consider endotracheal intubation, but be aware of the cardiovascular effects that intubation and positive ventilation can cause, such as bradycardia, hypotension or reduced venous return. Vascular access includes insertion of a (preferably two) large intravenous catheters, and obtaining necessary lab tests (CBC, blood culture, electrolytes, BUN, creatinine, glucose, calcium,

coagulation profile and blood gas). If vascular access is difficult to obtain, use an intraosseous (IO) device and insert this into the tibia. New guidelines allow IO use in children of all ages. There are 2 major types of fluid that can be administered, crystalloid or colloid. Crystalloid is either volume expanding isotonic (normal saline or Ringer's lactate) or hypertonic (3% saline). Crystalloid is an effective volume expander in resuscitation but requires 2-4 times the volume of blood loss to restore hemodynamic parameters. Of the isotonic volume infused into the extracellular compartment (i.e., intravenous or I.O.), only 25% remains intravascular, while 75% eventually goes interstitial. This has led to the use of hypertonic saline (3% sodium chloride solution) in certain situations (such as hemorrhagic shock), as it is an effective vascular volume expander using less volume, working by expanding the ECF by a greater amount than the volume infused because it pulls water from the ICF compartment. Although there is less potential for edema as a result of its use, there are complications including increased serum osmolarity, increased serum Na and C1 levels, metabolic acidosis, and cerebral dehydration and hemorrhage.

Colloid refers to 5% albumin, fresh frozen plasma (FFP) or blood. Albumin's major advantage is that it remains primarily within the intravascular space (less enters the interstitial space). In addition, it can draw extravascular water into the intravascular space because of its oncotic pressure effect. FFP is an effective volume expander with the added benefit of procoagulant factors, while blood (whole or packed RBCs) is an effective volume expander with the added benefit of oxygen carrying capacity.

Most often fluid administration in the form of volume resuscitation is accomplished by the infusion of 0.9% sodium chloride (normal saline) or Ringer's lactate 20 ml/kg IV bolus as quickly as possible. Then reevaluate and repeat the bolus depending on the clinical status/changes. Search for other causes such as sepsis or occult hemorrhage. Central venous pressure monitoring will help fluid management in critical patients. General guidelines are to be liberal and aggressive with fluid resuscitation, giving 20 ml/kg initially and repeating as needed. For septic shock, more than 40ml/kg in the first hour has been shown to improve outcome. When approaching 80 ml/kg, consider the use of an inotropic agent such as dopamine or epinephrine.

Pharmacologic support includes medications that: 1) augment cardiac contractility (inotropic/cardiotonic), vasoconstrictors to reverse inappropriate vasodilation, and sometimes vasodilator drugs to reduce preload and afterload in cardiogenic etiologies, 2) antibiotics (for septic shock), 3) sodium bicarbonate, 4) calcium, 5) immunotherapies, and 6) controversial therapy. However, before specific drugs are described, a review of adrenergic receptor physiology is indicated. Each receptor has a different physiologic response, as noted here:

Alpha:	Arteriolar constriction
Beta-1:	Increased myocardial contractility (inotropy)
	Increased heart rate (chronotropy)
Beta-2:	Peripheral vasodilation
	Bronchial smooth muscle relaxation
Dopaminergic:	Smooth muscle relaxation
	Increase renal blood flow

Examples of classic agonists include phenylephrine (pure alpha), isoproterenol (pure beta, both beta-1 and beta-2), dobutamine (selective beta-1), albuterol (selective beta-2), epinephrine (both alpha and beta).

Three commonly used inotropic drugs include dopamine, dobutamine and epinephrine. Dopamine effects are dependent on the dose infused. Low dose (1-2 mcg/kg/min) results in vasodilation of the splanchnic (renal) and cerebral vascular beds. Mid-dose (3-10 mcg/kg/min) has primarily a beta effect (chronotropic and inotropic), while a higher dose (> 10 mcg/kg/min) has a pure alpha effect (pressor). Dobutamine has a pure beta-1 (chronotropic and inotropic) effect, the effective dose used ranging from 2-20 mcg/kg/min or greater. Epinephrine at an infusion dose of 0.05-2 mcg/kg/min has both beta and alpha effects, and may cause severe peripheral vasoconstriction or arrhythmias.

Examples of vasodilator drugs used for "afterload reduction" in a failing heart to ease the work of "pumping" are nitrates such as nitroprusside and nitroglycerine. Nitroprusside, infused continuously at a rate between 1-10 mcg/kg/min, is a vasodilator working on both resistance and capacitance sides of the circulation; however with time, a toxic cyanide metabolite is formed.

Consider the use of sodium bicarbonate after assuring adequate volume resuscitation and ventilation, at a dose of 1-2 mEq/kg.

Calcium: Hypocalcemia can occur after tissue hypoperfusion of any etiology and can result in myocardial depression and hypotension. If hypocalcemia is documented in a symptomatic patient not responding to inotropes and pressors, then consider treating the hypocalcemia. The dose used is 10-20 mg/kg CaCl (0.1-0.2 ml/kg of 10% solution). Monitor ionized calcium levels to determine its need.

Antibiotics are used for septic shock (or presumed septic shock). For ages less than 6 weeks, a combination of ampicillin plus cefotaxime can be used. For ages greater than 6 weeks cefotaxime or ceftriaxone can be used.

Immunotherapies include the use of anti-endotoxin (HA-1A or E5), anti-tumor necrosis factor (TNFa) and interleukin-1 (IL-1) receptor antagonist. These are beyond the scope of this chapter, but will be important adjuncts to antibiotics and intensive care treatment in the future. Controversial therapy includes primarily the use of steroids. Although theoretically it may be of benefit modulating the immune response to sepsis, there has been no benefit (actually increased mortality) in humans, therefore it is NOT currently recommended. A more detailed description of additional medications utilized for resuscitation can be found in the chapter on pediatric pulmocardiac resuscitation.

Ongoing assessment of the patient in shock includes repeated reassessments of the physical exam, and monitoring equipment including pulse oximetry, cardiorespiratory monitoring, repeated blood pressures, central venous pressure (if indicated), and urine output through a catheter. Physical exam findings will be reflected in signs of improved perfusion which will include improvement in appearance, including alertness (mental status), eye contact, skin capillary refill, color and temperature, heart rate and pulse strength, urine output, respiratory pattern and rate, and blood pressure. Resolving metabolic acidosis and declining serum lactate levels are lab findings indicating improvement of perfusion.

In summary, shock is a clinical syndrome NOT defined by blood pressure alone. Worldwide, hypovolemic shock from diarrhea represents the leading cause of death. Normal circulatory function depends on three factors: cardiac function (the pump), vascular tone (the pipes), and blood volume (the fuel). A disturbance in one or more, resulting in inadequate delivery of oxygen and nutrients to the tissues, leads to shock. Shock is a progressive, dynamic process where early recognition and immediate management (initially in the form of IV fluids) is essential to prevent deterioration into decompensated and finally irreversible shock.

Questions

1. Prioritize the initial management of the child with shock:
    a. Administer oxygen
    b. Administer volume resuscitation
    c. Support a patent airway
    d. Support blood pressure and perfusion with cardioactive drugs
    e. Administer antibiotics
    f. Address oxygen carrying capacity with administration of blood if anemia is present

2. The most sensitive indicator of intravascular volume in the pediatric patient is:
    a. Cardiac output
    b. Preload
    c. Heart rate
    d. Stroke volume

3. In the trauma patient with compensated shock, who is otherwise stable blood should be considered as part of volume resuscitation:
    a. Immediately after the airway is secured and intravenous access
    b. After 20 cc/kg of isotonic fluid has been administered without clinical response
    c. After 40 cc/kg of isotonic fluid has been administered without clinical response
    d. After 60 cc/kg of isotonic fluid has been administered without clinical response
    e. After isotonic fluid administration has resulted in inadequate clinical response and the patient requires operative repair

4. Which circulatory finding is the hallmark of the diagnosis of late (decompensated) shock?
    a. Capillary refill of 4 seconds
    b. Altered mental status
    c. Depressed anterior fontanelle
    d. Hypotension
    e. Absent distal pulses

5. An alert, 6 month old male has a history of vomiting and diarrhea. He appears pale and has an RR of 45 breaths per minute, HR of 180 beats per minute, and a systolic blood pressure of 85 mm Hg. His extremities are cool and mottled with a capillary refill time of 4 seconds. What would best describe his circulatory status?
    a. Normal circulatory status
    b. Early (compensated) shock caused by hypovolemia
    c. Early (compensated)shock caused by supraventricular tachycardia
    d. Late (decompensated) shock caused by hypovolemia
    e. Late (decompensated) shock caused by supraventricular tachycardia

6. Appropriate initial management for the child described in question 6 would include which of the following?
    a. Initiation of oral rehydration therapy
    b. Placement of an intraosseous line, fluid bolus of 20 ml/kg of normal saline
    c. Placement of an intravenous (IV) line, fluid bolus of 20 ml/kg of normal saline
    d. Placement of an IV line, adenosine 0.1 mg/kg IV

7. A 2 month old infant is brought to the ED with a pulse of 180 and BP 50/35 mm Hg. A liver edge is palpable to the umbilicus. Skin is mottled, capillary refill is 6 seconds with weak distal pulses. Chest x-ray reveals cardiomegaly. During the administration of 20 ml/kg of Ringer's lactate, respirations become labored and rales are heard. The next step would be:
    a. Sodium bicarbonate 1 mEq/kg IV
    b. Repeat fluid bolus 20 ml/kg
    c. Dopamine 5 to 10 mcg/kg/min IV infusion
    d. Synchronous cardioversion 0.5 joule/kg
    e. Epinephrine 0.01 mg/kg of the 1:10,000 solution IV

Answers to questions

1. c,a,b,d,f,e
2. c
3. c
4. d
5. b
6. c
7. c. This represents a case of cardiomyopathy with four classic findings of congestive heart failure. Note that the patient's condition worsened with fluid administration. Dopamine would be the first agent to try. Epinephrine may be used later in desperation since its alpha effect may have detrimental consequences on overall circulation.

Chapter XIV.3. Respiratory Failure

Paula A. Vanderford, MD

A former 27 week premie, now 12 months old, arrives in the emergency room diaphoretic, cyanotic, and tachypneic, with a heart rate of 220. She has bronchopulmonary dysplasia (BPD), and is usually on home oxygen (30%) by tracheostomy collar. She is on routine albuterol and fluticasone aerosols for reactive airway disease. She has had cold symptoms for two days, slight fever and increased secretions. Today her parents report that she has had increased work in breathing with audible wheezing. Despite giving albuterol aerosols every two hours, she has worsened over the day. She "turned blue" about 30 minutes ago and an ambulance was called.

Exam: VS T 38.3, HR 220, R 90, BP 86/48, oxygen saturation 80% on an increased oxygen flow provided by paramedics. Her weight is 8 kg (25th percentile for a 9 month old, corrected post conception age). She has a tracheostomy tube in place. She is cyanotic and has poor aeration on auscultation. She has crackles, wheezing and a prolonged expiratory phase. Marked retractions and nasal flaring are present.

Suspecting a plug in her tracheostomy, her tracheostomy tube is suctioned and then changed when there is some resistance to passage of the suction catheter. Despite changing her tracheostomy, her status does not improve. She is bag ventilated via her tracheostomy and subsequently placed on mechanical ventilation. She is given IV methylprednisolone and more beta adrenergics. Her saturations rise from 80% to 98% and her aeration improves. Her tachycardia improves to 170 and her RR is now 50 (ventilator). She becomes more alert and her flaring and retractions subside. Her chest x-ray reveals chronic changes consistent with BPD, hyperaeration and scattered areas of atelectasis. Her nasopharyngeal RSV assay is positive for respiratory syncytial virus.

This is a case of respiratory failure due to RSV pneumonia in a patient with underlying BPD. In evaluating this child, multiple etiologies had to be considered, including problems with the tracheostomy. A plugged tracheostomy tube must always be considered as the cause of respiratory distress in a child with a tracheostomy.

There are multiple etiologies of respiratory distress, and the treatment obviously depends on the cause. Fortunately, the basic tenants of airway, breathing and circulation (the "ABCs") always apply. The goal is to recognize the early signs and symptoms of respiratory problems, intervene early, and hopefully prevent progression to respiratory failure.

What is respiratory failure? In the past, emphasis has been placed on arterial blood gas values. A more useful definition is based in clinical findings and history. Basically, respiratory failure is the inadequate ventilation and oxygenation, resulting in hypercarbia and hypoxemia severe enough to require ventilatory assistance. Evidence of respiratory failure includes cyanosis, tachypnea, apnea, slow respiratory rate, retractions, poor aeration, and appearance of fatigue. Depending on the etiology, the signs and symptoms will differ. Blood gases are useful if they are available and easily obtained. A blood gas obtained after multiple sticks in a dyspneic screaming, poorly perfused child may result in worsening of the child's status and provide little, if any, useful information. In the best of situations, an arterial blood gas (ABG) in a previously healthy child with a $PaCO_2 > 55$, $PaO_2 < 60$ is consistent with respiratory failure in most instances. She exhibited another common feature of respiratory failure, which is that she failed to adequately oxygenate despite maximal supplemental oxygen by mask. This can be easily assessed by monitoring the pulse oximeter readings while maximal supplemental oxygen by mask is administered. Note that in our case, the diagnosis of respiratory failure was made without obtaining a blood gas. Rather, respiratory failure was based on clinical findings alone. A blood gas might have delayed treatment and would not have changed the therapy. Given her BPD, we would expect her pCO_2 to be high at baseline, but with a fairly normal pH. In the setting of acute respiratory failure, a low pH is important in making this diagnosis in a child with chronically elevated pCO_2. Eventually in the therapy of a child with respiratory failure, blood gases will be helpful in managing therapy. Well warmed capillary blood gases are useful in following pH and pCO_2 in a child with good perfusion (as an alternative to ABGs). Oxygen saturation measured by pulse oximetry and end tidal CO_2 monitoring ($ETCO_2$) or transcutaneous CO_2 monitoring (TCM) are also useful for monitoring during therapy.

There are many etiologies of respiratory failure including neurologic disorders, respiratory infections and foreign bodies. Some specific conditions include: head injury, coma, status epilepticus, narcotics/sedatives, botulism, Guillain-Barre syndrome, airway foreign body, croup, asthma, tracheomalacia/tracheal stenosis, flail chest, burns, bronchiolitis, pneumothorax, pleural effusion, pneumonia, ARDS/neonatal RDS, pulmonary edema, etc.

While the specific treatment depends on the etiology, assessing and supporting the ABCs is the appropriate initial therapy. Managing the airway, supplying oxygen and assuring adequate ventilation are the goals regardless of the etiology. Specific treatments, however, depend on determining the location and cause of the respiratory distress. Chapters in multiple books have been written about each specific disorder. Given the limited scope of this chapter, only a few of the more common disorders will be described and their therapies outlined.

If there is evidence of upper airway obstruction, such as snoring or harsh stridor, repositioning the airway may be useful. Suctioning the naso/oropharynx may be helpful, and in certain cases airway adjuncts such as an oral airway or nasopharyngeal tube may be necessary. Upper airway problems are generally manifested by stridor and include epiglottitis, croup, laryngomalacia, vocal cord problems and airway foreign bodies.

Epiglottitis has become much less common since the wide spread use of the Haemophilus influenza B vaccine. Epiglottitis is characterized by high fever, a toxic appearance, drooling and a muffled voice. Therapy includes oxygen, endotracheal intubation and antibiotics.

Croup is much more common, occurs predominately in infants, and is characterized by a barking or seal-like cough, stridor and low grade temperature. Therapy includes oxygen, epinephrine aerosols and corticosteroids. Only rarely is endotracheal intubation necessary.

Laryngomalacia, vocal cord problems and foreign body aspiration are generally diagnosed by history and laryngoscopy/bronchoscopy. Oxygen is always an appropriate initial therapy, offered in the least threatening manner. Intubation may be required acutely for severe laryngomalacia and vocal cord dysfunction. Tracheostomy may be necessary for long term problems.

Foreign body aspiration should be suspected in a previously healthy child with the acute onset of respiratory distress. Frequently, unilateral wheezing or unequal breath sounds will be noted, along with unilateral findings on CXR (atelectasis or hyperaeration). Bronchoscopy and removal of the foreign body are usually the only therapy required for aspirated objects. In some cases where bronchospasm and airway swelling accompany the aspiration, bronchodilators, epinephrine aerosols and corticosteroids may be indicated.

Neurologic conditions that lead to respiratory failure, in contrast to airway or pulmonary problems, are not usually associated with signs/symptoms of respiratory distress. Respirations may be shallow, irregular or absent. Level of consciousness may be impaired, depending on the cause, but this may be difficult to assess due to muscle weakness. If the etiology is a sedative or narcotic overdose, oxygen and a reversal agent such as naloxone or flumazenil may be all that is necessary. For longer term conditions such as Guillain-Barre or botulism, intubation and mechanical ventilation are usually required until the neurologic problem resolves. Central hypoventilation and spinal cord injuries frequently result in the need for tracheostomy and long term ventilation.

Reactive airway disease, characterized by distal airway swelling, increased secretions and airway constriction is a common cause of respiratory distress/failure. Children with bronchiolitis, bronchopulmonary dysplasia (BPD) and asthma all have a component of reactive airways disease. Bronchiolitis is a viral illness, most commonly seen in infants. Oxygen is always indicated for the child in distress. Bronchodilators may be helpful. Corticosteroids are most helpful in those with a prior history of reactive airways disease. Children with a history of prematurity and prior long term mechanical ventilation will often develop BPD with scarring of the lung and hyperactive airways. BPD exacerbations are characterized by hyperaeration and wheezing, and are often initiated by URIs. Frequently they will be on chronic bronchodilators and nebulized corticosteroids or steroid inhalers. It is important to ask this history since children on corticosteroids recently may be adrenal suppressed and require stress dose (high dose) corticosteroids with acute illnesses. Corticosteroids will also be useful in treating acute airway inflammation. More frequent bronchodilators (or continuous bronchodilators) may be helpful. The use of heliox and magnesium have been reported to be useful in some patients, but are not yet considered standard therapies. Helium/oxygen mixtures have a lower density than nitrogen/oxygen (room air) mixtures and therefore flow with less turbulence. Magnesium is a smooth muscle relaxant and has been reported to be useful for severe asthma by some investigators.

Pneumonia reduces lung compliance and increases ventilation perfusion (V/Q) mismatching due to lung injury and filling of the alveoli. Areas of atelectasis are also common due to mucus plugging. The patient with pneumonia may have grunting respirations (closing the glottis prematurely in order increase their intrinsic airway distending pressure to keep the alveoli open: PEEP), in addition to hypoxemia, tachypnea, rales, retractions, and nasal flaring. Treatment of the child with pneumonia and respiratory failure may include oxygen, antibiotics (if a bacterial process is thought to be present), chest physiotherapy to help open atelectatic areas and promote drainage, and mechanical ventilation. The provision of PEEP (positive end expiratory pressure) improves V/Q matching by improving ventilation of the involved alveoli. In some patients, continuous positive airway pressure (CPAP) alone will be sufficient to adequately restore ventilation and oxygenation, but in most cases, provision of mechanical ventilation will be necessary.

Adult respiratory distress syndrome (ARDS) is a disorder characterized by diffuse lung injury, bilateral infiltrates and a large alveolar arterial oxygen gradient (hypoxemia despite high inspired supplemental oxygen) resulting in significant hypoxemia. There are numerous etiologies for ARDS, including pneumonia, near drownings, sepsis and burns. The disease involves alveolar filling as well as interstitial edema and infiltration with cells and fibrosis. The prognosis is poor even with intensive care. Treatment includes tracheal intubation and ventilation, usually with "permissive hypercapnia" techniques to reduce barotrauma. Patients with ARDS have very stiff noncompliant lungs and using tidal volumes and rates sufficient to normalize the pCO2 often result in air leak complications (such as pneumothorax). Therefore, a high pCO2 (50s to 60s) is permitted, as long as the pH remains acceptable (variable, depending on the center). Morbidity and mortality have been shown to be reduced in patients with ARDS with this technique. Due to reduced lung compliance and alveolar filling, high PEEP is generally required to maintain oxygenation in patients with ARDS. High frequency oscillation ventilation is also frequently used. Air leaks are a common complication.

Air leaks are another cause/contribution to respiratory failure. A discussion of air leak syndromes is found in a separate chapter in this book.

This chapter provides only a brief overview of respiratory failure; its causes, signs and symptoms, and approaches to treatment. Early recognition of respiratory distress and intervention will help prevent progression to respiratory failure and eventual cardiopulmonary arrest.

Questions

1. True/False: To diagnose respiratory failure one must obtain an ABG.

2. Etiologies of respiratory failure include:
   a. burns
   b. botulism
   c. asthma
   d. pneumonia
   e. c & d
   f. all of the above

3. Upper airway problems are generally manifest by:
    a. wheezing
    b. grunting respirations
    c. stridor
    d. tracheal deviation

4. A previously healthy child with acute onset of respiratory distress and unilateral wheezing should be suspected of having:
    a. reactive airway disease
    b. croup
    c. foreign body
    d. epiglottitis

5. Children with a neurologic conditions resulting in respiratory failure often display:
    a. retractions
    b. rapid abdominal breathing
    c. head bobbing
    d. none of the above

6. Reactive airway disease is characterized by:
    a. distal airway swelling
    b. increased secretions
    c. airway constriction
    d. wheezing
    e. all of the above

7. True/False: Respiratory distress in a child with a tracheostomy should be considered a plugged or misplaced tracheostomy tube, until proven otherwise.

8. ARDS is characterized by:
    a. large alveolar-arterial gradient
    b. reduced compliance
    c. low morbidity & mortality
    d. a & b

Chapter XIV.4. Intubation
Paula A. Vanderford, MD

This is a four month old male who presents to the ED with respiratory distress. His mother states that he has been ill for several days with a runny nose, fever and a cough. Last night she noted that he was breathing "funny". This morning he refused his bottle and has had increased difficulty breathing. He has had an episode of vomiting with cough, but no diarrhea.

His past medical history is significant for a home birth and no immunizations. He has been well since birth, with the exception of noisy breathing especially when he is in the supine position.

Exam: VS T 39.0, P 80, R 16, oxygen saturation 82% on RA, 90% on oxygen by mask, weight 6kg (50%ile), length 59cm (10%ile). He is in moderately severe respiratory distress with nasal flaring and marked chest retractions. He has unusual facies and a small jaw. His tongue is protruding from his mouth. He has a slightly sunken fontanel. His heart rate is rapid, but regular and no murmurs are noted. His breath sounds are equal but diminished. Crackles and diffuse wheezes are present bilaterally. His abdomen is full, but soft and his abdomen expands with each breath. His capillary refill time is 3 seconds. His pulses are 2+ to 4+ peripherally. His muscle tone is poor. Arterial blood gas (ABG) pH 7.12, pCO2 100, pO2 60, base excess -4. Chest x-ray shows diffuse bilateral patchy infiltrates, with hyperinflation and areas of atelectasis.

The child is correctly assessed to be in respiratory failure and he is sedated and pharmacologically paralyzed for intubation. Unfortunately, as the neuromuscular relaxant is given, the child becomes blue and bradycardic despite bag mask ventilation. The mask is repositioned and a good seal is obtained. However, there is poor chest wall movement with bagging. The child has upper airway obstruction and a nasal trumpet is placed. He is again bag mask ventilated and his saturations rise to 100%. Attempts to intubate the child are unsuccessful. His vocal cords cannot be visualized due to his relatively large tongue and small jaw. He is successfully bag mask ventilated until an anesthesiologist on call arrives and is able to intubate the child's trachea, using advanced techniques. He is placed on mechanical ventilation. His RSV assay is positive. He requires mechanical ventilation for approximately one week and is successfully extubated. During his hospital stay he is evaluated by a geneticist who confirms a diagnosis of Pierre Robin syndrome.

There are multiple indications for endotracheal intubation. These include respiratory failure secondary to lung disease, upper airway obstruction, CNS disease (such as increased ICP or apnea) or chest wall problems. Whatever the indication, endotracheal intubation should be carried out in a systematic, controlled fashion. This requires preparation before a patient in need arrives in your facility. Equipment must be available, appropriate to all sizes of children and adults, since many teenagers will require adult sized equipment. Equipment must be stored in an organized fashion and readily available. It should be checked frequently to assure that it is in good working order, especially the light source for the laryngoscope blade. Equipment should include: laryngoscope blades and handles, extra lights/batteries, endotracheal (ET) tubes (cuffed and uncuffed, all sizes), suction catheters, ventilation bag/masks in all sizes, oral and nasal airways, ET tube (ETT) stylets, Magill forceps, NG tubes, and tape. It should be noted that the term endotracheal tube (ETT), has recently been replaced by the term "tracheal tube" (TT). This chapter will use these two terms synonymously.

A croupy cough or stridor should alert the clinician of possible airway narrowing and a smaller than usual ETT should be available. The child's airway should be assessed, paying particular attention to any unusual anatomy that may prevent adequate visualization and successful endotracheal intubation. These include a small mandible, large tongue and a restricted mobility of the mandible. Obtaining a history of prior intubations is also important. A history of a difficult intubation should raise concerns regarding a potentially difficult airway and assistance should be sought from an anesthesiologist.

Once it has been determined that the patient requires endotracheal intubation, a decision must be made as to what, if any drugs will be used to facilitate the procedure. While newborns are commonly intubated without the use of any sedatives or neuromuscular relaxants, it is common practice in pediatrics to sedate and pharmacologically paralyze children for endotracheal intubation. Sedatives and/or analgesics and paralyzing agents make the procedure more comfortable for the patient and help blunt some of the hemodynamic responses to intubation. Neuromuscular relaxants make the procedure easier, as the tissues are relaxed, facilitating visualization and intubation. A description of all the agents used is beyond the scope of this chapter; however, midazolam, propofol, etomidate, ketamine, opiate narcotic analgesics, thiopental, rocuronium and succinylcholine are commonly used. The clinician must be aware of the potential side effects of each medication and their duration of action. As a general rule, long acting neuromuscular relaxants and arguably any neuromuscular relaxant should be avoided in a child with a potentially difficult airway. Pharmacologic paralysis could make a bad situation worse if endotracheal intubation is unsuccessful, as in the case presented. An anticholinergic, such as atropine may be given prophylactically to prevent bradycardia due to an exaggerated vagal response to intubation.

ETT size selection is critical to optimally ventilate a patient. One very easy guideline to remember is to use the size is the outer diameter of the 5th finger which should approximate the size of the outer diameter of the ETT. This rule sounds attractive, but it is difficult to use accurately in an emergency. Term newborns require a 3.0 or 3.5 ETT. 12 month olds generally fit a 4.0 ETT. For children over 2 years of age, the correct ETT size can be estimated by the formula: 4 + age/4

Uncuffed ETTs are used in children less than 8 years old. This is because the narrowest portion of a child's larynx is the cricoid, versus the glottis in adults. An ET tube a half size smaller and larger than the estimated needed size should be available. Straight blades (e.g., Miller) are most useful in infants and young children. The tip of the blade is used to lift (compress) the base of the tongue; however, often the blade is inserted farther and the tip of the epiglottis is lifted. For older children curved (e.g., Macintosh) blades are generally used to lift the tongue and expose the epiglottis and laryngeal opening. The size of the blade depends on the size of the child: Blade size 0 (newborns), size 1 (infant and small children), size 2 (older children), size 3 (adolescents and adults).

Once all the equipment has been assembled and checked, and medications are drawn up and available, the child is positioned supine in the "sniffing" position (the head is slightly extended with the jaw thrusting upward). Depending on the age of the child, a folded towel under the head may facilitate endotracheal intubation. This is generally not needed in infants due to the prominence of their occipital region. Placement of the head in this position allows for easier visualization of the epiglottis and vocal cords. If, however, the child is suspected of having a cervical spine injury, the neck should be stabilized in neutral position during endotracheal intubation. Ideally the child will have been NPO for several hours prior to intubation to avoid emesis and aspiration. If not, place a NG tube and aspirate the stomach contents. An NG tube is also useful to prevent insufflation of the stomach with air during preoxygenation and bag mask ventilation. If the child has not been NPO, "rapid sequence intubation" should be performed which minimizes bag mask ventilation and reduces the risk of aspiration (1). With the left hand, the blade of the laryngoscope is placed in the right corner of the mouth and the tongue is swept superiorly and to the midline. Avoid using the blade as a lever, instead lift up and away from you. Slowly pull back on

the laryngoscope blade until the vocal cords are visualized. Use your right hand to suction the oropharynx if needed, then use your right hand to pass the ETT between the cords. Do not force the tube if it does not pass easily. Stop the attempt if the child becomes bradycardic or if the saturations begin to fall, and resume bag mask ventilation. Once the ETT has passed between the cords, advance it until the "oral" mark on the ETT is at the level of the lip. As a rough guide, the lip to tip distance is 3 times the ETT size. A stylet may be used to facilitate intubation if there is difficulty placing the ETT anteriorly. Auscultate for breath sounds bilaterally and look for condensation in the ETT. If breath sounds are present on the right, but not the left, suspect a right mainstem intubation and slowly pull back on the ETT until breath sounds are heard bilaterally. Auscultate over the stomach as well, to rule out an esophageal intubation. End tidal CO2 monitors and detectors are the best means of confirming tracheal intubation in most instances. Then secure the ETT to both the upper and lower lip using an adhesive (such as benzoin) and tape. Appropriate respiratory support should be initiated immediately. A CXR should be obtained immediately to confirm proper positioning of the ETT. Remember that an intubated child is at risk for the displacement of the ETT, ETT plugging, pneumothorax or an equipment failure (ventilator malfunction). Assume that any deterioration in the child's status is an airway problem until that is ruled out as a cause. "DOPE" is a useful mnemonic to remember potential causes of airway/ventilation problems in intubated patients.

D: Displaced ETT
O: Obstructed ETT
P: Pneumothorax
E: Equipment failure (such as ventilator malfunction or disconnect)

Questions

1. True/False: Neuromuscular relaxants should always be used for endotracheal intubation.

2. The appropriate ETT size for a 4 y.o. is: a) 5.0 b) 4.0 c) 6.5

3. True/False: A cuffed ETT is appropriate for a 5 year old in respiratory failure.

4. True/False: Bag mask ventilation should be used to ventilate a child with dysmorphic features until an anesthesiologist is available for endotracheal intubation.

5. True/False: For infants, a Macintosh blade is the most useful for endotracheal intubation.

6. In an intubated patient the most likely cause of acute deterioration is:
   a. shock
   b. airway problems
   c. need for chest physiotherapy

Answers to questions

1. false, 2.a, 3.false, 4.true, 5.false, 6.b

Chapter XIV.5. Mechanical Ventilation
Paula A. Vanderford, MD

A 4 month old, 6 kg girl is admitted to the PICU for respiratory failure. She is cyanotic and retracting. She is intubated due to worsening tachypnea, increasing work of breathing, and fatigue. Her oxygen saturations have been falling and her pCO2 is 75 on an arterial blood gas. With intubation, her oxygen saturations briefly improve as she is hand ventilated, but her oxygen saturation falls into the high 80s when placed on mechanical ventilation, SIMV (synchronized intermittent mandatory ventilation) mode with a tidal volume of 80, IT=0.7 seconds, FiO2=100%, PEEP=5, and rate of 25. Her saturations again rise to 98-100% with hand bagging. After numerous attempts to ventilate her with volume ventilation she is changed to SIMV pressure control/pressure support mode, PIP=30, PEEP=6, FiO2=60%, RR=25, IT=0.7 and her saturations remain 98-100% on mechanical ventilation. CXR shows her ET tube to be in good position, but there are bilateral, patchy infiltrates and right lower lobe consolidation. She is placed on chest physiotherapy and IV antibiotics. Over the subsequent week, her ventilator rate, FiO2 and PEEP are gradually reduced. She is successfully extubated one week after admission to the PICU.

Mechanical ventilation is an art that remains in flux. While there are some basic tenants, each child and disease process have different characteristics. Therefore, the mode of ventilation chosen must be evaluated to be sure it is optimal for the child and their illness.

The two commonly used ventilation modes are pressure and volume, with many variations depending on the ventilator. The modes are based upon what variables cause the ventilator to cycle from inspiration to exhalation. These variables include time, flow rate, pressure, and volume. Air/oxygen is delivered to the patient under positive pressure until a certain volume is delivered, a certain pressure is achieved, or time/flow criteria are met. The ventilator then diverts flow and allows the patient to passively exhale. The positive end expiratory pressure (PEEP; which is the pressure which is maintained using flow resistance, during exhalation), is also set, depending on the child's underlying illness. The ventilator stops diversion of flow when this pressure is achieved and maintains the end expiratory pressure until the next positive pressure breath is initiated.

There are pros and cons to each type of ventilation and advocates for each. It is known that mechanical ventilation may cause lung damage either due to "volutrauma" (trauma due to rapid, repetitive changes in lung volume) and/or "barotrauma" (trauma due to rapid, repetitive changes in lung pressure). The repetitive expansion and collapse of the lung can cause parenchymal injury and may alter lung water and mucociliary clearance. Which mode of ventilation is superior (if there is a "best" mode) depends upon the patient and their disease process. The basic difference between the ventilator methods, is the parameter used to end the inspiration cycle (pressure or volume). In pressure controlled ventilation, a PIP (peak inspiratory pressure) and an inspiratory time (IT) duration determines the inspiratory cycle. The advantage of a pressure ventilator is that it should help protect the lungs from excessive pressures. However, tidal volume (TV) may then be compromised. TV and pressure are related by the equation:

Lung tissue compliance = change in volume / change in pressure

So, as a child's lung compliance worsens (decreases), the TV delivered will decrease for a given PIP. Similarly, if volume ventilation is chosen, the peak pressure will change based upon changes in lung compliance.

There are other characteristics of ventilators, such as the "mode", which should also be considered. These include:

Assist control modes: The ventilator delivers a set TV or PIP at a preset interval and with each patient's spontaneous respiratory effort (i.e., the patient's initial breathing effort, will trigger the ventilator to deliver another breath in synchrony). This mode is not commonly used in pediatrics.

IMV (intermittent mandatory ventilation): The ventilator delivers mandatory positive pressure breaths at a set rate. The patient may have unassisted spontaneous breaths between ventilator breaths, but the ventilator breaths are not synchronized with the patient's breaths.

SIMV (synchronized intermittent mandatory ventilation) pressure support: This method synchronizes the ventilator breaths with the patient's inspiratory efforts, thereby preventing the stacking of a ventilator breath on top of a spontaneous breath. Pressure support is the provision of a specified amount of positive pressure to assist the patient's own respiratory effort.

With some understanding of the modes of ventilation, the variables to be set on mechanical ventilators will be reviewed. These generally include respiratory rate (breath per minute), FiO2 (fraction of inspired oxygen), inspiratory time, and TV or PIP (depending on mode chosen). The starting respiratory rate (RR) is in part age determined, commonly: 30-50 in neonates, 25-30 in infants, 20 in children, 10-15 in teenagers. The rate is also dependent on the disease process. For example, patients who have air trapping/hyperinflation disorders (such as asthma) need a longer expiratory phase and therefore, a slower rate. You may have noticed that the set rate on the ventilator is often lower than that of a spontaneously breathing child of the same age/size. This is because the ventilator gives larger than normal tidal volumes "sigh breaths"). Spontaneous breaths are usually about 6-7cc/kg, whereas set tidal volumes are 10-l5 cc/kg. Recall that minute ventilation = TV x RR. So, if large tidal volumes are given, the RR needed to maintain the same minute ventilation will be lower.

In choosing a TV or PIP, the most important tenant to remember is, in general, to use a volume or pressure that causes good visible chest rise and air entry on auscultation. For TV ventilation, the starting range is usually about 10-l5 cc/kg. For pressure ventilation the pressure needed to move the chest will depend on lung compliance. A good way to judge this is to hand ventilate the child using an anesthesia bag with a manometer, to determine what pressure is required to move the chest. A typical range for a PIP in a lung with good compliance might be 16 to 20 mmHg vs up to 30 or 40 in a poorly compliant lung (20 being used for a mildly stiff lung such as a neonate with RDS).

The inspiratory time (IT or I-time) is also age and rate dependent and will also need to be altered depending on the child's disease. A guideline is 0.4-0.7 seconds for infants and 0.5-1 seconds for children and adults. Longer I-times increase mean airway pressure (by prolonging the inspiratory cycle) and therefore usually improve oxygenation.

In nonventilated patients, the glottis opens and closes during spontaneous respirations. Partial closure of the glottis provides a physiologic "PEEP" of 3-4mmHg by preventing complete emptying of the airway (i.e., we normally exhale against some resistance to maintain positive pressure in the alveoli during exhalation). In patients with good oxygenation and little pulmonary disease, a PEEP of 3-4 is adequate. Higher PEEPs are necessary for the patient with pulmonary edema, pneumonia, or atelectasis. High PEEP may also be useful for the post operative heart patient with surgical bleeding. Be aware that increasing PEEP increases mean airway pressure. Patients with high mean airway pressures may require volume infusions to maintain venous return and cardiac output. Inotropic support may also be needed in patients requiring very high PEEP (>10).

FiO2 is generally 100% during intubation but should be rapidly reduced, if possible, once mechanical ventilation is initiated. Weaning FiO2 can be done by monitoring pulse oximetry or ABGs. Oxygen is thought to be non toxic if the FiO2 is maintained at 40% or less. Since patients who are intubated are at high risk for ET tube plugging or displacement and resulting hypoxemia, we rarely reduce the FiO2 below 30%. Exceptions to this rule include children less than 34 weeks gestation (who are at risk for retinopathy of prematurity), and those with left to right shunts where the pulmonary vasodilation due to hyperoxygenation may result in excessive pulmonary blood flow. In general, saturations 95-100% are acceptable, although for children with severe ARDS (adult respiratory distress syndrome), BPD (bronchopulmonary dysplasia), or cyanotic heart disease, lower sats are expected/accepted.

In managing a ventilator, the settings of the ventilator should be adjusted to optimize the ventilatory support required by the patient. Too much oxygen or mechanical force may result in lung injury. Insufficient oxygen or mechanical force will result in hypoxia and hypoventilation. Assume that a normal blood gas is: pH 7.40, pCO2 40, pO2 100, BE 0, oxygen saturation 99% (refer to the chapter on interpreting blood gasses). In ICU patients, a higher pCO2 is sometimes tolerated (pCO2 45) to minimize ventilator trauma to the lung, and a lower pO2 is tolerated to minimize oxygen toxicity (oxygen saturation 95%). In premature infants, who are usually maintained with higher hemoglobins, lower pO2 values may be tolerated to minimize the risk of retinopathy of prematurity.

Adjusting the FiO2 will only affect the pO2 and oxygen saturation. Increasing the ventilator rate, will increase the minute ventilation so this decreases the pCO2 (and hence increases the pH). These are the two most basic changes that occur in ventilator management. One could also increase the minute ventilation (which would decrease the pCO2) by increasing the tidal volume (on a volume ventilator) or the PIP (on a pressure ventilator). Also realize that any parameter change which increases the mean airway pressure (MAP) will also increase the pO2. One could increase the mean airway pressure by increasing the PEEP, the inspiratory time, or the PIP. Increasing the tidal volume (TV) on a volume ventilator, in essence, increases the PIP so this also increases the MAP. Refer to the table below which describes the most commonly expected changes in pCO2, pO2 and MAP which occur with increases in the ventilator parameters in the column on the left:

Increase in:	pCO2	pO2	MAP
FiO2	no change	increase	no change
Rate	decrease	usually no change	increase
PIP/TV	decrease	increase	increase
Inspiratory time	usually no change	increase	increase
PEEP	usually no change	increase	increase

For example, a patient with an ABG: pH 7.28, pCO2 50, pO2 70, BE -3. One could improve oxygenation by increasing the FiO2, PEEP, IT, or/and PIP/TV. One could decrease the pCO2 and improve the pH by increasing the rate or/and PIP/TV. The best adjustment would be based on assessment of chest wall movement, aeration, expansion on chest x ray, the patient's pulmonary problems, and the current ventilator settings. For example, if the FiO2 is already at 95%, then it would be better to increase the PIP or IT rather than increase the FiO2.

Consider another ABG which may be encountered when the patient is improving: pH 7.45, pCO2 35, pO2 130, BE +0. The pCO2 is too low indicating that the minute ventilation is too high. The minute ventilation could be reduced by decreasing the rate and/or the PIP/TV. The pO2 could be lowered by decreasing the FiO2, PEEP, IT, and/or PIP/TV.

The rate and methods of weaning are quite variable, depending on the child's condition. It is therefore difficult to make general rules regarding this process. Some generalizations may be made:

The more acute the process, the faster weaning may take place.

ETCO2 monitoring or TCM monitoring may facilitate weaning and reduce the need for blood gases.

The child's baseline CO2 and O2 should be considered as weaning takes place. A "well" child with BPD may not have a normal CO2 of 40.

The child's clinical status should be considered as the weaning process takes place. An acceptable PCO2 is not evidence of "tolerating weaning" if the child is clinically in distress.

Prerequisites to extubation include:

1) A good cough/gag (to allow the child to protect their airway).
2) NPO about 4 hours prior to extubation (in case the trial of extubation fails and reintubation is required).
3) Minimize sedation.
4) Adequate oxygenation on 40% FiO2 with CPAP (or PEEP) = 4.
5) The availability of someone who can reintubate the patient, if necessary.
6) Equipment available to reintubate the patient, if necessary.

High frequency ventilation and negative pressure ventilation are specialized modes, which do not follow many of the "rules" of conventional ventilation. This is beyond the scope of this chapter but this is described well in a review article by Krishnan (4). High frequency ventilation is usually reserved for patients with very non-compliant lungs or those with air leak. Negative pressure ventilation (the old "iron lung" was a type of negative pressure ventilator) is infrequently used and is generally only useful for patients with neuromuscular disorders requiring long term ventilation at night.

Questions

1. SIMV stands for:
   a. synchronized intermittent mandatory ventilation
   b. simplified intermittent mechanical ventilation
   c. synchronized interspersed mechanical ventilation

2. Name 2 prerequisites for extubation.

3. True/False: The ventilator FiO2 should never be reduced below 40%.

4. True/False: There are very specific, pediatric evidence based protocols that will guide you, step by step, on ventilation management.

5. Minute ventilation = respiratory rate x _____

6. Physiologic PEEP is (in mmHg):
    a. 3-4
    b. 1-2
    c. 5-6

7. A good indicator of adequate tidal volume is:
    a. good chest rise
    b. adequate breath sounds
    c. oxygen saturation = 100%
    d. a and b

8. As compliance worsens in a child receiving pressure controlled mechanical ventilation, the TV delivered to the patient will:
    a. increase
    b. decrease

9. If the patient has the ABG: pH 7.28, pCO2 50, pO2 120, BE -3, which of the following ventilator changes would NOT be a good idea:
    a. decrease the FiO2
    b. decrease the I-time
    c. decrease the PEEP
    d. decrease the rate

Answers to questions

1. a
2. Coughing or gag intact. NPO. Minimized sedation. Adequate oxygenation on 40% FiO2 with CPAP less than or equal to 4. Availability of personnel to reintubate if necessary. Availability of equipment to reintubate if necessary.
3. False
4. False
5. tidal volume
6. a
7. d
8. b
9. d

Chapter XIV.6. Submersion Injuries
Francisco J. Garcia, MD

A 14 month old male infant presents to the emergency department via ambulance in full arrest. His mother left him playing in the living room. After 30 minutes, she was not able to find him inside the house. He was found at the bottom of the swimming pool. The screen door which leads to the pool was found to be open. Initially, he was cold, blue and limp. She started CPR after calling 911. The EMS team performs CPR and resuscitation en route to the hospital. The infant is intubated and epinephrine is administered via the tracheal tube. An intraosseous (IO) line is started and epinephrine is given IO as well. After 35 minutes of resuscitation efforts in the emergency department, the infant is pronounced dead.

Submersion injuries, which include drowning and near-drowning continue to be one of the leading causes of deaths in children, after motor vehicle accidents and cancer. In the United States, approximately 5000 children and adolescents die every year as a result of submersion injuries (1,2). Submersion injuries have a bimodal age distribution. The first peak is seen in infants and toddlers less than 4 years of age, who are susceptible to submersion in swimming pools, baths or household buckets (2). Lack of caregiver supervision, neglect, and suboptimal barriers are contributing factors. The second peak occurs in adolescents and is associated with risk-taking behaviors as well as alcohol and drug use. Coexisting trauma and suicide intent should always be considered in this older age group (3).

Drowning is defined as death within the first 24 hours of submersion, which includes death at the scene. Near-drowning is defined as submersion in which survival is greater than 24 hours, regardless of morbidity and mortality. The common pathophysiologic events in all drowning incidents are asphyxia and hypoxia. After a submersion incident, most victims will go through a period of struggle and breath-holding, or water will enter the oropharynx and larynx resulting in choking and laryngospasm (4,5). This will lead to hypoxia and loss of consciousness, followed by asphyxia and death. Loss of protective reflexes will occur in most victims, leading to water aspiration. This is known as "wet drowning." In 10% to 20% of victims, intense laryngospasm persists and no significant amount of water enters the lungs, even though the victim is unconscious (4,5). This is also known as "dry drowning." A great deal of controversy existed in the past regarding the pathophysiology of drowning and near-drowning. Sufficient research data has shown that there are no significant physiologic differences between salt water and freshwater submersions or wet and dry drowning. Salt water submersion victims will likely be hypernatremic and fresh water submersion victims will likely be hyponatremic, but this difference does not appear to be clinically important in most instances, and is largely due to swallowed water rather than aspirated water.

All organ systems are affected after a submersion injury as a result of asphyxia, hypoxia and acidosis. Respiratory failure, aspiration pneumonia, barotrauma, and adult respiratory distress syndrome (ARDS) are frequent complications. Arrhythmias as well as cardiogenic shock may also be seen. Renal dysfunction is a common finding (acute tubular necrosis). Liver and gastrointestinal dysfunction may also occur. However, it is the irreversible hypoxic-ischemic damage to the brain that accounts for most of the long term complications (2,6). Risk factors that have been identified as indicators of irreversible neurologic injury and mortality include (2,6):

1) Age less than 3 years.
2) Submersion longer than 5 minutes.
3) Resuscitation not attempted for 10 minutes after rescue.
4) Seizures, fixed/dilated pupils, decerebrate posture, flaccid extremities and/or coma.
5) Asystole on arrival to the emergency department.
6) Arterial blood pH <7.1.
7) Elevated blood sugar level.
8) Glasgow Coma Scale <5.
9) Apnea after cardiopulmonary resuscitation.

A classification of submersion victims based on neurologic function was developed by Conn and Baker (7,8). This classification has several advantages: 1) It estimates the magnitude of hypoxic insult. 2) It guides the selection of appropriate therapy. 3) It is highly predictive of outcome. The classification is as follows:

Category A: Awake, alert, fully conscious, minimal injury.

Category B: Blunted, obtunded to stuporous, normal central respiratory drive, purposeful responses to pain.

Category C: Comatose. Unarousable, abnormal central respiratory pattern, abnormal motor responses to painful stimuli, seizures may occur. Category C is further divided into subcategories based on worsening CNS function: C1) Decorticate, Cheyne-Stokes respirations. C2) Decerebrate, central hyperventilation. C3) Flaccid, apneustic or cluster breathing. Manifestations of multiorgan dysfunction failure appear in category C (7,8).

The management of the drowning victim starts in the field with bystander cardiopulmonary resuscitation (CPR) after activation of the Emergency Medical System (EMS). The goal is to improve oxygenation and ventilation as rapidly as possible to minimize cerebral hypoxic-ischemic damage. The neck should be immobilized if there is a suspicion of spinal cord injury (e.g., intoxicated adolescent). Patients should be kept warm and dry. Hypotension should be treated aggressively. All patients should be transported quickly to the emergency department for further evaluation and treatment. Initially, vital signs and core temperature are obtained, followed by respiratory, cardiovascular and neurologic evaluation. Traumatic injuries should be excluded. Initial laboratory tests include: arterial blood gas (ABG), chest radiograph, electrolytes and serum glucose. Optional tests to be considered include: CBC, renal function tests, liver function tests and urinalysis. Even the ABG is optional in many instances since oxygenation can be measured via pulse oximetry and metabolic acid-base status can be determined from the serum bicarbonate. Most patients with a significant submersion injury should be admitted to the hospital for observation; however category A patients, with no other significant injuries, may be discharged from the emergency department after a period of observation.

Although the survival rate has improved with advances in emergency care, prevention is the best strategy. Parental supervision of infants and children while in and around water is essential. Early swimming lessons have not been shown to reduce the incidence of drowning. The policy statement published in 2000 by the American Academy of Pediatrics entitled, "Swimming Programs for Infants and Toddlers" does not endorse swimming instructions for infants and children until after their fourth birthday (9). Moreover, children and adolescents prone to conditions such as syncope and seizures should always have a partner. So far, the only environmental preventive strategy that has decreased the number of submersion injuries in children is the installation of four-sided fencing that isolates the pool from

the house (i.e., the house itself should not open directly into the pool area). Finally, all parents should be trained in cardiopulmonary resuscitation (CPR), since rapid institution of effective oxygenation and ventilation after a submersion injury has been associated with improved outcomes.

Questions

1. All of the following are considered risk factors for drowning except:
    a. Head trauma
    b. Alcohol use
    c. Upper respiratory infection with wheezing
    d. Seizure disorder
    e. Illegal drug use

2. True/False: The American Academy of Pediatrics advocates swimming classes for all children over two years of age.

3. Which of the following factors is associated with a poor outcome in a drowning case?
    a. Low blood sugar level
    b. Submersion longer than 5 minutes
    c. Drug or alcohol use
    d. Return of spontaneous cardiac rhythm following CPR
    e. CPR for less than 3 minutes

4. Which of the following interventions will improve the outcome in a drowning victim?
    a. Early intubation
    b. Transfer to a trauma center
    c. Intravenous access
    d. Early bystander CPR
    e. Cervical spine precautions

5. All of the following are complications after a submersion injury except?
    a. Adult respiratory distress syndrome (ARDS)
    b. Arrhythmias
    c. Renal dysfunction
    d. Hypernatremia
    e. Aspiration pneumonia

Answers to questions

1. c
2. False. The AAP recommends against swimming lessons below the age of 4 years.
3. b
4. d
5. d. Hypernatremia may occur in a salt water submersion victim, but it is not considered clinically important in most instances and it is not considered to be a "complication".

Chapter XIV.7. Pneumothorax and Other Air Leaks
Edward W. Fong, MD

A father brings his 8 year old daughter into your office because "she is not able to catch her breath". He reports that she has just recently recovered from a cold, but has continued to cough. She often coughs in fits with post-tussive emesis, will sometimes turn blue in the face, and makes a "gasping-like" noise when she tries to inhale after a coughing episode. Currently, she complains about a pain in her chest and shortness of breath. According to her father, the onset of these symptoms began "after one of those coughing fits this morning". There is an ill contact in the house (a grandfather who has been coughing for the last 3 months).

Exam: VS T 37.1, HR 94, RR 28, BP 115/77, Oxygen saturation 93-95% in RA, height is 50-75th %ile, and her weight and head circumference are both in the 10-25th %ile. She is sitting on the exam table, leaning forward, taking quick breaths with some nasal flaring. She has slightly asymmetrical chest movements (her right chest wall moves less than her left) and she has decreased breath sounds with hyper-resonance and decreased tactile fremitus on the right as well. Her PMI and trachea are normally positioned, her sensorium is normal, and she has regular and symmetrical radial and femoral pulses. Since you suspect a pneumothorax, your nurse places the patient on 2 liters/minute of oxygen via nasal cannula while you arrange for medical transport to the Emergency Department.

Upon arrival at the ED, the patient's vitals are relatively unchanged except that her oxygen saturation is 100% on the 2 liters/minute of oxygen. She is switched to a non-rebreather mask with a FiO2 of 100% and sent for a PA and lateral CXR. Upon confirmation by the radiologist, she is diagnosed with a right, simple, primary spontaneous pneumothorax. It is estimated to be about 12% in size. She is admitted to the hospital for observation and continued oxygen therapy. She remains clinically stable overnight and her follow-up morning CXR showed a small decrease in the size of the pneumothorax. She is then taken off of oxygen and has another CXR performed the following morning. Although this CXR does not show any further decrease in the size of the pneumothorax, it had not increased. She is discharged home with instructions to follow-up with you the next day.

Air leak syndromes encompass a wide-spectrum of diseases including pneumomediastinum, pneumothorax, pneumopericardium, pneumoperitoneum, subcutaneous and interstitial emphysema, and pulmonary pseudocyst. Due to the pathophysiology of air leak syndromes, more than one of these disease processes are often present concomitantly. The exact prevalence and incidence of the differing air leak syndromes is hard to determine. The best estimates exist for pneumothoraces. From a study of Minnesota residents between 1959 and 1978, it has been estimated by extrapolating the data, that about 9000 people in the United States develop a primary spontaneous pneumothorax annually (1). In a recent American College of Chest Physicians (ACCP) Delphi Consensus Statement, it is estimated that, in the United States, both primary and secondary spontaneous pneumothoraces affect more than 20,000 patients and accounts for nearly $1.3 million in health care expenditures annually (2). Pneumothoraces are also found in about 5% of hospitalized asthmatic children and about 10-25% of cystic fibrosis patients older than 10 years old (3).

Thoracic air leak syndromes result from a free communication with the atmosphere, either from a pleura defect or from alveolar rupture. They are rarely caused by infection with a gas-producing microorganism (4). The type of air leak syndrome that develops will depend on the location and the nature of the communication. Although air leaks can be caused spontaneously, the majority of them are secondary to some type of trauma (intentional, accidental, mechanical, and iatrogenic). A retrospective case review by Kizer et al. found that over a 5 year period, 95% of patients who developed a pneumothorax while engaged in an outdoor sport had blunt chest trauma as the etiology (5). The mechanism of alveolar air leaks begins with positive intra-alveolar inflation pressure causing an increase in the air volume of the alveolus with a simultaneous decrease in the blood volume of the adjacent alveolar blood vessels. The difference between the changes in these respective volumes causes an attenuation of the tissue that tethers the perivascular sheath to the alveolar wall. When the traction force exceeds the tissue's tensile strength, a rupture of the base of the alveoli occurs allowing gas to escape into the perivascular space. The escaping air may then dissect along perivascular planes into the mediastinum (pneumomediastinum), into the pericardium (pneumopericardium), into the pleural space (pneumothorax), into the peritoneal cavity (pneumoperitoneum), out of the thorax along subcutaneous tissue planes (subcutaneous emphysema), and/or be confined to the interstitium of the lung (interstitial emphysema) (4). Since pneumothoraces are the most common type of air leak syndrome, the rest of the discussion will concentrate on this entity.

A pneumothorax is defined as the abnormal presence of air in the pleural space (6). Pneumothoraces are categorized as spontaneous or traumatic and classified as simple, communicating, or tension (1,7). Spontaneous pneumothoraces should be further categorized as primary or secondary. A primary pneumothorax occurs in an otherwise healthy person without underlying disease (rupture of a subpleural emphysematous bleb), while a secondary pneumothorax occurs as a complication of an underlying lung disease (COPD, tuberculosis, asthma) (1). Traumatic pneumothoraces may be caused by penetrating or blunt trauma, mechanical ventilation, central line placement, or toxic inhalations. A simple pneumothorax occurs when there is an accumulation of air without any communication to the atmosphere and without causing a shift of the mediastinum or hemidiaphragm. A communicating pneumothorax ("sucking chest wound") occurs when there is an associated defect in the chest wall (7). This defect may cause paradoxical chest wall movement (collapse during inhalation and expansion during exhalation) along with the sonorous sound of air entering and exiting the wound. A tension pneumothorax occurs when the progressive accumulation of air causes a shift of the mediastinum to the opposite hemithorax causing a subsequent compression of the contralateral lung and great vessels (7). Communicating and tension pneumothoraces may result in the rapid onset of hypoxia, acidosis, and shock.

Although the cardinal manifestation of a pneumothorax is the sudden onset of chest pain, symptoms will vary depending on the extent of lung collapse, degree of intrapleural pressure, rapidity of onset, age, and respiratory reserve of the patient (4,6). Symptoms that may be present include: tachypnea, dyspnea, tachycardia, and cyanosis. The chest pain may range from a localized sternal pain to an overwhelming pleuritic pain difficult to localize (6). Ipsilateral shoulder pain is common. There is usually a decrease in breath sounds, tactile fremitus, and a decrease in thoracic excursion while there is an increase in resonance to percussion on the affected side. Hamman's sign may be present in any type of air leak syndrome, which sounds like a fine rub (similar to Velcro). Hamman's sign is often mistaken for a pericardial friction rub.

If a tension pneumothorax is present, displacement of the trachea and PMI toward the contralateral side may occur as well as rapid deterioration with hypotension and bradycardia. In young children, tracheal displacement is not very common even with tension pneumothoraces.

The diagnosis of a pneumothorax should be confirmed by radiographs. Two views, AP and lateral, should be obtained. These may be supplemented by a cross-table lateral or lateral decubitus views. Expiratory views may help to visualize a small pneumothorax.

Radiographs will help to differentiate a pneumothorax from emphysema, an emphysematous bleb, diaphragmatic hernia, compensatory overexpansion, large pulmonary cavities, contralateral atelectasis, or other cystic formations. A CT scan is not necessary unless it is a recurrent primary spontaneous pneumothorax or a secondary spontaneous pneumothorax.

The treatment of a pneumothorax is determined by its classification. A tension pneumothorax usually results in cardiopulmonary compromise (shock, bradycardia, hypoxia) requiring immediate needle decompression (thoracentesis), which can be accomplished by inserting a large bore (16 or 18 gauge) needle (smaller gauge needles are satisfactory for premies, newborns and infants) through the second or third interspace (near the apex of the lung) in the midclavicular line. Immediate decompression cannot wait for radiographic confirmation. In fact it is often said, that if you see a tension pneumothorax on a CXR, the patient may already be dead or you are NOT looking at a tension pneumothorax, but something that is mimicking one instead. Tube thoracostomy (commonly called a chest tube) may be required after the initial decompression if the pneumothorax reaccumulates. A communicating pneumothorax should have the defect covered immediately, which helps to convert the condition to a simple pneumothorax. An occlusive dressing using petroleum gauze may be applied, but this must be done with caution as it can cause the development of a tension pneumothorax. Once the patient is in a hospital setting, he/she should be intubated and tube thoracostomy performed until she can be taken for definitive surgical repair.

There are two instances when a tension pneumothorax tends to occur more commonly: 1) positive pressure ventilation (i.e., in the ICU on a ventilator), and 2) external penetrating trauma (knife or bullet wound to the chest). The mechanics of this involve a valve effect of the air leak. A positive pressure ventilator pushes air into the pleural space through the leak, while during exhalation, the leak valve closes and does not permit the pleural air to escape. A penetrating wound to the chest may produce a slit into the pleural space, which sucks air into the chest when the patient inhales, but this air is trapped in the pleural space because the slit closes when the patient exhales. While a tension pneumothorax can occur in other conditions, it is largely these two conditions in which you are most likely to encounter a tension pneumothorax.

Management of a simple pneumothorax depends on its size and etiology. According to the ACCP Consensus Statement for primary spontaneous pneumothoraces, clinically stable patients with a small pneumothorax (occupying <15% of the hemithorax) (1) should be observed in the emergency department for 3 to 6 hours and discharged home if: 1) a repeat CXR demonstrates no progression of the pneumothorax, 2) the patient does not live a far distance from emergency services, and 3) there is reliable follow up care (2). If the patient is to be admitted to the hospital, oxygen therapy may be initiated since 100% oxygen will hasten the absorption of the pneumothorax (possibly by eventually enriching the pneumothorax with oxygen which is more soluble in blood). Clinically stable patients with a large primary spontaneous pneumothorax should be admitted to the hospital and undergo tube thoracostomy (2). The chest tube should not have negative pressure applied immediately, but rather it should initially be put to water seal to allow the trapped air to exit slowly. This precaution is done to avoid rapid reexpansion of the lungs, which can result in pulmonary edema.

The ACCP Consensus Statement for clinically stable patients with a small, secondary spontaneous pneumothorax recommends that these patients should all be hospitalized. The decision between observation and tube thoracostomy depends on the extent of the patient's symptoms, course of the pneumothorax, and practitioner choice (2). Clinically stable patients with a large secondary spontaneous pneumothorax should be treated similarly to the clinically stable patients with a large primary spontaneous pneumothorax. Any clinically unstable patient with a pneumothorax of any size should be immediately stabilized, decompressed, and hospitalized (2).

Procedures to prevent the recurrence of a pneumothorax should be reserved for secondary spontaneous pneumothoraces, a second episode of a primary spontaneous pneumothorax, or the persistence of an air leak regardless of whether or not it is the first episode of a pneumothorax. The procedure to prevent recurrence often involves bullectomy and/or pleurodesis usually through video-assisted thoracoscopy. However, the practitioner of a patient who may require lung transplantation in the future should consider consulting with the potential transplant team before undertaking pleurodesis.

The recurrence of spontaneous pneumothorax is common (40-87%), especially if the initial episode was slow to resolve (>7 days) or if the underlying disorder is not corrected (4). Activities that involve rapid or profound changes in barometric pressure (scuba diving, flying in unpressurized aircraft, etc.) should be avoided.

Pneumomediastinum and subcutaneous emphysema in the neck region are usually benign conditions if the patient is only minimally symptomatic, but they may precede a pneumothorax in some instances. If associated with respiratory distress, the air leaks signify a higher risk. Pneumopericardium is associated with cardiac tamponade and a high risk of mortality even if decompression is attempted.

Questions

1. True/False: A primary spontaneous pneumothorax in a tall thin boy does not require further work-up other than for treatment of the pneumothorax.

2. In order to emergently decompress a tension pneumothorax, one should insert a large bore needle between:
   a. the second and third interspace in the midaxillary line
   b. the fourth and fifth interspace in the midclavicular line
   c. either a or b
   d. neither a or b

3. List the different categories and classifications of pneumothoraces.

4. Pick the two conditions which you would most likely to encounter a tension pneumothorax:
   a. NICU ventilator patient for RDS.
   b. Near drowning patient on blow-by oxygen.
   c. Hydrocarbon aspiration.
   d. Blunt chest trauma.
   e. Stab wound to the mid lateral torso.

5. True/False: A chest tube is always the standard of care for the treatment of a pneumothorax.

6. A "sucking chest wound" refers to what kind of air-leak syndrome?
   a. Interstitial emphysema
   b. Simple pneumothorax
   c. Tension pneumothorax
   d. Communicating pneumothorax
   e. Pneumomediastinum

Answers to questions

1. False. A patient with this type of body habitus should have a work-up that includes looking for a connective tissue disorder such as Marfan’s syndrome.

2. d. It is the second or third interspace in the midclavicular line or the fourth or fifth interspace in the midaxillary line.

3. Categories: Spontaneous and traumatic. Subcategories: Primary and Secondary. Classifications: Simple, Communicating, and Tension.

4. a & e. Tension pneumothorax is most likely to occur on ventilator patients and hose with penetrating chest trauma. A stab wound to the lateral mid thorax is very likely to have entered the lower thorax.

5. False. Treatment depends on the classification of pneumothorax.

6. d.

Chapter XIV.8. Trauma

Alson S. Inaba, MD
Rodney B. Boychuk, MD

A 3 year old boy was hit by a car as he ran out into the street to chase his soccer ball. When the paramedics arrived at the scene he was unconscious and had sustained multiple abrasions to his face, chest, abdomen and extremities. His right thigh was noticeably deformed and swollen. Because he demonstrated very shallow respirations, he was immediately intubated with in-line cervical spine immobilization. Two large bore IV lines where placed and he was then rushed to the trauma center.

Exam: VS T 37.0, P160, RR ventilated via the tracheal tube at 20, BP 100/80, oxygen saturation 97%. He is still unresponsive and being ventilated via the tracheal tube. His pupils are briskly reactive to light. There is excellent chest wall rise and fall via ventilation through the tracheal tube. There are numerous abrasions over his face, chest, abdomen and lower extremities. The abdomen is distended with decreased bowel sounds. His pelvis is stable, but his right thigh is obviously swollen and tense. Distal perfusion to all four extremities seems adequate. The remainder of his physical examination is unremarkable.

A CT scan of his head reveals a small occipital lobe contusion but no cerebral edema or hemorrhage. The CT scan of his abdomen reveals a small splenic laceration and a mild contusion of the left kidney. Chest and extremity radiographs reveal a displaced midshaft right femur fracture and a small left pulmonary contusion. His cervical spine and pelvic radiographs are normal. After appropriate stabilization interventions, he is admitted to the pediatric intensive care unit. His intracranial, pulmonary and splenic injuries are managed with supportive care and his femur fracture is reduced with open reduction and internal fixation. He is eventually discharged from the hospital approximately three weeks later, neurologically intact, and he is back to playing soccer a year later.

Each year there are approximately 1.5 million injuries sustained by children (1). Although the majority of these children recover uneventfully, the overall mortality rate of pediatric trauma is estimated at 1.5% (1). Each year, 250,000-500,000 children are hospitalized with various trauma-related injuries. Of these children who are hospitalized, 50,000-100,000 are left with some degree of permanent disability (1).

Blunt trauma accounts for approximately 87% of all childhood injuries, with penetrating trauma accounting for only 10% (2). Motor vehicle-related accidents are responsible for 40% of blunt pediatric trauma and are the leading cause of trauma-related fatalities in children (1). Injuries due to falls are the second most common etiology of blunt trauma in children.

Although children are susceptible to the same mechanisms of injury as their adult counterparts, a child's physiologic and psychologic responses to trauma are very unique. Thus a thorough understanding of some of the unique anatomic and pathophysiologic differences of children will enhance the quality of care that is provided during the evaluation, stabilization and management of the pediatric trauma patient.

One of the first very obvious physiologic differences between children and adults is the variation of normal pediatric vital signs based on the age of the child. A thorough understanding of pediatric vital signs is imperative in being able to detect very subtle abnormalities in a child's heart rate and respiratory rate. For example a subtle tachycardia may be the only clue to the possibility of early hemorrhagic shock in a child who otherwise looks stable. A subtle tachypnea may be the earliest clue to possible intra-thoracic injuries in a child with a normal room air oxygen saturation. Thus, anyone involved in the emergency care of children must be aware of normal vital signs based on a child's age. A simplified method to easily and quickly recall pediatric vital signs is as follows (3):

	Heart rate	Respiratory rate
Newborn to 1 year old	140	40
1 to 4 years old	120	30
4 to 12 years old	100	20
>12 years old	80	15

A summary of some of the key anatomic differences in children are as follows (1):

a) Smaller body size.
b) Larger head-to-body ratio.
c) Greater body surface ratio.
d) Shorter trachea and relatively larger tongue size.
e) Glottic opening more anterior and superior.
f) Less protective muscle and body fat.
g) Abdominal organs more anterior.
h) Growth plates of long bones are more susceptible to injury.

Because of a child's smaller body size, traumatic forces can be distributed over a larger surface area, thus making multisystem trauma the rule rather than the exception with childhood injuries (1). Children often times sustain internal injuries with minimal to no evidence of trauma on the external surface of their bodies. The internal organs of a child are more susceptible to traumatic forces because of their decreased amount of protective muscle and surrounding subcutaneous tissue mass. The spleen is the most commonly injured organ associated with blunt abdominal trauma. The increased flexibility and resilience of the pediatric skeleton and surrounding soft tissues also permits traumatic forces to be transmitted deeper into the internal structures. Thus as a general rule, internal injury cannot be ruled-out in a child merely based on the absence of external signs of trauma.

The larger head-to-body ratio of infants and young children makes them more susceptible to head injuries during falls. The larger head size also affects the fulcrum forces along the neck, making upper cervical spine injuries more common in infants and younger children as opposed adults who more commonly sustain injuries to their lower cervical spine. The larger head size as well as the increased body surface area in children make them more susceptible to greater heat loss and hypothermia when they are exposed during the trauma resuscitation.

The unique anatomic differences of the pediatric airway are critical to keep in mind when assessing and managing airway, breathing and ventilation in children. The shorter tracheal length, larger tongue size and the more anterior/superior location of the glottic opening are

key points to remember when attempting intubation in children. Because the pediatric epiglottis is less cartilaginous, use of a straight laryngoscope blade may facilitate intubation rather than the curved blades.

Pediatric head trauma is associated with the highest degree of morbidity and mortality. Injuries to the chest and abdomen also account for a fair amount of disability and death. Hypoxia and hemorrhagic shock are the final common pathways involved in pediatric trauma-related fatalities. Thus very strict attention to the assessment of a child's airway, breathing and circulation (ABCs of resuscitation) will reduce the morbidity and mortality of pediatric trauma.

The assessment and management of trauma patients is divided into the primary survey and secondary survey. The "ABCDE" of the primary survey involves the assessment of the following components:

A=Airway (cervical spine immobilization).
B=Breathing.
C=Circulation (with hemorrhage control).
D=Disability (a brief neurologic examination assessing the level of consciousness and pupillary size/reactivity).
E=Exposure (total exposure of the patient to be able to assess the entire body for possible injuries).

The major components of the primary survey therefore involve the assessment, stabilization and management of all acute, life-threatening conditions such as airway compromise, respiratory distress and hemorrhagic shock. This portion of the ABCs of trauma resuscitation are basically the same as in other resuscitation scenarios with two major caveats. These two caveats involve the possibility of cervical spine injury and hemorrhagic shock. The proper sequence that should always be adhered to in any resuscitation can be remembered by the mnemonic "A-I-R" (1):

A=Assessment
I=Interventions
R=Reassessment after each intervention

During the assessment and management the airway of any trauma patient, one must always consider the possibility of a neck injury and maintain cervical spine immobilization. This is extremely important if you are considering endotracheal intubation, during which time the airway should never be opened using the head-tilt maneuver. The jaw-thrust maneuver to open the airway with in-line cervical spine immobilization is the safest method to intubate any child with a potential cervical spine injury.

When assessing breathing and ventilation, always consider traumatic etiologies that could potentially compromise the child's ventilation and breathing such as open chest wounds, pneumothorax, hemothorax, rib fractures, flail chest and pulmonary contusions. Some of these traumatic etiologies may require immediate interventions such as needle thoracentesis and/or placement of a chest tube during the primary survey. Gastric distention which is also very common in pediatric trauma patients, can also compromise ventilatory efforts secondary to upward displacement of the diaphragm. Thus an orogastric tube may be helpful to decompress the stomach and thereby facilitate ventilatory efforts.

The most common etiology of shock in the pediatric trauma patient is hemorrhagic shock, although concomitant cardiogenic (e.g., cardiac tamponade), obstructive (e.g., tension pneumothorax) and neurogenic (e.g., spinal shock) may also exist. The increased reserve of a child's cardiovascular system allows children to compensate and maintain normal blood pressures despite even moderate degrees of hemorrhagic shock. Children will maintain a normal systolic blood pressure for age until they have lost up to 30% of their circulating blood volume (4). The circulating blood volume of a child is 70-80 ml/kg as compared to the typical adult circulating blood volume of 60 ml/kg. A normal systolic blood pressure for a child can be calculated via the formula: (Age X 2) + 90 mmHg. The corresponding expected diastolic blood pressure should be 2/3 X (SBP). The initial compensatory mechanism that one should look for during the early stages of hemorrhagic shock is tachycardia. The other compensatory mechanism that occurs to maintain normal perfusion and blood pressure is an increase in the systemic vascular resistance, which is manifested clinically by mottled/cool extremities, weak/thready distal pulses, delayed capillary refill time and a narrowed pulse pressure. If the early clinical signs of hemorrhagic shock are not identified and corrected, the child may progress to a preterminal stage of decompensated shock, which is defined as hypotension for age. Hypotension (systolic) in any aged child is defined via the formula: (Age X 2) + 70 mmHg. Thus a 5 year old child who presents with an initial systolic blood pressure less than or equal to 80 mmHg is already in the phase of decompensated shock and clinical has loss at least 30% of his circulating blood volume. The minimum systolic blood pressures for age are:

a) Newborns to 1 month old: >60 mmHg
b) 1 month old-1 year old: >70 mmHg
c) > 1 years old: (Age X 2) + 70 mmHg

The keys to the treatment of hemorrhagic shock in the pediatric trauma patient includes recognition of the early signs of shock, controlling any external sites/sources of hemorrhage, rapid fluid resuscitation to restore the circulating blood volume, early consideration of blood replacement therapy and an early involvement of the surgical team. Rapid fluid boluses are administered as 20 ml/kg of warmed crystalloid solutions (i.e., normal saline or lactated Ringer's solution are the only two acceptable solutions to use during fluid resuscitation). It is imperative to reassess the child's perfusion parameters after each fluid bolus in order to determine if additional fluid boluses will be required. If more than 40-60 ml/kg of crystalloid solution is required to restore adequate perfusion, blood replacement must then be considered. Blood replacement can be administered as either 10 ml/kg of warmed packed red blood cells (either crossmatched, type-specific or O-negative PRBCs, depending on how much time is available) or as 20 ml/kg of whole blood (not routinely available nowadays). Children who require blood replacement therapy may need surgical interventions to control the ongoing hemorrhage. Injuries that have the potential for extensive hemorrhaging include intra-abdominal and intra-thoracic injuries, pelvic fractures and femur fractures. As a general rule, it is taught that intracranial bleeds in themselves do not result in hypovolemic/hemorrhagic shock. The one exception to this rule involves head trauma in infants. Because the suture lines of an infant's skull are not yet fused, the skull has the capability to expand and accommodate large volumes of blood during acute intracranial hemorrhage.

If there is any difficulty in establishing intravenous access for fluid resuscitation and/or the administration of blood products, intraosseous (IO) lines should always be considered. IO line placement can be inserted just as quickly or even faster than venous cutdowns or central line placement. Although the previous Pediatric Advanced Life Support guidelines only allowed for IO line placement in children under 6 years of age, the current guidelines now have no age limitation for the use of IO lines in children. Although the ideal site for IO line placement in children is the proximal, medial aspect of the tibia (2-3 cm below the tibial tuberosity), an alternative site is the distal anterior aspect of the femur (2-3 cm proximal to the superior edge of the patella). Another alternative site in older children and

adults is the distal tibia (2-3 cm proximal to the medial malleolus). The only clinical contraindications for placement of an IO line in a child's leg during trauma resuscitation would include: a) a suspected fracture of the underlying bone in which the IO line is placed, and/or b) a suspected traumatic disruption of the venous return proximal to the site of IO insertion.

The secondary survey begins with a reassessment of the life-threatening problems addressed during the primary survey and is then followed by a complete head-to-toe physical examination to assess and manage any non-life threatening injuries that were not identified during the primary survey. The assessment and management of specific head, neck, thoracic, abdominal, pelvic and extremity injuries is beyond the scope of this text. However a high clinical index of suspicion based on the mechanism of injury should always guide one's assessment and management. Although a more detailed assessment of child abuse is presented in another chapter of this textbook, the possibility of nonaccidental trauma (i.e., child abuse) should always be considered under certain circumstances (4): a) A discrepancy between the history that is presented by the caregivers and the actual physical examination findings. b) Injuries that are incompatible with a infant's neurodevelopmental capabilities. c) A delay in seeking medical advice/treatment for what appears to be a serious injury. d) Findings of multiple injuries at various chronological stages. e) Bites marks, cigarette burns or rope/cord marks. f) Burns with sharply demarcated margins. g) Genital or perianal trauma (including burns to these areas). h) Multiple subdural hematomas. i) Retinal hemorrhages. j) Rib fractures involving multiple ribs and/or at various chronological stages.

Successful resuscitation of the pediatric trauma victim involves more than just a systematic approach to the primary and secondary surveys. It also depends upon a thorough understanding of the unique anatomic and pathophysiologic differences in children. By keeping these unique differences in mind, trauma teams will be able to decrease the morbidity and mortality of pediatric trauma by providing more efficient and appropriate care for the injured child.

Questions

1. The first priority in the resuscitation phase of any pediatric trauma patient is:
    a. To immediately establish vascular access.
    b. To establish and maintain patency of the airway while maintaining cervical spine immobilization.
    c. To obtain immediate x-rays and laboratory studies in order to ascertain the patient's overall status.
    d. To alleviate any pain with intravenous analgesics in order to facilitate a more reliable physical examination.

2. The leading cause of death in children >1 year of age is:
    a. Sudden infant death syndrome.
    b. Lethal cardiac dysrhythmias.
    c. Meningitis.
    d. Trauma.
    e. Leukemia.

3. The most common etiology of shock in the pediatric trauma patient is:
    a. Neurogenic shock.
    b. Cardiogenic shock.
    c. Anaphylactic shock.
    d. Hypovolemic shock.
    e. Tension pneumothorax.

4. The main goal of the primary survey of trauma resuscitation includes:
    a. Obtaining STAT portable radiographs of the neck, chest and abdomen.
    b. Assessment and stabilization of the child's airway, breathing and circulation.
    c. Obtaining immediate vascular access with a central line.
    d. Performing immediate endotracheal intubation to prevent aspiration.
    e. A trauma surgeon must be present to perform the primary survey.

5. All of the following statements regarding pediatric trauma are true except:
    a. The majority of pediatric trauma-related fatalities are due to motor vehicle related accidents.
    b. The majority of trauma that occurs in children is due to blunt trauma rather than penetrating trauma.
    c. Cervical spine trauma is more common than abdominal trauma.
    d. Multisystem trauma is common in children who sustain motor vehicle related accidents.

6. The abdominal organ that is most commonly injured in children is the:
    a. Duodenum.
    b. Pancreas.
    c. Liver.
    d. Kidneys.
    e. Spleen.

7. What area of the body is associated with the greatest frequency of serious injuries in children?
    a. Head.
    b. Neck.
    c. Chest.
    d. Abdomen.

8. Which of the following scenarios would be most suspicious for possible child abuse?
   a. A 2 year old who presents with a tibial fracture after reportedly falling down a few steps.
   b. A 1 year old who presents with a forehead hematoma after reportedly falling out of a stroller.
   c. A 3 month old who presents with a nondisplaced femur fracture after reportedly rolling off the changing table.
   d. A 3 year old who presents with a spiral fracture of the tibia after reportedly getting his leg twisted while falling off a tricycle.

Chapter XIV.9. Toxicology

Alson S. Inaba MD

Case 1: A 2 year old boy reportedly ate 12 grape flavored chewable acetaminophen tablets that he found in the bathroom two hours ago. He already has had two episodes of vomiting. His mother calls the pediatrician and asks for advice. She states that her son is now playful and "looks fine." If you were this child's pediatrician, what recommendations would you give to his mother? In this case, the majority of the details regarding the ingestion are known yielding some data upon which treatment and management decisions can be made.

Case 2: A 15 year old girl reportedly took a whole box of diphenhydramine (Benadryl) tablets after she got into an argument with her boyfriend. She is brought to the emergency department by her parents who claim that she is "not acting right." She is slightly sleepy in appearance but seems to answer questions appropriately. She denies taking any other medications, alcohol or illicit drugs. She does not remember exactly when she took the diphenhydramine tablets. Her vital signs reveal HR 160, RR 18, BP 160/90, RA O2 sat 99%. Her physical examination is unrevealing. If you were the emergency department physician caring for this girl, what would be your assessment and plan of action? This case involves an intentional overdose situation involving a teenager which is a more difficult scenario to assess because the history that is provided is often incomplete and/or inaccurate/unreliable. For example, did she really ingest an entire box of diphenhydramine tablets as was reported? Is there the possibility that she ingested other substances in addition to the diphenhydramine? When did the reported overdose occur and is her degree of tachycardia and hypertension consistent with the medication that was allegedly ingested? Is it possible that this adolescent female is pregnant and if so, are any of your therapeutic interventions contraindicated in a pregnant female?

Case 3: A 3 year old boy is brought to the emergency department by the paramedics in status epilepticus. The father found his son seizing and immediately called 911. The child has never had prior episodes of seizures but he has had two days of low grade fevers along with a slight cough. He is not on any medications and his father denies any possibility of head trauma preceding the seizure. He requires IV anticonvulsants to terminate the seizure activity. Although you are contemplating the possibilities of meningitis and febrile seizures in your differential diagnosis, should the possibility of a toxic ingestion/exposure also be considered in the differential diagnosis in this case? This case illustrates how one must consider the possibility of a toxic exposure in the differential diagnosis of a patient who presents to the emergency department with severe, life threatening signs and symptoms (e.g., status epilepticus, coma, respiratory distress, cardiovascular shock, altered mental status, etc.).

Each year approximately two million poisoning cases are reported to poison control centers through the United States. Based on the 2000 Annual Report of the American Association of Poison Control Centers (AAPCC) Toxic Exposure Surveillance System, there were 2.1 million human exposure cases reported throughout the country last year (1). Keep in mind that the actual number of poisoning cases that occur each year is considerably higher than this since all poisoning cases that occur are not actually reported to a poison control center. The majority (75%) of these poisoning cases that are reported to the poison control centers each year are safely and effectively managed at home with phone advice from the poison control center's poison information specialists. Therefore only 25% of the callers are actually referred to emergency departments for further assessment and treatment.

Roughly 50% of the reported poisoning cases involve children under six years of age. Within the group of children that are <6 years of age, the largest group is the 18 month to 3 year age group. Therefore healthcare providers who deal with the pediatric population must be extremely knowledgeable in the assessment and management of poisonings. The substances that were most frequently reported involving poisoning in children under six years of age in the 2000 annual report are listed as follows: Cosmetics & personal care products (13%), cleaning substances (11%), analgesics (7%), foreign bodies (7%), plants (7%), topicals (6%), cough & cold preparations (5%), insecticides & pesticides (4%), vitamins (4%) (1).

Poisonings can occur through a variety of different routes of exposure, but the most common route of exposure is via oral ingestions. Each year approximately 75% of all poisoning cases are due to ingestions. Other routes are dermal (8%), inhalation (6%), ocular (5%) and bites/stings (4%).

The majority of the human exposure cases each year involve accidental exposures as compared to intentional overdoses. In 2000, 86% of the reported two million human exposure cases involved unintentional/accidental exposures, while only 11% involved intentional exposures (with the majority of the intentional overdoses involving adults) (1). Up to 90% of the poisoning cases each year occur in the victim's own home, while only 1% occur at schools.

The majority of the poisoning related fatalities each year involve adults. However each year approximately 20-35 of the annual fatalities unfortunately involve children under six years of age. In 2000, the substances that were responsible for these pediatric fatalities were: methanol, crotalid snake bite, pine oil cleaner, carbon monoxide/smoke, hair oil/conditioner, kitty litter (aspiration), lead, kerosene, aluminum phosphide pesticide, paraquat pesticide, acetaminophen, methadone, morphine, amitriptyline, diphenhydramine, norfloxacin, and diphenoxylate/atropine (antidiarrheal) (1).

The three clinical cases listed at the beginning of this chapter illustrate the wide spectrum of how poisoning cases may present to healthcare providers. Because it would be virtually impossible to cover every possible type of poisoning scenario that you may encounter in your career, a systematic and logical overall approach to poisonings will be emphasized throughout this chapter. Since 75% of all toxic exposures involve ingestions, this chapter will primarily focus on the assessment and management of toxic ingestions. Decontamination from ocular or dermal exposures basically involves copious washing/irrigation of the eyes or skin to prevent further absorption of the toxin.

The key points in the general approach to the poisoned child that will be covered in this chapter include the following:

1. Initial stabilization priorities
2. History (the What, When and How much of poisonings)
3. Decoding of the vital signs and the toxicologic physical examination
4. Toxidromes
5. Gastrointestinal decontamination and enhanced drug elimination
6. Laboratory studies
7. Antidotes and ongoing care
8. Patient disposition from the emergency department
9. Helpful poison prevention tips

The initial management of any poisoning case must first address the assessment and stabilization of the standard "A-B-C's" of emergency medicine. Regardless of what substance may have been ingested, the physician must assure that the child's airway, breathing and circulation have been assessed and stabilized first, before addressing other issues such as gastrointestinal decontamination and laboratory evaluations. If the patient is unable to maintain and protect his or her own airway or has a diminished gag reflex, one may need to first consider endotracheal intubation prior to performing any type of gastrointestinal decontamination in order to protect the airway from aspiration. One must also be ready to address and stabilize any seizures that the patient may be experiencing due to the toxic exposure. If a child develops hypoglycemic seizures secondary to a toxic ingestion, the child will require IV dextrose in addition to the standard anticonvulsant medications in order to eradicate the seizures. A rapid method to remember exactly how much IV dextrose to administer in these types of situations is my "Hawaii Five-O" rule (2).

An IV bolus of 0.5 gm/kg of dextrose will raise the patient's serum glucose level by approximately 60-100 mg/dL. Various concentrations of IV dextrose solutions (i.e., D5W, D10W, D25W or D50W) may be used to correct symptomatic hypoglycemia. A quick and easy method that I have devised to calculate how many "cc/kg" of any dextrose solution to draw up in order to administer 0.5 gm/kg of dextrose can be remembered by the following:

[dextrose concentration] x [?? cc/kg] = "50"

D5% 10 cc/kg
D10% 5 cc/kg
D25% 2 cc/kg
D50% 1 cc/kg

Therefore for a child with a hypoglycemic seizure, 5 cc/kg of a D10W solution would provide enough IV dextrose (0.5 gm/kg) to raise the child's serum glucose level by 60-100 mg/dL.

The three key questions that must be addressed in all poisoning cases are:

1) WHAT substance(s) was ingested?
2) WHEN did the ingestion occur?
3) HOW MUCH was ingested?

The answers to these questions will provide valuable information about:

a) The severity of the ingestion.
b) The potential benefits/efficacy of gastrointestinal decontamination.
c) Whether or not therapeutic interventions will be potentially necessary.
d) Accurate interpretation of specific drug levels.
e) Disposition of the patient (i.e., can the patient be safely discharged from the emergency department and after what period of time, or does the patient need to be admitted for further observation and treatment?)

When determining what substance(s) was ingested, one must be very specific. For example, many of the over-the-counter (OTC) medications frequently have various preparations with many different active ingredients. The exact milligram amount of the suspected ingested medication or liquid/syrup should also be confirmed since many medications (both OTC as well as prescription medications) are available in multiple milligram dosages and concentrations. If at all possible have a family member bring the bottle, box or container of the suspected toxin to the emergency department so that you yourself can verify the specific product and active ingredients. Local poison

control centers have computerized data bases of over a million substances, which can be accessed via a specific product name or via the individual active ingredients. If the suspected ingestion involved a plant, have a family member bring in as much of the actual plant for identification.

If the time from the ingestion to the time of arrival to the emergency department is within 1-2 hours, gastric lavage may be beneficial. In general, gastric lavage is not very effective if performed more than two hours post-ingestion. Knowing the time of the ingestion is also necessary when attempting to interpret specific drug levels. For example, an acetaminophen level of 100 mcg/ml cannot be interpreted and plotted on the nomogram unless the time of ingestion as well as the time of the blood draw are known. The level of 100 mcg/ml may not be toxic if it was obtained two hours post-ingestion, whereas the very same level would be considered toxic if it was obtained 20 hours post-ingestion.

Often, the most difficult aspect of the toxicologic history for the parents to answer is regarding the exact amount of the toxin or drug that may have been ingested. When confronted with this dilemma, the physician should always assume the worst case scenario rather than minimizing the amount that may have been potentially ingested.

The physician must be a medical detective in some aspects when attempting to estimate how much the child may have ingested. For example, if a child presents to the emergency department after potentially ingesting some tablets, questions which could be asked include the following (3):

a) Was the medication just recently purchased, and if so was the bottle completely full prior to the child getting to the pills?

b) If the bottle was not brand new or recently purchased, then how many pills were in the bottle before the child got to it?

c) If the medication was a prescribed medication, how many pills were originally prescribed, when was the medication prescribed and how many pills were already taken prior to the child getting to the bottle?

d) How many pills did the parents find remaining in the bottle?

e) How many pills did the parents find around the area where they found the child playing with the opened medication bottle?

f) How many pills did the parents find in the child's mouth?

Once the total milligrams of the potential ingestion has been determined, then one must calculate how much was ingested in mg/kg to determine severity potential. If more than one child may have been involved in an ingestion scenario, perform your mg/kg calculations for each child (based on each child's individual weight) assuming that all of the potentially ingested medication may have been consumed only by one child.

Although the majority of the substances that are typically ingested by children are either nontoxic or mildly toxic, there are a few substances that can potentially be fatal even when ingested in very small amounts. Some of these highly toxic substances with the corresponding amounts which could potentially be lethal for a 10 kg child are: amanita phalloides (one mushroom), amphetamines, antimalarials (one chloroquine tablet), calcium channel blockers (one nifedipine tablet), camphor (one teaspoon), clonidine (one 0.1 mg tablet), cocaine, cyclic antidepressants (one 150 mg imipramine tablet), ethylene glycol (one teaspoon), methylsalicylates (one teaspoon), narcotic medications, phenothiazines, theophylline (one 500 mg tablet) (4).

Toxic ingestions in children typically present to an emergency department in one of two scenarios. The first is that of a child who presents with a witnessed or suspected ingestion. The second scenario is that of a child who presents with a constellation of signs and symptoms which may include the possibility of a toxic ingestion within the working differential diagnosis. For example if a previously healthy 2 year old child presents to the emergency department after experiencing a brief afebrile seizure, the possibility of a toxic ingestion must be included within the differential diagnosis in addition to head trauma and other various etiologies for the child's afebrile seizure.

Every element of a child's vital signs must be carefully analyzed in any potential poisoning case scenario, which may give the physician a clue as to what the ingested substance might have been in the case of the unknown ingestion. The following is my quick and easy to remember method of simplified pediatric vital signs (5).

	Heart rate	Respiratory rate
Newborn to 1 year old	140	40
1 year old to 4 years old	120	30
4 years old to 12 years old	100	20
> 12 years old	80	15

The key elements of a toxicologic physical examination include the following elements (3):

a) Eyes: pupillary size, symmetry and response to light presence of nystagmus (vertical or horizontal).

b) Oropharynx: moist or dry mucus membranes, presence/absence of the gag reflex, presence of any particular or distinctive odors.

c) Abdomen: presence/absence and quality of bowel sounds.

d) Skin: warm/dry, warm/sweaty or cool.

e) Neurologic: level of consciousness and mental status, presence of tremors, seizures or other movement disorders, presence/absence and quality of deep tendon reflexes.

Toxidromes refer to a specific constellation of signs and symptoms which one may expect to see with a specific class or type of toxic substance. Toxidromes are based on the patient's vital signs as well as on the physical examination findings. The five distinct toxidromes and the common toxins of each of the toxidromal classes are listed below (3):

1. Anticholinergics (e.g., atropine, antihistamines, cyclic antidepressants, etc.): Tachycardia, hypertension, tachypnea, mydriasis, agitation, hallucinations/delirium, seizures, hypoactive bowel sounds, warm/dry skin, dry mouth.

2. Sympathomimetics (e.g., cocaine, amphetamines, PCP, decongestants, beta-agonists, theophylline, etc.): Tachycardia, hypertension, tachypnea, mydriasis, agitation, hallucinations, delirium, seizures, hypoactive bowel sounds, warm/sweaty skin.

3. Cholinergics (e.g., organophosphate and carbamate insecticides): "D-U-M-B3-E-L-S": Defecation, Urinary incontinence, Miosis, Bradycardia/Bronchospasm/Bronchorrhea, Emesis, Lacrimation, Salivation.

4. Opioids (e.g., codeine, morphine, meperidine, heroin, etc.): Bradycardia, hypotension, bradypnea, hypothermia, hyporeflexia, pinpoint, pupils.

5. Sedative-hypnotics (e.g., ethanol, benzodiazepines, barbiturates, etc.): Bradycardia, hypotension, bradypnea, hypothermia, hyporeflexia, miosis.

In 1985 ipecac administration was recommended in 15% of the poisoning cases handled throughout the country by the American Association of Poison Control Centers. However the recommended use of ipecac in the home has continually declined over the past several years to only 0.8% of poisoning cases reported in the year 2000 (1). Because of this, the American Academy of Pediatrics Committee on Injury and Poison Prevention is currently recommending that syrup of ipecac no longer be used as a poison treatment intervention in the home setting. The AAP is also recommending that pediatricians and other health care professionals advise parents to safely dispose of the ipecac syrup that they may currently have within their homes (6).

Gastric lavage has several clinical advantages over ipecac induced emesis. Gastric lavage provides a quicker, more controlled and safer route of gastric emptying than ipecac. The typical method of performing gastric lavage is to perform lavage with saline until the retrieved gastric contents are clear, then activated charcoal with sorbitol is instilled down the lavage tube.

Gastric lavage by itself is only effective at removing toxins that are still within the stomach. Lavage is not capable of removing any toxins that have already passed into the small intestines. Thus, if more than 1-2 hours have already elapsed prior to the patient's arrival in the emergency department, gastric lavage would probably not be very effective at preventing toxin absorption since the majority of the ingested substance has already probably passed out of the stomach and into the small intestines. In order to perform effective lavage, the internal diameter of the tube must be large enough to accommodate the pill fragments that are in the child's stomach. Thus, because large orogastric lavage tubes cannot always be safely placed in children, the option of gastric lavage may not be feasible and/or effective in smaller children. However, when the ingested substance is a liquid preparation, then a smaller sized tube would be sufficient, although it must be performed much sooner in order to be effective since liquid preparations are more quickly absorbed than pills or tablets.

Activated charcoal is very effective at adsorbing many ingested toxins and thereby prevents systemic toxicity. The majority of activated charcoal preparations currently available have adsorptive surface areas of 1,000 square meters per gram of charcoal. Some of the newer "super" adsorptive activated charcoal preparations reportedly have up to 2,000 square meters of adsorptive surface area per gram of charcoal. Because activated charcoal is able to prevent systemic toxicity by effectively binding so many different ingested toxins, many poison control centers have been recently recommending the administration of activated charcoal alone (without first performing gastric lavage) for ingestion cases of mild to moderate severity.

Although activated charcoal has been sometimes referred to as the "universal antidote" because it adsorbs so many different toxins, there are nine scenarios in which activated charcoal may not be clinically effective. My mnemonic to remember these nine scenarios is "C-H-E-M-I Ca-L Cam-P" (Cyanide, Hydrocarbons, Ethanol (and other alcohols), Metals, Iron, CAustics, Lithium, CAMphor, Potassium) (7). Even though charcoal has a very low affinity for cyanide, it may still be effective in preventing systemic cyanide toxicity if the amount of cyanide ingested is within the 100-500 mg range. Although charcoal is not necessary for ingestions of plain hydrocarbons, it should be considered if the ingested hydrocarbon contains systemic toxins (i.e., aromatic and halogenated hydrocarbons). If the ingested hydrocarbon does not pose any risk in terms of systemic toxic effects, charcoal administration should be avoided because the charcoal may predispose the patient to vomiting, which will definitely worsen the aspiration toxicity of the hydrocarbon. Although charcoal is very effective at adsorbing camphor, the administered charcoal may not be very effective depending on the time that the child presents to the emergency department. Because the majority of camphor containing products are typically found in liquid preparations, by the time the child presents to the emergency department, most of the liquid camphor has already been completely absorbed from the stomach and therefore there will be nothing left for the activated charcoal to adsorb. However if the child presents to the emergency department with 30 minutes after ingesting a potentially toxic amount of camphor, gastric lavage should probably be attempted in order to prevent systemic toxicity (e.g., camphor induced seizures). Multiple doses of activated charcoal (without cathartics) are sometimes used as a method of "gastrointestinal dialysis" for certain drugs that undergo enterohepatic circulation (e.g., theophylline, carbamazepine, cyclic antidepressants, phenobarbital, digoxin).

In the year 2000, activated charcoal was administered in 6.7% of the poisonings reported throughout the country (1). Although there have been a few studies that have looked at the efficacy of home administration of activated charcoal, the AAP does not currently recommend the routine use of activated charcoal as a poison treatment intervention in the home scenario at this time until their have been more studies which further investigate the risks and benefits of activated charcoal administration within the home (6).

Cathartic agents by themselves are not a very effective method of gastrointestinal decontamination. The main role of cathartics is to more quickly eliminate the charcoal bound toxin complex from the intestines before the toxins have the opportunity to dissociate from the activated charcoal. Sorbitol is the most commonly used of the cathartics because of its rapid gastrointestinal transit time. Sorbitol also comes premixed with activated charcoal ranging from 27-48 grams of sorbitol per 120 milliliter bottle of activated charcoal. Sorbitol can be safely used in children as long as it is administered only once per 24 hours and the stool output and the cardiovascular and hydration status are closely monitored.

Whole bowel irrigation (WBI) is a method of gastrointestinal decontamination that utilizes high volumes of iso-osmotic fluids to basically flush pills and other toxins out of the gastrointestinal tract. One advantage of WBI is that unlike gastric lavage, this method of decontamination will eliminate pills and toxins from the entire gastrointestinal tract and not just from the stomach. The second advantage WBI is that it can be utilized in those scenarios in which activated charcoal would not be very effective. The most common indication for WBI is an overdose of iron tablets.

The two iso-osmotic solutions which are currently utilized for WBI are GoLytely and CoLytely. Adults and teenagers can be given 1-2 liters of GoLytely per hour via a nasogastric tube until the ingested toxin is completely eliminated per rectum and the rectal effluent is clear in color. Typically the duration of WBI that is required to achieve this end point is roughly 4-6 hours. The recommended rate of WBI in children is 25 ml/kg/hour (up to a maximum 500 ml/hour). Any child undergoing WBI must also be carefully monitored for the risk of aspiration since high volumes of fluid may be required during this process.

Although there are multiple methods available to enhance the elimination of specific toxins from the body, the majority of pediatric poisoning cases can be treated with one or more of the decontamination methods mentioned above. The urinary pH can be manipulated in order to enhance the urinary excretion of certain drugs and toxins. The prime example is urinary alkalinization via the IV administration of sodium bicarbonate in order to enhance the urinary excretion of salicylates. Other more complex methods of enhanced elimination techniques include peritoneal dialysis, hemodialysis and hemoperfusion.

The exact laboratory tests which one would obtain in a poisoning case will depend upon the specifics of each individual case as well as the overall severity of the case. Although blood and urine toxicologic screens and specific drug levels may be obtained, the results of these studies typically are not available for several hours. Therefore, the initial stabilization and management of every poisoning case is clinically determined by the patient's presenting signs, symptoms, and vital signs. For intentional overdose cases, I would recommend an EKG rhythm strip (to quickly assess for any conduction abnormalities and/or dysrhythmias), acetaminophen levels, salicylate levels and a pregnancy test in females of child bearing age. An electrolyte panel may also be helpful to assess for metabolic acidosis. Once the results

of the electrolyte panel are known, one can also calculate the anion gap, which may provide helpful clues to the potential toxin in cases of the unknown or suspected ingestion. The anion gap can be calculated via the formula: Na - [Cl + CO2]

The calculated anion gap should normally be equal to 8-12 mEq/liter. Toxins that typically produce an increased anion gap metabolic acidosis may be remembered by the "M-U-D-P-I-L-E-S" mnemonic (Methanol, Uremia, DKA, Paraldehyde, Iron/Ibuprofen/INH, Lactic acidosis (e.g., carbon monoxide, cyanide and various other etiologies of lactic acidosis), Ethanol/Ethylene glycol, Salicylates).

Another very useful laboratory study is the measured serum osmolality and the serum osmolar gap. A patient's serum osmolality can be calculated via the formula:

2 x [Na] +[BUN/2.8] + [glucose/18]

Based on this calculated formula, the only three elements in the serum which are accounted for are the sodium, BUN and glucose. In contrast to this calculated formula, the actual measured serum osmolality also takes into account other substances in the patient's blood which could also affect the serum osmolality. Substances that classically elevate the measured serum osmolality (which are not part of the calculated osmolality) include the alcohols (i.e., ethanol, methanol, ethylene glycol and isopropyl alcohol). Thus a patient who has ingested one of the alcohols will typically exhibit an elevated measured serum osmolality despite a normal calculated serum osmolality.

The serum osmolar gap (measured serum osmolarity minus the calculated serum osmolarity) should be <5-10 mosm/Liter. The calculated osmolar gap is also valuable in that it can also be used to predict a patient's blood ethanol level via the formula:

[serum osmolar gap] x [4.6] = blood ethanol level in units of mg/dL

The 4.6 is a constant based on the density of ethanol. This factor will differ if the alcohol involved is something else such as ethylene glycol or methanol.

The mainstay to the treatment of the majority of poisoning cases involves supportive care and continued reassessment of the patient's airway, breathing and circulatory status. Although the majority of poisoning cases do not require any specific antidotes, some of the common toxins with antidotes are: acetaminophen (N-acetylcysteine), benzodiazepines (flumazenil), calcium channel blockers (calcium chloride), carbon monoxide (oxygen), cholinergics (atropine +/- pralidoxime), cyanide (cyanide antidote kit), cyclic antidepressants (sodium bicarbonate), digoxin (digoxin immune Fab antibodies), ethylene glycol or methanol (fomepizole), iron (deferoxamine), methemoglobinemia (methylene blue), opiates (naloxone), phenothiazine induced dystonic reactions (diphenhydramine), salicylates (sodium bicarbonate).

Because the majority of pediatric nonintentional ingestions typically do not involve highly toxic substances and/or large amounts, the majority of children who present to the emergency department with an accidental overdose can be safely discharged after a thorough assessment and an adequate period of observation. Hospitalization should be considered for the following situations:

a) Severe signs and symptoms upon presentation to the emergency department.
b) Unstable or abnormal vital signs.
c) A potentially severe ingestion based on the identity or potential toxic dose of the ingested substance.
d) Intentional overdoses.

Since prevention is the best method of reducing accidental poisoning in children, physicians should routinely incorporate poison prevention guidelines/tips into their healthcare maintenance discussions with their parents. Some of these points are listed below:

a) Keep the phone number of your local poison control center near the telephone.
b) If you suspect a poisoning, call the poison control center immediately for advice rather than waiting for your child to develop signs and symptoms of toxicity.
c) If you suspect a poisoning, never induce vomiting. Call the poison control center immediately for advice.
d) Store all medications and household products out of reach and out of sight (and preferably locked up).
e) Never refer to medicines as "candy," since a child may then try to eat more of the "candy," when you are least expecting them to.
f) Child resistant caps should be closed properly and remember that these types of caps are only child resistant and not "child proof".
g) Avoid transferring/storing household cleaning products, pesticides and automotive fluids in unmarked bottles or containers which could be mistaken for a beverage and consumed by unsuspecting child.

Questions

1. The majority of accidental ingestions in the pediatric population occur in which age group?
   a. 6 months to 1 year of age.
   b. 18 months to 3 years of age.
   c. 4 years to 6 years of age.
   d. 8 years to 12 years of age.

2. The most common route of toxic exposures is via:
   a. Inhalation.
   b. Dermal contact.
   c. Bites and stings.
   d. Ingestion.
   e. Ocular contact.

3. A mother of a 2 year old boy calls you because she suspects that her son may have eaten a few of his grandmother's "heart pills." She claims that her son seems fine and that the possible ingestion may have occurred 30 minutes ago. What is the best action for you to take as the child's pediatrician?

a. Have the mother induce vomiting immediately by sticking her finger in the child's mouth.
b. Immediately give the child eight ounces of water or milk to dilute the concentration of pills in his stomach.
c. Have her administer ipecac syrup immediately in order to induce vomiting.
d. Advise no interventions at the present time, but also advise her that if the child should begin to develop any symptoms to go to the emergency department for further treatment.
e. Call you local poison control center immediately for advice.

4. The gastrointestinal decontamination method of choice for a child who presents to the emergency department with multiple episodes of vomiting two hours after ingesting a toxic amount of iron is:

a. Syrup of ipecac.
b. Orogastric lavage.
c. Activated charcoal with sorbitol.
d. Multiple doses of activated charcoal.
e. Whole bowel irrigation.

5. A child with a suspected ingestion presents to the emergency department with delirium, tachycardia, mydriasis, dry mucus membranes and warm/dry skin. This child exhibits signs and symptoms of which toxidrome?

a. Anticholinergic.
b. Sympathomimetic.
c. Cholinergic.
d. Opioid.
e. Sedative hypnotic.

6. A parent suspects that her 18 month old son may have accidentally ingested a few pellets of rat poison. The mother should:

a. Not panic and simply wait to see if her son develops any signs and symptoms of toxicity before calling her pediatrician.
b. Call 911 immediately since this may be a medical emergency.
c. Call her local poison control center immediately for advice, rather than waiting to see if her son will develop signs and symptoms of toxicity.
d. Induce vomiting by giving her son a teaspoon of ipecac syrup.
e. Rush her son to the nearest emergency department for immediate gastric lavage and activated charcoal.

7. Activated charcoal would NOT be an effective method of gastrointestinal decontamination for which one of the following ingestions?

a. Albuterol.
b. Ferrous sulfate.
c. Amoxicillin.
d. Carbamazepine.
e. Phenobarbital.

Chapter XIV.10. Acetaminophen Overdose
Lynette L. Young, MD

A 16 year old female presents to the emergency department at 0500 with vomiting and nausea. Her mother reports that she (the patient) had an argument with her boyfriend last night. She woke her mom up early this morning saying that she feels sick. She admits that last night she took some pills at 2100. She has vomited 3-4 times at home. Her mom brought in the bottle of pills. She took acetaminophen 500mg tablets. Her mother reports it was a new unopened bottle with a quantity of 30 tablets. There are 8 tablets remaining in the bottle (maximum 11 grams of acetaminophen ingested).

Exam: VS T 37.2, P 88, R 18, BP 110/70, weight 50kg. She is alert, quiet, shaking her head yes/no to questions, with poor eye contact. Her skin is pink with good perfusion. Her oral mucosa is moist. Heart is regular with a normal rhythm and rate. Lungs are clear with good aeration. Her abdomen is soft, with normoactive bowel sounds, minimal epigastric tenderness, no rebound, and no guarding. She is alert, oriented, and walks about the room without difficulty.

She is given 50 grams of activated charcoal with sorbitol PO. She is also given 10 grams of N-acetylcysteine orally. An acetaminophen level, aspirin level, blood and urine toxicology screen and beta-HCG are drawn. The acetaminophen level drawn at 8.5 hours post-ingestion is 150 mcg/mL. She is hospitalized for further treatment as well as a psychiatric evaluation.

Acetaminophen (N-acetyl-p-aminophenol) or APAP is a common antipyretic and analgesic medication. It is a frequent toxic ingestion in young children and adolescents. Because acetaminophen is an ingredient found in many over-the-counter cold medications, it should be considered in intentional overdoses, as the patient may not realize that it is one of the components in the combination product taken.

Acetaminophen is metabolized in the liver via glucuronidation, sulfation, and through the cytochrome P-450 pathway. The majority of acetaminophen is metabolized via the sulfation and glucuronidation pathways into nontoxic products which are then excreted via the urine. Only a small percentage (5-15%) of the acetaminophen undergoes metabolism via the P-450 cytochrome oxidase system in the liver to produce the toxic intermediate N-acetyl-p-benzoquinoneimine (NAPQI). NAPQI is potentially toxic and may cause hepatic injury. However, the hepatic glutathione conjugates the NAPQI to produce APAP-mercapturate and APAP-cysteine which are both nontoxic metabolites. In severe overdoses, the glutathione stores become depleted and the toxic metabolite NAPQI builds up causing hepatocellular necrosis. In children 1 to 5 years, severe liver toxicity is rare with a single ingestion of acetaminophen, for reasons which are unclear.

There are four stages of acetaminophen overdose. In stage I (first 24 hours), the patient may have symptoms of anorexia, nausea, and vomiting. Sometimes they may have pallor and diaphoresis. In stage II (24-48 hours), the patient may show improvement in their clinical symptoms. The liver enzymes may begin to elevate. Stage III (72-96 hours) is called the hepatic stage. The patient may have vomiting, jaundice, abdominal pain, bleeding, confusion, lethargy, or even be in a coma. The patient may have coagulation defects, such as disseminated intravascular coagulopathy. The patient may progress to death. If the patient survives, the next period is stage IV (4 days to 2 weeks post-ingestion) which is called the recovery phase. Liver function tests return to normal in 1-3 weeks. Symptoms may resolve in 3-5 days.

In the management of acetaminophen ingestions the, basic principals of toxicology are followed. If it was an intentional ingestion, acetaminophen and aspirin levels should be obtained. Patients may present stating that they took "aspirin" when in fact they took acetaminophen. Blood and urine toxicologic screens should be done as well as a pregnancy test if the patient is a menstruating female. If the patient presents with altered level of consciousness, a co-ingestion must be suspected because acetaminophen does not produce any changes in mental status.

Acetaminophen is rapidly absorbed from the gastrointestinal tract. The peak plasma level ranges from 30 minutes up to 4 hours. Syrup of ipecac is not used as a form of gastrointestinal decontamination in the emergency department setting. Gastric lavage in a patient who presents to the emergency department is controversial. There are some toxicologists who feel that gastric lavage has not been proven to be helpful and should be used only if the ingestion is potentially rapidly fatal and the patient presents to the emergency department within 1 hour of the ingestion. In our patient's case, she was already vomiting so gastric lavage was not performed.

Another controversial area in the management of acetaminophen ingestion is activated charcoal administration. With intentional overdoses, there may be other occult co-ingestants that may be inactivated by the charcoal. Those that argue against giving charcoal believe that it may decrease the bioavailability of the antidote N-acetylcysteine (NAC). The proponents of giving activated charcoal recommend increasing the initial loading dose of NAC (140 mg/kg) by 30-40%.

For single acetaminophen ingestions a Rumack-Matthew nomogram is used to estimate the severity of the poisoning. The serum acetaminophen concentration is plotted against the time (hours) post-ingestion. The "toxic" level is a function of time after ingestion. If the APAP level is above the toxic level for that time after ingestion (i.e., the level is above the toxic line), there is possible risk for hepatotoxicity and NAC treatment is warranted. An acute single ingestion of acetaminophen of less than 140 mg/kg in children is likely to be nontoxic. There are some who have recommend a higher cutoff for the risk of toxicity in children, but there is no universal consensus on this. An adolescent/adult ingestion of 7.5 grams may be toxic to the liver. The acetaminophen level is best obtained 4 hours post-ingestion. The Rumack-Matthew nomogram is then used to interpret the level obtained. There are some that believe an acetaminophen level may be drawn as early as 2 hours post-ingestion in a child. They proposed that if the level is at or above 225 mg/L at 2 hours than treatment should be started (1,2).

The antidote NAC is available in the United States as an oral form which has an unpleasant odor and taste. An intravenous form is available in Canada and Europe but is not yet FDA approved in the USA. The patient may experience nausea and vomiting with the NAC treatment. Some suggestions include mixing it with soda or juice or administration via a naso-gastric or naso-duodenal tube. Antiemetics such as metoclopramide (Reglan) or ondansetron (Zofran) have been suggested. NAC given orally is very effective in preventing hepatotoxicity if it is given within 8 hours of the ingestion. If the ingestion has occurred close to this 8 hour time window, NAC should be given prior to receiving the acetaminophen level back from the laboratory, since waiting for the level will unnecessarily delay treatment. N-acetylcysteine is believed to act as a glutathione substitute. The sulfation is increased and less APAP is thought to enter the P-450 pathway so there is less toxic metabolite formed. Another theory is that NAC may bind directly to the toxic intermediates formed. The loading dose for NAC is 140 mg/kg. This should be increased by 30-40% if charcoal has been given. The dose is repeated if vomiting occurs within 1 hour. The maintenance dose is 70 mg/kg every 4 hours for 17 doses (total of 18 doses). There are some who advocate a shortened course of NAC treatment for those who are at low risk for hepatotoxicity (3,4). The alternative is to discontinue NAC if at 36 hours the liver transaminase level are normal and the APAP level is less than 10 mcg/mL.

The prognosis for patients of acetaminophen overdoses is generally good. Young children rarely progress to hepatotoxicity. Some believe that APAP is metabolized more via sulfation so there are less toxic intermediates formed. There are others that believe, since a child's liver and kidney are relatively larger than an adult, they are better able to clear the medication (5). Also children may vomit sooner after the ingestion, therefore eliminating the toxic substance. Children with accidental APAP overdoses are usually brought in earlier for medical care, as compared to adults with intentional APAP overdoses who typically present for medical care many hours or days after the overdose. Of the patients who progress past clinical stage III, 99% have clinical resolution.

Questions

1. The toxic intermediate N-acetyl-p-benzoquinoneimine is formed via which pathway?
    a. Sulfation
    b. Glucuronidation
    c. Cytochrome P-450
    d. Glutathionation

2. True/False: An adolescent presents with an acute ingestion of acetaminophen 5 hours prior. She is lethargic and is not responding appropriately. This clinical presentation is due to the acetaminophen toxicity.

3. If charcoal has been given, the dose of N-acetylcysteine should be increased by:
    a. Not increased.
    b. 5-10%
    c. 10- 20%
    d. 30-40%
    e. 50-60%

4. True/False: Hepatotoxicity is rare in children with a single dose acetaminophen ingestion.

5. N-acetylcysteine is most effective if given within how many hours of the acetaminophen ingestion?

6. Which is the first clinical stage that liver function tests may be abnormal?
    a. Stage I
    b. Stage II
    c. Stage III
    d. Stage IV

7. A patient arrives to the emergency department 7 hours after intentionally ingesting an unknown amount of acetaminophen. What should be done?
    a. Directly admit the patient to the floor and await a psychiatric consult.
    b. Draw a stat acetaminophen level and await the result before further treatment.
    c. Give the patient syrup of ipecac if she has not vomited and then administer activated charcoal.
    d. Draw a stat acetaminophen level and administer NAC.

Answers to questions

1.c

2.False. Acute ingestion of acetaminophen does not cause altered mental status.

3.d 4.True, 5. 8 hours, 6.b, 7. d

Chapter XIV.11. Iron Overdose
Lynette L. Young, MD

A 2 year old boy presents to the emergency department with a chief complaint of blood-tinged vomiting. His mother was tending to her newborn infant when the patient climbed up and grabbed his mom's bottle of iron pills from the counter. He was able to open the bottle and thinking that the pills looked like candy, he ate them. His mother brought in her bottle of ferrous sulfate 325 mg (65 mg elemental iron) tablets. Counting the iron tablets in the bottle there is a maximum of 15 tablets missing (975 elemental Fe/12 kg = 81 mg/kg of elemental iron ingested).

Exam: VS T 36.9, P 120, R 30, BP 88/60, weight 12kg (10th percentile). He is alert, and being carried by mom. His skin is pink and warm with good perfusion and capillary refill. HEENT exam is negative. His oral mucosa is moist and there are no lesions. His neck is nontender. Heart regular rhythm and normal rate. Lungs are clear with good aeration. His abdomen is soft and slightly tender in the upper quadrants, with active bowel sound and no guarding. His distal pulses are strong and his distal extremities are warm. He is responding appropriately to mom.

An abdominal series reveals radiopaque tablets in the stomach and intestine.

Iron is a serious and potentially fatal ingestion. It used to be one of the leading causes of fatal poisonings in the pediatric age group. Toxicity is based on the amount of elemental iron ingested. The most common forms of iron include: ferrous sulfate (20% elemental iron), ferrous fumarate (33% elemental iron), and ferrous gluconate (12% elemental iron). Children's multivitamin with iron preparations contain 8 to 18 mg of elemental iron per chewable tablet. A common iron containing medication is a prenatal vitamin, which has 325 mg ferrous sulfate (65 mg elemental iron) per tablet.

Iron is absorbed in the intestine. The peak serum level ranges from 2 to 6 hours after ingestion of iron. Iron is absorbed in the ferrous (Fe++) form and is oxidized to the ferric from (Fe+++) within the cells. It is transported in the blood bound to transferrin. The iron binding capacity (transferrin level) is usually 300-500 mcg/dl (TIBC) and normal serum iron levels are 50-150 mcg/dl. There is usually no free iron circulating in the blood. The body has no specific way to excrete iron. Iron toxicity may result from the caustic/corrosive effect directly to the gastrointestinal mucosa. This may lead to perforation causing fluid loss from the gastrointestinal tract. Hypovolemia and shock may result. The second mechanism of toxicity is due to the presence of free iron in the circulation. Free iron may affect any organ including the kidneys, brain, lung, and heart. It builds up mainly in the liver. Free iron is found to concentrate in the mitochondria. Oxidative phosphorylation uncoupling is a mechanism for cellular toxicity. There are other unknown mechanisms for cellular injury. Lactic acidosis results from tissue hypoperfusion/cellular hypoxia. Free iron may also cause direct damage to the heart leading to decreased myocardial contractility (negative inotropic effect on the myocardium). Coagulopathies may occur from effects of iron on clotting factors.

There are four clinical phases of iron toxicity. In Phase I (0-6 hours), symptoms are due to the direct caustic/corrosive effect to the gastrointestinal mucosa. The patient may have symptoms of abdominal pain, vomiting (often with blood), and diarrhea. With severe iron poisoning, the patient may be lethargic or lapse into a coma. Shock and metabolic acidosis may result from blood and fluid loss and tissue hypoperfusion. Phase II (6-48 hours) is called the "honeymoon phase" or latent period. In this phase the gastrointestinal symptoms subside. There is an apparent improvement in symptoms. The patient may appear to be stabilized with appropriate therapy. Phase III (12 hours-5 days) is also known as the shock phase. There may be recurrence of gastrointestinal bleeding. Other symptoms in this clinical stage may include cyanosis, profound metabolic acidosis, coma, seizure, shock, and coagulopathy. The patient may have cardiac failure, renal failure, hepatic failure, and may go on to cardiovascular collapse and death. In Phase IV (2-6 weeks), the consequences of the corrosive effects of iron to the gastrointestinal mucosa may be evident. There may be scarring leading to strictures in the gastrointestinal tract. Obstruction may occur at the gastric outlet or small intestines.

A patient who has ingested less than 20 mg/kg of elemental iron and is asymptomatic can be observed. If the patient remains asymptomatic 4-8 hours after ingestion, he/she can be discharged to home. A serum iron level should be obtained on arrival to the emergency department if the patient is symptomatic or has ingested >60 mg/kg of elemental iron. A serum iron level should be drawn 4-6 hours post-ingestion if the patient is asymptomatic and has ingested 20-60 mg/kg or an unknown amount of elemental iron. With a serum iron level of less than 300 mcg/dl, the patient is usually asymptomatic. There is potentially moderate toxicity with an iron level between 300 to 500 mcg/dl. Serum iron levels greater than 500 mcg/dl fall in the severe toxicity range. If the iron tablet is enteric-coated or a sustained-released tablet, the absorption may be delayed and a second level drawn 6-8 hours after ingestion should be considered. The serum iron level may not be reliable if deferoxamine has been given. Other laboratory tests that are recommended are serum electrolytes, BUN, and creatinine. A baseline CBC can be drawn. An abdominal radiograph to look for radiopaque iron pills may be helpful. There are several tests previously used in iron poisoning which are no longer recommended. These include the total iron binding capacity (TIBC) (1) and the deferoxamine challenge test. They are not good predictors of toxicity. Also, previously recommended white blood cell count >15,000/mcL and blood sugar level of >150 mg/dL should not be used to predict the severity of iron overdose (2).

For patients with serious iron ingestion, treatment should include gastric decontamination, intensive supportive therapy, and deferoxamine administration. Gastric lavage should be done for patients with a large ingestion or if they are symptomatic. Whole bowel irrigation (WBI) is recommended if there are iron pills seen on X-ray and for any significant ingestion. The pediatric dose is 25-40 ml/kg/h up to a maximum of 500 ml/h. The dose in adolescents and adults is 1.5 to 2 L/h (3). This is continued for 4-6 hours or until the rectal effluent is clear. There are no studies to prove the effectiveness of whole-bowel irrigation in iron poisoning. A follow-up radiograph may be indicated. Activated charcoal does not bind iron well, but it can be considered if there is a co-ingestion.

Supportive treatment may include intravenous crystalloid fluids to treat shock. Dopamine and norepinephrine can be used if the hypotension persists. Blood component therapy may be needed for those patients with blood loss. Exchange transfusion is sometimes considered in young patients who worsen despite deferoxamine therapy although its effectiveness is questionable.

Deferoxamine chelates the ferric ion (Fe+++). It is given intravenously to patients who are symptomatic with vomiting, diarrhea, increased anion gap metabolic acidosis, gastrointestinal bleeding, lethargy, or hypotension. Deferoxamine therapy is also recommended if the serum iron level is greater than 500 mcg/dl. The iron-deferoxamine complex (ferrioxamine) is water-soluble and is excreted in the urine. It may cause the urine to be pinkish-orange ("vin-rose"). The initial dose of deferoxamine is 15 mg/kg/h. The rate may be increased up to 25 to 40 mg/kg/h. Rapid infusion of deferoxamine may cause hypotension.

Mortality is low in iron poisoning patients if they do not have shock or coma. With supportive treatment of patients with shock or coma, the mortality rate is about 50%. If deferoxamine treatment is added, the mortality rate drops to 10%. Patients may be discharged

home from the emergency department after 4-6 hours of observation if they are asymptomatic, have serum iron levels less than 300 to 500 mcg/dl, and have a negative abdominal X-ray. A psychiatric evaluation is needed if it was an intentional ingestion.

Questions

1. True or False: Charcoal is effective in binding iron and should be given in significant iron ingestions.

2. A 3 year old female (15 kg) ingested 15 of her mom's prenatal (325 mg ferrous sulfate) iron tablet. How much elemental iron per kilogram did she take?
   a. 15 mg/kg
   b. 25 mg/kg
   c. 45 mg/kg
   d. 65 mg/kg
   e. 85 mg/kg

3. Deferoxamine chelates the:
   a. Ferrous ion (Fe++).
   b. Ferric ion (Fe+++).

4. The two basic mechanisms of iron toxicity include:
   a. Direct corrosive effect on the gastrointestinal mucosa.
   b. Formation of a toxic metabolite.
   c. Binding to the protein transferrin.
   d. Toxic effect of the free ion.

5. Gastrointestinal symptoms may improve in which clinical (latent) stage of iron poisoning?
   a. Phase I
   b. Phase II
   c. Phase III
   d. Phase IV
   e. Phase V

6. True or False: Total iron binding capacity (TIBC) is a reliable predictor of toxicity in iron poisoning?

7. The whole bowel irrigation rate in children is?
   a. 5 ml/kg/h.
   b. 25 ml/kg/h.
   c. 75 ml/kg/h.
   d. 100 ml/kg/h.

8. The deferoxamine infusion rate should initially be started at:
   a. 15 mg/kg/h.
   b. 25 mg/kg/h.
   c. 40 mg/kg/h.
   d. 50 mg/kg/h.

Chapter XIV.12. Child Abuse
Cynthia H. Tinsley, MD

A two month old male infant is brought to the emergency department (ED) with a chief complaint from the parents as having a "breath holding spell ". They describe the infant as turning blue and he stopped breathing. They shook the baby and blew a breath of air into his face. He started crying. There is no history of fever, coughing, congestion, vomiting or seizures.

He is the product of a full term delivery born to a 17 year old primigravida mother who is unmarried. She and the baby live with the grandmother. The 18 year old father is involved in the care of the baby. The infant's birth weight was 3.89 kg (8 pounds, 9 ounces) (90%ile). He now weighs 4.69 kg (10 pounds, 5 ounces) (25%ile). The mother says that the infant is doing well but he has not yet received any immunizations.

The infant is hospitalized for observation, monitoring and workup for an ALTE (apparent life threatening event) which could include the following: gastroesophageal reflux study, sleep study (for apnea), sepsis work up (CBC, blood culture, lumbar puncture, urine culture, chest x-ray). Since his growth percentile has fallen from the 90%ile to the 25%ile, a dietary history is obtained and the patient is observed in the hospital for weight gain. Since this is a single teenage mother, which places the infant at some risk for social and medical problems, a social work consultation is obtained.

The sepsis work up, reflux study and the sleep study are all normal. The dietitian determines that the mother, due to lack of knowledge, was giving the infant an inadequate amount of formula each day. He feeds well and gains weight in the hospital. The patient is sent home on a home monitor and the family is instructed to see the infant's primary physician in two days for follow-up weight checks.

He returns to the ED two months later (4 months of age) with repeated seizures during the afternoon. The mother describes that the infant fell off the couch at noon. He hit his face and had jerking motions of his arms and legs lasting 15 seconds. The mother states that the episode resolved and he seemed well. He was placed in a crib for a nap. Three hours later she went to his crib and found him having a tonic-clonic seizure of all extremities, which lasted one minute. He appeared lethargic. He vomited once and had three more similar episodes. When the grandmother returned home from work four hours later, they drove him to the ED where he is noted to be lethargic, with the following vital signs: P 120, R30, BP 70/40. Wt 6 kg (25%ile), Ht 66 cm (75%ile), HC 42 cm (50%ile). His exam is remarkable for a full fontanel, a weak cry, and dried blood on his upper gum with a frenulum tear. He has no signs of external head trauma or body bruises. His pupils are equal and reactive to light. The retina are difficult to examine.

When obtaining more history from the mother, she also notes that he still has not had any immunizations. She describes him as being irritable and a difficult baby to console, and a poor feeder. His stools are described as normal.

A CT scan of the brain shows a right subdural hematoma with generalized cerebral edema. He is admitted to the pediatric ICU. Initial labs are normal, but a skeletal survey demonstrates several rib fractures and a right tibia fracture. An ophthalmologist is consulted who determines that there are bilateral retinal hemorrhages.

What constitutes child abuse can differ among individuals and societies. In some societies child employment is viewed as abusive, while in others it is seen as necessary and normal. Child abuse must be defined within each society. We may define child abuse as any act that causes bodily injury, emotional or psychological harm, physical neglect or sexual abuse. Some child advocates strongly support a definition that includes not only overt acts that cause harm but includes acts that may have potential harm.

In the United States, federal and state legislation defines both child abuse and neglect. The Child Abuse Prevention and Treatment Act of 1974 (CAPTA) (1) is federal legislation that offers guidelines that states are required to incorporate into their legal definitions of child abuse. Each state develops its own definition based on these guidelines. Many states define abusive acts as ones that cause harm or potential harm. Some states specify conditions that are exceptions to the definition of abuse. An example of one such exception could be religious reasons for which parents choose not to seek medical care for their children. The parents would be exempt from charges of child neglect for not following medical advice. Other conditions that result from poverty, use of corporal punishment and traditional medical therapies may also be except in certain jurisdictions.

States are allowed to develop their own definitions of child abuse and neglect. Therefore they vary in how specific those definitions are. The definition may be very broad which allows the state child protective services to use their discretion in determining whether abuse has occurred. A common form adopted by states is a separate definition used for physical abuse, neglect, sexual abuse and exploitation, and emotional abuse. A few states have added abandonment in their definition of neglect.

In the state of Hawaii, child abuse has been defined as: the acts or omissions of any person that have resulted in the physical or psychological health or welfare of the child who is under the age of 18 to be harmed or to be subject to any responsible foreseeable, substantial risk of being harmed. The acts or omissions are indicated for the purposes of reports by circumstances that include but are not limited to (2):

1) When the child exhibits evidence of substantial or multiple skin bruising or any other internal bleeding, any injury to skin causing substantial bleeding, malnutrition, failure to thrive, burn or burns, poisoning, fracture of any bone, subdural hematoma, soft tissue swelling, extreme pain, extreme mental distress, gross degradation, death -- when such condition or death may not be the product of an accidental occurrence.

2) When the child has been the victim of sexual contact or conduct, including, but not limited to sexual assault as defined in the penal code, molestation, sexual fondling, incest or prostitution, obscene or pornographic photographing, filming, or depiction or other similar forms of sexual exploitation.

3) When psychological capacity of a child exists, as is evidenced by an observable and substantial impairment in the child's ability to function.

4) When the child is not provided in a timely manner with adequate food, clothing, shelter, psychological care, physical care, medical care or supervision.

5) When the child is provided with dangerous, harmful, or detrimental drugs.

All fifty states have specified which individuals are legally required to report potential child abuse cases. Generally people who have frequent interactions with children are mandated to report the case. Examples of professions that are frequently cited are teachers, social workers, law enforcement officers, health care providers, day care center employees, and coroners. Some states, such as Delaware, Florida and Tennessee require all individuals to be mandated reporters when they have a reasonable suspicion of child abuse.

How extensive is the problem of child abuse in the United States? In 1999 there were approximately 3 million cases referred to child protective services in the United States. In a third of these cases, child abuse was ruled out. Annually, there are 826,000 victims who suffer significant child abuse. Of these, approximately 480,000 (58%) were victims of neglect, 175,000 (21%) suffered physical maltreatment and 90,000 (11%) were subjected to sexual abuse (3).

The largest majority of children who are victims of child abuse are under the age of 3 years. This age group accounts for most of the fatalities. Of the 1100 children who died in 1999 of abuse, 470 (43%) of them were under 3 years of age and 946 (86%) of them were under 6 years of age. A significant number of these deaths are due to head injury, but neglect accounted for 420 of these deaths (3).

Child abuse can occur in any socioeconomic or cultural group. Epidemiological data has been reviewed to identify possible risk factors for the occurrence of child abuse. Factors that may have an increased risk include poor economic conditions (4), history of abuse in the caregiver, spouse abuse (5), premature infants, developmentally disabled children, and substance abuse in the caregiver. A history of a delay in seeking medical treatment, recent major stresses in the family, unrealistic expectations for the child, and a negative attitude toward the child are conditions that should alert the practitioner to the possibility of child abuse.

The types of physical abuse a clinician will encounter may range from bruising to severe head trauma with battering. A child may present with fractures, burns, cuts, bites, blunt trauma to the abdomen, and head trauma. To identify those injuries that are accidental and those that are intentional, a clinician must be familiar with the mechanisms of injuries, the developmental capabilities of the child and patterns of injuries.

DiScala et al, reviewed the differences between children who had injuries due to accidental trauma, and those who sustained injuries due to child abuse. In their review of over 18,000 children they found that children who were victims of child abuse were more likely to have been hurt by battering and shaking while accidental injuries were usually the result of falls. Abusive injuries were more likely to result in intracranial, thoracic and abdominal injuries. Child abuse resulted in more deaths, more severe injuries and more long-term disabilities (6).

One of the major keys in determining the difference between accidental injuries and abusive ones is that in abuse, the description of the incidents does not match the injury. A history of a minor fall in a child who presents with severe brain injury (brain swelling, subdural hematoma, ruptured intracranial blood vessels) is not compatible with a minor fall as the cause. The case at the beginning of this chapter presented a classic example of this, in which the history of a fall off the couch is alleged to have caused the seizures, cerebral hemorrhages, retinal hemorrhages and fracture.

Children may experience different fracture patterns than adults because of anatomical differences in the structure of their bones. The immature bone has different amounts of cartilage and the periosteum is thicker. Children have a growth plate and the metaphyseal and epiphyseal junction is prone to separation. Pediatric fractures are often associated with plastic deformation such that when the bone is bent, a permanent deformity occurs. The mechanism for fractures in children and adults can be the same, which includes blunt trauma to a bone with significant force to cause a fracture, twisting motions, and/or severe shaking that can fracture bones (7).

Injuries that are suspicious for child abuse are spiral fractures in non-ambulatory infants, which are due to twisting motions of the humerus and/or femur. The metaphyseal fractures of long bones that are often associated with severe shaking are particularly suggestive of child abuse. As occurred in the case study of this chapter, children who present with rib fractures without a history of significant chest trauma, are suspected of child abuse. Posterior rib fractures in a child who only has a history of minor falls are specific for intentional trauma. Other types of fractures that should alert the practitioner are multiple fractures, fractures of different ages, and a patient with fractures and other associated injuries. It is important to emphasize that a clinical history that is inconsistent with the type of fractures should raise suspicion of child abuse (8).

Skull fractures are the second most common skeletal injury seen in abused children (9). These fractures are often associated with intracranial injuries unlike unintentional injuries that are usually uncomplicated simple fractures. The size, location, numbers and whether a skull fracture is depressed is dependent on the degree and velocity of the force that impacts the child's head. It is important to emphasize that a clinical history that is inconsistent with the type of fracture should raise suspicion of child abuse. It is not credible that a child who is one month old can roll off a bed and fall a short distance to a carpeted floor and sustain a severe skull fracture with intracranial bleeding and retinal hemorrhages.

Bruising is due to bleeding into the dermis. Bleeding may be secondary to local trauma, coagulation abnormalities from clotting factor or platelet deficiencies, and vasculitis from various causes. Bruises have a tendency to follow different staging as they resolve. The area may initially be swollen, then turn a red or reddish blue color, then progress to green, yellow, brown, before clearing. Many authors have attempted to age bruises by their appearance. Many variables can affect the progression of a bruise including difference in circulation to the area, thickness of the skin, and depth and location of the bruise. Dating bruises to precise days or weeks, therefore, has been called into question (10).

Bruising is the most common external sign of child abuse, and it is also common in everyday childhood activities. As toddlers and children move forward, they may fall or bump into objects that can lead to bruising. Normally children who fall develop bruises that are located on their forehead, elbows, shins, and knees. Areas that are more likely to be bruised due to intentional injuries are the buttocks, genitals, perineal area, chest and back. Some bruises show patterns that may suggest the form of trauma. Examples are slap marks from fingers, bite marks, and pinching areas like the nose or ear lobes.

Some bruises are marks left by objects that are used to strike a child. Marks that look like loops are due to cords or rope that are looped before hitting a child. Bruising patterns have been described that match a belt buckle, spatula, iron, knife wounds, hairbrush, teeth marks, and numerous other objects. Often when authorities visit the home to investigate child abuse allegations, these objects are located.

Burns whether inflicted or accidental have a significant morbidity, mortality, and can require extensive medical, surgical, and physical therapy. These children may require plastic surgery and reconstructive surgery over months to years and sustain life long deformities. It is the obligation of health care providers to recognize those injuries that are suspect of child abuse and make reports to appropriate agencies.

A child may be burned from contact with hot liquids, hot objects or direct flames. Burns caused by hot liquids can have characteristic patterns when a toddler pulls a pot of hot liquid down or when someone pours a liquid over them. The liquid rolls down by gravity. The areas touched first receive the hottest liquid and the deepest burn, and those further down are less severely burned as the liquid cools. Since the liquid spills in a random splash, the burns are random. Immersion burns are more characteristic of child abuse. The child is held in hot liquid that creates burn lines where there are clear lines of demarcation of spared and burned areas. These burns may include the lower limbs only or the buttocks and perineum. Children who are put in hot water in a sitting position have a characteristic central clearing where the child's buttocks touches the bottom of the bathtub (which is slightly cooler). Limbs that are immersed have a demarcation that gives a stocking or glove pattern.

Cigarette burns are not uncommon skin lesions seen in child abuse. The marks left are circular with a deep center and devoid of hair. Toddlers may walk into a cigarette but these burns are not as deep and they are usually a single burn on the face or hands. Multiple cigarettes burns or burns located on the back, chest or legs are consistent with child abuse.

Lesions that can mimic child abuse include "coining" which is an Asian home remedy of heating coins and rubbing them on the child's back, which leaves linear bruising. Impetigo has been mistaken for cigarette burns. Bruising due to bleeding disorders like hemophilia, or platelet disorders, Henoch-Schonlein purpura, or Mongolian birthmarks have been misdiagnosed as inflicted injuries. Fractures may be due osteopenia in disabled children, and occult forms of osteogenesis imperfecta can be associated with pathologic fractures and bruising.

Children can be subject to numerous physical injuries but head trauma is the most common cause of death. The injuries can be due to direct impact or from acceleration and deceleration injuries. Patients can then develop extracerebral bleeding due to tearing of bridging vessels causing subdural and/or subarachnoid bleeding. The subdural hematomas often extend into the interhemispheric fissures. Cerebral edema often develops and may be the result of anoxia, poor perfusion, and/or direct tissue injury. While the areas of bleeding may be small on imaging studies, this does not reflect the degree of cerebral injury which is often substantial. Cellular death and axonal shearing are not easily visualized on CT scans. Neurosurgical evacuation of hemorrhage does not repair cerebral cellular and axonal injury.

These injuries are more common in infants and are the result of shaking battered child syndrome (also called shaken baby syndrome). Infants are more susceptible to these types of injuries due to the higher water content of the brain, poor neck control, proportionally larger head size, and more demyelinated nerve cells. The outcome of these injuries can result in brain death, cerebral atrophy, and chronic subdural collections. These children may remain in a coma, have developmental delays, seizure disorders, blindness and/or deafness (11).

The clinical presentation of shaken baby syndrome is often vague. There is usually minimal or no history of trauma and the spectrum of clinical signs range from poor feeding, vomiting, seizures to complete cardiopulmonary arrest. The symptoms are the result of intracranial injuries which may include subdural hemorrhage and/or subarachnoid hemorrhage, cerebral edema and shearing injuries to brain cells (12). Often these infants have no outward signs of abuse. Their intracranial injuries are associated with retinal hemorrhages and sometimes with long bone fractures or rib fractures. Since victims of shaken baby and other forms of child abuse can present with various signs and symptoms that at first glance may not suggest intentional trauma, the practitioner must have a high index of suspension and include child abuse in the differential diagnosis.

Besides head trauma, children may experience abdominal or thoracic injuries. These occur less often than other forms of physical injury. Abdominal injuries are most likely due to blunt trauma and can result in hematoma or laceration of the pancreas, duodenum and or the jejunum. These injuries can lead to hypotension, abdominal distention, vomiting, and ileus. These patients respond well to medical treatment. Blunt abdominal trauma may also result in visceral rupture to organs such as the liver, spleen pancreas, or major abdominal vessels. These children present very ill in shock with significant hemorrhaging, hypotension and possibly a full cardiopulmonary arrest.

Determining whether injuries sustained by infants and children are due to abuse or accident, can be difficult. The clinician should be alert to histories that do not adequately explain the injuries. It is then important to perform a complete assessment.

First and foremost, it is important to obtain a full medical history, which should include a complete description of the event in the caretakers own words. A story that is suspect, is one that does not match the injuries and changes over time. Include a developmental history and the current developmental capabilities of the child. Often, the history may include acts performed by the child that they are not developmentally capable of. For example, a seven month old infant is reported to have turned on the hot water faucet and got in the bath tub of hot water, when at seven months, they are not ambulatory, nor can they turn a faucet. Ask questions to determine if the family keeps medical appointments, the support system for the family, if any family stresses are present, the caretaker's perception of the child, and how they use discipline. Also obtain information about other hospitalizations, surgeries or previous injuries. A history of visiting multiple emergency rooms and numerous physicians may be a clue to attempts to avoid being reported to child protective services.

The physical exam should be complete and a record made of all outward signs of abuse. A body diagram should be used to describe the location, size, number, and characteristics of skin lesions. Good quality photographs should be taken to record the lesions. It is important to obtain measurements of height, weight, and head circumference and determine where the child plots on a growth curve. If there is any suspicion of sexual abuse, a specialist trained to do a complete medical and forensic evaluation should be consulted. Often a funduscopic exam is required to determine if retinal hemorrhages are present, and this exam is best done by an ophthalmologist after giving medication to dilate the pupils.

Laboratory tests and X-rays, will in part be determined by the clinical presentation of the child. Full skeletal survey x-rays should be obtained to diagnose obvious fractures and to look for occult fractures. A nucleotide bone scan may be considered because it may identify new fractures more clearly. The fractures should be aged as new or dated in various degrees of healing. Other x-rays to consider are chest x-ray, MRI or CT of the head and abdomen especially if there is any suspicion of possible intracranial or abdominal injuries. A CBC looking for any anemia or thrombocytopenia, electrolytes, PT, PTT, blood and urine cultures should be obtained. Other laboratory results to consider are liver enzymes and lipase if abdominal injuries are suspected.

Initially, a clinician, may not be able to confirm the presence of child abuse. However, the law requires that any suspicion of child abuse must be reported. Definite and/or severe cases of child abuse will require hospitalization or removal of the child from the home immediately. However, cases which are not confirmed and/or are not as serious, represent a dilemma for the clinician. Hospitalization and immediate foster placement is not necessarily indicated. But an immediate report to child protection authorities is still required because there is suspicion of child abuse. Should parents be told that you are about to report these circumstances to the child protection authorities? The answer to this is controversial, but it may be better to be honest with the parents, since they will probably find out who reported the incident later on. The best way to inform the parents that a report to child protection authorities is about to be made, is to point at an X-ray or injury and inform them that, "Whenever this type of injury occurs" (while pointing at the X-ray or injury), "the law requires that I report this to the child protection authorities. They might call you, so tell them what happened." If there is a fracture on an X-ray, point at the X-ray when saying this. If there is a bruise or burn, point at the bruise or burn when saying this. This is perceived as non-judgmental. It is almost as if you are reporting the X-ray or the injury, and not the parent or child. Compare this to "I have to report this to the child protection authorities, because this is suspicious for child abuse." This latter method often results in hostility, while the former method is non-judgmental which most often results in a neutral response from the parents.

There are unique forms of child abuse such as failure to thrive, Munchausen syndrome by proxy, maternal drug abuse and sudden infant death syndrome. Munchausen syndrome by proxy is a form of recognized child abuse in which a child presents with unexplained illnesses that are either fabricated or inflicted by the parents. Most often it is the mother who is the perpetrator. There are case reports of mothers that go to great lengths to make their children appear ill. Mothers have administered medication such as ipecac syrup to induce

vomiting, injected feces under the skin to produce infection, and induced apnea with a pillow over the child's head. Common characteristics of this syndrome include: 1) a child presenting with recurrent illnesses, 2) the parent has some medical knowledge, 3) the mother does not seem concerned about the child's illness, 4) the mother is hypervigilant in the hospital and will not leave the child's bedside, 5) the symptoms do not occur when the mother is away from the child, and 6) the father is often absent (13).

What is sudden infant death syndrome (SIDS) and how does it relate to child abuse? It is the sudden death of a child less than one year of age with no identified cause following a thorough investigation including an autopsy, and death scene investigation. Most cases are infants between 1 and 5 months of age. SIDS deaths occur more often in the winter months, and an association has been postulated with sleeping position, parental smoking or drug abuse, and infant and parent co-sleeping. Although most infant deaths are determined to be due to SIDS, a few deaths have proven to be infanticide. Further studies have identified infants initially presenting with recurrent apneic or cyanotic episodes, who were in fact victims of attempted suffocation (14).

Failure to thrive is defined as a child whose weight is below the 5th percentile for age. Organic causes of failure to thrive are numerous. A thorough history and physical examination will usually identify an organic cause due to neurologic, cardiac, gastrointestinal, genetic, endocrine or respiratory problems. A history of feeding practices, caloric intake and the child's ability to swallow needs to be evaluated. Laboratory studies may include a CBC, urinalysis with culture, blood urea nitrogen, creatinine, calcium, electrolytes, albumin, HIV testing and/or sweat chloride. If no organic cause can be determined, psychosocial causes need to be considered. Common causes are poverty, poor parental-child interactions, and child abuse. The child height, weight and head circumference should be plotted on to a growth chart. Children with non-organic causes of growth failure will show first a loss of weight, then height and lastly a decrease in head circumference. The practitioner may consider admission to the hospital to evaluate the parent-child interaction and the child's ability to gain weight with appropriate caloric intake. If the child gains weight quickly in the hospital with adequate calories, the diagnosis of nonorganic failure to thrive is highly probable. Once this diagnosis is made, a multidisciplinary approach to therapy to required to treat the psychosocial and economic causes while ensuring the safety of the child. Physicians, dietitians, social workers, nurses, and child protective services personnel may all be needed (15).

Perinatal drug abuse can have adverse effects on the fetus and newborn infant. Drugs used by the mother can have teratogenic effects on the fetus, cause premature delivery, growth retardation and cause withdrawal symptoms in the newborn. Perinatal substances abused include cocaine, amphetamines, alcohol, heroin, methadone, and barbiturates. Newborn withdrawal symptoms may include apnea, poor feeding, lethargy, seizures, irritability, tremors, and weight loss. Testing the newborn includes urine or meconium for drug exposure. The testing of newborns can bring into question confidentially concerns, and legal issues. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologist have taken the position that neonatal drug testing should be preferably performed with the consent of the mother. The information should be used to support rehabilitation of the mother and fostering healthy mother and child interactions without criminal prosecution. However, many states require referral to Child Protective Services and define perinatal drug abuse as child abuse and neglect. States such as California have committed to offering services such as education, and treatment for abuse.

Child abuse is a condition which medical practitioners who care for children will encounter in their practice. Our primary responsibility is the safety and welfare of the children in our care. To ensure that goal is accomplished, we must be advocates for the child and be vigilant in reporting any suspicious child abuse case.

Questions

1. A one year old child presents with facial bruising and a spiral fracture of the right femur. The parents state the child was bouncing on the bed and fell off and hit a nightstand. The leg is splinted in the emergency room. The patient has stable vital signs and does not appear to be in any pain. Child protective services has been contacted and a report has been filed. The hospital social worker wants to discharge the patient home pending the investigation. This child is medically stable for discharge. Should he be sent home?
2. What is Munchausen syndrome by proxy?
3. Define failure to thrive?
4. What is the key to determining nonaccidental injury as opposed to accidental injury?
5. True/False: Bruises that have different coloring can be used to date the time of the injuries.

Answers to questions

1. This child should be admitted to the hospital for his initial management and evaluation of potential child abuse. The hospital can offer the necessary diagnostic studies necessary to determine the presence and extent of other injuries. In addition the hospital environment offers and opportunity to observe child and family interactions by trained staff. It is the obligation of those caring for this child to insure that he be returned to a safe environment (16).

2. It is a unique from of child abuse where the child's caregiver inflicts or fabricates illness on the child.

3. When a child's weight is plotted on a growth curve and is found to be below the 5th percentile for their chronological age.

4. One of the major keys in determining the difference between accidental injuries and abusive ones is that the description of the incidents does not match the injury.

5. False. Many variables can affect the progression of a bruise. Bruises do tend to follow different stages progressing from red to green, yellow, brown and then clearing. An exact time frame cannot be established when the injury occurred, only that some bruises are older than others.

Chapter XV.1. Diabetes Mellitus
Greg Y. Uramoto, MD

This is a 9 year old boy who has enjoyed his usual state of good health until his polyuria started 2 months ago. He began to lose weight and reported worsening nocturia over this same period. His appetite increased although lately he has more episodes of stomachaches. Today, he had a noticeably sweet smell to his breath and he was breathing faster than usual so his mother brought him to his pediatrician.

Exam: VS T 37.0, RR 44, P 92, BP110/60, oxygen saturation 100% on room air. His weight was 25 kg (25%tile). He is alert and cooperative. His skin is warm to his wrists and ankles. His oral mucous membranes are tacky. His capillary refill is 3 seconds over his chest. His skin was otherwise normal. His thyroid gland is approximately 1.5 times the normal size. His heart rate is regular. He is slightly tachypneic with clear breath sounds. His reflexes are normal. His abdomen has normal bowel sounds has no tenderness. His genitalia and pubic hair are in Tanner stage I. The rest of the physical examination is unremarkable.

His pediatrician suspects new onset diabetes mellitus. A urine dipstick in the office shows 4+ glucose and 2+ ketones. No other dipstick abnormalities are noted. He is clinically stable. He is hospitalized for further management and treatment. His initial lab studies show Na 132, K3.3, Cl 99, bicarb 11, glucose 380, BUN 21, creatinine 0.4. He is started on an IV fluid infusion and subcutaneous insulin.

Prior to the purification of insulin, type 1 diabetes mellitus was uniformly lethal. Although we have made significant strides in the evaluation and management of diabetes, it remains a significant health problem in the general population. In the pediatric subset of the population, type 1 diabetes mellitus is especially challenging since so many factors need to be balanced. The basics on balancing all of these factors will be covered in this chapter.

In United States, the overall risk of developing type 1 diabetes mellitus is 0.2-0.4 percent in Caucasians. In siblings of patients with type 1 diabetes, the risk is approximately 6%. Children of fathers who have type 1 diabetes mellitus have a 6% risk of developing the problem. Children of mothers with type 1 diabetes mellitus have only a 3% chance of developing the problem. The overall incidence of the disease is 18.2 in 100,000/year among people less than 20 years old. The incidence is much higher in Scandinavian countries than in Asian countries.

The National Diabetes Data Group in 1979 divided the heterogeneous condition of diabetes mellitus into two main groups. Type 1 diabetes mellitus has also been called insulin-dependent (IDDM), juvenile onset, ketosis prone, or brittle diabetes. In this type of diabetes mellitus, islet cells are destroyed by an autoimmune process and insulin that these islet cells produce must be replaced. With our current understanding, type 2 diabetes mellitus is primarily an insulin resistant state with a gradual decrease in beta cell function. It was formally known as non insulin-dependent diabetes (NIDDM), adult-onset diabetes, or stable diabetes. Clinical diabetes mellitus can also result from a large number of pathologic processes. Beta cell destruction due to pancreatitis, cystic fibrosis, or surgery can lead to an insulinopenic state that requires insulin injections. Medications including streptozocin, cyclosporin, and corticosteroids can also lead to clinically high blood sugars.

Approximately 2 percent of the American population have some form of diabetes mellitus. Approximately 85 percent of all patients (adults and children) with diabetes mellitus are categorized as type 2. Since type 2 diabetes mellitus is often very subtle, the number of undiagnosed cases of diabetes mellitus is significant. The other 15 percent of patients with diabetes mellitus nationwide are categorized as type 1. In the pediatric population, type 1 diabetes makes up a larger proportion of the cases. Although our estimates are quite crude, some centers report that approximately 98 percent of their children with diabetes have the Type 1 variety. This estimate will certainly be revised in the future as we recognize more type 2 diabetes in children.

Insulin is the primary hormone that suppresses hepatic glucose production, proteolysis, and lipolysis. It is secreted in a biphasic manner in response to glucose. The first phase of insulin release is followed by a nadir and then by a relatively prolonged second phase of insulin release. Catecholamines, cortisol, growth hormone, glucagon, and gastrointestinal hormones among other hormones modulate the insulin response to glucose.

Due to the portal circulation in the gut, blood draining the islet cells of the pancreas goes to the liver before returning to the heart. This portal circulation exposes the liver to an immediately high concentration of insulin soon after a meal. When treating diabetes with exogenously administered insulin into the systemic circulation, we need to remember that this does not duplicate the physiologic state.

Insulin is an anabolic hormone that increases the transport of glucose into cells. With this transport, insulin will decrease the serum glucose. At the cellular level, glucose does not act alone. In reality, the insulin/glucagon ratio is important for determining the body's response to insulin. A high insulin state will induce glucose uptake and inhibit amino acid release in muscle cells. In the liver, insulin will decrease glucose release and decrease ketone body formation. In fat cells, insulin will increase glucose uptake and decrease lipolysis.

In our most current models, type 1 diabetes mellitus is an autoimmune disease. In our current understanding of the problem, people with type 1 diabetes mellitus have an underlying genetic predisposition to developing diabetes. On top of this predisposition, they are exposed to an environmental insult that triggers the immune response. In this way, not everyone who is genetically susceptible to type 1 diabetes mellitus will develop the problem. The identical twin of the patient with type 1 diabetes mellitus has a 25 to 50 percent risk of developing the problem in their lifetime.

Important genes for transmitting this susceptibility to diabetes include the human leukocyte antigens (HLA) that allow for some of the communication between white blood cells. The HLA-DR and HLA-DQ molecules are especially important. These are antigen-presenting structures that T-cells recognize. The antigens in these presenting molecules are the targets for the immune response. Mutations that lead to defects in the structure of this antigen presenting molecule predisposes to type 1 diabetes mellitus. One of the important residues in the structure of the HLA molecules is at position 57. Homozygosity for aspartic acid at this site confers nearly 100% protection against type 1 diabetes. Conversely, a non-aspartic residue at this spot can lead to a nearly 100 fold increase in the incidence of disease.

On top of this genetic predisposition, an environmental insult is likely to be required for the development of diabetes. The environmental factors are quite varied and we are only now beginning to isolate some of them. Congenital rubella cases provide compelling evidence that some of these environmental triggers are viral proteins. Approximately 20 percent of babies with congenital rubella will develop type 1 diabetes mellitus. Most of these cases do not appear until adolescence. Other viruses such as Coxsackie virus, cytomegalovirus, and hepatitis viruses have been implicated.

Polyuria, polydipsia, weight loss, fatigue, polyphagia, anorexia, deteriorating school performance, failure to thrive, and nocturnal enuresis can occur. Clinical symptoms become apparent when the blood sugar rises above the renal threshold and glycosuria induces an

osmotic diuresis. Insulinopenia allows hormone sensitive lipase to cut long fatty-acid chains into two carbon acetate fragments which are converted to ketoacids. Patients will present in varying degrees of decompensation as the serum pH decreases and as the dehydration progresses. New onset type 1 diabetes will frequently present with diabetic ketoacidosis of varying severity.

Secondary enuresis, unexplained weight loss, and polyuria should raise suspicions about diabetes. Testing should include random glucose levels, electrolytes, and ketones. The measurement of hemoglobin A1C and insulin can also be helpful. 90% of children will have elevated anti-insulin, anti-islet cell, or anti-GAD (Glutamic acid dehydrogenase) antibodies. Rarely, an IV or oral glucose tolerance test to evaluate for the degree of insulin-producing capacity may be considered in borderline cases, mostly to confirm type 2 diabetes.

Normal glucose levels should be <126 mg/dl in the fasting state. "Fasting" for this purpose should include no caloric intake for at least 8 hours. A random glucose of >200 mg/dl and elevated ketones in the urine or serum in the presence of classic symptoms of diabetes strongly supports the diagnosis of diabetes.

There is no single test that will definitively differentiate between type 1 and type 2 diabetes. Insulin levels should be high in the presence of high serum glucose levels. At least one of the above antibody tests are usually positive in type 1 diabetes. The clinical course is also helpful in differentiating type 1 and type 2. In the case of type 1 diabetes, the capacity to make insulin will decrease over the course of several months as islet cell destruction advances. In type 2 diabetes, the beta cell function is lost over the course of years to even decades.

Diabetic ketoacidosis (DKA) is a complex subject on its own, beyond the scope of this chapter. DKA occurs in an insulin deficient state when cellular starvation of glucose occurs. Despite hyperglycemia, glucose cannot be transported into many cells in the absence of insulin. Therefore, cellular energy metabolism utilizes lipolysis with resultant organic acid, ketone formation (i.e., ketoacidosis) and visible lipemia (blood samples may appear visibly turbid). Patients classically present with severe dehydration, vomiting, deep respirations (respiratory compensation for metabolic acidosis) and a ketotic odor to the breath. Management begins with IV fluids and insulin (0.1 u/kg) administration. Factitious hyponatremia is present with extreme values of hyperglycemia as seen in DKA. This will correct on its own as the glucose level normalizes. Complications such as cerebral edema may occur, the etiology of which is not fully understood. Fluid administration has not been demonstrated to be the cause of cerebral edema; however caution should be exercised in the rate of administering IV fluids. As a rule of thumb, it may be conservative to infuse normal saline at a rate of LESS than 10 cc/kg/hour (i.e., less than a fluid volume correction of 1% of body's weight per hour). A relatively stable patient can receive fluids at maintenance or 1.5 times maintenance. However, severely dehydrated or patients in shock will need more aggressive fluid administration rates. Cerebral edema occurs because the high extracellular glucose levels result in osmotic gradients which pull water from the cells creating cellular dehydration (similar to how a grape changes into a raisin). At some point, this cellular dehydration results in irreversible cellular injury. A less common phenomenon is known as the hyperosmolar non-ketotic state which is characterized by glucose levels in excess of 1000 mg/dl (DKA glucose levels are typically 300 to 800 mg/dl), little or no ketones (most easily assessed by urine dipstick for ketones), and depressed sensorium or coma. The hyperosmolar non-ketotic state has a substantial mortality rate in the 25% range especially if the patient presents in coma, because cerebral cells are subjected to greater degrees of cellular dehydration and a higher risk of irreversible injury. Why does DKA occur in most patients while the hyperosmolar non-ketotic state occurs in others? The answer is uncertain, but it may have something to do with differences in lipid metabolism between individuals.

Once patients are stabilized on the hospital floor, subcutaneous insulin is currently the standard treatment. This insulin can be delivered with injections or a pump. The back-up system for the pump, however, is injections so everyone should learn the basics of subcutaneous insulin injections.

The key to managing diabetes is to balance the factors that increase the blood sugar with the factors that decrease the blood sugar. The most important of these factors include insulin, diet, and exercise. Parents of children with diabetes need to learn enough about diabetes to take care of their children at home. At the very least, they will need to learn about: insulin injections, the types of insulin, blood glucose monitoring, the influences of diet on blood sugar, the influence of exercise on blood sugar, the influence of illnesses on blood sugar, symptoms of hypoglycemia, and the proper response to high and low blood sugars. Without this basic knowledge, patients cannot be discharged home. Several education sessions are usually needed to cover the large amount of information. With so many important aspects to the treatment of diabetes, a team approach that includes dietitians, counselors, diabetes educators, and doctors usually works best.

The insulin program should be tailored to match the family. The sophistication of the family and the ability of the child to give themselves their own shots are important considerations. Two common insulin programs include the mixed-split program and the multiple daily injection program.

In the mixed split program, two insulin types are mixed together and given in two injections. The two insulin types usually include an intermediate-acting NPH and a short-acting insulin such as Lispro or regular. Each shot is supposed to take care of two different meals so the morning shot will take care of breakfast and lunch. In this way, the child does not need to give a shot in school. This is important if the child is not old enough to give his/her own shots.

The multiple daily injection (MDI) program uses a long-acting insulin like Ultralente or insulin glargine to mimic the physiologic baseline of insulin. On top of this baseline, short acting insulin is given with each meal. This program is fairly flexible and usually leads to better control of the blood sugars.

Insulin doses should be tailored to the patient's needs. One unit per kilogram of insulin per day can be used as a starting dose of insulin in someone who presents in severe DKA. Careful monitoring of the glucose levels is required to adjust the doses on a daily basis while they are in the hospital. Because the insulin shots are not physiologic, we may need to tolerate a high post-prandial sugar in some patients. Some children and infants are continuously post-prandial so their blood sugar control is often quite complex.

The goals of treatment should also be tailored to the family and the patient. Aiming for excessively tight blood sugar control with a complex insulin program will likely fail in children with complex social issues at home. With this in mind long-term management would include getting as many blood sugar levels into a "goal range" as reasonably feasible. A typical goal range for infants and toddlers is between 100 and 200 mg/dl. A typical goal range for 5-11 year old children is between 80 and 180 mg/dl. For older children blood sugars in the normal range are reasonable. Hemoglobin A1C is a measurement of glycosylated hemoglobin. This level reflects the glycemic control over the previous 3 months. Goals for the hemoglobin A1C values should also be tailored to meet the needs of the family and the patient. In general, lower hemoglobin A1C values are desirable, but the incidence of hypoglycemia is important. Hemoglobin A1C values that are less than 8 are often attainable in elementary school children.

To achieve these lower hemoglobin A1 C values, adjusting the insulin doses are mandatory. Most families can learn enough about diabetes to adjust the insulin doses themselves. In the MDI program, trends in the blood sugars that are obtained several hours after the meal-insulin combination can be used to adjust the insulin doses. A consistently high pre-lunch blood sugar, for instance, would imply

that the breakfast insulin should be increased. Other factors that influence the blood sugar should also be considered. The insulin dose should be increased if the meal was not excessive and if the patient was not particularly active.

We are still learning about the pathophysiology of type 2 diabetes. There is some debate about whether insulin resistance or decreased insulin release is the initial problem. Both of these problems occur and the effects of the relative insulinopenia can be found in utero. Adults with type 2 diabetes are much more likely to have had an intrauterine growth retardation than the adults without type 2 diabetes. This is not surprising given the importance of insulin in the growth of fetuses. The early stages of type 2 diabetes are characterized by relatively normal fasting glucose levels but elevated post-prandial blood sugars. This occurs since the insulin that is available can eventually lower the blood sugar levels but cannot take care of the glucose load soon after a meal. As the disease progresses, islet cell function slowly declines in type 2 diabetes and the fasting blood sugars will rise as well.

The treatment of type 2 diabetes can be exactly the same as type 1 diabetes. The same insulin program with the same adjustment strategies will work very well in even the early phases of type 2 diabetes. When type 2 diabetes, as patients slowly lose their ability to make insulin, they will more closely resemble people with type 1 diabetes and insulin becomes a necessity. Before this loss of islet cell function, oral medications can be used. Theoretically, sulfonylureas, biguanides, and thiazolidinediones can be used in children as they can in adults. Studies that show efficacy and safety in children are not yet available so they must be used with caution.

Questions

1. What is a reasonable goal range for infants, children, and teens?
2. Which type of diabetes is primarily an autoimmune problem?
3. The identical twin of a patient with type 1 diabetes has what risk for developing type 1 diabetes?
4. Which antibodies are often present in type 1 diabetes?
5. What is a hemoglobin A1C?
6. In the early phases of type 2 diabetes, is the fasting blood sugar or the postprandial blood sugar elevated?

Answers to questions

1. Infants: 100-200. Children: 80-180. Teenagers: 70-120.
2. Type 1
3. 50 %
4. Anti islet cell, anti insulin, and anti GAD antibodies
5. HgA1C is the combination of hemoglobin and glucose. It is elevated when the glucose levels are high and it is a good marker for diabetes control.
6. Postprandial.

Chapter XV.2. Thyroid Disorders

Melanie L. Shim, MD

A previously healthy 14 year old female complains of a fast heart rate, weight loss, and fatigue over the past 2 months. Her family history is significant for a grandmother and aunt with Hashimoto thyroiditis.

Exam: VS T 37, HR 110, R 22, BP 120/50. On exam, she is comfortable without diaphoresis. She has a mild tachycardia without murmurs or gallop. She is found to have a smooth goiter with a bruit, a mild tremor, and exaggerated DTRs.

Labs: Elevated T4, undetectable TSH. Thyroid stimulating immunoglobulin assay is positive.

She is diagnosed with Graves' disease. She is treated with PTU (propylthiouracil) after which her thyroid function normalizes. Clinically, there is resolution of her tachycardia, weight loss, and fatigue, and her goiter decreases in size. Her thyroid function is monitored routinely and the dose of PTU adjusted as indicated to maintain a euthyroid state. Two years after diagnosis, she goes into remission and PTU is discontinued.

The hypothalamic-pituitary-thyroid axis regulates production and maintains peripheral concentrations of the biologically active thyroid hormones, thyroxine (T4) and triiodothyronine (T3). Pituitary thyroid stimulating hormone (TSH) secretion is modulated by the stimulatory effect of hypothalamic thyrotropin releasing hormone (TRH) and the inhibitory (negative feedback) effects of T4 and T3 influencing both TRH and TSH secretion. The major secretory product of the thyroid gland is T4. It is synthesized as a component of the large (660-kD) precursor thyroglobulin molecule. Iodine is the rate-limiting substrate, which must be actively transported in to the thyroid follicular cell by a plasma membrane sodium/iodide pump. Iodide trapping, thyroglobulin synthesis, and iodothyronine secretion are all stimulated by TSH. The iodothyronines are transported in blood bound to the thyroid hormone-binding proteins, thyroid hormone-binding globulin (TBG) and transthyretin (prealbumin). Thyroid hormones also bind to albumin and lipoproteins with lesser affinity (1,2).

Only small amounts of T4 and T3 are free or unbound. This free hormone is available to tissues. T4 serves largely as a prohormone and is deiodinated in peripheral tissues by several iodothyronine monodeiodinase enzymes to active T3 or biologically inactive reverse T3 (rT3). The major source of circulating T3 is peripheral conversion from T4, largely by the liver. Only small amounts of T3 are secreted

by the thyroid gland in euthyroid subjects ingesting adequate iodine. Normally, T4 is deiodinated to both T3 and rT3. The T3 mediates the predominant effects of thyroid hormones via binding to the 50-kD nuclear protein receptors, which function as transcription factors modulating thyroid hormone-dependent gene expression (1,2).

During the first trimester of gestation, the thyroid gland arises from the foramen caecum at the base of the tongue and migrates caudally to the neck site. By 12 weeks gestation, iodine trapping and T4 and T3 synthesis occur. Adequate quantities of iodide are essential for fetal thyroid hormone synthesis. The placenta imposes a relative barrier to the thyroid hormones and is impermeable to TSH, so the fetal hypothalamic-pituitary-thyroid system develops largely autonomous of the maternal system. The placenta is permeable to thionamide drugs used to treat maternal hyperthyroidism, which could result in fetal and early postnatal hypothyroidism. In term infants, following delivery, there is a postnatal surge of TSH which returns to normal by 2-3 days. T3 and T4 concentrations increase 2 to 6 fold, peaking at 24 to 36 hours after birth and gradually declining to levels characteristic of infancy over the first 4-5 weeks of life. Normal thyroid function parameters vary with age (1,2).

Thyroid Disorders in Children:

Primary hypothyroidism:

1. Congenital
2. Autoimmune (Hashimoto thyroiditis)
3. Iodine deficiency
4. Iatrogenic (goitrogen ingestion, radiation)
5. Transient (transplacental passage of antithyroid drugs, maternal transfer of antibodies)

Secondary hypothyroidism:

1. Central hypothyroidism (TSH deficiency)

Primary hyperthyroidism:

1. Autoimmune (Graves' disease)
2. Neonatal Graves' disease (transplacental passage of TSH receptor-stimulating antibody)
3. Factitious (ingestion of excess thyroid hormone)

Secondary hyperthyroidism:

1. Hyperthyrotropinemia (TSH excess)

Other thyroid disorders:

1. Thyroid nodules (benign vs. malignant)
2. TBG deficiency or excess
3. Synthetic defects - hormones or carrier proteins
4. Euthyroid Sick Syndrome

Congenital hypothyroidism (3) is an important cause of mental retardation that can be prevented with early identification and treatment. Newborn screening for congenital hypothyroidism is now routine in most industrialized societies. It is based on physiologic principle that primary hypothyroidism results in neonatal TSH hypersecretion. Screening tests are usually carried out with dried blood spot samples collected via skin puncture. In some areas T4 is measured initially, and TSH is measured in samples with the lowest 10-20% of T4 results. In other areas, direct TSH screening has been used. The preferred time for blood sampling is 3-5 days after birth. However, many newborns are now discharged from the hospital before 3 days of age. Early measurement increases the prevalence of infants demonstrating a modest elevation of TSH concentrations due to the physiological neonatal TSH surge; thus increasing the number of false-positive results (4). The prevalence of congenital hypothyroidism approximates 1 in 4000 births. Etiologies include thyroid dysgenesis, thyroid dyshormonogenesis, hypothalamic-pituitary (TSH) deficiency, and transient hypothyroidism (usually iodine, drug, or maternal antibody induced); the proportions approximate 75%, 10%, 5%, and 10%, respectively, of all cases of congenital hypothyroidism.

Thyroid dysgenesis describes infants with ectopic or hypoplastic thyroid glands as well as those with total thyroid agenesis. It is usually sporadic, with a 2:1 female preponderance. Ectopic glands may be located anywhere from the base of the tongue, along the thyroglossal duct, laterally, or as distant as the myocardium. A normal or near normal circulating level of T3 in the presence of low T4 suggests the presence of residual thyroid tissue, and this can be confirmed by a thyroid scan. A measurable level of serum thyroglobulin indicates the presence of some thyroid tissue; athyroid infants have no circulating thyroglobulin.

Dyshormonogenesis, or the inborn errors of thyroid hormone synthesis, secretion, and utilization, follows an autosomal recessive pattern of inheritance. The most common defect involves deficiency of thyroperoxidase enzyme, which is responsible for organification of iodide. When present with sensorineural hearing loss it is known as Pendred syndrome. Other defects may involve iodide trapping, coupling of tyrosyl rings, abnormal thyroglobulin synthesis, or deiodination of iodothyronines.

Transient congenital hypothyroidism may result from goitrogenic agents and transplacentally derived TSH receptor-blocking maternal autoantibodies. The presence of a goiter in an infant is supportive evidence of antithyroid drug- or goitrogen- induced transient hypothyroidism. Maternal TSH receptor-blocking antibody-induced hypothyroidism should be suspected in any case in which the mother has a history of autoimmune thyroid disease. The presence in maternal or neonatal blood of a high level of TSH receptor-blocking antibody is strong supportive evidence.

Confirmatory diagnosis of congenital primary hypothyroidism is based on measurement of T4 (low) and TSH (high). Optional studies include ultrasound and radionucleotide scan. Physical examination may reveal one of several early and subtle manifestations of hypothyroidism, including a large posterior fontanelle, prolonged jaundice, macroglossia, hoarse cry, distended abdomen, umbilical hernia, hypotonia or goiter. Fewer than 5% of infants are diagnosed on clinical grounds before the screening report, but 15-20% of infants have suggestive signs when carefully examined at age 4-6 weeks, after the screening results have been reported. For infants with congenital hypothyroidism, prompt initiation of levo-thyroxine (75-100-ug/m2/d) treatment is essential. Delayed institution of treatment (>45days) is clearly associated with diminished mean IQ.

Hashimoto thyroiditis (autoimmune hypothyroidism, chronic lymphocytic thyroiditis) is an autoimmune, inflammatory process causing 55-65% of all euthyroid goiters and nearly all cases of hypothyroidism in childhood and adolescence (5,6). Prevalence studies have found that as many as 1.2% of school-aged children have chronic lymphocytic thyroiditis as defined by an enlarged thyroid gland and detectable thyroid antibodies in the serum. Females predominate at a ratio of 2:1 with a peak age of onset in mid-puberty. It is rare under 4 years of age. The specific mode of inheritance is not known, but there is a high familial incidence. Thyroid inflammation and damage result from self-directed humoral and cell-mediated immunity. Antibody markers of the destructive process include anti-thyroglobulin and anti-thyroperoxidase antibodies. One or both of these antibodies are present in virtually all patients with chronic lymphocytic thyroiditis, but they are not specific for this disorder and may be found in other autoimmune diseases such as Graves' disease, Addison's disease, and Type 1 diabetes.

The initial presentation of Hashimoto thyroiditis can usually be categorized as thyromegaly with euthyroidism, toxic thyroiditis, or hypothyroidism with or without thyromegaly. The majority of patients are asymptomatic and present with an enlarged thyroid gland. The gland may be symmetrically or asymmetrically enlarged with a bosselated (cobblestone) texture. Toxic thyroiditis (Hashitoxicosis) is a transient, self-limited form of hyperthyroidism occurring in less than 5% of patients. If hypothyroidism is present, there may be a history of poor growth, fatigue, constipation, mild weight gain, dry skin and cold intolerance.

The initial screening of thyroid function should include measurement of serum free T4, TSH, and anti-thyroid antibodies. Again, most children are euthyroid initially (normal T4 and TSH). The incidence of hypothyroidism (low T4 and high TSH) is 3-13% and compensated hypothyroidism (normal T4 and high TSH, signifying possible impending hypothyroidism) occurs in up to 35%. In addition, serum T3 concentration should be determined if the patient appears to have hyperthyroidism.

Treatment involves replacement with levo-thyroxine (50-100 ug/m2/d) to normalize TSH and T4. Long-term follow-up studies indicated that chronic lymphocytic thyroiditis resolves in 50% of children. Replacement therapy should continue until the patient has achieved final adult height. At that time, a trial without medication may be considered. If a child has positive antibodies but is euthyroid, replacement therapy is not necessary, however thyroid function should be monitored regularly. Children with transient toxic thyroiditis can be treated with propranolol.

Graves' disease (autoimmune hyperthyroidism) is the autonomous production of excessive thyroid hormones by a usually enlarged thyroid gland that is not under pituitary control (7,8,9). It is the most common cause of hyperthyroidism in children. There is a high familial incidence, and females predominate in a 3:1 ratio. The peak incidence occurs during adolescence.

Graves' disease arises from autoimmune processes, which include production of immunoglobulins against antigens in thyroid, orbital tissues, and dermis. Thyroid-stimulating immunoglobulins (TSI) are present in nearly all patients. These antibodies bind to the TSH receptors on the thyroid cells and have a stimulatory (TSH-like) effect. TSI, like TSH, stimulates thyroid follicular cell growth to cause thyromegaly. Anti-thyroglobulin and anti-thyroperoxidase antibodies are also found in many patients, but in lower levels than in Hashimoto thyroiditis. Graves' disease and Hashimoto thyroiditis may in fact be a part of a spectrum of the same disease process.

The sustained state of an increased metabolic rate results in enhanced energy expenditure to cause a catabolic state. Clinical features include nervousness, irritability, palpitations, tachycardia, tremor, increased appetite with weight loss, diarrhea, difficulty sleeping, heat intolerance, poor school performance, irregular periods, and rapid height velocity. Most patients will have a goiter. Even though up to 50% of children with Graves disease manifest ophthalmopathy, this problem is not as severe as in adults. Lid retraction and stare are the most common, whereas chemosis (conjunctival swelling), lid eversion, and paresis of extraocular muscles are found predominately in adults. Graves dermopathy (pretibial myxedema) in children is virtually nonexistent.

The thyroid hormone profile characteristically shows elevated T4 and T3 levels, accompanied by very low or undetectable levels of TSH. In 15-20% of cases, the T3 level is elevated with a normal level of T4 (T3 toxicosis). This represents an early stage of thyrotoxicosis, prior to the elevation of T4.

The three forms of treatment for Graves' disease are medical, surgical, and radioactive iodine ablation. The mainstay of medical management is antithyroid mediations with methimazole or propylthiouracil. Both are equally effective at decreasing the production of T4 and T3 by the thyroid gland, but propylthiouracil also blocks the peripheral deiodination of T4 to T3. Side effects are infrequent, but include skin rashes, arthritis, hepatitis and agranulocytosis. Evidence suggests that with antithyroid medication alone, remission of Graves' disease (defined as being euthyroid for 1 year after stopping medications), occurs at a rate of 25% over 2 years. If medical treatment must be discontinued because of side effects, frequent relapses, or inability of comply with the treatment schedule, thyroid ablative therapy or thyroidectomy should be implemented (10).

Thyroid cancer in children (11). There is about a 30% chance that a nodule found in a child will be malignant. In children who have had other forms of cancer there is a 50-fold increased risk of thyroid cancer secondary to the use of radiation therapy. Basic thyroid function tests are usually normal. Thyroid scans using 123I or 99m Tc-pertechnetate are helpful in the evaluation of a thyroid nodule. A "cold" area (hypofunctioning) on scan increases the suspicion of malignancy while "hot" (hyperfunctioning) nodules are almost invariably benign. Needle biopsy is the most simple and direct method to help determine the architecture of a thyroid nodule.

Papillary cancer is the most common malignant thyroid tumor in children (60-80%). These tumors often consist of a mixture of papillary and follicular elements. Pure follicular carcinomas comprise about 10-15% of cases (12). Medullary carcinomas account for less than 7% of all thyroid cancers and may be sporadic, familial (autosomal dominant), or part of one of the multiple endocrine neoplasia syndromes. Malignant or suspicious lesions require surgical intervention and post-operative ablation with 131I followed by appropriate surveillance.

Questions

1. True/False: The major secretory product of the thyroid gland is T3.
2. True/False: A low T4 and low TSH at newborn screening suggests thyroid dysgenesis.
3. True/False: Most patients with Hashimoto thyroiditis present with a goiter and are asymptomatic.
4. True/False: Graves' ophthalmopathy is more severe in children than in adults.
5. True/False: Graves' disease occurs equally among males and females.
6. True/False: Papillary carcinoma is the most common type of thyroid cancer in children.

Chapter XV.3. Short Stature

Maureen M. Petersen, MD
Anita M. Pedersen, MD

A 10 year old girl presents to your clinic for evaluation of short stature. Parents report that she has always been the shortest girl in her class, but they have become concerned because the patient's 8 year old sister is now the same height as she is. The patient has not yet attained menarche and her mother reports no breast development. She has been well with no chronic medical problems, no hospitalizations, and no surgeries. She lives with her mother, father, and sister and she is currently a straight A student in the fifth grade. Her mother is 173 cm (5'8") and weighs 68 kg (150 pounds). She had menarche at age 12. The patient's father is 185 cm (6'1") and weighs 95 kg (210 pounds). He started shaving at age 15. There is no family history of any medical problems. On further history, you find that your patient was 43 cm (17 inches) long at term (average is 49.5 cm, 19.5 inches).

Exam: VS T 37.0, P 90, R 18, BP 100/60. Height 120 cm (<5%), weight 23 kg (slightly <5%). She is an alert, small appearing girl who is in no apparent distress. HEENT exam is normal. Neck is supple with webbed appearance. Heart regular rate, no murmurs. Lungs are clear. Abdomen is soft without masses. Tanner 1 breasts with wide-spaced nipples are evident. The carrying angle is increased. Tanner 1 pubic hair is noted.

Her growth chart is reviewed which demonstrates an average growth velocity of 3 cm per year. She is sent for a bone age that is read by the pediatric radiologist as 8 years and 6 months. CBC, ESR, TFT's, UA, and serum electrolytes are normal. Chromosomes are obtained revealing a 45XO pattern. The diagnosis of Turner Syndrome is made. You refer her for a renal ultrasound, cardiology evaluation, and a hearing screen. She is also seen by the pediatric endocrinologist and is started on growth hormone.

Growth is an important task for infants and children to accomplish. Short stature is a common pediatric problem with potential long-term sequelae if a pathologic cause remains undiagnosed. Physicians though, can be reassured that the majority of cases of short stature have a nonpathologic cause and by obtaining a thorough history, physical exam, and screening tests, short stature can be readily evaluated.

Growth is primarily controlled by the hypothalamus and pituitary gland. The pituitary gland has two lobes, the anterior lobe (adenohypophysis) and the posterior lobe (neurohypophysis). Growth hormone is secreted in a pulsatile fashion from the anterior lobe of the pituitary in response to two hypothalamic hormones, GH-releasing hormone (GHRH) and somatostatin. GHRH stimulates and somatostatin inhibits the secretion of growth hormone. GH stimulates the production of insulin-like growth factors (IGFs), especially IGF-1, mainly in the liver. These proteins then circulate and stimulate tissues to grow. GH can also directly act on growth plates to stimulate growth. IGF-1 and GH then feed back to the hypothalamus to inhibit secretion of GHRH and stimulate secretion of somatostatin.

Obtaining a complete and precise history in the work-up of a short child is crucial. It is important to inquire about prenatal history, gestational age at birth, weight and length at birth, and neonatal medical history. Adjustments must be made when plotting the weight, height, and head circumference of a former premature infant. In general, weight, height, and head circumference should be corrected until the child is about 24 months of age, unless the child's birthweight was less than 1500 grams in which case, correction until three years of age is recommended. Healthy, premature infants do display catch-up growth. Term infants can have intrauterine growth retardation (IUGR) that can affect the infant's weight, length, and even head circumference. Many causes of IUGR have been identified, including pregnancy-induced hypertension and maternal infections. Potential for future growth in infants with IUGR is variable and depends on the etiology. A neonatal history that includes hypoglycemia, prolonged jaundice, or microphallus should raise suspicions of hypopituitarism. Midline defects such as cleft palate may also be associated with panhypopituitarism or specific deficits in growth hormone or thyroid hormone production.

The medical history should also include the patient's past medical problems and current medications. Long-term corticosteroids, like those used in the treatment of asthma, can affect a child's height. Catch-up growth can be seen when the medication is discontinued, but this is also dependent on the underlying disease. Children with ADHD who are treated with stimulants are at risk of growth

retardation. There often is a noticeable growth spurt when the medication is discontinued. Gastrointestinal, renal, hematologic, or cardiopulmonary disease can cause growth failure. In a patient with Crohn's or celiac disease, linear growth failure may even be the presenting complaint.

The family history is important information that can aid in determining potential reasons for short stature, as well as the child's expected height. One measure that is used for comparison is the adjusted mid-parental height (AMPH). The AMPH in a girl is the average of the father's height minus 13 cm and the mother's height. The AMPH in a boy is the average of the mother's height plus 13 cm and the father's height. Most children achieve their AMPH within approximately 5 cm. The two most common reasons for short stature in otherwise healthy children are familial short stature and constitutional delay. In both conditions, children are normal size at birth, but gradually fall across growth percentiles to resume a normal growth velocity at or below the bottom of the linear growth curve by age two or three. A short child with a normal growth velocity and a less than average mid-parental height can be diagnosed with familial short stature. Parents should also be asked when they entered puberty. A family history of delayed puberty in a short child with a normal growth velocity can help make the diagnosis of constitutional delay of growth and puberty, which means that the child is likely to enter puberty later than his/her peers and finish growing later, ending up with a height that is roughly normal.

A thorough physical exam should be completed on a child with short stature. Time should be spent obtaining accurate growth measurements. Weight, height, and head circumference should be plotted on the appropriate chart. A length (supine measurement) should be plotted on an infant (0-36 month) growth chart. A standing height should be plotted on a growth chart for children 2-18 years. Using prior height measurements, the child's growth velocity should be calculated. A clinician should become concerned if a child's growth velocity is less than 5 cm per year between the ages of 4-10 years. A height age can be determined by drawing a horizontal line from the patient's height to the 50th percentile line for height and then dropping a vertical line to the baseline to determine the height-equivalent age. Arm span should be measured and the upper-to-lower extremity ratio (pubis to crown of head compared to pubis to floor measurements) should be calculated. If these are abnormal, a skeletal dysplasia such as hypochondroplasia should be contemplated and evaluated with further x-rays. Determining a child's weight-to-height ratio also has some diagnostic value. In a child with short stature secondary to endocrine pathology, the child's weight will continue to progress normally or even increase relative to his or her height. Physical characteristics that might indicate a short statured syndrome should be sought. Turner Syndrome, for instance is associated with short stature, and stigmata on physical exam can include webbed neck, low posterior hairline, edema of the hands and feet, and wide-spaced nipples. Of note, these findings may be subtle or even absent in a girl with Turner Syndrome. Chromosomes should be obtained if Turner Syndrome is suspected or if all other causes of growth failure are ruled out in a short girl. A complete physical exam in a short child might detect a heart murmur that could lead a clinician to the diagnosis of significant cardiovascular disease, which can affect a patient's height, or an enlarged thyroid gland, which might indicate hypothyroidism-induced growth failure. (Hypothyroidism can, however, be present with a normal thyroid exam.)

Growth hormone deficiency is a pathologic cause of short stature that should be suspected in a boy with micropenis or any child with a midline abnormality (e.g., cleft palate, septo-optic dysplasia, or holoprosencephaly). Physical findings may also include a childlike appearance (excess fat relative to lean mass) and excess downy hair on the back.

Following a complete history and physical exam, a clinician can use ancillary tests to screen for potential causes of a child's short stature. A bone age can help determine a child's skeletal maturation. This test is performed by obtaining a radiograph of a child's left hand and wrist. The epiphyseal centers seen on the radiograph are compared to age-appropriate standards to determine a bone age. In children less than 2 years, a hemiskeleton bone age should be obtained. This test is performed by obtaining radiographs of the child's entire left upper and lower extremity. The number of ossification centers is determined and again compared to age-appropriate standards to determine the bone age. It is very helpful in the classification of short stature to compare chronologic age, bone age, and height age. In familial short stature, the patient's chronologic age and bone age are equivalent and both are older than the patient's height age. In constitutional delay and malnutrition, the patient's bone age and height age are equivalent and both are younger than the patient's chronologic age. A patient with hypothyroidism can present with a chronologic age older than height age, and bone age much younger than both.

Commonly, thyroid function tests (free T4 and TSH), a complete chemistry profile to include LFT's, a urinalysis and urine culture, and a CBC with ESR are carried out to look for occult causes of poor growth. In the child with delayed bone age and poor linear growth velocity but normal weight, low serum IGF-1 and IGF-BP3 (insulin-like growth factor and IGF binding protein 3) measurements may give clues to the presence of growth hormone deficiency. These patients should be referred to a pediatric endocrinologist for further testing. Random determination of serum growth hormone is not useful. Growth hormone stimulation tests are generally carried out by endocrinologists using agents which cause growth hormone release (e.g., insulin, arginine, L-dopa, clonidine) to determine "provocative" growth hormone levels which are more diagnostic.

A child's growth hormone secretory capacity is not always clear, even after extensive evaluation and testing. If growth hormone deficiency is suspected, a six to twelve month trial of growth hormone therapy may be carried out after an MRI of the sella is obtained. Recombinant growth hormone has been available since 1985 and there are numerous completed and ongoing studies attempting to evaluate its effectiveness in many different clinical settings. Short stature alone is not sufficient criteria to begin a child on growth hormone, as it is not only expensive and not without serious potential side effects, but also there may be no ultimate height benefit. Outside of accepted indications, e.g., GH deficiency, Turner Syndrome, and chronic renal failure, GH should only be administered in a research setting. Recently, GH has been gaining acceptance as an intervention in Prader Willi Syndrome and in some cases of IUGR.

In summary, short stature is a complaint that pediatricians commonly encounter in the outpatient setting. The key to diagnosing a cause is a detailed history, thorough physical exam, and meticulous height measurements over time. Ancillary tests can be of benefit, but a differential diagnosis should be contemplated prior to ordering additional information. The therapeutic goal is to allow children to grow as tall as their genetic potential.

Questions

1. What is the AMPH of a girl whose mother is 175 cm (5'9") and father is 193 cm (6'4")?
2. A) How should height be measured on a 22 month old boy? B) How should height be measured on a 39 month old girl?
3. You are evaluating a boy with a height below the 5% for age and weight is at the 50% for age. You are concerned that his growth is secondary to an endocrine cause. Should you order a serum growth hormone level in your work-up?
4. How do you obtain a bone age on a 20 month old child?
5. What is the cause of short stature in a 14 year old boy with a normal growth velocity and Tanner 2 genitalia on physical exam?

Answers to questions
1. 177.5 cm (5'10")
2. A) supine B) standing
3. No, random serum growth hormone levels are generally unhelpful in the work-up of short stature.
4. hemiskeleton
5. constitutional delay of growth and adolescence

Chapter XV.4. Adrenal Disorders
Jose L. Gonzalez, MD, MSEd, JD

Case 1: A 17 year old single mom brings her first born one week old male infant to your office with a chief complaint of not feeding well. He is described as having one episode of vomiting yesterday and 2 episodes of spitting up with poor feeding today. There is no history of fever, diarrhea or coughing. His urine output is decreased. Perinatal history is positive only for an inconsistent prenatal care. He was born at term weight 3.2 kg. Family history is negative.

Exam: VS are all normal. Weight is 3.0 kg; length is at the 25th percentile. He is sleepy but arousable. When awake, he appears irritable, failing to be consoled by sucking on a pacifier. The anterior fontanel is somewhat sunken but the conjunctivae and the oral mucosa are both moist. Cardiac exam is positive only for a borderline tachycardia. There are no murmurs or extra heart sounds. His abdomen is soft and negative. Genitalia are prepubertal and adequately developed. Both testes are descended. His neurological exam is non-focal and physiologic except as described above. His skin is clear with good turgor and his capillary refill is 3 seconds.

Lab: Na 128, K 6.9, Cl 98, bicarb 18. Blood sugar 70. CBC is unremarkable except for evidence of hemoconcentration. Urinalysis is negative with a specific gravity of 1.025. Lumbar puncture reveals clear fluid with no cells or bacteria on gram stain. CSF glucose is 33, protein 45. A urine Na is ordered and this shows an inappropriately high urine Na of 50. A tentative diagnosis of salt wasting due to adrenal insufficiency and probable congenital adrenal hyperplasia is made. An EKG is normal except for slightly prominent T waves.

The infant is started on IV hydration with D5NS (without potassium). His clinical hydration status improves markedly after a total of 30 cc/kg is infused. After obtaining advice from an endocrinologist, additional blood studies are drawn and the infant is given IV hydrocortisone. A repeat chemistry panel 4 hours later shows a Na 134, K 5.2, Cl 98, bicarb 18, glucose 80.

Case 2: A nine year old female is brought to your office by her parents with a chief complaint of thickened nails. The thickened nails have been present for over six months and have not responded to topical ointments. Two visits to a podiatrist also failed to clear the problem although the nails did temporally improve after filing. She is now increasingly distressed because of an upcoming hula presentation (in her bare feet).

Her past medical history is negative. Review of systems is positive for a tanned complexion (even with only average sun exposure) and for intermittent complaints of lower leg cramps. The leg cramps are, at times, quite painful but resolve spontaneously after 1 to 2 minutes with rest and massage. They occur randomly without an association to increased exercise and were diagnosed by a local practitioner last year as growing pains. Family history shows that both parents are Swedish born, having migrated to the United States just shortly before the patient's birth. There is an older sister, aged 16 years, quite tall and post-menarchal. Her parents and sister have a fair skin complexion. There has been no recent travel.

Exam: VS T37, P80, R25, BP 90/70. Height and weight are both at the 50th percentile. HEENT, cardiac, pulmonary and abdominal exams are non-contributory. Breasts and genitalia are Tanner stage I. Neurological evaluation is physiologic and non-focal. Her complexion is well tanned even in areas that are not sun exposed. Her nails are thickened and brittle (8 of the 10 toenails and 4 of the 10 fingernails) consistent with a fungal process. The nails are not upturning.

Addison's disease is suspected on the basis of the tanned complexion and the onychomycosis. A serum cortisol level is low and an ACTH level is high. Treatment with oral hydrocortisone replacement is initiated.

The adrenal gland is basically composed of a cortex and medulla. The cortex produces glucocorticoids, mineralocorticoids (also known as mineralocorticoids), and small amounts of sex steroids (progestins, androgens). Excess glucocorticoids may result in hyperglycemia and symptoms and signs of Cushing's syndrome. Mineralocorticoid excess results in excess sodium retention and potassium depletion. Deficiencies of glucocorticoids and mineralocorticoids result in the opposite conditions. The adrenal medulla produces catecholamines. Adrenal disorders result when the production of any of these hormones is insufficient or in excess.

Adrenocortical insufficiency in pediatric patients is principally the result of two distinct pathophysiologic processes. The first type, and by far the most common in infants, is the salt-losing form of congenital adrenal hyperplasia (CAH) (see first case above). Approximately 95% of CAH is secondary to an inherited, autosomal recessive deficiency of the 21-hydroxylase adrenal enzyme (21-OHase CAH). Less frequent etiologic enzyme defects include deficiencies of 11-OHase and 17-OHase, both associated with hypertension as a result of the abnormal accumulation of adrenal precursor hormones with weak mineralocorticoid activity. The second type of adrenal

insufficiency in pediatrics is acquired, typically idiopathic and presents during childhood and adolescence (see second case above). Addison's disease classically refers to idiopathic acquired adrenal insufficiency, but autoimmune and other acquired conditions resulting in adrenal insufficiency are often also referred to as Addison's disease. Less common causes of primary adrenal insufficiency include congenital adrenal hypoplasia (as opposed to hyperplasia), fulminant sepsis, adrenal hemorrhage from various etiologies, inadequate replacement of adrenocortical hormones after surgical removal of adrenal neoplasms, and inappropriate tapering of corticosteroids in children who have received long-term, high dose adrenal glucocorticoid therapy. Additionally, rare forms of adrenal insufficiency result secondarily from a primary ACTH deficiency associated with various pathologic conditions of the hypothalamic-pituitary region.

Infants with 21-OHase CAH classically present with clinical virilization (obvious in females, much less obvious in males), hypotension and mild hypoglycemia from cortisol deficiency, and an associated aldosterone deficiency with a resultant sodium depletion and hyperkalemia. Although the exact pathophysiology for the lack of a normal aldosterone effect is still debatable, the resulting salt-wasting abnormalities can lead to severe life-threatening hyperkalemia, hyponatremia and acidosis. Approximately two-thirds of children with classical 21-hydroxylase deficiency will present clinically with the salt-losing form within the first 2 to 3 weeks of life. A rare condition that may mimic salt-losing congenital adrenal hyperplasia, and which must be considered in the differential diagnosis is pseudohypoaldosteronism. This "functional" aldosterone disorder is caused by a defect at the aldosterone receptor site. Although similarly hyponatremic and hyperkalemic, these latter patients, unlike 21-OHase CAH infants, are not virilized and display contrastingly elevated aldosterone levels and usually normal, or only mildly stress-increased adrenal androgen concentrations (e.g. 17-hydroxyprogesterone, androstenedione and DHEA-S).

Congenital, virilizing, 21-hydroxylase deficiency may be either salt wasting or non-salt-wasting. Infants with the salt-losing type are easier to diagnose and will present to medical attention sooner. Alternatively, infants, especially males, with the non-salt-losing type may be difficult to diagnose since they lack the typical electrolyte abnormalities of salt-losers and may remain unrecognized for years until clinical signs of excess early virilization become evident.

The basic biochemical pathway within the adrenal cortex converts cholesterol to aldosterone, cortisol and adrenal androgens. ACTH stimulates this pathway and the production of cortisol provides negative feedback to reduce ACTH stimulation. The 21-hydroxylase enzyme is required to convert precursors to both cortisol and aldosterone. In salt-wasting 21-hydroxylase CAH, cortisol production is deficient resulting in high ACTH levels. Similarly, the resultant aldosterone deficiency leads to elevated levels of plasma renin. In the non-salt-wasting variety of CAH, the aldosterone pathway remains intact, although renin levels may be inappropriately elevated, suggesting an inefficient mineralocorticoid production. In both CAH types, however, the elevated ACTH stimulates the adrenal cortex's biochemical pathway. This causes shunting of hormone production away from cortisol towards an excess accumulation of various androgenic precursors, such as 17-OH progesterone and androstenedione that lead to the evident virilization.

The usual infant with the salt-losing form of congenital adrenal hyperplasia will present with dehydration and signs of both acute and chronic hypovolemia, with or without peripheral vascular collapse, sometime between the third and 28th day of life. Such signs, however, may appear under uncommon circumstances as late as three to four months of age (e.g., premature infants receiving supportive salt-containing intravenous fluids). Male infants with salt-losing, virilizing CAH tend to have subjectively normal external genitalia at birth. In contrast, female babies with this condition will characteristically demonstrate virilized ambiguous external genitalia at delivery from a prolonged intrauterine exposure to excessive adrenal androgens; a dysfunctional response maintained by the absence of a negative pituitary ACTH feedback effect from the underlying primary cortisol deficiency. Although a disease with autosomal recessive inheritance, prior collected data has documented an unexpected majority (greater than 60%) of CAH female infants, suggesting that a substantial number of male infants with congenital adrenal hyperplasia remain undiagnosed. More recent studies based on newborn screening data, however, have revealed more predictable gender proportions, thus supporting the value-added benefits of such a prevention strategy of newborn screening for treatable metabolic defects.

Analysis of now available genetic information indicates that the genetic mutations leading to congenital adrenal hyperplasia have been mapped to the class III region of the HLA complex (specifically HLA-B and HLA-DR) located on chromosome six. Subsequent work by the pediatric endocrinology group at Cornell has successfully defined the precise 21-OHase gene structure. These investigations have shown that CAH patients with classic 21-hydroxylase deficiency, with and without clinical salt loss, have a similar genetic abnormality. Alternatively, although located at the same genetic locus, patients with the other non-classical, virilizing forms of 21-OHase CAH, carry a different and distinct allelic abnormality, a genetic pattern analogous to that seen with hemoglobin S and C diseases.

The diagnosis of CAH is established by laboratory findings of a low cortisol in the presence of elevated levels of ACTH and adrenal androgens, the latter either obtained randomly or after stimulation with ACTH. Patients with the salt-wasting form will additionally demonstrate laboratory evidence of hyponatremia and hyperkalemia in association with a suppressed aldosterone concentration and an elevated plasma renin activity. A simple test to demonstrate inappropriate salt wasting from aldosterone deficiency is to obtain a urine sodium measurement when the patient is hyponatremic. In contrast to the expected findings of appropriately low urine sodium in the setting of hyponatremia, the urine sodium in salt wasting states such as mineralocorticoid deficiency or resistance will be inappropriately high.

In the not too distant past, infection-associated causes of acquired adrenal insufficiency predominated and included, most commonly, tuberculosis and fulminant bacterial sepsis. Today, however, acquired, idiopathic adrenal insufficiency occurs principally as a result of an autoimmune destruction of the adrenal gland. Autoimmune Addison's disease may occur either as an isolated phenomenon or, more commonly, as part of a more generalized, autosomal dominant polyglandular autoimmune failure syndrome. Given the often subtle clinical symptoms of acquired primary adrenal insufficiency, most patients with the polyglandular failure syndrome, if Type I, present characteristically with complaints of recurrent oral thrush and chronic ungual candidiasis from the underlying T-cell immune dysfunction. Both finger and toe nails can be affected with findings of opaque, thickened, friable and brittle nails. The polyglandular failure syndrome itself occurs in two types and typically consists of the following constellations of endocrinopathies:

Type I	Type II
Hypoparathyroidism (90 %)	Addison's disease (100 %)
Addison's disease (60 %)	Autoimmune thyroid disease (70 %)
Hypogonadism (45 %)	Insulin-dependent diabetes (50 %)
Mucocutaneous candidiasis (75 %)	Hypogonadism (10 %)
Autoimmune thyroid disease (10 %)	Vitiligo (5 %)

Acquired adrenal insufficiency can also commonly occur from an iatrogenic suppression of the hypothalamic-pituitary-adrenal axis. Given the widespread use of corticosteroids as therapeutic anti-inflammatory agents in the treatment of such conditions as asthma, arthritis or as adjunctive chemotherapy, iatrogenic adrenal insufficiency is at present, probably the number one etiology of adrenal cortisol deficiency. Supraphysiologic dosages of exogenous corticosteroids for periods as short as 4 weeks have been associated with the prolonged (up to one year!) inhibition of ACTH-mediated cortisol production.

Even when temporally associated with an acute event (e.g., adrenal hemorrhage from sepsis-associated disseminated intravascular coagulation), the clinical presentation of acquired adrenal insufficiency is typically insidious as well as nonspecific in its symptomatology. Unless the health care provider carries a high index of suspicion, suggestive clinical symptoms of lethargy and easy fatigability and physical signs of postural hypotension and fasting hypoglycemia in at-risk patients will surely be missed. In patients with primary cortisol deficiency, and thus with elevated ACTH levels, the presence of a generalized bronzing ("tanning") of the skin from an excess ACTH effect can be diagnostically helpful in supporting the laboratory evaluation for a suspected adrenal insufficiency. With in-vitro findings of ACTH receptors in melanocytes, it is believed that the increased tanning of the skin results from excess melanin deposition in the dermis.

Patients with acute adrenal insufficiency may present with both hypothermia and shock from peripheral vascular collapse. Vital signs including systemic arterial blood pressure, heart rate, respiratory rate and temperature must be monitored hourly until stable. In addition, the ECG must also be monitored continuously since hyperkalemia can cause severe ventricular dysrhythmias. Patients who do not respond to the initial fluid challenges with an increase in systemic arterial blood pressure, peripheral perfusion and urinary output require a central venous catheter for appropriate monitoring of central venous blood pressure.

Serum electrolytes (Na, K, C1, and HCO3) must be obtained immediately upon admission and followed at 4 hour intervals for the first 24 hours of management. Prior to the start of therapy in infants, blood must also be obtained for ACTH, androstenedione, 17-hydroxyprogesterone (17-OHP) and plasma renin studies. The 17-OHP serum assay has been shown to be a dependable and reliable diagnostic technique in infants with congenital adrenal hyperplasia, even when acutely ill. Collection of 24 hour urine for determination of 17-hydroxycorticosteroids (17OHCS), reflecting blood levels of glucocorticoids, or 17-ketosteroids, the standard diagnostic test for evaluating adrenal androgen excretion in the past, is not presently considered practical in young children and much less so in those with vascular instability. In older children who present with primary adrenal insufficiency, a blood sample for determination of serum cortisol and ACTH levels must be similarly obtained prior to the initiation of steroid therapy. In patients with primary adrenal insufficiency, the cortisol level will be low, whereas the ACTH level will be substantially elevated as a result of an absent, negative pituitary feedback mechanism. Although optimal, dynamic studies such as ACTH stimulation tests should be avoided if they, in any way, compromise the patient's clinical status.

The aim of endocrine treatment is to replace the deficient adrenal steroids. Acute fluid therapy must be continued until hormonal replacement is, by itself sufficient to sustain the patient's clinical stability.

For glucocorticoid replacement, an initial bolus of glucocorticoids, such as hydrocortisone sodium succinate, or its therapeutic equivalent (See table 1), must be administered intravenously at a bolus dose of 60 to 80 mg per square meter (body surface area). Initial dosages less than 25 mg in an infant or greater than 100 mg in an older child should be avoided. The initial bolus of glucocorticoids should be repeated if there is an inadequate clinical response to treatment as judged by systemic arterial blood pressure, peripheral perfusion, and urine output. Intramuscular cortisone acetate (60 mg per square meter of body surface area) may be administered as a repository dose of glucocorticoid at the same time as the initial bolus treatment. The half-life of cortisone acetate is approximately 24 hours and its duration of action may last up to 2 to 3 days.

As soon as a pattern of clinical improvement has been established, one-third to one-half of the initial dose of intravenous hydrocortisone sodium succinate must be continued every 4 hours for the subsequent 24 hours, by which time effective glucocorticoid replacement should be complete. The half-life of hydrocortisone sodium succinate is approximately 60 to 90 minutes and its duration of action is about 4 hours. Upon effective completion of glucocorticoid replacement, and provided the patient's clinical status permits, the patient may then be switched to oral maintenance therapy with hydrocortisone at 15 mg per square meter per day divided into three equal doses, a dosage intended to approximate the physiologic daily secretory rate of cortisol, 12 mg per square meter of body surface area.

If adrenal insufficiency is severe at presentation, a regimen of intramuscular cortisone acetate 30 mg per square meter given every 12 hours should be continued for an additional 24 to 48 hours before changing to oral hydrocortisone maintenance.

Table 1 - Glucocorticoid Potency Equivalency

Cortisone	25 mg (least potent)
Hydrocortisone	20 mg
Prednisone	5 mg
Prednisolone	5 mg
Methylprednisolone	4 mg
Dexamethasone	0.75 mg (most potent)

For mineralocorticoid replacement, parenteral mineralocorticoid therapy as intramuscular aqueous deoxycorticosterone acetate (DOCA) has been unavailable for close to 10 years. Current recommendations for salt-wasting CAH patients presenting with hyponatremia and/or hyperkalemia consist of oral fludrocortisone acetate (Florinef), 0.05 to 0.2 mg/day given b.i.d. or as a single daily dose, started as soon as the patient is able to retain oral fluids. Unfortunately, although Florinef is an effective medication for long-term maintenance therapy, the acute biochemical mineralocorticoid effects of oral fludrocortisone acetate may be delayed by 48 to 72 hours. Until then, the continued infusion of salt containing intravenous solutions will be needed to correct the hyponatremia and hyperkalemia seen with salt-losing adrenal insufficiency.

To correct the initial hypovolemia and hyponatremia, patients with acute adrenal insufficiency must be treated with volume replacement as appropriate. Using hourly bedside monitoring, blood sugar levels below 60 mg/dl should be avoided and treated with intravenous dextrose as indicated. Subsequent fluid therapy should be continued as directed by the patient's clinical status and ongoing fluid losses. Evaluation of the patient's continuing fluid needs must be performed at 4 hour intervals to determine if the scheduled replacement is adequate to compensate for persistent volume and salt requirements.

Replacement intravenous fluids should be potassium free for the first 24 hours unless the serum potassium level drops below 3.5 mEq/L. When signs of hyperkalemic electrocardiographic toxicity exist, the patient must be treated aggressively to avoid clinical toxicity. If the patient develops a non-perfusing dysrhythmia due to extreme hyperkalemia (this frequently may resemble ventricular tachycardia on

the EKG), IV calcium should be given immediately. Although parenteral calcium is potentially effective in converting the dysrhythmia to a perfusing sinus rhythm, hyperkalemic dysrhythmias will recur unless the serum potassium level can be reduced. A fast, simple way to reduce the serum potassium although only temporarily, is by administering sodium bicarbonate 1 mEq/kg IV. Sodium bicarbonate is readily available and requires no special preparation to administer. Sodium bicarbonate works by raising the serum pH and shifting potassium intracellularly, thus lowering the serum potassium. Other rapid measures for treating severe hyperkalemia by similarly shifting potassium intracellularly include: 1) albuterol aerosol and 2) insulin (0.1 unit per kg) IV. It is important to administer insulin with a concurrent dextrose containing IV solution to avoid hypoglycemia. These latter potassium-lowering methods are only temporary since they merely shift potassium intracellularly. Excess potassium must be removed from the body by administering sodium polystyrene sulfonate (Kayexalate) resin. Kayexalate exchanges sodium for potassium thereby increasing the patient's serum sodium while removing potassium. Kayexalate may be given PO or as a retention enema. Furosemide IV may also be used to remove excess potassium through its effect in increasing renal sodium and potassium excretion.

Acute episodes of adrenal insufficiency usually resolve by the second day of appropriate therapy. Intravenous fluids containing a sodium chloride solution with dextrose should be continued until the institution and tolerance of oral feedings allows for adequate sodium intake. Patients with salt-losing adrenal insufficiency, especially infants, may require prolonged oral sodium replacement, which may be given in conjunction with feedings. Likewise, in the older child with adrenal insufficiency secondary to an acute episode of Addison's Disease, supplementary sodium may be similarly needed in some patients and may be added to their meals as tolerated.

In the chronic long-term management of CAH, insufficient glucocorticoids result in excess ACTH stimulation of adrenal androgen production, which leads to virilization and premature puberty with eventual short stature. Alternatively, excess glucocorticoids result in clinical findings of hypercortisolism such as central weight gain, striae, hypertension, and growth suppression. Adrenal androgen levels, 17OHP and androstenedione, can be monitored to assess the adequacy of glucocorticoid replacement. Elevated levels indicate inadequate glucocorticoid treatment with incomplete suppression of excess ACTH release. Low adrenal androgen levels may indicate that glucocorticoid dosing is excessive especially if associated with age-inappropriate growth rates or other clinical evidence of an excess glucocorticoid effect. The adequacy of mineralocorticoid dosing may be monitored through serial determinations of plasma renin and electrolyte levels. Elevated renin levels indicate an insufficient mineralocorticoid replacement regimen even in the absence of associated hyponatremia or hyperkalemia. Suppressed plasma renin may alternatively suggest an excess mineralocorticoid effect especially in the presence of an elevated blood pressure.

Other adrenal conditions in pediatrics are less common. Cushing's syndrome is a symptom complex that reflects an excessive, peripheral adrenal glucocorticoid effect. This hypercortisolism may be iatrogenic or endogenous, the latter either primary from autonomous adrenal hyperactivity (ACTH-independent) or secondary to an excess ACTH stimulation (ACTH-dependent). When caused by excessive pituitary ACTH production, the condition is called Cushing's Disease. As suggested above, Cushing's syndrome may also be iatrogenic and result from exogenously administered corticosteroids used as therapy for various medical conditions. Symptoms of hypercortisolism from any cause are typically subtle, often nonspecific and slow to develop. Common findings consist of an increased subcutaneous fat deposition, especially in the temporal areas of the face ("moon facies"), the posterior neck ("buffalo hump") and the abdomen. These findings, however, are also seen with simple obesity. Other symptoms of hypercortisolism include facial plethora, easy bruising, cutaneous atrophy, striae, elevated blood pressure and, in children and adolescents, growth failure. This latter characteristic, especially when associated with increasing weight, is the most common presentation of Cushing's syndrome in pediatrics. Although not limited to Cushing's syndrome, decreasing height percentiles is a helpful diagnostic sign in differentiating hypercortisolism from exogenous obesity given that dietary overweight does not lead to poor growth and may in fact cause growth acceleration. In children less than 8 years, Cushing's syndrome is more commonly ACTH-independent and caused by either adrenal adenomas or carcinomas. Of interest, children with Cushing's syndrome from a virilizing adrenal carcinoma may actually present with growth acceleration from an associated, increased adrenal androgen production rather than with the growth failure commonly seen with hypercortisolism. Alternatively, in older children, ACTH-dependent Cushing's from pituitary corticotroph adenomas (Cushing's disease) accounts for about 50 percent of the cases.

The diagnosis of Cushing's syndrome is confirmed by findings of elevated, non-suppressible levels of glucocorticoids, determined either as serum cortisol concentrations or as 24-hour urinary excretion rates of 17OHCS or free cortisol. Differentiation of ACTH-dependent and independent types, as well as localization of the source of the hypercortisolism, may be achieved through a variety of suppression and stimulation studies. Their discussion, however, is beyond the scope of this book. Treatment of Cushing's syndrome is usually surgical, with subsequent adrenal hormone replacement, and is directed at correction of the primary cause. Medical therapy is often of last resort and only poorly effective.

Adrenal disorders localized to the adrenal medulla are even more rare, especially in pediatrics. Pheochromocytomas are catecholamine-producing tumors of neural crest origin. The vast majority are benign and localized to the adrenal gland although extra-adrenal pheochromocytomas are not uncommon in children. The presenting clinical symptoms are directly related to the excess catecholamines released by these tumors. Relevant among these are cold clammy skin, tachycardia, anxiety, agitation and potentially life-threatening hypertension from systemic vasoconstriction. Because release of catecholamines by these tumors is typically episodic, so may the patients' symptoms be also intermittent. The diagnosis may thus be difficult to establish and may require multiple investigations. The diagnosis however, may be confirmed by findings of significantly elevated blood and/or urine levels of catecholamines and their metabolites especially at the time of clinical symptoms. Pheochromocytomas may occur as unilateral or bilateral adrenal tumors (bilateral is more common in children) and either as an isolated or a familial phenomenon, the latter being often part of the Multiple Endocrine Neoplasia syndromes. Treatment is directed at surgical removal of the primary tumor with pre-operative, medical stabilization of the associated hypertension.

Neuroblastomas, ganglioneuromas and ganglioneuroblastomas are additional tumors of the adrenal medulla. Although these tumors may excrete catecholamines, characteristically dopamine and its metabolite, homovanillic acid (HVA), most are nonfunctional and detected through findings, often incidental, of an abdominal mass. Treatment is surgical with subsequent chemotherapy as indicated by the pathology findings.

Questions

1. Urinary excretion rates of 17-hydroxycorticosteroids (17-OHCS) reflect the blood levels of:
   a. Mineralocorticoids
   b. Glucocorticoids
   c. Sex steroids
   d. Adrenal androgens

2. The daily secretory rate for plasma cortisol is approximately:
   a. 5 mg / square meter / day
   b. 12 mg / square meter / day
   c. 25 mg / square meter / day
   d. 50 mg / square meter / day

3. Congenital adrenal hyperplasia due to 21-alpha-hydroxylase deficiency is inherited as a(n):
   a. Autosomal recessive trait.
   b. Autosomal dominant trait.
   c. X-linked recessive trait.
   d. Sporadic disorder from a spontaneous gene mutation.

4. Acquired adrenal insufficiency in school age children and adolescents may present with:
   a. Hypertension and a "Buffalo Hump".
   b. Hypernatremia and hypokalemia.
   c. Hypoglycemia and postural hypotension.
   d. Biochemical findings of suppressed ACTH levels.

5. Chronic, primary adrenal insufficiency (Addison's disease) in children is most commonly due to:
   a. Tuberculosis
   b. Adrenal hemorrhage
   c. Autoimmunity
   d. Tumor

6. True/False: If patients have received large doses (i.e., greater than physiologic replacement) of glucocorticoids for a short period of time (i.e., less than one month) or small doses (i.e. less than physiologic replacement) for any period of time, adrenal function will likely resume shortly after cessation of therapy.

7. Which of the following is a hypertensive form of congenital adrenal hyperplasia?
   a. Simple virilizing 21-hydroxylase deficiency
   b. Salt-losing 21-hydroxylase deficiency
   c. 11-hydroxylase deficiency
   d. 3-beta dehydrogenase deficiency

8. Which of the following laboratory tests are most appropriate for monitoring the effectiveness of steroid replacement therapy in acquired, primary adrenal insufficiency ?
   a. 17-OH progesterone, androstenedione and ACTH levels.
   b. fractionated catecholamines and homovanillic acid (HVA) levels.
   c. post-dexamethasone urinary free cortisol and 17OH corticosteroids levels.
   d. ACTH, plasma renin and serum electrolyte levels.

9. A 2 week old infant presents with projectile vomiting and dehydration. The infant's electrolytes are as follows: Na 126, K 6.5, Cl 92, Bicarb 15, glucose 60. These electrolyte results are most compatible with which of the following diagnosis ?
   a. pyloric stenosis with bicarbonate loss from repeated vomiting.
   b. congenital Cushing's syndrome from excess mineralocorticoid effect.
   c. pheochromocytoma from excess catecholamine effect.
   d. salt-wasting CAH from mineralocorticoid deficiency.

10. Cushing's syndrome is characterized by the presence of:
   a. hyponatremia and hyperkalemia.
   b. an elevated urinary free cortisol excretion.
   c. genital virilization from excess adrenal androgens.
   d. low serum cortisol and increased ACTH levels.

Chapter XV.5. Antidiuretic Hormone

Daniel C. H. Kidani, MD

This is a 1 year old male who presents to the office with a chief complaint of increased urination and thirst. Over the past month, he has been wetting an increasing number of diapers, >15 per day which is associated with increased fluid consumption. He always has a bottle or training cup in his hand, and his parents feel that this is abnormal.

Exam: VS are normal. Weight is at the 75th percentile. He is alert and active, in no distress. He is slightly large for age. No abnormalities are detected on physical examination. No ketosis is detected and he exhibits no signs of dehydration.

Labs: UA is normal. Urine specific gravity is 1.005. No glycosuria is noted. CBC WBC 8.0, Hgb 16.5, Hct 48.7, Platelet count 324,000. Chemistry: Na 149, K 4.4, Cl 99, CO2 22, Glucose 102.

How would you work this patient up?

Antidiuretic hormone (ADH) is a short peptide also known as 8-arginine-vasopressin (AVP) (1). It is synthesized in the supraoptic and paraventricular nuclei of the anterior hypothalamus and is subsequently transported via neurons to the posterior pituitary gland where it is stored as granules and released into the systemic circulation through the cavernous sinus and superior vena cava (2).

The main biologic effect of ADH is to reduce the rate of urine flow by increasing the reabsorption of solute-free water from the filtrate in the distal tubules and collecting ducts of nephrons (1). This response is mediated by specific V2 receptors located on the basolateral surface of the principle cells of collecting ducts to induce water reabsorption. In their resting state, V2 receptors are inactive, and the distal tubules and collecting ducts are impermeable to water (2). Once V2 receptors are activated by ADH, a G-protein-coupled adenylcyclase is activated which converts ATP to cAMP which then activates a protein kinase. This protein kinase induces vesicles containing water channels, made up of the protein aquaporin-2 (2), to migrate to the apical cell membrane resulting in increased permeability to free water. Water is reabsorbed into the cell and passes through the freely permeable basolateral membrane into the peritubular capillaries (1). As a result of the increased permeability, most of the water in the diluted filtrate that reaches the distal nephron back diffuses down the osmotic gradient created by the hypertonic milieu of the surrounding renal medulla. This back diffusion of water in the absence of solute increases urine concentration and reduces urine flow by an amount proportional to the level of ADH. ADH also increases NaCl reabsorption in the thick ascending loop of Henle. These effects of ADH result in tubular conservation of water, increased urine osmolality, decreased plasma osmolality, and negative free water clearance without significant alteration in solute excretion. However, ADH is rapidly reversible once plasma levels decline as its half-life is between 5 and 15 minutes (1).

ADH also acts on V1 receptors located in smooth muscle and can cause contraction of the GI tract as well as all parts of the vascular bed (vasoconstriction), especially the small arterioles and venules (hence, its other name, vasopressin) (1). This effect on the contractile elements are neither antagonized by adrenergic blocking agents nor prevented by vascular denervation.

Granules of ADH are released when hypothalamic osmoreceptors sense an increase in serum osmolality, even as little as 1% above normal. The threshold range for ADH secretion is 280-290 mOsm/liter. Once the threshold range is exceeded, there is a steep rise in the release of ADH, resulting in a decrease in serum osmolality back toward normal while increasing the osmolality of urine (1).

Regulation of ADH secretion is mediated by osmoreceptors that are thought to be located in the anteromedial hypothalamus near the neurohypophyseal cell bodies in the supraoptic nucleus. These osmoreceptors are normally sensitive to small changes in effective osmotic pressure such that a decrease in plasma osmolality as small as 1% to 2% rapidly suppresses ADH secretion to levels that permit a maximum water diuresis. Above this set-point, plasma ADH rises steeply in direct proportion to plasma osmolality and reaches a level sufficient to produce a maximum antidiuresis before plasma osmolality or serum sodium exceed the normal range; typically 275 to 295 mOsm/lit in a healthy individual. However, the sensitivity and the slope of the ADH response varies widely between individuals, and is thought to be genetically determined. This set-point is reduced during pregnancy and the luteal phase of the menstrual cycle (hence, more fluid retention), but increased in the elderly (hence, less fluid retention) (2).

Non-osmotic variables can also influence ADH secretion. Reductions in blood volume or arterial pressure of more than 10% to 20% stimulate release of ADH. This is thought to be due to lowering the set-point of the osmoregulatory system, mediated by neural pathways that originate in stretch receptors in the walls of the left atrium and large arteries. These pathways project via the vagal and glossopharyngeal nerves to the brain stem and eventually to the hypothalamus where they interact via an as of yet unknown way with input from osmoreceptors. Under normal conditions, this pathway seems to have little or no influence on ADH secretion; however, in conditions such as severe congestive heart failure, adrenal insufficiency, and other diseases associated with large reductions in blood pressure or blood volume, this pathway may have a profound effect (2).

ADH released via this pathway is released in concentrations 10-1000 times greater than normal. At these high concentrations, ADH acts as a vasoconstrictor, especially at the outer renal cortex. This is mediated by activation of V1 receptors which exist on vascular smooth muscle, glomerular mesangial cells, and the vasa recta and is mediated through the phosphatidyl-inositol pathway (1). Thus, hypovolemia-induced secretion of ADH is a more potent stimulant for ADH release than is serum osmolality and contributes to the SIADH (fluid retention, hypoosmolality, and hyponatremia) seen in postoperative patients (1).

Nausea is another potent stimulus for ADH release under pathologic conditions (e.g., vasovagal reactions, emotional stress with a vasovagal reaction, hyperemesis gravidum, diabetic ketoacidosis, chemotherapy, motion sickness). Even if transient and unassociated with emesis or changes in blood pressure, nausea can result in rapid 20- to 500-fold increases in plasma ADH levels (2).

The function of ADH is to decrease water loss; however, its ability to do so is limited because it cannot reduce the rate of urine output below the amount required to excrete a given solute load and cannot eliminate insensible losses such as the evaporation of water from the skin and lungs. Thus, another mechanism to replace this water loss must exist. This vital function is carried out by the thirst mechanism (2).

Thirst is regulated primarily by hypothalamic osmoreceptors; however, these osmoreceptors are less sensitive than those for ADH release. The osmotic threshold at which thirst begins is about 5 to 10 mOsm/kg higher than the threshold for ADH release (2).

Diabetes insipidus is an uncommon syndrome characterized clinically by increased fluid intake and the excretion of abnormally large volumes of urine of low specific gravity. It is caused by a deficiency of or a resistance to ADH (3). The most common cause is a primary deficiency of ADH secretion, usually referred to as pituitary, neurogenic, neurohypophyseal, cranial, or central diabetes insipidus. It is almost always the result of irreversible destruction of more than 80% of ADH-producing magnocellular neurons secondary to acquired, congenital, or genetic diseases (2).

Congenital causes include septo-optic dysplasia, cleft lip and palate, other midline craniofacial defects, holoprosencephalic syndromes, and agenesis/hypogenesis of the pituitary. Primary central diabetes insipidus can also be caused by head trauma, primary tumors (craniopharyngiomas, adenomas, meningiomas, dysgerminoma), and metastatic (breast, lung) tumors, lymphomas, granulocytic leukemias, neurosarcoid, histiocytosis, xanthoma disseminatum, chronic meningitis, viral encephalitis, toxoplasmosis, autoimmune conditions (lymphocytic infundibuloneurohypophysitis, scleroderma, Wegener's granulomatosis, SLE), Sheehan's syndrome, carotid aneurysms, hypoxic encephalopathy, snake venom, as well as idiopathic causes.

The most common genetic form of central diabetes insipidus is transmitted in a completely penetrant autosomal dominant fashion and involves the AVP-NPII gene on chromosome 20. The AVP (ADH) deficiency is not present at birth but develops several months to years later and may gradually progress from partial to severe (>95%). It is hypothesized that the mutant AVP-NPII gene produces a defective AVP prohormone which cannot be secreted, and thus accumulates within neurons and leads to neuronal death. A much rarer form of congential central diabetes insipidus is transmitted in an autosomal recessive mode which also involves the AVP-NPII gene, but unlike its autosomal dominant counterpart, leads to the production of a mutant AVP with little or no antidiuretic effect (2).

A primary deficiency of plasma ADH can also occur during pregnancy and is known as gestational diabetes insipidus. In this case, the deficiency is a result of degradation of ADH by a vasopressinase produced in the placenta. Polyuria, thirst, and polydipsia typically occur during the third trimester which usually remits 3 to 6 weeks after delivery (3).

Decreased ADH is not always the cause of diabetes insipidus. Rather, a deficiency in the responsiveness of ADH at its site of action may also cause polyuria. This form of diabetes insipidus is termed nephrogenic. These patients have normal secretion of AVP and are unresponsive to exogenous vasopressin. The abnormality lies in a defective expression of vasopressin V2 receptors or vasopressin-sensitive water channels (3).

The most common form of genetic nephrogenic diabetes insipidus is transmitted in an X-linked recessive mode. It is congenital and often results in repeat episodes of hypernatremic dehydration during the first 2 years of life. It is refractory to the antidiuretic effect of normal to modestly increased levels of plasma ADH, but it may respond to high pharmacologic doses of deamino-D-arginine vasopressin (DDAVP, a synthetic vasopressin) (2).

Less common forms of congenital nephrogenic diabetes insipidus are transmitted in autosomal dominant and autosomal recessive modes. These conditions are caused by mutations in the coding region of one or both aquaporin-2 genes and usually result in severe or complete resistance to ADH (2).

Acquired forms of nephrogenic diabetes insipidus are usually less severe than genetic forms. It is seen in pyelonephritis, renal amyloidosis, myeloma, potassium depletion, Sjogren's syndrome, sickle cell anemia, hypercalcemia, sarcoma, and neurosarcoid of the kidney. Acute tubular necrosis may also be associated with a transient nephrogenic diabetes insipidus. Glucocorticoids, diuretics, demeclocycline, lithium, foscarnet, and methicillin may all cause nephrogenic diabetes insipidus (2).

The pathophysiology that underlies central, gestational, and nephrogenic diabetes insipidus are similar. In all three, the kidneys are unable to concentrate urine resulting in a diuresis that results in a slight (1% to 2%) decrease in body water and an increase in basal plasma osmolality and sodium. Increased serum osmolality stimulates thirst and a compensatory increase in water intake, preventing further dehydration. Thus, unless the thirst mechanism is damaged or the patient is unable to increase fluid intake, water and osmolar homeostasis are maintained.

In all types of chronic diabetes insipidus, the maximum urinary concentrating capacity is reduced and is proportional to the severity of the diabetes insipidus. It is thought that this may be the result of washout of the medullary concentration gradient or inhibition of aquaporin-2 synthesis. However, it usually corrects within 24 to 72 hours if polyuria is eliminated (2).

The hallmarks of diabetes insipidus are polyuria (2-20 liters per day) and increased fluid intake (3). Polyuria results in symptoms of urinary frequency, nocturia, incontinence, or enuresis. Fatigue may be an associated complaint resulting from frequent disruption of sleep. Polyuria is always accompanied by a proportionate polydipsia that is usually, but not always, attributable to increased thirst (2).

Physical exam findings including vital signs and routine laboratory studies are usually unremarkable. However, dehydration and hypernatremia may be present especially after hypothalamic damage secondary to shock or anoxia (3). Neurologic symptoms may be present depending on the etiology of the DI, such as hyperphagia, visual field defects, anosmia, weight loss, etc. (2).

Evaluation for DI should include a 24-hour urine collection for volume, glucose, and creatinine as well as serum studies for glucose, urea nitrogen, calcium, uric acid, potassium, and sodium (3).

There is no single diagnostic test to make the diagnosis of diabetes insipidus. The diagnosis is made mainly on clinical grounds with some laboratory supportive evidence. However, hyperuricemia implicates central diabetes insipidus as decreased V1 stimulation decreases urate clearance. If diabetes insipidus is suspected, a supervised vasopressin challenge test should be administered. Desmopressin acetate (DDAVP, a vasopressin analogue) which has a long duration of action and an antidiuretic/pressor factor of approximately 3000 when compared to AVP (4), is given in an initial dose of subcutaneously, or intravenously, with measurements of urine osmolality obtained 12 hours prior and 12 hours after administration. If basal plasma ADH is low, or if the osmolality of urine collected 1 or 2 hours after subcutaneous injection of DDAVP is more than 50% greater than the pretreatment value, the patient has central diabetes insipidus. The dosage of desmopressin is doubled if the response is marginal. Patients with central diabetes insipidus notice a marked decrease in polyuria and polydipsia (2). In contrast, if basal plasma ADH is elevated, or if the administration of DDAVP results in

little or no increase in urine concentration, the patient has severe nephrogenic diabetes insipidus. A two day trial of DDAVP with ad lib fluid intake can also help to distinguish between central and nephrogenic diabetes insipidus (2).

Magnetic resonance imaging of the brain with and without gadolinium contrast may also be useful in determining the type and etiology of the diabetes insipidus. It cannot differentiate between central and nephrogenic diabetes insipidus, but it may be able to differentiate diabetes insipidus from primary polydipsia (2).

Central diabetes insipidus must be distinguished from other causes of polyuria. Therefore, Cushing's syndrome as well as glucocorticoid therapy, diabetes mellitus, drugs (carbamazepine, lithium), psychogenic polydipsia, central nervous system sarcoidosis, as well as intravenous fluid administration must be considered (3). Psychogenic water drinking can be extremely difficult to distinguish from DI. Withholding water from such patients will often result in anxiety, but withholding water from patients with DI, is dangerous. Thus, until the diagnosis can be confirmed, an evaluation for DI in uncertain cases, must often be done as an inpatient to establish the diagnosis. In theory, psychogenic water drinkers should not have hypernatremia.

The signs and symptoms of diabetes insipidus can be eliminated completely by replacing the AVP deficiency with DDAVP. DDAVP is a synthetic analogue of vasopressin but is more resistant to degradation, has less of a pressor effect, and can be given by mouth, nasal spray, or injection (4). The dose required to normalize the 24-hour urine volume and concentration varies from patient to patient and must be determined empirically. The typical requirements in adults are 50 to 200 mcg by mouth two to three times a day, 5 to 20 mcg by nasal spray two to three times a day, or 1 to 2 mcg by subcutaneous injection once or twice a day. Patients rarely develop water intoxication due to homeostatic mechanisms; however, patients on DDAVP should be advised to drink only when truly thirsty (2). Adverse reactions to DDAVP include nasal irritation, agitation, and erythromelalgia (throbbing and burning pain in the skin often precipitated by exertion or heat). Hyponatremia is rare if the patient is placed on the minimum effective dose and thirst is allowed to occur periodically (3).

The signs and symptoms of nephrogenic diabetes insipidus are completely unaffected by standard doses of DDAVP unless the process is partial in which case tenfold higher doses are effective. The expense and inconvenience of this treatment, however, make this regimen impractical. If hypokalemia, hypercalcemia, or the use of lithium is present, the correction of the underlying problem may correct the diabetes insipidus (lithium can cause nephrogenic DI); however, in many cases this is difficult to accomplish. Treatment usually consists of a low sodium diet coupled with an empirically determined combination of chlorothiazide, hydrochlorothiazide, amiloride, or indomethacin. Patient's typically experience a 50% to 70% decrease in urine volume (2).

The syndrome of inappropriate ADH secretion (SIADH) is a disorder characterized elevated levels of ADH which hinders the ability of the kidneys to dilute urine resulting in water intoxication with hypotonicity and hyponatremia (4). In pediatrics, SIADH is most commonly encountered in patients with bacterial meningitis. A urine sodium should be immediately obtained once hyponatremia is identified. A low urine sodium (coupled with hyponatremia) is abnormal and indicative of SIADH.

Patients may develop symptoms of hyponatremia ranging from mild headaches, anorexia, and confusion to nausea, vomiting, coma, convulsions, and death (2). However, hyponatremia may be asymptomatic if it has developed gradually. Symptomatic hyponatremia has a mortality of 10 to 15%, and the mortality rate is higher when the serum sodium level is below 110 mEq/L (4).

Patients may experience weight gain because of water retention; however, edema is not present because the retained water is distributed among both extracellular and intracellular compartments. Signs of congestive heart failure, cirrhosis, nephrosis, or hypovolemia are also absent (2).

Acute water retention causes neurologic symptoms by rapidly increasing the intracellular volumes of brain cells and thus inducing cerebral edema. It is probable that chronic hyponatremia is less symptomatic because there is time for activation of compensatory volume-regulatory mechanisms in the central nervous system. Brain cells compensate for volume gain by activating ion transport processes that pump out intracellular KCl and NaCl. This compensation has therapeutic importance, because rapid correction of hyponatremia by infusion of hypertonic saline produces a transient hypertonic encephalopathy as water is drawn out of the already contracted intracellular space. This can cause permanent neurologic damage, for example central pontine myelinolysis and death (4).

In most patients with SIADH, the defect in urinary dilution is caused by ectopic production, exogenous administration, or osmotically inappropriate neurohypophyseal secretion of ADH. Associated conditions (not necessarily etiologies) include brain malformations, midline defects, ectopic secretion from neoplasms (e.g., small cell lung cancer), other cancer conditions, drugs, severe neurological conditions (meningitis, severe head trauma, encephalitis, coma, etc.), severe pneumonia, respiratory failure (with mechanical ventilation), etc. (4).

ADH is synthesized as a prohormone of 166 amino acids that is processed to produce three peptides: the mature octapeptide hormone, a midregion 10,000-molecular-weight peptide with vasopressin-binding activity called neurophysin II, and a C-terminal glycopeptide. Both the vasopressin (ADH) and the neurophysin are packaged within the neurosecretory granule (4).

Neuroendocrine tumor cells produce ADH in a similar fashion, secreting both vasopressin and neurophysin II. However, vasopressin's sister peptide oxytocin together with its binding protein, neurophysin I, are also commonly secreted. The proximity of the genes for vasopressin and oxytoxin, less than 12kb within the human genome, is thought to explain this phenomenon as a single transcription factor could activate both promoters (4).

Water retention leads to expansion of both the extra and intracellular compartments. The expansion of extracellular fluid volume (likely secondary to suppression of aldosterone and increased atrial natriuretic peptide release) leads to natriuresis (sodium excretion) and a reduction in fluid volume in patients with an adequate sodium intake.

Plasma AVP and AVP analogues do not significantly lower serum sodium unless total water intake (dietary plus insensible) exceeds total output (urinary plus insensible). When such imbalance occurs, the excess water cannot be excreted as quickly as is normal because urinary concentration cannot decrease sufficiently to permit a fully compensatory water diuresis. Consequently, water is retained in the extracellular and intracellular compartments; the concentration of sodium and other solutes in body fluids is diluted; plasma urea, uric acid, rennin and aldosterone activities are reduced; and urinary sodium excretion increases as an appropriate response to the expansion of plasma and extracellular volume, via ANP (4). The natriuresis aggravates the dilutional hyponatremia but partially offsets the extracellular volume expansion, preventing edema or other signs of hypervolemia. The rate at which these abnormalities develop varies widely depending on the magnitude of the imbalance between the total rate of water intake and excretion by renal and extrarenal routes. If the defect in urinary dilution is minor or if insensible loss of water is abnormally high, even markedly increased rates of water intake may be insufficient to induce hyponatremia. On the other hand, if urinary concentration is fixed at a high level and insensible loss is low, even an apparently normal basal rate of fluid intake may be sufficient to produce the syndrome (2).

SIADH is generally diagnosed by finding a low serum osmolality in conjunction with a relatively high urine osmolarity. This is abnormal since the urine should be very dilute if the plasma is hypo-osmolar. Checking the serum and urine sodium levels are often sufficient since hyponatremia in conjunction with an elevated urine sodium is similarly abnormal, although this can also be caused by diuretics, mineralocorticoid deficiency (Addisonian crisis) and salt losing nephropathy.

The clinical presentation of SIADH can vary appreciably owing to differences in the type of osmoregulatory defect present. The most striking and potentially confusing variant is that caused by downward resetting of the osmostat. In this type of defect, plasma AVP and urine concentration continue to be osmoregulated and can still be maximally suppressed if fluid intake is great enough to lower plasma osmolality/sodium to the new threshold or set point. Consequently, patients with this variant of SIADH may present with hyponatremia and maximum urinary dilution, leading to the false conclusion that polydipsia alone was responsible for the fluid-electrolyte imbalance. If the measurements of urine osmolality are repeated during therapeutic fluid restriction, the true cause becomes apparent because urinary concentration begins long before serum sodium rises to normal. Close monitoring of urine output and serum sodium is important for effective clinical management in all variants of SIADH because the abnormal AVP secretion of any type can suddenly remit, allowing a brisk water diuresis that raises the serum sodium more rapidly than may be safe. Such remissions are relatively common in SIADH because it is usually an acute self-limited disorder that lasts only a few days or weeks (2).

The SIADH must be differentiated from hypervolemic, hypovolemic, and other forms of euvolemic hyponatremia. These distinctions can usually be made on the basis of the clinical history, physical examination, and routine laboratory tests. Hypervolemic hyponatremia occurs in patients with severe congestive failure, cirrhosis, or nephrosis, and is always associated with edema. The osmotic suppression of plasma AVP and urinary dilution are also impaired, but, in this case, the defect is caused by a reduction in effective blood volume, which stimulates AVP release via the baroregulatory system. Because of this effective hypovolemia, plasma urea, uric acid, renin activity, and aldosterone are also usually elevated, and the urinary excretion of salt and water is decreased.

Hypovolemic hyponatremia occurs in conditions such as diuretic abuse, mineralocorticoid deficiency, or gastroenteritis, which result in excessive loss of sodium and water. The resultant depletion of intravascular and interstitial fluid results in physical signs of hypovolemia, such as tachycardia and postural hypotension. It also increases plasma AVP and urine concentration and decreases renal perfusion. Consequently, plasma urea, uric acid, renin activity, and aldosterone are elevated, whereas urinary excretion of salt and water are reduced (unless a diuretic or sodium-losing nephropathy is responsible).

In addition to SIADH, euvolemic hyponatremia can result from isolated cortisol deficiency or emesis. The pathophysiology and clinical characteristics of the latter two forms of euvolemic hyponatremia are identical to SIADH, with the exception that they are associated with hypocortisolemia or a history of nausea and vomiting and can be corrected completely by treatment with cortisol or antiemetics (2).

In some patients, SIADH can be cured by eliminating the tumor, drug, or disease responsible for the syndrome. In others, it is an acute self-limited disorder that remits spontaneously within 2 to 3 weeks. The most common therapy used to treat SIADH is fluid restriction. This reduces free water retention and allows the hyponatremia to resolve gradually. If the hyponatremia is severe, or accompanied by symptoms such as nausea, vomiting, coma, or seizures, it may be desirable to correct part of it more rapidly by combining fluid restriction with a slow intravenous infusion of hypertonic (3%) saline. Hypertonic saline infusion is dangerous, requiring close monitoring and frequent stat sodium measurements (a turnaround time of 1 hour is not fast enough since the sodium may have risen to excessive levels before then). When infused at a rate of approximately 0.05 mL/kg/min, 3% saline raises serum sodium by about 2 mEq/L per hour. With this therapy and all other methods of treatment, urine output and fluid intake should be monitored closely because SIADH can remit spontaneously at any time, and, when it does, the resultant water diuresis may raise serum sodium too fast or too far if water intake is not allowed to increase. The objective should be to raise serum sodium no faster than 24 mEq/L in 24 hours and to a final level no greater than 135 mEq/L. Although this issue is not yet settled, raising the serum sodium faster or farther may cause acute osmotic demyelinization, a serious complication characterized by severe neurologic abnormalities, including quadriparesis, mutism, pseudobulbar palsy, seizures, behavioral disturbances, and movement disorders (2).

Chronic SIADH usually cannot be controlled by fluid restriction alone because thirst is also increased inappropriately; however, the hyponatremia may be corrected or prevented by treatment with demeclocycline (induces nephrogenic diabetes insipidus) or fludrocortisone (mineralocorticoid with aldosterone-like activity). When given at doses ranging from 150 to 300 mg two to four times a day, demeclocycline increases urinary free water excretion by interfering with the antidiuretic action of AVP. This effect may not occur for several weeks and is usually reversible when treatment is stopped. Demeclocycline may also cause photosensitivity, azotemia, or other signs of nephrotoxicity, but these side effects are usually also reversible. Treatment with fludrocortisone in doses of 0.1 to 0.3 mg twice a day can also be effective, presumably because it promotes sodium retention; however, it may also act in part by inhibiting thirst and fluid intake. The abnormalities in AVP secretion and AVP action are not affected by fludrocortisone. The principal side effects are hypokalemia and hypertension, which may necessitate potassium supplementation or reduction of the dose. AVP antagonists may also prove to be effective treatment for chronic SIADH in the future (2).

Questions

1. What is actions does ADH have?
2. What clinical manifestations might one see in a case of diabetes insipidus?
3. How might one distinguish nephrogenic from central diabetes insipidus?
4. Are levels of ADH under regulatory control in SIADH?
5. What is the most common neoplastic cause of SIADH?
6. If hyponatremia is found, what is the most useful next test to determine the etiology of the hyponatremia.
7. True/False: 3% sodium chloride solution (hypertonic saline) can be used safely to raise the serum sodium level in SIADH.

Answers to questions

1. The main biologic actions of ADH are to reduce the rate of urine flow by increasing the reabsorption of solute-free water from the filtrate in the distal tubules and collecting ducts of nephrons. This occurs via V2 receptors. When ADH acts on V1 receptors it causes vasoconstriction and contraction of smooth muscle elements.
2. Besides polyuria and polydipsia, physical exam and lab studies are typically within normal limits. However, in severe cases, signs and symptoms of hypernatremia and dehydration may be present.
3. Vasopressin challenge test: polyuria and polydipsia are corrected in central diabetes insipidus, but not corrected with standard doses in nephrogenic diabetes insipidus.
4. Yes and No. There are 4 types, only one is regulated by osmolality; however, the osmostat is reset to a lower osmolality.
5. Small cell lung cancer
6. The urine sodium is the test that should be done next. If the urine sodium is low, then the hyponatremia is due to total body sodium depletion. If the urine sodium is high, then the hyponatremia is due to SIADH, Addisonian crisis, diuretics, or salt losing nephropathy.
7. False. Hypertonic saline infusion is dangerous.

Chapter XV.6. Calcium Disorders
David F. Crudo MD

This is a 16 month old female, who presents to the ED with an acute onset of her hands and feet "drawing up". Her parents report that she cries when touched in her hands and feet and has refused to walk. She had a low-grade fever, vomiting, diarrhea, and decreased urine output attributed to a viral gastroenteritis beginning four days ago. Past medical history reveals that she had been a healthy term infant with no previous hospitalizations or significant illnesses.

Exam: VS T 37.7, P 140, R 20, BP 90/64, length 74.5 cm (10%ile), wt 9.2 kg (10%ile). She is fussy but awake and alert. HEENT, neck, heart, lungs and abdomen exams are normal. Both her hands are flexed at the wrists with hyperextended fingers at the proximal and distal interphalangeal joints and flexion at the metacarpophalangeal joints. Both thumbs are flexed upon the palm. Her feet are plantar flexed. Neurologic exam reveals symmetric hyperreflexia, decreased muscle strength and tone.

Laboratory: Na 135, K 3.8, Cl 102, bicarbonate 24, BUN 5 mg/dL, creatinine 0.3 mg/dL, glucose 82 mg/dL, calcium 5.6 mg/dL (normal 8.5 to 10.5), phosphorus 2.2 mg/dL (normal 3.5 to 6), alkaline phosphatase 1020 U/L (normal 125 to 450), ionized calcium 0.50 mmol/L (normal 1.00 to 1.30). CXR shows enlargement of the costochondral junctions. The normal enlarged thymic shadow of infants and toddlers is present. Radiographs of hands/wrists demonstrate cuffing, fraying, and widening of the epiphysis and metaphysis.

A diagnosis of vitamin D deficiency rickets with acute hypocalcemic tetany is made and she is treated with 1 mL/kg of 10% Ca gluconate solution IV over 1 hour. A dietary history reveals that she had been breast-fed since birth that has continued at least twice a day at present. Table foods were introduced at 10 months of age, but she is described as a picky eater and does not drink whole milk. She does not take any vitamin supplements. A review of her growth curve shows her decreasing from the 50%ile for length and weight at birth to the 10%ile for both parameters now. The diagnosis is confirmed with serum 25-OH vitamin D level of <5 ng/mL (normal 10 to 55), with an appropriately increased PTH level of 270 pg/mL (normal 10 to 55). 1,25-dihydroxy vitamin D level is 40 pg/mL (normal 15 to 90) (The plasma concentration of 25-OH D is the most sensitive index of vitamin D nutritional status. Most untreated vitamin D deficient patients have normal or elevated levels of 1,25-dihydroxy vitamin D due to secondary hyperparathyroidism which increases activity of renal 1 alpha-hydroxylase, which converts 25-OH D to 1,25-diOH D).

She is admitted to the hospital and treated with oral supplementation of 250 mg calcium carbonate every six hours and 4,000 IU of vitamin D (ergocalciferol) per day. She has no further episodes of tetany and is discharged 2 days later continuing on calcium and vitamin supplementation. Clinical and radiographic improvement is noted over the next several months, and the vitamin D dose is reduced to the recommended daily allowance of 400 IU.

Calcium (1,3) is an essential component of the mineral portion of bone and as its divalent cation (Ca++) is necessary for the function of every cell. Maintenance of calcium homeostasis is a dynamic process involving calcium absorption and excretion in the intestine, filtration and reabsorption in the kidneys, and storage and mobilization in the skeleton. Nearly all of the total body calcium (98%) is present in very slowly exchangeable skeletal hydroxyapatite crystal. It is the rapidly exchangeable calcium in recently deposited bone (1% of body calcium) and in the extracellular, intracellular, and vascular spaces (1%), that plays critical roles in intracellular communication, interneuronal transmission, muscle contraction, clotting, cellular proliferation, synthesis of secretion of endocrine and exocrine factors, and as an enzyme cofactor. Total serum calcium is divided into three fractions: 40% is bound to albumin and globulin, 10% is complexed to anions, while 50% exists in the free ionized state that is necessary for most metabolic functions.

The serum concentration of calcium is maintained at normal levels by an integrated system involving the Ca++ sensing receptor (CaSR), parathyroid hormone (PTH), vitamin D, and calcitonin. The CaSR is a membrane protein that binds Ca++ and determines the set-point for PTH secretion. PTH is an 84 amino acid peptide that increases calcium concentration by stimulating reabsorption of calcium in the kidney, enhancing the rate of calcium resorption from bone and increasing the rate of absorption of calcium from the intestine through increased renal formation of 1-25-dihydroxy vitamin D (1,25-diOH-D). Vitamin D3 (cholecalciferol) is synthesized in the skin from 7-dehydrocholesterol by exposure to UV light and heat. Vitamin D3 is hydroxylated in the liver to 25-OH-D (calcidiol), then further hydroxylated in the kidney to the biologically active 1,25-diOH-D (calcitriol). 1,25-diOH-D stimulates the absorption or reabsorption of calcium in the intestines, bone, and kidney. Calcitonin is a 32 amino acid peptide secreted by the parafollicular (C) cells of the thyroid gland, secreted in response to a rise in the serum calcium concentration. Its major biological effect is to decrease the calcium resorption in bone by inhibiting osteoclast activity.

Etiology of Hypocalcemia in Children and Adolescents (2,3,4)

1. Hypoparathyroidism
   - Congenital
     - Transient neonatal
     - Familial
     - DiGeorge syndrome
   - Acquired
     - Autoimmune
     - Post-surgical
     - Infiltrative
   - Resistance to PTH
     - Pseudohypoparathyroidism
     - Pseudopseudohypoparathyroidism
2. Vitamin D deficiency
3. Other
   - Ca deficiency
   - Hypomagnesemia
   - Hyperphosphatemia
     - Includes chronic renal failure (renal osteodystrophy)
   - Hypoproteinemia
   - Drugs (furosemide, calcitonin, antineoplastic agents)
   - "Hungry bones"
   - Critical illness

The child with hypocalcemia may be asymptomatic and identified through chemistries obtained for another reason or present with intermittent muscular cramping, paresthesias, tetany, carpopedal spasms, laryngospasms, or seizures. Review of symptoms and past medical history may reveal intermittent symptoms associated with hypocalcemia. Commonly, the physical exam is unremarkable other than that of increased neuromuscular irritability: hyperreflexia, Chvostek sign (twitching of the circumoral muscles when tapping lightly over the facial nerve) or Trousseau sign (carpopedal spasm when maintaining a blood pressure cuff 20 mmHg above the systolic blood pressure for 3 minutes), and occasionally cataracts or abnormal dentition. The physical exam may disclose the characteristic phenotype of Albright hereditary osteodystrophy (short stature, round facies, shortened metacarpals, subcutaneous calcification; pseudohypoparathyroidism type Ia), the DiGeorge syndrome (typical facies, cardiac abnormalities), or rachitic changes (bowed legs or "knock knees", widened metaphyses of the long bones, prominent costochondral junctions, frontal bossing) in the case vitamin D deficiency.

DiGeorge syndrome is usually classified as an immune deficiency, but it usually presents initially with congenital heart disease or with hypocalcemic seizures or tetany. During embryogenesis, the thymus and parathyroid glands originate from the same branchial pouch, which explains why the two abnormalities occur together. Congenital heart disease may be detected during the newborn period. Subsequently, the child will present with hypocalcemic tetany or seizures during the first few months of life, before any opportunistic infection is likely to occur. A chest X-ray will show a cardiac silhouette without the usual thymic shadow. Thymic absence with hypocalcemia, is highly indicative of DiGeorge syndrome.

The laboratory evaluation of a hypocalcemic child requires measuring serum total and ionized calcium, PTH, magnesium, phosphate, creatinine, alkaline phosphatase, and urinary calcium. If there are concerns of a metabolic bone disease, serum levels of 25-OH-D and 1,25-diOH-D should also be obtained.

Calcium and magnesium tend to be antagonistic, so hypocalcemia will occur in association with a high magnesium load, which most commonly occurs in premature neonates of mothers treated with magnesium tocolytics. Severe hypomagnesemia will also result in hypocalcemia since magnesium is a required co-factor for PTH release. Thus, both extremes of magnesium, will result in hypocalcemia.

A patient with hypocalcemia, hypocalciuria, hyperphosphatemia, and low serum PTH levels has hypoparathyroidism caused by a primary defect in PTH synthesis or secretion. An elevated PTH level indicates a compensatory increase in response to hypocalcemia or a resistance to PTH (pseudohypoparathyroidism).

Management of symptomatic acute hypocalcemia is intravenous 10% calcium gluconate (93 mg elemental Ca in 10 mL), 1-2 mL/kg over 10 minutes. Although calcium chloride can also be used, some texts discourage the use of calcium chloride because it can lead to metabolic acidosis. After acute symptoms have resolved, an intravenous infusion of calcium should be initiated at a rate to keep the serum calcium levels in the low normal range while an investigation of the etiology ensues. Therapy for patients with hypo- or pseudohypoparathyroidism is individualized using calcitriol (20-60 ng/kg/day) and supplemental oral calcium (30-75 mg elemental Ca/kg/day). Frequent measurements of serum calcium and creatinine and renal ultrasonography are done to monitor for hypercalcemia, hypercalciuria, and nephrocalcinosis.

Etiologies of Hypercalcemia in Children and Adolescents (2,3,4)

1. Hyperparathyroidism
   - Sporadic
   - Familial (isolated or MEN 1 and 2A)
   - Secondary/tertiary (renal failure)
2. Familial hypocalciuric hypercalcemia (FHH)
3. Hypervitaminosis D
   - Nutritional
   - Granulomatous disease (sarcoidosis, TB, histoplasmosis)
4. Immobilization
5. Neoplasia
   - Bony metastases
   - Production of PTH related protein (PTHrP)
   - Cytokine/osteoclast-activator production
6. Other
   - Hyperphosphatemia
   - Drugs (thiazides, lithium, vitamin A, alkali)
   - Hyperthyroidism
   - Hypoadrenalism
   - Pheochromocytoma

Clinical features are dependent on the underlying disorder and degree of hypercalcemia. Nonspecific symptoms include polydipsia, polyuria, anorexia, constipation, nausea, vomiting, abdominal pain, weakness, and altered consciousness. The patient may show signs of dehydration or altered mental status, otherwise the physical exam is usually normal. Commonly a shortened QT interval can be found on EKG and nephrocalcinosis and renal calculi demonstrated by ultrasonography.

The initial laboratory evaluation of a hypercalcemic child requires measuring serum total and ionized calcium, urinary calcium, PTH, phosphate, creatinine, 25-OH-D and 1,25-diOH-D levels. If the patient is hypocalciuric, the probable etiology is FHH (familial hypocalciuric hypercalcemia). This diagnosis can be confirmed by finding asymptomatic hypocalciuric hypercalcemia in one of the parents. In the absence of secondary hyperparathyroidism (chronic renal failure, ingestion of thiazides or lithium), consistently elevated PTH levels are indicative of primary hyperparathyroidism. Calcidiol levels are increased in patients with hypercalcemia caused by excessive intake of vitamin D. Calcitriol levels are increased in patients with granulomatous, chronic inflammatory, and lymphomatous diseases or those receiving that vitamin. PTHrP (PTH related peptide) levels are high in the children with humoral hypercalcemia of malignancy.

Appropriate management depends on the severity and cause of the high calcium levels. If the calcium level is <12 mg/dL and the patient asymptomatic, treatment may be delayed pending evaluation of the cause. Symptomatic patients and those with calcium levels >12 mg/dL should be treated because of the adverse effects of hypercalcemia on the cardiac, renal, gastrointestinal, and central nervous systems.

Treatments are: 1) intravenous fluid therapy (NS at twice maintenance) to restore volume, dilute serum Ca++ levels, and promote calciuresis; 2) calciuresis by IV furosemide (1 mg/kg) only after restoration of volume; and 3) inhibition of bone resorption by bisphosphonates or calcitonin. Dialysis may be indicated if the patient is resistant to conventional therapy.

Surgery is indicated for primary hyperparathyroidism. The secondary hyperparathyroidism of chronic renal failure is best treated by lowering the serum phosphate to the extent possible while maintaining the serum calcium level in the low-normal range with calcitriol (1,25-diOH-D).

Glucocorticoids are effective in lowering excess calcium levels due to vitamin D ingestion, granulomatous and inflammatory diseases, or malignancies, by inhibiting renal 25-OH-D-1-alpha-hydroxylase activity. A low calcium diet, copious fluids, avoidance of vitamin D, and early mobilization are indicated in the immobilized child to avoid hypercalcemia.

Etiologies of Rickets (2,5)

1. Abnormality of vitamin D intake or metabolism
   - Nutritional deprivation (low birth weight infant, malabsorption, drugs)
   - Metabolic factors
   - 25-hydroxylase deficiency (loss-of-function mutation, severe liver disease)
   - 25-OH-D-1-alpha-hydroxylase deficiency (loss-of-function mutation, chronic renal insufficiency)
   - Loss-of-function mutation of vitamin D receptor
2. Calcium deficiency
   - Nutritional
   - Hypercalciuria
3. Phosphorus deficiency
   - Nutritional (low birth weight infant, aluminum-containing antacids)
   - Hyperphosphaturia
     - X-linked familial hypophosphatemic rickets
     - X-linked recessive hypophosphatemic rickets
     - Autosomal recessive hypophosphatemic rickets with hypercalciuria
     - Autosomal dominant hypophosphatemic rickets
     - Oncogenic hypophosphatemic osteomalacia
     - Renal tubular acidosis
4. Hypophosphatasia

Rickets and osteomalacia are disorders that result from demineralization of bone matrix. Rickets occurs in the growing child and involves the growth plate and can lead to skeletal deformities. Osteomalacia refers to demineralization of mature bone and is associated

with an increased fracture risk. Rickets is primarily calcipenic (nutritional deficiency of calcium or vitamin D or abnormality in vitamin D action) or phosphopenic (abnormality in renal reabsorption of phosphate).

Clinical signs of rickets in ambulatory children include bowed legs or "knock knees", widening of the long bones metaphyses, prominence of costochondral junction (rachitic rosary), frontal bossing, and short stature. Symptoms may include hypotonia, weakness, anorexia, and delayed walking. Hypocalcemia, tetany, and seizures may be seen in a severely vitamin D deficient infant.

Radiographically, the long bones are the earliest and most common sites of change. There is decreased bone density, thinning of the cortex, and widening, cupping, and fraying of the distal ends of the shaft.

In children with vitamin D deficiency, the serum calcium levels are normal or low, phosphate low, alkaline phosphatase elevated, calcidiol low, and calcitriol variable (i.e., it is sometimes normal as in the case). Prevention is the best treatment for vitamin D deficiency, but once deficiency has been established, treatment consists of vitamin D replacement (1000-4000 IU/day orally for several weeks; 10,000-50,000 IU IM monthly for 3-6 months; or 600,000 IU IM once). Calcium supplementation (elemental Ca 40 mg/kg/d) should be given to avoid hypocalcemia resulting from remineralization ("hungry bone" syndrome).

There is an association of prolonged breast-feeding and vitamin D deficiency. Breast milk has only 15-30 IU/L vitamin D. In 1997, the American Academy of Pediatrics issued a statement recommending vitamin D supplementation "for those infants whose mothers are vitamin D deficient or those infants not exposed to adequate sunlight" (6). However in 2003, the AAP revised this statement recommending vitamin D supplementation for all infants and children (7).

Rickets caused by inadequate dietary calcium has been observed in infants and children receiving a diet containing less than 200 mg elemental calcium per day. Ensuring adequate calcium intake established for growing children (1000-1300 mg/d) is preventative and therapeutic. Phosphate is abundantly present in most foods, so rickets from dietary phosphate deficiency is unusual. Dietary phosphate deficiency can be found in patients taking aluminum-binding antacids (which bind phosphate), or in patients on prolonged parental nutrition with inadequate phosphate, and in premature infants on breast milk without phosphate supplementation.

Rickets caused by a liver 25-hydroxylase deficiency is exceedingly rare since there appears to be several enzymes capable of carrying out this reaction. A loss-of-function mutation in the 25-OH-D-1-alpha-hydroxylase enzyme is termed pseudovitamin D-deficiency rickets (PDDR) or vitamin D-dependent rickets type I. There is hypocalcemia, hypophosphatemia, and hyperphosphatasia, and elevated PTH levels. Serum calcidiol levels are normal and calcitriol levels low and do not respond to administration of vitamin D. Treatment is with small doses of calcitriol (10-20 ng/kg/d). An inactivating mutation of the vitamin D receptor leads to resistance to calcitriol and is termed vitamin D-dependent rickets type II. Patients have the typical biochemical and radiographic findings of rickets, and their serum calcitriol and PTH levels are markedly elevated. Clinically patients also exhibit severe onset of bone deformities in infancy, alopecia, and growth retardation. Treatment consists of high dose calcitriol (up to 6 mcg/kg/d) and supplemental calcium (up to 3 gm/kg/d elemental calcium).

X-linked hypophosphatemic rickets is one of the most common causes (1:20,000 births) of rickets in developed countries. It is caused by an as yet unidentified phosphaturic agent produced possibly by osteoblasts. Serum calcium, PTH, calcidiol levels are normal, and there is marked hypophosphatemia and hyperphosphaturia. Calcitriol levels are inappropriately low. The primary agents employed in treatment are calcitriol (30-70 ng/kg/d) and elemental phosphorus (0.25-2 gm/kg/d in 4-6 divided doses).

Questions

1. True/False: The main biochemical findings in hypoparathyroidism are hyperphosphatemia and hypocalcemia.
2. True/False: Calcitonin injections can be used to raise a patient's serum calcium level.
3. True/False: Breast feeding prevents rickets.
4. True/False: Elevated levels of parathyroid hormone always result in hypercalcemia.
5. True/False: Vitamin D alone is curative all various forms of rickets.

Answers to questions

1. True.
2. False. Calcitonin lowers serum calcium levels.
3. False. Breast milk contains low levels of vitamin D. Vitamin D supplementation will prevent rickets.

4. False. A compensatory increase in PTH in response to hypocalcemia (such as with rickets) will usually result in low or normal calcium levels. High PTH levels should result in hypercalcemia; however, pseudohypoparathyroidism is an end-organ resistance to PTH, so despite an elevated PTH, patients have hypocalcemia.

5. False. The mainstay of therapy in hypophosphatemic rickets is oral phosphate replacement. Calcitriol is used to decrease the amount of phosphate needed (increases intestinal phosphate absorption), and prevent hypocalcemia and secondary hyperparathyroidism.

Chapter XVI.1. Systemic Lupus Erythematosus
Kara S. Yamamoto, MD

A 14 year old female presents with a 6 week history of fatigue and facial rash. Her rash seems to be exacerbated by sun exposure. She has recently developed pain and swelling in her fingers and wrists. She has no significant past illnesses. Family history is significant for an aunt with lupus and a grandmother with thyroid disease.

Exam: VS T 37.8, P 88, R 20, BP 110/66. Height and weight are at the 20th percentile. She is alert and cooperative. She has thinning hair over her front scalp with some fine short hairs. She has an erythematous maculopapular rash over her malar areas spanning the bridge of her nose, erythema of the hard palate and a few shallow gingival ulcers. Joint exam reveals mild swelling and tenderness to palpation and range of motion in the proximal interphalangeal joints of several of her fingers and both wrists. Heart, lung, abdomen, back and neurological examinations are within normal limits.

Laboratory: WBC 2.5 with 87% segs, 5% lymphs, 6% monos, 2% basophils. Hgb 10. Platelet count 167,000. ANA 1280. ESR 45. Urinalysis without protein or blood. No cellular casts or significant red or white cells.

Systemic Lupus Erythematosus (SLE) is a multisystem, inflammatory disease of autoimmune origin, characterized by the production of auto-antibodies directed against elements of the cell nucleus. The disease is often chronic with episodic flares of disease and remissions (1).

The etiology of lupus is unknown and thought to be complex and multifactorial. Many lines of evidence point to both host (endogenous and genetic) and environmental (e.g., environmental exposures and infection) factors, which contribute to development of disease. Although numerous susceptibility foci and genetic linkages or associations have been reported, there is no predominant or single one identified. Genetic associations found in one race may not apply to other races or even subsets within a particular race. Genes which confer susceptibility to developing the disease may differ from individual to individual and may result in different clinical manifestations and severity of disease.

Family studies offer compelling evidence of genetic predisposition. Connective tissue disease other than SLE has been reported in 10% of families of patients with SLE (1). There is an increased risk of developing SLE in first degree relatives of patients with SLE (2). A person with SLE has increased risk of having a sibling with SLE versus the general population having a sibling with SLE (2,3). Twin studies show higher rates of SLE in monozygotic versus dizygotic twins (4).

Studies have suggested that lupus is more prevalent in non-Caucasian ethnic groups such as African-American, Hispanic, Asian, Native American Indian, Alaskan Indian and Indian populations, which lends support for there being some genetic basis for disease susceptibility. We recently reviewed pediatric lupus patients in our rheumatology clinic in Hawaii, demonstrating that children of Samoan, Filipino and Japanese ancestry have increased odds ratio of developing SLE (5).

Other factors such as ultraviolet radiation, stress, and infection may also play a role in pathogenesis. Drugs such as hydralazine, isoniazid, sulfonamides, penicillin, beta-agonists and anticonvulsants have been associated with "drug-induced" lupus which is dependent upon the presence of the drug.

The true incidence and prevalence of lupus is not known, but is generally thought to be lower in children than in adults. Lupus is most common in women of child bearing years, but about 20% or more of patients with SLE are children. Lupus is rarely seen before the age of 5 years, is more common after 9 to 10 years, and tends to cluster around the age of puberty. Female predominance of the disease is less pronounced before puberty.

Clinical manifestations of lupus can vary widely. Lupus can present with non-specific and milder symptoms over an extended period of time, but children typically have a more acute onset. Constitutional symptoms are common, such as fever, fatigue, decreased appetite, and weight loss. High fevers should be suspect for an underlying infection in patients with lupus who are immunocompromised due to their disease and the immunosuppressive medications they are on.

Rash is common and variable. The classic malar "butterfly" rash is usually symmetric, spanning the bridge of the nose, but sparing the nasolabial folds. The rash may be photosensitive and involve other sun exposed areas such as the forehead, ears and the "V" of the neck and upper chest. Rash may involve other parts of the body, including the palms of the hands. Most heal without scarring or pigmentation. Severe vasculitis or thrombosis may result in ulcerations or even gangrene. Discoid lesions, which often lead to scarring, atrophy, and pigmentation changes, seem to be less frequent in children. Nail bed involvement with periungual erythema may occur. Livedo reticularis may also occur. Alopecia is common and is associated with active disease. It often involves the frontal scalp and may be generalized or patchy. Mucocutaneous lesions may include vasculitis and ulceration of the hard palate, aphthous stomatitis, and less frequently ulcers or perforation of the nasal mucosa or septum.

Vasculitis affects small blood vessels in lupus. Children with lupus may have Raynaud's phenomenon, manifested as sequential color changes (blanching to cyanosis and hyperemia) in their distal extremities often related to exposure to cold or stress. It can vary in severity. Ischemia may lead to pain and ulcers, and in severe cases, atrophy, necrosis and gangrene. Treatment may include biofeedback, behavior modification, vasodilators, and nerve blocks.

Arthritis and arthralgias are common. Arthritis is usually transient and usually does not result in permanent deformity, although it can be quite painful. Occasionally it can be persistent and erosive. Patients with lupus, especially those requiring long term corticosteroid therapy, are at risk for avascular necrosis particularly in weight bearing joints.

Myalgia and even myositis may occur often related to vasculitis. Corticosteroid therapy may also contribute to corticosteroid myopathy with weakness.

Nephritis is one of the most common complications of lupus and affects about 75-80 % of children with SLE. It usually is manifested in the first 1-2 years of disease. Microscopic hematuria is common. Proteinuria, including nephrotic syndrome and hypertension may occur. Acute renal failure at presentation is rare. Renal histology on tissue obtained on a renal biopsy allows classification of the type of glomerulonephritis based upon the World Health Organization Classification of Renal Nephritis.

The most common cardiopulmonary manifestations are pericarditis and pleural effusions. Pulmonary hemorrhage and acute lupus pneumonitis can occur. Pulmonary infection is also frequently encountered. Myocarditis can occur. Myocardial infarction and valvulitis (Libman-Sacks endocarditis) are less frequent in children than adults.

Lymphadenopathy is quite common in children with SLE, sometimes associated with splenomegaly. Hepatomegaly can also be present.

Gastrointestinal complaints frequently occur in children with SLE. Serositis, pancreatitis or bowel vasculitis can occur. Bowel vasculitis can be complicated by hemorrhage, perforation, ischemia, or infarction. Corticosteroids may mask or suppress symptoms, making the diagnosis difficult.

Central nervous system involvement is a major cause of morbidity and mortality in children with lupus. Some estimate that up to 50% of children and adolescents with SLE have CNS involvement at disease onset. CNS involvement is variable in severity and manifestation. Symptoms may be subtle and difficult to detect or diagnose. CNS problems include neuropsychiatric manifestations, headache, seizures, cerebrovascular accidents, chorea, peripheral neuropathy, papilledema, visual loss, vertigo, myelopathy. Depression and difficulty with memory and concentration are common. Psychosis with hallucinations and paranoia may also occur. Cognitive impairment may cause a child to have difficulty with school. Headache is a common problem. Difficulty in coping with the disease, its manifestations and side effects of medications is common, particularly for adolescent patients.

Associated phenomenon may include antiphospholipid syndrome characterized by episodes of thrombosis, spontaneous recurrent abortions, cardiovascular crises, and menorrhagia. Thrombocytopenic purpura (TTP) and Evans' Syndrome (acute hemolytic anemia) has been seen in association with SLE. Sjogren's syndrome is rare in children (keratoconjunctivitis sicca, xerostomia). Autoimmune thyroid disease may occur in children with lupus.

Laboratory Evaluation

Antinuclear antibodies (ANA) are a hallmark of SLE and present in virtually all children with active SLE. The most specific pattern of nuclear immunofluorescence is "peripheral" suggesting the presence of ds-DNA (double stranded DNA), however the "homogeneous" pattern is the most common. The ANA is a very non-specific test and may be present in other diseases or children without rheumatic disease.

Anti-ds DNA antibodies are more specific for SLE and are often found in children with active SLE, particularly those with active nephritis. Antibodies to extractable nuclear antigens (ENA) may be useful. Anti-Sm antibodies (pronounced anti-Smith) are strongly associated with SLE. Antibodies to SS-A/Ro and SS-B/La are strongly associated with SLE, neonatal lupus, and Sjogren's syndrome. Anti-RNP antibodies (anti-ribonuclear protein) may be present in SLE, but in high titers are associated with mixed connective tissue disease. Antihistone antibodies are present in children with SLE and drug-induced SLE.

LE cell preparations and false positive tests for syphilis (i.e., VDRL and RPR) have largely been replaced by the tests above for proof of the immunologic disorder in diagnosing SLE.

Antiphospholipid antibodies may also be associated with lupus in children. Laboratory testing for lupus anticoagulant and/or anti-cardiolipin antibodies is useful. Positive anticardiolipin antibodies are responsible for the false-positive VDRL seen in lupus. Antiphospholipid antibodies can prolong the partial thromboplastin time (PTT). These antibodies are associated with thrombosis (paradoxical since one would expect an anticoagulant to do the opposite), thrombocytopenia, livedo reticularis, and recurrent miscarriages. They can also be seen without the presence of SLE. Rheumatoid factor is present in some children with SLE, but high titers may suggest the presence of an overlap syndrome.

Immune complexes are thought to play a major role in the pathogenesis of SLE, however due to problems with reproducibility of assays and variability in correlating with disease activity, measuring immune complexes is of limited utility.

Decreases in serum complement particularly C3, C4, and CH50 may reflect active disease and are important in assessing disease activity, especially lupus nephritis.

Hematologic abnormalities such as anemia are common. Anemia may be secondary to chronic disease (normocytic, hypochromic) or due to autoimmune hemolysis with a positive Coombs test. Hypersplenism and drug sensitivity may complicate the anemia. Leukopenia, especially lymphopenia, and immune thrombocytopenia frequently occurs. Some patients may initially present as idiopathic thrombocytopenic purpura (ITP) with a positive ANA, and later progress to SLE.

Acute phase reactants such as ESR are often increased during disease activity. This is a non-specific test, however, and cannot distinguish between flares of disease and infection.

Urinalysis may show abnormal urinary sediment in patients with glomerulonephritis, as well as proteinuria. Determinations of urine protein and creatinine excretion are helpful in assessing renal disease.

The diagnosis of SLE is based upon clinical and laboratory findings. Classification criteria for SLE from the American College of Rheumatology, revised in 1982 have also been widely used for diagnosis (8). In adults, the presence of 4 out of 11 criteria are required for diagnosis with a sensitivity and specificity of 96% percent. In children, one study reported a sensitivity of 96% and a specificity of 100%, as compared with a rheumatic disease control group (7). The 11 criteria are: malar rash, discoid rash, photosensitivity, oral ulcers (oral or nasopharyngeal ulceration), arthritis, serositis (pleuritis or pericarditis), renal disorder (persistent proteinuria, cellular casts), neurologic disorder (seizures or psychosis), hematologic disorder (hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia), immunologic disorder (positive LE cell preparation, anti-DNA antibodies, anti-Sm antibodies, or false positive serologic test for syphilis), and antinuclear antibody.

Treatment

Corticosteroids (glucocorticoids) are indicated for the treatment of SLE with major organ involvement. Intravenous methylprednisolone may be useful in certain patients, particularly those with severe disease. Treatment is usually on a long term basis with tapering over a prolonged period of time raising concerns over potential complications such as growth suppression, susceptibility to infection, hyperlipidemia, hypertension, hyperglycemia, psychosis, myopathy, osteoporosis, cataracts, increased intra-ocular pressure, glaucoma, gastric irritation and Cushing's syndrome. Other effects may include hirsutism, acne, striae, and weight gain.

Nonsteroidal anti-inflammatory drugs (NSAIDs) may be used to manage musculoskeletal complaints, but may not be appropriate in children with renal disease. Hydroxychloroquine is an antimalarial which may be helpful as an adjunct to corticosteroid therapy and may allow tapering of the corticosteroids. It can be useful for treatment of the arthritis and rash of SLE. Children taking this medication should be closely monitored for retinal toxicity.

Immunosuppressive agents such as cyclophosphamide, azathioprine, methotrexate, cyclosporin, and mycophenolate mofetil have been used to treat SLE. Cyclophosphamide pulsing (intravenous) is important in the treatment of severe SLE, particularly lupus nephritis and CNS disease. It has contributed to the increased survival of patients with nephritis. Toxicity may limit use, particularly concerns over the increased risk of infertility, infection, and malignancy. The role of plasmapheresis in treating lupus is not well defined, although it has been used in severe life threatening disease.

Course of the disease

Over the past 30 years or so, the life expectancy of children with SLE has significantly increased. Improvements in therapy, monitoring, and supportive care have all contributed to this improvement. Long term quality of life and outcomes have become increasingly important. The course of lupus in any child is unpredictable and varies from individual to individual. Most have chronic disease with disease remissions and exacerbations, although some patients may remain in remission for long periods of time. Close monitoring and follow up is essential to prevent significant morbidity and mortality.

Infection is the one of the major causes of morbidity and mortality in children with SLE. Infection has surpassed renal disease as the most common cause of death. Children with SLE are susceptible to infection as a consequence of both the disease and therapy, particularly corticosteroids and other immunosuppressive agents.

Growth abnormalities due to lupus and long-term corticosteroid therapy may result in short stature and delayed onset of puberty. Corticosteroids may cause cushingoid facies, hirsutism, and increased appetite leading to significant weight gain. These factors may have significant impact on children and especially adolescents, who are often very concerned about body image and peer acceptance.

Many patients experience difficulty in coping, psychological distress, and even depression with their SLE and complications relating to the disease and therapy. This can complicate assessment of neuropsychiatric problems secondary to central nervous system lupus. Neuropsychiatric deficits can adversely impact a child or adolescent's functioning and quality of life. Mental health services can play an important role in positive outcomes.

With the improved survival of children with SLE, cardiovascular complications are becoming an important problem of the illness. Abnormal lipid metabolism, long term complications of corticosteroid therapy, hypertension, and cardiac involvement secondary to lupus may all be contributing factors.

Avascular necrosis is also a problem with childhood SLE. This can occur with or without long term corticosteroid treatment and may result in significant pain and disability, even requiring joint replacement. The availability of alternate immunosuppressive therapies to corticosteroids may help decrease the incidence of this complication. Potential ophthalmologic complications from SLE and treatment with drugs such as hydroxychloroquine and corticosteroids require monitoring by an ophthalmologist.

Sun avoidance and protection is important in management of SLE. Many patients are photosensitive resulting in exacerbation of their rash. UV rays from other sources besides sunlight, such as fluorescent and halogen lights can also aggravate lupus. Sunscreen, protective clothing, and other devices to block UV emissions are helpful. A well balanced and nutritious diet, physical rest, and reducing emotional stress are also important in maintaining health.

The outlook for children with lupus has markedly improved. The continuing development of new treatments, improved surveillance of disease activity, and advances in supportive care promise to further enhance not only survival, but the quality of life for these children. Early diagnosis and prompt, aggressive treatment are also important in managing the disease and its complications.

Questions

1. List at least 6 of the 11 diagnostic criteria for SLE.

2. Name 3 drugs which are used for the treatment of SLE.

3. Which of the following statements are false?
   a. Leading causes of morbidity and mortality for children with SLE are infection, renal disease, and CNS involvement.
   b. ANA, anti-ds DNA antibodies, anti-Sm antibodies are part of the criteria for diagnosis of lupus
   c. Ophthalmologic complications are infrequent in children with SLE
   d. UV emissions may exacerbate lupus

4. True/False: A positive ANA test is a useful screening test for SLE?

5. True/False: Patients with a lupus anticoagulant have a prolonged PTT and they have hemorrhagic tendencies similar to patients with hemophilia.

Answers to questions

1. Malar rash, discoid rash, photosensitivity, oral ulcers, arthritis, serositis, renal disorder, neurologic disorder, hematologic disorder, immunologic disorder, antinuclear antibody

2. Corticosteroids, NSAIDs, hydroxychloroquine, cyclophosphamide, azathioprine, methotrexate, cyclosporine, and mycophenolate mofetil

3.c. Retinal toxicity may be a complication of hydroxychloroquine therapy. Long-termed corticosteroid therapy may be complicated by cataracts, glaucoma, and increased intra-ocular pressure. Rare cases of orbital/ocular vasculitis may occur.

4. The answer is true, depending on your interpretation. The ANA test is non-specific in that a positive ANA test by itself is not diagnostic of SLE. The ANA is frequently positive in normal individuals. However, a screening test is not a diagnostic test, but it is just used to screen. A negative ANA suggests that the patient does not have SLE. The answer to this question true, but it should be noted that the ANA is frequently ordered excessively and inappropriately.

5. False. It is true that patients with a lupus anticoagulant have a prolonged PTT. However, the lupus anticoagulant paradoxically is associated with and increased risk of thrombosis, rather than hemorrhage.

Chapter XVI.2. Juvenile Rheumatoid Arthritis

Kara S. Yamamoto, MD

This is a 4 year old female who has been limping with swelling of her right knee for several months. Her parents note that she cannot fully extend her right knee. She sometimes does not want to walk in the morning, but seems fine later in the morning and the rest of the day. Her past medical history is unremarkable. Physical examination demonstrates swelling (effusion) of her right knee, flexion contracture of 10 degrees and flexion to 120 degrees. No increased heat or pain upon range of motion is present. She appears unconcerned about her limp and swelling. Labs: WBC 8,600 with 45 polys, 47 lymphs, 8 monos. Hgb 12. ESR 20. UA normal. Rheumatoid factor negative, ANA 1:640 speckled.

Juvenile rheumatoid arthritis (JRA) is a chronic arthritis of childhood comprised of several different subgroups. It is one of the most common rheumatic diseases of childhood. Because the majority of children are rheumatoid factor negative, it is also known as juvenile idiopathic arthritis or juvenile chronic arthritis. Although the true incidence and prevalence of JRA are unknown, its incidence is estimated at 2 to 20 per 100,000 children per year based on the American College of Rheumatology (ACR) criteria (1,2).

Neither the etiology nor risk factors of JRA have been identified. It is considered to be an autoimmune disease. Chronic synovitis, T-cell abnormalities, abnormal immunoregulation and cytokine production, autoantibodies, immune complexes, and complement activation suggest that cell mediated and/or humoral processes are involved. Infection may have a possible role in developing JRA.

Complex and probably multi-factorial genetic factors are likely to play a role in the genetic predisposition to developing JRA as is evidenced by associations with HLA genetic polymorphisms which have been identified in some patients with JRA (3). There may also be associations with other autoimmune diseases such as insulin-dependent diabetes mellitus and autoimmune thyroiditis.

Currently there is no universal consensus on the classification of JRA. Several distinct subgroups have been suggested. The American College of Rheumatology criteria require that the age at onset of arthritis be less than 16 years, and that arthritis be present in one or more joints for at least 6 weeks. Other causes must be excluded. The onset type of JRA is determined by the first six months of disease and includes pauci- or oligo- articular JRA, polyarticular JRA, and systemic-onset JRA (4). The ACR criteria do not include seronegative spondyloarthropathies and related diseases (juvenile ankylosing spondylitis, juvenile psoriatic arthritis, and arthropathies associated with inflammatory bowel disease). More inclusive classification criteria such as the EULAR (European League Against Rheumatism) and ILAR (International League of Associations for Rheumatology) are also used. This chapter will describe the following subgroups:

A. Pauci-articular JRA
   1) Early childhood onset
   2) Late childhood onset
B. Polyarticular JRA
   1) Rheumatoid Factor Seronegative
   2) Rheumatoid Factor Seropositive
C. Systemic-onset JRA
D. Juvenile Psoriatic Arthritis

Arthritis is characterized by synovial tissue inflammation including hypertrophy of the synovium and increased secretion of synovial fluid. Affected joints may be warm, stiff or painful, swollen, limited in range of motion, and occasionally erythematous. Two or more of these signs is necessary for the diagnosis of arthritis (5). Synovial fluid analysis is not specific for JRA and may show an elevated total white count that is predominately polymorphonuclear neutrophils and mononuclear cells, and glucose levels may be decreased. The clinical course of the various subtypes of JRA is diverse. Depending upon the type of JRA, the degree of destruction of synovium and surrounding structures is variable. Rheumatoid factor positive disease tends to be more destructive, whereas the synovitis of seronegative JRA may not cause joint destruction, even after persistent activity.

JRA may involve other organ systems besides the joints depending upon the type of onset. Iridocyclitis/uveitis may be present in all subtypes of JRA, but especially in the pauci-articular disease of early childhood. All children with JRA should have regular ophthalmologic examinations including slit-lamp examinations. Rheumatoid factor positive JRA may demonstrate rheumatoid nodules and vasculitis. Systemic onset disease can develop multiple systemic manifestations. Growth retardation or limb length discrepancies can complicate the course of children with JRA.

Pauci-articular JRA describes the involvement of 4 or fewer joints and affects an estimated 40-60% of children with JRA. At least two distinct subgroups have been identified: Early childhood onset (frequently associated with positive anti-nuclear antibodies and iridocyclitis) and late childhood onset. Some classification criteria further divide early childhood onset into oligoarthritis and extended oligoarthritis.

Early childhood onset pauci-articular JRA affects predominantly girls under the age of 6 years. More common in Caucasian children, it accounts for about 30-40% of patients with JRA. About 50% have monoarticular arthritis. Large joints of the lower extremities are most often involved, including knees and ankles, occasionally elbows. This subtype is associated with positive ANAs

(anti-nuclear antibodies) and chronic iridocyclitis. It has been estimated that up to 30% of these children have a risk of chronic iridocyclitis/uveitis in the first several years of disease. Eye involvement is usually insidious with few if any symptoms or signs. These patients require routine slit-lamp examinations to detect early inflammatory changes. Late sequelae of chronic iridocyclitis include posterior synechiae, band keratopathy, cataract formation, glaucoma, visual loss or blindness. Hips are infrequently affected. These children are not systemically ill and usually function well without a great deal of pain. There is a subset of these children who initially present as pauci-articular in the first 6 months of disease, but progress to poly-articular disease thereafter (extended oligoarthritis).

The late childhood onset subgroup of pauci-articular JRA is associated with HLA B27 and development of enthesitis and sacroiliitis. The terms Juvenile Spondyloarthropathy or Juvenile Ankylosing Spondylitis have also been used. It is usually oligoarticular at onset and affects approximately 10-15% of children with JRA. There is a male predominance with the age of onset usually after 8 years of age. The onset of arthritis can be insidious or acute. The clinical course may be episodic and variable resulting in little to significant joint destruction. It often affects the large joints of the lower extremities (hips, knees, ankles). Frequently these patients develop enthesitis (swelling along tendons and at sites of tendonous/ligamentous insertion into the bone). Achilles enthesitis is common. Tarsal involvement may occur. A subset of children who initially present with only enthesitis later develop arthritis. Some patients develop acute iridocyclitis (eye pain, red eyes and photophobia). Although usually absent at onset, some patients develop thoracic and lumbar spine involvement with loss of flexion meeting criteria for ankylosing spondylitis. HLA-B27 is present in about 80% of these children. A family history of spondyloarthropathy such as ankylosing spondylitis, Reiter's disease, inflammatory bowel disease with spondylitis, psoriatic arthritis, and acute iridocyclitis is often obtained.

Polyarticular JRA affects approximately 35% of children with JRA. It can be further sub-divided into Rheumatoid factor positive (seropositive) and Rheumatoid factor negative (seronegative) disease.

The seronegative JRA subtype typically presents at less than 5 years of age, although it may occur at any age during childhood. There is a female predominance. It occurs in 20-30% of patients with JRA and is characterized by a negative test for IgM rheumatoid factor. Symmetric involvement frequently occurs, most commonly in the large joints. The small joints of the hands and feet may also be involved. Cervical spine involvement with limitation of range of motion in the neck and temporomandibular joint involvement are common. Micrognathia may be noted with time. Boutonniere deformities and flexion contractures occur more frequently than swan-neck deformities. Leg length discrepancies, angular deformities and brachydactyly may occur. Morning stiffness and gelling or stiffness after inactivity are frequent. Patients are usually not systemically ill, but low-grade fever, mild anemia, mild lymphadenopathy and hepatosplenomegaly may occur. These children often respond well to therapy and can have little joint destruction despite a number of episodes over several years. Recurrent episodes may tend to cause progressive joint damage and deformity. Uveitis occurs in about 10% of these children and regular ophthalmology examinations are important.

The seropositive JRA usually occurs in children over the age of 8 years with a female predominance. It occurs in 5-10% of patents with JRA and is likely the equivalent of adult rheumatoid arthritis (RA). Like RA in adults, it is frequently an aggressive, destructive and erosive joint disease with joint destruction occurring within 1 year of onset. It can have a poor prognosis with high risk of permanent joint disability and compromised functioning. Early and aggressive therapy is necessary to prevent poor outcomes. It is characterized by extra-articular manifestations such as rheumatoid nodules (sub-cutaneous nodules often found over pressure points such as the elbows, heels, knuckles and extensor surfaces of the finger, and the first metatarsophalangeal joints). Rheumatoid vasculitis resulting in ulcerative lesions may be seen. Felty syndrome (splenomegaly with leukopenia) or Sjogren syndrome (parotitis, dry eyes and mouth) are occasionally noted, but more often in adult disease.

Systemic-onset JRA, also sometimes known as Still's disease, is characterized by high, intermittent fevers and other organ system involvement. It affects about 10% of children with JRA, occurring equally in males and females. It often begins before 5 years of age, but can occur throughout childhood into adult life. Fevers of 39.4 degrees (103 F) or higher occur once or twice a day with interim normal or even subnormal temperatures. Fevers tend to occur in the evening, sometimes also in the mornings. Fevers may last from weeks to months. Most patients develop a characteristic, transient rash often described as salmon pink, or red and maculopapular. The rash can occur anywhere on the body and often accompanies the fever. It may occasionally be pruritic. Some patients will also develop lymphadenopathy and hepatosplenomegaly. Pleuritis and pericarditis may occur in up to 50% of patients, for which symptoms may include chest pain and difficulty breathing, although many may be relatively asymptomatic. Rarely, myocarditis may occur. Abdominal pain may occur. Laboratory findings often include an elevated peripheral white blood cell count, sometimes with a left shift, anemia and elevated platelet counts. Mild transaminase elevations or hyperbilirubinemia may be noted. Occasionally severe anemia or disseminated intravascular coagulation and severe hepatic dysfunction may occur. Iridocyclitis is usually absent. Recurrent systemic episodes occur in up to 50% of these children. Children often complain of myalgias and arthralgias. Arthritis may not develop until sometime into the course of the systemic manifestations. These children are often first seen for evaluation of fever of unknown origin and go through the process of eliminating other causes of fever from the differential. Many of these children will develop persistent arthritis within the first few months of onset, although arthritis developing years after the initial febrile episode have been reported. Arthritis is variable and may be polyarticular affecting both small and large joints. Chronic polyarthritis may become the primary problem.

Juvenile psoriatic arthritis affects males and females equally. These children are usually Caucasian. Arthritis often presents asymmetric and oligoarticular with small and large joint involvement. The toes are often involved. Dactylitis is common. Isolated DIP involvement or spondylitis may occur. Other associations include chronic uveitis and nail pitting. Psoriasis or a family history of psoriasis are needed for the diagnosis. ANA may be positive and HLA-B27 is present in about a third of these children. RF is negative.

The diagnosis of JRA depends upon a comprehensive history and physical examination demonstrating the presence of chronic arthritis for at least 6 weeks and exclusion of other conditions. There is no "diagnostic test" for JRA. Laboratory studies may reflect changes consistent with inflammation, but are not diagnostic. Some children have normal labs despite active arthritis. A positive rheumatoid factor in the presence of chronic arthritis and a pattern of disease helps to make a diagnosis in the small percentage of children who have seropositive disease. ANAs are strongly associated with early childhood-onset pauciarticular JRA and chronic iridocyclitis. HLA B27 is strongly associated with spondyloarthropathies, but can also be found in a number of healthy individuals. It is useful if a child presents with history and clinical findings consistent with JRA or spondyloarthropathy, since this may help in classification. X-rays, other imaging tests, joint synovial fluid aspiration and synovial biopsy may be helpful, especially in excluding other conditions. X-rays help detect joint changes, including atlantoaxial subluxation in children with cervical spine involvement. Joint aspiration and biopsy are particularly helpful in monoarticular arthritis where the differential is much broader than for polyarticular arthritis.

The list of differential diagnoses causing arthritis or arthropathy is large. Some of these are as follows. Infection related arthritis must be considered in the differential of JRA, including septic arthritis, viral arthritis, toxic synovitis, Lyme disease, reactive arthritis, and osteomyelitis. In Hawaii, acute rheumatic fever (ARF) must be included in the differential particularly in patients of Polynesian descent,

who seem to have a predisposition to developing ARF. Malignancy such as leukemia, neuroblastoma, lymphoma, Hodgkin disease, rhabdomyosarcoma and bone tumors may cause frank arthritis or musculoskeletal complaints that mimic arthritis. Trauma must also be considered. Other autoimmune diseases such as systemic lupus erythematosus and dermatomyositis can present with joint pain and/or arthritis, but are often associated with other systemic symptoms. Other vasculitides such as Henoch-Schonlein purpura and Kawasaki disease usually have other extra-articular manifestations in addition to arthropathy.

The differential diagnosis of joint pain may also include growing pains, fibromyalgia, psychogenic pain, avascular necrosis syndromes, osteochondroses (Osgood-Schlatter), enthesitis, patellofemoral or chondromalacia patella syndrome, discitis, and inherited or congenital syndromes. Hypermobility due to either benign hypermobility syndrome, Ehlers-Danlos syndrome or other connective tissue defects such as Marfan syndrome can also cause joint pain and sometimes swelling.

The goals of therapy are to control pain and inflammation; to prevent joint damage; to preserve range of motion and muscle strength; strive for normal function, growth, nutrition, physical and psychosocial development; and to control systemic manifestations. Treatment depends upon many considerations including a child's individual clinical manifestations, overall prognosis, the child and family's social situation, the child's functionality and extent of joint deformity. A multi-disciplinary team approach is essential in optimizing results. Physical therapy and occupational therapy are important for some patients. Orthopedic surgeons may also help in management. Patient and family understanding and participation in management are important. Education of the patient and family is vital and should include the disease, findings, prognosis, outcomes, medications, monitoring, and ancillary therapies. Patients and families need to be supported. Children should be encouraged toward normal play, except for those activities which may damage inflamed joints. Bicycle riding and swimming are usually good activities to avoid too much stress on involved joints.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are important initial agents in the treatment of JRA. In the United States these include naproxen and ibuprofen. Tolmetin is approved for use in children, but is used less frequently. A number of other have been used, but may not be approved for use with JRA in children. Salicylates can also be very effective; however concerns about salicylate toxicity and the association with Reye syndrome have decreased its usage in the United States. Cox-2 specific inhibitors are being evaluated for use in children. It may be necessary to try two or more NSAIDs sequentially as some patients may respond better to one agent versus another. There is no way to predict which patient will respond better to which agent, although it may be useful to try different chemical classes of NSAIDs. In addition to the arthritis, NSAIDs may also help the fever and some of the other manifestations of systemic-onset JRA. They may also have some effect on the iridocyclitis of JRA. NSAIDs can be associated with gastrointestinal side effects, even gastritis or ulcer disease. Renal and hepatic toxicity can occur. A child who is dehydrated or has renal disease is at increased risk for renal toxicity. Headaches or behavior changes have been noted. Pseudoporphyria with photosensitivity has been reported, particularly with naproxen. NSAIDs can also interfere with platelet function and cause prolonged bleeding.

Controlled studies in small numbers of patients have shown that hydroxychloroquine, oral gold salts, and D-penicillamine are not more effective than placebo (6). However, hydroxychloroquine is sometimes used as an adjunct for the treatment of JRA in older children. Ophthalmological exams every 6 months are necessary to monitor patients on hydroxychloroquine since retinopathy can occur. IM gold is used less frequently since the introduction of methotrexate, perhaps in part due to the requirement of weekly injections, the need for close monitoring, and the potential for serious side effects.

Methotrexate is an effective agent in children with severe JRA and is frequently used to treat children who have failed to respond to NSAIDs. Its once a week dosing (parenteral or oral) may help with compliance. Side effects can include bone marrow suppression, gastrointestinal symptoms, alopecia, dermatitis, oral ulcers, headache, acute interstitial pneumonitis, and pulmonary fibrosis. Hepatic fibrosis or cirrhosis is a rare finding in children.

Sulfasalazine may be effective in treatment of JRA, although drug toxicity may be a problem. Side effects include gastrointestinal irritation, dermatitis, oral ulcerations, bone marrow suppression and hepatic toxicity. Sensitivity to salicylates or sulfa, impaired hepatic or renal function, porphyria or glucose-6-phosphate dehydrogenase deficiency are contraindications to its use.

Glucocorticoids may be useful in the short-term treatment of severe systemic disease, severe JRA refractory to other therapies, and iridocyclitis. It is usually used in conjunction with other anti-inflammatory or anti-rheumatic medications. It is desirable to avoid prolonged use because of complications such as growth retardation, osteopenia/osteoporosis, infection, fractures and cataracts. Intravenous pulse dosing of corticosteroids may be helpful in some patients with more severe disease, such as systemic onset arthritis. Intra-articular glucocorticoids may be a therapeutic option in JRA, particularly when activity persists in a few joints despite treatment. Simultaneous injection of multiple joints may also be useful in certain cases.

New biologic agents targeted against TNF-alpha and IL-1 have been approved for use in adult RA and are being studied in children. TNF-alpha antagonists have been studied for use in older children with certain types of JRA.

Immunosuppressive and cytotoxic agents have been used in life-threatening disease or severe progressive arthritis. IV gamma globulin has been used with mixed results and its role in the treatment of JRA is unclear. Autologous stem cell transplantation is also being evaluated in a small number of children with severe disease.

Prognosis varies with the onset type or subtype and clinical course. However, studies indicate that many children with JRA are without serious disability and are able to work and function normally. Amyloidosis is a cause of mortality in some parts of the world, but is very rare in the United States. Even systemic-onset JRA is rarely fatal with our current therapies. The highest risk of morbidity appears to be children with systemic-onset disease and seropositive disease. Iridocyclitis can cause serious disability. Some children who develop spondyloarthropathy may have a more severe course, but their prognosis is fairly good.

Questions

1. Which of the following tests has a high positive predictive value for JRA
    a. erythrocyte sedimentation rate
    b. C-reactive protein
    c. HLA-B27
    d. antinuclear antibody
    e. white blood count

2. True/False: JRA is largely a clinical diagnosis.

3. True/False: All patients with suspected JRA should be referred to an ophthalmologist for a thorough eye examination.

4. Name three types of JRA and how are they different.

5. List some pharmacologic treatments for JRA that have been used or are being studied.

6. Non-steroidal anti-inflammatory drugs (NSAIDs) inhibit inflammation, reduce fever and reduce pain. Theoretically, how does the action of NSAIDs in treating JRA differ from the action of NSAIDs treating an ankle sprain?

Answers to questions

1. None of these answers are correct. None of these tests have a high positive predictive value for JRA.
2. True.
3. True. Iridocyclitis may be difficult to diagnose by a non-ophthalmologist.
4. Polyarticular, pauci-articular, systemic JRA. Refer to the chapter for how they are different.
5. NSAIDs, Cox-2 inhibitors, hydroxychloroquine, oral gold, D-penicillamine, methotrexate, sulfasalazine, glucocorticoids, TNF-alpha antagonists, IV gammaglobulin.
6. In JRA, NSAIDs inhibit an inflammatory reaction which is pathological and destructive. The inflammation which occurs in an ankle sprain is largely a repair process. The benefit of using NSAIDs to inhibit this type of inflammation is less clear.

Chapter XVI.3. Vasculitis
Donald A. Person, MD

This is a five year old boy who presents to the Emergency Department with acute right ankle arthritis. His ankle is red, hot, tender, and obviously swollen. His mother states that he refuses to bear weight on that leg. She further notes that he complained of left knee pain the previous day and that he has not been himself since an upper respiratory infection a week previously. He is anorexic and has lost 2-3 pounds over the past week, thought to be due to recurrent, crampy abdominal pain.

Past medical history and family history are noncontributory.

Exam: VS T 39, HR 160, RR 24, BP 130/90. He is ill-appearing, irritable, and febrile. HEENT exam is positive for mild pharyngitis. His neck is supple. His chest shows some pre-sternal edema with clear lungs and a gallop rhythm. Abdomen: His liver is tender to deep palpitation and percussion. Borborygmus is auscultated. Genitalia: Circumcised male with bilaterally descended testes. There are extensive ecchymoses on his scrotum with swollen, weeping red involvement of the corona of the glans penis. He may have a borderline effusion of his left knee and 2+ swelling, erythema, tenderness, pain-on-motion and limitation-of-motion of the right ankle. His skin exam is positive for slightly raised petechial rash on his legs, most prominent on his ankles, posterior thighs and buttocks. Some lesions have coalesced into ecchymotic purpura.

Laboratory: CBC WBC 36,600, Hgb 8.2, Hct 26, platelet count 750,000. UA: cloudy, amber; sp gr 1.029, blood 3+, protein 2+, rbc casts 2-3 per hpf, and granular casts 1-2 per hpf. Erythrocyte sedimentation rate, 90 mm/hr. ANA, negative, RF, negative, ASO 250 Todd units, IgG 1280, IgM 280, IgA 600 mg/dl. Blood and urine cultures were negative. Stool guaiac 2+. Uric acid 6.5mg/dl, BUN 30mg/dl, Cr 1.3mg/dl, SGOT 90, SGPT 110. A skin biopsy demonstrates leukocytoclastic vasculitis on light microscopy and IgA staining of the vascular endothelium on fluorescent microscopy.

This patient has perhaps the most common vasculitis of childhood, namely Henoch-Schonlein purpura (HSP, also called anaphylactoid purpura or rheumatoid purpura).

The vasculitides of childhood are a complex and poorly understood group of inflammatory conditions whose etiologies appear to be on an immune basis. Several classification schema have been proposed based on: 1) vessel size, 2) presumed immunopathophysiology, or 3) organ involvement. The more common vasculitides are listed below:

I. Small and Medium Vessel Vasculitis
   A. Immune Complex Mediated
      1. Henoch-Schonlein Purpura
      2. Hypersensitivity vasculitis
      3. Polyarteritis nodosa (PAN)
      4. Urticarial vasculitis
      5. Cryoglobulinemia
      6. Connective tissue diseases (SLE, JRA, dermatomyositis, scleroderma, Behcet disease)
   B. Antineutrophil Cytoplasmic Antibody (ANCA) Associated Disorders:
      1. Wegener's granulomatosis*
      2. Microscopic polyarteritis
      3. Churg-Strauss syndrome*
      4. Drug-induced vasculitis
   C. Miscellaneous
      1. Erythema elevatum diutinum
      2. Paraneoplastic*
      3. Infection
      4. Inflammatory bowel disease
II. Large vessel vasculitis
   A. Temporal arteritis*
   B. Takayasu arteritis

*rare in childhood

Henoch-Schonlein purpura (HSP) is characterized by a tetrad including: palpable purpura, arthritis, abdominal pain and glomerulonephritis. The rash of HSP has been described as palpable purpura. Certainly petechiae are very common early and often tend to coalesce. Target lesions, ecchymosis, lymphangitic streaks and purple or bloody suffusions are sometimes seen. The distribution of the rash is typically from the waist down. Occasionally the rash involves the upper extremities and I have seen the rare child with a generalized rash of the entire body to include involvement of palms, soles, and even the scalp. Histopathologically, leukocytoclastic vasculitis is observed and immunopathologically, IgA is deposited in involved vessel walls and the renal glomerulus. In spite of there being two subtypes of IgA (i.e., IgA1, IgA2) only IgA1 is involved in HSP. Arthritis is often extremely acute and may be quite inflammatory. Large joints of the lower extremities are most commonly involved, especially ankles and knees. The arthritis is much like that of acute rheumatic fever, often very acute, sometimes migratory and often, exceedingly responsive to nonsteroidal anti-inflammatory drugs (NSAIDs). Hypertension usually responds to diuretic therapy and judicious fluid management. Renal involvement is relatively mild to moderate and is of the nephritic type. Occasionally, a nephrotic syndrome may occur instead. The gastrointestinal tract is commonly affected and most often, crampy abdominal pain is the primary manifestation. Diffuse bleeding from the GI tract is treated medically. Rarely intussusception complicates the picture and obstruction or perforation may necessitate emergency surgery. Testicular vasculitis maybe confused with testicular torsion. Corticosteroids must be reserved for serious complications of the disease and should not be instituted for treatment of the rash or arthritis. Mild recurrent abdominal pain likewise is best managed conservatively.

Polyarteritis nodosa (PAN) was the first described vasculitis and it is a prime example of medium vessel vasculitis. Although occasionally seen in children, it is distinctly far more common in adults. Infantile polyarteritis nodosa (IPAN) is a rare and often lethal inflammatory disease of small and medium-sized arteries. Clinically, IPAN is often considered part of the spectrum of Kawasaki Disease

(KD), in spite of the fact that IPAN was described nearly 130 years ago. Specifically, IPAN, with aneurysmal involvement of major coronary arteries and fatal KD are clinically and pathologically indistinguishable. Indeed, the primary distinction between KD and IPAN is that the diagnosis of KD is based entirely on clinical criteria while the diagnosis of IPAN is based on histologic findings. Additionally, a major distinction between polyarteritis and KD is the profound difference in prognosis; much worse for IPAN.

Microscopic polyarteritis is a necrotizing vasculitis, which affects small vessels (capillaries, venules and arterioles) in the kidneys and lungs. It is commonly associated with the presence of circulating antineutrophil cytoplasmic antibody (ANCA). Clinically, necrotizing glomerulonephritis occurs in the majority of patients. Hemoptysis and life-threatening pulmonary hemorrhage may supervene. This vasculitis is distinguishable from Wegener's granulomatosis in that respiratory tract symptoms are less and granulomatous inflammation is not present in microscopic polyarteritis.

Hypersensitivity vasculitis: Cutaneous involvement includes palpable purpura, papules, urticaria, erythema multiforme vesicles, pustules, ulcers and necrosis. Typically the rash involves dependent regions and occurs in crops. The patient is usually asymptomatic, but occasionally complains of burning/tingling. With regard to treatment, one must: 1) exclude systemic involvement, and 2) identify and remove offending allergens/agents, most often medications.

Urticarial vasculitis is an entity with three subtypes which have been described: normocomplementemic; hypocomplementemic, and the hypocomplementemic urticarial vasculitis syndrome (HUVS). The latter disease resembles systemic lupus erythematosus (SLE). The skin involvement is by definition, urticarial. Those patients with the lupus-like syndrome may require corticosteroid treatment and those with normal complement levels are usually self-limited.

Cryoglobulins are antibodies that precipitate in the cold and resolubalize on warming. Cryoglobulinemic vasculitis is associated with autoimmune conditions in childhood. Cryoglobulins may contain IgA, IgG or IgM, some have rheumatoid factor activity and they have been classified into types I, II and III. Types II and III may be associated with vasculitic syndromes. Immune complexes of mixed cryoglobulins, deposit in vessel walls, activate complement and produce recurrent palpable purpura with cutaneous ulceration. Hepatis C virus infections account for the majority of cases.

Vasculitis complicates several of the connective tissue diseases of childhood. These would include systemic lupus erythematosus juvenile rheumatoid arthritis, dermatomyositis, scleroderma, and Behcet disease. Clinically the vasculitic manifestations may be as minimal as a purpuric skin rash in SLE to telangiectasis of the nail beds in dermatomyositis to necrosis and gangrene of one or more digits to life threatening central nervous system vasculitis.

Wegener's granulomatosis or lethal midline granuloma is a rare vasculitis characterized by a triad of necrotizing vasculitis of the upper respiratory tract, the lower respiratory tract and focal segmental glomerulonephritis. Patients present with fever, malaise, weight loss, arthralgias, myalgias, rhinitis, sinusitis, nasal and oral ulceration. Pulmonary symptoms include dyspnea, chest pain, bloody sputum, and hemoptysis. A majority of patients develop antineutrophil cytoplasmic antibodies (ANCA) have been recognized since 1985 and are classified as cytoplasmic (c) or perinuclear (p) depending on the fluorescence location. ANCAs may have some diagnostic and prognostic significance. A tissue diagnosis is required to differentiate this condition from another rare vasculitis, lymphomatoid granulomatosis, perhaps more prevalent in children than Wegener's.

Churg-Strauss syndrome was initially reported under the descriptive title of allergic granulomatosis and angiitis. Churg-Strauss syndrome is virtually non-existent in children.

Takayasu arteritis is the prototype vasculitis involving large vessels. Takayasu arteritis (also known as pulseless disease of Japan) involves the aorta and its branches. It is exceedingly uncommon in children; however it is seen in teenagers from Micronesia and should always be considered in an adolescent girl with severe hypertension and a peripheral or abdominal bruit. Non-specific symptoms such as malaise and arteralgia (pain over blood vessels) are seen early on as the disease progresses. The involved vessels progressively narrow producing inequality in pulses, claudication and ischemia. The diagnosis should be suspected in young women with a systemic inflammatory illness, altered arterial pulses, or bruits. The diagnosis is confirmed by angiography and in our recent experience, treatment is often accomplished by interventional radiology/angiography procedures such as angioplasty.

The terms "purpura", "petechiae", and "ecchymosis" are frequently used in the clinical descriptions of vasculitic and other conditions. Note that in HSP, the term purpura is preferred over ecchymosis although the dictionary definition of these terms are the same or almost the same. The implied difference is that purpura have a sharply demarcated border and imply that vasculitis is the etiology, while ecchymosis has a diffuse border which implies that trauma or a hemorrhagic diathesis is the etiology. In HSP, the lesions are sharply demarcated (i.e., a vasculitis) which clinically appears as petechia (smaller lesions) and purpura (larger lesions). Compare this to idiopathic thrombocytopenic purpura (ITP), in which these lesions can be sharply demarcated resembling petechia and purpura, but ultimately, they develop frank bruising (i.e., ecchymosis). HSP is a vasculitis, while ITP is not.

Questions

1. Which immunoglobulin is prominently involved with the lesions of Henoch-Schonlein purpura?
2. What is the tetrad of Henoch-Schonlein purpura?
3. What histopathological term is used to describe the light microscopic findings in the skin biopsy of HSP?
4. Infantile polyarteritis nodosa (IPAN) is considered by some to be the severe end of the spectrum of which other vasculitis of childhood?
5. Name three connective tissue diseases of childhood, which are sometimes complicated by vasculitis.

Answers to questions

1. IgA.
2. purpura, arthritis, abdominal pain and glomerulonephritis.
3. leukocytoclastic vasculitis.
4. Kawasaki disease.
5. JRA, SLE, dermatomyositis, scleroderma and Behcet disease.

Chapter XVII.1. Neonatal Conjunctivitis and Eye Prophylaxis
Sheree Kuo, MD

This is a 4 week old male infant born to a 26 year old G2P2 O+, rubella immune, group B strep negative, HBsAg negative, VDRL negative, GC and Chlamydia negative married female at 40 weeks gestation via spontaneous vaginal delivery with Apgar scores of 8 and 9 at 1 and 5 minutes. Pregnancy, delivery and postpartum hospital course were uncomplicated. He presents with his mother to your office with a two day history of bilateral eye drainage. He had been in good health until two days ago when he developed yellow drainage and mild periorbital swelling. Review of systems is negative except for the recent development of a cough that he "probably caught from his older brother".

Exam: VS T37.5, P 120, RR 60, BP 60/40, oxygen saturation 94% in room air, weight 4.0 kg (50%ile) He is a well developed, well nourished, non-toxic male infant with mild tachypnea and staccato cough, but in no acute distress. His upper and lower eyelids are edematous. There is mild conjunctival injection with moderate amounts of mucopurulent drainage bilaterally. Pseudomembranes are seen with eversion of the upper eyelids. Coarse breath sounds are appreciated bilaterally with occasional rales and fine expiratory wheezes. The remainder of his exam is unremarkable.

You swab the conjunctiva for gram stain, culture and chlamydia direct fluorescence antibody staining. Complete blood count is remarkable for eosinophilia. Chest radiograph reveals bilateral patchy infiltrates with hyperinflation. After receiving positive chlamydia DFA results, you inform the mother of the diagnosis. Initially shocked, she admits that six months ago she and her husband had separated briefly, but are now back together.

Ophthalmia neonatorum is the most common ocular disease in the newborn, occurring in 2-12% of neonates (includes chemical conjunctivitis). The major causative agents of neonatal conjunctivitis are chemical, chlamydial and bacterial. Viral ocular infection, usually by herpes simplex virus, occurs infrequently. The mode of infectious transmission is believed to be acquisition during passage through a colonized or infected birth canal (1,2). While nearly every bacterial species has been implicated, ocular infection with Neisseria gonorrhoeae is felt to be one of the most serious because of its potential to damage vision and cause blindness (1,3).

Gonococcal ophthalmia prompted the widespread use of silver nitrate for prophylaxis in the neonate since the 1880's. Consequently, Chlamydia trachomatis is now the most common infectious agent causing neonatal conjunctivitis in approximately 0.4%-2.8% births in this country (4,5). Recognizing the irritant effects of silver nitrate (frequently causes chemical conjunctivitis), 0.5% erythromycin ointment, 1% tetracycline ointment and 2.5% povidone-iodine solution have all been suggested and utilized as less chemically irritating alternatives in preventing neonatal gonococcal conjunctivitis. However, none have been shown to consistently prevent chlamydial conjunctivitis or nasopharyngeal colonization (1-4,6-9).

The presentation of ophthalmia neonatorum varies with the causative agent. Inflammation due to chemical irritation (usually silver nitrate drops) is first appreciated 6-12 hours after birth with spontaneous resolution by 24-48 hours. In contrast, the incubation period for N. gonorrhoeae is 2-5 days (sometimes longer) with the appearance of symptoms seen from birth to beyond 5 days of age. Beginning with a mild inflammation and serosanguineous drainage, gonococcal ophthalmia soon results in thick, profuse purulent discharge and tense eyelid edema with marked chemosis (swelling of the conjunctiva) (2,10).

Chlamydial conjunctivitis in the neonate can present from 3 days to beyond 6 weeks postnatal age, but most commonly occurs during the 2nd week of life. Infants present with conjunctival inflammation, mucopurulent discharge (that may be profuse), eyelid edema and pseudomembranes in the palpebral conjunctiva (5,10).

A distinct pneumonia occurs in 10-20% of infants exposed to C. trachomatis (2,5). Patients typically present with a history of afebrile illness for several weeks. The infant usually appears well with tachypnea and prominent "staccato" cough. Auscultation of the chest often reveals rales and wheezing. Fifty percent of these patients also have concomitant conjunctivitis. Chest radiograph reveals bilateral, diffuse, patchy infiltrates and hyperinflation. CBC commonly reveals moderate eosinophilia (5).

The list of causative agents of ophthalmia neonatorum includes, but is not limited to, chemical irritants, Neisseria gonorrhoeae, Chlamydia trachomatis, Staphylococcus aureus, group A or B streptococcus, S. pneumonia, Haemophilus influenzae, Pseudomonas aeruginosa and Herpes simplex virus (1,2).

Shortly after birth, ophthalmic prophylaxis for gonorrhea should be administered to all infants, including those delivered by cesarean section since ascending infection can occur. Two drops of a 1% silver nitrate solution or a 1 cm ribbon of antibiotic ointment (0.5% erythromycin or 1 % tetracycline) are applied to each lower conjunctival sac. The eyes should not be flushed or irrigated (8). Currently, there is no antibiotic agent effective for use as prophylaxis for Chlamydia ophthalmia neonatorum (1-4,6-9). Chemical conjunctivitis is self-limiting and requires no treatment.

Diagnosis of ocular infection with N. gonorrhoeae can be made following identification of gram negative oxidase positive diplococci on gram stain or culture of conjunctival swabbings or eye drainage. Cultures of blood, CSF, or other sites of infection should be obtained in infants with gonococcal ocular infection to rule out disseminated infection. Tests for concomitant C. trachomatis, T. pallidum, and HIV infection should also be performed. For nondisseminated N. gonorrhoeae ophthalmia neonatorum, infants should receive ceftriaxone (25-50 mg/kg IV or IM) once. Alternatively, 100 mg/kg of cefotaxime (IV or IM) can also be given. Therapy is extended to 7 days for septicemia and 10-14 days for meningitis. Frequent saline irrigation of the eyes should also be performed until the discharge is eliminated. Infants born to mothers with untreated gonococcal infection should receive a one-time dose of IM or IV ceftriaxone or cefotaxime (9).

Chlamydia can be detected by PCR, ligase chain reaction (LCR), DNA probe, direct fluorescent antibody (DFA) tests, enzyme immunoassays (EIAs), or by isolating the organism in tissue culture. Diagnosis of chlamydial infection should prompt testing for other STDs in the infant as well as examination of the mother and her sexual partners. Infants who develop chlamydial conjunctivitis with or without pneumonia should be treated with oral erythromycin (50mg/kg/day in 4 divided doses) for 14 days. Treatment with topical antibiotics will not eliminate nasopharyngeal colonization and conjunctivitis may recur (5). In cases where the infant is less than 6 weeks of age, parents should be counseled regarding a reported association between oral erythromycin and infantile hypertrophic pyloric stenosis. Retesting for C. trachomatis is not indicated once treatment has been completed unless symptoms persist (3).

Without prompt treatment, N. gonorrhoeae ocular infection may spread to the deeper layers of the conjunctiva and cornea (2,10). Corneal ulceration and perforation, iridocyclitis, anterior synechiae, and panophthalmitis from untreated gonococcal ophthalmitis may result in permanent vision loss and blindness (1,4,6). Disseminated gonococcal disease can result in scalp abscess, bacteremia, arthritis, meningitis or endocarditis (9).

Left untreated, chlamydia conjunctivitis will subside within 2-3 weeks, but chronic infection is common. Chlamydia pneumonia, not conjunctivitis, is the most serious consequence of neonatal C. trachomatis infection (4). The pneumonia is usually mild and deaths attributed to chlamydial pneumonia have not been reported (5). However, the disease can lead to chronic cough and long term pulmonary impairment (4,5).

Questions

1. Which details of this patient's presentation (in the case) distinguish his illness from neonatal N. gonorrhoeae infection?
2. Besides the infant presented in the case vignette, which other family members should be treated for this condition?
3. What etiologies should be considered when a neonate presents with eye drainage?
4. Of 1% silver nitrate solution, 0.5% erythromycin ointment, 1% tetracycline ointment and 2.5% povidone-iodine solution, which is/are considered effective for prophylaxis of ocular chlamydial infection?
5. What is the treatment for C. trachomatis ophthalmia? For N. gonorrhoeae ophthalmia?
6. What are the long-term complications of N. gonorrhoeae ophthalmia neonatorum? Of neonatal C. trachomatis infection?
7. Infants under 6 weeks of age are at increased risk for the development of what disease following treatment with erythromycin?

Answers to questions

1. Late presentation, presence of pseudomembranes and accompanying pneumonia.
2. The patient's mother and her sexual contacts should seek medical attention and treatment for urogenital chlamydia and other sexually transmitted diseases.
3. Chemical irritants, Neisseria gonorrhoeae, and Chlamydia trachomatis are the most common causes. However, Staphylococcus aureus, group A or B streptococcus, S. pneumonia, Haemophilus influenzae, Pseudomonas aeruginosa and Herpes simplex virus should also be remembered as potential pathogens.
4. None.
5. Infants who develop chlamydial conjunctivitis with or without pneumonia should be treated with oral erythromycin (50mg/kg/day in 4 divided doses) for 14 days. For nondisseminated N. gonorrhoeae ophthalmia neonatorum, infants should receive ceftriaxone (25-50 mg/kg IV or IM) once. Alternatively, 100 mg/kg of cefotaxime (IV or IM) can also be given.
6. Without prompt treatment, N. gonorrhoeae ocular infection may result in corneal ulceration and perforation, iridocyclitis, anterior synechiae, and panophthalmitis leading to permanent vision loss and blindness. Left untreated, chlamydia conjunctivitis will subside within 2-3 weeks, but chronic infection is common. Chlamydia pneumonia is the most serious consequence of neonatal C. trachomatis infection. The pneumonia does not appear to be life threatening; however, the disease can lead to chronic cough and long-term pulmonary impairment
7. Infantile hypertrophic pyloric stenosis.

Chapter XVII.2. Primary Care Eye Examination
Vince K. Yamashiroya, MD

This is a 6 month old baby girl who comes to your office for a well child examination. She has had no problems in the past with her eyes and according to her parents, she tracks well and reaches for objects. Her parents deny any crossing of the eyes when she looks at objects from a distance; however, her mother mentions that she had a lazy eye when she was a child and needed to be operated on.

Exam: Vital signs are normal for age. Her red reflex and corneal light reflex test are normal. Cover test is negative for strabismus. Her extraocular movements appear intact and she is able to follow objects 180 degrees.

You conclude that her eye examination is normal and reassure the mother. You schedule her next appointment when she is 9 months old or earlier if her mother notices a problem.

The examination of the eye is an essential part of an examination since disease or pathology of the eye can result in vision loss. Although there are diseases that are easily noticed, such as conjunctivitis, there are other conditions that are much more subtle. These conditions include leukokoria of retinoblastoma and strabismus that can lead to amblyopia. Without a careful examination of the eyes, these problems can be missed and result in blindness. There are times that patients will come to us because of pain, itchiness, blurriness, redness, or discharge of the eye. As primary care physicians, we should be comfortable with the eye examination to be able to correctly diagnose, treat, or refer our patients for specialty care by an ophthalmologist. This chapter will focus on screening of the eye in the well child since some serious conditions can only be detected early enough through screening.

In order to know how to examine the eye, a basic knowledge of the anatomy of the eye is important. It would be helpful to refer to a diagram of the eye. The eye is made up of three coats. The outer part is the sclera, which is a white shell of the eye, and the cornea. Next comes the uvea, which is made up of the choroid, the ciliary body, and iris. The choroid is a vascular layer between the retina and sclera. The ciliary body, which produces aqueous humor, is on the sides of the lens that focusses the lens. Immediately anterior to the lens is the iris, which is a colored diaphragm that contracts or dilates and regulates the amount of light entering through the lens. And the innermost part is the retina, which contains rods and cones. A part of the retina is the macula, which is minimally vascular and is responsible for the most acute vision. A pit in the middle of the macula is the fovea, which corresponds to the central fixation of vision. Medial to the macula is the optic nerve, which transmits signals from the retina to the brain. There are two chambers, the anterior and posterior chamber, which are divided by the lens. The lens is a media that focusses light. The anterior chamber is between the cornea and the lens, and is filled with the aqueous humor, which is a clear fluid. The posterior chamber contains the vitreous humor, which is a clear jelly filling. The conjunctiva is a mucus membrane that covers the anterior portion of the sclera (bulbar conjunctiva) and the inner part of the eyelids (palpebral conjunctiva).

There are six extraocular muscles that move the eye. They are the superior, inferior, medial, and lateral rectus muscles, and the superior and inferior oblique muscles which are innervated by cranial nerves 3, 4, and 6 (1,2).

The examination of the well child is primarily dependent on his or her age since infants and young children are less cooperative with the examination compared to older children. Also, screening for specific problems is essential at an early age to prevent vision problems later in life.

From birth to 6 months of age, screening tests that can be done are the red reflex, corneal light reflex, and external examination. An infant's eyes are examined from a distance with an ophthalmoscope to look for a red reflex. If the pupillary light reflex (also known as the red reflex) is totally absent in one or both eyes, then corneal opacity, cataracts, retinal detachment, or a large hemorrhage should be suspected. If a pupillary light reflex is present, but it is white (i.e., not red), this is called leukokoria and retinoblastoma should be suspected. Retinoblastoma is often detected by parents when viewing flash photographs of their infant when a white eye reflex is noted while everyone else in the photo has a "red eye". Ideally, the physician should notice this on routine screening before this happens.

Many times, an infant's eyes are closed during the first several days of life. One trick to having them open their eyes is to gently swing them from a vertical to semi-upright position. Turning off the lights would also help dilate the eyes to make the red reflex easier to see.

Another is the corneal light reflex test in which the eyes are viewed with an ophthalmoscope to see if the corneas are symmetrical. The reflection of the light off the cornea should be symmetric. Asymmetry could signify strabismus and warrants a referral to an ophthalmologist.

In doing the external examination, the orbits and globes are examined for symmetry in terms of shape, position, and movement. The eyelids are likewise noted for symmetry and movement. Asymmetry may signify proptosis, cranial nerve palsy, or lid masses (3). Note if the pupils are round and symmetrical. Irregularity could signify an iris coloboma, which is a "keyhole" shaped defect, caused by an embryological defect of closure of the eye. In a child with choanal atresia and ear anomalies, a coloboma (eye defect) can be part of CHARGE syndrome. Corneal size should be assessed since large corneas, together with excessive tearing and photophobia is a sign of infantile glaucoma.

From birth to 3 months of age, healthy infants can appear to have disconjugate or uneven gaze. However, constant jiggling of the eyes, or nystagmus, is abnormal at any age. Scleral or retinal hemorrhages in neonates can occur as part of birth trauma, and will resolve on its own. The color of the sclera should also be noted, since a blue sclera, in addition to multiple bone fractures can signify osteogenesis imperfecta. Also a yellow sclera or icterus can be seen in jaundiced babies. At times, there is mucoid discharge around the medial canthus of the eye, which can be due to nasolacrimal duct obstruction. This problem is corrected by massaging the duct, and most of the time, this will resolved by 1 year of age. However, if it continues past a year, then an ophthalmological referral should be considered for probing and dilation of the nasolacrimal duct.

Visual acuity can be assessed by having the child regard a face or track a brightly colored object. Babies seem to notice faces more than other objects, especially faces that are smiling and showing teeth. At birth, they should be able to focus on a face at about an arm's length away, which is their point of focus (4). At 1 month of age, they can follow to the midline. At 2 months of age, they can follow an object past midline, and at 5-6 months of age, they can follow to 180 degrees (5). It should also be noted that they are very far-sighted at this age.

From 6 months to 4 years of age, in addition to the methods described for the birth to 6 month old, the Cover Test can be used to assess strabismus and vision. This test is done by covering one of the eyes and seeing if the opposite (uncovered) eye shifts, or when uncovered, if the same eye refocusses (this eye shifts away when covered). The best way to do this is to have the child focus on something at a distance (such as a light), and using your thumb as the occluder while holding the head still with your hand so that it does not move.

Before doing the Cover Test, the corneal light reflex can also be done to assess for strabismus, and is less intimidating. The parents or caretakers can be questioned regarding whether they notice one eye being "crooked" when the child looks at something. A note of warning is that "crooked eyes" can be mistaken for pseudostrabismus, especially in a child with epicanthal folds. Pseudostrabismus can be differentiated from true strabismus by the aforementioned tests.

Visual acuity can be assessed by having them follow a face or object, or by testing for optokinetic nystagmus. This is done by having the child look at a slowly rotating drum or cloth with alternating black and white stripes (or colored and white stripes) and noting if the normal nystagmus with this stimulus is present. The two phases of this normal nystagmus are a slow phase when the eyes focus on the target, and a quick, jerky phase when the eyes return to the subsequent target. The drum or cloth should be about an arm's length away. Also, the red reflex should be assessed at this age. Extraocular muscles can be assessed in one of several ways. One is by spinning which is used for infants. What this entails is holding the child up and turning your body several times in one direction, then in the opposite direction, while watching the child's eyes. Another way is to have a child track an object in an imaginary rectangle around his face. Lastly, turning the head quickly will elicit eye movements through vestibular means, although the child will be angry afterwards (4).

From 4 years of age and onward, the eye exam can be performed the same as in adults. Besides looking at the pupils and assessing extraocular movements, funduscopy can be done, and can even be performed in younger children. Although the older child can be cooperative and focus on a stationary object while you view his fundus, in the younger child, funduscopy can be a frustrating experience. One method would be to stay still while viewing the eye, and have the child move his eye for you on his own. When you are about 12 inches away, note if the red reflex is equal in all four quadrants of the fundus. As you get closer, view the optic disk as it passes by. Lastly, look at the bright fovea reflection by telling the child to look at your magic light. Make sure you have the lights off to have maximum pupillary dilatation.

Visual acuity can be assessed by several means, such as having a wall mounted Snellen chart or "E" chart (4). There are also charts available that can be viewed through a desktop instrument. A more technologically advanced tool is Welch Allyn's SureSight Vision screener, which can provide objective data in 5 seconds without any cooperation from the patient; however, it costs about $4,500 in 2002 (6). Keep in mind that an acuity of 20/40 is generally accepted as normal for 3 year olds, 20/30 typical for 4 year old, and 20/20 vision attainable by most 5 to 6 year old children. Referral to an ophthalmologist is indicated if the vision is 20/50 or worse in a 5 year old child, and 20/40 or worse in a 6 year old child (3).

The eye examination is one of the most difficult, yet rewarding experiences in pediatrics. Unfortunately, the only way to become proficient, is to do as many as possible. Remember to do the least intimidating step first (which may be external observation or assessing the red reflex or corneal light reflex), and the most intimidating test last (such as the funduscopic exam). With practice and diligence, the eye examination will become easier and the rewards for discovering preventable pathology that much greater.

Questions

1. What is the differential diagnosis of an absent pupillary light reflex (red reflex)?
2. What condition causes leukocoria?
3. A parent is worried that her Asian baby has crooked eyes. How would you assess whether this is pseudostrabismus?
4. What is the distance of focus for infants?
5. At what age can an infant follow an object to the midline, past the midline, and 180 degrees?
6. How can you assess extraocular movements in the uncooperative or young child?
7. What is one way you can look at the fundus in the uncooperative child?

Answers to questions

1. Cataracts, retinal detachment, and other pathology that is obscuring the vitreous or aqueous clarity.
2. Retinoblastoma.
3. Performing a Cover Test and corneal light reflex test.
4. About an adult's arm length.
5. To the midline is 1 month, past the midline is 2 months, and 180 degrees is 5-6 months.
6. Two methods are to spin the child and turning his head, both of which use the vestibular systems.
7. By being patient, looking at the child's red reflex in all four quadrants in a stationary position from about 12 inches away, and as you move closer, viewing the optic disk as it passes by, and lastly the fovea by telling the child to look directly at your "magic light."

Chapter XVII.3. Strabismus and Amblyopia

Julie K. Nishimura, MD

A 6 month old female infant presents with crossed eyes. Her parents say her eyes have been crossed since birth, and the left eye seems to cross more than the right. She seems to see fine. She plays with toys and recognizes people across the room. She was a full term infant without perinatal complications, and has no known medical problems.

Exam: She is alert and playful. External: Her left eye is clearly crossed inward (esotropic). There is no facial hemiparesis. Vision: She tracks toys well using both eyes. With the left eye covered, she fixes and follows easily. However, she fusses when the right eye is covered and has more trouble following with this left eye (i.e., she is fussing when the right eye is covered because she can't see as well with her left eye). Motility: Full extraocular movements. There does not seem to be any retraction of the globe on adduction. No nystagmus. Pupils: Equally round and reactive to light; no afferent pupil defect. No leukocoria. Corneal reflection test (Hirschberg test): A penlight is directed toward the cornea, and the reflected image is located temporal to the center of the left pupil. Cover-uncover test: On covering the right eye, there is an outward shift of the left eye. When the eye is uncovered, the left eye shifts back inward. Alternate-cover test: On switching the cover to the left eye, there is an outward shift of the right eye. When the cover is alternated from one eye to the other, there is always an outward shift of the opposite eye.

Clinical course: A referral is made to a pediatric ophthalmologist. No structural ocular abnormalities are found, and there is no significant refractive error. The patient is diagnosed with 1) infantile esotropia and 2) amblyopia, left eye. She wears a patch 6 hours a day over the right eye for a month, and vision in her left eye improves so that she can follow toys equally well with either eye. This also means that either eye crosses spontaneously. She then has surgery to correct her strabismus. Her medial rectus muscles are recessed at age 8 months. Postoperatively, her eyes are straight (orthophoric).

Strabismus (ocular misalignment) is a common pediatric health problem, affecting approximately 5% of U.S. children. If left untreated, strabismus can lead to severe visual consequences, including poor vision and inability to use the eyes together. Strabismic amblyopia is defined as poor vision (usually in one eye, often termed "lazy eye") that results from prolonged ocular misalignment. Amblyopia can be very pronounced (sometimes able to see only hand motions in the affected eye) and is a major cause of blindness among children. Amblyopia can be prevented with timely, appropriate intervention.

There are 2 main forms of strabismus: esotropia and exotropia. Esotropia is an inward deviation of the eyes, and exotropia is an outward deviation. Less common forms include hypertropia (upward deviation) and hypotropia (downward deviation).

Infantile esotropia is the most common type of infantile strabismus. It is defined as an esotropia present by 6 months of age. Previously it was termed congenital esotropia, but many no longer use this term as it is often not noted from birth. There can be a family history of strabismus. Children with infantile esotropia are usually otherwise healthy, although a higher incidence is noted with cerebral palsy and hydrocephalus.

The deviation is usually large, with a definite "crossed-eyes" appearance. The vision can actually be equal in both eyes, but up to 40% will have associated amblyopia. It is actually a good sign if the eyes alternate crossing inward, because this often indicates that vision is approximately equal between the two eyes.

An estimate of the amount of esodeviation can be made with corneal reflection testing. The Hirschberg estimate involves shining a light onto the cornea. If an eye is deviated inward, the light reflex will be temporal to the pupil center.

The definitive method of testing for strabismus is the cover-uncover test. An occluder is placed over the fixing eye. The opposite eye is observed. If there is a deviation of the opposite eye, a tropia is present. If the opposite eye shifts outward, an esotropia is present. If the opposite eye shifts inward, an exotropia is present.

There are a few other entities in the differential diagnosis of infantile esotropia. Pseudoesotropia (pseudostrabismus) is the most common, where a wide, flat nasal bridge with prominent epicanthal folds gives a crossed appearance. Accommodative esotropia is also frequent, where the patient is far-sighted (hyperopic) and the strain to focus causes the eyes to turn inward. This usually occurs in patients older than 6 months of age and is treated with glasses. Sixth-nerve palsy should be ruled out by checking for abduction in both eyes. Sensory deprivation esotropia is caused by unilateral vision-limiting lesions, such as retinoblastoma or cataract. Nystagmus-blockage syndrome features nystagmus dampened by convergence, leading to esotropia. Rarer entities are Duane syndrome (agenesis of the sixth nerve nucleus, accompanied by globe retraction on adduction) and Mobius syndrome (palsy of sixth, seventh, and twelfth cranial nerves).

Treatment of infantile esotropia begins with addressing amblyopia, if present. The stronger eye is patched several hours each day, to develop vision in the weaker eye. Once the vision seems approximately equal, chances for success with surgery are greater. Surgical alignment is usually done with bilateral medial rectus recessions. This procedure involves detaching the medial rectus muscles from their scleral insertion sites, then suturing them to the sclera several millimeters behind the original insertion sites. This effectively weakens the muscles, diminishing their adducting effect. Surgical alignment has traditionally been recommended by two years of age, but more recent studies have supported alignment by one year of age. Earlier surgery provides better levels of stereoscopic depth perception (called stereopsis).

Children need to continue to have close follow-up after surgery, to monitor for postoperative misalignment or amblyopia. They can become overcorrected (exotropia) or have residual esotropia. They sometimes require further surgery for recurrent misalignment and other motility disorders. Alignment to near-orthophoria is the typical goal. This results in a stable alignment with an excellent appearance.

Questions

1. What is the most common form of infantile strabismus?
2. What is the upper age limit in the definition of infantile esotropia?
3. How is amblyopia most commonly treated?
4. Name 3 entities in the differential diagnosis of infantile esotropia.
5. By what age should surgery be undertaken for infantile esotropia?
6. What is the consequence of not recognizing infantile strabismus in a timely fashion?

Answers to questions

1. Infantile esotropia.
2. 6 months.
3. Patching.
4. Possible answers: pseudoesotropia, accommodative esotropia, sixth nerve palsy, sensory deprivation esotropia, nystagmus-blockage syndrome, Duane syndrome, Mobius syndrome.
5. 1 year of age.
6. The child will have a permanent reduction in visual function. This can range from reduction of stereopsis to total blindness in one eye. It is possible for stereopsis to be lost even if visual acuity is preserved (i.e., measured visual acuity is 20/20) since stereopsis is dependent on vision, plus integration and processing of the images by the brain.

Chapter XVII.4. Eye Infections and Conjunctivitis

Peggy M. Liao, MD

A 28 month old female presents to the pediatrician with a swollen right upper eyelid for one day. Her mother says that the eyelid had a small red lump 2 days prior, but the eyelid became progressively swollen. The patient has a low grade fever, but she is otherwise still playful. The pediatrician diagnoses that the patient has right upper eyelid cellulitis and prescribes oral antibiotics and warm compresses. After 2 days of antibiotics, the eyelid is still swollen and red. The patient is admitted to the hospital for intravenous antibiotics and within 48 hours, and eyelid is less swollen and the patient is discharged for a total of 14 days of systemic antibiotics.

Preseptal eyelid cellulitis (periorbital cellulitis) is an infection confined to the tissues anterior to the orbital septum. External trauma, such as cuts and insect bites, as well as internal inflammation, such as hordeolum and dacryocystitis can cause eyelid cellulitis. Symptoms include tenderness, swelling and redness of the involved eyelid. Young children may also present with fever. Signs include edema, erythema, warmth and pain of the eyelid. Visual acuity, eye motility, and pupillary reaction are normal. The conjunctiva can be injected, and there should be very little pain on eye movement.

Teenagers and adults can be treated with oral antibiotics, and followed as outpatients. Preseptal cellulitis in infants and children caused by Haemophilus influenzae type B, can spread to septicemia and meningitis, therefore all febrile children with preseptal cellulitis were hospitalized in the past and treated with IV antibiotics. However, since widespread Haemophilus influenzae type B vaccine has virtually eliminated this pathogen, cellulitis with group A strep and Staph aureus are less likely to cause septicemia, thus, they can usually be treated as outpatients with clindamycin. Cultures from conjunctiva and blood can be obtained, but the yield is not high. Conjunctival cultures do not necessarily reflect the etiology of the cellulitis and blood cultures are only positive in bacteremic or septic patients. CSF should be obtained via a lumbar puncture if meningitis is suspected. Diagnostic imaging may be necessary if the patient does not respond to treatment or a subcutaneous abscess is suspected. Antibiotic selection is based on history and examination, but staphylococcus aureus and streptococcus are the most common organisms in patients with eyelid cellulitis caused by trauma.

When the orbital structures posterior to the orbital septum are infected, it implies orbital cellulitis (as opposed to periorbital cellulitis). Signs include proptosis, restricted ocular motility (or pain with eye movement), decrease in visual acuity and sometimes, abnormal pupillary reaction. CT scan is mandatory in these patients to detect possible subperiosteal abscesses. Diagnostic imaging also helps in detecting infections extending from periorbital sites which are not uncommon. They include paranasal sinuses, dental infections and trauma with retained orbital foreign bodies. Draining of abscesses may be necessary for the patient to improve. Otolaryngology consultation should be sought if sinusitis is present to consider draining the sinuses as well.

A chalazion is a granulomatous mass results from an obstruction of the meibomian gland. Meibomian glands are oil-producing glands with openings just posterior to the eyelash line (the tarsal margin). When the openings of the glands are plugged, the sebum is released into the surrounding tissue, inciting an inflammatory response with pain, erythema and a mass. They are not considered infectious, unless eyelid cellulitis ensues. The main treatment includes warm compresses, topical and/or systemic antibiotics, topical anti-inflammatory medications and eyelid hygiene. The term "hordeolum" usually refers to the acute phase of a chalazion.

The conjunctiva is a thin layer of non-keratinized mucous membrane which covers the surface of the eyeball (bulbar conjunctiva) and inner layers of the eyelids (tarsal or palpebral conjunctiva). Conjunctivitis describes inflammation of the conjunctiva and is a nonspecific entity. It is easiest to classify conjunctivitis into infectious versus non-infectious.

Infectious conjunctivitis can be further sub-classified into etiologies, such as viral, bacterial, chlamydial (or trachoma), and others. Non-infectious conjunctivitis can include allergic, chemical, or toxic conjunctivitis.

Watery and thin mucus discharge accompanied by red and swollen eyelids are signs of viral conjunctivitis, usually caused by adenovirus. Onset can be acute, and bilateral involvement is usual, but one eye can be involved first. Preauricular adenopathy is common, along with conjunctival membranes or pseudomembranes. Patients may have URI symptoms prior to the onset of the conjunctivitis. Treatment is supportive, with cool compresses and artificial tears. Conjunctivitis may take up to 21 days to resolve. Viral conjunctivitis is very contagious, especially for the first few days. Patients should be told to wash their hands, avoid touching their eyes, sharing towel,

bedsheets or pillow cases. Similarly, other household members should wash their hands frequently and avoid touching their eyes to reduce their likelihood of acquiring the infection from the household. Children should stay away from school for at least the first 3 to 7 days.

Herpes simplex can cause conjunctivitis indistinguishable from other viral conjunctivitis, but herpetic skin vesicles along the eyelids should raise the suspicion. Topical antiviral therapy and sometimes systemic antiviral therapy are recommended.

Purulent discharge is an important sign of bacterial conjunctivitis. If the onset is hyperacute, i.e., within 12 hours, a smear should be taken from the eye to rule out gonococcal conjunctivitis. Otherwise, a routine culture should be taken and a topical broad-spectrum antibiotic, such as erythromycin ointment or sulfacetamide drops can be used for 5 to 7 days.

Chlamydial inclusion conjunctivitis is a sexually transmitted infection, typically occurring in teenagers and young adults. It is usually chronic with typical tarsal conjunctival follicles. A definitive diagnosis can be made by direct chlamydial immunofluorescent test and or chlamydial culture. Both the patient and the sexual partners must be treated with oral erythromycin or doxycycline for 3 weeks.

Trachoma can present in a similar fashion to chlamydial conjunctivitis, but this principally occurs in immigrants from underprivileged countries. Trachoma (due to chlamydia trachomatis) is the leading cause of acquired blindness in many countries, but it is rare in the U.S. Trachoma is classically acquired by workers in rug factories where the occupational risk of poor air quality (dust and rug fibers presumably) places the factory workers at risk for trachoma.

Allergic conjunctivitis is the most common non-infectious conjunctivitis. Itching, watery discharge, chronicity, red eyes and a history of allergies are typical symptoms. Some allergic conjunctivitis are seasonal, but others can be year-long. If the inciting agent can be identified, such as cat fur and animal dander, it should be eliminated. Cool compresses help decrease itchiness, and are preferable to rubbing the eyes. Over-the-counter artificial tears and vasoconstrictor drops (naphazoline/pheniramine) can be used for mild cases.

Topical mast-cell stabilizers (cromolyn, Alomide) work well as preventive measures if the patient's allergies are seasonal. Topical antihistamines have a faster onset of action. In severe cases, topical corticosteroids may be needed, but patients must be monitored for side effects associated with prolonged topical steroid use, such as cataracts, and glaucoma. Concomitant oral antihistamines are helpful if the patient has systemic allergies.

Acute allergic conjunctivitis frequently presents with impressive edema of the conjunctiva. The conjunctiva can become so edematous that it lifts off the sclera and frequently protrudes out. The pale, watery edema resembles a lychee fruit (without the skin). Topical vasoconstrictors and antihistamines are used to treat this.

When an eye is exposed to acidic or basic chemicals, copious irrigation with water or normal saline should be started as soon as possible. Litmus paper can be used to test the tears for neutrality. If the cornea has been burned with the chemical, an ophthalmology consult needs to be obtained. Otherwise, the conjunctivitis can be treated with frequent artificial tears and moisturizing eye ointments.

Occasionally, prolonged exposure to topical eye medications can cause conjunctivitis, especially the aminoglycosides, such as gentamicin and tobramycin, and certain glaucoma medications. Additionally, patients may have allergic reactions to other topical antibiotics such as sulfonamides.

Questions

1. Herpes simplex conjunctivitis:
   a. may be chronic.
   b. may be associated with skin vesicles.
   c. may recur.
   d. all of the above.

2. Common causes of periorbital cellulitis include the following:
   a. sinusitis
   b. chalazion
   c. dental infection
   d. eyelid skin laceration

3. A three-year old boy presents with an acute red lump in his right upper eyelid, the pediatrician diagnoses that it is an acute chalazion. What are the proper treatments?
   a. warm compress
   b. antibiotic eyedrops
   c. oral antibiotics
   d. topical corticosteroid

4. An 18 year old female presents with a chronic follicular conjunctivitis and a diagnosis of chlamydial conjunctivitis is made. What is the proper treatment?

5. A four month old male has congenital tear duct obstructions and has symptoms of chronic tearing and mucus. His primary care physician prescribes topical sulfacetamide drops three times a day to clear up the mucus, but after using the drops for one month, his eyelids are more erythematous than ever and the conjunctiva is more swollen and he constantly rubs his eyes. What should be done?

References

1. Friedberg MA, Rapuano CJ. Wills Eye Hospital Office and Emergency Room Diagnosis and Treatment of Eye Disease. 1990, Philadelphia: J.B. Lippincott Company.

2. Orbits, Eyelids, and Lacrimal System. Basic and Clinical Science Course, Section 9., American Academy of Ophthalmology.

Answers to questions

1. The answer is d. Herpes simplex conjunctivitis can present with all of the above.

2. The answer is all of the above. Although a skin laceration is easily diagnosed, a sinusitis needs to be confirmed with a CT scan. A chalazion is usually diagnosed by history or a fluctuant skin mass in the eyelid. A dental infection involving the upper teeth can easily spread itself into the orbit.

3. Topical corticosteroid is the only choice that is not appropriate for a primary care physician to prescribe. The rest of the choices are appropriate, although most chalazia do not require oral antibiotics.

4. Topical erythromycin for two weeks and oral erythromycin for two weeks for the patient AND oral erythromycin for two weeks for her sexual partner.

5. The baby is probably developing an allergic reaction to the long-term use of topical sulfacetamide. The eyedrops should be discontinued right away and patient can be treated with tear duct massage and another antibiotic eyedrop on an as-needed basis.

Chapter XVII.5. Corneal Abrasions
Peggy M. Liao, MD

An 8 year old boy presents to the emergency department with moderately severe left eye pain 6 hours after riding his bicycle through some low hanging leaves from a tree. He didn't notice the tree branches until a few leaves hit him in the face. He has no bleeding wounds.

Exam: VS are normal. He does not want to open his left eye because of discomfort. Some anesthetic eye drops are instilled into his left eye. He complains that this burns a lot and he begins to cry. After 10 minutes (topical anesthetic usually works within minutes), he is able to open his eye. His visual acuity was 20/20 in the right eye and 20/30 in the left eye. His pupils are equal and reactive. His conjunctiva is slightly injected. No hyphema is visible. A drop of saline is placed on a fluorescein paper strip. This drop is then touched to his lower eyelid so fluorescein dye flows over the surface of his eye. With an ultraviolet light, a 0.5 cm linear abrasion is seen in the lateral aspect of his left cornea.

His eye is rinsed with saline to remove excess fluorescein. A single drop of a cycloplegic agent (such as homatropine) is instilled into his left eye. Antibiotic ointment is instilled into his eye and a pressure eye patch is applied. He is instructed to take over-the-counter analgesics for pain.

The next day he is checked by his primary care physician. The fluorescein exam is repeated and no corneal abrasion is seen. No further treatment is necessary.

The cornea is composed of three layers: the outer epithelium, the middle stroma and the inner endothelium. The outer epithelium is the only layer capable of regenerating. Injuries to the stroma and endothelium usually result in permanent scarring of the cornea, and reduced vision for the eye. Cornea has a high density of neuronal pain receptors, making injury to the cornea very painful.

Epithelial damage is commonly called corneal abrasion. The most common cause is external blunt trauma, such as foreign objects scratching the cornea. Other causes include chemical burn, thermal burn (such as welding and sun lamps), or prolonged exposure to ambient environment, such as decreased blinking and dry eyes, and contact lens wear. Occasionally, there is no history of trauma. Symptoms of corneal abrasion include pain, redness, photophobia, tearing, and foreign body sensation. Signs of corneal abrasion include conjunctival injection, or redness, swollen eyelid, and sensitivity to light. Occasionally, a visible irregularity of the corneal surface can be seen.

It is very important to document visual acuity when examining a patient with an eye injury. A topical anesthetic, such as proparacaine or tetracaine, can be instilled to decrease pain for the patient to facilitate the examination. Visual acuity should then be obtained and documented. Take note of any periorbital injuries, such as eyelid trauma, or possible orbital wall fractures. These separate injuries should be treated appropriately as well.

Ideally, an eye should be examined with a slit lamp for signs of corneal abrasion. Fluorescein is applied topically, and using cobalt blue light, the size, shape and location of the abrasion should be documented. Slit lamp examination is also helpful in determining if the injury involves deeper layers of the cornea, and possibly penetrating injury to the eyeball. Despite this advantage, most non-ophthalmologists use a plain ultraviolet light (Wood's lamp) with fluorescein to examine the cornea for abrasions. Eyelids are everted to look for foreign bodies.

The traditional treatment for corneal abrasion involves "pressure patching" the eye after topical cycloplegic and antibiotic drops or ointment are applied. The cycloplegic reduces the pain due to ciliary muscle spasm and the topical antibiotics provide prophylaxis against infection developing in the abrasion. A gauze eye patch is folded in half and placed over a closed eye. A second gauze eye patch is applied over the first eye patch, making sure the eye is completely closed. Paper tape is applied tightly over the patches from the forehead to the cheek. This type of treatment ensures that the epithelium can regenerate without having the eyelid abrading further on the corneal abrasion. Narcotic analgesics are sometimes necessary to treat the pain. The patches are left on 24 hours at a time, and the eye is reexamined for progress. Most corneal abrasions heal in 24 to 72 hours. If infiltrates are observed at any time, patching is discontinued and the patient needs to be treated for a corneal ulcer by an ophthalmologist.

A pressure patch is not recommended for abrasions which are at significant risk for infection, such as scratches from a tree branch, from a dirty fingernail, and abrasions in a contact lens wearer. These eyes are treated with every 1 to 2 hour applications of topical antibiotic ointment, until the abrasions heal completely. Eye patches are not always necessary and it is not possible to keep these on some young children.

Excessive ultraviolet light exposure to the cornea (and retina as well) can occur when observing a welding arc or flame, or with extremely bright sunlight exposure such as looking at the sun, during high altitude skiing (commonly called snow blindness), and occasionally at the beach. The welding arc produces invisible high intensity ultraviolet radiation which must be blocked by an ultraviolet light shield. Just as in a sunburn, patients with ultraviolet corneal burns do not notice much discomfort initially, but after 1 to 2 hours have passed, the burning sensation becomes very painful. Fluorescein examination reveals multiple, tiny pitting defects of the corneal surface, called superficial punctate keratopathy. Since this is usually a bilateral problem, bilateral eye patching is not usually feasible. Frequent topical antibiotic ointment is recommended and oral narcotic analgesics may be necessary for comfort. If only confined to the cornea, and not involving the retina, this problem is generally self limited.

A hyphema is defined as blood in the anterior chamber of the eye. It is usually caused by blunt trauma. The eye ball is compressed and it results in distortion of the iris and angle, thus causing tears in the iris and the angle vessels. It can present as a microhyphema,

where only circulating red blood cells are present, or as a visible blood clot. The blood is generally reabsorbed by the trabecular meshwork over time. The greatest danger of hyphema is re-bleeding, which usually occurs between the 2nd and the 5th day after the initial injury. Re-bleeding is probably caused by clot retraction and fibrinolysis. Re-bleeds are associated with an increased incidence of glaucoma and decreased final visual acuity.

The management of hyphema remains controversial, but most experts agree that children should be placed on bed rest with bathroom privileges for at least 5 days and refrain from strenuous activities for 10 days. A fox shield (a metal shield) is also recommended to decrease the chance of further blunt injury in the early days. Topical corticosteroids, oral corticosteroid, and aminocaproic acid (anti-fibrinolytic agent) have all be advocated to decrease the incidence of re-bleeds. Occasionally, surgical evacuation of a blood clot is necessary to decrease complications, such as uncontrollable intraocular pressure, and corneal blood staining (permanent opacification of the cornea from infiltration of hemoglobin and hemosiderin).

Questions

1. An eye with a corneal abrasion should be patched if:
    a. it is associated with a corneal infiltrate.
    b. it has been scratched by a fingernail.
    c. it occurs in a contact-lens wearer.
    d. it is large and is in the center of the cornea.

2. A 4 year old boy was playing with sparklers on the 4th of July. He held it up high and his parents think that some sparks fell into his eye. He has some small blisters around his eyelids and he is complaining of intense eye pain. He refuses to open his eyes for an examination because of pain. Which of the following are possible options (more than one correct answer is possible):
    a. topical proparacaine as a single dose to facilitate an examination.
    b. intramuscular morphine to facilitate an examination.
    c. topical proparacaine now and p.r.n. at home for discomfort.
    d. acetaminophen with codeine syrup.

3. A 10 year old boy presents to the pediatrician with a red and teary eye for a day. He had been to a soccer practice on the day before presentation and the red eye began after that. The pediatrician does not see a corneal abrasion with fluorescein and sends him home with topical antibiotics. He still has the same symptoms the next day. What should the pediatrician do?

4. A 16 year old female presents to the primary care doctor with the complaint of bilateral red and painful eyes since waking up. She had forgotten to take off her soft contact lenses the night before because she was too tired. The primary care physician does not see any corneal abrasions but there are some small "white" dots in the corneas. What should be done?

5. A 4 year old boy presents to the emergency room with a red and painful right eye after a swing had accidentally hit the eye on the playground. On examination, he does not like to have the left eye covered because he "cannot see". The eyelids are swollen and ecchymotic and the conjunctiva has hemorrhages. The physician sees a blood clot covering 65 percent of the anterior chamber. What is the appropriate management?

References

1. Friedberg MA, Rapuano CJ. Wills Eye Hospital Office and Emergency Room Diagnosis and Treatment of Eye Disease. 1990, Philadelphia: J.B. Lippincott Company.

2. Orbits, Eyelids, and Lacrimal System. Basic and Clinical Science Course, Section 9., American Academy of Ophthalmology.

Answers to questions

1. Choice d is the correct answer. A corneal abrasion which is at significant risk for infection should not be patched. Choices a, b, and c are all at higher risk for infection.

2. Choices a and b are all reasonable answers. Choice d would be too slow for an office or emergency department, but it would be reasonable if one is willing to wait for it to take effect. Choice c is incorrect because topical ophthalmic agents should not be sent home with patients. Prolonged corneal anesthetic use often results in corneal complications because this blocks the eye's natural protection reflexes to minimize further corneal injury.

3. The differential diagnosis consists of corneal foreign body, conjunctival foreign body, early conjunctivitis. The eyelids should be flipped to look for small foreign bodies. If possible, the cornea should be inspected again with some magnifying glasses to look for a foreign body as well.

4. Whenever the cornea has white lesions, one should always suspect corneal ulcers or infiltrates. Overnight contact lens wear is the most significant contributor to the development of corneal ulcers in a contact lens wearer. The patient should be referred to an ophthalmologist as soon as possible and the patient should be advised to discontinue contact lens wear until treatment is completed.

5. The patient should have an ophthalmology consult as soon as possible. A metal shield should be placed on the eye, NOT a gauze eye patch (which can press on the eyeball), to decrease further chance of injuring the eye. He probably should be admitted to the hospital for bedrest and observation to decrease the chance of re-bleed.

Chapter XVIII.1. Neurologic Examination
Vince K. Yamashiroya, MD

A mother brings her 4 year old son into your office for headaches occurring for the past month which are getting worse. In the beginning, he would complain of headaches during the daytime but these would resolve after several hours and he would run out and play. During the past several days, he has been complaining of worsening headache, sometimes waking him from sleep in the early morning, occurring almost every day. These recent headaches have been associated with vomiting and he has been clumsier on the playground. There has been no history of trauma, fever, respiratory symptoms, or visual problems.

PMH is unremarkable. His growth and development have been normal.

Family history is significant for migraines in his mother and other relatives.

Exam: VS T 37.0, P 80, R 20, BP 120/80, Weight 17 kg, Height 105 cm, HC 50 cm (all in the 50th percentile). He is a healthy appearing, alert boy in no distress. No unusual odors are present. No rashes or neurocutaneous stigmata are visible. His head is normocephalic and atraumatic. No dysmorphic features are seen. TMs are clear. Throat is normal. Lungs, heart, and abdomen are all normal. There are no sacral dimples on his back.

Neurologic exam: Pupils are equal and reactive to light. Extraocular movement is impaired on lateral gazing of the left eye. The rest of his EOMs are intact. Horizontal nystagmus is exaggerated towards the left, no vertical or rotatory nystagmus is present. Funduscopic examination reveals papilledema without retinal hemorrhages. Visual acuity is 20/20 for both eyes. No facial asymmetry noted when smiling or closing his eyes. Hearing tested with tuning fork is equal on both sides. His gag reflex is intact. He is able to shrug his shoulders and turn his head in both directions. His tongue is midline. His biceps, triceps, deltoids, knee flexors and extensors strength are 5+/5. He is not able to do finger to nose testing. Dysdiadochokinesia is present. He has a stumbling gait. His temperature sensation is intact. He is able to discriminate coins, paper clips, and rubber bands. His deep tendon reflexes are +2/4. No clonus present. He has a negative Babinski.

The history is significant for signs of increased intracranial pressure with headache and vomiting. You wonder about cerebellar dysfunction because of his clumsiness. The physical examination confirms this with papilledema and cerebellar signs with dysdiadochokinesia. You determine that the lesion probably originates from the cerebellum and may be on the left side because of the left eye paresis on lateral gaze and exaggerated horizontal nystagmus to the left. Putting all of this information together, especially remembering that four year olds normally do not complain of headaches and the additional fact that the headaches are severe enough to wake him at night, makes you suspect that this child has a tumor in his cerebellum. An MRI of his brain demonstrates acute hydrocephalus and a cerebellar astrocytoma.

Physicians are often thought of as detectives since it is their goal to determine where any lesion or problem is. They have to be systematic in their approach in order not to miss anything. By careful history taking and physical examination, they try to determine where the problem is, and only then do they obtain further diagnostic studies to confirm or localize the area of involvement. The pediatric neurologic examination is often challenging to those who have primarily worked with adults since infants and younger children are often uncooperative. This chapter will focus on two major areas of the examination, the history and physical examination.

History. A careful and accurate neurologic history is the most important part of the assessment. In evaluating the history of present illness, it is important to note the onset of symptoms in chronological order, and their frequency, duration, and associated characteristics (1). Also, it would be useful to know whether the problem is static, progressing, or improving. Children who are older than 3 to 5 years may be able to give answers to questions if done appropriately, which may not only be helpful but could be more accurate than the parent's. The review of symptoms is also important since vomiting, fever, clumsiness, and other symptoms can be associated with the presenting problem. A birth history should be obtained, focusing on prenatal, perinatal, and postnatal events. Ask about the gestational age, complications during pregnancy (including infections), maternal drug and alcohol use, Apgar scores, problems during delivery - like meconium, and feeding difficulties. The past medical history should include immunization status, accidents, chronic medical problems, and medications (including anticonvulsants). A good developmental screening assessment with milestones can be performed (such as the Denver II). Family history can also be useful since some diseases are transmitted through dominant genes like some neurocutaneous syndromes and migraines, or through recessive genes such as the case of many neurodegenerative disorders (2).

General Physical Examination. The following is a list of items that should be performed in the general examination (2).

1. Height, weight, blood pressure, and head circumference. For neonates, nurseries commonly include the chest circumference. If the head circumference is significantly smaller than the chest circumference, then there might be microcephaly. A nice rule of thumb for head circumference is the 3 & 9 rule. A newborn has a head circumference of 35 cm, a 3 month has a circumference of 40 cm, a 9 month has a circumference of 45 cm, a 3 year old has a circumference of 50 cm, and a 9 year old has a circumference of 55 cm (3).
2. General appearance, including dysmorphology.
3. Skin examination for neurocutaneous lesions, such as ash leaf spots, cafe au lait spots, angiomas, axillary freckling, adenoma sebaceum, or shagreen patches.
4. Location of the hair whorl and appearance of palmar creases. Abnormal hair whorl location can signify the presence of cerebral malformations.
5. Quality of scalp hair, eyebrows, and nails. Friable, kinky hair may signify Menkes kinky hair disease that is associated with mental retardation and optic atrophy.
6. Examination of the midline of the back and neck for sacral dimples, tufts of hair, or other signs of spinal dysraphism.
7. Comparison of thumbnail sizes and their convexity. Abnormalities may signify a growth disturbance, which may be a sign of hemiparesis.
8. Presence of unusual body odor, which is present in some inborn errors of metabolism.

Neurologic Examination of the Child. The process is the same as that of the adult, although one must remember that children are often frightened of those with white coats and their attention span is rather short. Therefore, the following general tips should be kept in mind:

1. Use items such as a tennis ball, small toys (including a toy car), bell, and an object that will attract the child's attention (like a pinwheel).
2. Do not wear a white coat.

3. Postpone uncomfortable tasks until the end, such as funduscopy, corneal and gag reflexes, and sensory testing.

4. Make the most of every opportunity to examine the child. See how he or she plays, taking into account handedness and motor deficits.

5. Examine the younger child in the parent's lap. Be patient and wait for the child the make the first move before touching him or her. Give the child a toy to establish rapport.

The examination can be summarized in the following steps: 1) Examination of the skull. 2) Cranial nerves. 3) Strength. 4) Cerebellar function. 5) Sensory. 6) Reflexes.

The examination of the skull can lead to the discovery of microcephaly, macrocephaly, and craniosynostosis (or premature closure of the cranial sutures). Prominence of scalp veins may signify increased intracranial pressure. Flattening of the occiput is seen in children who are developmentally delayed, while prominence of the occiput may signify Dandy-Walker syndrome. Ridging of the cranial sutures is a sign of craniosynostosis. Percussion of the skull showing areas of tenderness may signify osteomyelitis. Macewen (cracked pot) sign is where the sutures are separated, which may indicate increased intracranial pressure. Palpation of the anterior fontanelle is also important since one can estimate intracranial pressure. If the anterior fontanelle is bulging, then increased intracranial pressure may be present. The skull can be auscultated using the bell of the stethoscope in six locations for bruits: globes, the temporal fossae, and retroauricular or mastoid areas. Intracranial bruits are heard in many cases of angiomas, which are often accompanied by a palpable thrill. They can also be heard in anemia, thyrotoxicosis, and meningitis (2).

Cranial nerves (2). CN I (olfactory) is rarely tested although it can be by asking the patient to smell something. Olfactory sensation appears at 5 to 7 months of age. CN II (optic) can be tested through various means. Funduscopic examination can be performed, and appearance of the optic disk, macula, and retina noted. An early sign of papilledema is obliteration of the disk margins and absent pulsations of the central veins. Visual acuity can be tested by a vision chart or by offering toys of various sizes to the younger, uncooperative child. Rotating a striped drum or drawing a strip of cloth with black and white squares in front of the eyes can test for optokinetic nystagmus. A homemade drum can be made by attaching a paper with alternating black and white stripes around an empty soda can with a metal wire piercing through it (4). Alternatively, optokinetic nystagmus can be elicited by passing a vertically striped cloth horizontally across the patient's visual field. Optokinetic nystagmus can be elicited starting about 4 to 6 months of age and it confirms cortical vision, in addition to supporting the integrity of the frontal and parietal lobes and visual fields. Visual fields can be tested in children less than a year of age by having one examiner attracting the attention of the child to a toy after which another examiner in back of the child brings another toy into the field of vision, with the location at which the child turns his or her head towards this second toy noted. The blink reflex, which is where an object is rapidly brought close to the child's eyes, appears at about 3 to 4 months. It is present in about 50% of babies at 5 months, and 100% of children at 12 months.

CN III, IV, and VI (oculomotor, trochlear, abducens) can be checked by extraocular movements and pupillary size and reaction to light. Pupils may be large and not responsive to light in babies earlier than 30 weeks gestation. A mnemonic to remember the cranial nerves which innervates the extraocular muscles is the formula (LR6 SO4). CN 6 innervates the lateral rectus, CN 4 innervates the superior oblique, and CN 3 innervates the other ocular muscles.

The Doll's eyes phenomenon can also be used to assess extraocular movements in a comatose patient with an intact brainstem. In these patients, horizontal eye movements can be elicited when the head is suddenly turned to one side resulting in the eyes moving to the opposite side in a symmetrical fashion. Also, vertical eye movements can be demonstrated by rapidly moving the head up and down, with the eyes moving in the opposite direction of the head, again in a symmetrical fashion. If a patient were brain dead with no brainstem function, then no Doll's eyes movement would be seen. In effect, the eyes would be stationary when the head is turned. In conscious patients, the cerebrum would interfere with the Doll's eyes phenomenon. Although the Doll's eyes phenomenon can determine whether the brainstem is still functional, a better test would be to do cold calorics. In order to do this test, 5 mL of ice water is squirted into the external ear canal in comatose patients or 0.5 mL in alert, awake patients, and the action of the eyes are noted. There are three possible responses to this test. In the comatose patient with an intact brainstem, the eyes move in the direction of the stimulus. In alert, awake patients, there is nystagmus with the quick component in the opposite direction of the stimulus. Lastly, in patients without a functioning brainstem, there is no movement of the eyes when cold calorics are performed. One needs to remember that cold calorics do not test for extraocular movements, but for vestibular function (CN VIII).

A special note about pupils is inserted here because of a common medical student error. PERRLA stands for pupils equal round and reactive to light and accommodation. Some individuals write PEARL which might stand for pupils equal and reactive to light. The latter is probably satisfactory although it might be better to write PERRL (leave out the A). The accommodation reflex is difficult to see on light eyed individuals, it is impossible to see on dark eyed individuals, and it is impossible to accomplish on non-cooperative subjects such as infants and toddlers. Thus, to write PERRLA on a 6 month old or a comatose patient is an obvious error. If you are in the habit of writing PERRLA, ask yourself this. Do you really check the accommodation reflex and did you really, truly see the proper reaction? What is the clinical utility of checking the accommodation reflex? It has almost no clinical utility other than to identify the Argyll Robertson pupil of neurosyphilis. In the medical malpractice literature, a chart entry such as "PERRLA" has been used to discredit the physician's credibility since a jury can be easily convinced that the accommodation reflex was not or could not be done. If you still believe that you must do the accommodation reflex, then you should write "PERRL + intact accommodation" and note the patient's eye color, to show that you really did it. A medical student once saw a patient for fever and in the PMH, he wrote that the patient has a glass eye because of a traumatic injury. The exam section of his note indicated: PERRLA. Be careful, the pupil of the glass eye does not react to light, nor accommodation.

CN V (trigeminal) is assessed by checking the sensation of the face. Noting the action of the temporalis and masseter muscles can test the motor roots of this cranial nerve. The corneal reflex also checks the ophthalmic branch of CN V. CN VII (facial nerve) dysfunction is seen with facial asymmetry. Taste in the anterior two-thirds of the tongue is innervated by the chorda tympani branch of VII, and can be checked by applying salt or sugar solutions by cotton-stick applicators. CN VIII (auditory) which conducts cochlear and vestibular function can be tested by the child's response to a bell or by recalling a whispered word or number. Noting the eye movements after turning the child several times in a clockwise and counterclockwise direction can check vestibular function. CN IX, X (glossopharyngeal, vagus) function is determined by the position of the uvula and palate. If there is a vagal nerve problem, the uvula will deviate toward the unaffected side, and the palate will move away from the affected side. The gag reflex actually tests parts of IX and X, since IX is the afferent sensory limb (sensory to the back of the pharynx) and X controls the muscles of the pharynx and elevation of the palate. CN XI (spinal accessory) is tested asking the patient to turn his/her head against resistance, which involves the sternocleidomastoid muscle. CN XII (hypoglossal) dysfunction is seen when the tongue deviates toward the affected side.

The above tests should be considered basic. Several cranial nerves cannot be tested fully since they have multiple functions. For example, the multiple functions of CN X (vagus) cannot be tested fully and we really don't check CN IX's sensory limb from the carotid sinus function. Thus it would be less than truthful, if one wrote down "cranial nerves intact", "CNs II-XII intact", or "cranial nerves grossly intact". These statements are actually assessments rather than descriptions of observations which is what the physical exam should state. Additionally, it would not be possible to honestly state that the cranial nerves are intact since several cranial nerve functions were not tested (because they cannot be easily done). For example, to assume that CN X is intact just because the patient gags is a bit of a stretch. The term "grossly intact" usually means that a cranial nerve exam was not done, but the patient's facial function is symmetric. Perhaps it would be more honest to state that the "the patient's facial function is symmetric". In the medical malpractice literature, statements such as "CNs II-XII intact" have been used to question the credibility of the physician's chart entries since a jury can be easily convinced that an exam to support such a statement is not easily done.

Motor System (2). Observing the child's posture and simple maneuvers such as retrieving a ball or running outside the examination room can check motor integrity. The following grading system can be used for assessing muscle strength:

0 - No muscle contraction
1 - Flicker or trace of contraction
2 - Active movement without gravity
3 - Active movement against gravity
4 - Active movement against gravity and resistance
5 - Normal strength

A sensitive test to assess the strength for the upper extremities is the pronator sign. Have the child raise his/her arms and note the position of the arms. Weakness of the arm is seen by hyperpronation and elbow flexion. Strength of the flexors of the knee can be tested by the Barré sign, which is performed by having the child keep both knees at right angles while lying prone.

Cerebellar function (2). Observing how a child reaches for and manipulates toys can check for coordination. Other tests include finger-to-nose and heel-to-shin. Rapid pronation and supination of the hands, or rapid tapping of the foot can assess for dysdiadochokinesia, or the impairment to perform rapidly alternating movements indicative of cerebellar dysfunction.

The Romberg test is often mistaken to be a test for cerebellar function, but it is actually a test of proprioception (dorsal columns). This test is done by asking the patient to stand with his arms outstretched forward. He must close his eyes and rely on proprioception to keep his body erect and balanced (without any visual information). He can be gently pushed to see if he can maintain balance.

Sensory. This can be assessed in an older child by pinprick, light touch, position, and vibration sense. Object discrimination, which tests for higher cortical functions, can be done using coins, paper clips, or rubber bands.

Reflexes. The segmental levels of major deep tendon reflexes are: Jaw jerk (CN V), biceps (C5-6), triceps (C6-8), brachioradialis (also known as the radial periosteal, C5-6), patellar (also know as quadriceps, L2-4), ankle (also known as Achilles, S1-2). The best known sign of pyramidal tract dysfunction is the Babinski's sign. This sign can be elicited when the plantar surface of the foot is stimulated with a stiff object (e.g., key) from the heel through the lateral aspect of the foot, crossing over the distal metatarsals, ending in the big toe. A positive Babinski's sign is seen when there is dorsiflexion (extension) of the great toe and fanning of the toes. This response can be normally seen in children up to 2 years of age or sometimes after a seizure. A positive Babinski's sign is also called an upgoing plantar reflex, as opposed to the normal downgoing plantar reflex which is called a negative Babinski's sign. Another sign is clonus that can be tested by maintaining dorsiflexion of the foot. Sustained clonus is abnormal at all ages and signifies a lesion in the pyramidal tract or the cortical origin of the pyramidal tract.

Neurological examination of the infant. The neurological examination of the infant can be organized in the following fashion: 1) Posture and muscle tone, 2) Primitive reflexes, 3) Age invariable items.

Posture and muscle tone. This can be divided in three ways: 1) resting posture, 2) passive tone, 3) active tone. Resting posture can be performed by observing the infant undressed. The infant should have flexion of the elbows, hips, and knees (varying with age). Hypertonia in the extremities decreases after 3 months of age, with the upper extremities then the lower extremities. At the same time, tone in the trunk and neck increases. Passive tone is done by determining resistance of passive movements of the joints while the infant is awake and not crying. One can do this by flapping the hands and feet, and by other maneuvers. The scarf sign is where the arm is pulled across the chest and if the elbow passes the midline, then hypotonia is present. Active tone can be assessed by the traction response up to 3 months of age. The infant's hands are held with the examiner's thumbs in the infant's palms, and the fingers around the wrists. The infant is slowly pulled to a sitting position. Normally the elbows flex and the neck raises the head. If hypotonia is present, then the head lags backward, then as the erect position is assumed, the head then drops forward. If hypertonia is present, the head is maintained backwards.

Primitive reflexes. Primitive reflexes are usually present from the time of birth and represents spinal reflexes until the infant becomes older and higher cortical functions suppress them. Although there are many types of reflexes, it would be a good idea to do some of them and not necessarily all since they would not give more information than what was already done.

Vertical suspension. The infant is suspended by holding the chest with both hands and lifting the patient in an upright position, with the legs dangling. If scissoring or hyperextension of the legs is seen, then spasticity is present. If there is scissoring of the legs, then spasticity may be present making it suspicious that cerebral palsy may be present.

Horizontal suspension (Landau reflex). To perform this reflex, the infant, while prone with the examiner's hand under the trunk, is gently lifted upwards. Normally, the spine extends a little so that the eyes are looking just below the horizontal. If the body collapses into an upside down "U" shape, then hypotonia is present.

Segmental medullary reflexes. An example is the sucking reflex that involves afferent fibers of CN V and IX, and efferent fibers of CN VII, IX, and XII.

Moro reflex. This is done by having the head hyperextended, falling back about 3 centimeters in relation to the trunk. A normal response is seen when the infant opens his hands, extends and abducts the arms, and then brings them together, followed by a cry. It is present in all newborns and disappears before the age of 6 months.

Tonic neck response. Also called the fencer's stance, this reflex can be elicited when the head is turned to the side while the rest of the body lies flat on the table. A normal response is extension of the arm and leg on the side that the head is turned, and flexion of the arm and leg on the opposite side (similar to a fencing stance). Abnormal responses occur when this response is sustained or if it occurs

differently when the head is turned to the right or left (i.e., the response is not the same when tested on both sides). It usually disappears about 6 to 7 months of age.

Palmar and plantar grasp reflexes. They are performed by applying gentle pressure to the palm or sole. An abnormal response occurs when this response is absent before 2 to 3 months of age, persistence after this time, or asymmetry.

Parachute response. The infant is suspended horizontally with the face down, and is brought quickly down toward the floor, making sure that the infant is firmly held. A normal response is seen when the arms are extended and the hands open.

Reflex placing and stepping responses. Reflex placing is seen when the dorsum of the foot is placed against the edge of the examination table. Reflex stepping is seen when the sole of the foot is placed on the table, and the infant appears to be walking. This reflex disappears at about 4 to 5 months of age.

Questions

1. Name the steps involved of the older child's neurological examination.
2. Name five primitive reflexes.
3. What extraocular muscles are innervated by abducens and trochlear nerves?
4. What does optokinetic nystagmus signify? When can it be performed in an infant?
5. What is the pronator sign? What does it test for?
6. In what two instances can a positive Babinski's sign be seen in normal patients?

3. Inaba AS. Personal communication, 1999.

4. Tottori M. Personal communication, 2001. A black sheet paper is used and multiple strips of white tape (about 2 cm wide) are attached so that there are alternating strips of black and white. A photocopy of this is made and is then wrapped around an empty soda can. A straight piece of metal, such as from a dressing hanger, is used to pierce the top and bottom parts of the can and is thus the handle to rotate the drum.

I would like to thank Dr. Yoshio Futatsugi for his review of this chapter. His assistance is greatly appreciated.

Answers to questions

1. Examination of the skull, cranial nerves, strength, cerebellar function, sensory, and reflexes.
2. Ventral suspension, horizontal suspension (Landau reflex), Moro reflex, tonic neck response (fencer's stance), palmar and plantar grasp reflexes, parachute response, reflex placing and stepping responses.
3. Lateral rectus and superior oblique muscles, respectively.
4. Signifies that cortical vision is intact, in addition to showing the integrity of the frontal and parietal lobes, and visual fields. It can be performed at about 4 to 6 months of age.
5. When the arms are lifted, a positive sign is when an arm is hyperpronated with the elbow flexed. It tests for strength of the upper extremities, and a positive sign signifies weakness.
6. In what two instances can a positive Babinski's sign be seen in normal patients? In newborns up to 2-1/2 years of age and sometimes in patients just after a febrile seizure.

Chapter XVIII.2. Cerebral Palsy
Mari Uehara, MD

Roy is a 13 month old male who has been followed in the Pediatric outpatient clinic. He was born at term by normal vaginal delivery without complications and his birth weight was 3300g. His mother did not have any problems during the pregnancy. At 6 months of age, you noticed his head control was poor. Currently, he calls everyone "mama" and follows one-step commands. He is able to drink from a cup. He is able to roll over from his stomach to his back but he is not able to sit or stand. His height and weight are both between the 25-50th percentiles and his head circumference is within 2 standard deviations of the mean. Some primitive reflexes such as the Asymmetric Tonic Neck Reflex (ATNR) persist and he has increased muscle tone, especially in his legs. His deep tendon reflexes are exaggerated.

Cerebral palsy (CP) is defined as a non-progressive, but often clinically changing motor impairment due to an abnormality of the developing brain. It is a symptom complex or a descriptive term rather than a specific disease. Intellectual, sensory, and/or behavioral problems may also exist although the primary abnormality must be a motor deficit. The prevalence is estimated at about 2 per 1000 early school aged children (1).

In more than 50% of the children who have CP, an etiology may not be evident (1). The insult to the brain may occur prenatally (e.g., congenital malformation, intrauterine infections, teratogens), perinatally (e.g., birth trauma, anoxia), or postnatally (e.g., infections, accidental or non-accidental trauma, intracranial hemorrhage). The majority of the cases are not caused by hypoxic ischemic incidents occurring perinatally as it was believed until recently. 70-80% cases are prenatal in origin (3). Infants who weigh less than 1500g at birth have a 10% to 20% risk of developing CP (2). Although prematurity is the most common known antecedent of CP, the majority of children who develop CP are born at term.

CP is often classified according to the predominant type of motor impairment: spastic, dyskinetic, ataxic, or mixed. Spastic CP is the most common type and affects 70-80% of individuals with CP. It is characterized by a generalized increase in muscle tone. CP can be further classified based on which limbs are involved, the suspected etiology or functional capacities. For example, in spastic diplegia, the lower extremities are more involved than the upper extremities. In hemiplegia, one side of the body is more involved. All the extremities and often trunk and oral motor function are also affected in spastic quadriplegia.

Choreoathetoid CP is a subtype of dyskinetic CP. Athetosis are slow writhing involuntary movements and involves distal limbs. Choreiform movements are asymmetric, uncoordinated, involuntary muscle contractions. These movements are more prominent under stress and their intensity may change. It may not be apparent until about 12 to 18 months of age when a toddler starts to show athetoid or dystonic posturing on voluntary movements. One known cause of this form of CP is encephalopathy associated with very high bilirubin levels during the neonatal period.

Ataxic CP is characterized by cerebellar dysfunction. This is the least common type with a frequency of 1% among individuals with CP. Mixed CP involves both symptoms of upper motor neuron and extrapyramidal symptoms. For example, a child who has spastic quadriplegia may also have choreoathetoid movements.

The diagnosis of CP is essentially clinical and depends on knowledge of normal development and its variation. While no factors or combination of factors is an absolute predictor of CP, certain situations warrant closer monitoring. It is also important to remember that the neurological picture may change as the child grows older and the CNS matures. It is often difficult to diagnose children with CP before 6 months of age.

During infancy, feeding difficulty is an important sign. A child may continue to need gavage (tube) feedings. He or she may be difficult to feed, or require an excessive amount of time for feeding. A child may have failure to thrive or a poor rate of head growth due to a serious insult to the brain. Constipation is another symptom among infants with CP. He/she may be quiet and very easy, or irritable during infancy. The child may show a premature handedness preference during the first 18 months of life. This can be an early sign of hemiplegia.

There are several useful parameters for the assessment of neuromotor function.

A) Muscle function: Muscle tone and strength should be examined. By simple observation, you may be able to see poor head control, scissoring of the lower extremities, or flexor posturing of upper extremities.

B) Patterns of movement should be assessed. There are three patterns of movements: 1) Normal movements, 2) Abnormal movements which are never seen in normally developing children (e.g., restricted movements in children with spastic diplegia or hemiplegia, or involuntary movements seen in children with athetoid CP), 3) Atypical movements which may be seen in normally developing children (e.g., bouncing along the floor while supine, or log-rolling as methods of mobility).

C) Structure or alignment of the body. A child with spastic CP may have dislocation of the hip due to adductor and abductor muscle tone imbalance and resultant poor joint development. Children with spastic CP also have the tendency for plantar flexion of the feet. Scoliosis can be a problem for all children with CP.

D) Reflexes should be assessed. Physicians are generally very familiar with the deep tendon reflexes. Of equal significance are so-called developmental reflexes. Children with CP may have persistent primitive reflexes such as the Moro reflex and the asymmetric tonic neck reflex (ATNR). Also, children with CP may present with delayed emergence of righting reactions (natural tendency to position the body/head upright) and protective/equilibrium responses (e.g., parachute reflex) as signs of delayed maturation or CNS injury.

E) Gross motor skills are usually affected but other developmental milestones should be also assessed to determine if delays are more global.

Many co-existing conditions are frequently seen in children with CP. These may include sensory impairments, seizures, cognitive impairment, orthopedic problems, impaired speech and language, feeding issues, dental problems, skin breakdown and respiratory infections. Because CP is the result of an insult to the developing brain, some of these problems may not be treatable or they may only partially respond to medical/surgical treatment. The treatment plans and programs must be individualized and modified over time as the child grows.

Children with CP have a high incidence of visual impairments (4,5). They may have refractive errors, visual fields defects, or cortical blindness. Strabismus is very common and may lead to the development of amblyopia. There is also an increased incidence of sensorineural and conductive type hearing impairment. Hearing impairments can further delay speech and language development of children with CP.

25-50% of children with CP may also experience seizures (4,5). Seizures are most commonly seen among the children with spastic quadriplegia and hemiplegia. Generalized tonic-clonic and partial seizures are the common types. Approximately half of the children with CP have mental retardation. Although children with more severe motor involvement tend to have mental retardation more frequently, this is not always the case. Among children with normal intelligence, there is a higher incidence of learning disabilities. Feeding difficulties (e.g., with sucking, chewing, and/or swallowing) are common among children with CP as a result of impairment of oral motor muscle function. This may also cause problems with speech articulation. Drooling and gastroesophageal reflux may also occur. Aspiration can cause pneumonia which is the leading cause of death in children with CP.

Because of the difficulties in motor control, assistance is needed to maintain good posture and alignment and good range of motion of the joints. Subluxation or dislocation of the hip are common in children with CP. The incidence is higher among children with spastic quadriplegia. Dislocated hips can develop arthritis and severe pain. Poor posture or positioning can result in scoliosis due to the unequal muscle tension. Spasticity and limited muscle use may lead to contractures. The interventions used to treat these conditions include physical therapy, orthopedic surgery, muscle tone management (e.g., intrathecal Baclofen infusion), and orthoses (e.g., ankle-foot orthosis, body shell).

The life expectancy of children with CP depends on the type and the severity of the condition. Although the projected life span of children with CP is less than that of the general population due to complications of motor dysfunction, the majority of affected children will survive well into adulthood if given appropriate medical attention.

The prognosis regarding ambulation is also dependent on the type and the severity of the motor dysfunction. Overall, children with hemiparesis will walk by 18 months to 36 months. With or without assistive devices, 80-90% of children with diplegia, 70% of children with dyskinesia and 50% of children with quadriplegia may achieve some degree of ambulation (1). Ambulation may be predicted based on the achievement of motor milestones. For example, there is a good prognosis for attaining some ambulation if a child is able to sit independently by 24 months.

Because of multisystem involvement and various psychosocial and medical needs, no one discipline can assess and manage all aspects of the child with CP alone. It is important to be interdisciplinary to have a successful management program. The child's physician has to be familiar with community resources such as early intervention programs and support groups. It is important for the primary care physician to communicate with the therapists, specialists, and school personnel. The physician needs to advocate for the necessary services for the child and his/her family. Primary care physicians should be aware of the different problems and needs that the children experience as they get older and help them transition from the toddler to school age to adulthood as smoothly as possible. The goal for the treatment program is to maximize function and optimize development to help them participate in as many activities as possible in multiple social settings.

Questions

1. Cerebral Palsy may have changing clinical features in: (select one)
    a. The brain abnormality.
    b. Effects on the motor system.
    c. That seizures are usually not treatable after a few years.
    d. Subtypes - first a person has the choreoathetoid type, then the spastic type, and then becomes quadriplegic.
    e. Decrease in IQ over time.

2. Currently, most cases of cerebral palsy with a known etiology are thought to be
    a. Prenatal in origin.
    b. Perinatal in origin.
    c. Postnatal in origin.

3. What is the most common type of cerebral palsy?
    a. Spastic
    b. Choreoathetoid
    c. Ataxic
    d. Mixed
    e. All are equally common

4. Which of the following is NOT a worrisome sign that may indicate cerebral palsy?
    a. Poor rate of head growth
    b. Hand preference at 6 months of age
    c. Scissoring of the legs
    d. Obesity
    e. High muscle tone

5. True/False: Because of the neuromotor dysfunction and associated conditions, children with cerebral palsy rarely live into adulthood.

6. True/False: Children with hemiplegia have a higher rate of ambulation than diplegia and quadriplegia

Chapter XVIII.3. Febrile Seizures
Vince K. Yamashiroya, MD

An ambulance brings a 15 month old boy to the emergency department with a seizure associated with fever. He has been in good health except for a high fever that developed today to about 103-104 degrees. His mother gave him a small dose of acetaminophen. About 20 minutes ago when the mother was checking up on her child, she noticed shaking of the arms and legs and his eyes had a blank stare. This went on for what seemed like 5 minutes. She called 911 and an ambulance was dispatched. He has been ill with a high fever today and a slight cough and mild nasal congestion. Just prior to the seizure, he was playing with some toys. There is no vomiting, diarrhea, rash, or fussiness.

Past medical history is unremarkable.

Family history is significant for an uncle who has epilepsy.

Exam: VS T 39.8 degrees C (103.6 degrees F), P 165, RR 30, BP 90/60, O2 sat 100% on RA. He is clingy, alert to his surroundings, and otherwise is in no distress. His mother appears anxious and there appears to be good bonding between her and her child. Skin is without bruising or neurocutaneous stigmata. Anterior fontanelle is closed. Pupils are equal and reactive. EOMs are conjugate. The red reflex is present bilaterally. There is no sunsetting of the eyes. TMs are normal. His mouth exam shows moist mucosa without erythema. The Brudzinski and Kernig signs are difficult to assess. Respirations are regular. Neurologically, he moves both arms and legs equally. His tone appears normal. The rest of the examination is normal.

Febrile seizures are broadly defined as seizures occurring in the presence of fever, but in the absence of central nervous system (CNS) infection, in children ages 6 months to 5 years of age. It is the most common reason for convulsions in children less than 5 years of age, and they occur in 2 to 5% of all children, although it has been reported to be more frequent in Asian countries. In Japan, the rate has been reported to be 7% and in the Mariana Islands 14%. It is thought that the rates in these areas are higher because some of the common infections of childhood may occur earlier in life when children are most susceptible to febrile seizures. Also, since more families sleep in the same room, this may make recognition better than in Western countries (1). The age at which febrile seizures most frequently occur is in the second year of life, and they occur slightly more commonly in boys than in girls. Febrile seizures can be divided into two types: simple and complex. Simple febrile seizures are characterized by the following: duration less than 15 minutes, and generalized. Complex febrile seizures have the following features: duration greater than 15 minutes, multiple within 24 hours, and/or focal (2).

The risk of recurrence after the first febrile seizure is about 33%, and about 9% will have three or more recurrences. The risks for recurrence are: occurrence of the first febrile seizure at a young age; family history of febrile seizures; short duration of fever before the seizure; relatively low fever at the time of the initial seizure; and possibly a family history of an afebrile seizure. It has been observed that the time of recurrence is usually within the first year of onset. Although complex febrile seizures are not usually associated with recurrent febrile seizures, they may be a risk factor for epilepsy later in life. Febrile seizures seem to run in families, but their mode of inheritance is unknown. The risk for other siblings developing febrile seizures is about 10-20%, but may be higher if the parents also have a history of febrile seizures themselves (2).

Febrile seizures usually occur in the first 24 hours of the onset of fever. It has been suggested that it is the rapid rise in the child's temperature, which causes a febrile seizure rather than the actual height of the fever itself; however, there is no substantial proof to support this suggestion. The seizures are usually generalized and tonic-clonic, but other types may be present as well. Parents may describe stiffening, jerking, apnea, cyanosis and incontinence, usually followed by drowsiness (commonly called post-ictal for short). There may be variations to this such as staring without stiffness, jerking movements without prior stiffening, and localized stiffness or jerking. Simple, benign febrile seizures should be short, usually 1 to 2 minutes, but some may be longer (up to 15 minutes). Because of the short duration, medical attention usually occurs after the seizure has ended (2).

Although the diagnosis of febrile seizure is likely in a 6 month to 5 year old with fever and a convulsion, one should consider other causes such as meningitis, encephalitis, Shigella gastroenteritis, medications/toxins (such as diphenhydramine, tricyclic antidepressants, amphetamines, and cocaine), hypoglycemia, electrolyte abnormalities (that could be due to dehydration), shaken baby syndrome, accidental head trauma, and epilepsy (2). Many of these other diseases can be ruled out by a good history, physical examination, and clinical appearance after the seizure has ended.

How should these patients be managed in terms of diagnostic work-up and treatment? Given that febrile seizures are a relatively common phenomenon, should every child with fever and seizures have a lumbar puncture done to rule out meningitis, or CT scan and EEG to look for CNS abnormalities? The American Academy of Pediatrics attempted to answer this in two practice parameters on the evaluation and treatment of children with febrile seizures that were published in 1996 and 1999 (3,4). The recommendations of these two practice parameters are listed below. It should be kept in mind that these are guidelines only and that each case should be individualized according to the particular child, and the situation. One should remember that these guidelines are written for practitioners with a wide range of experience and training; therefore, the points mentioned here are meant to be conservative. Also these guidelines are written for children from 6 months to 5 years of age who had a simple febrile seizure and are neurologically normal. The guidelines do not include children with complex febrile seizures.

1. Lumbar puncture. An LP should be strongly considered in all infants less than 12 months of age because signs and symptoms of meningitis may be minimal or absent in this age group. An LP should be considered in children between 12 months to 18 months of age, since signs of meningitis might be subtle. An LP does not need to be done in children older than 18 months unless they show signs of meningitis (neck stiffness, Brudzinski and Kernig signs) or have symptoms of a CNS infection. Infants and children who were treated with

antibiotics prior to the seizure should be strongly considered to have an LP done. This is because antibiotics can mask the signs and symptoms of meningitis (partially treated meningitis). Even if an LP is performed and the results are negative, it is still prudent to be cautious and vigilant since spinal fluid may be normal in the early stages of meningitis (3). The clinical appearance of the child after the seizure has ended plays a very significant role, in that the playful, active child who appears normal, probably does not have meningitis.

2. EEG. An EEG does not need to be performed as part of the work-up for a first time simple febrile seizure. Although the EEG may be abnormal (occipital slowing) in the first month after the seizure, there has been no correlation of this to recurrence risk or the risk for developing epilepsy in the future (3,5). An EEG done 4 to 6 weeks following the seizure should be normal. If it is not, then epilepsy is more likely. In clinical practice this is not usually done after a single simple febrile seizure since an EEG is difficult to do in young children and 4 to 6 weeks have passed, presumably without any more seizures.

3. Laboratory studies. Laboratory tests, such as a CBC, serum electrolytes, calcium, magnesium, phosphorus, and glucose, need not be done routinely. It should instead be tailored to the presenting symptoms. For example, electrolytes and glucose can be checked in a patient who is vomiting.

4. Neuroimaging. CT scan of the head does not need to be done routinely. There is no data available showing that children with febrile seizures have an increased incidence of CNS abnormalities, nor any evidence that febrile seizures lead to structural brain damage.

Recommendations are not as clear-cut for children who develop complex febrile seizures; however, the threshold for performing blood tests, neuroimaging, and EEG is lower. A lumbar puncture should be strongly considered if the patient is young, if there are signs and symptoms of meningitis, if the patient is already on antibiotics, if there is no rapid improvement, or if the patient does not regain full consciousness (5).

If the child develops another seizure, then supportive measures are recommended. During the time the seizure is occurring, the patient should be placed on his/her side to prevent aspiration, and the airway should be maintained. Also nothing should be placed in their mouths. If it is prolonged, then diazepam (Valium) should be given either intravenously or rectally. If the patient has a fever, avoiding overheating by removing blankets and heavy clothes can prevent febrile seizures, in addition to administering antipyretics such as acetaminophen and giving cool baths. Diazepam can also be used to prevent future recurrences of febrile seizures for the next several hours, although its administration as a preventive measure is controversial (5).

Should a patient be hospitalized? Probably not, although it depends what the circumstances are. It is recommended that patients who had a febrile seizure be observed in the emergency department for several hours and reevaluated. After this time, most children would have improved, and if the cause of the fever is known and treated, they can then be sent home. Similarly, in a doctor's office, they can be observed if they are rapidly improving. If they are not improving, then the diagnostic studies mentioned previously should be considered. Circumstances when they should be hospitalized for overnight observation are: the clinical situation is still unstable, there is a possibility of meningitis, and/or the parents are unreliable or unable to cope with the child developing another seizure (1).

An essential component of management is parental counseling. Reassurance should consist of three components. First, parents should be reassured by informing them that although the febrile seizure is frightening, it will not cause brain damage, and the possibility of their child developing epilepsy is small. Secondly, they should also be told that there is a possibility that it could happen again, especially in the first 24 hours. Also one third of children will have at least another febrile seizure later, with most occurring within one year of the episode. Thirdly, if a seizure occurs, the child should be kept on his/her side, and they should observe their child. If the seizure does not stop in 3 minutes, then emergency medical services should be contacted (1).

Long-term pharmacotherapy is probably unnecessary, especially for simple febrile seizures. Although the AAP Practice Parameters discourage use of anticonvulsants in simple febrile seizures, it does mention that giving diazepam during the start of fever in patients with parents having high anxiety is an option. Diazepam is given orally using a dose of 1 mg/kg/day in three divided doses when the child is febrile. Disadvantages of using diazepam are lethargy, drowsiness, ataxia, and masking of a CNS infection. Other medications that have been used to prevent recurrences are phenobarbital and valproic acid. A dose of 5 mg/kg/day of phenobarbital is given once to twice a day. Although they can prevent 90% of recurrences of febrile seizures, they are not without significant side effects. Phenobarbital has been associated with behavioral problems (hyperactivity) and hypersensitivity reactions. Valproic acid has a risk of developing fatal hepatotoxicity, thrombocytopenia, weight changes, gastrointestinal problems, and pancreatitis. These medications have been considered in those patients who have focal paralysis after a seizure, multiple seizures in a young child, and high parental anxiety despite reassurance (1,4). Phenytoin and carbamazepine have no demonstrated efficacy in preventing febrile seizures.

Despite the frightening appearance of the episode, and the parental belief that their child is going to die, simple febrile seizures remain a benign condition with the majority of children having no neurological sequelae. In other words, it does not lead to brain damage or cognitive abnormalities. Although the risk of developing another febrile seizure is moderate, the possibility of epilepsy is very small. For this reason, long-term therapy anticonvulsant therapy is not usually recommended, but practitioners should provide reassurance, education of what to do when their child has another febrile seizure, and antipyretic therapy when a fever is present.

I would like to thank Dr. Yoshio Futatsugi for reviewing this chapter and Dr. Robert Bart for his helpful suggestions and input.

Questions

1. At what ages do febrile seizures occur? How common is this problem?
2. In what percentage of patients will febrile seizures occur a second time?
3. What are the differences between simple and complex febrile seizures? Why is it important to know this distinction (think of recurrence risk of febrile seizures, development of epilepsy, and work-up)?
4. A febrile seizure is a diagnosis of exclusion. What other diagnoses should be considered in a child with fever and seizures?
5. According to the guidelines put forth by the American Academy of Pediatrics' Practice Parameter, who should be strongly considered to receive a lumbar puncture?
6. Most patients with febrile seizures can be discharged home. What are three indications for a child who should be hospitalized for overnight observation?
7. Although diazepam (Valium) can be used to prevent recurrences when given at the start of a febrile illness, what are its disadvantages?
8. A key part to management is reassurance. What are three ways parents should be reassured and educated?

Answers to questions

1. 6 months to 5 years. It occurs in 2-5% of all children and is the most common reason for convulsions in children less than 5 years of age.
2. 33%.
3. Simple seizures are characterized by being less than 15 minutes duration and generalized. Complex febrile seizures are greater than 15 minutes duration, multiple within 24 hours, and focal. Simple febrile seizures have a higher risk for febrile seizures. Complex febrile seizures have a higher risk for epilepsy. One should have a lower threshold for performing tests and hospitalization in cases of complex febrile seizures.
4. Meningitis, encephalitis, Shigella gastroenteritis, medications and toxins, hypoglycemia, electrolyte abnormalities, shaken baby syndrome, accidental head trauma, and epilepsy.
5. Infants less than 12 months of age.
6. Unstable clinical situation, possibility for meningitis, and parents unreliable or unable to cope with the child developing another seizure.
7. Disadvantages include lethargy, drowsiness, ataxia, and masking of a CNS infection.
8. 1) Seizure will not cause brain damage and the risk of a child developing epilepsy is small. 2) Possibility that it can happen again, especially in the first 24 hours. One third of children will have at least another febrile seizure with most occurring within one year of the episode. 3) If seizure occurs again, child should be kept on his or her side. If seizure does not stop within 3 minutes, then emergency medical services should be contacted.

Chapter XVIII.4. Epilepsy

Keith K. Abe, MD, MS

A previously healthy 9 year old boy is brought to the emergency department because of the sudden onset of left-sided paralysis. His parents were aroused at night by a thrashing noise from his bedroom. They rushed to his room and found his bedsheets awry. He was lying in bed, breathing deeply, difficult to arouse, and could not stand or move his left arm or leg. There was no prior history of trauma, but he was noted to have a small tongue laceration. There is no history of toxic ingestions, fever, emesis or incontinence. EMS was called and he became more arousable during transport.

PMH is negative for any seizures or other serious medical conditions. His development has been normal. Family history is negative for seizures, strokes or brain tumors. His social history is negative for any problems at home. He is doing well in school.

Exam: Vital signs are normal. He is now alert, oriented, lying supine and not moving his left extremities. He appears non-dysmorphic and non-toxic. His head appears normal and without trauma other than the tongue laceration. Neck is supple with full range of active motion. No Brudzinski or Kernig signs. Pupils are equally round and reactive to light. Extraocular movements are intact. No facial asymmetry. His heart is regular without murmurs. Lungs are clear. Abdominal exam is unremarkable. Skin is without neurocutaneous stigmata or signs of trauma. Neurologic evaluation reveals decreased strength (grade 2 out of 5) on the left. No sensory loss. Deep tendon reflexes are more brisk on the left and a Babinski sign is present on the left as well. Coordination is intact on the right. Coordination on the left and gait are not tested.

Labs: CBC and electrolytes are normal. Glucose is slightly elevated. CT scan of his head is normal.

He is hospitalized for observation. The next day, his left-sided weakness and neurologic abnormalities on exam have resolved. An EEG reveals centrotemporal spikes. After a discussion with his parents, it is decided to discharge him on no anticonvulsant medications. It is concluded that his lethargic episode was due to an unwitnessed seizure with subsequent post-ictal drowsiness.

A second nocturnal seizure occurs a year later, and he is started on carbamazepine. Over the next two years, he experiences no further seizures. He is treated until age 12 when his medication is weaned off and he does well thereafter.

A seizure is a sudden, involuntary, stereotypical, repetitive alteration in behavior, including a change in motor activity, in autonomic function, in consciousness, and/or in sensation, which is caused by hypersynchronous discharges from a group of cerebral neurons (1,2). Epilepsy is a condition in which an individual is predisposed to recurrent seizures because of a central nervous system disorder (although about two-thirds have no identifiable cause). Recurrent seizures are the symptomatic expression of underlying brain pathology, not a disease in the usual sense (3).

While all people with epilepsy have seizures by definition, not everyone who has a seizure has epilepsy. Four to six percent of all children will have at least one seizure in the first 16 years of life; however, most of these are benign febrile seizures, and the cumulative risk of epilepsy during this time is only about 1-2% (4,5). In other words, less than one third of children who experience a seizure ever develop epilepsy. Over one half of first-time seizures are simple febrile seizures (see the chapter on febrile seizures) and another third are single isolated seizure events or seizures associated with a non-epileptic medical illness. Overall, about half of the lifetime risk of

developing epilepsy is realized during the pediatric period, and it is the most common chronic neurologic disorder seen in children. Rates are highest during the first year of life.

As described, seizures are the clinical manifestations of epilepsy. Although other clinical manifestations may also be relevant, such as the neurologic exam, development, etc., this chapter will focus on general classifications and characteristics of epileptic seizures as proposed by the International League Against Epilepsy. Patients with epilepsy usually have a characteristic seizure type although some may have combinations of the following seizure types. The simplest classification is partial versus generalized. Partial seizures can be simple or complex. Generalized seizures can be absence or tonic-clonic. More classifications exist, but this chapter will focus on these four basic categories.

Partial or focal seizures are often caused by identifiable focal brain lesions which are related to the seizure activity expressed. They may be associated with an aura which is an altered sensation heralding or characterizing partial seizure activity. Any partial seizure can secondarily generalize into a tonic-clonic seizure which is discussed further below.

A simple partial seizure does not have an associated alteration of consciousness. Seizure manifestations may include tonic and/or clonic motor activity (e.g., originating from a contralateral motor cortex lesion), somatosensory phenomena (e.g., feeling a breeze, seeing light flashes, hearing buzzing, smelling odors, sensation of vertigo), and/or autonomic symptoms (e.g., gastric sensations, sweating, flushing). Of these, partial tonic-clonic seizures are the easiest to recognize. The others may be attributable to some other process and thus, are frequently not diagnosed as seizures.

Complex partial seizures also have focal origins but include an impairment of consciousness which implies alteration of functioning in the mesial temporal lobes, orbito frontal lobes, or in more widespread areas of the brain. The impaired consciousness is usually associated with a lack of understanding and memory of the brief event. They may involve more complicated behaviors such as frantic running, uncontrollable laughing, partial undressing, or facial automatisms. Partial complex seizures used to be called temporal lobe seizures because they often originate in the temporal lobes. Partial complex seizures also used to be called psychomotor seizures because they frequently include behavioral symptoms (e.g., auras, fear, déjà vu, facial grimacing).

Generalized seizures typically involve a loss of consciousness and/or a stereotypic motor activity. Absence seizures involve a few seconds of impairment of consciousness with eye blinking or staring which may occur as clustered events. Myoclonic seizures are usually seen in specific epilepsy syndromes and involve quick muscle jerks usually without associated impairment of consciousness. Tonic, clonic, or tonic-clonic seizures involve the abrupt onset of the described muscle activity for several minutes, often followed by post-ictal confusion and fatigue. Atonic seizures involve a sudden loss of postural tone, usually resulting in an abrupt collapse, which may not have any loss of consciousness. Generalized absence seizures are still sometimes called by their old name, petit mal seizures. These occur most commonly in the elementary school age group. Generalized tonic clonic seizures are still sometimes called by their old name, grand mal seizures.

Epileptic Seizure Classifications (1,5)

I. Partial
   A. Partial simple: Previous names include partial elementary seizures, focal motor seizures. Typical onset at any age.
   B. Partial complex: Previous names include temporal lobe seizures, psychomotor epilepsy. Typical onset at any age.
   C. Partial with secondary generalization: Previous names include Jacksonian march. Typical onset at any age.

II. Generalized
   A. Generalized tonic clonic: Previous names include grand mal seizures. Typical onset at any age.
   B. Generalized absence: Previous names include petit mal seizures. Typical onset at elementary school age.
   C. Other types including: myoclonic, tonic, clonic, atonic (akinetic, drop attacks).

III. Epilepsy syndromes: Seizure syndromes including: infantile spasms (also known loosely as West's syndrome, Salaam attacks, hypsarrhythmia on EEG), benign epilepsy of childhood (Rolandic), Lennox-Gastaut, and juvenile myoclonic epilepsy.

The differential diagnosis of seizures requires consideration on several levels. The first question needing to be answered is whether a seizure truly occurred. The history of the event may classically characterize seizure activity, or a patient may present in status epilepticus (see chapter on status epilepticus), in which case the answer to this question is clear. However, often times with non-medical personnel observing what seems to be seizure activity and the emotional anxiety that accompanies it, whether a seizure truly occurred may be unclear. Phenomena which may seem to be partial seizure-like activity include: tics, paroxysmal REM sleep behavior, benign sleep myoclonus (jerks as one falls asleep), night terrors, migraine, and benign paroxysmal vertigo. Phenomena which may seem to be generalized seizure-like activity include: syncope, breath-holding spells, panic attacks, psychogenic seizures/pseudoseizures/conversion reaction, gastroesophageal reflux, staring spells, and startle reflexes (infants).

Syncope is a common presentation which may be mistaken for a seizure. In general, syncope tends to be more gradual in onset, may be posturally related, and is without post-event focal neurologic findings or confusion. Seizures, however, are usually associated more with an abrupt onset, secondary injury, and may have post-ictal confusion, headache, incontinence or focal neurologic signs (e.g., Todd paralysis) as well as an abnormal EEG. Syncope may have some brief clonic or myoclonic extremity movements associated with it which can add to the confusion between the two types of events. In general, most true seizure motor activity does not have a reproducible trigger (e.g., a slamming door) and if the seizing body part is restrained, the seizure activity will persist.

If a seizure did occur, an important second question to be determined in evaluating a seizure is whether there were acute and reversible provocative causes such as: excessive stimulant medication or stimulant drug abuse, withdrawal from sedative drugs or alcohol, high fever (see chapter on febrile seizures), hypoglycemia, electrolyte imbalance (e.g., sodium, calcium, magnesium), hypoxia, or hypertensive encephalopathy. Answers to this question will play a pivotal role in selecting immediate therapy and determining future prognosis. Although a patient may have more than a single seizure attributed to these problems, these types of seizures would not typically be classified as epileptic.

A third question to be answered in the evaluation of what is determined to be a first-time, not acutely reversible seizure, is whether further seizures are expected to occur. This includes an evaluation to determine if the seizure is symptomatic of other pathology and could result in recurrent seizures (i.e., symptomatic epilepsy). These include the following:

Vascular etiologies:
- Arteriovenous malformation
- Aneurysm, subarachnoid hemorrhage
- Stroke
- Venous thrombosis
- Blood dyscrasias (eg sickle cell anemia)
- Vasculitides (e.g., SLE)

Infectious etiologies:
- Abscess
- Encephalitis, meningitis
- Rasmussen's syndrome (presumed viral)

Tumors and Congential etiologies:
- Heterotopias (refer to the chapter on developmental brain anomalies)
- Cortical dysplasias
- Neurocutaneous syndromes (e.g., Sturge-Weber, Neurofibromatosis, Tuberous Sclerosis, Ataxia-Telangiectasia, von Hippel-Lindau)
- Other intracranial neoplasms

Traumatic etiologies:
- Prenatal and perinatal (refer to the chapter on neonatal seizures)
- Child abuse
- Other head injuries

Less than 50% of patients with epilepsy have an identifiable cause. Those without a known underlying pathology are described as "cryptogenic" (likely an undetectable pathologic explanation) or "idiopathic" (presumed genetic) (1,4). Further consideration is also required to determine whether the seizure may be part of an epileptic syndrome which, by definition, would imply expected recurrent seizure activity without treatment. Epileptic syndromes in pediatrics are defined by known ages of onset, seizure patterns, EEG findings, and/or prognosis. These include: benign neonatal familial convulsions, infantile spasms (West's syndrome), benign childhood epilepsy with centrotemporal spikes, childhood epilepsy with occipital spikes, childhood absence, juvenile myoclonic epilepsy, and the Lennox-Gastaut syndrome. With all that has been mentioned, there are still numerous other epilepsy syndromes as well as combinations of seizures and EEG patterns which may not fit into the categories noted above.

All seizures involve abnormal paroxysmal hypersynchronous neuronal excitation. Cerebral manifestations include increased blood flow, increased oxygen and glucose consumption, and increased carbon dioxide and lactic acid production. If a patient can maintain appropriate oxygenation and ventilation, the increase in cerebral blood flow is usually sufficient to meet the initial increased metabolic requirements of the brain; however, prolonged seizures may result in permanent neuronal injury (2).

Systemic manifestations of massive sympathetic discharge may occur with seizures and include: pulse increase, BP increase, pupil dilatation, and increased blood glucose. Salivation may increase secondary to parotid stimulation with masseter muscle contraction. Respirations may cease or be irregular and the patient may have facial cyanosis due to a tonic increase in intrathoracic pressure and impeded venous return associated with maximal muscle group contractions. Failure of adequate ventilation can lead to hypoxia, hypercarbia, and respiratory acidosis. Prolonged skeletal muscle activity can lead to lactic acidosis, rhabdomyolysis, hyperkalemia, and hyperthermia.

Postictally (after the seizure event), effects of the massive neuronal depolarization and metabolic activity may include confusion, lethargy or a comatose state. Vomiting may occur, and patients with impaired consciousness may be unable to protect their airway and are at risk for aspiration. Impaired consciousness may also be associated with airway obstruction from the tongue or respiratory secretions. Head trauma may have precipitated a seizure event, but traumatic falls may also occur interictally and contribute to postictal altered mental status and other injuries.

Transient postictal focal deficits, e.g., Todd paralysis (transient paralysis which occurs after a seizure), may occur, but typically do not last beyond 24 hours. The mechanism is not well understood, but it may be attributed to neuronal dysfunction or neurotransmitter exhaustion. The duration and severity of the seizure do not correlate with the degree of postictal paralysis, and the paralysis is usually, but not always, noted in the area of the focal seizure activity (6).

Systemically in the postictal state, deep respirations may be present to compensate for respiratory and metabolic acidosis, and blood pressure and temperature quickly return to normal. Due to the catecholamine surge noted above, patients are usually mildly hyperglycemic. Headache and muscle soreness may also occur in association with muscle fatigue and acidosis.

The diagnosis of epileptic seizures involves determining: 1) if seizures occurred, 2) the type of seizures, 3) the cause of the seizures, and 4) if they are characteristic of an epileptic syndrome. Furthermore, any life-threatening causes of seizures (e.g., intracranial hemorrhage, meningitis/encephalitis, toxic ingestions), should be ruled-out or addressed in a timely fashion.

The history is the most important part of the diagnostic evaluation of a patient's seizure disorder. This may include:

Source: Reliable witnesses?

HPI: Seizure or not seizure? If a seizure, what type? Any complications?

Etiology: Provoked (trauma, drugs, fever)/unprovoked? Underlying seizure disorder, history of previous seizures or other neurologic disorder? If on an anticonvulsant drug (anti-epileptic drug or AED), has there been a change in dosing/compliance? Other signs of systemic illness or reasons for provocative causes: headache, vomiting, diarrhea, ataxia, altered mental status.

Onset: Prodromal symptoms (aura)? Rapid/gradual?

Characteristics: Partial/generalized? Duration (see chapter on status epilepticus if prolonged)? Evolution, motor activity of head, eyes, face, trunk, extremities, other complicating factors (cyanosis, trauma, emesis).

Postictal state: Incontinence, confusion/sleepy, headache, focal neurologic deficits, time to recovery of normal function (nearly immediate for syncope, minutes to hours for postictal, but usually less than 24hours)?

Past medical history (predisposing factors): Chronic illnesses (endocrine, hepatic, neoplastic, renal), history of seizures, CVA, CNS infection, autoimmune disease, head trauma, medications.

Development: Appropriate for age?

Family history: Seizures, epilepsy, neurocutaneous syndromes, other neurologic disorders?

Social history: Risk of physical abuse? Drug/alcohol abuse?

Physical examination should note the following: General appearance (dysmorphic features, associated injury pattern, signs of infection), vital signs, growth and head circumference percentiles, head (trauma, VP shunt), eyes (pupils, papilledema, retinal hemorrhages, angiomatosis, pigmentation), ears (hemotympanum, otitis media), nose (CSF rhinorrhea), mouth (drooling indicates aspiration risk, tongue laceration is suggestive of a seizure), neck (injury, meningeal signs), lungs (aspiration pneumonia), heart (rhythm abnormalities, congenital heart disease), incontinence, extremities (injuries), and skin (trauma, neurocutaneous stigmata). Neurologic evaluation should include: time to recovery, retrograde amnesia, speech difficulty, cranial nerves function, herniation signs, posturing, postictal deficits such as Todd paralysis, sensory loss, pathological reflexes, coordination or gait changes

Diagnostic tests for seizures are usually low-yield without historical or exam findings to suggest possible abnormalities. Routine screening labs, depending on the setting, may include electrolytes, glucose, Ca and Mg. Hyponatremia and hypoglycemia can cause seizures, whereas hypocalcemia and magnesium abnormalities resulting in hypocalcemia may cause tetany which resembles seizures. If the patient is on chronic AEDs for seizure control, then obtaining blood levels provides valuable information regarding compliance, drug efficacy, and possible toxicity. CBC, BUN/Creatinine, liver function tests, and PT/PTT are particularly of low yield unless the clinical circumstances suggest a specific problem related to these. An ABG, CPK, potassium and bicarbonate may have some benefit if the seizure was prolonged (see chapter on status epilepticus) and if there is a risk of rhabdomyolysis. Drug screens may be considered based on the social history. Toxicology can be used to screen for cocaine, amphetamines, PCP, TCA (tricyclic antidepressants) as well as possible withdrawal from benzodiazepines, alcohol, and barbiturates. Other drugs in overdose may cause seizures such as antipsychotics, methylxanthines, INH, antihistamines, and narcotics. If brain hemorrhage or infection is suspected, a lumbar puncture is indicated once elevated intracranial pressure (ICP) has been ruled out by history, exam, and possibly an imaging study.

Structural imaging studies of the brain, computed tomography (CT) and/or magnetic resonance imaging (MRI), are typically indicated in afebrile seizures and non-simple febrile seizures of unclear etiology. An emergent CT scan may be indicated in the following situations: 1) signs of symptoms of elevated ICP, 2) focal seizure or persistent focal neurologic deficit, 3) seizures with head trauma, 4) status epilepticus of unclear etiology. The CT is appropriate for detection of intracranial vascular lesions, acute bleeding and certain tumors larger than 1 cm. The MRI has better resolution for smaller and isodense lesions (e.g., low-grade gliomas). MRI may also provide better images in some areas (e.g., posterior fossa) and for some lesion types (e.g., neuronal migration disorders, lesions of neurocutaneous syndromes, AVM). The trade-off with MRI is that it is typically more difficult to schedule acutely, they take more time to complete and they require deeper sedation levels for young children. 50% or more of neuroimaging studies may be normal in patients with epilepsy (5).

The electroencephalogram (EEG) is a crucial tool in the diagnosis of seizures. It consists of a systematic measurement of electric potentials emanating from the brain's cortical surface which are less than 1/100th that of cardiac voltage on ECG. Numerous channels are recorded simultaneously from standard electrode placements to map brain electrical activity. Potentially provocative maneuvers (procedures known to provoke seizure potentials) known as activation procedures, such as hyperventilation, photic stimulation (e.g., blinking lights), and spontaneous sleep induction and emergence are employed to increase the yield of positive EEG findings by helping to trigger seizure potentials during the study. Because epileptiform activity may be present only at brief intervals, only 50-60% of routine EEGs are positive even in patients with known epilepsy. Activation procedures increase this yield. Seizure activity on EEG does not always accompany a visible seizure clinically. In general, although normal EEGs have low utility because they may be falsely negative, positive findings can be very helpful in determining the presence and classification of epilepsy to help direct treatment.

There are a wide variety of positive EEG findings. The classic epileptiform EEG abnormality is the sharp spike or wave which may be focal or generalized. Generalized spiking is usually large and obvious, while focal spikes (especially temporal lobe spiking) may be smaller and more subtle to see. Focal spikes or waves may help define an epileptic syndrome (e.g., benign childhood epilepsy with centrotemporal spikes). Other generalized patterns may also be definitive such as the 3-per-second spike and slow waves of childhood absence epilepsy (petit mal). Other mixtures of signals may also display characteristically defined patterns such as the mixture of spikes and slow waves that are different in each hemisphere described as hypsarrhythmia which is typical of infantile spasms. Postictal slowing may suggest a previous epileptic event if similar changes are not seen in a preseizure EEG. After a diagnosis of epilepsy is made, follow-up EEGs may sometimes be helpful in assessing response to therapy.

The yield on an EEG is dependent on multiple factors. Increasing positive findings with provocative measures was discussed previously. False negative results can be associated with epileptogenic foci that are deep to the cerebral surface, discharges that are orthogonal to the cerebral surface, excessive muscular artifact, or simply due to limitations in monitoring duration in comparison with the frequency of epileptiform EEG activity. Although there may be a variety of other abnormal EEG findings, such as focal slow waves or asymmetries of signals, they are non-specific regarding a diagnosis of epilepsy and are more useful in providing general information about cerebral function, encephalopathies, focal lesions, etc.

Epileptic seizure classifications by EEG are generally as follows: Partial simple seizures display spikes in a localized portion of the brain. Partial complex seizures display small spikes, usually in the temporal lobes. Partial seizures with secondary generalization demonstrates focal spikes progressing to generalized spiking. Generalized absence seizures display a 3 per second spike and slow wave pattern which is often precipitated by hyperventilation. Generalized tonic-clonic seizures display generalized spiking (photic stimulation may be a useful activation procedure). Infantile spasms, sometimes seen in severe developmental brain anomalies and tuberous sclerosis, display a hypsarrhythmia pattern (disorganized mixture of spikes and slow waves, different in each hemisphere). Benign epilepsy of childhood (Rolandic seizures) displays centrotemporal spikes or sharp waves ("Rolandic discharges") against a normal background. The Lennox-Gastaut syndrome displays slow spike and waves on an abnormal slow background.

Therapy for the acutely seizing patient is described in the chapter on status epilepticus. The decisions on whether to start chronic anti-epileptic drug (AED) therapy involves weighing risks and benefits of therapy with an in-depth discussion with the patient and family. If a seizure occurs secondary to an acutely reversible provoking factor (e.g., fever, hyponatremia, hypoglycemia, benzodiazepine withdrawal, post-impact, etc.), the treatment is directed toward the underlying cause. Short-term anti-seizure medication is used as needed, but no long-term anticonvulsant medication is typically employed.

Chronic therapy with AEDs should be started for seizures associated with any known structural lesion (e.g., brain tumor, AVM, intracranial bleeding, or infection such as HSV encephalitis). If there is no known underlying pathology, chronic AED therapy is also indicated for seizures associated with: 1) A family history of epilepsy in siblings (but not if in parents), 2) EEG with definite epileptic pattern, 3) History of prior acute unprovoked seizure(s), 4) Status epilepticus at onset, or 5) Remote history of head trauma, stroke, CNS infection, or static encephalopathy from birth with mental retardation or cerebral palsy. All of these factors suggest a higher risk of recurrence. The decision to start chronic AED therapy is less clear if there is a first-time unprovoked seizure without the above risk

factors. The risk for a second seizure in five-years is approximately 30% whereas it is approximately 46-73% for a seizure with any one of the above risk factors (7). The risks/costs of treatment include the side-effect profile of the intended AED, financial cost, impact of implementation on daily routine, and the chance that even with good compliance, the medication may not definitively prevent a seizure recurrence. For example, if a child's first seizure occurs at age 6 years, it is difficult to predict whether the next seizure will occur, tomorrow, next year, in another 6 years, or never at all. It is not beneficial for children to take daily medication for years to prevent an incident that may not be destined to occur during that time period.

The benefits of treatment include reducing the risk of recurrent seizures and their potential consequences such as associated injury, effects on self-esteem, and numerous restrictions such as loss of driving license privileges. In general, AED therapy is not indicated for the child who experiences a brief first seizure if the history confirms that the episode is truly an initial event, there is no family history of epilepsy, the neurologic examination is normal, and the EEG does not confirm a specific epileptic syndrome. The patient must be educated about the risk of subsequent seizures and should be advised about state driving regulations (8).

The initial selection of AED is typically based on seizure type. Carbamazepine (Tegretol) and phenytoin (Dilantin) are considered the initial medications to consider in all partial seizures and in generalized tonic-clonic seizures (with the exception of infants). Infants are usually treated with phenobarbital, since this drug is less toxic and the other drugs have some unattractive characteristics in infants such as poor GI absorption, poor oral formulations, etc. Generalized absence seizures are treated with ethosuximide (Zarontin). Valproic acid (Depakene, Depakote) may be effective both for partial and generalized seizures including absence seizures, but it is typically used only if initial therapy is not successful due to its side-effect profile. Oral benzodiazepines are also used as AEDs in some instances, usually in combination with other AEDs. Other newer AEDs cleared by the FDA since 1993 include felbamate, gabapentin, lamotrigine, topiramate, tiagabine, oxcarbazepine, zonisamide (9). The reader is referred to the reference list for further information on these medications and therapy for other epileptic syndromes. Approximately 80% of all persons with primary generalized seizure epilepsy and 65% of patients with partial seizure epilepsy achieve satisfactory control of seizures with AED therapy (10). The indications, pharmacology, and adverse effects of carbamazepine, phenytoin, phenobarbital, and valproic acid will be discussed briefly:

Carbamazepine is a first-line AED for the treatment of simple partial, complex partial, and general tonic-clonic seizures. The mechanism of action of carbamazepine is thought to be through use-dependent blockade of voltage sensitive sodium channels which results in stabilization of neuronal membranes and inhibition of repetitive firing of neurons. It may be orally or rectally absorbed, has a half-life of 12 to 17 hours and is extensively metabolized in the liver via the cytochrome P450 system. Dose-related side effects of carbamazepine include vertigo, ataxia, diplopia, and drowsiness. Approximately 4% of people treated with carbamazepine develop dermatologic reactions including erythematous and pruritic rashes, toxic epidermal necrolysis, erythema multiforme and Stevens-Johnson syndrome. The onset is usually within the first month of treatment but can be delayed up to 6 months. Serious blood dyscrasias, such as aplastic anemia and agranulocytosis have been reported, and although rare, occur at a frequency 5 to 8 times higher than that of the general population (11).

Phenytoin is used for the treatment of simple partial, complex partial, and generalized tonic-clonic seizures. The mechanism of action is similar to carbamazepine by use-dependent blockade of voltage-sensitive sodium channels. Phenytoin may be administered orally or intravenously. Because intravenous infusion rates of phenytoin are limited due to associated cardiac side-effects, fosphenytoin (an ester of phenytoin which is cleaved to phenytoin in the body) is commonly used for emergent loading (refer to the status epilepticus chapter). Phenytoin is metabolized in the liver in a concentration dependent, non-linear fashion. As a result, the half-life and time to steady state are dose dependent. Dose related side effects include nystagmus, ataxia, sedation, mental status changes, ophthalmoplegia and increased seizure frequency. Cosmetic side effects, including gingival hyperplasia, hirsutism and acne, are commonly seen and can be barriers to compliance in adolescent patients. A rash is the most common idiosyncratic reaction seen in 5-10% of people treated with phenytoin. It is typically morbilliform, may be accompanied by fever, and usually occurs in the first 3 months of treatment. Serious side effects such as agranulocytosis, aplastic anemia, hepatitis, and nephritis are rare (11).

Phenobarbital is frequently used in the treatment of neonatal seizures (see chapter on neonatal seizures) and seizures that occur in the first year of life. It is effective for both generalized tonic-clonic seizures, and partial seizures at all ages, but unfavorable cognitive side effects and concerns about the potential for adverse effects on the developing brain limit its use. Phenobarbital acts by various mechanisms including potentiating inhibitory neurotransmission by increasing the duration of time that gamma-aminobutyric acid (GABA) mediated chloride channels remain open. It is absorbed enterally and can also be given intravenously or intramuscularly. Phenobarbital is metabolized in the liver by the cytochrome P450 system, and it can induce the rate of metabolism of itself and other drugs that are metabolized thought this system. The clearance of phenobarbital is slow, with a half-life of 1 to 5 days. The dose-related adverse effects of phenobarbital include sedation, slowed thinking and ataxia. In children, however, paradoxic irritability and hyperactivity are also common side effects. (11).

Valproic acid has a broad spectrum of AED activity which includes generalized seizures such as myoclonic, tonic, atonic, absence, generalized tonic-clonic seizures and partial onset seizures. The mechanism of action of valproic acid is not completely understood. It has several different actions in vitro which may contribute to its AED effect including enhanced GABA-mediated inhibition and blockage of voltage-activated sodium currents. Valproic acid is orally administered, hepatically eliminated, and has a half life of 8 to 9 hours. Dose-related adverse effects of valproic acid include tremor, sedation, fatigue, and ataxia. Valproic acid can produce local gastrointestinal irritation that can lead to abdominal pain, nausea, diarrhea, or pancreatitis. Potentially fatal hepatotoxicity has been observed, usually within the first 6 months of therapy, and typically in children under 2 years of age. Valproic acid should be used with caution in women of child bearing age due to its teratogenic effects and association with polycystic ovaries (11).

All of the above AEDs have extensive protein binding and are hepatically metabolized. As a result, their levels are significantly affected by conditions and other medications which may affect protein binding and hepatic enzyme function.

Reasons for failure to respond to single AED therapy include noncompliance, inadequate serum AED levels, incorrect classification of seizure type, and continued exposure to seizure precipitants. If AED therapy is changed, the transition should include a slow wean off the original AED. If two trials of AEDs as monotherapy are ineffective, the chances of obtaining seizure control with additional medication trials are less than 15% (5). Trials of combinations of AEDs with different mechanisms of action are is also an alternative although this increases the risk of drug-drug interactions. About 30% of all patients with epilepsy continue to have seizures that appear to be resistant to all pharmacologic manipulations (1,4).

Nonpharmacological therapies for seizure control are usually reserved for medically refractory cases of epilepsy. These modalities include epilepsy surgery, vagus nerve stimulation, and the ketogenic diet.

Epilepsy surgery may be considered for patients with medically refractory seizures that interfere significantly with their lifestyle. Medical refractoriness is not well defined, but it can generally begin to be considered when seizures continue despite adequate monotherapy trials of two AEDs. Patients with simple partial seizures alone are generally not considered for surgery because the risk is likely to exceed the benefit. However, patients with complex-partial seizures or generalized motor seizures occurring as infrequently as once every few months can be candidates if these sufficiently impede academic or job performance, driving, and employment opportunities (12). Epilepsy surgery is contraindicated in children with benign focal epilepsy of childhood, idiopathic generalized epilepsy, and progressive medical or neurologic disorders (12). Presurgical evaluation is focused upon delineation of the epileptogenic zone (the region of cortex capable of generating seizures). The evaluation includes clinical history, ictal and interictal video, EEG, possibly invasive EEG, neuroimaging (MRI, SPECT, PET, magnetic resonance spectroscopy), and neuropsychologic assessment. A recommendation for surgery is made when the epileptogenic zone has been adequately defined, and the proposed procedure is believed to be associated with a high likelihood of seizure relief and a low risk of neurologic and cognitive morbidity (12).

The types of surgery performed in patients for refractory epilepsy included corticectomy, lobectomy, lesionectomy, hemispherectomy, corpus callosotomy, multiple subpial transection, and newer procedures including gamma knife surgery and deep brain stimulation (11). Early consideration for surgery is important to capitalize on the plasticity of the developing brain and to minimize losing developmental and behavioral milestones.

Vagus nerve stimulation (VNS) is FDA approved for use as adjunctive therapy for adolescents over 12 years of age and adults whose partial-onset seizures are refractory to AEDs (1,5). These patients are also usually not epilepsy surgery candidates. The mechanism of action of VNS is uncertain. A generator is placed surgically and it delivers programmed electrical pulses which may help to interrupt seizures or reduce seizure severity. Patients who experience auras warning them of an impending seizure can stop or shorten the length of the seizure by activating the VNS.

The ketogenic diet is a high fat, low protein and low carbohydrate diet used to treat intractable epilepsy. It was originally developed in the 1920s at the Mayo Clinic and was widely used until the 1940s when more effective and easier to use AEDs were developed. The ketogenic diet is still used by some neurologists today; however mostly for children who endure multiple daily seizures. The diet places the body in a state of starvation which forces it to utilize more fat than usual for energy, which results in more ketone by-products (hence the name "ketogenic") which serve as an alternative energy source for the brain. The exact mechanism for the ketogenic diet's efficacy is unclear, and it is on the FDA list of "experimental treatments" (1).

Lifestyle factors can contribute to seizure control and attempts should be made to manage them while encouraging normal development. Some lifestyle modifications may include: 1) Taking chronic AED medications regularly. 2) Getting enough sleep, avoiding alcohol, drugs other interacting medications. 3) Emergency plan of access to medical care, medical condition identification bracelet, and possibly rectal diazepam to be used in an emergency for a prolonged seizure. 4) Ongoing monitoring of AED levels, side-effects, adequacy of seizure control. 5) Ongoing monitoring of development, school performance. 6) Water and fall precautions. 7) Restrictions, especially as they relate to a driver's license. 8) Maintaining previous normal activity and disciplinary measures as much as possible and avoiding over-protection.

About 60-70% of patients with newly diagnosed epilepsy enter long-term remission, usually on a single AED. Patients who remain seizure-free for several years may be considered for weaning off AED therapy. Factors affecting the decision to wean AEDs and when to do this depend primarily on the type of epilepsy syndrome present (e.g., benign epilepsy with centrotemporal spikes tends to be "outgrown" while a structural lesion such as a brain tumor or AVM may have a perpetually high risk of seizures despite good control). Other factors that favor successful withdrawal include: single type of seizure, normal neurologic examination, normal IQ, and normal EEG following treatment. The benefits of withdrawal (freedom from daily medication, reduction of side effects, decreased risk of teratogenic effects) must be balanced against an approximately 20-30% probability of seizure recurrence (with possible loss of job, injury, effects on self-esteem) (1). If the decision to discontinue AED therapy is made, the medication should be gradually weaned over weeks to months to avoid withdrawal seizures.

Short occasional seizures are not felt to be associated with additional brain injury of long-term significance. About 30% of patients with epilepsy continue to have seizures that appear to be resistant to all pharmacologic manipulations (7). The response to the first AED is the most powerful predictor of long-term prognosis. Presuming that the correct type of seizure was diagnosed and therapeutic levels of the correct AED are obtained, a patient may be considered to have refractory epilepsy if seizure control is not achieved after the first two to three AEDs used. These patients are usually treated with multiple AEDs, which in combination, may produce sedative and adverse behavioral effects. However, high seizure frequency, prolonged seizures, and episodes of status epilepticus can lead to cognitive decline. In some patients, excessive seizure activity may be associated with detrimental cerebral histologic changes such as dendritic sprouting, synaptic reorganization, glial proliferation, and cell death (7). Also associated with AED toxicity and/or excessive seizure activity are psychosocial dysfunction, poor academic achievement, diminished self-esteem, dependent behavior, and a restricted lifestyle.

In the case at the beginning of the chapter, a developmentally normal boy with no personal or family history of seizures has an acute event that is suggestive of a seizure given its abrupt onset and description, as well as the persisting focal neurologic deficit which gradually resolves (which is likely a Todd paralysis). The exam finding of a tongue laceration is also suggestive of a seizure. The transient left hemiplegia and hyperreflexia are consistent with a Todd paralysis. The elevation in blood glucose is postictal hyperglycemia. The CT was indicated due to persisting focal neurologic deficits in the patient although he did not have a history suggestive of trauma, infection, or focal structural lesions.

The patient is appropriately hospitalized for observation given his persisting neurologic deficit. The EEG confirms the diagnosis of benign Rolandic epilepsy with centrotemporal spikes, an idiopathic epileptic condition with characteristic EEG findings. Given this diagnosis and the fact that the patient experienced a first-time seizure, observation without AED therapy is reasonably employed. Although he has a recurrent seizure, he does well on carbamazepine. He is successfully weaned off therapy after adolescence which is consistent with the good prognosis of this particular epileptic syndrome.

Questions

1. List 4 basic types of seizures (hint: two are partial and two are generalized).
2. List some of the old names that correlate to each of the above 4 seizure types and indicate the reason these old names were used.
3. A 14 year old girl is found unconscious. Witnesses say that she had some facial twitching. She gradually awakens and tells you that she smelled some burning rubber just prior to feeling faint. She tried to call for help, but couldn't speak. She now seems to be normal. A CT scan demonstrates a left temporal lobe arteriovenous malformation. What seizure type is she likely to have had and why?
4. Can the term petit mal be used to describe a seizure of small jerking movements of one arm?
5. Name some tests/studies which would be ordered for a 7 year-old girl who presents to the emergency department actively having a generalized seizure which stops spontaneously. She is afebrile and was brought in by her babysitter who is unaware of any history except that she may have been on some kind of medicine.
6. Why would an eventual MRI be useful for the patient in questions 5 if there are no obvious reasons for the seizure?
7. If a patient has no epileptiform activity on an EEG does that rule-out epilepsy? Why?
8. What are typical EEG findings in generalized absence seizures? In infantile spasms?
9. What AEDs (anti-epileptic drugs) are used for treatment of generalized absence seizures?
10. What percent of children with epilepsy eventually enter long-term remission? What percent of children with epilepsy never become seizure free on AEDs?

Answers to questions

1. Partial simple (also called "partial elementary" or "focal motor"), partial complex, generalized tonic-clonic, generalized absence.
2. Focal motor seizures (partial simple) because only one part of the body exhibits tonic clonic seizures. "Jacksonian seizures" describe focal motor seizures, while "Jacksonian march" describes a partial simple with secondary generalization because of gradual spread of motor activity. Temporal lobe epilepsy (partial complex) due to lesions in the temporal lobe. Psychomotor seizures (partial complex) because they display behavioral changes in addition to facial motor abnormalities, such as twitching and grimacing. Grand mal (generalized tonic-clonic) because they exhibit grand abnormalities as manifested by generalized jerking. Petit mal (generalized absence) because they exhibit smaller abnormalities limited to the eyes and face in most instances, and also because these patients are generally in elementary school and thus petit in size.
3. Partial complex seizures. She has experienced an aura (burning rubber smell). The witnesses suggest mostly facial motor symptoms. She lost consciousness. The temporary expressive aphasia suggests a temporal lobe origin which is confirmed on CT scan which identifies a lesion in the left temporal lobe (which is why this used to be called temporal lobe seizures). Students will often confuse this presentation with generalized absence seizures, which usually occurs in elementary school aged children who have just a few seconds of impaired/loss of consciousness. This is not a partial simple seizure because there are motor, aura, aphasia and olfactory symptoms, in addition to loss of consciousness.
4. No, petit mal refers to generalized absence seizures. Jerking of one arm (even if they are small jerks) are partial simple seizures (focal motor), not generalized absence (petit mal).
5. Electrolytes, glucose, toxicology, AED levels, CT of the head, lumbar puncture would be a basic set of initial tests. An eventual EEG would be in order if no obvious precipitating factors were found.
6. The MRI has better resolution for smaller and isodense lesions (e.g., low-grade gliomas). MRI may also provide better images in some areas (e.g., posterior fossa) and for some lesions types (e.g., neuronal migration disorders, lesions of the neurocutaneous syndromes, AVM).
7. No, a negative EEG does not rule out epilepsy. False negative results can be associated with epileptogenic foci that are deep to the cerebral surface, discharges that are orthogonal to the cerebral surface, excessive muscular artifact, and simply due to limitations in monitoring duration in comparison with the frequency of epileptiform EEG activity. Of all the seizure types, partial complex seizure foci are the most difficult to reliably identify on EEG.
8. Generalized absence seizures typically have a generalized 3 per second (Hertz) spike and slow wave EEG pattern, often provoked by hyperventilation. Infantile spasms have a hypsarrhythmia pattern on EEG which has an asymmetric disorganized mixture of spikes and slow waves.
9. Ethosuximide and valproic acid are used to treat generalized absence seizures.
10. 60-70% of children with epilepsy eventually have good seizure control on AEDs and enter into long-term remission, but 30% will never become seizure free on AEDs.

Chapter XVIII.5. Status Epilepticus

Loren G. Yamamoto, MD, MPH, MBA

A 6 year old male is noted by his mother to have a generalized tonic clonic seizure. He is unresponsive and his eyes are rolled up. She tries to blow on his face and shake his shoulders, but the seizure continues. His face is turning blue so she calls 911. The sequence of events proceeds as below:

Time 0: Onset of seizure.
Time 3 minutes: Mom calls 911 (activating EMS).
Time 12 minutes: Ambulance arrives at home.
Time 14 minutes: Ambulance crew at the patient's side. Oxygen saturation 80%. Patient still seizing.
Time 20 minutes: Mask ventilation with oxygen, IV started. Oxygen saturation improves to 95%.
Time 25 minutes: Lorazepam 0.1 mg/kg IV given. Patient being transported, treatment en route. Oxygen saturation is now 100%.
Time 31 minutes: Patient arrives in the emergency department, still seizing.
Time 33 minutes: Lorazepam 0.1 mg/kg IV repeated.
Time 34 minutes: Phenytoin or fosphenytoin 10 minute infusion started (larger patients may require longer infusion times).
Time 44 minutes: Patient still seizing so another anticonvulsant such as phenobarbital is administered.
Time 54 minutes: Seizures continue.

Status epilepticus is defined as prolonged seizures which continue or occur in rapid succession with relatively brief intervals in between. A minimum time duration is not part of a universal definition. The most severe form of SE is generalized tonic clonic SE which results in respiratory compromise (hypoxemia and hypercapnia), with hypermetabolic cerebral activity (excessive cerebral oxygen demand). This results in respiratory and metabolic acidosis. Skeletal muscle contraction may result in rhabdomyolysis and hyperkalemia. Other forms of status epilepticus may not be as obvious. Partial complex SE and absence (petit mal) SE, are less common and may be difficult to recognize. The discussion in this chapter will focus on generalized tonic clinic status epilepticus.

Status epilepticus may be due to several causes. Patients with epilepsy or brain anomalies may present with SE, or they may have breakthrough seizures presenting with SE. SE can also result from periods of anticonvulsant non-compliance. SE may be due to encephalitis or other brain infections. SE may be due to drug overdose toxicity (e.g., isoniazid), traumatic brain injury, neoplastic conditions, metabolic derangements, encephalopathy or cerebrovascular accident.

The desired goal in the management of status epilepticus is to terminate the seizures and restore the patient to baseline as soon as possible while maintaining oxygenation, circulation and normoglycemia (1). Prognosis is determined by the etiology and the duration of SE (1). Complications of prolonged SE include hypoxic ischemic brain injury which may be due to the combined factors of prolonged hypoxia, hypermetabolic cerebral oxygen demand, and respiratory acidosis.

In addition to terminating the seizures, treatment for possible treatable causes of SE should be initiated. Acyclovir and ceftriaxone are commonly administered while treating SE, since the etiology of SE may not be determined until much later.

Since benzodiazepines have the most rapid anticonvulsant onset, it is well accepted that the initial drug to treat SE should be a benzodiazepine. Phenytoin and barbiturates can also be used IV, but their onset time is slower. Other IV drugs such as lidocaine and magnesium have been reported to have anticonvulsant activity, but their use in SE is not routine. Paraldehyde is difficult to use and is no longer pharmacologically available in the United States (2). Reports of propofol and inhaled anesthetics having efficacy in SE have been cited elsewhere (1,2). IV valproic acid has been suggested as an additional agent (3).

IV lorazepam (Ativan) is the most commonly recommended benzodiazepine for SE, because of its longer duration. Diazepam (Valium), which can be given IV or rectally, is also very effective. Midazolam (Versed) can also be used, with its main advantage being that it can be given IM, while the IM route is not recommended for lorazepam and diazepam. If the patient has an IV, lorazepam should be given (diazepam can be used if lorazepam is not available). If an IV is not available, then rectal diazepam or IM midazolam can be used. If rectal diazepam is used, its dose should be doubled or quadrupled in order to get the same effect as the IV dose. A commercially available unit dose rectal diazepam (Diastat) is available or one could administer the IV form of diazepam by: 1) For small doses, a 1cc syringe could be used with lubricant applied to the syringe itself. Then the barrel of the syringe can be directly inserted into the rectum. 2) For larger doses, the diazepam can be drawn into a larger syringe and a rubber catheter or feeding tube can be attached to the hub with the other end inserted into the rectum. The diazepam is pushed through the tube or catheter, followed by an air bubble to clear the tube.

SE is often treated in a stepwise approach with an anticonvulsant drug given every 5 to 10 minutes until SE terminates. A benzodiazepine is administered first (e.g., lorazepam 0.1 mg/kg). This can be repeated in 5 to 10 minutes, if SE continues. In most instances, in patients who were not previously on chronic anticonvulsants, IV loading with one of the phenytoins (phenytoin or fosphenytoin) should immediately follow the first benzodiazepine dose without waiting to see if the benzodiazepine will work. Infants, and especially neonates, may be an exception where phenobarbital may be preferred (1) . For epilepsy patients who are already on anticonvulsants, stat drug levels should be obtained to determine if these are within the therapeutic range. If they are not, an IV or oral dose (or via nasogastric tube) can be given to raise their level appropriately.

In many instances, this first or second benzodiazepine dose will terminate SE and restore the patient to their baseline state (1). These cases are relatively simple and are at less risk for complications. For the purpose of this discussion, this chapter will refer to this as simple status epilepticus. It should be expected that once the benzodiazepine wears off, seizures may recur unless a longer acting anticonvulsant has been administered or a subtherapeutic anticonvulsant level has been brought back up into the therapeutic range.

When the first one or two doses of a benzodiazepine fail to terminate SE, these patients are at higher risk for prolonged SE and complications secondary to this. Refractory status epilepticus can be loosely defined as SE which continues despite an initial anticonvulsant drug regimen (such as a benzodiazepine and phenytoin). If SE continues after two doses of a benzodiazepine, refractory SE should be anticipated. The treatment of refractory SE is more complex and controversial.

The case described in the beginning of the chapter indicates a typical sequence of drugs administered in an attempt to terminate status epilepticus. This sequence may seem fast or slow to you depending on your perspective. It is actually fast since these times are highly ideal and medications are given rapidly without hesitation or pause for prehospital communication. In most instances when conditions are less than ideal, it is common for one hour to elapse while initial anticonvulsant agents are still being administered. One published sequence which completes its second line of drugs within 30 minutes is deceivingly fast because "time 0" is when treatment (ABC+vascular access and glucose) is initiated and only 5 minutes is given to complete an IV benzodiazepine, IV glucose, IV phenytoin

(published recommended infusion times for this drug alone are longer than 5 minutes), brief history and neuro exam, reassessment of vital signs, a check of anticonvulsant levels and a repeat phenytoin mini bolus (all between Time=10 minutes to Time=15 minutes) (1).

Another published sequence defines its "time 0" when the first benzodiazepine is administered IV (this equates to Time=25 minutes in the sequence described in the case). This sequence uses two doses of a phenytoin and two doses of phenobarbital to end at approximately 68 minutes from the time that the first benzodiazepine was administered (4) (add about 25 minutes to this for the total duration of SE).

Neither of these published sequences provides for a period of observation following the administration of an anticonvulsant to see if the drug is successful in terminating SE. This is a common practice and it adds to these time sequences which already approach or exceed one hour. One source states that "the treating physician should allow adequate time for the anticonvulsants to reach therapeutic levels in the brain" (5). A major problem with this approach is that the "wait and see" time periods add up rapidly if SE is not terminated. This time is frequently further prolonged by delays in obtaining IV access, longer prehospital transport times, medication administration delays and if smaller initial doses of benzodiazepines are initially used (e.g. 0.05 mg/kg of lorazepam). No agent or combination of agents is universally reliable in terminating SE (1). It is easy to see how SE can sometimes continue for 2 or 3 hours before it is finally terminated. This is not ideal.

Since it is best to minimize the time of SE, it is best to minimize the time in which anticonvulsants are administered (1). Because of this, it may be unwise to give small doses and wait between anticonvulsants to see if it works (1). Larger full loading doses of anticonvulsants should be preferred. The onset time pharmacology of these drugs may have to be ignored (onset times range from 2 to 30 minutes) in order to minimize the duration of the anticonvulsant sequence. This "wait and see" approach should be modified to a "give, look and give another" approach when managing refractory SE. Refractory SE can be suspected early (as opposed to simple SE) when the first two doses of a benzodiazepine fail to terminate SE.

In the pharmacologic management of refractory SE, there are three basic approaches: 1) the "wait and see" approach, 2) the "give, look and give" approach, 3) the early rapid sequence intubation approach. While the first approach ("wait and see") is commonly used, this practice should be discouraged in managing refractory SE; thus, it should be eliminated from consideration in order to minimize the duration of refractory SE as discussed above. This leaves only two reasonable approaches.

In the early rapid sequence intubation (RSI) approach, refractory SE is recognized early once failure to respond to the first two large doses of benzodiazepines and the phenytoin load is noted. RSI (intubation facilitated by pharmacologic paralysis and deep sedation) has been discussed elsewhere and is beyond the scope of this chapter (6). Early RSI will paralyze the patient to optimize oxygenation, restore ventilation (reversing respiratory acidosis) and halt skeletal muscle contractions (halting rhabdomyolysis and excessive peripheral oxygen consumption). Its commonly recognized disadvantage is that continued seizure activity cannot be determined without the use of continuous electroencephalography (EEG) which is not available in most centers (7). However, the treatment for continued seizures is more anticonvulsants. RSI is often accompanied by a potent anticonvulsant and cerebroprotective agent such as thiopental. Etomidate is often used as a sedative in RSI, but this agent may worsen a seizure condition or cause myoclonus (8). RSI facilitates the administration of maximal anticonvulsant therapy since there is no risk of respiratory depression (the patient is already paralyzed and intubated). Loading with maximal doses of IV phenytoin and phenobarbital can now take place. Although the patient is paralyzed and continued seizure activity cannot be recognized, maximal doses of a benzodiazepine, phenytoin and phenobarbital have been administered. What more could be done even if the clinician could still see the seizures? Adding barbiturate coma, a high dose benzodiazepine infusion, propofol or IV valproic acid could be considered (1,2,3). Short acting paralyzing agents allow reasonably prompt recovery to regain the ability to witness continued seizure activity (4). General anesthesia with barbiturate coma with paralysis is commonly recommended for SE exceeding 60 minutes (5), yet the decision to initiate RSI (a similar procedure) a few minutes earlier, is paradoxically frowned upon by some. Refractory SE durations approaching and exceeding an hour are not uncommon. Since neuronal damage may occur long before 60 minutes of seizures (5) and barbiturate coma may be time consuming to initiate, RSI performed earlier may provide its benefits early and facilitate the rapid initiation of barbiturate coma if it is required. RSI also facilitates expedient neuroimaging which is frequently necessary in SE patients. Several reports recommend endotracheal intubation in the management sequence of refractory SE (1,5,9). If this is so, then should intubation be performed early versus late?; without RSI versus with RSI? These preferences determine if one will be an advocate of an early RSI approach.

The "give, look and give" approach is also a reasonable approach for those who judge the disadvantages of early RSI to outweigh its advantages. Continued seizures after the first two large doses of a benzodiazepine and the phenytoin load should signify refractory SE and a high risk patient. There is a high risk of apnea when phenobarbital is given in combination with benzodiazepines, thus intubation may be necessary (1). Barbiturate coma, benzodiazepine infusion, propofol, IV valproic acid (1,2,3) and/or rapid sequence intubation (if not already done) can be considered after this point.

The table below describes a typical time sequence difference between the "Give look and give" approach compared to the "Early RSI" approach. The comparison starts at time=20 minutes when paramedics or medical personnel first arrive.

Time	"Give look and give" approach	"Early RSI" approach
20 min.	Oxygen + p.r.n. mask ventilation.	Oxygen + p.r.n. mask ventilation.
25 min.	Lorazepam 0.1mg/kg IV.	Lorazepam 0.1mg/kg IV.
27 min.	Phenytoin 15-20mg/kg IV over 10 min.	Phenytoin 15-20mg/kg IV over 10 min.
37 min.	Lorazepam 0.1mg/kg IV.	Lorazepam 0.1mg/kg IV.
42 min.	Phenobarbital 15mg/kg IV slowly.	RSI drug sequence begins.
46 min.	Visible seizures continue.	Visible seizures stop. Patient intubated.
47 min.	Phenobarbital infusion continues.	Phenobarbital 25 mg/kg IV.
50 min.	Visible seizures continue.	Phenobarbital infusion complete.
52 min.	Phenobarbital infusion complete.	
53 min.	Apnea develops.	
55 min.	Intubation done under difficult conditions.	
60 min.	Additional phenobarbital 10mg/kg IV.	

In refractory SE, when maximal anticonvulsant administration may be required, the early RSI approach completes drug administration faster and intubation is facilitated. Additionally, the patient is paralyzed and intubated earlier facilitating oxygenation and

halting skeletal muscle activity. Phenobarbital must be given slowly following a benzodiazepine to prevent apnea, but this often happens anyway. The time sequence can be shortened by using fosphenytoin which can be given IV faster than phenytoin, or interrupting the phenytoin infusion to give the second lorazepam dose.

In summary, to minimize the duration of SE, the "wait and see" approach should be discouraged in favor of the "give look and give" approach or the early rapid sequence intubation approach in order to minimize the duration of drug administration and the duration of SE. Refractory SE risk should be recognized earlier (when SE continues despite the first two benzodiazepine doses), so that anticonvulsant administration can be done more aggressively since time is critical.

Questions

1. After oxygen, the first drug that is administered to a patient in status epilepticus is from what drug class?
2. Name three other anticonvulsant drugs, not belonging to the class above, that can be given IV?
3. Name two ways that diazepam can be given in status epilepticus?
4. Which benzodiazepine has the longest duration?
5. In status epilepticus, what drug should be administered after a benzodiazepine in most instances (other than in neonates)?
6. What is the most serious complication of status epilepticus?
7. Name 5 causes of status epilepticus?

Answers to questions

1. Benzodiazepines.
2. Phenytoin (or fosphenytoin), phenobarbital, valproic acid.
3. IV and rectal.
4. Lorazepam.
5. Phenytoin (or fosphenytoin).
6. Hypoxic ischemic brain injury, death.
7. Epilepsy, encephalitis, neoplasm, drug overdose, metabolic derangement, cerebrovascular accident, trauma, etc.

Chapter XVIII.6. Infant Botulism
Daniel W. Ulrich, MD

This is a 3 month old male who presents to the pediatrician's office with a chief complaint of decreased activity, poor feeding and constipation. Pertinent past medical history reveals that the infant was born at 39 weeks gestation, with no complications during the pregnancy or birth. The infant is exclusively breast fed, up to date on immunizations and has suffered from no previous illness. On further questioning, his mother reports her son has not been himself for the past week. He has had no fever and there are no sick contacts. He has been less active, with a weak cry during this time. His mother also notes the infant has not been as interested in feeding and has suffered from constipation. His urine output is decreased with only four wet diapers in the last 24 hours. Typically, he has 3-4 soft stools per day, usually after feeds, but has had no bowel movement in the past 5 days.

Exam: VS 37.0, P 114, R 22, BP 98/62, Wt. 5.3 kg (75%), Ht. 57cm (50%). He is awake, non-toxic appearing, with expressionless facies and a weak cry. His anterior fontanel is flat and soft. He has poor head control. He has diminished pupillary reflexes, absent corneal reflexes, bilateral ptosis, and decreased tearing. He has a weak suck and gag reflexes with increased oral secretions. His neck is supple without adenopathy. Heart and lungs are normal. Aeration is good. His abdomen is soft, full, non-tender, with decreased bowel sounds throughout. No hepatosplenomegaly. Rectal exam shows no stool in the rectal vault and decreased anal sphincter tone. His extremities are slightly cool, with delayed capillary refill. His skin shows no rash or petechiae. He has decreased muscle tone throughout and diminished deep tendon reflexes.

He is hospitalized for possible infant botulism. A sepsis work up is done and he is started on IV fluids and empiric antibiotics for sepsis. Stool samples are sent for Clostridium botulinum toxin assays. His cultures are subsequently negative. His clinical condition worsens such that he cannot feed and he eventually develops hypoventilation and respiratory insufficiency requiring mechanical ventilation. An electromyography study is done which shows brief, small, abundant, motor unit potentials, known by the acronym BSAP, a characteristic pattern associated with infant botulism (1). He gradually improves and he is weaned off the ventilator after 8 days. His stool assay returns positive for botulism toxin. He continues to gradually improve over the next three weeks such that he is able to feed on his own and he is then discharged from the hospital.

Clostridium botulinum is a gram negative, spore forming obligate anaerobe whose natural habitat worldwide is soil, dust, and marine sediments. It is found in a wide variety of fresh and cooked agricultural products including fruits, vegetables and honey (2). Due to a number of cases being linked to ingestion of honey in infants (honey is often used to treat constipation), it is recommended that no infant be given honey under 1 year of age (2,3,4). However, it should be noted that the source of clostridium spores is often not conclusively proven in most cases, with environmental exposure to spores in dirt or soil often thought to be a more likely exposure route (associated with a parent who works in construction or earth moving occupation).

The usual incubation period is estimated at 3 to 30 days from time of exposure to spores (2). Infant botulism has been reported from all inhabited continents except Africa. Notably, the infant is often the only ill family member. The most striking epidemiological feature of infant botulism is its age distribution, in which 95% of cases are found between the ages of 3 weeks to 6 months of age, with a peak between 2-4 months of age (2). Ingested spores of C. botulinum germinate, colonize the infant colon, and slowly produce neurotoxin within the GI tract. The toxin is subsequently absorbed and carried by the blood stream to peripheral cholinergic synapses, in particular the neuromuscular junction, where it binds irreversibly (3). The neurotoxin action results in a flaccid paralysis and hypotonia, with the autonomic nervous system less severely affected. Function is regained only when new motor endplates are regenerated which can take weeks to months (1).

The clinical spectrum of infant botulism ranges from mild disease to sudden infant death. The onset can be insidious or fulminant. The disease typically manifests as a descending flaccid paralysis of the cranial nerve musculature with ptosis, blurred vision, diplopia, dysphagia, dysarthria and decreased gag and corneal reflexes. In fact, it has been stated that it is not possible to have botulism without having multiple bulbar palsies (5). However, in infants, symptoms of poor feeding, weak suck, feeble cry and even obstructive apnea (from a floppy tongue) are not often initially recognized as bulbar in origin (5). The classic picture of infant botulism is an initial presentation of constipation (defined as 3 or more days without defecation in a previously regular infant), listlessness, and poor feeding together with maternal breast engorgement. The typical patient often has an expressionless face, feeble cry, ptosis, poor head control, generalized weakness and hypotonia. Patients are most often afebrile unless a secondary infection is present and most initial laboratory tests are normal. The differential diagnosis includes sepsis (the most common admitting diagnosis), dehydration, constipation, hypothyroidism, other neurologic disease, inborn errors of metabolism or poisoning (5). The diagnosis is best confirmed with isolation of C. botulinum organism in the stool (often detectable only in the early stages of disease) or C. botulinum toxin in serum or stool. The toxin can be identified in the stool of infected infants for as long as 4 months (4), which explains why the clinical course can last for a few weeks for a few months. Although the electromyographic findings in infant botulism are unique, the procedure is painful and generally unnecessary unless the diagnosis is in question.

Treatment of infant botulism is fundamentally supportive and depends on the anticipation and avoidance of potentially fatal complications. Antibiotics should not be used routinely and should only be used to treat secondary infections (pneumonia, urinary tract infections, otitis media), because their use may result in the lysis of intraintestinal C. botulinum with liberation of additional neurotoxin (3). Of note, aminoglycoside antibiotics, which are weak pharmacologic neuromuscular blocking agents, should be particularly avoided since they will worsen paralysis acutely, often precipitating an acute respiratory arrest in unsuspected infant botulism patients initially being treated for sepsis (3,5). Human botulinum immunoglobulin (BIG), which acts by interrupting the neuromuscular blockade, has been approved for the treatment of infant botulism. A single intravenous dose of BIG has been shown to reduce the typical course of hospitalization from 5.5 to 2.5 weeks with a two-thirds reduction in the rate of intubation/mechanical ventilation (4).

Most infants will show gradual improvement over a period of 10 days to 2 months with rare cases of relapse. Common complications including respiratory failure (requiring mechanical ventilation), secondary infections (e.g., pneumonia and UTI) and SIADH require appropriate management to optimize the infant's ultimate prognosis, which is potentially excellent with a full neurologic recovery.

"Infant botulism" differs from "botulism" in that food-borne botulism results from the ingestion of a food in which C. botulinum has produced pre-formed toxin so its onset is more rapid compared to infant botulism. It is most commonly seen in older children and adults and often occurs in outbreaks traced to spoiled, low acidity canned foods (2). While all forms of botulism produce disease through a similar pathway, food-borne botulism more often begins acutely with gastrointestinal symptoms such as nausea, vomiting and diarrhea. A characteristic pattern of dysarthria, dysphagia, dry mouth, diplopia, and blurred vision with ptosis evolves during the onset of disease.

Fulminate and extensive paralysis, respiratory distress and apnea are more likely to be experienced with food-borne botulism. Wound botulism is an exceptionally rare disease, but is important to pediatrics because adolescents and children are disproportionately affected.

Questions

1. The mother of a 4 month old infant asks if it is okay to coat a pacifier with honey to soothe her baby, what is your response?
2. What is the basic mechanism of action of botulinum toxin?
3. Describe the typical clinical presentation of infant botulism. Why may the diagnosis be unclear initially? What is the classic age distribution?
4. What are the principle methods that can be used to confirm infection by C. botulinum?
5. What are the indications for antibiotic treatment in an infant with infant botulism? Why are aminoglycoside antibiotics contraindicated?
6. What is the role of human botulinum immunoglobulin in the treatment of infant botulism?
7. What is the prognosis for an infant infected with infant botulism?
8. Describe the basic difference between "botulism" and "infant botulism".

Answers to questions

1. It is recommended to not give honey to any infant under 12 months of age.
2. Botulinum toxin is released by bacteria within the infant's GI tract. From here, the toxin is absorbed and carried by the blood stream to peripheral cholinergic receptors where it binds irreversibly. Clinically, the most important of the peripheral cholinergic receptors is the neuromuscular junction. Here the toxin's action results in flaccid paralysis and hypotonia, which are the classic clinical signs of infant botulism.
3. Initially, infected infants often present with a history of poor feeding, decreased activity and constipation. The diagnosis may not be considered initially because signs of an evolving bulbar palsy, flaccid paralysis and hypotonia may be subtle. Additionally, the infant may be worked up for sepsis if he appears toxic or "lethargic", or for constipation until the "classic" manifestations of infant botulism become apparent. The classic age distribution for infant botulism is 3 weeks to 6 months of age.
4. Isolation of the clostridium botulinum organism in stool can be accomplished in the early stages of disease, it is rarely isolated in blood. The most common method for proving infection is to isolate botulinum toxin in blood or stool samples. Toxin can be detected in the stool of infected infants for up to 4 months. Electrophysiological testing, specifically electromyography, can aid in ruling out other neurologic disorders such as Guillain-Barre syndrome, congenital myopathies, and myasthenic conditions.
5. The use of antibiotics in infant botulism should be reserved only for proven secondary infections such as pneumonia, otitis media or urinary tract infections. Aminoglycosides should be avoided as they are weak pharmacologic neuromuscular blocking agents which may potentate paralysis acutely or cause respiratory failure in an unsuspected infant with botulism being treated for sepsis.
6. Human botulinum immunoglobulin (BIG), which acts by interrupting the blockade of nerve receptors by botulinum toxin, has been shown to reduce the need for mechanical ventilatory support and shorten overall duration of hospitalization.
7. If recognized early and given appropriate supportive care minimizing complications, full recovery and a normal neurologic function can be expected.
8. Classic "botulism" is a food born disease in which high levels of toxin can be ingested in spoiled food. It often occurs in outbreaks linked to a particular source, and typically afflicts older children and adults. Wound botulism is rare, but is seen disproportionately in adolescents and children. Infant botulism has a more gradual onset. All types of botulism produce disease through a similar pathogenesis.

Chapter XVIII.7. Guillain-Barre Syndrome
Judy T. Okimura, MD

A 12 year old Caucasian female presents to the emergency room with a chief complaint of leg weakness. One week prior, she had a fever of 101.4 with vomiting and diarrhea. After 3 days, the vomiting and diarrhea resolved. She was doing well until this morning when she fell while trying to get out of bed and could not stand or walk without support. She has no headache, blurred vision, tinnitus, vertigo, dysphagia, or incontinence. There is no history of toxic ingestion. Her immunizations are up to date. While in the ER she complains that her arms feel weak.

Exam: VS T 37.0, P 84, R 24, BP 102/64. Height and weight are at the 25th percentile. She is alert, slightly tearful but cooperative. HEENT: She has no nystagmus and no papilledema. Her extraocular movements are intact. Pupils are equal and reactive to light. No facial weakness or asymmetry is present. Heart, lung and abdomen exams are normal. Neuro: Strength 4/5 in the upper extremities, 3/5 in the lower extremities. DTRs 1-2+ in the upper extremities and absent in the lower extremities. Sensation is intact in all extremities. Cerebellar function is normal except for the weakness. No cranial nerve abnormalities are noted. She refuses to walk.

CBC, electrolytes, BUN, creatinine, glucose, calcium and liver function tests are normal. Urine toxicology screen is negative. A lumbar puncture is performed. Opening pressure is normal. CSF analysis shows protein 146 mg/dL (high), glucose 70 mg/dL, 5 WBC per cu-mm, 1 RBC per cu-mm, and gram stain shows no WBCs and no organisms.

She is hospitalized for further management with a tentative diagnosis of Guillain-Barre syndrome. An MRI of the brain and spinal cord is normal. She is started on IVIG and over the next few days, she slowly regains strength in her arms and legs. However, she still requires assistance with walking at the time of discharge. She is referred to a rehabilitation hospital to continue outpatient physical therapy. She gradually improves over the next 5 months and eventually returns to normal activity.

Guillain-Barre syndrome (GBS) is an acute demyelinating polyneuropathy of the peripheral nervous system characterized by progressive flaccid paralysis (1). It is an acquired disorder that affects people of all ages, although only rarely in children under one year of age (2,3). It has a slight male predominance of 1.5 to 1 and has an estimated annual incidence rate of 1/100,000 (1,2).

The disease mainly affects motor nerves but can involve sensory nerves as well (3). Although typically presenting as a fairly symmetric ascending paralysis, GBS is now believed to be a heterogenous disorder with a wide range of clinical manifestations. It includes the classic demyelinating form, or acute inflammatory demyelinating polyneuropathy (AIDP), the axonal forms which include the acute motor axonal neuropathy (AMAN) and acute motor sensory axonal neuropathy (AMSAN), and clinical variants such as the Miller-Fisher Syndrome characterized by the triad of ataxia, areflexia, and ophthalmoplegia (4,5). AIDP is the most common subtype found in North America and Europe, while the axonal forms are more commonly seen in China (6).

Most cases in developed countries occur following an upper respiratory or diarrheal illness (1). Although the pathogenesis of the disorder remains unclear, GBS is suspected to cause an immune-mediated demyelination and axonal injury due to certain bacteria or viruses sharing antigenic sites with peripheral nerve myelin and/or axons (1,2). Campylobacter jejuni enteritis is the most commonly identified antecedent infection and is associated with more severe symptoms (4,6). Cytomegalovirus, Epstein-Barr virus, Mycoplasma pneumoniae, and Haemophilus influenzae have also been implicated in GBS (2,5).

Current research suggests that antiganglioside antibodies play an important role in the pathogenesis of GBS. Gangliosides are glycolipids containing sialic acid residues and are the surface components of many cells, including nerve cells. Many patients with GBS have antibodies to various gangliosides such as GM1, GD1a, GD1b, and GQ1b. Anti-GM1 antibodies are often found in classic GBS (AIDP), while anti-GQ1b antibodies are more commonly seen in the Miller-Fisher Syndrome (7). The outer membrane of Campylobacter's and other gram-negative bacteria is composed of lipopolysaccharides (LPS) which are complex glycolipids. The LPS of Campylobacter is unique in that it contains sialic acid and therefore resembles human glycoconjugates. It has been found to have antigenic molecules related to ganglioside GM1 and GQ1b (1,7). Through a process called molecular mimicry, antibodies against the C. jejuni LPS may crossreact with peripheral nerve myelin to cause demyelination (1).

Progressive weakness usually develops first in the lower extremities, then the trunk, upper extremities, and bulbar muscles. This pattern of ascending paralysis is fairly symmetric and develops gradually over a period of days or weeks. The child may develop an inability or refusal to walk and may later develop flaccid quadriplegia (3). However, 5-10% of children may initially have more weakness in the upper extremities, and some may have more proximal than distal muscle weakness (2).

Deep tendon reflexes are usually lost early in the course of the disease, although the proximal reflexes may still be present initially (2,3).

Sensory disturbance is also common and may occur in a glove-and-stocking distribution (8). Pain or paresthesias in the extremities, around the mouth, or on the back may be the presenting complaint in about 40% of patients. Pain in a band-like distribution may be present, and position and vibratory senses may be diminished (2). Muscle pain is also common initially in cases where there is an abrupt onset (3).

Approximately 50% of cases have bulbar involvement with the potential for respiratory insufficiency. Cranial nerve involvement may lead to facial weakness, difficulty swallowing, and problems with ocular motility. Dysphagia and facial weakness may herald respiratory failure requiring mechanical ventilation, a complication which occurs in 15-20% of patients (2,3). Autonomic dysfunction is uncommon but may present as arrhythmias and blood pressure instability including orthostatic hypotension (2).

The most common clinical variant of GBS is the Miller-Fisher syndrome with its triad of external ophthalmoplegia, ataxia, and areflexia. It is presumed to have a similar immune-mediated pathogenesis and pattern of recovery to classic GBS (1).

The cerebrospinal fluid (CSF) in affected patients is characterized by an elevated protein level without a WBC count elevation (i.e., normal cell counts) (3). This albuminocytologic dissociation is virtually diagnostic of GBS (1,3). About one-half of patients develop an elevated CSF protein during the first week of illness and most patients will show an elevation after the first several weeks of illness. The CSF protein peaks between 80 to 200 mg/dL. The CSF WBC count should not exceed 10 per cu-mm. A WBC count >50 per cu-mm or a predominance of segmented neutrophils should prompt the search for an alternative diagnosis such as meningitis, encephalitis, or transverse myelitis (2). The CSF glucose level should be normal and the culture negative.

Electrodiagnostic studies should be performed if there are atypical features, a rapid progression of illness, weakness that is severe or very mild, if there is delayed recovery, or if the diagnosis is unclear (2). Nerve conduction studies reveal slowing in both motor and sensory nerves (1,3). Electromyelography (EMG) may show acute denervation of muscle (2,3), but it does not show a primary myopathic process.

The differential diagnosis of GBS is large. A child with acute cerebellar ataxia may present with an acute gait disturbance and diminished tone. CSF pleocytosis is common and the protein level is usually normal (2). Spinal cord disease should be considered in a child presenting with acute lower extremity weakness, especially if there is a distinct spinal level of sensory loss, given the potential for irreversible cord injury by a compressive mass lesion (2). Transverse myelitis can present similarly, with back pain, a distinct sensory level, and rapidly progressive paralysis (2,8). Areflexia will be seen initially below the level of the lesion but hyperreflexia later develops. The CSF may show elevated protein, pleocytosis, and an increase in gamma globulin (8). MRI of the spinal cord should be obtained when the distinction is unclear. Poliomyelitis, now rare due to the routine immunization of children, can manifest as acute diffusely symmetric weakness, although it more commonly causes an asymmetric paralysis (2,8). Fever, meningeal signs, and muscle tenderness and spasm may also be present (8). It does not cause sensory disturbance and bowel and bladder function are almost never affected (2).

Myasthenia gravis may present with weakness which is often episodic and slowly progressive. There is almost always an associated ptosis or ophthalmoplegia, with preservation of sensation and reflexes (2). Botulism should be considered in a child less than 1 year of age presenting with weakness, a poor sucking reflex, weak cry, and constipation (8). Other common findings include swallowing difficulties and poorly responsive pupils. Older children will present with bulbar symptoms and weakness. CSF results will be normal and EMG reveals brief small abundant potentials which are diagnostic (8). Other causes of acute polyneuropathy include heavy metal intoxication, glue sniffing, tick paralysis, porphyria, SLE, and other collagen vascular diseases (2).

GBS is generally self-limited in children and full recovery can usually be expected (9). However, because of the potential for respiratory failure requiring mechanical ventilation, forced vital capacity, negative inspiratory force, and vital signs should be measured every 6 hours early in the course of illness to establish a trend. Rapidly decreasing vital capacity, dyspnea or fatigue, and deterioration of arterial blood gas values are indications for intubation and mechanical ventilation. Patients with dysphagia, shoulder weakness, or cardiovascular instability may also require assisted ventilation (2).

In the past, management of GBS was limited to supportive care, which included nursing and respiratory care, physical therapy, and maintenance of adequate nutrition. However, over the past two decades, treatment has evolved to include plasma exchange (plasmapheresis) and intravenous immunoglobulin (IVIG) (1). Both therapies have been shown to improve the rate of motor recovery (5). The patients most likely to benefit are those who present with moderate or severe progressive weakness, particularly children who are unable to walk, have a rapidly progressive course, or have bulbar paralysis and impending respiratory distress (1,2). Those with mild symptoms or with little progression typically have rapid and complete recovery, and do not require immunotherapy. Patients who present several weeks after the onset of illness are least likely to obtain benefit (1).

Plasma exchange is believed to work by removing antibodies against myelin and other soluble proteins from the circulation (1). The recommended protocol is 250 mL of plasma/kg divided into four to six sessions during the first week of illness, using albumin or fresh frozen plasma as replacement volume (2).

IVIG is generally preferred over plasmapheresis in children since IVIG does not require central venous access and does not decrease blood volume. IVIG has been safely administered in children as young as 2 years of age (1). The recommended dose is 2g/kg divided over two to four days (2).

Spontaneous recovery usually occurs 2-3 weeks after onset of disease, with most patients regaining full muscle strength and deep tendon reflexes. Residual weakness may remain in some patients. Improvement in strength usually occurs in reverse order, with bulbar muscle strength returning first and lower extremity strength returning last. Deep tendon reflexes are often the last function to recover (3).

The mortality rate is 2-5%, usually related to complications from ventilator-dependence or autonomic dysfunction (1). Factors associated with better outcomes include younger age at onset, milder clinical course, and slower progression of disease (9). With modern intensive care management and respiratory support, most children can be expected to have a full recovery from GBS.

Questions

1. What is the most commonly identified antecedent infection in Guillain Barre syndrome?
2. What is meant by albuminocytologic dissociation?
3. True/False: Improvement in strength occurs in the order in which it was affected.
4. Why is IVIG preferred over plasmapheresis in children?
5. When should a child with GBS be intubated?

Answers to questions

1. Campylobacter jejuni enteritis.
2. Lack of cellular response (normal WBC count) in the CSF despite an elevated protein level. In the clinical setting of progressive flaccid paralysis, this is diagnostic of Guillain-Barre syndrome.
3. False. Improvement in strength occurs in reverse order (bulbar muscle strength returns first and lower extremity strength returns last).
4. IVIG does not require central venous access and does not decrease blood volume.

5. A child should be intubated if she/he has a rapidly decreasing vital capacity, dyspnea, fatigue, or deterioration of arterial blood gases. Dysphagia, shoulder weakness, and cardiovascular instability are also indications that mechanical ventilation may be necessary.

Chapter XVIII.8. Multiple Sclerosis
Lori S. Murayama

This is a 10 year old female who presents to the office with a chief complaint of clumsiness and blurred vision. She had been well until approximately 2 weeks ago when she noticed a loss of sensation and strength in her left leg, a rapid deterioration in vision, and a decrease in coordination. There is no history of fever, vomiting, or seizures. One year prior to this event, she presented to the hospital with poor coordination, dizziness and headaches. A left hemiplegia was noted as well as an asymmetric gait. A full recovery was made 5 days later, and she was discharged from the hospital without further treatment or a definite diagnosis.

Exam: VS are normal. Her weight, height, and head circumference are all at the 50th percentile. She is alert but subdued. Her HEENT exam is notable for severe visual loss and pale optic discs on funduscopy. Her heart, lungs, and abdomen are normal. She is noted to have a hyporeflexive paraparesis noted on the left.

She is hospitalized. A CT scan shows slightly enlarged ventricles, and an MRI scan shows multiple lesions in the periventricular white matter and cerebellum. Pattern visual evoked responses showed markedly delayed latencies. She is treated with corticosteroids and a full recovery results within a few weeks. Over the next 3 years, she has 2 more attacks with symptoms of right hemiplegia and bilateral visual loss. At the age of 15, she continues to be followed and has shown no further episodes.

Multiple sclerosis (MS) is an uncommon demyelinating disease characterized by focal disturbances in CNS function that usually follows a relapsing and remitting course. Because MS is known to most commonly affect adults in their 20's to 40's it is often an overlooked diagnosis in children. 3-5% of all MS cases are, however, diagnosed in patients below the age of 16 years, with 80% of these cases found between 10-15 years of age.

Although the exact cause of MS is unknown. It has been suggested that its etiology is multifactorial. One popular view is that MS is initiated by a viral infection in early life that alters a susceptible patient's immune status, thus predisposing him/her to develop an autoimmune CNS reaction to systemic infections. Although this is a widely held view, efforts to actually identify an infectious agent have been unsuccessful. In addition to speculation about a viral etiology, it has also been noted that MS occurs 10-20 times more in families of a MS patient than in the general population (1). There also appears to be a higher risk in females (2:1), people of western European descent, and those who lived in temperate (cold) climates before the age of 15. Thus it is believed that environmental (viral) as well as hereditary factors, a disordered autoimmune response, and the age of the individual at exposure plays a role in the pathogenesis.

The pathophysiology of the various neurological manifestations found in MS can be explained by multiple lesions disseminated throughout the CNS that spontaneously improve. Consequently, this also explains why the combination of signs and symptoms are limitless and why the symptoms often remit after a period of time.

Many of the clinical manifestations of childhood onset MS are similar to adult-onset MS (1). Table 1 below shows some of the symptoms found in the initial episode of MS in a study analyzing 56 children with MS. In general, visual disturbances such as blurring and diplopia are common in childhood MS with one study finding optic neuritis in 25-70% of children with MS (2). Paresthesia, motor disturbances, unstable gait, ataxia, vertigo, headaches, and sphincter problems also seem to predominate in childhood onset MS. Ghezzi et al. found that of 149 children who were diagnosed with MS before the age of 18, 25% had brainstem dysfunction, 18% had motor and sensory disturbances, and 9% had cerebellar disturbances (2). Transiently impaired consciousness and slowly progressive dementia have also been found in a significant number of children with MS (1).

Table 1: Number of children (out of 56) with these symptoms during the initial episode of MS (1):

Ataxia or muscle weakness:	31
Disturbance or vision (blurring, diplopia, blindness):	19
Numbness or paresthesia:	13
Dizziness, headache, vomiting:	10
Vertigo:	6
Urinary incontinence:	2
Facial weakness:	1
Hearing loss:	1
Partial seizures:	1

While there are many similarities found between childhood and adult onset MS, there are some clinical differences. Bye et al. found a higher incidence of partial seizures in childhood onset MS (3) and brainstem dysfunction had also been noted to be more frequent at the first attack in children. Vestibular symptoms, however, were noted to be less common in childhood MS (3).

There are numerous laboratory tests that can be used to help include/exclude MS, but no definitive diagnosis can be based just on these investigative findings. In terms of MRI and CSF abnormalities, childhood MS appears to be similar to adult onset MS. MRI findings are positive in 80% of cases with multiple lesions found in the brainstem, cerebellum, and central white matter (most notably in the periventricular region) on T2 weighted images. CSF examination reveals abnormalities in more than 2/3 of children with tests showing an elevated total protein, an increase in gammaglobulin, and electrophoresis revealing IgG oligoclonal bands in 85% of cases. Pleocytosis is also seen (50-100 lymphocytes per cubic mm) with a tendency to be more markedly elevated in childhood MS (1). Visual, brainstem auditory, and somatosensory evoked potentials support clinical suspicion as well, by demonstrating the existence of multiple demyelinating lesions within the CNS. These neurophysiological tests have been found to be abnormal in 70%, 50%, and 75% of MS children respectively (1).

Because of the endless combination of signs and symptoms in MS, its slowly progressive nature, and the lack of definitive investigative testing, diagnosing MS in children is often difficult. In order to establish a criteria for MS in adults, the Poser Committee created the following categories that can be applied to childhood onset MS as well:

1. Clinically definite MS: 2 attacks plus clinical signs or investigative evidence of 2 lesions.
2. Laboratory supported definite MS: 2 attacks plus clinical signs or investigative evidence of 1 lesion. Abnormal CSF (oligoclonal bands) is also found.
3. Clinically probable MS: 2 attacks plus clinical signs or investigative evidence of 1 lesion.
4. Laboratory supported probable MS: 2 attacks plus abnormal CSF (oligoclonal bands).

This diagnostic criteria are particularly useful in diagnosing MS in children because other demyelinating diseases can appear clinically similar. The following are some of the more common demyelinating disorders of childhood: Schilder's Disease, childhood MS, Devic disease (neuromyelitis optica), acute disseminated encephalomyelitis, acute necrotizing encephalomyelitis, central pontine myelinolysis, Leber optic atrophy, acute hemorrhagic leukoencephalitis, adrenoleukodystrophy.

Other diseases that should be considered in the differential diagnosis of MS include diseases with similar presentations. Disseminated lupus is one disease that can also produce recurrent hemiplegia. There are many other disease processes that fit in this category including Behcet's disease, arteriovenous malformation, vitamin B12 deficiency, and Lyme disease.

Until recently, there were not many treatment options available for children with MS and while there has been recent advancements in therapeutic interventions, most of the information has been derived from adult onset MS. The bottom line is that there is no cure for MS. There are, however, treatments available to shorten the duration of an attack, lengthen remission, and alleviate the symptoms.

Symptomatic treatment may be needed for treating spasticity, neurogenic bladder, bowel symptoms, pain, fatigue, and seizures. As for shortening the duration of acute relapses, corticosteroids can be used. It should be noted, however, that while corticosteroids speed the recovery from an acute attack, the actual extent of recovery is unchanged and it does not prevent future relapses.

In order to reduce the frequency of attacks for patients with relapsing-remitting or secondary progressive course of MS, beta-interferon or daily subcutaneous administration of copolymer I may be beneficial. Interferons such as Beta IB and IA lessens the frequency of relapses by 1/3 by down-regulating antigen recognition. However, like corticosteroids, it has no effect on the extent of disability. Copolymer I, a synthetic polypeptide, has also shown similar results with both showing the ability to decrease active and new lesions as demonstrated on MRI.

The natural history of MS can be unpredictable. Some children have only one attack during their childhood with many years of remission. Others have multiple recurrences that occur within a few months. In order to aid in the determination of prognosis, it is important to understand that the clinical course of MS can be divided into 4 categories:

1. Relapsing/remitting MS: A clearly defined disease that relapses with either full recovery or with sequelae and residual deficit on recovery.
2. Secondary progressive MS: A disease that initially follows a relapsing/remitting course but becomes progressive.
3. Primary progressive MS: A disease that progresses from the onset with only temporary plateaus and relatively minor improvements.
4. Progressive-relapsing MS: A disease that progresses from onset with clear acute relapses.

The prognosis of childhood MS appears to be similar to adult onset MS in terms of the clinical course, rate of progression and rate of relapses. In general, childhood MS presents primarily as a relapsing-remitting course, with one study finding that 56% of children had a relapsing-remitting course, 22% with a primary progressive course, and 22% with a mixed course (2).

In summary, MS is a common demyelinating disease that should not be overlooked in children. The etiology has not been fully elucidated, nor has a cure been found. Identification of the disease, determining its clinical course, and providing the appropriate therapies currently available, appear to be the essential clinical steps thus far.

Questions

1. True/False: Childhood MS most commonly occurs in children between the age of 10-15 years.

2. The etiology of MS is probably related to:
   a. A dysfunction in autoimmune regulation
   b. Environmental factors
   c. Hereditary factors
   d. All of the above

3. True/False: Visual disturbances is one of the most common manifestations of childhood MS.

4. True/False: Laboratory investigations usually provide a definitive diagnosis for MS.

5. True/False: Corticosteroids can speed the recovery from an acute attack.

Chapter XVIII.9. Hydrocephalus
Andrée M. Bouterie, MD

A 12 week old female infant presents to the emergency department with progressive vomiting, lethargy, and difficulty feeding over the past two days. Her mother reports that the infant has been increasingly irritable in the last week, and does not appear to be herself. She has been less interactive, and her cry has become more high-pitched and weak. She has not been breastfeeding well. Additionally, her mother is concerned because she thinks her infant's head has grown, and the "soft spot" on her head appears more tense. She thinks that the infant has felt "warm", but she has not measured the temperature with a thermometer. The infant has had fewer wet diapers and no bowel movements today.

She reports that the infant was born on time and that there were no prenatal or perinatal complications. The infant was released after a 48 hour stay in the regular newborn nursery, and had follow-up initially with her pediatrician about one week after discharge. She has had no further follow-up. From the previous medical records it is confirmed that the infant was born at term. There was poor prenatal care, but the labor and delivery were unremarkable. Mother's prenatal labs were normal. The infant weighed 2900 grams at birth (25th percentile), measured 47.8 cm in length (10th - 25th percentile), and had a head circumference of 34 cm (25th percentile).

Exam: VS: T 36.5 C, P 165, R 45, BP 98/65. Weight 4.20 kg (5th percentile), length 57 cm (10th - 25th percentile), HC 42.6 cm (95th percentile). In general this is a lethargic infant with a weak, high-pitched cry. Her head is oddly shaped and looks like an inverted pear. Her scalp veins are prominent, and the anterior fontanelle is tense and bulging. Eyes show pupils which are equal and round, but are sluggishly reactive to light. Red reflex is present bilaterally. EOMs are clearly dysconjugate. There is mild tachypnea with slight intercostal retractions. Lung fields are clear to auscultation bilaterally. Her heart exam reveals tachycardia with a regular rhythm and a grade 2/6 systolic ejection murmur at the left sternal border. Capillary refill is 2 seconds. Her spine is straight without protrusions or apparent defects. Her upper extremities show good tone and full range of motion with slightly brisk reflexes. Her lower extremities show increased tone with brisk reflexes bilaterally. There is 4+ clonus bilaterally. On neurologic examination, her eyes show rotated downward gaze bilaterally. There is a poor suck. The startle response is minimally present. The grasp and glabellar reflexes are present. No parachute reflex can be elicited. The Moro is present.

Imaging studies demonstrate hydrocephalus and aqueductal stenosis. A ventriculoperitoneal shunt procedure is performed by a neurosurgeon. Following surgery, the patient's anterior fontanelle is concave and the head circumference has decreased.

Hydrocephalus is the pathologic enlargement of the cerebral ventricles secondary to increased intracranial pressure caused by a mismatch between the production of cerebrospinal fluid (CSF) and its absorption (1). CSF is produced mostly by the ependymal cells of the choroid plexus within the ventricular system. CSF flows in a directional, pulsatile movement (2,3) from the lateral ventricles through the Foramina of Monro into the third ventricle. It then drains through the cerebral aqueduct (of Sylvius) into the fourth ventricle. CSF then exits the ventricular system through the Foramina of Luschka and Magendie, where it thereby gains access to the basilar cisterns, which communicate with the subarachnoid spaces over the cerebrum and spinal cord. Finally, CSF is returned to the vascular system by absorption through the subarachnoid villi and granulations.

A blockage of CSF along any point in this pathway may result in increased intracranial pressure and subsequent dilatation of the ventricular system upstream to the obstruction. Classically, hydrocephalus has been divided into two subtypes: communicating and non-communicating. Non-communicating hydrocephalus results from obstruction of CSF within the ventricular system. This includes obstruction at the outlet foramina of the fourth ventricles. Therefore, if CSF flow does not pass into the basilar cisterns, the corresponding hydrocephalus is classified as non-communicating. Some authors will utilize the term obstructive hydrocephalus to indicate non-communicating hydrocephalus.

Communicating hydrocephalus implies that there is free-flowing CSF within the ventricular system (and through its outlet foramina), and usually occurs secondary to impaired absorption at the subarachnoid villi and granulations. It should be noted from a pathophysiologic standpoint, however, that in almost every case, an obstructive process produces hydrocephalus. The single exception to this is the rare case of a congenital choroid plexus papilloma, where the mismatch between CSF production and absorption occurs as a function of excessive CSF production (1,3). Additionally, the term hydrocephaly should be distinguished from the terms macrocephaly and megalencephaly. Macrocephaly is a descriptive term for any head circumference larger than two standard deviations from the mean. Megalencephaly refers to an increase in brain parenchymal volume.

The differential diagnosis of hydrocephalus may be considered by age (3). Congenital hydrocephalus has an estimated incidence of about 3 to 4 per 1000 live births (4,5). The most common causes of congenital hydrocephalus are due to structural defects such as Chiari malformations and aqueductal stenosis (3,6). Dandy Walker is also an important cause of congenital hydrocephalus, although it occurs less frequently. Additionally, intrauterine infections, especially toxoplasmosis, rubella, cytomegalovirus, and syphilis, may be associated with congenital hydrocephalus. In the neonatal period, acquired causes of hydrocephalus include perinatal infections and intracranial bleeding secondary to trauma or anoxia. Premature infants are particularly susceptible to intraventricular hemorrhage (IVH), which may subsequently lead to hydrocephalus. AV malformations of the Great Vein of Galen, or the straight sinus may also present in this period and may cause hydrocephalus secondary to blockage or rupture. Much less common causes of hydrocephalus in the neonatal period

include arachnoid cysts, congenital choroid plexus papillomas, and tumors (1,3). The common causes of congenital and neonatal hydrocephalus will be discussed below.

Chiari malformations are a very common cause of congenital hydrocephalus, and account for up to 40% of cases (3). Chiari malformations refer to a set of congenital anomalies of the hindbrain where there is a downward displacement of the brainstem and cerebellum through the foramen magnum. There are three types depending on the degree of herniation though the foramen (1,7). Chiari type I is caudal displacement of the cerebellar vermis or tonsils through the foramen. In type II, the fourth ventricle and lower medulla are also herniated. The Chiari type III malformation involves extension of the cerebellum through the foramen magnum and into an associated cervical spina bifida. Chiari type II is the most common of the Chiari lesions and almost always occurs in conjunction with a myelomeningocele and hydrocephalus (1,7).

Aqueductal stenosis is also a very common cause of congenital hydrocephalus. With an occurrence of 0.5 to 1.0 per 1000 live births, it accounts for approximately 20% of hydrocephalus cases (3). Although commonly recognized at birth, the disorder may have an insidious onset, and should be considered in the differential diagnosis of hydrocephalus at any age. Aqueductal stenosis refers to narrowing of the fourth ventricular aqueduct of Sylvius and results in obstructive, non-communicating hydrocephalus. One form of aqueductal stenosis, associated with a syndrome called X-linked hydrocephalus, is caused by a mutation of the X-linked recessive L1 gene, which is responsible for the production of specific neuronal cell adhesion molecules (3,6). Aqueductal stenosis may also be associated with gliosis, which results after destruction of ependymal cells after a hemorrhagic or viral infectious process. Hydrocephalus that occurs as a result of toxoplasmosis or cytomegalovirus is usually the result of aqueductal stenosis (4). There are also multiple case reports of aqueductal stenosis after viral encephalitis caused by mumps (9,10,11).

The Dandy-Walker malformation is a cystic dilatation of the fourth ventricle following partial or complete agenesis of the cerebellar vermis, which leads to obstruction of CSF outflow though the foramina of the fourth ventricle. The syndrome occurs in approximately 1 per 30,000 live births (2,3), and is associated with less than 5 percent of all cases of hydrocephalus (4). Although the defect is present at birth, hydrocephalus does not always present in the neonatal period. Approximately 80% of all Dandy-Walker malformations will be diagnosed by one year of age, although some diagnoses may be delayed until adolescence or adulthood (3,12).

Intraventricular hemorrhage (IVH) is becoming an increasingly important cause of hydrocephalus secondary to the increased survival of very low birth weight infants (<1,500 grams) (13). Intraventricular hemorrhage is the result of vascular instability of cerebral vessels in the germinal matrix at the level of the head of the caudate in the premature infant. Bleeding of these vessels has been classified into 4 grades. Grade I is hemorrhage within the germinal matrix only. Grade II is hemorrhage from the matrix into the ventricles, but without ventricular dilatation. Grade III is IVH with resultant ventricular dilatation. Grade IV is IVH with ventricular dilatation and extension of the bleeding into the surrounding brain parenchyma. When present, IVH usually occurs in low birth weight infants within 72 hours of delivery, and 50% of these occur without immediate clinical symptomology (13). Post-hemorrhagic hydrocephalus may occur immediately as a result of clotting of blood in the ventricular system, which leads to obstruction. More commonly, however, communicating hydrocephalus develops within weeks to months after the hemorrhagic event as the breakdown products of blood lead to diffuse fibrosis of the leptomeninges (13). In order to detect asymptomatic intraventricular hemorrhage, it is recommended that all premature neonates of gestational age <30 weeks of life undergo screening cranial ultrasound at 7 to 14 days of life. If none is detected, a follow-up cranial ultrasound is recommended at 36 to 40 weeks postconception (14).

After the newborn period, common causes of hydrocephalus are hemorrhage, and post-viral or post-bacterial meningitis. The mechanism of formation of hydrocephalus secondary to hemorrhage in other age groups is the same as for premature infants described above, except that the origin of bleeding is different and may be due to rupture of an AV malformation, subarachnoid bleed, or as a result of a traumatic injury. In bacterial meningitis, clumping of increased cellular and infectious matter within the CSF may produce non-communicating hydrocephalus. However, communicating hydrocephalus that occurs as a result of permanent scarring of the meninges is the most common outcome, and occurs in up to 1% of survivors of bacterial meningitis (5). Tumors, cysts, and other space occupying lesions should be considered in the differential diagnosis of hydrocephalus at any age, although they become more important causes in this age group.

The signs and symptoms of hydrocephalus may also be considered as a function of age. The most visually dramatic cases of hydrocephalus occur in infants prior to the close of the anterior fontanelles at 18 months, where the increase in head size may become very large secondary to decreased containment of swelling by open sutures. Subsequently, limited expansion of the more developed sutures leads to earlier neurologic signs, which promote detection of lesions prior to the onset of massive hydrocephalus. Before 2 years of age, hydrocephalus will invariably present with some enlargement of the head. There may be cephalofacial disproportion, possibly with frontal bossing. Sutures may be splayed, and scalp veins may be very prominent. The "setting sun" sign is an ocular abnormality where the eyes appear to look downward such that the whites of the sclera form an arc above the irises. Papilledema is a rare finding; however, long-standing hydrocephalus may be associated with optic atrophy. In infants, primitive reflexes may persist and there may be delayed development of the more mature reflexes. Motor spasticity with hyperreflexia and clonus may be present and will be more prominent in the lower extremities before the upper extremities. This is secondary to increased stretching of the motor fibers of the lower extremities as they traverse longer pathways (1,3). It should be noted that if the onset of hydrocephalus is acute with rapid progression, then vomiting, lethargy, seizures, and cardiorespiratory compromise may occur in infants despite open sutures (3). In older infants, pressure on the brainstem bilaterally may lead to a condition known as pseudobulbar palsy where poor oral-motor control is manifest by difficulty with swallowing and changes in speech.

In older children with hydrocephalus, more focal neurologic signs will be apparent and suggestive of the lesion. Older children present with more classic signs of increased intracranial pressure such as headache and vomiting that is worse in the morning especially upon wakening. Papilledema and strabismus will likely be present. The "bobble head doll syndrome" is a manifestation of obstructive lesions around the third ventricle or aqueduct and is characterized by 2 to 4 oscillations of the head per second along with psychomotor retardation (2,3). Spasticity is particularly prominent in the lower extremities, and there may be a positive Babinski sign. Endocrine abnormalities may be apparent due to long-standing perturbation of the hypothalamic-pituitary axis and may result in growth derangements, delay or acceleration of sexual maturity, fluid and electrolyte disturbances, and thyroid dysfunction (2,3). Cognitive deficits may be suggestive of the lesion, and emotional lability may be a presenting sign.

The diagnosis of hydrocephalus is made more readily apparent with the increasing availability of imaging techniques. Ultrasonography may be used to detect hydrocephalus in the fetal and neonatal periods. In older infants and children, computed tomography (CT) may be utilized. However, magnetic resonance imaging (MRI) is the preferred diagnostic tool in this age group as it provides superior resolution of the brain, spinal cord, and subarachnoid spaces such that specific lesions are more easily detected (3,15). The characteristic lesion of non-communicating hydrocephalus will show dilatation of the ventricles proximal to the site of obstruction

with periventricular edema of the adjacent white matter caused by disruption of the ependymal lining in the affected area. In communicating hydrocephalus, the entire ventricular system will be dilated with distinct enlargement of the subarachnoid space over the cerebrum.

Once the underlying etiologic condition has been addressed, the mainstay of therapy for progressive hydrocephalus is a shunt procedure, which allows for diversion of CSF with the overall goal of ventricular decompression. In general, CSF fluid proximal to the site of obstruction is shunted through a catheter and drained into a body space that allows for absorption of the ventricular fluid. The most common and preferred site of drainage is into the peritoneum (VP-ventriculoperitoneal shunt), although many other sites have been utilized (16,17). The most common secondary sites are the pleural space and the venous system or right atrium. The shunt catheter contains a valve to assure one-way CSF flow and is concealed within a subcutaneous tract. Extra tubing is usually curled into position at the distal catheter end to allow for growth of the infant or child. Other treatments for hydrocephalus include the endoscopic third ventriculostomy, which involves fenestration of the third ventricle in obstructive hydrocephalus to provide a direct communication with the subarachnoid space. Additionally, lumboperitoneal shunts may be utilized in cases of communicating hydrocephalus (16,17).

Medications that reduce intracranial pressure such as mannitol may be utilized for cases of rapidly progressive hydrocephalus as a palliative measure while awaiting surgery. Additionally, specific medications that decrease the production of CSF may be useful such as acetazolamide and furosemide. These latter medications may also be utilized temporarily for slowly progressive hydrocephalus or hydrocephalus that is transient, e.g., while awaiting shunt revision (1,16).

Shunt malfunction is a fairly common occurrence with a one-year failure rate of 30-40% (18,19). Higher rates of failure have been described in younger patient populations with the most significant risk occurring in patients younger than 6 months of age at the time of implantation (18,20). The most common time for shunt failure to occur is within six months of surgery (18,21), and causes of shunt malfunction include obstruction, infection, and over-drainage (16,18,21). Obstruction occurs generally because of collection of organic matter in the catheter tubing. Symptoms of shunt malfunction include headache and vomiting. Sunsetting of the eyes, vision changes, diplopia, and distended veins may also be noted. CT scanning is fairly reliable in identifying shunt malfunction. Enlargement of the ventricles is diagnostic of shunt malfunction. Unfortunately, a baseline CT (i.e., when the shunt is working) is not always available for comparison. Frequently, the patient's previous CT scans were obtained when the shunt was malfunctioning. This must be taken into consideration when comparing the size of the ventricles.

Infections usually come to attention about two months after shunt insertion, suggesting that infection may be occurring at the time of surgery, although subsequent infection through contaminated skin surfaces also occurs (2,18). Infection rates vary from 1-10% (3,18,20,21). The most common causative agent of infection is coagulase-negative staphylococci, especially Staphylococcus epidermidis, although Staphylococcus aureus has also been implicated. Treatment usually mandates removal of the shunt, and intraventricular as well as intravenous antibiotics may be required. If shunt revision is necessary, sterility of the CSF is first documented by culture prior to surgery. In cases of community-acquired meningitis, however, treatment may be given as usual with the shunt left in place, as the usual causative agents are unable to colonize the shunt and the catheter may actually lessen the severity of symptoms (16,20).

The overall outcome and prognosis of hydrocephalus is highly dependent on multiple factors including the age of onset, etiology, ventricular expansion, and extent of neurologic damage prior to correction of the intracranial insult. Mortality rates have been reduced to less than 5% in ten years after shunt placement (22). In one study of 129 children followed ten years post-operatively, who had had shunts placed prior to the age of two, 60% were found to have motor deficits, 25% had visual or auditory deficits, and 30% had epilepsy (22). About 1/3 of children had IQs above 90, 28% had IQs between 70 and 90, and another 30% had IQs below 70. Twenty-one percent had IQs less than 50. The presence of behavioral disorders was frequent in this study. Other researchers have also found a relationship between hydrocephalus and behavior problems (23,24). Among higher functioning children, a discrepancy has been noted between verbal and nonverbal (performance) IQs, with nonverbal skills being reduced in hydrocephalic children (23,24,25,26). It has been postulated that disruption of cerebral white matter tracts leads to this decrease in nonverbal skills, which may promote behavioral maladjustment in these children. These studies indicate that despite the decreased mortality associated with hydrocephalus, there is still much long-term morbidity associated with the disorder. Multidisciplinary planning and close follow-up is needed to ensure the maximal developmental potential of these children.

Questions

1. Define hydrocephalus and distinguish this term from macrocephaly and megalencephaly.
2. What are the two classic classifications of hydrocephalus and give examples of each?
3. What are the most common causes of congenital hydrocephalus?
4. What is X-linked hydrocephalus?
5. True/False: The Dandy-Walker syndrome is usually diagnosed at birth.
6. What is the purpose of routine cranial ultrasound screening in the very low birth weight infant?
7. True/False: CT is the best imaging method for the diagnosis of hydrocephalus after the neonatal period?
8. What is the frequency of shunt failure after initial surgical treatment of hydrocephalus?
9. What is the rate of infection after shunt insertion, and what is the most likely etiologic agent?
10. True/False: Most children with hydrocephalus go on to have IQs consistent with mental retardation.

Answers to questions

1. Hydrocephalus refers to pathological enlargement of the cerebral ventricles secondary to a mismatch between the amount of production of CSF and its drainage. Macrocephaly is a general term for any head circumference greater than two standard deviations from the mean. Megalencephaly refers to increased volume of the brain parenchyma.

2. Hydrocephalus is divided into two types: communicating and non-communicating. Communicating hydrocephalus is used if CSF flows freely throughout the ventricular system. Non-communicating hydrocephalus indicates that obstruction of CSF occurs somewhere within the ventricular system, including the outlet foramina of Luschka and Magendie. Communicating hydrocephalus may occur from scarring of the leptomeninges after viral or bacterial meningitis, or after a hemorrhagic brain event where the breakdown products of blood lead to diffuse fibrosis of the meninges. Non-communicating hydrocephalus occurs in cases of discreet obstruction within the ventricular system, such as occurs with aqueductal stenosis, the Chiari Malformations, the Dandy-Walker malformation, or mass effect from brain tumors or other mass lesions.

3. The most common causes of congenital hydrocephalus are Chiari malformations and aqueductal stenosis.

4. X-linked hydrocephalus is a form of aqueductal stenosis in which there is a mutation on the X-linked recessive L1 gene, which produces a family of abnormal neuronal cell adhesion molecules that leads to narrowing and obstruction at the level of the cerebral aqueduct.

5. False. The Dandy-Walker malformation, although present at birth, is responsible for less than 5% of cases of congenital hydrocephalus. Approximately 80% of cases will eventually be detected by one year of age.

6. When present, intraventricular bleeding in the very low birth weight infant usually occurs within the first 72 hours of life. Because up to 50% of these events will occur without immediate clinical symptomology, it is recommended that routine screening be performed between days 4 to 7 of life.

7. False. MRI is the preferred imaging method for the diagnosis of hydrocephalus after the neonatal period as it will also elucidate more precisely than CT the specific etiology of the hydrocephalus. However, in an emergency situation, CT is preferred because it can be done rapidly.

8. Shunt malfunction is a fairly common occurrence with a one-year failure rate of 30 to 40%.

9. The rate of infection after shunt insertion varies among different institutions, and has been reported from 1 to 10%. The most likely etiologic agent is Staphylococcus epidermidis.

10. False. The overall outcome and prognosis of hydrocephalus is highly dependent on multiple factors, including age of onset, etiology, the rate of ventricular expansion, and the extent of neurologic damage prior to shunt placement or other corrective intervention. In one study that looked at 129 children 10 years after shunt placement (shunts were placed prior to age two), approximately 60% had IQs over 70, which is generally considered the cutoff for one of the diagnostic criteria for mental retardation.

Chapter XVIII.10. Neural Tube Defects
Mari Uehara, MD

A C-section is scheduled for a 16 year old G1P0 mother at 37 weeks. Prenatal care was not sought until 32 weeks gestation. Mother did not take any vitamins or folate supplements prior to that time. Initial prenatal lab studies were significant for an elevated alpha fetoprotein. A prenatal ultrasound done at 34 weeks demonstrated a meningomyelocele. No hydrocephalus was noted at that time. A neurosurgeon was consulted. A C-section is scheduled to deliver the infant as non-traumatically as possible with the availability of the neurosurgeon close by.

At delivery, the infant is delivered with Apgar scores of 7 and 8. Birthweight is 3.2 kg. A translucent membrane sac overlying the mid-lumbar region is noted. It is leaking xanthochromic fluid. Upper extremity movement is noted to be good, but lower extremity movement is not as vigorous. The infant is transferred to the NICU where vascular access is obtained and initial stabilization measures are performed. Five hours later, the infant is taken to the operating room where a neurosurgeon closes the meningomyelocele defect over the lower back. Post-operative recovery in the NICU is unremarkable. Lower extremity movement is moderate. A head ultrasound study shows mild hydrocephalus. Two months later, the hydrocephalus is worsening on ultrasound, so a VP shunt is surgically placed.

Neural tube defects (NTDs) are a group of birth defects which are associated with a defective closure of the neural tube and the subsequent development of the central nervous system (brain and spinal cord). It is one of the most common birth defects occurring in approximately 0.7-1.0 per 1000 live birth each year (1,2). There are three types of NTDs: anencephaly, encephalocele, and spina bifida. Spina bifida, the most common NTD, means "split spine" in Latin and is a result of failure of the neural tube to close during the 3rd-5th week of pregnancy. The terminology can be confusing since multiple terms have been used for various conditions depending on the extent of the involvement of the spinal cord and surrounding structures.

Spinal dysraphism and spina bifida apply to a heterogeneous group which has defects of closure affecting the spinal canal (which may encompass the meninges and spinal cord itself in addition to bony vertebral elements). Myelodysplasia refers to defects of spinal cord development, which commonly occurs with spina bifida; however not necessarily associated with failure of fusion of the arches of the vertebral spine, so this could include entities such as syringomyelia and diastematomyelia. Spina bifida occulta is the simple failure of fusion of the spinal arches (i.e., bony involvement only), such that the neural elements are covered by skin and do not protrude above the level of the back. Occult spinal dysraphism means that spina bifida occulta is present with overlying cutaneous markers such as dimple, fistula, hair patch, and hemangioma. These markers may indicate the presence of cord tethering with a lipoma or a dermoid cyst. Spina bifida cystica is the commonest type of NTD which includes meningocele, meningomyelocele/myelomeningocele, lipomyelomeningocele. A meningocele is a lesion which does not involve neural elements in the cystic outpouching of the meninges. Meningomyelocele or myelomeningocele means that dysplastic neural elements protrude through the unfused vertebral arches. It can be completely covered with meninges and skin (closed meningomyelocele) or there may be a connection of spinal fluid to outside (open meningomyelocele). Lipomeningocele and lipomyelomeningocele are closed meningomyelocele with overgrowth of fatty tissue involving the meninges alone or including the spinal cord. The term spina bifida is ambiguous in that it is often used to describe conditions from spina bifida occulta to spina bifida with myelomeningocele.

The manifestations of the spina bifida depend on the level of the spinal cord involvement at which neural tube closure was incomplete. The lesion is located in lumbosacral area in more than 80% of the cases (3).

Children with the less common thoracic lesions, have flaccid paralysis of lower extremities with variable weakness in abdominal and trunk musculature. These defects are frequently associated with serious complications (e.g., respiratory compromise). Children with high lumbar lesions (L1, L2) have flaccid paralysis of knees and ankles and may walk with extensive braces and crutches. Children with midlumbar lesions (L3) have paralyzed ankles and toes. These children can accomplish independent ambulation with braces. Children with low lumbar lesions (L4, L5) often have weak ankle and toe mobility. They are particularly prone to ankle or foot deformities and often need orthosis for independent ambulation.

Bladder and bowel problems are present in more than 90% of children with meningomyelocele regardless of the level of lesion (1). Some children may have problems with bladder emptying, while others may have problems with storing the urine adequately. Despite the type of neurogenic bladder, it is crucial to prevent urinary tract infections and protect the upper urinary tract since renal failure is one of the important causes of death among these children. Bowel continence requires normal external sphincter control, internal sphincter reflex relaxation, rectal sensation and colonic motility. Lack of sensation and inability to control external sphincters makes these children unable to sense or control stool passage. Bowel management programs with regularly scheduled toileting, use of stool softeners, and dietary measures (i.e., additional fiber) are important to avoid constipation and soiling.

Spina bifida is often not only an isolated birth defect of the spinal cord and spine, but there commonly are associated congenital malformations of the brain. Hydrocephalus is a major complication of meningomyelocele and is present at birth in 85-95% of cases as shown by ultrasonography (3,4). These children with hydrocephalus require ventriculoperitoneal shunt (VP shunt) placement. Shunt malfunction and infection are frequent complications and most children eventually require shunt revision (30-40% within one year of insertion of the shunt). Lethargy, vomiting, irritability, bulging and tense fontanelle, and headache, are common symptoms of shunt malfunction. Seizures also occur in up to 17% of the children with meningomyelocele and almost always occur in those with hydrocephalus (5).

Arnold-Chiari II malformation (the cause of the hydrocephalus) is present in the majority of children with meningomyelocele. The cerebellum and medulla oblongata are shifted caudally, so this resultant packing into the cervical spinal canal results in deformation. The symptoms are due to progressive hydrocephalus (if untreated) and dysfunction of the lower cranial nerves, respiration and swallowing. Hydrocephalus occurs in most children secondary to aqueductal stenosis or obstruction to CSF flow around the medulla.

Any clinical changes in children with meningomyelocele should prompt a search for an underlying cause. By far, the most common cause of deterioration is shunt malfunction. Another important cause is tethering of the spinal cord. Up to one third of children with myelodysplasia may experience spinal cord tethering. A tethered spinal cord results from traction on the conus medullaris and cauda equina, which causes spinal cord stretching and ischemia with subsequent loss of neurological function. Symptoms of a tethered spinal cord include spasticity, weakness, decreased sensation in the lower extremities, changes in urinary and bowel functions, or back pain, progressive scoliosis and foot deformity. Some children with occult spinal dysraphism (i.e., no overlying meningomyelocele) are asymptomatic and truly have an occult spinal cord condition. An MRI scan will identify the spinal abnormality. Surgery is indicated in

symptomatic patients. Prophylactic intervention among asymptomatic children can prevent the long-term disabilities associated with this condition.

Mastery of bowel and bladder continence is crucial to optimal functioning and is of the major importance for social acceptance. The voiding program may include medications, intermittent catheterization, and possibly operative reconstruction. Clean intermittent catheterization is the most commonly used method to help urinary continence. It is used to remove residual urine, improve urinary drainage, and provide decompression. The goal is to have this task accomplished by early school age. A child's physical abilities and psychological readiness for toileting should be assessed and continued assistance may be necessary for some children.

Children with physical disabilities are often described by their disabilities, and not by their strengths or abilities, which are also important. Children with spina bifida are often automatically placed in regular classes or classes for children with orthopedic problems. Although this is frequently the best placement, there are children whose orthopedic problems are secondary and their learning disability associated with spina bifida may be the major disability. Children with spina bifida and hydrocephalus may have problems with motor skills, attention, memory and organization. These issues should be understood and addressed in the Individualized Education Program (IEP).

Latex allergy has been common among children with spina bifida (about 20-70%) (6). Although the cause of latex allergy in children with spina bifida is not known, it may be due to the early, intense, constant exposure to rubber products among these children. Latex comes from the sap of the rubber tree Hevea brasiliensis. After the commercial purification process there are small amount of residual proteins that could cause allergy symptoms ranging from mild skin rashes or sneezing to hives, respiratory distress and anaphylactic shock. Many products contain rubber components of which we are unaware and environmental exposure to rubber products in both the community and hospital is widespread (e.g., rubber bands, erasers, gym mats, certain paints and glues, elastic waist or leg bands in clothing and disposable diapers). There are some food items (e.g., bananas, avocado, chestnuts) which can also cause cross-reactions. Prevention is the best approach. This allergic condition should be documented on medical and school records, communication devices such as medical alert bracelet should be provided as well as auto-injectable epinephrine as a part of the emergency plan for these children. In fact, it is commonly recommended that all children with spina bifida and/or myelodysplasia be kept latex free even if allergy has not yet been demonstrated.

The initial treatment for spina bifida is early surgical closure of the defect. Because of the multisystem involvement of this condition as stated above, management of this condition requires a comprehensive, multidisciplinary team approach. This team may include pediatricians, nurses, specialists (neurologists, neurosurgeons, urologists, orthopedists, developmental-behavioral pediatricians), physical therapists, occupational therapists, social workers, and special education teachers.

Alpha-fetoprotein (AFP) is elevated in maternal serum (MSAFP) and amniotic fluid (AFAFP) in open NTDs such as encephalocele, meningomyelocele and anencephaly. It is also increased in other conditions such as abdominal wall defects (gastroschisis and omphalocele). AFP becomes measurable in maternal serum at the end of first trimester. Maternal blood sample measurements are collected between 16-18 weeks of gestation to provide enough time for more definitive testing as necessary and to allow sufficient time for decision making regarding continuation or termination of an affected pregnancy. The MSAFP level is affected by gestational age and the number of fetuses. Elevated AFP level in amniotic fluid is more definitive than MSAFP, identifying 90-95% of affected fetuses with open NTDs. Acetylcholinesterase assay is more specific for neural tissue with a 99% accuracy rate. Ultrasonography also has been increasingly accurate in prenatal diagnosis of fetal anomalies.

Folic acid is a synthetic compound used in dietary supplements and fortified foods. The term folate includes all compounds that have the vitamin properties of folic acid (folic acid and naturally occurring compounds in food). The average diet in the United States contains 200 microgram of naturally occurring folate, which is less bioavailable than folic acid. Studies have demonstrated that 50% or more NTDs can be prevented if women consume a folic acid supplement before and during the early weeks of pregnancy. The American Academy of Pediatrics endorses the US Public Health Service recommendation that all women capable of becoming of pregnant consume 400 microgram of folic acid to prevent NTDs.

Studies have shown improved long term outcome regarding ambulation, urinary continence, and social continence of stool. One of the studies also showed that about 60% of children with spina bifida attended regular school programs. These outcomes depend on the level of lesion and the severity of complications.

Questions

1. True/False: Vitamin supplementation prior to pregnancy has been found to reduce the risk of neural tube defects.
2. True/False: Spina bifida patients have neurogenic bladders.
3. True/False: Hydrocephalus develops in meningomyelocele patients because of cord tethering.
4. True/False: Children with meningomyelocele have a high risk of developing latex allergy, therefore, they should not be exposed to latex from birth.
5. True/False: High meningomyeloceles result in lower extremity paralysis, but most patients with low lying meningomyeloceles are able to ambulate on their own or with assistive devices.

Answers to questions

1. True. Folate supplementation prior to pregnancy and in early pregnancy reduces the risk of neural tube defects.
2. True, in that nearly all patients with myelodysplasia have bladder/bowel dysfunction; however, patients with spinal bifida occulta may only have a vertebral anomaly, without myelodysplasia, in which case, their bladder function will be normal.
3. Controversial question, but probably false. The hydrocephalus is usually due to a Arnold Chiari malformation in the brain (the other end of the neural tube) which results in hydrocephalus. It is probably not cord tethering which causes the hydrocephalus.
4. True.
5. True.

Chapter XVIII.11. Neurofibromatosis
Vince K. Yamashiroya, MD

A 6 month old infant female is seen in your office as a new patient for a well baby visit. Her family moved from here from Asia recently, where she was born. There were no prenatal or postnatal complications, and she has had no significant medical problems since birth. Her family history is positive for her father who has a condition in which his body is covered with fleshy small growths, similar to skin tags, and on the father's side, there are several family members with the same warty growths, seizures, and high blood pressure.

Exam: VS are normal. Her growth parameters are in the 25-50th percentiles. Her examination is otherwise unremarkable except for multiple coffee colored spots on her trunk and abdomen.

You suspect neurofibromatosis based on her cutaneous findings and the family history. You schedule her for a follow up visit tomorrow to discuss this further. You have overnight to prepare yourself to initiate a proper evaluation and treatment plan, and to counsel the family.

Neurofibromatosis is one of the more common types of neurocutaneous syndromes that is well known because of its clinical features. Its hallmark sign is the neurofibroma, which is a tumor of nerve connective tissue (1). There are actually two types of neurofibromatosis. The first type is NF-1, which is the most common type and its clinical features include cafe au lait spots and neurofibromas. The second type, NF-2, only accounts for 10% of the cases of neurofibromatosis, and its clinical feature is bilateral vestibular schwannomas (or acoustic neuromas), with cafe au lait spots and skin neurofibromas being less common (2). Neurofibromatosis was recognized as a disease for well over a hundred years. In 1882, Friedrich von Recklinghausen published his famous monograph describing this entity, and this disease became known as von Recklinghausen disease, which is NF-1. Other people have also recognized this disease as early as the eighteenth century, such as Tilesius and Akenside. In 1981, Dr. Vincent Riccardi recognized NF-2 as a clinically distinct entity from NF-1 (3).

Today, we know much more about both types of neurofibromatosis. Through molecular genetic studies, it was discovered in 1990 that the NF-1 gene is on the long arm of chromosome 17 and encodes for a protein called neurofibromin. It is believed that perhaps the NF-1 gene is a tumor suppressor gene, and that neurofibromin allows for the dephosphorylation of ras-GTP to ras-GDP. In patients with NF-1, there is a mutation in the NF-1 gene, therefore ras, which is thought to be a proto-oncogene, is not dephosphorylated and sends intracellular signals to inhibit apoptosis (programmed cell death) and stimulate cellular proliferation (4). The NF-2 gene was discovered in 1987 to be in the long arm of chromosome 22, and in the 1990's, its gene product was determined to be in the band 4.1 families of proteins that are associated with the cytoskeleton; however the function of the NF-2 gene is still not known (5).

We do know that both types of neurofibromatosis are autosomal dominant, just like tuberous sclerosis, which is another type of neurocutaneous syndrome. Interestingly, new mutations occur in about 50% of patients with NF-1 (6) and NF-2 (7), making these gene loci one of the highest known mutation sites in humans.

NF-1 is one of the most common types of neurocutaneous syndromes, with an incidence of 1/4000 (2). There is no sex or ethnic predilection (8). NF-2, on the other hand, is uncommon, having an incidence of about 1 in 40,000 births (7). This type of neurofibromatosis usually presents later in life, and is therefore seen by internists, rather than pediatricians.

The diagnosis of NF-1 is still a clinical one, despite the recognition of the gene causing NF-1 and its gene product. In 1987, the U.S National Institutes of Health Consensus Development Conference developed a list of criteria for the diagnosis of this disease. NF-1 is present in a patient who has two or more of the following signs:

1. Six or more cafe au lait macules greater than 5 mm in greatest diameter in prepubertal individuals or >15 mm in greatest diameter after puberty.
2. Two or more neurofibromas of any type or one or more plexiform neurofibromas (see definition below).
3. Freckling in the axillae or inguinal region (Crowe sign).
4. A tumor in the optic pathway.
5. Two or more Lisch nodules (iris hamartomas).
6. A distinctive osseous lesion, such as sphenoid wing dysplasia or thinning of the cortex of the long bones (with or without pseudoarthrosis).
7. A first degree relative (parent, sibling, or offspring) with NF-1 by the above criteria.

The signs of NF are age-dependent, with more signs appearing at older ages. Because of this, about 90% of children who are older than six years of age can be diagnosed using these criteria, but younger children may be missed (9).

Neurofibromas are benign tumors arising from large and small nerves, and are a cardinal feature of neurofibromatosis. They are mainly composed of Schwann cells and fibroblasts, and can occur anywhere in the body outside of the brain and spinal cord proper. There are four different types of neurofibromas: discrete cutaneous neurofibromas, discrete subcutaneous neurofibromas, deep nodular

neurofibromas, and diffuse plexiform neurofibromas. The cutaneous neurofibromas are sessile or pedunculated masses on the skin, which are fleshy and non-tender, and can vary in size. The subcutaneous neurofibromas lie deeper and look like bumps on the skin, which can sometimes be tender. The deep nodular neurofibromas involve tissues and organs underneath the dermis, and resemble cutaneous and subcutaneous neurofibromas. The diffuse plexiform neurofibromas differ from the others in that it has fronds that penetrate normal tissue, making them difficult to remove. These plexiform neurofibromas can vary in severity from no skin involvement to severe disfigurement, sometimes resulting in elephantiasis with limb hypertrophy or severe facial disfigurement. The deep nodular neurofibromas and diffuse plexiform neurofibromas share a common feature in that they can become malignant peripheral nerve sheath tumors. The single most important sign that a tumor has become malignant is persistent, unexplained pain. Neurofibromas can occur at any time of life, although the cutaneous, subcutaneous, and deep nodular types usually appear in late childhood to early adolescence, and sometimes later. The number and size of the neurofibromas increase throughout middle and late adulthood. By 16 years of age, all patients will have cutaneous and/or subcutaneous neurofibromas. The ones that occur earlier in life are the diffuse plexiform neurofibromas, which are actually thought to be congenital. An interesting finding is an abnormal hair whorl over the spine, called the Riccardi sign, which represents a congenital paraspinal plexiform neurofibroma, which can lead to dysplastic scoliosis later in life (8,10).

Cafe au lait spots are spots with the color of coffee with milk, being tan colored. They can vary in size from smaller than 10 mm to as big as covering a body part on one side, although the typical lesions are 1-3 cm ovoid spots, which are uniform in color. They can occur anywhere on the body except for the scalp, eyebrows, palms, and soles. Histologically, they are giant melanosomes within melanocytes. Although they are a hallmark feature of NF-1 and occur in almost all individuals with this disease, they can also be seen in normal individuals as well. They are usually one of the first signs that will alert the clinician to the presence of NF-1 since they usually appear at the time of birth (11).

Axillary freckling is akin to cafe au lait spots except they are smaller, about 1 to 3 mm in size, and occur in clusters. They usually appear in intertriginous areas like the axillae, inguinal area, upper eyelids, the base of the neck, breast folds in women, and skin folds in obese patients.

Lisch nodules are another characteristic finding of NF-1 occurring more frequently as an affected individual ages. In those who are 5 years old, the frequency is 25%, at age 10 years it is 50%, and by age 20 years it is more than 95%. They are pigmented hamartomas appearing as translucent masses with a gray-tan hue due to the melanin-containing cells that are on the iris. Usually they are bilateral and do not affect vision. Lisch nodules are diagnostic for NF-1, and they can be seen on slit-lamp examination by an ophthalmologist.

Optic gliomas are benign tumors which can form anywhere along the optic tract from the globe all the way to the optic radiations out of the occipital lobe. They occur in about 15% of NF-1 patients, but only 33% of these are symptomatic. These symptoms include decreased visual acuity, visual field deficits, proptosis, strabismus, optic atrophy, headache, nausea, anorexia, hypothalamic dysfunction, and precocious puberty. Current recommendations are for patients to have a full ophthalmologic examination when first diagnosed with NF; follow-up full ophthalmologic examination annually up to age 6 years; tests for visual acuity, color vision (Ishihara test), and slit-lamp examinations at 8, 13, and 20 years of age; and full ophthalmologic examinations at 10, 16, and 25 years of age. If a tumor is suspected, then neuroimaging is indicated. If an optic glioma is asymptomatic, then it can be observed. However, if it becomes progressive or symptomatic, then surgery, medical, or radiation therapy should be considered.

Neurofibromatosis should be considered a multiorgan disease in that tumors can occur in any part of the body. Other manifestations are hypertension from renal artery stenosis, seizures, scoliosis, long bone dysplasia, sphenoid bone dysplasia, short stature, macrocephaly, and peripheral nerve sheath malignant tumors. Mental retardation is not common (about 5%), while learning disabilities are more common (30-60%).

The diagnosis of NF-2 is based on criteria that were first developed in 1987 by the NIH. The Clinical Care Committee of the National Neurofibromatosis Foundation later revised this in 1997, the criteria of which is seen below (7):

Definite NF-2: Bilateral vestibular schwannomas (VS) or family history of NF-2 (first-degree relative) plus: 1) Unilateral VS (<30 years of age), or 2) Any two of the following: meningioma, glioma, schwannoma, juvenile posterior subcapsular lenticular opacities.

Presumptive or Probable NF-2: Unilateral VS (<30 years of age) plus at least one of the following: meningioma, glioma, schwannoma, juvenile posterior subcapsular lenticular opacities. Or multiple meningiomas (two or more) plus unilateral VS (<30 years of age) or one of the following: glioma, schwannoma, juvenile posterior subcapsular lenticular opacities.

The vestibular schwannoma, previously known as the acoustic neuroma, is the hallmark tumor of NF-2. This tumor arises from the vestibular branch of cranial nerve VIII, and is universal in patients with this type of neurofibromatosis (12). Although this tumor arises from the vestibular branch, the patient usually notices hearing problems before vestibular problems (e.g., balance). The average age of onset is 18 to 22 years, although it ranges from 10 years to over 35 years of age. The patient may first present with hearing problems, such as when using the telephone. The onset is gradual, although sometimes it can occur suddenly. Besides tinnitus and deafness, other signs and symptoms include facial weakness, visual problems, and painful peripheral nerve tumors. Children present differently from adults in that they show manifestations not involving cranial nerve VIII. These include spinal cord compression by gliomas or meningiomas, and ophthalmologic problems such as cataracts, strabismus, and amblyopia (7).

Cafe au lait spots can be a sign of neurofibromatosis or a part of other neurocutaneous syndromes. The following is a list of diseases that involve cafe au lait spots:

1. McCune Albright syndrome
2. Tuberous sclerosis
3. Fanconi anemia
4. Bloom syndrome
5. Ataxia telangiectasia
6. Russell-Silver syndrome
7. Multiple lentigines (LEOPARD) syndrome
8. Multiple endocrine neoplasia type 2b
9. Bannayan-Riley-Ruvalcaba syndrome

Solitary cafe au lait spots are commonly seen in the healthy population, although three or more spots can be seen in 0.2 to 0.3% of normal children, and six or more spots in less than 0.1% of healthy children. To suspect NF-1, there should be six or more cafe au lait spots that are larger than 0.5 cm in prepubertal patients, and larger than 1.5 cm in postpubertal patients. These spots are not a major feature

of NF-2, and these patients may have only a few spots present. McCune Albright syndrome includes precocious puberty and multiple endocrine problems. The cafe au lait spots are often large and irregular. It has been compared to having the shape of the coast of Maine, compared to the smooth shape of NF, which is likened to the coast of California.

Tuberous sclerosis (TS) is discussed in a separate chapter. Although cafe au lait spots are not as common as the hypopigmented macules in TS, they can be present. These spots can be seen in 25% of patients with Fanconi anemia, which presents with aplastic anemia, mental retardation, generalized hyperpigmentation, radial ray defects, eye anomalies, and other multiorgan problems. NF patients, unlike Fanconi anemia, do not have anemia. Bloom syndrome is an autosomal recessive disorder that features areas of hypo and hyperpigmentation, prenatal and postnatal growth retardation, thin triangular facies, telangiectatic rash in sun exposed areas, and malignancies (leukemia, breast, and gastrointestinal). Ataxia telangiectasia can also have cafe au lait spots, but probably only in a minority of patients. This disease includes progressive neurodegeneration, bulbar conjunctival telangiectasia, immunodeficiency, and increased risk for malignancies. Russell Silver dwarfism can also have cafe au lait spots but some studies report that it might not be different in frequency to the normal population. This disorder includes prenatal growth retardation, small triangular facies, and short and curved fifth fingers.

The management of a patient with neurofibromatosis should focus on genetic counseling and evaluating for the development of new tumors. The patient should be referred to a neurofibromatosis clinic if one is available, because of the multidisciplinary assistance that can be received. Blood pressure should be obtained at every visit because of the higher risk for hypertension. Those with scoliosis should be referred to an orthopedist for treatment. Learning disabilities can occur and the patient should be evaluated for this annually in terms of his or her academic performance. Dermal neurofibromas can be removed surgically or by laser. Annual eye examinations should be performed annually for the first six years of life, with less frequent examinations thereafter. Prenatal diagnosis is available for NF-1 by amniocentesis or chorionic villus sampling, and can be performed if one of the parents has NF. However, NF is of variable severity, therefore, the value of determining whether a fetus has NF is controversial (9).

The management of NF-2 includes genetic counseling, annual hearing screenings, and surgery for tumors. Because of the risk for deafness, learning sign language and wearing hearing aids should be considered (7).

The prognosis for NF-1 is not a promising one. Throughout life, these individuals develop more lesions, with new types of tumors such as Lisch nodules, neurofibromas, and optic gliomas appearing. A feature of neurofibromatosis is its clinical variability, so it is difficult to determine who will be having severe, debilitating, and disfiguring disease. However, the life expectancy for NF-1 patients is reduced in general, with most deaths occurring in childhood or middle adulthood. Deaths in childhood are usually caused by an intracranial tumor, however, a malignant peripheral nerve sheath tumor, leukemia, or an embryonal tumor can be the cause as well. Sometimes, death can also be due to the growth of a plexiform neurofibroma in the cervical to upper mediastinum region. Deaths in middle adulthood are due to a malignant peripheral nerve sheath tumor or sarcoma from another type of tissue. Other causes are acute hydrocephalus, severe seizures, gastrointestinal hemorrhage, intracranial hemorrhage due to vasculopathy, progressive spinal cord encroachment by plexiform neurofibromas or unstable dysplastic scoliosis, and complications of hypertension due to arterial dysplasia or pheochromocytoma.

NF-2 patients do not fare well either. The average life expectancy is 36 years with death being due to surgically inoperable tumors. These patients also suffer from vision and hearing deterioration, chronic pain from tumors, and loss of ambulation.

We have now identified the gene and gene products for neurofibromatosis. With new discoveries and technologies, gene therapy may be used to treat and prevent this disease in individuals at risk in the near future.

Questions

1. How many cafe au lait spots are needed to diagnose neurofibromatosis? How big do they need to be in prepubertal and postpubertal patients?
2. What is the hallmark tumor in NF-2? How is it manifested in a patient?
3. If you see a patient with cafe au lait spots who you suspect has von Recklinghausen's disease, what tests or evaluations need to be performed?
4. What types of neurofibromas can become malignant?
5. What skin manifestations occur in the newborn period? How about in older children and adults?
6. What is the genetic inheritance pattern for neurofibromatosis? What percentage of cases occur without a family history of NF (sporadic)?
7. What are the eye tumors that you can find on the iris of NF-1 patients called?

Answers to questions

1. 6 spots. >5 mm in prepubertal and >15 mm in postpubertal patients.
2. Vestibular schwannoma (acoustic neuroma). It is manifested by hearing problems.
3. Blood pressure measurements and eye examinations.
4. Deep nodular neurofibromas and diffuse plexiform neurofibromas.
5. Cafe au lait spots in newborn period. Discrete cutaneous and subcutaneous neurofibromas, axillary freckling in the older patient.
6. Autosomal dominant. 50% occur without a family history.
7. Lisch nodules.

Chapter XVIII.12. Tuberous Sclerosis Complex
Vince K. Yamashiroya, MD

A 10 month old girl presents to the emergency room for tonic-clonic seizures lasting a few minutes. This baby girl is a product of a normal pregnancy and was delivered full-term by normal spontaneous vaginal delivery. There were no postnatal complications and this infant was discharged from the hospital at 48 hours of life. Her history is significant for jerking movements (onset at 5 months of age) described as sudden flexion of the neck, arms, and legs onto the trunk preceded by a cry. Her parents were not too worried about this behavior since the child would return back to normal and they attributed it to colic or "gas". There was no history of fever, coughing, vomiting or diarrhea. She has been gaining weight appropriately and eating normally. She is on solid foods and formula, which the parents prepare correctly. Her immunizations are up to date. She is on no medications and her development has been normal. She is able to sit up, crawl, cruise with both hands, and combines syllables.

Her family history is also unremarkable in that there is no history of seizures, mental retardation, or consanguinity.

Exam: VS T 37.0, P 100, R 26, BP 90/60, O2 sat 100% on RA, weight 9.0 kg (50%ile), length 73 cm (50%tile), HC 44.5 cm (50%tile). She is alert and active in no distress. She is not toxic. She tracks well. She has good bonding with mother. She has multiple small 1-2 cm oval, irregular hypopigmented macules on her trunk and extremities. HEENT is normal. Her neck is supple without lymphadenopathy. Heart, lungs and abdomen are normal. Neuro: She has no facial asymmetry. She moves all her extremities well. There are no focal deficits. She does not exhibit cortical thumbing or scissoring of her lower extremities. She tracks well. She has good head control and is able to support herself on her legs.

In the ER, her work-up includes a head CT scan revealing cortical tubers in the cerebral cortex and multiple subependymal nodules in the lateral ventricles. She is admitted to the floor where an EEG shows "hypsarrhythmia". An echocardiogram and a renal ultrasound are also done showing tumors in both the heart and kidneys. A diagnosis of tuberous sclerosis is made. She is started on ACTH, unfortunately her condition fails to improve and she continues to have intractable seizures in addition to being mentally retarded.

Tuberous sclerosis was probably first described by Friedrich Daniel von Recklinghausen in 1862, when he presented a baby who died "after taking a few breaths". She had pathological findings of tumors bulging from the heart, which Dr. Recklinghausen named "myomata" and described in few words, the brain having "a great number of scleroses." Then in 1880, Désiré-Magloire Bourneville first described the brain of a diseased individual in greater detail, and used the term "tuberous sclerosis of the cerebral convolutions" because of the gross nodular appearance of the brain tumors resembling tubers, or roots of a plant (1).

Over a century later, we know much more about tuberous sclerosis complex (TSC). It is one of the neurocutaneous syndromes because it is thought that TSC is due to a defect in differentiation of the primitive ectoderm, which gives rise to the nervous system and skin. Therefore, it is in the same family of disorders, which includes neurofibromatosis, Sturge-Weber disease, von Hippel-Lindau disease, ataxia telangiectasia, linear nevus syndrome, hypomelanosis of Ito, and incontinentia pigmenti (2). It was also thought to be similar to neurofibromatosis and von Hippel-Lindau disease as being one of the phakomatoses, which is derived from the Greek word phakos, meaning "spot." This "spot" refers to a congenital grouping of nevus cells that is found in several organs and has the potential of enlarging and forming a tumor by cellular proliferation.

TSC is inherited as an autosomal dominant trait like neurofibromatosis; however, at least half of the cases are due to new mutations. The estimated frequency is 1 in 6000, and there is no racial predilection; therefore, we have seen several of these patients in Hawaii. There have been two genes implicated in TSC discovered so far, called TSC1 and TSC2 which are located on chromosomes 9q34 and 16p13 respectively. The TSC1 gene encodes for a protein called hamartin and the TSC2 gene encodes for tuberin. Although these two gene products have been discovered, the diagnosis of TSC is a clinical one and is not dependent on a blood test yet. The complicating feature of TSC is its wide clinical expression. Therefore, one patient could be asymptomatic while another patient could have seizures and severe mental retardation. Although variable expression is a feature of TS, it is doubtful that there is incomplete penetrance, meaning that a person with an autosomal dominant gene defect does not show any signs of the disease (3). This makes genetic counseling very difficult since one cannot predict what the phenotypic expression of the offspring will be, even though the chances of an individual having TSC is 50% given that one of the parents have the dominant allele. Also, because of the variable expression of this disease, it is imperative that in obtaining a family history, one asks if there is a history of mental retardation; seizures; obstructive hydrocephalus; brain or cardiac tumors; cardiac dysrhythmias at an early age; stillbirths (especially with hydrops); kidney, lung, or bone cysts; pulmonary failure; spontaneous pneumothorax; renal angiomyolipomas or failure; fibromatous growths around or under the nails or on gums; enamel pits; retinal phakomas; skin lesions such as hypopigmented macules, facial angiofibroma and shagreen patches; poliosis (premature white hair) or canities (white hairs) of the scalp, lashes, or brows; and iris depigmentation, in addition to recognizing that these signs can be mistaken for vitiligo, refractory acne, or autosomal dominant polycystic kidney disease. However, family history is often insufficient; therefore, family members should be examined for hypopigmented macules (with a Wood's lamp) and brain anomalies by computed tomography. Because

of the possibility for other tumors, ophthalmologic examination, renal radiographic studies, chest radiography, and echocardiogram are often ordered.

TSC is classified as a neurocutaneous syndrome meaning that its manifestations include neurologic and dermatologic features. Vogt proposed a diagnostic triad for TSC in 1908 being mental retardation, seizures, and adenoma sebaceum; however, because of the variable clinical expression, this triad of symptoms may not be present all together, and is therefore not used. Tuberous sclerosis is a multiorgan disease and does not only include the brain pathology; therefore, "tuberous sclerosis complex" may be a better term for this disease (4).

The diagnosis of TSC is still made clinically and as mentioned previously, the identification of TSC1 and TSC2 and their gene products have not changed the way it is diagnosed. The Consensus Conference on TSC by the National Tuberous Sclerosis Association in 1998 categorized major and minor diagnostic features (listed below) for the diagnosis of the tuberous sclerosis complex. A definitive diagnosis of TSC is made by either 2 major features, or 1 major and 2 minor features. Probable TSC is made by 1 major plus 1 minor feature. And possible TSC is made by either 1 major feature or 2 or more minor features (4).

Major Features
1. Facial angiofibromas or forehead plaques
2. Nontraumatic ungual or periungual fibroma
3. Hypomelanotic macules (more than 3)
4. Shagreen patch (connective tissue nevus)
5. Multiple retinal nodular hamartomas
6. Cortical tuber
7. Subependymal nodule
8. Subependymal giant cell astrocytoma
9. Cardiac rhabdomyoma, single or multiple
10. Lymphangiomyomatosis
11. Renal angiomyolipoma

Minor Features
1. Multiple randomly distributed pits in dental enamel
2. Hamartomatous rectal polyps
3. Bone cysts
4. Cerebral white matter radial migration lines
5. Gingival fibromas
6. Nonrenal hamartomas
7. Retinal achromic (pale, without color) patch
8. "Confetti" skin lesions
9. Multiple renal cysts

TSC can sometimes present during the first year of life with infantile spasms. In two studies, infantile spasms were the presenting complaint in 69% of patients. Infantile spasms usually begin between the ages of 4 and 8 months, and present with brief symmetrical contractions of the neck, trunk, and extremities, which can either be in flexion or extension, or both. Clusters of seizures may last for minutes with a brief period occurring between each seizure, and may be preceded or followed by a cry. Because of this, the spasms are sometimes mistaken for colic. The spasms have a tendency to occur when the infant is drowsy or upon awakening. Infantile spasms have a very unique pattern on EEG, called hypsarrhythmia, which consists of chaotic, high-voltage, bilateral, asynchronous, slow-wave activity (5).

Perhaps more characteristic of TSC is the development of other types of seizures. The seizures are thought to be due to the cortical tubers or its surrounding cortex that occur in the brain of these patients, although they can sometimes be secondary to cerebral cortex next to a subependymal giant cell astrocytoma. Seizures are the presenting symptom in about 90% of patients with this disease, most of who are children. Although they can occur at all ages, they usually occur in the first year of life. The most common seizure types, besides infantile spasms, are partial simple, partial complex, and partial with secondary generalization (6).

Given that TSC involves hamartomatosis, a condition in which benign tumors form from dysplastic cells that multiply excessively, imaging is extremely important. Because of the CNS manifestations, CT and MRI are essential in the evaluation of a patient suspecting of having TSC, especially if signs of cerebral involvement are present. Cortical tubers, which are most characteristic of TSC, are primarily located in the cerebral cortex and underlying white matter, and are called hamartias, or groups of dysplastic cells that do not grow more rapidly than the other normal cells. They are sometimes calcified, often multiple, and hypomyelinated. Two hamartomatous brain lesions are subependymal nodules and subependymal giant cell tumors. Subependymal nodules are growths that are usually on the outer walls of the lateral ventricles, nearly always next to or within the caudate nucleus. They are generally less than 1 cm and may calcify. They are found in about 80% of patients, and are the single most diagnostic feature by CT scan of TSC. Another unique brain lesion is the subependymal giant cell tumor. These tumors usually lie adjacent to the foramen of Monro and are histologically identical to the subependymal nodules. The difference between the giant cell astrocytomas and subependymal nodules is the propensity for growth in the former. Because of its location, there is a propensity of these tumors to cause hydrocephalus from obstructing the flow of CSF through these foramina (7).

After seizures, mental retardation and other psychiatric problems are also commonly seen in tuberous sclerosis patients. Patients who have never had seizures, infrequent seizures, or seizures after 4 years of age, will most likely have normal intelligence and development. Behavioral and psychiatric problems that are seen in TSC includes ADHD, sleep problems, childhood schizophrenia, and autism.

Ash leaf spots are irregular, hypopigmented macules resembling the leaves of the ash tree (also similar to Hawaiian maile leaves) (8). These lesions occur in the majority of patients with TSC and are often seen at birth, although they can appear months or years later. They appear on the trunk and extremities, number anywhere from 3 to 4, to more than 100, and are usually 1.0 cm or larger. At times, numerous tiny macules are grouped together, resembling confetti, and are usually located in the distal parts of the extremities. Although ash leaf spots appear at birth and may last throughout life, they can become less obvious with time and disappear. These hypomelanotic

macules are best seen with a Wood's lamp or ultraviolet light, since melanin absorbs light in the wavelength of 360 nm, making the macules that are deficient in melanin stand out (9).

Adenoma sebaceum or facial angiofibroma is a pathognomonic finding in TSC and was found in over 80% of patients over 5 years of age in one study. They are tiny red or pink papules with a glistening surface found bilaterally over the cheeks, chin, and nasolabial folds in a butterfly fashion. Larger angiofibromas can occur on the scalp or forehead, and appear as large, flesh-colored plaques that can be soft and doughy to hard. These lesions persist for life.

Another characteristic dermatologic manifestation is the shagreen patch. The word shagreen comes from the French words, peau chagrinee, which mean, "skin with the appearance of untanned leather." This lesion usually appears after the first decade of life and persists throughout life. They are usually found in the lumbosacral area, but sometimes are located elsewhere on the trunk. They are yellowish brown or pink in color, feel like pigskin or an orange peel, and can be few millimeters to over 10 cm in size. They are the second only to ash leaf spots as being the most common lesion in TSC that is found in the trunk.

Ungual fibromas, another characteristic sign of TSC, are flesh colored, or red papules or nodules found on the finger or toe nail bed, with the toes being more common than the fingers, ranging from 1 to 10 mm in size. These fibromas occur more commonly in females, grow back when removed, and appear during or after puberty.

For ophthalmologic lesions, the most common retinal hamartoma is the noncalcified tumor, which appears as a smooth, salmon-gray colored, circular lesion with indistinct borders. These tumors are usually located superficially to a retinal artery and are found in over half of patients with eye involvement. The second type of retinal tumor is the calcified mulberry tumor. Despite the lesions that can occur in the eye, blindness is rare, except in cases where the tumor involves the fovea or optic nerves (10).

Another common tumor is the cardiac rhabdomyoma, which can occur in about 50% of patients. These tumors can occur in any of the four chambers, although it is most commonly located in the left ventricle. Echocardiography is an essential component in the work-up of these individuals (11).

Renal involvement occurs in about 80% of patients with TSC. The lesions include angiomyolipomas, cysts, and renal cell carcinomas. Angiomyolipomas are localized proliferations of blood vessels, smooth muscle and fat. They can be associated with chronic renal failure, with the risk increased if there are also cysts. Cysts can develop in infancy and usually present with severe hypertension due to a mass effect of the cyst into the renal vessels (12).

The differential diagnosis of tuberous sclerosis complex is dependent on the presenting symptom, which in most cases are seizures. There are many causes of seizures, however, it is important to note whether any neurocutaneous stigmata such as ash leaf spots or cafe au lait spots are present since they will be clues that neurocutaneous syndromes like tuberous sclerosis or neurofibromatosis may be the cause. Therefore, a careful skin examination is essential in the evaluation of seizures.

There are many manifestations and degrees of severity of tuberous sclerosis; therefore, management should be aimed at treatment and evaluation of the symptoms. Patients with seizures should have an imaging test such as CT, and an EEG performed to look for anatomical abnormalities or abnormal EEG patterns such as "hypsarrhythmia". If tuberous sclerosis is suspected, the patient should also have an echocardiogram and renal ultrasound or CT done since the chances for cardiac and renal tumors are high. A good funduscopic examination is essential to determine the presence of retinal hamartomas.

The treatment of seizures is difficult because these seizures are often refractory to antiepileptic drugs. The best drug we have available for infantile spasms (also called hypsarrhythmia seizures) in the United States is intramuscular ACTH, however, the drug of choice is vigabatrin because it is safer and more effective. Vigabatrin is an anticonvulsant which inhibits GABA transaminase, which breaks down GABA (an inhibitory neurotransmitter) (13). However, the U.S. Food and Drug Administration has been reluctant to approve it because of its risk of psychosis (about 1-2%), clefts in the myelin sheath of peripheral nerves seen in rodents, and case reports of permanent peripheral vision loss. ACTH can lead to hypertension and other side effects of corticosteroids, such as osteoporosis, weight gain, Cushingoid appearance, avascular necrosis of the femoral head, etc.

Genetic counseling is very important in the management of TSC. A good family history should be obtained in addition to examining the family members for any signs and stigmata of TSC. Since it is autosomal dominant, the chances that an offspring will have this disorder is 50%; however, given the phenotypic variability of this disease, predicting the outcome of the couple's future children can be difficult. For example, because less than 50% of individuals with tuberous sclerosis will have mental retardation, the couple should be told that their offspring will have about a 25% chance of being mentally retarded. Other alternatives for having children should also be discussed; those being adoption, artificial insemination with donor sperm, and in vitro fertilization with a donor egg. If there is a negative family history and sporadic disease is likely, then the chances for future offspring having the disease is probably less than 2%, although one of the parents could still carry the gene and not thought of having the disease since its expression may be very mild. Prenatal diagnosis may be possible as early as 22 to 25 weeks by detecting the presence of cardiac or brain tumors; however, this is not always possible. If it is known that this family has a TSC1 or TSC2 gene mutation, then it may be possible to detect this mutation in the fetus through chorionic villus sampling.

The outcome of tuberous sclerosis complex is variable, depending on the severity of the disease. Some individuals may have a normal lifespan and not know that they have the disease, whereas, others could succumb to a lifetime of intractable seizures, mental retardation, or the development of other hamartomas throughout their adult life leading to new problems.

I would like to thank Dr. Robert Bart for reviewing this chapter and his useful comments and suggestions.

Questions

1. How is tuberous sclerosis complex inherited?
2. What percentage of TSC is sporadic (due to new mutations)?
3. Name three dermatological features of TSC. At what ages do each of these lesions occur?
4. What is the treatment of choice for infantile spasms that is approved by the FDA?
5. What is the EEG pattern of infantile spasms?
6. If a patient is diagnosed with TSC by computed tomography of the brain, what other tests must be done in the work-up?

Answers to questions
1. Autosomal dominant.
2. 50%.
3. Ash leaf spots (birth), adenoma sebaceum or facial angiofibroma (5 years old), shagreen patch (after 10 years old).
4. ACTH.
5. Hypsarrhythmia.
6. Echocardiogram and renal ultrasound.

Chapter XVIII.13. Head Trauma and Hemorrhage
Floyd S. Ota, MD

Two days ago, this 6 month old male infant was sitting in an infant carrier which was placed on top of a stroller. The carrier accidentally fell approximately 3 feet onto the ground. He hit his head on the plastic portion of the car seat. There was an immediate cry and no loss of consciousness. His behavior, activity, and feeding pattern were reported as normal. Two days later (today) his mother notes a boggy swelling in the right temporal area of the head and because of this, she brought him to the emergency room for evaluation. He continues to have normal activity and no vomiting.

He has been previously healthy. There is no history of substance use, or child protective services (CPS) involvement in the family.

Exam: VS T 36.9, P 120, R 18, BP 92/50, oxygen saturation 100% in room air. Height, weight and head circumference at the 25th to 50th percentiles. He is alert, active, easily arousable on exam and clean in appearance. He has a 9 by 7 cm swelling over the right temporal/parietal region that is soft, possibly tender, with no palpable bony deformity. No lacerations or wounds are noted. His anterior fontanel is soft and flat. Pupils are 3 mm bilaterally and reactive to light. EOMs are conjugate. There is no hemotympanum, no nasal discharge, and his mucus membranes are moist. His heart, lung, and abdomen exams are normal. Neurologic and extremity exams are normal.

A head CT scan shows a subgaleal hematoma (hematoma under the aponeurosis of Galen), a non-depressed linear skull fracture, and a normal brain. He is discharged home to the care of his parents. He followed up with his pediatrician the next day without sequelae.

Head injuries are the most common cause of traumatic death in children. Head injuries result in about 600,000 visits to the emergency department, and 250,000 hospitalizations annually (1,2). The main causes of head injuries in children overall in descending order are falls, motor vehicle crashes, pedestrian accidents, bicycle injuries, and other injuries (e.g., sports injuries, assault, and non-accidental trauma) (2). Motor vehicle accidents are the most common cause of traumatic death due to head injuries. The diagnostic dilemma for treating head injured children lies in identifying those patients who require more acute attention, and differentiating them from stable patients.

Younger children are at higher risk for sustaining serious head injury. Anatomical considerations that predispose the younger child to head injuries are a large head to body ratio, a relatively weak neck, a thinner skull, and a larger subarachnoid space in which the brain can move freely (2). The pathophysiology of head injuries can be subdivided into two types. The injury directly caused by the mechanical force of the trauma is called primary injury. This type of injury is due to shear force, direct contact, and tissue penetration. Secondary injury is created by the body's response to the primary insult. In secondary injury excitatory neuropeptides, cytokines, free radicals, metabolic and oxygenation insufficiencies cause further tissue damage. Little can be done about primary injury once it has occurred. However, medical management theoretically attempts to minimize the damage caused by secondary injury.

It is important to realize that unlike injuries to other parts of the body, injury to the brain occurs within a confined volume, the intracranial space. The intracranial space is made up of three components; brain volume (90%), blood volume (5%) and cerebral spinal

fluid volume (5%). Initially, as the brain swells in response to injury, the increase in brain volume is accommodated by a reduction of cerebral spinal fluid volume, and then blood volume. However, in the finite space of the calvarium, the mass effect caused by acute brain edema and hemorrhage may reach a point at which this volume can no longer be accommodated. Thus, at some point, even the smallest increase in brain volume or hemorrhage produces an exponential increase in intracranial pressure (ICP), at which point, brain perfusion is seriously compromised. This dramatic rise in pressure impedes cerebral perfusion and results in the herniation of brain tissue across the tentorium, falx or through the foramen magnum causing significant morbidity and often death. Intracranial hypertension, or elevated intracranial pressure is harmful as it can decrease cerebral perfusion, inciting further hypoxia and cell death. This relationship between ICP, mean arterial pressure (MAP), and cerebral perfusion pressure (CPP) can be appreciated by the equation CPP=MAP-ICP (1). In normal children ICP is <20 mm Hg, and MAP is 70-80 mm Hg, which provides a normal CPP ranging from 50-60 mm Hg (1). Thus, accordingly an increase in ICP, or decrease in MAP can decrease blood flow into the brain. When CPP is <40 mm Hg, ischemia occurs as proper cerebral blood flow (CBF) cannot be maintained (1). This simplified equation attempts to explain a very complicated pathophysiologic process. Controlled by chemical mediators that produce vasoconstriction and vasodilatation of the blood vessels, CBF is constantly changing to meet the brain's metabolic demands. The most potent chemical mediator is the arterial partial pressure of carbon dioxide (pCO2), which is directly proportional to CBF. The arterial partial pressure of oxygen (pO2) is indirectly proportional to CBF, but it is not as potent a vasoactive mediator as pCO2. In the acute management of the patient with a severe head injury, these values are manipulated via intubation and mechanical ventilation to maximize CPP.

The initial clinical assessment is extremely important in determining the clinical management of a victim with head trauma. The primary survey should begin with the standard ABCs of basic life support and a focused physical exam looking for concurrent life-threatening injuries involving the chest, central nervous system, pelvis, and abdomen. All the while, the patient's mental status is closely monitored. The Glasgow Coma Scale (GCS) has been found to be helpful for this purpose (1). The GCS is a clinical rating scale developed based the patient's clinical assessment in three categories; motor, verbal, and eye opening response. The GCS scale ranges from 3-15. The GCS scale is as follows:

Motor response: 6=normal spontaneous movements, 5=withdraws to touch, 4=withdraws to pain, 3=abnormal extension (decorticate rigidity), 2=abnormal flexion (decerebrate rigidity), 1=none.

Verbal response: 5=oriented, 4=confused, 3=inappropriate words, 2=nonspecific sounds, 1=none.

Eye opening response: 4=spontaneous, 3=to speech, 2=to pain, 1=none (1).

A modified Glasgow Coma Scale for infants was created for pre-verbal children. The GCS is not useful in ruling out serious brain injuries such as hemorrhages since many patients with brain hemorrhages have GCS scores >13, and some even have 15 (normal) GCS scores. Once the patient is clinically stable, a more detailed secondary survey can be carried out.

The majority of head injuries (90%) fall into the minor category. If the head injury has been determined to be mild, a history looking for symptoms of possible intracranial injury should be elicited. This would include questions pertaining to loss of consciousness, headache, amnesia, seizures, nausea, vomiting, or focal neurological defects. Minor head trauma is a difficult clinical dilemma, and multiple studies have shown that no single symptom consistently identifies the presence of an intracranial injury (ICI) in children (3,4). Two prospective studies found that the following clinical findings were commonly associated with intracranial injury in children with minor head trauma: focal neurological deficits, loss of consciousness, amnesia, a GCS less than 15, and altered mental status (3,5). It turns out that a 14 GCS is close to 15, but there is a substantially higher risk of serious head injury if the GCS is 14 compared to 15. Thus, if these clinical findings are present during the assessment, then computed tomography (CT) scanning is indicated. Computed tomography scanning of the head is the diagnostic procedure of choice to determine the presence of acute intracranial injury (6). CT scanning is often easily accessible and a very good test to screen for the presence of acute bleeding and brain swelling. Unfortunately, some children require sedation to perform a CT scan, and thus the risks and benefits of procedural sedation must be weighed. However, the need for procedural sedation is declining with the advanced technology of faster spiral CT scanners. Skull x-rays have a limited role in children with head injuries, since they do not identify intracranial injury. However, these images may be helpful when CT scanning is not available. Plain x-rays can detect a skull fracture, and the presence of a skull fracture was found to be helpful with predicting the presence of intracranial injury (5). However, a normal skull series does not rule out a brain injury. Magnetic resonance imaging has no role in the initial evaluation of an acute head injury since it is time consuming, expensive, and not usually readily available. In minor head injuries, management is almost always observation and parental education. Hospitalization is utilized if there is concern about proper follow up, since most complications will occur within the first 24 hours following the injury (6). Parents should be instructed on what signs to look for and when to return for further care. Separate practice guidelines have been recommended for the management of minor head injuries in children ages 2-20 years and <2 years of age by the American Academy of Pediatrics (6,7).

Skull fractures can occur with even mild trauma. Infants are especially susceptible to linear skull fractures, because of their thinner skull. Half of skull fractures occur from a fall from a height of 4-5 feet, and 70% involve the parietal bone (1). Very often superficial scalp lacerations and hematomas are also present on exam. It is important to mention that in infants, scalp lacerations can cause significant bleeding if left unrecognized. The presence of scalp hematoma has a 95% association with finding an underlying linear skull fracture in infants (8). Thus, diagnostic imaging is recommended for any infant with an obvious scalp hematoma. (7,8). Despite the fact that only close observation is all that is required for a linear skull fracture, proper follow up is important. Rarely, a growing skull fracture can develop. This occurs when a portion of the meninges herniates through the fracture line and does not allow for proper healing. A fluid collection cyst can be produced by the pinched meninges, which is called a leptomeningeal cyst. Leptomeningeal cysts (hence, growing skull fractures) are rare complications, but the clinician should still look for them during follow up weeks after a skull fracture is found.

A subgaleal hematoma will often form around a parietal skull fracture. It is common for these to present several days after the head trauma incident. The infant or young child strikes his/her head during a fall. If a skull fracture is sustained, without a brain injury, the child will appear to be alert and active without signs of brain injury. Bleeding from the skull fracture collects in the subgaleal layer of the scalp. It is initially tense, but over the next few days as the hematoma begins resorption, the hematoma becomes very soft, which is often alarming to parents, prompting them to bring the child to a physician. Skull radiographs frequently identify a small linear fracture beneath the subgaleal hematoma which does not require further diagnostic or therapeutic intervention if the child is doing well clinically. However, radiographs occasionally demonstrate large fractures, comminuted fractures, or multiple fractures which suggest more serious injury and/or non-accidental injury.

A skull fracture that is pushed in a distance equivalent to the thickness of the skull table is called a depressed skull fracture. This is a neurosurgical emergency and must be corrected expeditiously. Lastly, basilar skull fractures (BSF) may occur from head trauma, and can be diagnosed by clinical exam. Physical exam findings associated with a BSF include: blood in the mastoid air space (Battle's sign which is bruising over the mastoid process), blood collection in the periorbital space (Raccoon eyes), hemotympanum, and CSF

rhinorrhea. BSF were found to be associated with the presence of ICI (5). Thus, radiographic imaging should be performed if these clinical signs are found. A small increase in the risk for meningitis is associated with a BSF due to the break in protective covering that the meninges provide. This risk is small and prophylactic antibiotics are not routinely recommended. However, this needs to be considered in the febrile child with a recent history of a BSF during follow up care.

The most mild type of brain injury is a concussion. A concussion is defined as, "a trauma induced alteration of mental status that may or may not involve a loss of consciousness" (1). Very often, confusion and/or amnesia may accompany the event. In concussions, CT scans are normal and close observation is all that is required. The "Second Impact Syndrome," is characterized by rapid death due to a second concussion prior to a return to baseline functioning after an initial one. Sudden death is thought to occur due to a rapid rise in ICP from local vasospasm and edema (9). This has been reported to occur in adolescent athletes in contact sports, and the appropriate time to return to activity after sustaining a concussion is under much debate. Practice guidelines for the return of activity after sustaining a concussion have been recommended in the literature (10).

An epidural hematoma (EDH) can develop if blood collects in the potential space between the dura and the inner table of the skull. Very often the blood is arterial originating from the middle meningeal artery in association with a parietal skull fracture. However, in younger children, 20% of epidural hematomas are due to venous blood (1). The classic clinical coarse is that of a child who sustains a head injury and may have been rendered unconscious. He may then have the "classic" lucid interval at which time he may be able to interact with the examiner. This is because, the initial brain injury itself is only a concussion. Subsequent middle meningeal bleeding causing the hematoma results in ensuing decompensation from the expanding blood collection, causing increased intracranial pressure and a reduction in cerebral perfusion (a secondary injury). An epidural hematoma is best diagnosed by CT scan, which will show a lenticular (football shaped) hyperdense (white) hemorrhage along the skull table. EDH can cause a significant increase in ICP, illustrated by a midline shift and small ventricles on CT scan. This is a neurosurgical emergency, and craniotomy with evacuation of the hematoma can be life saving. If neurosurgical intervention is early and successful, EDH has a good prognosis since the initial brain injury was only a concussion in most instances (i.e., the brain itself is not significantly injured in an EDH, since the bleeding originates from outside the brain parenchyma).

A subdural hematoma (SDH) is the accumulation of blood in the subdural space. This is most often due to venous blood from the bridging veins that traverse this space. Very often a SDH is created by acceleration-deceleration injury in which the brain parenchyma is damaged from the surface of the calvarium. CT scanning of these lesions will show a crescent shaped hyperdense (white) hemorrhage. The majority of SDH are managed medically, and observation with supportive care is all that is required. This is usually not a neurosurgical emergency, since evacuation of the clot will not usually reverse the significant primary damage inflicted on the brain parenchyma. However, neurosurgical intervention may be warranted when a significant mass effect is present, and the patient would benefit from an acute reduction in ICP. When a child presents with unexplained vomiting, lethargy, and/or head trauma, non-accidental injury must be included in the differential diagnosis. Especially when subdural hematomas are found, the possibility for child abuse must be explored. Associated findings of non-accidental trauma are failure to thrive, retinal hemorrhages, intra-abdominal injuries, and various fractures of different ages. In one retrospective review, cases of acute head injury caused by child abuse were often initially misdiagnosed if the patient was well appearing, Caucasian, and living with both biological parents (11). Thus, the examining clinician should have a low threshold to perform a skeletal survey and attain ophthalmology consultation for suspicious cases of head injuries.

This type of acute subdural hematoma is very different from the type of subacute subdural hematoma found in the elderly. Acute subdural hematoma is associated with substantial brain parenchymal injury. Subacute subdural hematoma in the elderly results from a slow bleed from bridging brains often due to minor head trauma. As the hematoma expands, ICP increases and cerebral perfusion is compromised. If the hematoma is identified and evacuated early, the brain is preserved with little injury. The difference between acute subdural hematoma (usually a poor prognosis) should be contrasted with subacute subdural in the elderly (usually a good prognosis). The latter is more similar to an epidural hematoma (usually a good prognosis as well).

The concept of primary versus secondary injury is important in understanding the prognosis. Most epidural hematomas have mild primary injury, but have the potential for severe secondary ischemic injury if failure to evacuate the hematoma in a timely evacuation leads to excessive ICP increase and brain ischemia/infarction. Compare this to an acute subdural in which case, there is substantial primary brain injury (damage) which cannot be reversed with evacuation of the hematoma.

Sometimes a subarachnoid hematoma and an intracerebral contusion can accompany a subdural hematoma. Subarachnoid blood can be distributed widely throughout the subarachnoid space, and its symptoms can sometimes mimic meningitis. On CT scan hyperdense blood collections are found along the falx, and in the basilar cisterns. Intracerebral contusions are actual injury within the brain parenchyma. Due to tissue edema, these lesions are at high risk for producing a mass effect and increased ICP. In this type of injury, the GCS is often low, and focal neurologic symptoms, loss of consciousness (LOC), and visual changes are often present. CT scan shows a mixture of hypo and hyper dense lesions within the brain parenchyma. Secondary injury may further complicate the clinical picture by producing infarcts due to local vasospasm. Medical and neurosurgical management are often required, and the prognosis is usually poor.

In moderate to severe head injuries, medical and surgical management is aggressive and complex. Patients often present in an obtunded or combative state. Late clinical findings include unequal and non-reactive pupils, focal neurologic findings, abnormal posturing, and Cushing's triad (hypertension, bradycardia, and irregular respirations). These clinical findings are usually indicative of severe injury and probable brain herniation. These clinical signs require expeditious medical management, and close monitoring in the intensive care unit. Expeditious CT scanning to determine the extent of brain injury is required. Neurosurgical consultation is required because the only way to accurately access and monitor ICP is to measure it with a direct device such a Richmond bolt or a ventriculostomy. This device, placed by the neurosurgeon, can directly monitor acute changes in ICP. The targeted value for adequate CPP is an ICP <20 mm Hg in the presence of a normal systemic arterial blood pressure. The two physiologic parameters that must be avoided are hypoxia and hypotension. The brain is an obligate aerobic organ and systemic hypoxia leads to increased CNS morbidity. Furthermore, maintaining adequate MAP is critical to maintaining proper CPP.

Monitoring and maintaining the intravascular volume status is crucial. Intravascular volume may be decreased due to capillary leak, an acute bleeding process, or overzealous use of hyperosmotic agents. Very often, vasopressor agents such as dopamine, dobutamine, or epinephrine may be required to maintain proper MAP. The head of the bed should be elevated to 30 degrees to facilitate venous drainage. Sedation and analgesia may aid to decrease dramatic shifts in ICP due to generalized motor activity and anxiety. If these pharmacological interventions fail to adequately minimize changes in ICP, paralytic agents may also be added. If the patient has seizure activity, benzodiazepines or fosphenytoin can be used. Fosphenytoin for seizure prophylaxis may be indicated in the presence of an obvious parenchymal injury. Manipulation of pCO_2 and pO_2 values via intubation and mechanical ventilation may be useful to optimize CPP. However, this is controversial and recommendations are evolving. While moderate hyperventilation was an accepted treatment modality

(with the targeted pCO2 in the 30-35 mmHg range) to reduce ICP, this is controversial since it may reduce net cerebral perfusion by vasoconstricting the cerebral arteries. Perhaps hyperventilation should be reserved for impending brain herniation only.

Osmotic agents such as mannitol or 3% saline are given intravenously to achieve a hyperosmolar intravascular compartment. The hyperosmolarity of the intravascular compartment draws free-water from the interstitial space potentially lowering intracranial pressure and thus improving cerebral blood flow (1,12). Serum electrolytes, and serum osmolarity must be closely monitored. Hyponatremia can result from the inappropriate release of anti-diuretic hormone (SIADH), and hypernatremia may result from diabetes insipidus, dehydration and osmotic diuresis due to the use of hyperosmolar medications. Mannitol and hyperventilation have not been shown to be of clear benefit in the long-term management of increased ICP, and their benefits appear to be primarily helpful in the acute setting dealing with impending brain herniation (1). Despite aggressive attempts at medical management, severe head injuries may continue to progress to a level of refractory intracranial hypertension leading to significant morbidity and/or death.

The prognosis for minor head injuries is very good. Minor effects of the injury that may persist include headache, concentration problems, and hesitation to return to normal activities. These typically resolve and the patient will return to baseline functioning with time (13). For children who survive major head injuries, significant morbidity is common. However, when compared with adults, children with a GCS of <8 often have better outcomes (12). Intensive rehabilitation therapy may be required long after hospitalization and the acute phase is complete. Prognosis may be poor, and for some, a persistent vegetative state may be the result. Head injuries are a major cause of morbidity and mortality in children, and only through primary injury prevention will this problem be decreased.

Questions

1. True/False: Epidural hematomas have a crescent shaped mass on CT scan
2. True/False: Epidural hematomas are mostly produced by venous blood.
3. True/False: The prognosis for epidural and subdural hematomas are about the same as long as the hematomas have been evacuated early.
4. True/False: Since epidural hematoma is always a neurosurgical emergency and subdural hematoma is less often a neurosurgical emergency, epidural hematomas are more serious (i.e., the prognosis is poorer) than subdural hematoma.
5. True/False: Infants are at low risk for having intracranial injuries.
6. True/False: Hypotension and hypoxia are two monitoring parameters that are extremely important to avoid in a child with a moderate to severe head injury.
7. True/False: The equation to calculate cerebral perfusion pressure is: CPP=MAP-ICP.
8. True/False: Hypernatremia can occur secondary to inappropriate anti-diuretic hormone release in moderate to severe head injuries.
9. True/False: A 4 year old male child fell and hit his head on the carpet about 5 hours ago. There is no reported history of loss of consciousness or vomiting. His PE is normal, and he is acting appropriately at the time of the visit. A CT scan should be ordered to assess this child for intracranial injury even though the risk of serious injury is remote.
10. True/False: A patient has a GCS of 9 if he can open his eyes to a noxious stimuli, has inappropriate speech, and flexes his extremities to pain.

Answers to questions

1. False. Epidural hematomas are a neurosurgical emergency and have a lenticular (lens or football shaped, also called biconvex) shape on CT scan.
2. False. Only 20% of epidural hematomas are produced by venous blood in children.
3. False. Acute subdural hematoma is associated with substantial brain parenchymal injury so its prognosis is poor compared to epidural hematoma.
4. False. Epidural hematoma is a neurosurgical emergency because its prognosis is dramatically better with early evacuation, while subdural hematoma is less of an emergency because the prognosis is already poor even with hematoma evacuation.
5. False. Infants are at higher risk for sustaining serious head injury. Anatomical considerations that predispose the younger child to head injuries are a large head to body ratio, a relatively weak neck, a thinner skull, and a larger subarachnoid space in which the brain can move freely.
6. True.
7. True.
8. False. Hyponatremia occurs with SIADH. Free-water is retained in the collecting tubules due to anti-diuretic hormone causing a dilutional effect of the serum sodium. Hypernatremia is usually caused by the use of hyperosmotic agents such as mannitol or diabetes insipidus.
9. False. In well appearing children 2-18 years of age with no loss of consciousness and a normal neurological exam, no imaging studies are required. Close observation and parental education is all that is needed (6).
10. True. GCS=9: motor=4, verbal=3, and eye opening=2.

Chapter XVIII.14. Muscular Dystrophy

Vince K. Yamashiroya, MD

In neurology clinic, your next patient is a five year old boy who was referred by his pediatrician because of an abnormal gait. He was adopted from another country about a year ago, and his adopting parents have noticed that he is clumsy when he runs where he falls often. He runs on his tiptoes, which has occurred since they started taking care of him. Otherwise, he has no other problems. He is doing well in kindergarten despite his language difficulty. His teacher notes that he has trouble getting up from a sitting position at school. His parents deny that he has chronic fevers, leg pain, weight loss, seizures, skin rash, urinary or bowel incontinence, or frequent colds.

His past medical history, developmental history, family history, and birth history are unknown. His immunizations are up-to-date and his PPD this year has been negative.

Exam: His vital signs are normal. His height, weight and head circumference are at the 50th percentile. He is alert, active, shy, well-nourished and slim in no distress. His skin shows no neurocutaneous stigmata. His head is normocephalic and atraumatic. His pupils are equal, round, reactive to light. No nystagmus is evident. His fundi are normal with sharp disk margins. His TMs are clear. His throat is normal with a uvula midline. His lungs, heart, and abdomen are normal. His back shows no sacral dimples.

Neurologic exam: A standard cranial nerve exam reveals no deficits. His strength is +4/5 in his deltoids, knee flexors and extensors; +5/5 in his biceps and triceps. His calves are visibly enlarged with a firm, rubbery feeling. He gets up to a standing position using a Gowers' maneuver. No dysdiadochokinesia. Negative Romberg sign. Sensation to light touch is intact. His reflexes are +2/4 in his biceps, triceps, brachioradialis, patella and ankle. His plantar reflex is downgoing (negative Babinski sign). No clonus is elicited. Normal anal wink and abdominal reflexes are present. His gait is best described as a wide based waddling. When running, he tends to run on his toes. He is unable to jump.

You have a suspicion of what he might have, and send off some blood tests and make an arrangement for a muscle biopsy to be performed.

Muscular dystrophy is a term used to describe a primary myopathy that is genetically acquired, is progressive, and is characterized by death and degeneration of various muscle fibers during different periods of the disease. The word dystrophy means abnormal growth, being derived from the Greek word, trophy, meaning nourishment. Therefore, muscular dystrophy can be thought of as an abnormal growth of muscle (1). Although there are many different types of muscular dystrophies, the most well known of them is Duchenne muscular dystrophy (DMD), which is the most common type of muscular dystrophy occurring in childhood.

The inheritance pattern for DMD muscular dystrophy is X-linked recessive. Therefore only males express the disease, with females being carriers. If a female were a carrier, then according to Mendelian genetics, she would have a 50% chance of having an affected son, and a 50% chance of having a daughter who is a carrier. Although family history is usually positive, there is a high rate of spontaneous mutations; about one-third of all cases of DMD are sporadic or new mutations (2).

There are several different types of muscular dystrophies, each with different modes of inheritance, chromosome gene locations and products, and presentations. The types of muscular dystrophy and modes of inheritance are listed below:

1. Duchenne muscular dystrophy (X-linked recessive)
2. Becker muscular dystrophy (X-linked recessive)
3. Myotonic dystrophy (autosomal dominant-expansion of unstable CTG trinucleotide DNA sequence) and congenital myotonic dystrophy (maternally transmitted)
4. Congenital muscular dystrophy (autosomal recessive)
5. Limb girdle muscular dystrophy (autosomal dominant or recessive)
6. Facioscapulohumeral dystrophy (autosomal dominant)
7. Emery-Dreifuss muscular dystrophy (X-linked recessive)

The incidence of Duchenne and Becker muscular dystrophy is 1 in 3,500 male births. Myotonic dystrophy is the most common dystrophy presenting in adulthood, with an incidence in all age groups being 13.5 per 100,000. The incidences of the other types of muscular dystrophies including facioscapulohumeral dystrophy, limb-girdle dystrophy, and congenital muscular dystrophy, are less common then the other muscular dystrophies (2).

When someone mentions muscular dystrophy, we think of Duchenne muscular dystrophy (DMD) since this is the most common of the muscular dystrophies. Therefore, this chapter will focus on the clinical presentation and diagnosis of DMD. The underlying problem in DMD is abnormal or absent dystrophin production. In normal individuals, there is very little dystrophin; however, in DMD patients, this protein is absent or nonfunctional. Although it is known that dystrophin is a cytoskeletal protein, the exact mechanism whereby the absence of this protein leads to muscle degeneration and necrosis is not clear. Dystrophin is transcribed from a gene located in the Xp21 locus. About 70% of cases are due to a gene deletion, 5-10% are due to gene duplications, and the remaining 20-25% are due to point mutations (3).

Duchenne muscular dystrophy usually presents insidiously and after several years of age. The first sign is usually a delay in learning to walk. Normal children usually start walking on the average about 12 months of age; however, in DMD, 56% start walking at 18 months of age, and about 25% learn how to walk after 2 years of age. An inability to run properly is a hallmark sign and appears to be present in almost all cases. Other early signs are a waddling gait, walking unsteadily with frequent falling, walking on toes, and difficulty at climbing stairs. Almost all patients show signs of this disease by 5 years of age, although occasionally, this disease can present as late as 8 to 9 years of age. Another early sign is pseudohypertrophy of the calf muscles. The calf muscles feel firm or woody, in addition to being enlarged. The pseudohypertrophy is due to excessive amounts of adipose and connective tissue secondary to muscle necrosis and destruction from the lack of dystrophin. Despite its size, the muscles are weak. In addition to the calves, other muscles where pseudohypertrophy can be present are masseters, deltoids, serratus anterior, and quadriceps. In general, the pattern of muscle weakness is lower extremities and proximal muscles first, and upper extremities and distal muscles later. This pattern of muscle weakness leads to several clinical symptoms. One is the waddling gait that is seen, which is due to weakness of the gluteus medius and minimus muscles. Another is the lumbar lordosis during walking, which is caused by weakness in the gluteus maximus muscle. Because of an imbalance between the plantar and dorsiflexors, these patients also walk on their toes. After age 4 to 5 years, the Gowers' maneuver can be observed. A positive sign is seen when a child climbs up on his thighs in order to extend his hips and push up his trunk when going from a sitting to standing position. This is due to weakness of the knee and hip extensors. By age 4 years, there is weakness of the pectoral girdle muscles in that the child slides through the examiner's arms when grasped around the chest and is pulled up. Winging of the scapulae can be seen later. Although there is no pain, sometimes children will complain of muscle cramping and stiffness, especially in the calves (4).

The muscle disease is progressive and these patients are usually wheelchair bound before 13 years of age. After the loss in ambulation, equinovarus deformities of the feet and scoliosis develop rapidly. Weakness of the intercostal muscles causes a progressive restrictive respiratory disease to occur leading to nocturnal hypoventilation in the late teens to early 20s. Later, respiratory failure occurs, requiring ventilator support. Patients start to become symptomatic from progressive cardiomyopathies around their teen years, although EKG changes are seen in the early stages of the disease.

Not only does this disease affect muscle, but the central nervous system as well. About 30% of affected boys have lower intelligence quotients, especially in the verbal subtests, although boys having normal intelligence have been reported. Also emotional problems appear higher than in other disorders. The exact mechanism for the lower intelligence and emotional problems is not known; although it is known that dystrophin is normally located in the cortical synapses, and its absence might account for the CNS abnormalities. Seizures and visual and hearing problems are not present in DMD (5).

A similar entity to DMD is Becker muscular dystrophy. This type of muscular dystrophy is also due to mutation of the dystrophin gene, but instead of having a nonfunctional or absent protein product, the dystrophin itself is defective but still partially active. Therefore, these patients have milder forms of muscle weakness, and they usually present later compared to DMD. Progression is also much slower, and these patients may be ambulatory until 16 years of age or older. Cardiac problems may be severe. About 15% of patients younger than 16 years have clinically significant cardiomyopathy, and about 75% of individuals have that problem after age 40 years. Affected patients may live into late adulthood, compared to patients with DMD who die much earlier (2).

Myotonic muscular dystrophy is not due to dystrophin but to an abnormal protein kinase due to an expansion of an unstable trinucleotide repeat in chromosome 9. This disease is characterized by an older age of onset, facial weakness and greater distal muscle weakness, cardiac muscle involvement leading to arrhythmias, cataracts, and endocrine problems (such as diabetes, testicular atrophy, and menstrual irregularities).

Another type of myotonic muscular dystrophy, congenital myotonic dystrophy, is transmitted maternally and is manifested by marked hypotonia in the infant, leading to early death usually due to respiratory insufficiency. If this type of dystrophy is suspected, the mother should be tested for myotonia (2). Congenital muscular dystrophy presents with hypotonia and weakness at birth. There may also be joint contractures, respiratory and swallowing difficulties.

There are some types of congenital muscular dystrophies, such as Fukuyama type, muscle-eye-brain disease, and Walker-Warburg syndrome, which have mental retardation, seizures, hydrocephalus, and structural brain and eye abnormalities. These are autosomal recessive (2).

Limb-girdle dystrophy is a heterogeneous disorder involving several different gene loci. It can be autosomal recessive or dominant (2).

Facioscapulohumeral muscular dystrophy usually presents in late childhood to early adolescence with facial weakness, and weakness of the scapulohumeral muscles. Deltoid muscle strength is spared. It is autosomal dominant (2).

DMD can be suspected clinically; however, there are several tests that can greatly assist in its diagnosis. Serum creatine phosphokinase (CPK or CK) is an enzyme present in muscle, and when there is damage in the muscle cells, CPK is released. Therefore, CPK is highly elevated in DMD, commonly 50 to 100 times normal values in Duchenne and Becker muscular dystrophies (15,000-35,000 IU/L). CPK is usually highest in the early stages of the disease, but then decreases with progression. CPK is not specific for muscular dystrophy. It may also be elevated in spinal muscular atrophy, normal vaginal delivery, acute hypoxic-ischemic cerebral injury, intramuscular injections, muscle trauma, and recent vigorous exercise. Other lysosomal enzymes present in muscle, such aldolase and aspartate aminotransferase are also elevated in muscular dystrophy; however, they are also nonspecific (6).

Electromyography (EMG) may identify a myopathic process, but it is not specific for muscular dystrophy and plays a minor role in its diagnosis. The EMG shows low-amplitude, short-duration polyphasic motor unit action potentials in this disease.

A specific test using molecular genetic techniques can be performed using a blood sample in which the identification of specific gene deletions or mutations is done by PCR. This has obviated the need for muscle biopsies since deletions in the Xp21 gene can be identified to confirm the presence of Duchenne and Becker muscular dystrophy in two thirds of the cases (2). The other cases that are not diagnosed by PCR can be confirmed by the dystrophin immunocytochemistry test on muscle biopsies.

Muscle biopsy is probably very helpful and specific for Duchenne and Becker muscular dystrophy, in addition to other types of muscular dystrophies. Muscle degeneration and regeneration and connective tissue proliferation are present. Staining for dystrophin and other associated proteins through specialized immunocytochemical techniques can be done. Cardiomyopathy can be screened for using chest radiographs, EKG, or echocardiography.

There is a myriad of diagnoses possible for weakness; however, the neurologist is concerned about where the lesion causing the weakness is. The problem can be in the upper motor neurons, peripheral nerves, neuromuscular junctions, or in the muscles themselves. The history and examination can point to the cause of weakness being due to the muscles, and not to other parts of the nervous system. Clues include intact ankle reflexes without clonus or hyperreflexia, no loss of sensation, and pseudohypertrophy. There are several diseases that affect muscles. Myositis is one, although the muscles are tender in this group of diseases. Although dermatomyositis can also present insidiously with a positive Gowers' maneuver, and elevated aldolase and CPK, there are also rheumatologic signs such as a heliotrope rash on the eyelids, rash on sun-exposed areas, and Gottron papules, which muscular dystrophies lack. Some types of spinal muscular atrophies (SMA), such as Werdnig-Hoffman (type 1) and type 2, can be easily differentiated from DMD because these diseases present at a much earlier age with marked hypotonia and weakness, in addition to the presence of fasciculations and a normal to slightly elevated CPK level. Type 3 SMA (or Kugelberg-Welander disease), might be confused with DMD because of its presentation later on in childhood and its pattern of muscle weakness being mainly in the proximal muscles. However, Kugelberg-Welander disease, like the other SMA's, lacks pseudohypertrophy of the calf muscles, muscle fasciculations are present, and deep tendon reflexes are absent. Another differentiating sign is the presence of minipolymyoclonus, which is a fine tremor in the outstretched hands, which is present in the SMA's but absent in the muscular dystrophies (7). Lastly, muscle immunocytochemistry for dystrophin and PCR for Xp21 gene deletions should be able to confirm the diagnosis for Duchenne and Becker muscular dystrophies.

Sadly, there is no definitive treatment for Duchenne muscular dystrophy. Supportive care includes daily passive stretching of joint contractures, night splints, bracing if there is loss of ambulation, orthopedic surgery (including surgical tendon releases and surgery for scoliosis), and ventilatory support measures. The only medication proven to be beneficial in DMD is corticosteroids. Several studies have shown that prednisone at 0.75 mg/kg/day appears to increase muscle strength within 10 days, with its effects being maintained for at least 18 months. Because of its impressive results, patients who are older than 5 years and are ambulatory may receive steroids, with close monitoring for side effects. Another drug, deflazacort, which is a derivative of prednisolone, has also been studied because of having fewer side effects than prednisone; however this drug is not available in the United States (2). Because it is a genetic disease, genetic counseling is an important part of DMD management. Prenatal diagnosis is also possible for male fetuses using molecular genetic techniques like PCR through amniocentesis or chorionic villus sampling (8).

The prognosis for Duchenne muscular dystrophy is not good. Affected males with this progressive muscular disease become wheelchair bound before 13 years of age, are ventilator dependent in their late teens to early 20s due to respiratory failure, with death in their late 20s to 30s due to cardiac or pulmonary problems. Patients with Becker muscular dystrophy fare much better. Many remain ambulatory after age 16 years and survive through late adulthood (2). Despite the depressing nature of the muscular dystrophies, we are entering into a new age of molecular genetics, and perhaps in the near future we will have a cure for this crippling disease through gene therapy.

Questions

1. How are Duchenne and Becker muscular dystrophy inherited?
2. What protein is absent in Duchenne muscular dystrophy?
3. What is the Gowers' maneuver (or sign)?
4. What are some early signs and symptoms of Duchenne muscular dystrophy?
5. What is the average life expectancy for Duchenne muscular dystrophy? What do they die from? When do they lose ambulation?
6. By what age do almost all patients with Duchenne muscular dystrophy present with weakness?
7. Name three other organ systems, besides the musculoskeletal system, that are affected in Duchenne muscular dystrophy.
8. What is the only medication proven to improve weakness in DMD?

I would like to thank Dr. Yoshio Futatsugi for reviewing this chapter on muscular dystrophies. He has made many suggestions which is very much appreciated.

Answers to questions
1. Both Duchenne and Becker muscular dystrophy are X-linked recessive.
2. Dystrophin.
3. The Gowers' maneuver is seen when a child climbs up on his thighs with his hands when going from a sitting to standing position. This is due to weakness in the knee and hip extensors.
4. Delay in walking, waddling gait, walking unsteadily with frequent falling, walking on toes, and difficulty at climbing stairs, Gowers' maneuver, and pseudohypertrophy of the calves.
5. 20 to 30 years. They die from pulmonary or cardiac problems. They lose ambulation before 13 years old.
6. 5 years.
7. Pulmonary, cardiac, and neurological (CNS).
8. Corticosteroids.

Chapter XVIII.15. Myopathy and Myositis
Dominic C. Chow, MD, MPH

A 6 year old girl presents to your office complaining of progressive weakness for the past two days. Her mother was alarmed this morning when her daughter had difficulty getting out of bed. Yesterday, she slept through most of the day and had a decreased appetite. She developed a low-grade temperature over night. For the past week, she has had a facial rash, which initially began as a reddish raised rash over both cheeks that has expanded to include the bridge of the nose. Coincidentally, her mother has also noticed a dry rash which developed over her daughter's elbows and knees, which she attributed to eczema. The child's medical history is unremarkable and she has been growing and developing appropriately. She is not on any prescribed or over-the-counter medications. Family history is negative for any connective tissue diseases or congenital disorders.

Exam: VS T 37.8, P 120, RR 18, BP 100/50. Wt 20 kg (50%tile), Ht 115 cm (50%tile). She appears subdued and weak. An erythematous plaque encompasses the cheeks and bridge of nose with diffuse borders, resembling a butterfly pattern. You notice a purplish-reddish hue over the upper eyelids along with some periorbital edema. There are several erythematous, scaly, and atrophic papules over her elbows and knees. A similar rash is seen over her interphalangeal joints of the hands. Examination of the nails reveals nailfold telangiectasias and erythema at the cuticles. She has trouble getting to the sitting position, and extreme difficulty getting to the standing position. No hypertrophy or atrophy of any muscle is noticed. Your examination confirms that she has profound symmetrical proximal muscle weakness. Cranial nerve testing and deep tendon reflexes are normal. Muscle fasciculations and infantile reflexes are absent.

Laboratory results: Antinuclear antibodies of (ANA) 1:640 speckled (normal range <1:160), sedimentation rate (ESR) 60 mm/hr (normal range 4-20), creatine kinase (CK) 490 IU/L (normal range 10-55), aspartate aminotransferase (AST) 500 IU/L (normal range 0-35), alanine aminotransferases (ALT) 250 IU/L (normal range 1-30).

Her initial symptoms are nonspecific except for the malar rash and eczema-like lesions on the flexor surfaces. Although this clinical picture is similar to systemic lupus erythematosus (SLE), the cutaneous findings along with the profound proximal muscle weakness make juvenile dermatomyositis (JDM) the more likely diagnosis. Treatment with prednisone (2mg/kg/d) is initiated and within days, she has resolution of her weakness. Her dermatologic symptoms gradually improve and the prednisone is gradually tapered over the course of several weeks.

The approach to the classification of neuromuscular disorders has aimed at distinguishing primary disorders of the muscle (myopathies and myositis) from disorders affecting peripheral nerves (peripheral neuropathies) (1). The spectrum of myopathies ranges from predominantly muscle disorders such as the muscular dystrophies, congenital myopathies, and myositis to multisystem disorders with muscle tissue involvement such as metabolic myopathies and myotonic dystrophy. Fortunately, the incidence of myopathies and myositis is rare. Myositis, which is the inflammation of muscle tissue, makes up the majority of these cases, with JDM as the dominant clinical entity.

In 1903 Steiner defined JDM as an acute, subacute or chronic disease of unknown origin, characterized by a gradual onset with vague and indefinite prodromata followed by edema, dermatitis, and multiple muscle inflammation (1). It is now classified as a rheumatologic condition whereby vasculitis is the etiology of the pathologic condition. JDM occurs in 3-4 cases per 1,000,000 with a predilection for females (2:1) and Caucasians (2). The peak age is 6 years, although there is a bimodal distribution of 5-9 and 10-14 years of age (2). Increased cases of JDM have been reported during the months of February through April (3). Familial cases of JDM are rare but there may be an immunogenetic predisposition among individuals who have the human leukocyte antigens HLA B8 and DR3 (4). The incidence of familial autoimmune diseases is not increased in cases of JDM. Although more common in adult dermatomyositis, JDM is not associated with underlying malignancy (5,6).

Myopathy and myositis commonly present as muscle weakness. The proximal muscles are usually involved although generalized weakness can be seen, especially in infants. Delayed motor milestones can be attributed to myopathic conditions, whereas delayed language and social adaptive behavior, and sensory impairment suggest a cerebral or neuropathic etiology. Myositis is often associated

with muscle tenderness over the affected muscles. The clinical presentation of JDM is insidious, often initiating as only fever and malaise. The clinical hallmarks of JDM are the characteristic dermatologic manifestations and profound weakness of the proximal muscles. An erythematous malar rash is commonly found, along with periorbital edema and violaceous discoloration of the upper eyelids (referred to as a heliotrope rash). Pathognomonic of JDM is the finding of Gottron papules, which are erythematous, scaly, atrophic plaques that occur symmetrically over the extensor surfaces of large and small joints. As seen with other vasculopathies, erythema at the cuticles and nailfold telangiectasias may be noted. Palpable and radiographically visible subcutaneous calcinosis is a common finding, occurring in 30-70% of cases (3). The muscle weakness is symmetrical and typically begins at the thighs, and later becomes generalized. A typical presentation entails difficulty in walking up stairs, difficulty in getting up from a chair or bed, and difficulty in combing one's hair. The Gowers sign (where the patient has difficulty rising to a standing position, using his/her hands to "climb up the legs") may be present. In the younger age group, generalized weakness often presents as the initial symptom. Prolonged muscle weakness may eventually lead to muscle contractures. Weakness of the oral muscles can result in nasal speech and dysphagia. Oral ulcers and abdominal pain stemming from vasculitis of the GI tract have been reported. Sun exposure may exacerbate JDM episodes.

Myopathic conditions such as JDM should be considered when evaluating patients with progressive muscle weakness. A methodical assessment of the patient's history and clinical examination is essential in determining the level of the lesion. Hypotonia can be broadly subdivided into myopathies (in which the pathology is confined to the muscle itself, with no associated abnormality in peripheral nerve) and neuropathies (in which muscle weakness is secondary to an abnormality along the peripheral nerve, such as the anterior horn cell to the neuromuscular junction). Myopathies typically present with muscle weakness that is accompanied with proximal atrophy with and without distal pseudohypertrophy, absent muscle fasciculations and infantile reflexes, normal to decreased deep tendon reflexes, and normal sensation (7).

Other hypotonic conditions can be distinguished from myopathies, using several clinical and electromyographic (with nerve condition studies) criteria. Deep tendon reflexes are usually hyperreflexic in upper motor neuron conditions (brain and spinal cord dysfunction), while they are hyporeflexic in anterior horn cell, peripheral nerve, neuromuscular junction and myopathy conditions. A Babinski sign and other primitive reflexes are likely to be present in upper motor neuron (brain and spinal cord) conditions, but they would likely be absent in most other conditions. Muscle fasciculations are likely to be seen in upper motor neuron and anterior horn cell conditions, but not likely to be seen in muscle or neuromuscular junction conditions. Electromyography (EMG) and nerve conduction studies can usually distinguish myopathic conditions from neuropathic conditions.

Inflammatory myopathies (myositis), which includes JDM, polymyositis, inflammatory myopathy associated with other connective tissue diseases, and acute viral myositis, can present with mild to severe muscle weakness. These disorders often have a bacterial, parasitic or viral origin, and have been linked with connective tissue diseases. The common feature of inflammatory myopathies is the involvement of the muscle through an inflammatory process. The above case is a classic presentation of JDM, where the dermatologic and progressive proximal muscle weakness are characteristic of the disease. Exact criteria for the diagnosis of JDM is as follow:

1) Characteristic rash.
2) Progressive symmetrical proximal muscle weakness.
3) Elevated muscle derived enzymes.
4) EMG changes - myopathic pattern.
5) Muscle histopathology - inflammatory changes.

Consistent clinical and laboratory findings are often enough to initiate therapy, sparing the patient from the invasive EMG and muscle biopsy procedures. EMG and muscle biopsy are beneficial when clinical and laboratory findings are inconsistent, or if initial therapy fails to resolve symptoms. Increased antibody titers and viral isolation of Coxsackie virus has led many investigators to consider it to be the causative agent for JDM (3).

The clinical presentation of polymyositis is identical to JDM except for the lack of the dermatologic manifestations. Polymyositis is predominantly a disease of adults, and is thought to have a rheumatologic etiology. In contrast to JDM, polymyositis has less primary vessel involvement seen on muscle biopsy and soft tissue calcifications are rare (3). Viral myositis can also present with proximal muscle weakness, but differs from other inflammatory myopathies by its propensity to affect calf muscles. Severe pain over affected muscle is typical and more pronounced than in JDM. Viral myositis usually occurs 1-2 days after an upper respiratory infection and is commonly attributed to influenza A and B infections (8). Rapid resolution occurs within weeks. Inflammatory myopathy in SLE is rare, especially in children. In rare cases of SLE induced myopathy, there is elevated double stranded DNA, reduced serum levels of complement, and presence of immune complexes much higher than that seen in JDM (3).

Hereditary myopathic disorders, such as muscular dystrophy and metabolic myopathies, can present as proximal muscle weakness. They typically manifest at birth but can present later in life. As discussed in the muscular dystrophy chapter, the neurologic findings of muscular dystrophies are consistent with a myopathic pattern, presenting as hypotonia in infancy or progressive weakness of proximal to distal muscles in childhood. Muscular dystrophies, however, lack the dermatologic changes seen in JDM and are gradual and progressive in nature. Some hereditary metabolic myopathies are not detected until late in childhood. Metabolic myopathies are rare and frequently fatal. They result from specific metabolic defects of glycogen, lipid, or energy metabolism, often due to mitochondrial dysfunction. These diseases, such as glycogenoses disorders, carnitine deficiencies, Kearns-Sayre syndrome, and myoclonic epilepsy and ragged red fibers (MERRF), often involve multi-organ systems such as the skeletal muscular, hepatic and nervous systems. Patients with hereditary metabolic myopathies report exercise intolerance, and muscle weakness/pain after exercise or stress. Dermatologic findings are absent.

Endocrinopathies can induce myopathic conditions, although the clinical symptoms associated with endocrine induced myopathies are typically that of muscle cramps and contractures. Derangements in thyroid and adrenal functions are the common endocrinopathies associated with myopathy. Thyrotoxicosis causes proximal weakness and wasting through the binding of thyroxine to myofibrils, which impair contractility. Hyperthyroidism may also induce myasthenia gravis and hypokalemic periodic paralysis (9). Likewise, hypothyroidism can cause muscle weakness, diffuse muscle hypertrophy ('myoedema') and inflammation (10). The correction of thyroid function results in the resolution of the myopathic condition. Corticosteroid induced myopathy (Cushing disease and Cushing syndrome) is associated with a nonspecific proximal myopathy with selective type 2 fiber atrophy (3). Adrenal failure produces nonspecific muscle weakness and in chronic cases, muscle contractures. Myopathy associated with diabetes and hyperparathyroidism have been described but are rare.

Hypokalemic periodic paralysis is an inherited autosomal disorder with full penetrance. The etiology of this paralysis is thought to be an abnormality of the muscle cell membrane, particularly an impairment of the calcium ion channel. Attacks of profound generalized weakness begin suddenly during the first and second decade of life. These episodes usually last for several hours and are triggered by

vigorous exercise, heavy carbohydrate meals, or anxiety. These patients present with profound hypokalemia (often less than 2.0). Potassium replacement usually results in fairly rapid recovery. Compared to JDM, patients with hypokalemic periodic paralysis are usually asymptomatic prior to and after these attacks.

Non-myopathic conditions should also be considered in patients with proximal muscle weakness. Guillain-Barre Syndrome (GBS) is an inflammatory polyradiculopathy, whereby the nerve roots and peripheral nerves are involved. Weakness follows an ascending pattern, progressing for several days to weeks, reaching a plateau, and then recovers over a period of several months. Reflexes are diminished, and patients can experience sensory abnormalities and severe back pain. There are no dermatologic findings in GBS. Lesions of the neuromuscular junction, such as myasthenia gravis, Lambert-Eaton myasthenic syndrome and botulism, can result in proximal muscle weakness. The weakness, often presenting as ptosis and diplopia, worsens with use and recovers with rest. In JDM, extraocular and facial muscles are rarely involved. Abnormalities of the peripheral nerve and neuromuscular junction do not have elevations in muscle derived enzymes and EMG findings are characteristic of the level of the lesion. Metabolic abnormalities such as hypophosphatemia and hypokalemia can result in muscle weakness but these symptoms are generalized.

Muscle derived enzymes (CK, myoglobin, AST, aldolase and lactic dehydrogenase) are elevated in JDM, representing damage to the muscle either through reduction in vascular supply or by direct immunogenic cytotoxicity. The CK elevation in JDM is usually in the range of several hundred, versus the much higher elevations in muscular dystrophies. Inflammatory markers such as ESR, white blood cell count, and ANA are commonly elevated. Von Willebrand factor-related antigen, a sensitive indicator of endothelial cell damage, has recently been used as a marker for JDM therapy (3).

EMG is a valuable tool in differentiating between myopathies and neuropathies, but is limited in further delineating the diagnosis. An EMG is performed by inserting a fine needle electrode into affected muscle to record its contractions. The procedure is painful and should be avoided in areas where future muscle biopsy may be planned. The typical EMG pattern in myopathies is that of low amplitude, polyphasic, potentials of short duration. Nerve conduction velocity is normal and unchanged with repetitive stimulation. These myopathic features suggest a myopathy as opposed to neuropathic findings which suggest a neuropathy.

A muscle biopsy can be beneficial in establishing the definitive diagnosis, especially in hereditary or congenital myopathies. Muscle biopsy is limited in that it is invasive and painful. It may not provide a specific diagnosis, if the muscle biopsied is not significantly affected by the disease process or if it not obtained appropriately. The quadriceps or biceps are typically biopsied in accessing proximal muscle weakness. The muscle histopathology of JDM shows infiltration with inflammatory cells, perifascicular atrophy, and capillary necrosis. Besides the usual histologic examination of the muscle tissue, specific staining procedures should be employed in differentiating JDM from hereditary disorders. Biochemical analyses on dystrophin protein levels assist in evaluating muscular dystrophies. Hereditary metabolic disorders should be evaluated with assays for glycolytic enzyme activity, respiratory chain enzyme complexes (i.e., oxidative phosphorylation enzymes largely found in mitochondria), carnitine levels, and fatty acid chain transport substrates. Electron microscopy can assist in evaluating mitochondrial abnormalities.

The treatment of JDM consists of immunosuppression and supportive care. Prompt initiation of corticosteroids reduces the long term complications of calcinosis and muscle contractures. Initial therapy can control muscle inflammation and gastrointestinal bleeding that results from vasculitis of the GI tract. Not uncommonly, the elevated muscle derived enzymes will normalize after the initial doses of corticosteroids. A maintenance dose of corticosteroids is titrated to normalize creatinine kinase levels and this is continued for approximately 1-2 years when re-occurrences, though rare, may develop (1,6). Other immunosuppressive agents, such as methotrexate, cyclosporin, and azathioprine are employed if corticosteroids are unable to reduce the inflammatory process. Nasogastric tube feedings may be necessary to protect the airways and in cases of severe dysphagia. Malabsorption of nutrients and medications can occur in cases of severe GI vasculitis, thus requiring parenteral nutrition and medication. Physical and occupational therapy programs are employed to avoid excessive deconditioning and to reduce muscle contractures.

Questions

1. True/False: Can sun exposure result in flare-ups in JDM?

2. What is the rate of recurrence in JDM?

3. Myopathies are most likely to cause:
   a. Delayed language skills.
   b. Sensory impairment.
   c. Delayed developmental motor milestones.
   d. Delayed social adaptive behavior.

4. Each of the following is true about myopathies, except:
   a. Distal weakness suggests a myopathic condition.
   b. Weakness is the primary symptom.
   c. Weakness or pain following exercise is a common feature of metabolic myopathies.
   d. Pain is not usually a feature of muscular dystrophies.

5. Which of the following (may be more than one) are typical of acute viral myositis but not JDM?
   a. Acute onset.
   b. Pain.
   c. Biceps involvement.
   d. Elevated CPK.
   e. Elevated ESR.
   f. Spontaneous resolution.

Answers to questions

1. True. Sun exposure can exacerbate JDM dermatologic lesions and myositis, even during therapy. It is important to advise patients with JDM about appropriate sun protection - large rimmed hat, clothing over majority of body in sun, sunblock with a SPF of 15 or higher.
2. Unknown, but thought to be low. The risk of recurrence of JDM is highest in the first year after diagnosis, therefore maintenance prednisone is usually continued for 2 years.
3. c.
4. a
5. a, b and f are correct. Pain is typically greater in viral myositis than in JDM. Acute viral myositis has a propensity to affect the calf region, rather than the biceps. Both viral myositis and JDM have elevated CPK and ESR so these tests do not distinguish the two.

Chapter XVIII.16. Developmental Brain Anomalies

Kaipo T. Pau

This is an 5 month boy who is brought to the emergency room after his mother noted that he had a seizure. His mother adds that she is also concerned because her son has always seemed weak for his age and that his head seems to be progressively swelling, increasing out of proportion to the rest of his body. In addition, his strength and degree of development does not seem to follow that of his older brother. There is no recent history of fever, vomiting, diarrhea, poor appetite or urinary abnormalities.

He is the second child born to 31 year old parents. There is no family history of recurrent abortions, consanguinity, or mental retardation. Pregnancy was uncomplicated and he was born with a weight of 2500 g, a length of 47 cm, a head circumference of 32 cm, and Apgar scores of 8 and 9.

Exam: VS T 37.2, P 100, RR 38, BP 75/55. Height 64 cm (25%ile), weight 6.8 kg (25%ile), and head circumference 45 cm (98%ile). He is subdued in no distress. He is not irritable, but he does not move about much. Diffuse hypotonia is obvious upon visual inspection and the child is lethargic and inactive. His head is macrocephalic. His anterior fontanelle is open and rather large for age. Abnormal facies showing a short nose with nostrils displaced forward is noted. Deep tendon reflexes are very brisk (3+) and there is a positive Babinski sign bilaterally. His eyes are opened wide and a downbeat nystagmus is present.

A CBC and chemistry panel are normal. A CT scan of the brain shows a smooth appearance of the cerebral cortex, with shallow sulci and thick gyri (pachygyria). The ventricles are dilated (hydrocephalus) and a Chiari malformation obstructing CSF outflow is noted. After his mother agrees, he is taken to the operating room for insertion of a ventriculoperitoneal shunt.

Although the incidence of nervous system malformations in living newborns is 1%-3%, such malformations are present in 40% of infant deaths. The etiologies associated with developmental anomalies may result from a variety of insults from genetic to environmental. Abnormalities associated with the neural tube and the neural plate generally occur within the first 28 days of gestation. On the other hand, abnormalities associated with cellular proliferation and migration in the CNS generally occur after the 28th day of gestation. This chapter will cover malformations associated with both of these periods. Included among these malformations are Arnold-Chiari malformations and a group of disorders collectively referred to as neuronal migration defects (1).

Professor Hans Chiari, a German pathologist described a group of malformations characterized by the displacement of the cerebellum. He classified the manifestations into types based on the order of increasing severity (type I being least severe) and these became known as Chiari malformations (2). Of note, type II Chiari malformations (CM) are also known as the Arnold-Chiari malformation. However, other publications use "Arnold Chiari" malformations as the umbrella term for the four types of cerebellar displacement. This chapter will look at the Chiari malformations that are more commonly seen (1,3).

Type I CM is defined as a caudal displacement of the cerebellar tonsils below the foramen magnum by 5 mm. Hydrocephalus is present in 90% of patients and syringomyelia may also be present. Patients may live asymptomatically up until the third or fourth decade of life or later, when signs and symptoms of this disorder may present. The presentation is dependent upon the degree of the abnormality and associated manifestations, on neural structures. These can include lower cranial neuropathies, downbeat nystagmus, ataxia, vertigo, vocal cord paralysis, and eye movement abnormalities (3). Additional skeletal anomalies include scoliosis (especially from syringomyelia) and skull base abnormalities (2). The differential diagnosis of type I can vary tremendously, depending on the neural structures involved. A diagnosis of type I can be made on the basis of imaging (MRI is preferred) along with clinical information. Treatment is done surgically by cervical bony decompression of structures in the foramen magnum and along the spinal cord if necessary. This process involves removal of bone (usually by cutting through bones of the spine). Relief of signs and symptoms related to the compression of the brain

stem is better than those related to the spinal cord (2). Treatment of hydrocephalus involves finding an alternative route of drainage of the cerebrospinal fluid in the ventricles. This is usually accomplished by a ventriculoperitoneal shunt (4). Successful interventions may allow the individual to have normal mental development, if there are no additional CNS malformations (2).

Type II (Arnold-Chiari) malformation is the commonest type of CM malformation (4). It is manifested by an increased caudal displacement of the cerebellum into the foramen magnum, along with the lower brainstem. Myelomeningocele is usually associated with this type II malformation usually resulting in hydrocephalus (80% or more). There is an increased likelihood to develop hydrocephalus if the meningomyelocele is more rostral. As in type I, the presentation of signs and symptoms depends upon the degree of the abnormality and associated manifestations, on neural structures. Symptoms related to hindbrain dysfunction may develop which include difficulty feeding, choking, stridor, apnea, vocal cord paralysis, pooling of secretion, and spasticity of the upper extremities. An increased head circumference may be present due to hydrocephalus. Ventricular enlargement may be slow or rapid and cause a bulging anterior fontanel, dilation of scalp veins, irritability, and vomiting. Diagnosis is the same as type I but a more severe displacement is seen, and a myelomeningocele is usually obvious on gross inspection. Treatment is done surgically to repair the myelomeningocele and to relieve the hydrocephalus. Bony decompression may also be performed. Prognosis depends on the site and severity of myelomeningocele. Improved prognosis is associated with a more caudal lesion. It is also advisable to recommend a multivitamin with folate for expectant mothers to reduce the risk of subsequent neural tube defects (3).

Type III (rare) CM is characterized by a cerebellar displacement into an occipital encephalocele. An occipital encephalocele is a defect in the closure of the neural tube near the base of the skull, a condition known as occipital encephalocele. Prognosis is poor (4).

Neuronal migration defects form a group of developmental brain anomalies. Abnormal cerebral cortical development is generally viewed as an improper migration of neural tissue. In other words, neurons fail to reach their destination in the cortex in the period of cortical neurogenesis beginning around 10 to 12 weeks of gestational age or earlier. Environmental factors such as retinoic acid, radiation, and methylmercury have been implicated in the pathogenesis. Viral infections in utero are also known to result in migrational abnormalities, although the mechanism of action is unknown. The abnormalities, which may present together, can be grouped into three general categories. They include lissencephaly/pachygyria, polymicrogyria, and heterotopia.

It is thought that lissencephaly and pachygyria are different representations of the same manifestation. Lissencephaly (means smooth brain) refers to a more diffuse bilateral brain abnormality and pachygyria (thick gyri) is a more focal or multifocal abnormality. The basic abnormality, seen on imaging and on gross pathologic examination, is the smooth surface of the cerebral cortex. The cortex is also noticeably thickened with a relative abundance of gray matter, compared to white matter which is variably preserved. There are at least 2 types of lissencephaly (2).

Autosomal and X-linked forms of type I lissencephaly have been identified, but this type may also be associated with other syndromes such as the Miller-Dieker Syndrome (about 15% of cases) (5). A cross-section of the brain reveals an extremely thick cortex organized into four abnormal layers, rather than the usual six. In type I lissencephaly, seizures and severe mental/psychomotor retardation are present. Most cases of type I present in the neonatal period with marked hypotonia, and later with weakness in all four extremities. In the Miller-Dieker syndrome, characteristic facial features are present in childhood and include a prominent forehead, bitemporal hollowing, a short nose with anteverted nostrils, a prominent upper lip, and jaw abnormalities. Lissencephaly as an isolated abnormality is distinguished from the Miller-Dieker Syndrome based on these facial characteristics. Diagnosis of lissencephaly is based on the smooth surface finding along with a widely opened Sylvian fissure on neuroimaging. Cytogenetic studies may often reveal a deletion on the LIS-1 (lissencephaly gene) in chromosomal region 17p13.3. Treatment of the disorder involves seizure medications and supportive care. The prognosis for type I lissencephaly, when associated with other entities, is generally poor and many patients do not survive into childhood.

The inheritance for type II is autosomal recessive but there has not been any association with a specific gene or locus. In contrast to type I, type II lissencephaly is often associated with congenital muscular dystrophies that often involves the eyes as well. Examples are the Walker-Warburg syndrome and the Finnish muscle-eye-brain disorder. In type II lissencephaly the surface of the cerebral cortex usually presents as a diffuse smooth brain appearance. A cross-section reveals an increased thickening of grey matter. Clinical manifestations, when seen with associated muscular dystrophies will involve abnormalities of muscle and CNS development. This may include neonatal hypotonia and eye abnormalities (e.g., retinal dysplasia, cataracts, microphthalmia), and joint contractures. Laboratory results reveal elevated creatine kinase levels (from the muscular dystrophy). Diagnosis is made by careful examination of the MRI of the cortex. Treatment and prognosis of type II is basically the same as in type I.

Polymicrogyria (also known as microgyria, meaning small gyri) is also considered to be a migrational disorder (defects seem to occur between week 17 to 18 and weeks 24 to 26 gestation). Unlike lissencephaly and pachygyria, the border between the polymicrogyria and normal cortex is distinct. Polymicrogyria usually reveals a cerebral cortex with a complex set of small gyri appearing fused together. This gives the surface of the cortex a fine stubbling appearance. A number of malformations and abnormalities have polymicrogyria as one part of an overlying CNS manifestation. For instance the polymicrogyria-schizencephaly complex is a disorder with clinical features including delayed development, pyramidal signs, motor speech dysfunction and epilepsy. Schizencephaly (means cleft brain) is the presence of fused or unfused, unilateral or bilateral clefts within the cerebral hemispheres as a result of abnormal morphogenesis (3). Polymicrogyria presents with psychomotor retardation and frequent focal seizures. The differential diagnosis for this disorder can include Aicardi's, Neu-Laxova, Zellweger, and Smith-Lemli-Opitz syndromes. Removal of a focal area of polymicrogyria may be curative. Multifocal removal may result in improved seizure control. The prognosis is variable, but usually poor.

Cerebral heterotopia are defined as focal or multifocal disorganized nodules of gray matter at inappropriate places in the cerebrum. The heterotopia may be found incidentally on imaging or there may be associated clinical manifestations that present itself. The main presenting feature is a childhood seizure disorder of various types including focal, multifocal, and generalized. Motor and mental retardation may also be present depending upon the extent of the heterotopia abnormality. Focal area heterotopia removal may improve seizures (2).

Questions

1. What is the most common type of Chiari malformation?

2. What CNS structure is displaced in Chiari malformations?

3. What are the 3 general categories of neuronal migration abnormalities?

4. What basic abnormality is revealed with lissencephaly on MRI imaging and gross inspection?

5. What other abnormalities are often found with type II Chiari malformations?

Answers to questions

1. Type II (Arnold-Chiari malformation).
2. Cerebellum.
3. Lissencephaly/pachygyria, polymicrogyria, heterotopia.
4. Smooth surface of the cerebral cortex.
5. Myelomeningocele and hydrocephalus.

Chapter XVIII.17. Reye Syndrome
David W. Boldt

This is a 2 year old child who appears to be recovering from an upper respiratory infection when he develops vomiting. He may have taken aspirin (given by his grandmother), but he was supposed to have taken acetaminophen. He initially presents to the emergency department with irritability and restlessness. He subsequently develops convulsions which are treated with anticonvulsants and he is admitted to the ICU.

Exam: VS T 37.8, P 100, RR 50, BP 110/70, oxygen saturation 99% in room air. Height, weight, head circumference are at the 50th percentile. He is agitated and not cooperative. Head shows no signs of external trauma. Pupils are equal and reactive to light. Conjunctiva are clear, sclera non-icteric. EOMs cannot be fully tested, but they are conjugate. TMs are normal. Mouth is not easily examined. Neck reveals no adenopathy. He is agitated so it is not possible to be certain that his neck is supple. Heart regular without murmurs. Lungs are clear. Abdomen is flat with normal bowel sounds. It is difficult to tell if he has any hepatosplenomegaly. No definite tenderness. No inguinal hernias are present. Testes are normal. He moves all extremities. Reflexes are not testable because of his agitation.

Labs: Serum bilirubin: Normal. Serum AST and ALT: increased. Serum ammonia: increased. Prothrombin time: prolonged. A CT scan of the brain is obtained which shows cerebral edema.

His neurologic symptoms rapidly worsen and he becomes unresponsive. He is intubated and put on mechanical ventilation.

Reye syndrome is suspected. A confirmatory liver biopsy reveals diffuse, small lipid deposits in the hepatocytes (microvesicular steatosis) without significant necrosis or inflammation. These findings are consistent with the diagnosis of Reye syndrome.

Reye syndrome (also called Reye's syndrome) is a rare illness seen exclusively in children less than 15 years of age. It is characterized by fatty changes in the liver and encephalopathy that often leads to coma. The number of cases of Reye syndrome has decreased in the last decade due to increased awareness concerning the use of aspirin (salicylates) in children.

Common signs and symptoms include vomiting, agitation, irrational behavior, progressing to lethargy, progressive stupor, restlessness, and convulsions. The usual progression of Reye Syndrome follows the following course: A febrile illness, chickenpox, or upper respiratory infection, occurs in a previously healthy child, followed by a period in which the child seems to have recovered. Subsequently, vomiting ensues 5-7 days after the onset of the initial illness. Simultaneously or within a few hours of this onset of vomiting, delirium, restlessness, and stupor usually occur. In severe cases, the neurologic symptoms rapidly progress to seizures, coma, and eventually death.

Reye Syndrome can be broken down into five stages. This may be preceded by a stage of agitation sometimes called Stage 0. Stage I: Patient is quiet, lethargic, sleepy, and is vomiting. Lab values indicate liver dysfunction. Stage II: Characterized by deep lethargy, confusion, delirium, combative behavior, hyperventilation, and hyperreflexia. Stage III: The patient is obtunded. Seizures may be present at this stage. There is decorticate rigidity with intact pupillary light reflexes. Stage IV: Seizures are present and are accompanied by a deepening coma, decerebrate rigidity, loss of oculocephalic reflexes, and fixed pupils. Stage V: Characterized by coma, areflexia, respiratory arrest, fixed and dilated pupils, and intermittent flaccidity and decerebrate posturing. The EEG at this point is isoelectric.

There is almost always a history of a preceding viral illness, especially influenza A or B, or varicella. Examination may reveal a positive Babinski sign and hyperreflexia, consistent with cerebral edema; dilated, sluggish pupils, and hyperpnea with irregular respirations. Hepatomegaly is sometimes present, but splenomegaly is absent.

Lab findings include hyperammonemia, normal or slightly elevated bilirubin and alkaline phosphatase, prolonged prothrombin time, hypoglycemia (variable), and moderate to severe elevations in AST, ALT, and lactate dehydrogenase. Hyperaminoacidemia (glutamine, alanine, and lysine) and hypercitrullinemia can be found but these require special tests. Tissue histopathology demonstrates microvesicular steatosis of the liver, kidneys, and brain. The CSF analysis is normal, but the CSF pressure (i.e., ICP) is elevated.

Epidemics of Reye syndrome seem to occur during epidemics of influenza B virus. The use of salicylates (aspirin) is associated with Reye Syndrome, and therefore its use is contraindicated in children (acetaminophen or ibuprofen is usually recommended instead).

The proposed pathological mechanism in Reye is mitochondrial damage caused by salicylate metabolites or some other toxin during a viral infection. Mitochondrial damage leads to elevated short chain fatty acids, hyperammonemia, and directly to cerebral edema. In very young children, metabolic defects in fatty acid oxidation may contribute to the pathogenesis.

The diagnosis of Reye syndrome is based largely on clinical findings, after ruling out other causes of neurologic deterioration such as other encephalopathies, encephalitis, toxins, neoplasms, hepatic failure, fulminant hepatitis, fatty acid oxidation defects, other metabolic disorders, hemorrhage, etc. Histopathology and electron microscopy of a liver biopsy can be used to confirm the diagnosis, but this is usually not done clinically. Urine gas chromatographic analysis and serum acyl-carnitine levels will help to differentiate Reye Syndrome from metabolic disorders. Systemic carnitine deficiency (SCD) (which is an inherited defect of fatty acid oxidation), results in hypoglycemia, hyperammonemia, hypoprothrombinemia, and acute episodes of encephalopathy. SCD mimics the clinical picture seen in Reye Syndrome. In these patients, acyl-carnitine levels would be elevated, whereas they would be normal in patients with Reye syndrome.

Brain imaging studies (CT, MRI) are useful to rule out other causes of CNS dysfunction. Patients with Reye syndrome will generally exhibit findings of cerebral edema and increased intracranial pressure.

Treatment for Reye syndrome is supportive. Hypoglycemia is corrected if present. Measures to lower intracranial pressure (ICP) are initiated. Intensive care measures to monitor fluid status and physiologic function should be initiated (NG tube, Foley catheter, oximetry, ECG, arterial and central venous pressure lines). If the patient is in grade 3 coma (see below), mechanical ventilation may be necessary.

Coma can be scored using the Glasgow coma scale. A simpler method is the AVPU scale (A=alert, V=responds to verbal stimuli, P=responds to painful stimuli, U=unresponsive). Similarly, grades can be used as follows: Grade 1=Subject is able to obey simple commands. Grade 2=No response to commands, but purposeful responses to pain are elicited. Grade 3=Non-purposeful responses to pain (e.g., sternal rub). Grade 4=No response to painful stimuli. Grade 5=Autonomic dysfunction with hypothermia, cardiovascular instability and absent spontaneous respiration.

Intracranial pressure should be monitored directly which is best done with a ventricular catheter and kept below 15-20 mmHg through the use of periodic mannitol infusions (0.5-1g/kg every 4 hours), barbiturates, or ventricular CSF drainage. Systemic blood pressure should be monitored and kept high enough to maintain cerebral perfusion pressure (the difference between mean arterial pressure and intracranial pressure) above 45-50 mmHg.

Maintenance fluids using 10% glucose (to reverse hypoglycemia and to some degree as an osmotic agent) should be given at a rate sufficient to produce a urine flow of 1.0-1.5 ml/kg/h. Vitamin K, 3-5 mg intramuscularly, should be given to reduce the likelihood of coagulopathy due to vitamin K dependent factor depletion. Induced hypothermia (30-33 degrees C) and pentobarbital (10-50/mg/kg/day) can be used to decrease the brain's metabolic needs during periods of elevated intracranial pressure.

Reye syndrome is a serious neurologic condition, but roughly 70% of patients with Reye syndrome survive. Survival is related to the depth of the coma and the peak ammonia level on admission. Complications due to coma such as aspiration pneumonitis and respiratory failure also affect the prognosis. If death results, it is usually from refractory cerebral edema. Severe neurologic dysfunction may be present in children who recover from prolonged grade 3 or 4 coma. All patients should be screened for fatty acid oxidation defects and other metabolic defects.

Questions

1. True/False: Reye syndrome is most often preceded by a history of viral illness.

2. The cause of Reye syndrome is:
   a. liver failure
   b. brain abscess
   c. unknown
   d. too much fat in the diet

3. Which drug is associated with the development of Reye syndrome?
   a. antidepressants
   b. salicylates
   c. cancer chemotherapy
   d. barbiturates

4. Reye syndrome is primarily a disease of:
   a. adults
   b. the elderly
   c. children and adolescents
   d. infants

5. What is/are the most common feature(s) of Reye syndrome?
   a. liver infection
   b. rapid accumulation of fat in the liver
   c. inflammation of the brain
   d. b and c

6. Treatment of Reye syndrome focuses on:
   a. Maintaining cerebral perfusion.
   b. Ammonia removal or detoxification.
   c. Treating hypoglycemia.
   d. Preventing urinary tract infection.

Answers to questions
1.True, 2.c, 3.b, 4.c, 5.d, 6.a

Chapter XVIII.18. Brain Tumors
Wade T. Kyono, MD

A 10 year old female with intermittent headaches for 3-4 months, complains of blurry vision. She is referred to a pediatric ophthalmologist for her blurry vision, when she is noted to have medial deviation (adduction) of her left eye. An MRI scan is done and this shows a pituitary mass. She is referred to a pediatric neurosurgeon who performs a gross total resection of the primary tumor. The tumor pathology is consistent with the diagnosis of craniopharyngioma. A follow-up MRI scan done within 48 hours of her tumor resection demonstrates no residual tumor. While she continues to have no recurrent tumor 2 years after her resection, she has persistent clinical problems related to the craniopharyngioma and its resection. Vision in her left eye is severely impaired. Cognition, concentration and memory appear to be adversely affected with decreased school performance. Growth has decreased and she requires growth hormone and thyroid hormone replacement. Neuropsychiatric testing is performed by a clinical psychologist. An individualized education plan is developed and she receives support services/tutoring.

Central nervous system (CNS) tumors have the dubious distinction of being the most common solid tumor of childhood. They represent the second most common malignancy in children (17%). There are approximately 2500 new brain tumor cases per year nationally. Infratentorial cerebellar and brain stem tumors are more common in children than adults. In contrast, cerebral tumors, mostly astrocytomas, are most common in adults. Of the pediatric brain tumors, 35-50% are astrocytomas, 10-20% medulloblastomas/primitive neuroectodermal tumors (PNET), 10-20% brain stem gliomas, 5-10% ependymomas, 5-10% craniopharyngiomas, 1-2% pineal tumors, and 10-15% other. Many of these tumors are undifferentiated and defy standard histologic classification. The incidence is higher in males versus females. There appears to be a small peak in embryonal tumors with a relative paucity of adult type gliomas until adolescence. One third of all brain tumors in children younger than 15 years of age occur in children under 5 years of age. The overall incidence of childhood brain tumors has been increasing over the past several decades, with some of this increase due to improved detection with computed tomography (CT) and magnetic resonance imaging (MRI) scans. Overall mortality and morbidity likely exceeds that of other common solid tumors and leukemia. Long term side effects of CNS tumors account for high rates of morbidity due to the location of primary lesions and aggressive therapy received by patients.

Factors that are associated with an increased risk of pediatric brain tumors include being male (medulloblastoma/PNET, ependymomas), ionizing radiation, and genetic conditions (neurofibromatosis, tuberous sclerosis, Turcot syndrome, and Li-Fraumeni syndrome). Cured meats and polyomaviruses (simian virus 40, JC, BK) have been also been implicated in the development of brain tumors. In general though, the majority of pediatric brain tumors arise with no obvious risk factors present.

Despite the progress made over the last 20-30 years in treating childhood cancer, pediatric brain tumors have demonstrated only modest improvements in survival. While from 1975-1995 the mortality rate for leukemia and all other non-central nervous system (CNS) cancers declined by over 50%, CNS cancers had only a 20% improvement in survival. The lack of improvement in brain tumor treatment is dependent on many factors which include: 1) the presence of the blood brain barrier, 2) the low regenerative capacity of the brain, and 3) the inability to intensify CNS toxic treatment without unacceptable long term developmental side-effects (pronounced in younger children). Despite the development and use of chemotherapy agents and radiation therapy over the last 20 years, the primary determinant of survival for the majority of pediatric brain tumors remains the degree of surgical excision. Improvements in the delivery of localized radiation therapy (conformal radiation), stereotactic radiation (gamma knife), dose-intensified treatment with bone marrow transplantation, and the development of new, targeted anti-tumor therapies hold promise for future improvement in treatment.

The most common presentations of brain tumors in children include flu-like symptoms; frequent headaches that are worse in the morning and associated with nausea and vomiting; seizure activity (more likely in slowly growing supratentorial tumors); unsteady gait; vision changes; and deterioration of school performance without explanation. Age of children also affects diagnosis, with younger children and infants suffering from more nonspecific symptoms. Infants with open fontanelles and cranial sutures that are not fused may be very nonspecific signs of tumor progression. The nonspecific nature of these symptoms are often misleading to the general practitioner so that care must be taken in evaluating children with persistent or worsening symptoms.

For older children infratentorial tumors generally present with problems of truncal steadiness, coordination, gait, or cranial nerve function. Nonlocalizing presenting signs suggestive of increased intracranial pressure are often found with tumors that fill the posterior fossa, while infiltrative tumors of the cerebellar hemispheres often present with an asymmetric inability to coordinate and direct limb movements. Seizures are most frequently found in slow growing supratentorial gliomas so that CT or MRI scans are indicated for all children with new onset focal and complex seizures, and most children with unexplained generalized seizures to rule out a brain tumor. Children with metastatic tumors (some primitive neuroectodermal or germ cell tumors) often present with metastases to the spinal cord and cauda equina, and may have back pain, urinary incontinence, or focal extremity weakness or sensory loss.

CNS symptoms associated with brain tumors can be used to determine brain tumor location. Brain stem tumors often result in motor and sensory changes, and the impairment of vital functions (cardiac, respiratory, vasomotor). Cerebellar lesions often present with abnormalities in balance, posture, or motor coordination (including eye movements). Frontal lobe tumors may affect attention, behavior, abstract thought, reflection, problem solving, creative thought, emotion, intellect, judgment, initiative, inhibition, coordinated movements,

generalized and mass movements, some eye movements, muscle movements, skilled movements, sense of smell, physical reaction, or sexual urges. Parietal tumors may affect the appreciation of form through touch (stereognosis), tactile sensation, response to internal stimuli (proprioception), sensory combination and comprehension, some language and reading functions, or some visual functions. Occipital lobe lesions may affect reading or vision. Pituitary gland lesions affect hormonal body processes, physical maturation, growth (height and form), sexual maturation, and/or sexual function. Spinal cord tumors result in sensory and motor defects. Temporal lobe defects may affect auditory memories, hearing, visual memories, visual pathways, memory, music, fear, language, speech, or behavior.

Common findings within more general classifications of brain tumors occur as follows:

INFRATENTORIAL (Brain stem and cerebellar).

Brain stem: 1) inability to deviate both eyes conjugately, 2) problems with adducting an eye on lateral gaze, 3) cranial nerve V, VII, and IX defects.

Cerebellopontine angle: facial weakness, hearing loss, unilateral cerebellar deficits.

Brain stem or posterior fossa: peripheral VII nerve palsy (upper and lower facial weakness).

Above pons: central VII nerve palsy (lower facial weakness).

Hypothalamic, brain stem, or upper cervical cord: partial Horner's syndrome (ipsilateral ptosis and miosis).

SUPRATENTORIAL.

Upper motor neuron signs: hemiparesis, hyperreflexia, clonus and sensory losses.

Frontal or parietal-occipital, third ventricle: may have no focal deficits (present with increased ICP).

Optic nerve or chiasmal defect: visual deficits, Marcus Gunn pupil (afferent pupillary defect), bitemporal hemianopsia (classic chiasmal tumor), unilateral or bilateral nystagmus with head tilt (chiasmal).

Hypothalamic: "diencephalic syndrome" (failure to thrive and emaciation in a happy and hungry child).

Pineal tumors: Parinaud's syndrome - poor upward gaze, slightly dilated pupils that don't react to light but react to accommodation, retraction or convergence nystagmus, lid retraction.

The initial diagnosis is largely based on imaging. A CT scan is often used in initial screening because of its relative speed or in cases where MRI is not available. MRI scan is the neuroimaging scan of choice. T2 weighted images enhance the differences between normal and tumor tissues. Gadolinium-DPTA, given as a contrast agent, further improves the sensitivity of MRI. MRA (magnetic resonance angiography) is useful if tumor vascularity is a concern.

Cerebrospinal fluid examination in conjunction with MRI will help to demonstrate spinal cord lesions caused by PNETs, anaplastic gliomas, and germinomas. PET scanning is useful in distinguishing between radionecrosis/scar tissue and recurrent or residual tumor. Neuropathologists experienced in pediatric brain tumor histopathology and cytology add considerably to the accuracy of pathologic diagnosis.

Specific tumor types tend to occur in specific areas of the brain, which can provide useful information in determining the tumor diagnostic type. Infratentorial tumors are likely to be brain stem gliomas, cerebellar astrocytomas, primitive neuroectodermal tumors (medulloblastomas), or ependymomas. Supratentorial tumors are likely to be choroid plexus tumors, otic/hypothalamic astrocytomas, or high grade gliomas. Pineal tumors are likely to be pineoblastoma, germ cell tumors, or astrocytoma. Craniopharyngiomas tend to occur in the suprasellar or intrasellar region. Gliomas in the visual pathway are likely to be a low grade pilocytic astrocytoma, or fibrillary astrocytoma. Intramedullary spinal cord tumors are likely to be astrocytomas, ependymomas, oligodendroglioma, gangliogliomas, or malignant gliomas. Disseminated brain tumors (15% of primary tumors) are likely to be medulloblastoma, germ cell tumors, ependymoma, or high grade gliomas.

Treatment options include neurosurgery, radiotherapy (radiation therapy) and/or chemotherapy. Acute complications of radiotherapy include: alopecia (temporary or permanent), erythema and desquamation of skin, otitis externa/media, hearing loss, and bone marrow suppression. Late complications include: radiation necrosis, headache, personality change, seizures, lethargy, hemiparesis, ataxia, increased ICP, focal neurologic signs, vasculitis with transient ischemic attacks and infarction, second malignancies (soft tissue sarcomas, meningiomas, others), somnolence syndrome (4-8 weeks after radiation therapy), necrotizing leukoencephalopathy (4-12 months after therapy), neuropsychologic damage (peaks 3 years after treatment), and endocrine dysfunction. Chemotherapy is limited by the blood brain barrier. In the majority of studies utilizing post-operative chemotherapy, overall survival is most directly related to the degree of primary resection. Efforts to delay radiotherapy by using chemotherapy first have generally resulted in poorer outcomes. High dose chemotherapy, often in conjunction with autologous bone marrow transplantation and reduced radiotherapy doses, in infants and younger children is being investigated. Future use of immunotherapy, gene transfer therapy, blood brain barrier disruption, and novel molecularly targeted therapy hold hope for future treatment efforts.

In general, prognosis is worsened by younger age (particularly infants), increased tumor size, metastatic disease, subtotal resection, unresectability, histologic aggressiveness, decreased radiotherapy, and molecular markers associated with poor outcomes. Side effects are probably most pronounced in children who are the youngest at diagnosis and treatment. IQ decreases, memory problems, fine motor, and visual disturbances may cause long term problems. Cognitive deficits, learning problems, and behavioral problems often occur.

Routine MRI surveillance should be performed every 3 to 6 months during the first 2 years, every 6 to 12 months for the next 2 to 3 years, and every 3 to 5 years thereafter to detect late events (meningiomas from radiation therapy). Medulloblastoma and other embryonal tumors should have spinal MRIs done for the first 2 years. Neuroendocrine problems include growth retardation from impaired growth hormone secretion, hypothyroidism, premature or delayed puberty, all of which may not be immediately obvious. Yearly endocrine and neuropsychologic testing is highly recommended for all CNS tumor patients. Evaluation and/or services for children with special health care needs should be initiated for all brain tumor patients to deal with long term sequelae.

Questions

1. Which statement(s) about pediatric brain tumors are true:
    a. Most common childhood solid tumor.
    b. Brainstem and cerebellar locations more common than adults.
    c. Incidence rate appears to be increasing.
    d. Overall survival has not kept pace with other childhood tumors.
    e. All of the above.
    f. b and d only.

2. Which of the following is not a common presenting sign of brain tumors?
    a. Visual problems
    b. Fever
    c. Seizure
    d. "flu-like" symptoms
    e. Headaches with early morning emesis

3. Brain stem tumors:
    a. Should always be biopsied
    b. Are infratentorial
    c. Can be cured with aggressive resection
    d. May present with cranial nerve abnormalities
    e. All of the above
    f. b and d only

4. Which of the following is most consistent with improved long-term survival in children with brain tumors?
    a. Young age at diagnosis
    b. Subtotal tumor resection
    c. Brain stem location
    d. Gross total tumor resection
    e. The use of regular-dose chemotherapy

5. Long term sequelae of brain tumors in children include:
    a. Decreased cognition
    b. Impaired memory
    c. Growth hormone deficiency
    d. Delayed puberty
    e. All of the above

Chapter XVIII.19. Arteriovenous Malformations
Chia Sonia Granda

This is a ten year old male who presents to the emergency department (ED) via ambulance, unconscious. His soccer coach accompanies him and reports that before practice began, he was complaining of a headache, and one hour later, he fell and began convulsing while practicing on the soccer field. A parent called 911. He seized for approximately five minutes. An ambulance arrived about 5 minutes later. An IV was started and he received phenytoin en route to the ED. His mother arrived shortly afterward, reporting that her son has a history of occasional headaches and that his teacher feels that he may have difficulty concentrating.

Exam: VS T 37.1, P 90, RR 24, BP 90/60, oxygen saturation 100% in room air. Height, weight, head circumference are at the 50th percentile. He is drowsy with a good respiratory effort. A contusion is noted on his left forehead. His pupils are equal and reactive. Auscultation reveals a bruit over the right eyeball. Ear and mouth examination is normal. Neck, heart, lung, and abdomen exams are normal. His muscle tone is diminished and his deep tendon reflexes are normal. He has a questionable Babinski sign bilaterally. His overall color and perfusion are good.

A CT scan demonstrates a large arteriovenous malformation (AVM) in the basal ganglia. He is admitted to the hospital. An MRI scan demonstrates that the AVM is most likely inoperable, and this is confirmed by angiography. The patient and his parents are warned of the possible risks associated with treatment of his AVM, and choose embolization as their treatment choice. Five years later, he dies due to a hemorrhagic stroke in his posterior cranial fossa.

An arteriovenous malformation (AVM) is defined as a tangled collection of abnormal blood vessels where there is an abnormal communication between the arterial and venous systems. They are not neoplastic despite their tendency to expand with time and the descriptive term "angioma" is occasionally applied. The afferents flow directly into the venous efferents without the usual resistance of an intervening capillary bed. They are mostly congenital. AVMs represent abnormal embryonic and fetal morphogenesis during the retiform stage of development of endothelial channels (approximately day 48 of human embryogenesis).

These lesions are neither neoplastic nor proliferative, rather growing commensurate with the child. If large enough, they may produce a shunt of sufficient magnitude to raise the cardiac output. In extreme circumstances, this can cause high output congestive heart failure. Common sites include skin, liver, brain, brainstem and spinal cord, where they may cause headaches, seizures or bleeding (subarachnoid hemorrhage). These lesions do not improve or resolve with time. In children, AVMs are the most common lesion associated with spontaneous hemorrhage. Only cerebral AVMs, of this broad classification, will be considered in this chapter.

Patients with small AVMs are more likely to present with hemorrhage than are those with large AVMs, partly because small AVMs are less likely to cause seizures and progressive neurologic deficit since a small cortical area is usually involved. About 40-60% of patients with an AVM present with hemorrhage, often with an intracerebral or intraventricular component. In comparison with saccular aneurysms, AVMs tend to bleed in younger patients, i.e. 20-40 years, and are less likely to have a fatal outcome. Lesions in the posterior fossa have a greater incidence of death from hemorrhage. The evidence is controversial as to whether patients who harbor an AVM that has bled are more likely to suffer further bleeds than those patients with other presentations.

Children present in a similar way to adults, but they may also present with high output cardiac failure if there is a high volume shunt, and they may rarely present with hydrocephalus. Approximately one third of patients present with seizures. Generalized or partial seizures commonly occur in patients with AVMs, especially if the lesion involves the cortical surface. Of patients presenting with hemorrhage, 30% have a history of epilepsy. Lesions close to the Rolandic fissure are particularly likely to present with seizures. About 10% of patients present with neurological deficit. This typically includes cognitive deficits and memory problems. However, some patients develop gradual weakness or visual loss.

Large AVMs, especially those involving the basal ganglia, may present with a slowly progressive dementia, hemiparesis or visual field defect, probably as a result of a "steal" effect, in which blood is shunted away from functional cerebral areas. The infrequent brain stem AVM may also produce a motor or sensory deficit, with or without cranial nerve involvement. Attacks of well localized headaches (unilateral and throbbing) occur in a proportion of patients subsequently shown to have a large AVM. Auscultation, especially over the eyeball, occasionally reveals a bruit.

Capillary vascular malformations are initially pale with normal overlying skin texture but may darken as the patient ages. Nodularity and a darker purple pigmentation may occur in adulthood due to increasing dilation of the dermal vessels. AVMs may demonstrate increased warmth, audible bruits, palpable thrills, or visible pulsations. Hypertrophy of the involved limb or structure may be apparent.

Other problems to consider when doing the work-up for AVMs, include Kasabach-Merritt syndrome, vein of Galen malformation, and Sturge-Weber syndrome. Kasabach-Merritt syndrome is a capillary hemangioma associated with platelet consumption resulting in thrombocytopenia and progressively enlarging vascular malformations which may involve large portions of their extremities. Bleeding commonly develops in the first year of life, secondary to chronic disseminated intravascular coagulation triggered by stagnant blood flow through the tortuous abnormal vessels. Anemia is caused by red cell damage as blood passes through deformed vessels of the tumor.

The vein of Galen is located under the cerebral hemispheres and drains the anterior and central regions of the brain into the sinuses of the posterior cerebral fossa. Aneurysmal malformation of the vein of Galen (a type of AVM with a dilated Galenic system serving as the venous outflow for an adjacent adenoma) typically results in high output congestive heart failure in neonates resulting from the decreased resistance and high blood flow in the lesion, or this may present later with developmental delay, hydrocephalus, and seizures.

Angiomatosis affecting the facial skin, eyes, and leptomeninges produces the characteristic features of the Sturge-Weber syndrome, which is characterized by capillary nevus over the forehead and eye, epilepsy and intracranial calcification. There is no clear pattern of inheritance. Practically all cases are sporadic, and many are associated with occipital AVMs. Epilepsy occurs in 75% usually presenting in infancy. Hemiparesis, homonymous hemianopia occur in 30%, and behavioral disorders with mental retardation occur in 50%.

Most AVMs are evident on CT scan unless masked by the presence of an intracranial hematoma. A double dose of intravenous contrast may aid visualization, especially with small lesions. Following IV contrast, streaks of enhancement representing dilated feeding and draining vessels, irregular lesions strongly enhancing with contrast, and calcification may be apparent. Conventional MRI will clearly demonstrate the AVM, with associated signal change within or around the lesion from areas of old hemorrhage or gliosis. MRI is the investigation of choice in identifying cavernous vascular malformations (a rare, often congenital disorder of the venous system in which the hemangioma is a mass resembling a tumor, consisting of large blood-filled spaces which can occur at any site in the body). These are often missed on unenhanced CT scanning because it may be isodense with the surrounding brain. Most lesions show marked signal

change around this lesion due to a rim of hemosiderin deposition. Four-vessel angiography confirms the presence of an AVM and delineates the feeding and draining vessels. Occasionally small AVMs are difficult to detect and only early venous filling may draw attention to their presence. In the presence of a hematoma, angiography should be delayed until the hematoma resolves, otherwise local pressure and surrounding hemorrhage may mask demonstration of an AVM. If the angiogram is subsequently negative, then MRI is required to exclude the presence of a cavernous malformation.

Patients presenting with AVMs pose the clinician with difficult management choices. First, there is no consensus as to how AVMs should be classified or even defined. The natural history of an AVM is hard to predict. There are three disciplines, surgery, interventional radiology and radiation therapy, all offering their own treatments and with some disagreement as to which treatment modality is superior.

The various methods of treating AVMs all risk further damage. The urgency of the patient's clinical condition and the risks of treatment must be weighed against the risk of a conservative approach. Indications for intervention include: 1) expanding hematoma associated with the AVM, 2) progressive neurological defect, and 3) high risk of hemorrhage especially in younger patients (with many years of future risk), with the AVM less than 3 cm in diameter and in a non-eloquent site. "Eloquent" is a term used to indicate that the anatomic brain location is very important for vital neurological functions such as movement, language, and memory. Non-eloquent refers to brain areas that can be injured or removed without significant functional neurological deficit. Operative removal may not benefit epilepsy control.

Methods of treatment include operation (excision), stereotactic radiotherapy, embolization, and occlusion of feeding vessels. Complete excision of the AVM (confirmed by pre- or postoperative angiography) is the most effective method of treatment. Image guided surgery may aid localization of small AVMs or cavernous malformations. Some deeply situated lesions in the basal ganglia or brain stem are inoperable in view of the risk of neurologic deficit.

Standard radiotherapy is of no value in the treatment of AVMs, but focused beams either from multiple cobalt sources or from a linear accelerator, can obliterate up to 80% of lesions under 3 cm in diameter within two years of treatment. Results are far less encouraging for larger lesions, although combinations of embolization and stereotactic radiotherapy may provide an alternative treatment method for large inoperable AVMs in the future. Although avoiding direct operative damage, stereotactic irradiation destroys tissue locally at the target site. The larger the dose, the greater the chance of AVM obliteration, but the greater the risk of neurological deficit from local tissue destruction. A further disadvantage is the possible delay of up to two years before obliteration occurs. Despite this, stereotactic irradiation may prove ideal for some deeply situated lesions.

Skilled catheterization permits selective embolization of feeding vessels with isobutyl-cyanoacrylate, although this technique is not without risk. Embolization alone is unlikely to produce complete obliteration, but if used preoperatively, it may significantly aid operative removal. Occlusion of feeding vessels, whether by direct operation or by an endovascular balloon, fails to prevent persistent filling of the AVM because of the development of collateral vascularization.

Prognosis varies greatly with severity and presentation. Vasospasm and delayed ischemic complications rarely develop. Generally speaking, small AVMs are a greater risk of bleeding than larger lesions. The risk of initial and recurrent bleeding over a 5-year period in patients with a previously unruptured AVMs is approximately 15% (i.e. 2-3% per year); however, the risk increases to 50% over 5 years for lesions under 3 cm in size. After hemorrhage, the chance of a further bleed is slightly increased in the first year but beyond that, the risk reverts to that of an unruptured AVM. In contrast to the high mortality following aneurysm rupture, hemorrhage from an AVM carries the relatively low mortality rate of approximately 10-20%.

Questions

1. True/False: AVMs represent abnormal embryonic and fetal morphogenesis during the retiform stage of development of endothelial channels (approximately day 48 of human embryogenesis).

2. All of the following are used in the treatment of AVMs except:
   a. Excision
   b. Stereotactic radiotherapy
   c. Embolization
   d. Cryotherapy
   e. Occlusion of feeding vessels

3. True/False: The rare AVM that produces a very enlarged "vein of Galen aneurysm" can cause heart failure in infancy as a result of large volume blood flow through the shunt.

4. True/False: Occipital AVMs are frequently associated with hemangiomas of the face (Sturge-Weber syndrome).

5. True/False: The decision to treat an individual patient with an AVM requires balancing the natural history of the disease and in particular, the risk of hemorrhage against the risk of an interventional procedure.

6. True/False: Significantly decreased perfusion pressure is uncommon in areas adjacent to an AVM.

Chapter XIX.1. Fractures
Annemarie Uliasz

This is a 13 year old male who presents to the emergency department with a chief complaint of right forearm pain. While playing soccer earlier that day, he patient fell onto his right hand and heard a snapping sound. He reports that the pain in his forearm increases with movement. It is visibly swollen and deformed.

Exam: VS are normal except for a resting tachycardia secondary to pain. He is alert and cooperative, but subdued, in moderate pain. His head, neck and torso, show no signs of external trauma. Heart, lungs and abdomen are normal. Upper extremities: Swelling and deformity is observed at the right mid-forearm, corresponding to his area of greatest pain. Radial pulses and sensation are intact.

An IV is started and he is given 3 mg of IV morphine. AP and lateral radiographs of his right forearm demonstrate displaced, angulated fractures of the radius and ulna with overriding (overlapping) ends. An orthopedic surgeon is consulted. The patient is sedated and given additional analgesia. A closed reduction is performed with good alignment of the radius and ulna. Immobilization is accomplished with a fiberglass cast extending from the hand to the proximal humerus.

The skeletal system of children is anatomically, biomechanically, and physiologically different from that in adults. The presence of growth plates (or physes) in the pediatric skeleton is one major difference. The growth plate is composed of cartilage. It can be thought of as the "weakest link" in the pediatric bone. It may separate before an adjacent joint ligament tears. Injuries to the growth plate may result in deformities.

Another difference seen in children is a thicker periosteum surrounding the bones. As a consequence, fractures in children tend to be more stable and less displaced than those seen in adults. The greater bone-forming potential of the pediatric periosteum results in faster bone healing in children. Non-unions are rare in pediatric fractures.

A third difference is the increased porosity, due to larger, more abundant Haversian canals, and decreased density of pediatric bones. This feature makes children's bones more prone to buckling when compressed, or bowing when bent.

Finally, remodeling is more rapid in children than in adults. Imperfect reductions have been known to remodel into satisfactory alignment. The differences between pediatric and adult fractures result in different fracture patterns, problems of diagnosis, and management techniques.

Description of a pediatric fracture includes the anatomic location and configuration of the fracture, as well as, the relationship of the fracture fragments to each other and to the adjacent tissue. The anatomic location of the fracture can be described as diaphyseal (involving the central shaft of a long bone), metaphyseal (involving the ends of the shaft of a long bone), physeal (involving the growth plate), or epiphyseal (involving the ends of a long bone).

There are several configurations unique to pediatrics that may describe the fracture. A plastic deformation occurs when the bone is bowed beyond elastic recoil, without an actual fracture. This is called a bowing fracture (most common in the ulna) when the bone appears to be bent without any fracture line evident. A buckle fracture (or torus fracture) occurs due to axial compression of bone at the metaphyseal-diaphyseal junction. These fractures are inherently stable and heal within 2-3 weeks with immobilization. A greenstick fracture occurs when a bone is angulated beyond the limits of plastic deformity. The force of impact was insufficient to cause a complete fracture. Instead, there is a fracture on the tension side and plastic deformity with an intact cortex and periosteum on the compression side. A complete fracture describes a fracture in which both sides of the bone are fractured. Complete fractures may be subclassified according to the direction of the fracture line. A transverse fracture line is at 90 degree angle to the long axis. A spiral fracture line encircles a portion of the shaft and is oblique in orientation. Oblique fracture lines are 30-40 degrees to the long axis. A fracture site revealing multiple fragments is comminuted and is unusual in children.

The relationship of fracture fragments to each other can be classified by the extent of displacement. Angulation describes the angle of deviation between the pieces of bone at the fracture site. Translocation describes transposition of segments of bone. Impaction occurs when one fracture surface is driven into the opposing fracture surface. Overriding describes the slipping/overlapping of either part of a fractured bone past the other.

The relationship of the fracture fragments to the surrounding tissue can be classified as open or closed. In an open fracture (also called compound fracture), a break in the skin is present due to penetration of the skin by a fracture fragment from within or because a sharp object has penetrated the skin to fracture the bone. An open fracture increases the risk of infection. The skin is intact over the fracture site in a closed fracture.

The Salter and Harris system is used to classify growth plate injuries. Physeal injuries are classified into five groups:

Type I: Fracture through the physis without involvement of the metaphysis or epiphysis. A non-displaced type I fracture is not visible on X-ray, but a displaced type I fracture can be identified because the epiphysis and metaphysis will not be aligned.

Type II: A fracture through the physis and metaphysis, with a fragment of the metaphysis remaining attached to the physis.

Type III: A fracture involving the epiphysis and the physis.

Type IV: A fracture involving the epiphysis, physis, and metaphysis.

Type V: The physis is crushed (compressed) without fracture of the epiphysis or metaphysis.

Generalized prognostic information regarding risk for premature physeal closure and indications for treatment can be determined according to the Salter and Harris classification. Type I and type II fractures can be treated with cast or splint immobilization. They do not require perfect alignment and have an excellent prognosis. Type II fractures of the distal femur are an exception, however. Unless anatomic alignment is attained by closed or open techniques, these fractures have a poor prognosis. Type III and type IV require precise anatomic reduction to minimize future joint or growth abnormalities. Type V fractures are usually recognized in retrospect as a consequence of premature physeal closure. Prognosis is poor due to premature growth cessation.

With knowledge of the most common types of injury for a child's developmental level, a physician may predict the type of injury sustained. Fractures in the newborn and infant are frequently the result of child abuse. In young children, falling onto an outstretched hand is a common mechanism of fracture. As a consequence, upper extremity and clavicle fractures have a greater incidence than lower extremity fractures. Bicycle and motor vehicle accidents are often the cause of fractures in children approaching the teens.

Analgesia may be administered to reduce the child's pain and anxiety during examination of the injury. Before palpation, the skin must be examined for breaks. The neurovascular status of the limb must be assessed prior to and after splinting and reduction. Although it is not necessary to palpate the site of an obvious fracture, palpation of adjacent or distant areas may be required to determine if more than

one fracture may exist. A baseline motor examination should be completed. Assessment of the joints above and below the injury should be included.

Prior to obtaining radiographs, the limb should be temporarily immobilized to minimize soft tissue trauma and improve patient comfort. Views in the anteroposterior and lateral planes, are required. An oblique view may be necessary in areas such as the elbow or wrist. Comparison views of the opposite limb may be helpful in distinguishing growth plates from fracture lines (2).

Open fractures carry a high risk of infection. Debris should be removed immediately. Pressure applied with a sterile pressure dressing will control hemorrhage. The limb should be splinted. The wound should be irrigated with saline and covered with saline-soaked sponges. Intravenous antibiotic prophylaxis, usually a first-generation cephalosporin should be initiated. Tetanus prophylaxis should also be administered (3).

Operative treatment under general anesthesia is required for approximately 4-5% of pediatric fractures (1). Indications for surgical stabilization include displaced epiphyseal fractures, displaced intra-articular fractures, unstable fractures, fractures in the multiply injured child, and open fractures. Three basic techniques are used in the surgical management of pediatric fractures: open reduction and internal fixation (ORIF), closed reduction and internal fixation, and external fixation. Open reduction refers to intraoperative surgical reduction of the fracture ends, while closed reduction refers to manipulating the fracture externally to achieve reduction. Internal fixation refers to the insertion of metal pins, screws, plates or other hardware to stabilize or fixate the fracture once reduction is achieved, while external fixation refers to fixation of bones by splints, plastic dressings, or transfixion pins. Casts are sometimes considered external fixation but they are usually referred to as external support.

Open reduction and internal fixation may be required for displaced epiphyseal fractures (especially Salter-Harris types III and IV fractures, intra-articular fractures, and unstable fractures). Other indications include neurovascular injuries requiring repair, failure to obtain anatomic alignment, and occasionally, open fractures of the femur and tibia.

Closed reduction and internal fixation is indicated for specific displaced epiphyseal, intra-articular, and unstable metaphyseal and diaphyseal fractures. Common indications include supracondylar fractures of the distal humerus, phalangeal, and femoral neck fractures. Multiple closed reductions of epiphyseal fractures may cause repetitive damage to the physeal germinal cells, and are therefore contraindicated.

The clavicle is the most frequently fractured bone in children (4). The most common site of fracture is between the middle and outer thirds. Clavicle fractures can be the result of birth injuries in newborns but are more typically the result of a fall on an outstretched arm in older children. The diagnosis is easily made by physical and radiographic evaluation. The patient will have pain with shoulder and neck movement. Crepitus and local swelling may be present. Neurovascular injury is rare. An AP radiograph of the clavicle is usually sufficient for diagnosis. Clavicle fractures in the newborn require no further treatment. A palpable callus can be detected several weeks later. In older children, a sling or shoulder immobilizer (a sling with another strap holding the horizontal forearm portion against the torso) is used to elevate the upper extremity to reduce downward pull on the distal clavicle. Figure-of-eight clavicle straps which extend the shoulders to minimize the overlap of fracture fragments, may also be used, but most patients find this uncomfortable and there is no clinical advantage over a sling or shoulder immobilizer. A palpable callus can be detected several weeks later which remodels in 6-12 months. Clavicle fractures usually heal rapidly in 3-6 weeks.

Proximal humerus fractures are usually the result of a fall backwards onto an extended arm. Neurovascular injury is rare. However, axillary nerve damage should be suspected if the patient experiences abnormal deltoid function and paresthesia or anesthesia over the lateral aspect shoulder. Treatment includes immobilization by a sling-and-swathe (a broad elastic bandage holding the humerus against the body) for 3-4 weeks. Because of the significant remodeling potential of this area, a certain amount of deformity is acceptable. Fractures with extreme angulation (greater than 90 degrees) may require surgical reduction.

Supracondylar fractures (distal humeral metaphyseal region proximal to the elbow) are the most common elbow fracture in children (4). They occur most frequently between the ages of 3 to 10 years old. This fracture is often the result of a fall onto an extended arm. The patient will hold the arm in pronation and resist flexion because of pain. Neurovascular injury is common in severe displacement. Because flow through the brachial artery can be affected, this injury should be treated as an acute emergency. Swelling, if severe, can block venous and arterial structures. A careful neurovascular examination is necessary. Compartment syndrome of the volar forearm can develop within 12-24 hours. Volkmann's contracture due to intracompartmental ischemia may follow (5). Pins are often used to fix the fracture after closed or open reduction. The more common less severe supracondylar fractures without neurovascular compromise can be splinted with the elbow in a position of comfort flexed at 90 degrees, and the forearm splinted in pronation or neutral position.

Lateral humeral condyle fractures are the result of falls in which the radial head drives into the capitellum of the humerus. An oblique shearing fracture of the lateral joint surface occurs. There is usually severe swelling even though the fracture appears small on X-ray. There is a high risk of malunion and nonunion in these fractures. Because both the growth plate and the joint surface are displaced, open reduction and fixation with percutaneous pins may be required. A cast without pinning may be satisfactory for non-displaced fractures.

Radial head (proximal radius) fracture is often associated with other elbow injuries. Radial head fractures are common and can often be diagnosed clinically since they may be difficult to see on X-rays. Patients with radial head fractures have most pain with supination/pronation while having mild pain with flexion/extension of the elbow. The radial neck may angulate as much as 70-80 degrees. Angulation of 45 degrees or less usually remodels spontaneously. Closed manipulation is required in larger degrees of angulation.

Forearm fractures are a common result of falls. If both bones are involved, one bone may be completely displaced with the other bone only suffering a greenstick fracture. Closed reduction and casting are used in the treatment of stable fractures. Closed intramedullary pinning and open reduction and internal fixation are operative options for unstable fractures.

Torus (or buckle) fractures of distal radial metaphysis are common. They are usually the result of a minor fall onto the hand with wrist in dorsiflexion. The fracture is impacted and there is minimal soft tissue swelling or hemorrhage. There is usually a minor distal ulna fracture associated with these distal radius fractures. Treatment is by a short-arm cast. Fractures typically heal in 3-4 weeks.

A Salter-Harris type I fracture frequently occurs through the distal radial physis. Unless the epiphysis is displaced, it will not be visible on X-ray. Thus, it must be diagnosed clinically. Any patient with a suspected distal radius fracture, presenting with tenderness over the distal radial physis should be presumed to have a non-displaced Salter-Harris type I fracture. They should be placed in a splint and followed clinically 2-3 days later. These injuries are commonly mistaken for wrist sprains. If at follow-up, the distal radius is non-tender, then a fracture is unlikely. However, if tenderness over the physis persists, then a fracture is likely and immobilization should be continued and referral to an orthopedic surgeon is appropriate.

The Monteggia injury is a fracture of the mid or proximal ulna associated with a dislocated radial head. The radial head should be pointing at the capitellum in all views. Such ulna fractures are often large, obvious and distracting making it easy to miss the dislocated radial head. Whenever a mid or proximal ulna fracture is noted (including olecranon fractures), critically inspect the alignment of the radial head with the capitellum. It is likely that a Monteggia injury occurs with many mid and proximal ulna fractures. Closed reduction of the radial head dislocation is necessary in addition to reduction and casting of the ulna fracture. Chronic elbow motion may be lost if the radial head dislocation is not properly reduced.

Phalangeal fractures in children are usually the result of crush injuries, such as slamming a finger in the door or a hyperextension injury from a basketball. If the distal phalanx is involved there may be a painful subungual hematoma which can be drained for pain relief. Occasionally, the growth plate is involved (Salter-Harris type II). Treatment is usually by splint immobilization. Closed reduction is rarely necessary; however, if there is angulation or malrotation, it may be required.

Carpal bone fractures are uncommon in children. As in adults, scaphoid fractures may be occult and difficult to identify on X-rays. Tenderness over the scaphoid (the floor of the anatomic snuff box) should indicate the possible presence of a scaphoid fracture even if X-rays fail to demonstrate a fracture. A thumb spica splint should be applied so that the thumb and wrist are immobilized. The blood supply to the scaphoid is injury prone, which puts the patient at risk for avascular necrosis and chronic pain. Scaphoid tenderness should be splinted aggressively. If the scaphoid is non-tender in a few days, then a fracture is not likely; however, persistent tenderness suggests the possibility of a fracture and referral to an orthopedic surgeon is appropriate.

Pelvic fractures are the result of major blunt trauma. Treatment is usually symptomatic due to the thick periosteum which confers stability. The patient should be assessed for intra-abdominal injuries.

Hip fractures are usually due to motor vehicle crashes, bicycle crashes, or falls from heights (4). Patients present with pain on gentle hip movement. There is a greater risk in children for avascular necrosis and growth cessation or deformity due to the vascularity and presence of a physis. Femoral neck fractures are unstable. They are treated with open or closed reduction and internal fixation to stabilize the fracture.

Femoral shaft fractures are the result of high-energy trauma. In younger children, the possibility of abuse must be considered. In children under 3 years old, approximately 70% of femur fractures are non-accidental (i.e., inflicted) (4). Although most femur fractures are closed, bleeding into soft tissues of the thigh may result in significant blood loss. Femoral shaft fractures may shorten and angulate due to longitudinal muscle pull and spasm. Length restoration and alignment are attained by longitudinal traction. Overgrowth of approximately 1.0 to 2.5 cm is commonly seen in femur fractures in children between 2-10 years old. Casts are used in this age group to allow for some shortening. Perfect reduction is unnecessary because remodeling is so rapid. A solid union is usually attained within 6 weeks.

Non-displaced oblique tibial fractures can occur in children less than 3-4 years old (toddler fracture) as the result of a rotational injury sustained while running or playing. Clinical features include pain, unwillingness to bear weight, and refusal to walk. Physical exam may be difficult to locate the site of the injury except for a refusal to bear weight on the affected lower extremity. The fracture may be radiographically subtle. Careful inspection of AP, lateral and sometimes oblique radiographs may identify the fracture. Evidence of new bone formation may be seen radiographically within 1-2 weeks, and requires an additional 2 weeks of immobilization. Large distal tibia fractures (as opposed to small subtle ones as in the toddler's fracture) in young children are more likely to be associated with intentional injuries as in child abuse.

Ankle fractures may involve the medial or lateral malleolus. Medial malleolus fractures are uncommon. In children, a Salter-Harris type I fracture of the distal fibular physis cannot be confirmed radiographically so it must be suspected clinically based on tenderness over the physis. These fractures are difficult to distinguish from ankle sprains. If a fracture is suspected, they should be placed in a splint. Ankle sprains are far more common than fractures in older children and adolescents. The Ottawa ankle rules have been validated as a decision tool for ordering ankle X-rays in adults. These rules probably work for children as well, but validation data for children have yet to be presented. The rules indicate that radiographs should be ordered if there is swelling or tenderness of either of the malleoli, or inability to bear weight after the injury.

Foot fractures can occur in the tarsal bones, metatarsals and/or the phalanges. Fractures of the metatarsal shaft are usually the result of direct trauma to the foot resulting from a fall, bicycle, or sledding injury. Injury is followed by soft tissue swelling and, sometimes, ecchymosis. Palpation reveals tenderness directly over the fracture. Fifth metatarsal tuberosity fractures (dancer's fracture) are also common and consist of an apophyseal avulsion fracture at the peroneus brevis tendon insertion. Swelling, ecchymosis, and localized tenderness to the fifth metatarsal tuberosity suggests a fracture. Contraction of the peroneal musculature increases the tenderness.

Toe phalangeal fractures are common and are usually the result of direct blows. They usually occur when the child is barefoot. The toes are swollen, ecchymotic, and tender. Mild deformity may be present. Closed reduction is not indicated unless the toe is significantly displaced. Casting is not usually necessary. Adequate alignment can be achieved by "buddy" taping the fractured toe to an adjacent stable toe.

Questions

1. Why do pediatric fractures heal faster than adult fractures?
2. How is a fracture described?
3. How is external fixation different from internal fixation?
4. What is the most frequently fractured bone in pediatric patients?
5. What kind of fracture is sustained in a toddlers fracture?
6. How can a toddler's fracture be distinguished from child abuse?
7. What other injury is commonly associated with a mid or proximal ulna fracture?
8. Name at least three fractures that are difficult to identify on X-rays and must often be diagnosed clinically?

Answers to questions

1. Fractures in children heal more rapidly than those in adults because the pediatric bone has a thicker periosteum and more efficient remodeling.

2. A fracture is described by its anatomic location, configuration, relationship of the fracture fragments to each other, and relationship of the fracture fragments to the surrounding tissue. Physeal fractures can be described according to the Salter-Harris system.

3. External fixation refers to fixation of bones by splints, casts or transfixion pins. A cast is sometimes considered merely external support, rather than external fixation. Internal (or intraosseous) fixation is stabilization of the bone fragments by direct fixation to one another with surgical wires, screws, pins, rods, or plates.

4. The clavicle is the most frequently fractured bone in the pediatric population.

5. A toddler's fracture is a subtle non-displaced spiral fracture resulting from a rotational injury while running or playing.

6. A toddler's fracture is subtle and non-displaced, while a large distal tibia fracture is more likely to be associated with severe trauma (not just falling while walking) or child abuse.

7. Radial head dislocation (the Monteggia injury).

8. a) Non-displaced Salter-Harris type I fracture of the distal radius, b) scaphoid fracture, c) radial head fracture, d) Non-displaced Salter-Harris type I fracture of the distal fibula (lateral malleolus).

Chapter XIX.2. Splinting
Erick M. Itoman

This is a 7 year old female who presents to the clinic with a chief complaint of left wrist pain. She was rollerblading with several friends, and was accidentally pushed from behind. She fell forward with outstretched, pronated arms. She denies hitting her head, loss of consciousness, vomiting, and abdominal pain.

Exam: VS T37.0, P105, R20, BP 117/75. She is comfortable, alert and appears to be in no distress. Mild abrasions are noted on her left knee and palmar surfaces of both hands. No obvious puncture wounds are present. She has mild discomfort upon palpation of her left knee, but she is able walk, stand, and jump without difficulty or discomfort. Her right wrist is normal, but tenderness is elicited upon palpation of her left distal radius. Slight wrist swelling is noted, but no angular deformity is present. The remainder of her exam is unremarkable.

Radiographs reveal a non-displaced distal radius fracture of the left wrist without angulation. She is placed in a forearm sugar tong splint, and her mother is given instructions to follow-up with an orthopedic surgeon.

Splints are used to temporarily immobilize fractures, subluxations, sprains or soft tissue injuries. Other indications for splinting include acute arthritis, severe contusions and abrasions, skin lacerations or burns across joints, tendon lacerations, tenosynovitis, animal bites, deep space infections, joint infections, and puncture wounds (1). The goal of splinting is immobilization to minimize pain and prevent further damage to nerves, vessels, muscle, skin, etc. (2). Immobilizing tender joints, as seen in tenosynovitis, hemarthrosis, or acute arthritis, reduces pain and inflammation. Abrasions and lacerations that cross joints can be stretched open if the extremity is not immobilized. Regardless of the initial event, tissue damage results in inflammation. Immobilization of the injured limb minimizes irritation and reduces edema (1). Immobilization of fractures reduces the risk of further displacement, minimizes hemorrhage, soft tissue damage, and risk of neurovascular injury.

All injuries that present with immobility, pain with movement, swelling, reproducible pain on palpation, anatomic deformity, discoloration, or crepitus should be evaluated with appropriate radiographic studies (3). Severe musculoskeletal injuries need immediate orthopedic consultation. These injuries include open fractures, fractures with neurovascular compromise, fractures that are too deformed, angulated, or displaced to adequately splint, and any dislocation that cannot be reduced in the ED. Pediatric patients with sprains warrant special attention. A Salter-Harris type 1 injury may not exhibit any radiographic evidence of a fracture, and may present like a sprain. All children who present with tenderness over the physis (growth plate) of a long bone should be presumed to have a Salter-Harris type 1 fracture injury and immobilized in an appropriate splint (3). The presence of a non-displaced Salter-Harris type 1 fracture is identified clinically during the follow up examination. Persistent tenderness several days after the injury implies the presence of a fracture (to be confirmed by additional radiographs which may show new born formation 7 to 10 days after the injury). Rapid resolution of tenderness implies the absence of a fracture.

The two categories of splints are classified based on their raw materials, plaster and fiberglass. Cardboard, aluminum and other semi-rigid or malleable materials can also be used for temporary splints. Plaster splints are made from gauze material impregnated with plaster of Paris, which is made from gypsum. Gypsum, when heated, loses water and is reduced to a powder. When water is added, the gypsum-powder hardens as the calcium sulfate dihydrate molecules recrystallize (1). The reaction is exothermic and can possibly burn the patient, but most of the time, it just feels warm. Depending on the temperature of the water (hot water allows for a quicker set time) the plaster may take anywhere from 2-8 minutes to set. Although hard, the plaster takes about a day to reach its maximum strength. Plaster has the distinct advantage of molding to the individual's anatomy, but it can be messy and difficult to work with (1). An upper extremity injury may require anywhere from 8-10 layers of plaster while the lower extremity may take 10-20 layers (4). Despite the large amount of material used, plaster is still relatively inexpensive (1). Once the plaster is set, water must be avoided. Excessive water will cause the crystallization to become unstable, making the splint soggy. The newer fiberglass splint materials comes prepackaged with padding. The prepackaging reduces the steps needed to prepare the limb prior to splinting, but increases the cost. The padding also absorbs water and sweat well, minimizing the accumulation of moisture (1). Fiberglass has several other advantages over plaster. It is lighter, stronger, has a quicker set time, and is not as messy as plaster. The fiberglass hardens in minutes and cures in approximately 10-20 minutes (1,4). Fiberglass, because of its prepackaged nature, does not mold to the individual's anatomy as well, so kinking may occur where the splint is bent to fit the limb (4). Kinks, although small, may be a potential sight of irritation causing skin breakdown and pressure injury.

The procedure for splinting should always start with a general inspection of the limb. Abrasions, cuts, and lesions need to be cleaned and dressed. Next, the limb should be rechecked for signs of compartment syndrome and neurovascular compromise. The splint width should be approximately half as wide as the circumference of the extremity. The following steps in the procedure will vary based on the type of split used.

For plaster splints, the plaster strips should be measured and cut to length. Since the splint is used to support the limb, the posterior surface is usually used as a measuring guide. Strips should be cut to a length slightly longer than needed. This will allow the splint to be folded upon itself to provided a smooth edge. A longer length will also allow for contraction of the plaster as it crystallizes (4). Optionally, stockinette (tube sock) can be rolled over the limb and cut to a length slightly longer than needed. The stockinette should look as if a long sock with an open hole has been placed over the extremity. Take time to smooth out the stockinette to prevent pressure spots and kinks at flexion creases. Also, make sure the stockinette is positioned so that there is extra material both proximal and distal to the area to being splinted. Cast padding (e.g., Webril cotton padding rolls) should be rolled over the extremity in a distal to proximal direction. If stockinette has been used, then the cast padding is rolled over the stockinette. Each successive roll of cast padding around the extremity should cover the previous roll by approximately 50-60% (4). This will ensure a double layer of padding over the area to be splinted. Make sure that the "extra" stockinette distal and proximal to the area being splinted is not covered with cast padding. Extra padding should be placed over the bony prominences and the fracture site. This will minimize pressure and discomfort. The plaster should now be immersed in water. The warmer the water, the quicker the plaster will set. With children, the water should be on the cooler side. The plaster will heat up as it hardens, and this may scare and burn a child but this is unlikely. Place the wet plaster on an open towel. Remove excess water, smooth the plaster, then apply the strip to the extremity. Adjust and position the plaster accordingly while smoothing to the contour to the patient's anatomy. While the plaster still soft, fold the proximal and distal ends of the plaster back over itself to provide a smooth edge. If a stockinette is used, fold it over itself, the cast padding, and the plaster. A smooth padded edge should be present at both ends of the splint. An optional cast padding layer can be applied over the splint to prevent the soggy plaster from

incorporating into the elastic wrap applied in the next step. Roll an elastic bandage over the outside of the extremity, usually in a distal to proximal fashion, securing the plaster to the extremity. Keep the limb in the desired position until the plaster thoroughly hardens.

Water soluble fiberglass splints involve fewer steps. Fiberglass splint materials come encased in cast padding material rather than as bare sheets of fiberglass. Once the limb has been inspected, and the proper splint width and length are selected, cut the length needed and place the fiberglass splint in water. The warmer the water, the quicker the fiberglass will harden. Remove the fiberglass splint from the water, and place it on a dry towel. Removed the excess water from the fiberglass splint by rolling it in a dry towel and applying pressure to remove water from the fiberglass. This can be repeated until the outside of the fiberglass splint material feels dry. Because the fiberglass is prepackaged, it has enough padding to be directly applied, but stockinette and additional cast padding can be optionally applied over the whole extremity, or just over the bony prominences (4). Once the fiberglass is placed over the extremity it should be molded to the desired shape. The padding material should be stretched over the end of the fiberglass to prevent the sharp fiberglass ends from poking the patient. An elastic bandage should then be applied to secure the fiberglass splint in place (4).

The final step in any splitting procedure should be to check the extremity for signs of neurovascular compromise. Capillary refill should be brisk, and sensation to light touch and pin prick should be intact. The patient should also be able to move the distal anatomy with minimal discomfort.

The patient and or parents need to be advised of the complications of splinting. In fracture cases, where swelling is prominent, the limb may expand in girth. Because the splint is not a rigid cylinder, the elastic wrap permits some expansion due to extremity swelling preventing harmful circumferential pressure by the splint. Nevertheless, neurovascular injury may occur and produce signs such as tingling, numbness, increasing pain, and/or paresis which may indicate the development of a compartment syndrome. If any of these signs or symptoms develop, the patient should be counseled to return to the emergency department immediately. Preventative measures should be taken such as limb elevation and periodic monitoring of the distal anatomy (1). Finally, the patient should be instructed to keep the splint clean and dry. Moisture will soften the skin and the splint, promoting itching, infection, pressure sores, and cast breakdown. Any discomfort on the skin could suggest pressure sores. The patient should be given instructions for follow-up with a contact number in case of complications.

Some common extremity splints include the following examples. Cast padding is applied to the extremity (stockinette optional), the splint material is applied as noted below, and an elastic bandage is rolled on over the extremity such that the splint material properly molds to the shape of the extremity without pressure spots.

Long Arm Posterior Splint (3). Indicated for elbow and forearm injuries, and/or immobilization. The elbow should be flexed at approximately 90 degrees to a position of comfort, and the forearm should be medially rotated 90 degrees (such that the volar side of the forearm is toward the body) with slight dorsiflexion at the wrist. If splinting a supracondylar fracture, position the forearm in a slightly pronated position. The splint should extend from the metacarpophalangeal joint to the upper arm, just distal to the axilla. The splint will be applied on the ulnar surface of the wrist and forearm and extend to the posterior surface of the upper arm.

Posterior Ankle Splint (3). Indicated for ankle sprains and non-displaced fractures of the ankle, foot, and distal fibula. The ankle should be in the proper anatomic position, flexed at approximately 90 degrees. The splint will extend distally from the foot (plantar side of the metatarsal phalangeal joints) to the proximal lower leg (level of the fibular head near the knee), and provides support to the posterior leg and foot. The splint should not impinge on the popliteal fossa when the leg is flexed. The patient should be given crutches (if the child is old enough to use crutches), otherwise encourage light weight bearing or non-weight bearing on the splint.

Ankle Stirrup Splint (also called ankle sugar tong splint) (3). Indicated for injures to the ankle, and ankle immobilization. Unlike the posterior ankle splint, the ankle stirrup splint provides lateral and medial support. The ankle stirrup splint provides superior immobilization for a fracture near the ankle compared to the posterior ankle splint. The splint is folded into a U-shape stirrup. The splint will wrap from the lateral surface of the calf (just distal to the knee), around the plantar aponeurosis and heel, to the medial surface of the calf just distal to the knee. Ideally, wide splint material should be used so that the bottom of the "U" will support the heel to the metatarsal phalangeal joints on the plantar side of the foot. The ankle should be flexed at 90 degrees (the same as for the posterior ankle splint).

Volar Forearm/Wrist Splint (1). Indicated for minor fractures near the wrist, soft tissue injuries to the hand and wrist, and fractures of the carpals and metacarpals. Extend the splint from the metacarpal heads of the palm to the volar surface of the forearm proximal to the elbow. The forearm is placed in the neutral position and the wrist should be slightly dorsiflexed. The palmar end of the splint should be rolled so that the hand can rest in a flexed position over the roll.

Ulnar Gutter Splint. Indicated for fractures of the 4th and 5th metacarpals. The splint material is folded on its long axis such that the ulnar side of the forearm fits into the long gutter formed by the splint. This should extend from the distal 5th finger or metacarpal to the proximal forearm (just distal to the elbow).

Forearm Sugar Tong Splint (3). Indicated for distal radius, wrist, and forearm fractures. Prevents supination and pronation of the wrist, flexion/extension of the forearm, and blunt trauma to the fracture site. This type of splint provides superior immobilization compared to the volar forearm and ulnar gutter splints. Extend the splint from the palmar aspect of the MCP joints, around the elbow, and to the dorsal aspect of the MCP joints. The thumb should be unopposed, and the remaining digits should be allowed 90 degrees of flexion. Flex the elbow approximately 90 degrees to allow a position of comfort. The volar surface of the forearm should be facing the body. The palmar end of the splint should also be folded over (i.e., rolled) to allow the fingers to rest in a flexed position over the roll.

Thumb Spica Splint (3). Indications include a nonrotated, nonangulated, nonarticular fracture of the thumb metacarpal or proximal phalanx. This type of splint can also be utilized for ulnar collateral ligament injuries, and scaphoid tenderness (fracture or suspected fracture). A thumb spica splint is often placed together with a volar wrist splint for suspected scaphoid fractures. The radial aspect of the forearm is placed in the splint so that the splint can form a long U-shape down the length of the splint (similar to the ulnar gutter, but on the radial side). The U-shaped splint will extend from the thumbnail to the mid-forearm. The thumb will be encircled by the distal part of the splint (with the tip of the thumb exposed) to completely immobilize the thumb, and as the splint extends proximally it will open wider to receive the radial surface of the forearm and wrist. The thumb should be slightly abducted and the wrist should be slightly dorsiflexed.

Questions

1. What are the common indications for splinting?
2. What is the purpose of splinting?
3. What are the complications involved with splinting, and how should these complications be evaluated by the patient?
4. Should sprains be splinted in a pediatric patient?
5. Briefly compare and contrast plaster and fiberglass splints.

6. What conditions warrant an orthopedic consult prior to splinting?
7. When choosing a splint strip size, what is the general rule of thumb?
8. What temperature of water should an inexperienced person use when splinting?
9. What is the first step in splinting?
10. What are some reasons for preferring splinting over casting?

Answers to questions

1. Splints are generally used to temporarily immobilize fractures, subluxations, or soft tissue injuries such as ankle sprains.

2. Splints immobilize the extremity, reducing damage to the nerves, vasculature, muscle, and skin. This will minimize edema and pain. Splints also stabilize fractures and prevent further displacement of subluxations.

3. If the splint is too tight it will compress the swollen extremity causing decreased sensation, paresthesia, and pain. The patient should be educated to check for brisk capillary refill, mobility of distal anatomy, numbness, tingling, burning, and increased pain. The immobility of the joint may cause contractures. Mobility of the distal anatomy should be evaluated. Stiffness of the immobilized joint should be expected. Wrinkles in the splinting material may cause pressure sores and skin breakdown, especially over bony prominences. Skin breakdown often starts with burning or itching, and may progress to ulceration.

4. Conservative treatment involves splinting of the extremity. The general rule is, when in doubt, splint. Splinting is indicated with sprains overlaying an open physis, because of the similar presentation to a Salter-Harris type 1 fracture. However, many sprain injuries (ankle sprain is the best studied example), will improve faster with gentle activity compared to total rest or immobilization.

5. Plaster is inexpensive and it allows for anatomic molding. However, it is relatively heavy and it can take longer to set and cure. Fiberglass is a more expensive, prepackaged, strong and light splint that cures quickly, but does not allow exact anatomic molding. For example, for an ankle fracture, plaster splinting results in a heavy splint, compared to a fiberglass splint which is stronger and lighter.

6. Complicated fractures include open fractures, fractures with any neurovascular compromise, fractures that are too deformed/angulated/displaced to adequately splint, and any dislocation which cannot be reduced in the ED.

7. The strip should be approximately 50% of the circumference of the extremity.

8. Cold water slows the curing process in both plaster and fiberglass, but ROOM TEMPERATURE water rather than cold water should be used. Warm water is best avoided since it will add further heat to the exothermic reaction.

9. Inspection. Wounds must be cleaned and dressed. Neurovascular compromise should be ruled out, and documented.

10. Casting forms a rigid cylinder over the extremity. In the first 24 hours following a fracture, swelling within the cylinder may result in vascular compromise (i.e., compartment syndrome). Splinting initially, then casting later is associated with fewer complications compared to early casting. Additionally, if the extremity is already swollen and a cast is applied, the fit of the cast will be loose once the swelling resolves. Casts are generally applied by orthopedic surgeons who are not always available for minor fractures. Splints provide an immediate means of immobilizing the extremity and do not require the immediate presence of an orthopedic surgeon.

Chapter XIX.3. Scoliosis
Robert C. Durkin, MD

A 12 year old girl is referred to the office with a chief complaint of "back looks funny". Her mother noticed the deformity incidentally when her daughter tried on swimsuits at the mall approximately 1 month prior to the visit. The patient did not notice any deformity herself. Previous examinations on annual visits for school did not mention a spinal deformity. Her mother also reports that her child has been growing rapidly for six months, but she has not begun her menses.

PMH is unremarkable.

ROS: She denies back pain, headaches, difficulty urinating or making bowel movements, numbness or tingling in the extremities or weakness. No abnormal skin rashes or birthmarks are appreciated. She denies shortness of breath, palpitations, fatigue or malaise. Frequent bleeding or bruisability is denied. No endocrine abnormalities are reported.

FH: Family history is significant for adolescent-onset scoliosis in a maternal aunt. No treatment was recommended. Pertinent review with the mother regarding family history is negative for short stature syndrome, neurofibromatosis, bone dysplasia, neoplasia, hereditary neuromuscular disease or other syndromes.

Exam: VS are normal. Standing height 152 cm (60 inches), weight 41 kg (90 lbs). Her mother's standing height is 165 cm (65 inches). She is an active and vibrant young girl. Her standing station (erect, feet together) demonstrates a level pelvis and level shoulders. Her gait shows smooth reciprocal heel-toe foot placement. Her forward bending test demonstrates right thoracic rib prominence with rotation of ribs 8 degrees at mid thorax by scoliometer. Her extremities show normal symmetric range of motion of all joints. No leg length discrepancy is present. Pulses are full and equal. Her neurologic exam is intact.

Imaging: Standing posteroanterior radiographs of the thoracolumbar spine are obtained. These images demonstrate an S-shaped curvature across the thoracic and lumbar spine. The larger curve magnitude measures 25 degrees by Cobb angle. Risser stage is 0.

Clinical course: You reassure the family that the condition is not life threatening but recommend follow up in 6 months. Repeat radiographs and examination are planned. The family moves out of state for one year after your initial examination. The patient returns to your office for check up 15 months after your initial visit. She has no back pain or complaint except rib prominence on forward bending. Examination shows her height is 163 cm (64 inches). Rotation on forward bending approaches 12 degrees at the mid-thorax. Neurological examination is normal. Her shoulders and pelvis are level. She began her menses 6 months ago. Radiographs show an increase in her curve magnitude to 32 degrees by Cobb angle. She is now Risser stage 2. Due to her progression by radiographic criteria and relative skeletal immaturity, you recommend a brace to control the curve. The child is compliant with the brace and wears it 23 hours a day for 12 months. No progression of the curvature is noted with brace treatment. At skeletal maturity, she has a well-balanced spinal deformity. Maximal curve magnitude is 28 degrees. She is active in sports and reports no pain.

Idiopathic scoliosis is the most common type of scoliosis. Scoliosis is characterized by lateral curvature of the spine on two-dimensional radiographs. In truth, the deformity is three-dimensional and rotation is a critical component. By definition, the etiology is unknown and the diagnosis can only be made after all other causes of spinal deformity have been excluded. The true prevalence in society is unknown and estimates are dependent on the method of measurement. By radiographic criteria (Cobb angle greater than 10 degrees), the prevalence is approximately 2-3%. For curves greater than 20 degrees, the prevalence drops ten-fold to approximately 0.3%. Females are predominately affected. Boys tend to have smaller curves and are less likely to progress. The female to male ratio is 1.4 to 1 for curves 11 degrees to 20 degrees. The ratio increases to 5:1 for curves greater than 20 degrees.

Idiopathic scoliosis is often divided by age of onset. Infantile curves are noted from birth to 3 years. Juvenile curves are recognized between 4 and 10 years. Adolescent curves are diagnosed after 10 years of age.

The family history is positive for scoliosis in approximately 30% of cases suggesting that inheritance has some role. Recognition of scoliosis in a family member is not helpful for determining curve magnitude or risk of progression. Inheritance patterns (sex-linked, autosomal dominant or recessive) are debated. Hormonal interactions and growth alterations have been implicated but are also controversial (1). Rapid growth is associated with curve progression, but this does not explain how the deformity initiates. Biomechanical forces must play a role as larger curves and the unbalanced spine tend to progress more than small well-balanced curves. Disorders of the connective tissue and matrix proteins are also suspect. The most viable hypothesis relates to abnormalities of the vestibular and equilibrium systems in the central nervous system. Disorders of equilibrium are probably the most widely supported as the cause of idiopathic scoliosis (2,3).

The diagnosis begins with a complete history. Back pain should be well characterized with respect to severity and duration as the presence of pain may suggest an irritant focus such as infection or tumor (4). Radicular signs, numbness, changes in bowel or bladder habits, tingling in the extremities or perineum imply a neurologic origin. Any history of trauma should be investigated thoroughly. Information regarding skeletal maturity may be helpful to determine the risk of progression and, therefore, one should inquire about menstrual history and sexual development (Tanner staging).

The physical examination begins with inspection from the back. The patient is standing with her/his feet together. Palpation of the tops of the iliac crest will assess pelvic tilt and leg length discrepancy. Screen the spine for midline dimples or cutaneous changes as these findings suggest a defect in the underlying spine. The "Forward Bending Test" is routinely used to screen for spinal deformity. The child is asked to bend forward at the waist with her hands clasped together. The head and arms are allowed to hang dependent in a relaxed manner. Inspection from the rear allows the examiner to sight tangentially down the spine. Attention should be paid for asymmetry of the rib or trunk height. Rotation of the spine is reflected in prominence of the ribs on the convexity of the curve. A Scoliometer (trademark) is an inclinometer used to measure trunk rotation in degrees. Each level of deformity should be measured (thoracic, thoracolumbar, and lumbar).

Objective measurement of spinal deformity begins with a standing posteroanterior (PA) radiograph of the entire thoracolumbar spine. The image is taken on a long cassette (36 in) to include the thoracic and the lumbar spine on one view. PA imaging is used to limit the radiation exposure to the breast and thyroid in an adolescent female. The Cobb angle can be determined by measuring the horizontal (transverse plane) endplate of the most tilted vertebrae at each end of the curve. The angle formed by the perpendicular to these two endplates is measured. True scoliosis is defined as a structural curvature of the spine with a Cobb angle greater than 10 degrees. Curves below 10 degrees should be labeled "minimal spinal curvature" as they represent positional curves and will likely regress spontaneously. For true scoliosis, radiographs are repeated every six months until skeletal maturity. Thereafter, annual rechecks are recommended until stability is confirmed.

Monitoring ossification of the iliac apophysis on radiographs can assess skeletal maturity. Normal ossification begins laterally and progresses medially as the child matures. By dividing the crest into quadrants, five stages of maturation can be assigned according to the system of Risser. Complete ossification requires approximately one year. Risser stages 0 - 2 imply relative immaturity. Risser stages 3 - 5 suggest that spinal growth is nearly complete.

Idiopathic scoliosis is diagnosis of exclusion. Scoliosis can result from congenital, irritative, neuromuscular, degenerative, and traumatic causes.

Congenital scoliosis is the product of the failure of formation or segmentation of spinal elements in prenatal life. Irritative curves are due to infections or neoplasms. Neuromuscular curves develop due to muscle imbalance in children with encephalopathy, spina bifida, or myopathies. Degenerative curves are seen in adulthood and result from biomechanical failure of the arthritic spine. Trauma can result in scoliosis if the injury weakens the integrity of the spine by fracture or dislocation.

Accurate knowledge of the natural history of a disease is mandatory for determining appropriate management of patients. The natural history of spinal curvature in the skeletally immature is different from expectations for curves presenting after spinal growth ceases. The probability of curve progression is the primary consideration when planning treatment (5,6).

Progression of spinal deformity is known to be associated with growth (7). Therefore, determination of skeletal maturity is often helpful in predicting risk of progression. The onset of puberty is associated with a rapid increase in spinal growth velocity. Menarche occurs after the peak velocity has been reached (8). For girls, the end of spinal growth corresponds to Risser stage 4. For boys, spinal growth can occur after Risser stage 4 and is less well defined. The risk of curve progression is higher for a child in Risser stage 0 - 2 compared to a child in Risser stage 3 - 5.

Larger curves at presentation are at higher risk of progression. The probability of progression greater than 10 degrees by Cobb angle is 67% for curves 40 -50 degrees. The corresponding probability for curves 20 -30 degrees is 30% (7). Thus, for young patients with scoliosis, the major factors determining risk of progression are skeletal maturity, curve magnitude, and curve type. Optimal interval of follow-up is determined by the ability to detect a real difference in the curve magnitude by Cobb angles. A widely accepted estimate of error in measurements of Cobb angles is approximately 5 degrees (9). During the peak velocity of spinal growth, the curvature may progress by 1 to 2 degrees per month. Therefore, rechecks should be scheduled every six months to allow sufficient time for a true change in the curvature to be detectable (greater than 5 degree error). More frequent follow up should be scheduled if rapid curve progression is noted.

Most patients with an established diagnosis of idiopathic scoliosis do not require treatment. For minor curves (less than 25 degrees) or the mature patient, examination and radiographs are repeated twice a year to monitor the curve. If the risk of progression is high due to curve magnitude and skeletal maturity, a brace is often recommended. The goal of bracing is to prevent progression. In fact, the brace does not attempt to correct or to improve the magnitude of the curvature with any lasting effect. Correction in the brace should be greater than 50% to achieve its goal. Bracing is used in a carefully selected patient to achieve a curvature under 30 degrees at skeletal maturity. The effect of the brace is dose-dependent. Therefore, the current recommendation is for the brace to be worn 23 hours a day for optimal results. Compliance can be a problem even with appropriate counseling (10-12). Physical therapy regimens and electrical stimulation have not been shown to affect the natural history of adolescent idiopathic scoliosis (12).

Surgical indications are based on many factors including the curve type, skeletal maturity, and curve magnitude. Documented progression on radiographs or parameters that suggest a high risk of progression must also be noted. In general terms, the immature patient who presents with a curve beyond the limits of effective bracing (greater than 40 - 50 degrees) or who has demonstrated significant progression despite effective bracing is a candidate for fusion. Standard techniques have evolved considerably over the last fifteen years. Instrumentation uses a combination of rods, hooks, and screws to correct the spine over individual segments. The ability to straighten the spine and maintain that correction until effective fusion occurs is tremendous. Depending on the specific characteristics of the patient, different approaches can be used. The standard posterior spinal fusion requires a long fusion construct. Anterior approaches allow a shorter construct and maintenance of flexibility by saving spinal segments. Thorascopic and laparoscopic techniques are being developed to allow microinvasive approaches to instrument and fuse the scoliotic spine (13).

Overall, the prognosis is favorable (14,15). Progression in adulthood is generally much slower than in adolescence. Curves less than 30 degrees at maturity are unlikely to progress. However, curves greater than 50 degrees have a 68% chance of progression. For curves between 50 and 75 degrees, the curves will progress by 1 degree per year. Therefore, surgical stabilization of the spine is recommended for curves greater than 50 degrees at skeletal maturity (5,6).

Mild to moderate idiopathic scoliosis in adulthood has no negative effect on pregnancy or delivery method. Generally, normal pulmonary function is found in patients with scoliosis. Restrictive pulmonary function does not occur until the curve reaches 100 degrees (16). No increased risk of mortality is found for adults with adolescent-onset idiopathic scoliosis (17). In most studies, the incidence of back pain does not differ significantly from the general population (4). Patients frequently note cosmetic concerns related to scoliosis. Severe psychological reactions to scoliosis are uncommon.

Questions

1. How is idiopathic scoliosis defined clinically and radiographically?
2. Who is more commonly affected - males or females?
3. As a diagnosis of exclusion, what other causes of scoliosis must be eliminated?
4. What physical findings are present in patients with scoliosis?
5. In the forward bending test, what physical finding suggests scoliosis?
6. What are the primary considerations when planning treatment?
7. What three forms of treatment are valid?
8. What is the long term prognosis for a patient with scoliosis in adulthood?

Answers to questions

1. Clinical - side-to-side (sagittal) curvature of the spine. Radiographic - curvature of the spine whose curvature is greater than or equal to 10 degrees.
2. Females are affected more commonly than males.
3. Congenital, neuromuscular, traumatic, infectious, neoplastic, inflammatory, syndromic and degenerative causes.
4. Side-to-side curvature of the spine, rib hump, shoulder elevation, chest wall deformity, prominence of the scapula on one side.
5. Asymmetry of the rib hump
6. Risk of progression - skeletal maturity and magnitude of curvature.
7. Observation, brace, and surgery
8. Curvature less than 30 degrees - asymptomatic, non-progressive. Curvature greater than 50 degrees - progression in adulthood (1-2 degrees/year).

Chapter XIX.4. Osteomyelitis
Floyd S. Ota, MD

A 5 year old male presents with decreased appetite and intermittent tactile fever for the last five days. He complains of pain in his right leg and he has been having an increasingly difficult time walking over the last 2 days. He has a history of falling seven days ago. His mother denies reports of recent weight loss, cough, or dysuria. He has no previous medical problems.

Exam: VS T 39.4, P 110, R 16, BP 95/50, oxygen saturation 99% RA. He is alert and non-toxic appearing. His heart, lungs and abdomen are normal. Examination of his extremities reveals swelling, warmth and tenderness to his right proximal tibia. He has some palpable inguinal lymphadenopathy on the right. He has difficulty bearing weight and walks with a slight limp. There are no cutaneous skin lesions. His neurologic and joint exams are non-contributory.

Laboratory studies show WBC 18,000, 68% segs, 7% bands, 20% lymphs, 5% monos, H/H 13.4/40, Platelet count 290,000. ESR 60 and CRP 15. Plain radiographs of his right tibia and fibula are normal. An MRI scan shows a hyperintense signal in the marrow with a small pocket pus elevating the periosteum and soft tissue swelling of the right proximal tibia suggestive of osteomyelitis.

An orthopedic consultation is obtained, and a closed needle drainage of the area is done. IV vancomycin is started and subsequent blood and wound cultures grow out methicillin sensitive Staphylococcus aureus. His antibiotics are changed from vancomycin to oxacillin. While in the hospital, his fever declines and his function returns. He is discharged on oral antibiotics to complete four weeks of treatment.

Osteomyelitis by definition is inflammation of the bone. The annual incidence of acute osteomyelitis is about 1/5000 children under 13 years old (1). This disease appears to affect males more often than females, and the majority of the cases occur in patients less than 20 years old. The most common cause of osteomyelitis is bacterial; however, fungal and viral causes are also possible.

Acute bacterial osteomyelitis can be thought of in three different categories: 1) hematogenous seeding, 2) contiguous spread, and 3) direct inoculation of the bone either from surgery or trauma. Of the three categories, acute hematogenous osteomyelitis is the most common presentation in children. Acute hematogenous osteomyelitis has a predilection for the long bones of the body. Long bones consist of two distinct types of bone. The diaphysis or shaft is made of a dense lamellar bone, which is relatively acellular and slow growing. The ends of the bone near the growth plate (the metaphysis) is made of a maze like bone called cancellous bone. This maze like structure allows for spreading of the infection via small channels in the bone that leads into the subperiosteal space. It is here in the rapidly growing metaphysis that osteomyelitis often develops. The process begins when thrombosis and bacterial emboli transmigrate through the end capillaries as a result of local trauma or stasis of local blood flow. This results in bacterial seeding creating a nidus for infection that can be difficult to remove due to a relative lack of reticuloendothelial cells. Pus collects in the subperiosteal space and surrounding edema produces a mass effect that further decreases blood flow perpetuating tissue ischemia and necrosis. Isolated pieces of dead bone, or sequestrations can result from this process. As the remodeling process continues, an involucrum can be created when new bone is deposited over an area of dead bone. The pathophysiology of osteomyelitis differs slightly by age group. In neonates, blood flow from the metaphysis is continuous with the joint space and thus a concurrent septic arthritis may develop. Furthermore, in this age group the periosteum is thinner and thus more likely to rupture into surrounding tissue. This is in contrast to older children in which the infection is contained due to a well developed periosteum resulting in focal physical findings.

The signs and symptoms of acute osteomyelitis may be subtle, especially in the very young. The chief complaint of a child suspected of having osteomyelitis may be refusal to walk and bare weight on the affected limb, or the refusal to utilize a specific body part. Often a recent history of upper respiratory symptoms or trauma is elicited. The very young infant may present with only a history of a poor appetite and fever, or be ill appearing in fulminate septic shock. Objective findings are fever, swelling, point tenderness, and erythema of the affected body part. The child may have a pseudoparalysis of the affected limb. The most common long bones involved in descending order are the femur, tibia, humerus, fibula, radius and ulna (2). Flat bones are affected less than 20% of the time; of these the calcaneus and pelvic bones are the most common and about equal in incidence (2). Occasionally the physical findings are very subtle, such as a loss of natural body curvatures or normal skin creases. Thus, examination of the opposite side for symmetry is an important aspect of the physical exam. Lastly, assessment of the patient's gait for a limp may also help to make the clinical diagnosis.

Laboratory studies are helpful in making the diagnosis of osteomyelitis. The most useful laboratory values are the acute phase reactants, the erythrocyte sedimentation rate (ESR) and the C-reactive protein (CRP). These values are often highly elevated in the presence of acute osteomyelitis, and are non-specific indicators of acute inflammation. The ESR is determined by the rate that red blood cells fall through plasma. This value is dependent on the content of fibrinogen in the blood. The value for ESR usually starts to increase at about 48-72 hours from the start of the infection process. CRP is a protein created by the liver. The theoretical advantage to CRP is that it is said to rise earlier than the ESR, about six to ten hours after the onset of inflammation. It also declines much more rapidly after initiation of therapy, and thus may be a good way to monitor therapeutic efficacy (3). The white blood cell (WBC) count has been found to be unreliable in diagnosing acute osteomyelitis (4). Often, a normal WBC count may be misleading to the clinician in the presence of osteomyelitis. Despite this fact, a CBC can be helpful to rule out other diagnoses, and thus it is an integral part of the workup. Bacterial cultures, when positive, are very helpful in the diagnosis and management of acute osteomyelitis. Blood cultures have been reported to be positive 30-50% of the time (4). Sterile needle aspiration of the affected area yields an organism about 60% of the time if pus is attained (4). Identification of the offending organism and antibiotic sensitivities is an extremely important aspect to guide therapy. The most common organism isolated is Staphylococcus aureus (70-90%) (2). This is followed by group A Streptococcus, Streptococcus pneumonia, and Haemophilus influenza (2). Salmonella and other enteric pathogens must be considered in patients with sickle cell disease. In the newborn period, group B Streptococci, Escherichia coli, and Staphylococcus epidermis are often the cause of osteomyelitis. Lastly, Pseudomonas aeruginosa is a common cause of infection due to plantar puncture wounds that are sustained through sneakers.

Radiographic imaging is an important component in making the diagnosis of osteomyelitis, and should always start with plain radiographs of the affected area. Despite the fact that plain radiographs will only begin to show osteogenic changes five to seven days into the disease process, plain radiographs are helpful to rule out other etiologies of bone pain. A nuclear medicine bone scan is a very sensitive test to diagnose osteomyelitis. This procedure is done in three phases, and utilizes technetium 99m to create images that determine areas of infection and bone remodeling dependent on local blood flow. The sensitivity of the bone scan is high (>90%), and this test is often helpful when the exact location and extent of the infection in the body is unknown (5). CT scanning allows for three dimensional examination of bone and the surrounding soft tissues. This imaging modality can help to show periosteal reaction, cortical bone destruction and if any sequestration or involucrum is present (5). Ring enhancing soft tissue abscesses can also be found. Magnetic

resonance imaging (MRI) is an extremely useful imaging modality in acute osteomyelitis. Findings on MRI accurately illustrate the extent and structure of the area involved in the pathologic process. Sensitivity has been reported to be 88-100% with a specificity of 75-100% (5). Fat suppression sequences allow for better detection of bone marrow edema; however, this cannot differentiate between infection and inflammation (5). MRI may be the imaging modality of choice for infections involving the spine, pelvis, and limbs due to its ability to provide fine details of the osseous changes and soft tissue extension in these areas. MRI does have the disadvantages of high cost and requiring sedation for young children.

The differential diagnosis of a child who presents with fever, bone pain and tenderness includes rheumatic fever, septic arthritis, cellulitis, Ewing sarcoma, osteosarcoma, neuroblastoma, leukemia, thrombophlebitis, bone infarction due to sickle cell disease, and toxic synovitis.

The mainstay of treatment focuses on eradication of the offending organism and the minimization of tissue damage. The first is accomplished through initiating parenteral antibiotics. In the older child, the focus is against the more common gram positive organisms (S. aureus and group A Streptococci). A beta lactamase resistant penicillin (oxacillin, methicillin or nafcillin) or a cephalosporin will cover Group A Strep, but only 70% of Staph aureus. Thus, these antibiotics are unacceptable coverage since the risk of resistance is too high. All patients should be started empirically on vancomycin. In the younger child and patients with sickle cell anemia, gram negative pathogens such as Haemophilus and Salmonella must be considered, thus the addition of ampicillin or a third generation cephalosporin (cefotaxime or ceftriaxone) is important. The duration of treatment is somewhat controversial; however it appears that at least four to six weeks is required. Shorter courses have shown to have an increased incidence of recurrence (2). Peripherally inserted central IV catheters can be placed and home antibiotics can be arranged with home care. Recently, oral antibiotics have become an accepted option to complete therapy. However, the following criteria must be met: organism identification (with sensitivities), the ability to take and keep down oral antibiotics, a clear response to parenteral treatment, and assured routine compliance (4). Often, the dose of oral agents is two to four times the normal dose to maintain adequate drug levels. MIC and MBC (minimum inhibitory and minimum bactericidal concentrations) data may be useful in predicting a therapeutic success. Following laboratory results such as the CBC, CRP and ESR at routine intervals may be helpful to monitor clinical progress and monitor iatrogenic side effects.

Surgical debridement helps to decrease the tissue damage that occurs due to the inflammatory reaction caused by the infection. The removal of the inflammatory products allows for a more optimal environment to maximize the efficacy of medical therapy. Two criteria that help to make the decision to perform surgical debridement are the ability to aspirate pus from the lesion and a failure to see a clinical response within 36-48 hours of the initiation of medical treatment (4). Samples attained from debridement should be sent for pathology identification, cultures and antibiotic sensitivity.

Chronic osteomyelitis can occur due to a penetrating injury/inoculation or inadequate therapy (often due to non-compliance with outpatient antibiotics). This poses an extremely complicated medical and surgical task for the clinician. Like in acute osteomyelitis, Staph aureus is often the organism isolated by culture. However, chronic osteomyelitis has a higher incidence of gram negative rods, anaerobes, and non-bacterial pathogens such as fungus and yeast. Very long term antibiotic therapy and repeat surgical interventions may be required (with occasional amputation), and recovery is long and complication prone. The prognosis for a normal outcome with chronic osteomyelitis can be poor.

Questions

1. True/False: The most common pathogen in acute hematogenous osteomyelitis is Group A streptococci.
2. True/False: A sequestration is an area of loose necrotic bone that is a result of acute osteomyelitis.
3. True/False: The duration of antibiotic therapy for acute hematogenous osteomyelitis is typically 7-10 days.
4. True/False: Two clinical conditions for surgical intervention in acute osteomyelitis are the ability to aspirate pus from the lesion and a lack of response to medical treatment in 36-48 hours.
5. True/False: Plain X-rays will always show bony changes within the first few days of the onset of acute osteomyelitis.
6. True/False: The most common bone involved in acute hematogenous osteomyelitis in children is the tibia.
7. True/False: Osteomyelitis has a propensity to involve the diaphysis of the long bones.
8. True/False: Since Staph aureus is the most common organism involved in osteomyelitis, initiating therapy with an anti-Staph aureus penicillin such as oxacillin is generally accepted as adequate.

Answers to questions

1. False. S. aureus is the most common. Group A strep is the second most common.
2. True
3. False. Typically the course is for 6-8 weeks, always starting with IV antibiotics and finishing with PO antibiotics if possible.
4. True
5. False. Plain films usually begin to show acute changes 5-7 days into the course of the disease process.
6. False. The femur is the most commonly involved bone. The tibia is the second most commonly involved.
7. False. The metaphysis is the most common site.
8. False. The rate of methicillin resistant S. aureus is too high to use oxacillin/methicillin as empiric therapy. Vancomycin should be initially started.

Chapter XIX.5. Septic Arthritis
Floyd S. Ota, MD

A 2 year old male presents with fever and refusal to walk for two days. He complains of pain and points to his right lower extremity. The pain has become increasingly worse, and he is unable to sleep at night. His appetite is decreased. There is a recent history of an upper respiratory tract infection about two weeks ago, but no recent trauma. The pain is not known to migrate. He has no past medical history but his immunizations are delayed (last immunizations at two months of age). There is no history of cough, headache, abdominal pain, vomiting, diarrhea, hematuria, or known tick exposure. Family history is negative for sickle cell disease and arthritis.

Exam: VS T 39.5, P 120, R 18, BP 100/50, oxygen saturation 100% in RA. Wt 10%ile, Ht 50%ile. He is thin appearing and refuses to walk. He is not fussy and nontoxic. HEENT exam is normal. His neck has good range of motion without pain. Heart, lungs, abdomen, and genital exams are normal. He is lying in a hospital bed with his right lower extremity externally rotated, abducted, and motionless. He has severe discomfort with minimal internal and external rotation of the right hip despite attempts to distract him. His other joints and neurological exam are normal. There are no notable skin lesions.

Laboratory studies show WBC 20,000, 80% segs, 10% bands, 8% lymphs, 2% monos, H/H 14/43, Platelet count 265,000. ESR 45. CRP 12. Serum glucose 95. UA SG 1.020, negative for blood. EKG normal sinus rhythm. Hip radiographs show widening of the acetabular space on the right.

An orthopedic surgeon is consulted. An arthrocentesis of the right hip is performed which shows WBC 110,000, glucose 35, gram stain shows many WBCs and few gram positive cocci. Surgical debridement of the right hip is performed. Empiric treatment with vancomycin and ceftriaxone is initiated after cultures are obtained. ASO, ANA and rheumatoid factors are negative. PPD and control is negative. Synovial fluid culture grows out Staph aureus sensitive to methicillin. Blood culture is also positive for methicillin sensitive Staph aureus. Vancomycin and ceftriaxone are discontinued and the patient is treated with oxacillin. Within three days of treatment onset, his fever declines and he slowly begins to ambulate. His appetite returns and he is eventually transitioned to high dose oral antibiotics to complete four weeks of treatment. He is discharged with home care physical therapy services.

Septic arthritis generally refers to bacterial infection of the joint space; however fungal and mycobacterium can also cause disease. Septic arthritis is a medical emergency and failure to provide prompt diagnosis and treatment may lead to severe morbidity and disability. The incidence is estimated to be 5.5 - 12 per 100,000 individuals (1). Septic arthritis is a disease primarily of young children in the first decade of life.

Diarthroidial joints have a synovial lining that separates the adjacent articular cartilages. This histologic lining is extremely vascular and lacks a basement membrane. This tissue produces synovial fluid, a viscous media that has an electrolyte and glucose concentration similar to that of plasma and acts as a lubricant to the adjacent cartilage. This fluid is normally sterile, but if invaded by bacteria, it provides a good environment for bacterial growth. The three main routes of joint infection are: 1) hematogenous (most common in children), 2) contiguous spread, and 3) direct inoculation from a procedure or trauma. The amount of blood flow to the synovium is high, equivalent to that of the brain. Thus, transient bacteremia can cause a large number of organisms to be delivered to this region. Bacteria normally cleared by synovial macrophages can be overwhelmed when presented with a large quantity of organisms. Proteolytic enzymes produced by bacteria and inflammatory cytokines incite damage to the articular cartilage. This process begins early in the infection, and its effects may render the articular surface susceptible to future degenerative joint disease. Furthermore, swelling of the joint capsule may predispose the femoral head to avascular necrosis due to ischemia of the capital femoral epiphysis. Dislocation or subluxation can also result from the increased intracapsular pressure (2). An important concept to emphasize is that the inflammatory process and tissue damage may progress despite the fact that the causative organisms have been eradicated.

Children with septic arthritis all present with one common feature, pain to the affected limb. This is due to stretching of the joint capsule from edema or an effusion. Joint pain may present as refusal to walk, to bear weight, or to utilize the affected limb. Often the children have fever and they can appear toxic to well appearing in their presentation. A history of trauma or upper respiratory infection in the weeks prior is sometimes elicited, which may mislead one from the true diagnosis of septic arthritis. Furthermore, septic arthritis may be a complication for patients with a history of recent surgery, urinary tract infection, and infection due to varicella zoster virus (due to secondary cutaneous infection of the lesions with Staph aureus or group A strep) (1).

On physical exam, swelling, tenderness, erythema, and warmth may be apparent to joints with little overlying tissue. However in a deep (well enclosed) joint such as the hip, these findings may be minimal to absent. Subtle findings such as a loss of natural body curvatures or normal skin creases may be all that is present. Thus, examination of the opposite side for symmetry is an important aspect of the physical exam. Range of motion is the most sensitive method to determine the presence of joint effusion (2). Children with septic arthritis often have significantly decreased and painful range of motion since any movement that stretches the joint capsule produces severe discomfort. In infants with septic arthritis of the hip, the classic physical finding is of a child lying motionless with his/her leg externally rotated and abducted. In septic arthritis of the axial skeleton and pelvis, direct compression of the joints may be the only way to produce clinical signs. It is important to examine all the joints of the lower extremities in a child with a limp, because the child may complain of knee pain, when in fact it is the hip that is affected. The most commonly affected joints are the knees and hips (67%). These are followed in incidence by the ankle, elbow, wrist and shoulders (1). Examination for signs of meningitis and performing a lumbar puncture when indicated is important in children who are susceptible to Haemophilus influenza, type B (but one would not necessarily know this until gram stain and/or culture information is available). One study found that 30% of children with septic arthritis due to this organism had concurrent meningitis (2). Haemophilus influenzae, type B (HiB) infections are currently almost nonexistent because of widespread effective HiB immunization. In the neonatal period septic arthritis often is present concurrently with acute osteomyelitis of the adjacent bone.

The differential diagnosis of a child with fever and joint pain includes: septic arthritis, transient synovitis, reactive arthritis, trauma, acute rheumatic fever, Henoch-Schonlein purpura, Kawasaki disease, serum sickness, lyme disease arthritis, inflammatory bowel disease, hematologic cancer, and connective tissue disease (i.e., juvenile rheumatoid arthritis, systemic lupus erythematosus, etc.). Toxic synovitis (also known as transient synovitis) of the hip is a viral or post infectious process causing acute arthritis that is important because it often causes a diagnostic dilemma for the clinician. Transient synovitis of the hip is often preceded by an upper respiratory tract infection or pharyngitis in previously healthy children. The peak incidence is 3-6 years of age (3). The etiology is unclear; however children with this condition may have a predisposition for hypersensitivity reactions. CBC, ESR and CRP studies are often (but not always) normal or only minimally elevated, and radiological studies often fail to show impressive changes. Rarely is joint aspiration performed, despite the

presence of a hip effusion if the clinical findings and laboratory studies are suggestive of this diagnosis. Toxic synovitis is a diagnosis of exclusion, and treatment consists of non-steroidal anti-inflammatory medications and bed rest. Overall prognosis is usually good (about 70% of patients have resolution of their symptoms within two weeks) (3), but avascular necrosis may occur in some patients.

Laboratory studies are helpful in diagnosing septic arthritis. The most useful laboratory values are the acute phase reactants, the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). These values can be elevated in the presence of acute septic arthritis, and are non-specific indicators of acute inflammation (Refer to the chapter on osteomyelitis for a discussion of CRP and ESR). A retrospective study found that patients with an ESR >20 combined with a fever >37.5, identified 97% of cases of septic arthritis and recommended joint aspiration if these values were present in a child with an irritable hip (4). The peripheral white blood cell (WBC) count is often obtained in the work up of septic arthritis. As a single value, it is unreliable to make the diagnosis of septic arthritis, or to rule it out. Despite this fact, a CBC can be helpful to rule out other diagnoses (such as leukemia), and thus it is an integral part of the workup. Joint aspiration is the most helpful test to make the diagnosis of septic arthritis. The synovial WBC count usually is greater than 80,000 with a predominance of segmented neutrophils. Glucose concentrations are decreased to about 30% of the serum glucose (2). This helps to differentiate septic arthritis from other etiologies of acute joint pain. Typically WBC count and glucose values are not as dramatically affected in cases of transient synovitis, reactive arthritis, and JRA. Bacterial culture and gram stain, when positive, are very helpful in the diagnosis and management of acute septic arthritis. Identification by gram staining is important because joint aspirates are sterile about 30% of the time in patients with septic arthritis (2). Identification of the offending organism and antibiotic sensitivities are an extremely important aspect to guide therapy. The most common organism isolated is Staphylococcus aureus (50%). This is followed by group A Streptococcus (25%), Streptococcus pneumonia (4%), and HiB (16%) (1). The percentage for HiB is probably substantially lower today because of widespread immunization. Neisseria gonorrhoeae (GC) should be considered in neonates and sexually active adolescents. GC septic arthritis may present with a polyarticular presentation, which is unusual for other causes of septic arthritis. Other pathogens to consider in the newborn period are group B Streptococci, and Escherichia coli. Recently, Kingella kingae has become a more recognized pathogen (1).

Imaging should start with plain film radiographs. When looking at the hip, AP and frog leg views should be obtained. The findings on plain radiographs that suggest septic arthritis are displacement of normal fats plains and widening of the joint space due to capsular swelling from an effusion. These signs are subtle and may not be present early on in the disease process. Ultrasound is a quick and noninvasive means of detecting the presence of a hip effusion. CT, MRI, and bone scans all have limited value in the diagnosis of straightforward septic arthritis. However, MRI and nuclear bone scan can help to differentiate between septic arthritis in the presence or absence of a concurrent osteomyelitis. Nuclear bone scans are also helpful when the foci of infection are unclear. All imaging modalities discussed above are able to detect the presence of a joint effusion, however none can differentiate between infectious and non-infectious causes of the effusion. Direct aspiration of the joint fluid is the most definitive means of diagnosis. Joint aspiration does not affect subsequent bone scan results (2).

Treatment of acute septic arthritis consists of surgical debridement and antibiotic treatment. The risk for poor prognosis is increased if any of the following factors are present: a delay in initiation of treatment, age less than six months, history of prematurity, the presence of S. aureus as the infectious etiology, and the presence of a concurrent osteomyelitis (5). Early intervention is required to minimize morbidity. Surgical arthrotomy for large joints is the rule; however this clinical intervention is not always indicated for involvement of smaller joints. The purpose of surgery is to produce an environment with minimal inflammatory products so that antimicrobial therapy is maximized. After surgical intervention, empiric parenteral antibiotic coverage for Staphylococcus aureus should be initiated. The drug of choice is vancomycin due to the high risk (currently about 30%) that the organism may be resistant to cephalosporins and methicillin (MRSA). Clindamycin is another choice that will cover most strains of MRSA, but it is not 100%, so vancomycin is preferred. A third generation cephalosporin should be added if the child is at risk for H. influenza or gonococcal disease. If CNS infection is suspected, meningitic doses should be implemented. The antibiotic regimen can then be narrowed once the cultures and sensitivities are received. As a rule, treatment duration is 3-4 weeks (6). Peripherally inserted central IV catheters can be placed and home antibiotics can be arranged with home care. Recently, oral antibiotics have become an accepted option to complete therapy. This can be done because antibiotic concentrations in the synovium are often higher than that of the serum due to slow reabsorption of the drugs (from the synovium). However, all of the following criteria must be met: organism identified and sensitivity to oral antibiotics is documented, the patient is able to take and keep down oral antibiotics, a clear response to parenteral treatment is demonstrated, and routine compliance is assured (2). Following the CBC, CRP and/or ESR at routine intervals may be helpful to monitor clinical progress and monitor iatrogenic side effects.

In conclusion, for straight forward cases of septic arthritis, the overall prognosis is good. Differentiating infectious from non-infectious etiologies of joint pain can be a clinical dilemma. The clinician must utilize a broad range of clinical tools to expeditiously diagnose and treat this condition so that outcomes are favorable.

Questions

1. True/False: Septic arthritis is a disease most commonly found in adolescent males.
2. True/False: In septic arthritis, the hips and knees are the most commonly affected joints.
3. True/False: In a child with septic arthritis of the hip, redness, swelling, and warmth are often detectable on physical exam.
4. True/False: Children with toxic synovitis never present with fever.
5. True/False: The ESR and CRP can usually distinguish between toxic synovitis and septic arthritis.
6. True/False: The most common bacterial etiology of septic arthritis is Staph aureus.
7. True/False: Haemophilus influenzae type B used to be a common cause of septic arthritis in young children, but this is very uncommon today.
8. True/False: Surgical arthrotomy is always warranted for cases of septic arthritis.

Answers to questions

1. False. It is a condition that usually affects younger children early in the first decade of life.
2. True
3. False. The hip joint is deep and has a significant amount of surrounding tissue, thus inflammation may not be easily detected on physical exam. Exam findings may be subtle, such as asymmetry or loss of function. Decreased and painful range of motion is the best way to detect an effusion by physical exam.
4. False. They also can present with fever. This is why differentiating between toxic synovitis and septic arthritis can be a difficult clinical problem.
5. No definite answer here. Low ESR and CRP values make septic arthritis unlikely. Very high ESR and CRP values make septic arthritis more likely. Intermediate ESR and CRP values are not very helpful in distinguishing toxic synovitis from early septic arthritis.
6. True
7. True
8. False. In larger joints surgical intervention is almost always performed. However in cases of septic arthritis of smaller joints, medical management can be carried out with good results. Orthopedic surgical consult should always be obtained expeditiously whenever the diagnosis is considered.

Chapter XIX.6. Hip Conditions
Robert C. Durkin, MD

A 12 year old boy is brought to your office for evaluation of limping for one month. His parents cannot recall a specific episode of trauma. Further probing may correlate the limp to a fall from his scooter at home. His left distal thigh near his knee is sore with prolonged walking. He cannot run or jump without severe medial left knee pain. He has difficulty squatting or rising from a deep chair. Previous examinations of his knee by another physician were reportedly normal. He has been taking ibuprofen for a "bursitis" without improvement. His limp is getting worse.

PMH is significant for asthma, sleep apnea and severe obesity.

ROS: He denies any radiation of pain below the knee, paresthesias or tingling in the feet, back pain, morning stiffness, swollen joints, fevers, chills or recent infection. He has no symptoms of endocrine abnormalities or hypothyroidism.

FH: Significant for multiple individuals with severe obesity.

Exam: VS T36.8, P 80, RR 24, BP 130/76. He is extremely obese but in no significant distress. He has difficulty standing with both feet together and prefers to externally rotate his left foot. His gait is notable for his left foot turned outward. He has a truncal sway to the left side with the swing phase of his right foot. He cannot squat. His spine is straight. His neurological exam is intact. His knee examination is normal bilaterally. His left hip flexion is decreased to 40 degrees. He has obligate external rotation of the hip with attempted flexion. Internal rotation causes severe thigh pain. Internal rotation is essentially zero degrees. His pulses are full and symmetric.

Although his chief complaint relates to pain near his knee, your examination suggests that his problem is in his hip. AP pelvis and lateral views of both hips demonstrate a left slipped capital femoral epiphysis.

He is placed on crutches with toe touch weight bearing on the left side. He is referred immediately to an orthopedic specialist for consultation. The pediatric orthopedist admits him to the hospital for insertion of a screw to secure the unstable growth plate. He remains on crutches for six weeks after surgery. After six weeks, he is allowed to walk freely. Swimming is encouraged. Activity restrictions include no running or jumping (no sports) until the growth plate has closed radiographically. Complete closure can take six to eighteen months. Since the slip is mild, he has a good to excellent prognosis. Many years of productive activity can be expected. Due to the deformity, mild arthritis may occur in the fifth to sixth decade of life.

Limping in the child can be the result of a multitude of causes. A careful history is critical to narrowing the differential diagnosis. The physician must consider any information that may direct the investigation. Three questions to consider are: 1) Is it painful? 2) How old is the child? 3) What is the duration of symptoms?

Pain is not a specific complaint, but may help the examiner to localize the area of interest to a specific joint or limb. Absence of pain does not narrow the list of causes as infection and neoplasia can present with a painless limp.

The age of the child can narrow the differential diagnosis. Broad overlap can occur so one should not ignore a possible diagnosis just because it is not typical in a certain age group. Leg length discrepancy and neuromuscular conditions such as cerebral palsy can affect the gait pattern of a child at any age. In the toddler (age 1 to 4 years), primary consideration should be given to infectious causes such as septic joint or osteomyelitis. Non-infectious causes include transient synovitis, trauma, or a late presentation of developmental dysplasia of the hip (DDH). In the child/juvenile (age 4 to 10 years), infection and transient synovitis must be excluded. Trauma is common in this age group. Legg-Calve-Perthes disease (idiopathic avascular necrosis of the hip) or juvenile rheumatoid arthritis (JRA) may be first diagnosed at this age. Benign bone tumors can also cause limping in this age group. The adolescent (age 11-16 years) commonly limps due to trauma. Neoplasia may affect children in the second decade. Conditions affecting the growth plate such as slipped capital femoral epiphysis (SCFE) must be excluded in any adolescent presenting to the office with limp and hip, thigh or knee pain. It should be noted that hip pathology may deceptively present with thigh or knee pain. Thus, the hips must be thoroughly examined in patients presenting with thigh or knee pain.

Developmental dysplasia of the hip (DDH) may be diagnosed in any age group. The age of the child will determine the presenting signs and symptoms. In the newborn, DDH is identified by instability of the hip on initial examinations. In the ambulatory child, the dislocated or dysplastic hip will be evident by a limp, waddle, or leg-length difference on examination. Early recognition of the dysplastic or unstable hip is important so that treatment can be instituted before significant deformity occurs and at a time when sufficient growth remains to enhance hip development (1). If the diagnosis is missed, patients may present in late childhood or in their teen or adult years with severe degenerative damage to the hip.

The human hip begins as a continuous structure in the embryo. A cleft forms at the 7th week of development and the gross structure of the joint is formed by the 11th week. Growth of the hip joint is dependent on mechanical and genetic factors. The development of the acetabulum and the femoral head is dependent upon concentric reduction of the round ball in the cup. Dislocation of the femoral head from the acetabulum will cause deformity of both parts of the hip. Growth of the depth and width of the cup is determined genetically by the acetabular cartilage and the triradiate cartilages (2).

DDH is found in 1.0-1.5 per 1000 live births. Risk factors include female gender, first born child, and breech lie in pregnancy (1). A history of DDH in the family is also very significant as the incidence of DDH in parents of affected children is approximately 10 fold greater than the general population (3). Although the etiology is unknown, idiopathic, capsular laxity, hormonal, genetic, crowding, and syndromic causes have been proposed. Support for genetic relationships are noted by the 25 to 50 fold increase rate of DDH in American Indian and Polynesian populations (4,5). DDH is rarely seen in certain African populations or ethnic Chinese (6,7). Evidence for the crowding phenomenon is noted by the relationship of torticollis, hip dysplasia, oligohydramnios, and metatarsus adductus (8). Certain syndromes (Larsen syndrome and arthrogryposis) contain DDH as part of their constellation of findings.

Clinical findings are age-dependent. The newborn may have marked instability of the hip (9). The Ortolani maneuver involves dislocation and relocation of the hip. The palpable clunk associated with the relocation of the femoral head is often called the Ortolani sign. This Ortolani finding disappears as the soft-tissues around the dislocated hip become contracted in the first two-weeks of life. Similarly, the Barlow sign is likely present in the first few weeks of life, but this sign gradually disappears soon thereafter, making it imperative that a thorough examination of the hips be performed and documented several times during the newborn period. In the older child, limited abduction of the hip is the sentinel finding. In addition, the dislocated hip effectively shortens the thigh length giving the appearance of limb length discrepancy or the Galeazzi sign. The apparent thigh shortening often leads to dramatic asymmetry of the

gluteal skin folds. With regards to prognosis, hip stability (stable/unstable) and the resting position of the hip (dislocated/reduced) are important concepts to recognize. A newborn with an unstable but reduced hip requires treatment directed at maintenance of stability. More active intervention such as surgery is needed for the ambulatory child with a fixed dislocation (2).

Treatment must be directed in achieving a concentric reduction of the femoral head in the acetabulum, stability of the hip joint, and proper remodeling of the growth cartilages throughout childhood. Treatment algorithms are age dependent: birth to six months, six months to 18 months, and greater than 18 months. The risk of complications such as deformity, avascular necrosis, and arthritis increases directly with the complexity of the treatment regimen. In the infant (birth to six months), a flexible harness designed to hold the hips in a reduced position and allow some movement is the primary form of treatment. The Pavlik harness is the simplest and most commonly used harness in the United States. Success with the Pavlik harness can approach ninety-five percent. Pavlik failures are associated with bilateral dislocations, Ortolani negative hip, application of the harness after 7 weeks of age, and noncompliance (10,11). Although early success with the Pavlik harness can be expected to result in development of a normal hip in the majority of cases, late dysplasia can be found in 10-20% of adolescents or adults (12,13). Therefore, long-term radiographic monitoring must be maintained. For the child (six months to 18 months), closed manipulation and application of a body cast are often employed to reduce the dislocated hip. In the older child or juvenile, open surgical reduction of the hip with reconstruction of bone deformity of either side of the hip joint is often required. In the adult with untreated DDH, significant deformity of the hip will be present. The decision for reconstruction will depend on the magnitude of arthritis already present at the time of diagnosis. Whatever the age, the treatment algorithm for DDH should adhere to the following principles: avoid complications, obtain a concentric reduction, achieve a stable hip, and promote growth and remodeling of the hip joint.

Clinical Practice Guidelines for Early Detection of DDH (1)

Newborns:
All newborns are to be screened by physical exam.
Ultrasonography of all newborns is not recommended.
Use of triple diapers is not recommended.
If exam is positive, refer to an orthopedist (ultrasonography is unnecessary).
If exam is equivocal, repeat exam by pediatrician in 2 weeks.

2 week exam:
If positive, refer to orthopedist.
If suspicious, consider orthopedic referral or ultrasound at 4 weeks.
If negative, periodic exams with well baby visits.
Consider risk factors if suspicious or negative.

Risk factors and recommended actions:
Female: Follow periodicity schedule.
Positive family history (male): Follow periodicity schedule.
Positive family history (female): Optional future imaging.
Breech (male): Optional future imaging.
Breech (female): Recommend imaging (ultrasound/X-rays).

Legg-Calve-Perthes Disease (LCP disease) is commonly diagnosed in the juvenile patient (4-8 years old). The condition is characterized by limp, loss of hip internal rotation and abduction, and progressive deformity of the femoral head. The shape of the head, congruency of the hip joint, and range of motion of the hip at maturity determine long term prognosis.

LCP disease is more common in boys than in girls (5:1). The incidence of bilaterality is 10-15%. There is no evidence to suggest LCP disease is inherited. The disease is more common in certain geographical locations especially urban centers. Affected children are thought to manifest a specific psychological profile such as hyperactivity. In addition, 89% of those children affected have a delayed bone age. Ethnic variations show a higher risk in Japanese, Eskimos, and central Europeans while American Indians, Polynesians, and African Americans have a lower risk. Anthropometric studies document small stature in height and weight. Normalization of stature occurs in early adolescence. Growth abnormalities may represent alterations of growth hormone dependent somatomedin activity (14-16).

Although the etiology is unknown, most current theories involve vascular compromise to the femoral epiphysis. Two episodes of infarction are thought necessary to cause the changes consistent with LCP disease in humans. Increased blood viscosity, thrombophilia, and intraosseous venous hypertension have been proposed as mechanisms for vascular compromise (17-19).

The syndrome is typified by certain classic radiographic stages: initial, fragmentation, reossification, and residual phases (20). The femoral head deformity may occur in many ways. In general, softening of the femoral head marks the period of fragmentation. Synovitis and restricted hip motion lead to deforming forces that compress the femoral head. Deformity may also result from physeal arrest of the femoral epiphysis. Reossification of the deformed head fixes the abnormal shape. Potential for remodeling of the deformity is related to the age of onset as a younger child has more years of growth remaining to reshape the head. Therefore, age of disease onset is the second most important factor related to outcome, preceded only by residual deformity. In general, affected children younger than 8 years of age at onset have a better prognosis. Attempts to estimate risk of deformity and overall prognosis by radiographic criteria in the early stages of LCP disease have met with variable success (20-24).

The clinical presentation is most commonly an insidious limp. Although pain in the thigh or knee should prompt a thorough examination of the hip, pain is not a frequent finding in LCP. Physical examination is marked by limited abduction and internal rotation of the hip. Flexion contracture of the hip is an important finding. The Trendelenburg test, which tests gluteus medius strength, is often positive. It is done by standing behind the patient and checking that the pelvis is level. The patient is then asked to stand on one leg which should result in gluteus medius muscle contraction on the weight bearing side and the contralateral pelvis should elevate on the unsupported side, indicating that the gluteus medius muscle on the weight bearing side is working properly (negative Trendelenburg sign). A positive Trendelenburg sign is recognized if the pelvis on the unsupported side does not elevate.

Limb length should be measured as any significant discrepancy may predict a poor prognosis if due to head collapse. Imaging should begin with plain radiographs. Early in the disease course, the x-rays will show increased density of the femoral head. Progressive

fragmentation of the epiphysis will follow. Weakness of the bone may lead to collapse. With reossification of the femoral head, the deformity will become fixed in the new bone (25). Other modalities such as magnetic resonance imaging (MRI) and bone scan may be helpful in diagnosis and to direct treatment. Arthrography is often used to document true head deformity in the younger child especially in early phases of the disease (26). The differential diagnosis may be broad and careful selection of laboratory and radiographic studies should make the diagnosis clear. Specific consideration should be given to the following: transient synovitis, septic joint, osteomyelitis, trauma, hypothyroidism, multiple epiphyseal dysplasia, chondrolysis, Gaucher disease, hemophilia, juvenile rheumatoid arthritis, neoplasia, mucopolysaccharidoses, Meyer's dysplasia, or residuals of congenital hip dysplasia (27).

Treatment protocols abound (19,22,25,28-32). The primary goals in the treatment are to prevent deformity, to minimize growth disturbance, and to prevent degenerative joint disease. The critical concept is the containment of the femoral head in the acetabulum through the period of risk of deformity (19). The treatment remains controversial. Non-operative and operative advocates abound. Non-operative treatment requires maintenance of sufficient range of motion through therapy and bracing protocols. Surgical treatment is oriented toward redirecting the softened femoral head into the acetabulum to cover the vulnerable regions and to provide a mold for femoral head remodeling (25,32). For the hip that cannot be contained in the socket, sophisticated surgical techniques are used to treat pain, length discrepancy, and restricted motion. Well controlled studies with uniform treatment protocols in patients matched for age, gender, degree of head involvement, and other factors are needed to determine direct management of this complex disease in the future.

Slipped Capital Femoral Epiphysis (SCFE) remains one of the most common disorders affecting the hip in adolescence (33). This condition is characterized by a displacement of the femoral head through the physeal plate. Since the femoral head is held securely in the acetabulum, the femoral neck displaces anteriorly causing an apparent varus deformity of the proximal femur. Weakening of the perichondral ring associated with puberty leads to a separation of the physis through the widened zone of hypertrophy.

SCFE has been reported in 2 to 10 per 100, 000 population. Children with SCFE tend to be obese because this excess weight places excessive downward stress on the femoral epiphysis. Lower rates are seen in eastern Japan. Higher rates have been reported in African Americans and Polynesians (34,35). SCFE is more common in boys than girls (3:1). Boys are commonly affected between ages 9-16 years and girls are affected between 8-15 years of age.

Children with SCFE are usually obese. An antalgic gait or painful limp (Trendelenburg gait) with the foot turned outward is commonly seen. Knee pain is reported in 25-50% (36). Whenever knee or thigh pain is the chief complaint, the hip must be thoroughly evaluated since the pathology may be originating from the hip. Hip examination is notable for limited true flexion. Due to the deformity of the femoral head, the hip will turn in external rotation to prevent impingement of the femoral neck on the acetabulum with hip flexion (obligate hip external rotation with flexion). The hip has little or no internal rotation. For the acute slip, ability to bear weight may be limited.

The differential diagnosis includes trauma, infection, neoplasia, rheumatoid disease, avascular necrosis, congenital hip dysplasia or dislocation.

The goal of treatment is to prevent further displacement. The child should be restricted in his/her activity immediately after recognition of the problem. The child should remain non-ambulatory until the hip is stabilized. Preferably the child will be placed on bed rest or restricted to a wheelchair. A single screw is placed percutaneously to fix the slipped epiphysis in situ. Screw placement is guided by fluoroscopic imaging under anesthesia. A single screw is adequate fixation if properly placed (37). The patient is restricted to crutch assisted ambulation for 6-12 weeks after surgery. Corrective osteotomy may be planned for severe deformity. Due to the excellent long term prognosis for the hip, osteotomy should be delayed at least 2 years to allow bone remodeling (28).

Long term follow up data of patients with SCFE are available (28,29). In general, the prognosis is good to excellent. Mean hip activity scores were related to the severity of the slip. Degenerative arthritis is seen in almost all hips with moderate to severe slips. Two-thirds of mild slips had degenerative changes on radiographs at 41 years average follow up. Only one hip replacement surgery had been performed for this group over 41 years. Hips that were pinned in situ had less complications and higher activity scores than hips that underwent corrective surgery (29).

Complications such as avascular necrosis and chondrolysis can adversely affect outcome. Bilateral slipped capital femoral epiphysis can occur simultaneously or sequentially. Identifying those patients at risk for a slip on the contralateral asymptomatic hip is difficult. Children with endocrine disease (thyroid deficiency), renal failure, and previous radiation of the femoral epiphysis are at highest risk of bilateral slip (16,38).

Questions

1. What three questions should be considered in the limping child? Why?
2. What are three common causes for limping in the toddler? Juvenile? Adolescent?
3. What physical findings are noted in a newborn with DDH?
4. What physical findings are found in the toddler with hip dislocation?
5. What three factors are required for normal hip development to guide treatment for DDH?
6. What is the proposed etiology of LCP?
7. What are the four radiographic stages of LCP?
8. What factors influence the long-term prognosis most significantly for LCP?
9. What is the typical body habitus for a patient with SCFE?
10. What physical findings are present in SCFE?
11. What is the overall prognosis with proper treatment for SCFE?

Answers to questions

1. Is it painful? How old is the child? What is the duration of symptoms? These three questions will help to narrow the differential diagnostic possibilities.

2. Toddler: transient synovitis, infection, trauma. Juvenile: trauma, transient synovitis/infection, Legg-Calve-Perthes disease. Adolescent: slipped epiphysis, trauma, neoplasia

3. Hip instability - Ortolani sign. Asymmetric gluteal skin folds.

4. Leg length discrepancy, Galeazzi sign (apparent thigh length difference), waddling gait.

5. Concentric reduction of femoral head, stability, remodeling and growth of acetabular cartilage.

6. Although the etiology is unknown (commonly stated as idiopathic), most current theories involve vascular compromise of the femoral epiphysis. Two episodes of infarction are thought necessary to cause the changes consistent with LCP disease in humans. Increased blood viscosity, thrombophilia, and intraosseous venous hypertension have been proposed as mechanisms for vascular compromise.

7. 1. Initial, 2. Fragmentation, 3. Reossification, 4. Residual.

8. Age of patient at onset and proportion of femoral head involvement. Children who have LCP disease before age eight have a better prognosis over children greater than eight years of age at time of onset. The proportion of head involvement forms the foundation for several classification schemes. Maintenance of the height of the lateral column of the femoral epiphysis appears to have the most prognostic significance in children in any age group. Whole head involvement or collapse of the lateral column by more than fifty percent carries a poor prognosis.

9. Obese, delayed maturation of skeletal age.

10. Trendelenburg gait or antalgic limp, obligate external rotation of the hip with flexion, limited internal rotation of the hip.

11. Good to excellent. High activity level. Slow degenerative process of the hip with few cases requiring prosthetic hip replacement.

Chapter XIX.7. Common Sprains and Dislocations
Brian T. Garcia

This is a 12 year old male who presents to your clinic with a 1 day history of pain and tenderness over his right ankle. He states that he stepped on someone's foot at basketball practice and "landed funny". It is painful to bear weight on his ankle, but he can do so if asked. He has been applying ice to the area since incurring the injury, with some relief of the pain.

Exam: VS are normal. His exam is unremarkable except for the right ankle, which is positive for moderate swelling and tenderness over the lateral malleolus. No ecchymosis or gross deformity is noted. Passive inversion and plantar flexion of the ankle produces pain. Anterior drawer test of the right anterior talofibular ligament is negative for gross laxity.

An X-ray of his ankle is obtained which does not reveal any fractures.

He is advised to rest the affected joint for today and is instructed to elevate his ankle and wear a compression bandage around the ankle. He is also instructed on performing pain-free range of motion exercises and light activity as tolerated.

The ankle is one of the most common sites for acute musculoskeletal injuries, with sprains accounting for 75 percent of ankle injuries (1). A sprain refers to stretching or tearing of a ligament. The most common mechanism of injury in ankle sprains is a combination of plantar flexion and inversion (1). The ankle joint is a hinge joint normally permitting movement in one plane (dorsiflexion and plantar flexion). In addition, up to 18% of axial rotation of the talus may occur within the tibial mortise (3). The lateral ligamentous complex consists of the three fibular collateral ligaments: the anterior talofibular ligament (ATFL), the calcaneofibular ligament (CFL), and the posterior talofibular ligament. These ligaments stabilize the ankle laterally, and are commonly injured in ankle sprains (2). The ATFL is the most commonly injured ankle ligament (4). Ankle sprains range in severity from grade I to grade III (1). Grade I refers to partial tearing of the ligaments. Grade II refers to partial to complete tear of the ATFL, and partial tear of the CFL. Grade III involves complete rupture of the ATFL and CFL (4).

History of the mechanism of injury allows the clinician to infer the pathologic status and structures involved (2). Patient will often report a twisting injury of the foot. The signs and symptoms of ankle sprains are varying degrees of pain, tenderness, and swelling over the lateral aspect of the ankle (4). Other signs are mild to moderate ecchymosis, loss of motion and function, and mechanical instability (1). Careful physical examination should include inspection, palpation, ability to bear weight on the affected ankle and special tests (1,3). Special tests include the anterior drawer test, which is used to assess the integrity of the ATFL. The inversion stress test is used to assess the integrity of the CFL (1). A positive "squeeze" test, which is occurrence of distal pain on compression of the fibula and tibia at the midcalf, may indicate the presence of a syndesmosis (the membranous ligamentous connections between the tibia and fibula) sprain (1). The positive findings of the affected ankle should be compared with the other, uninjured ankle (4). Traditionally, standard AP, lateral, and mortise views have been recommended in the evaluation of all cases of ankle injuries to rule out the possibility of occult fractures and osteochondral injuries and to assure articular congruity and alignment (2). The Ottawa Ankle Rules for obtaining radiographs of ankle injuries have modified this approach. These rules recommend radiographs if there is bony tenderness in the posterior half of the lower 6 cm of the fibula or tibia (i.e., lateral or medial malleolus tenderness), or inability to bear weight both immediately after the injury or during the medical examination (2).

The differential diagnosis of acute ankle sprains can include fibular fractures (lateral malleolus), tibial fractures, osteochondral fracture of the talar dome, peroneal tendon subluxation, congenital tarsal fusion, talar fractures, calcaneal fractures, and subtalar subluxation (4).

Early management of acute ankle sprains includes RICE (rest, ice, compression and elevation) (1). RICE and partial weight bearing are indicated as tolerated with optional crutches depending on the patient's ability to ambulate (4). Ibuprofen and/or acetaminophen may help with pain relief. Range of motion and gradual ambulation result in faster recovery compared to total rest (4). Surgery is indicated only in patients with recurring instability. Most patients have an excellent prognosis (4).

Nursemaid's elbow (also called subluxed radial head) is an injury which occurs when infants or children are lifted or pulled by the hand or arm. This pulling injury results in the radial head slipping through parts of the annular ligament resulting in the injury. Stubborn behavior (pulling away) may also cause this type of injury (4). This is one of the most common elbow injuries in young children between the ages of 1-5 years (4). The child may complain of pain in the elbow following a traction (pulling) injury. No significant swelling or angular deformity should be visible. They do not use their upper extremity and will hold their elbow at the side with their forearm on their lap (4). A classical physical exam finding of a nursemaid's elbow is refusal and pain with attempted forearm supination. Some parents may complain that the child has injured the wrist or shoulder, but in this age group, a pulling injury is most likely to affect the elbow. Physical examination of the infant may note point tenderness over the radial head, but this is not reliable (5).

The differential diagnosis of nursemaid's elbow includes buckle or greenstick fracture of the distal humerus, growth plate injury of the distal humerus or proximal radius. A history of a pulling injury makes a fracture unlikely. Radiographs may be necessary to rule out a fracture if the history is not consistent with a pulling injury or a fracture is suspected for other reasons. Treatment involves a reduction procedure. Various reduction procedures have been described. The most common procedure is the supination of the forearm (usually with the elbow in flexion, but it can also be done in other ways). Hyperpronation of the forearm with the upper extremity held up high has also been described. A click may be palpated at the level of the radial head suggesting successful reduction (5). The response to reduction of the displaced ligament is diagnostic. The child starts using the arm again, and there is usually no residual tenderness (4). The elbow may be immobilized in a sling for a day (usually not necessary), and if needed, acetaminophen can be given for pain (5). Parents are advised that this injury may recur up to age 5 or 6 years, but it does not signify any elbow problems in later life. It is prudent to minimize the risk of a pulling injury.

Knee problems are a common musculoskeletal presentation in primary care. The anatomy of the knee joint is very complex. Detailed description of all of its structures goes beyond the scope of this chapter. It is important to discuss some of the anatomical features of the knee that are more commonly injured. The tibiofemoral joint is a combination of a hinge, a sliding, and a gliding joint. There are several ligaments at this joint which are susceptible to injury. The medial collateral ligament (MCL) resists valgus angulation of the knee. The lateral collateral ligament (LCL) resists varus angulation. The anterior cruciate ligament (ACL) resists anterior displacement of the tibia on the femur. These ligaments are commonly injured. The menisci of the joint act to deepen the articular surfaces for load transmission, reduce stresses on joint surfaces, and act as a secondary stabilizer to enhance joint stability. These structures are also susceptible to injury. (8)

Patient history is a key element in evaluating the knee. Onset, type, quality, location, and duration of pain or other symptoms; (alleviating and aggravating factors), attempts to remedy the problem and any associated symptoms help to make the diagnosis (7). The mechanism of injury is a key factor in evaluating knee injury. Pivoting injury with a "pop" and swelling suggest an ACL injury. Twisting injury with a history of knee locking may indicate a meniscal tear. Varus or valgus forces point to the probability of LCL or MCL injury respectively. Physical examination of the knee includes observation, palpation of the soft tissues and bony anatomy, and range of motion of the affected knee in comparison to the unaffected knee. Specific testing of the knee for laxity of ligaments are helpful in making the diagnosis of knee injury. Some examples of these tests include the anterior drawer test to determine ACL laxity, and the valgus and varus stress tests to determine MCL and LCL laxity (8). McMurray's test and Apley's grind test are used to assess possible meniscal injury (4). It is important to remember that injury to one of the ligaments or menisci of the knee may be associated with other concomitant injuries to the knee. Therefore, it is important to examine the patient for those possibilities. Imaging procedures to evaluate knee injury include anteroposterior and lateral plain radiographs to rule out fractures. MRI may be appropriate to rule in possible ligamentous or meniscal injuries. Treatment depends on the type and severity of injury, which may include hinged bracing, analgesics for pain, surgical treatment and pursuant physical therapy. Most medial collateral ligament injuries may heal without surgery. Patient education on preventative measures such as proper conditioning prior to athletic activity is helpful (4).

Shoulder injuries in young athletes can be of various types. Acute dislocation and acute subluxation of the glenohumeral joint, chronic subluxation, impingement syndromes, rotator cuff injuries and acromioclavicular injuries are common injuries of the young athlete (6). Anterior dislocations comprise 85-95% of all shoulder dislocations and can occur in dominant and nondominant extremities (6). Patients often present holding the arm in slight abduction and internal rotation and report pain upon attempting to rotate the arm. A mass (the humeral head) may be palpable over the anterior shoulder (deltopectoral groove). The patient may also report "dead arm" syndrome; transient loss of sensation, numbness and tingling of the involved extremity. Axillary nerve injury may occur in this type of injury and presents by loss of sensation over the lateral deltoid as well as decreased strength of the deltoid.

A thorough history and physical examination are key to identification of shoulder instability. In patients with an acute injury, pertinent historical information include arm dominance, previous episodes of injury, and neurologic symptoms. Position of the extremity and direction of the force when the injury occurred are also important. Examination should include assessment of the neurovascular system, palpation of the musculature and the bony anatomy. Rotator cuff strength and range of motion, as well as documentation of external rotation are important findings that suggest acute dislocation. Standard radiologic studies of the shoulder include: anteroposterior views with shoulder in internal and external rotation, an axillary or modified axillary view and the Stryker notch view (6).

X-ray confirmation of a shoulder dislocation is preferable before a reduction procedure is attempted. It should be noted that fractures of the humerus are more common in children, while shoulder dislocations are more common in older teenagers. Acute dislocation requires prompt reduction. There are several common reduction methods. The Stimson technique utilizes a weight which is taped to the forearm. The patient lies prone with the weighted upper extremity hanging over the side of an elevated gurney. Reduction occurs gradually. The external rotation method is probably the easiest method, requiring the least assistance and equipment. With the patient lying supine or sitting upright, the procedure starts with the elbow flexed at 90 degrees with the forearm in a position of comfort and the humerus and elbow held adducted against the side of the chest. The humerus is slowly externally rotated using the forearm as a lever, keeping the elbow against the body. With gradual external rotation, reduction occurs spontaneously as the forearm begins to point away from the body in the coronal plane (i.e., extreme external rotation) (9). Following reduction, the arm should be immobilized for three weeks in a shoulder immobilizer (a sling with an additional strap to hold the forearm against the torso). In patients under age 25 years, many orthopedic surgeons believe surgical repair should be a consideration to prevent further episodes of anterior dislocation and arthritic changes. Rehabilitation of the injured shoulder involves exercises and close follow-up with a physical therapist or athletic trainer (6).

Questions

1. What is the usual mechanism of injury in an ankle sprain?
2. Which ankle ligament is most commonly injured?
3. Early management of acute ankle sprain employs RICE. What does this mnemonic stand for?
4. What is the mechanism of injury in nursemaid's elbow?
5. How do you reduce subluxation of the radial head (nursemaid's elbow)?
6. If you suspect an ACL knee injury in a patient, what specific test can you do to assess ACL laxity. Should you be worried about other injuries in this patient?
7. What nerve is commonly injured in an anterior dislocation of the shoulder. What are the typical neurologic deficits associated with this injury?
8. Describe two procedures to reduce an anterior shoulder dislocation.

Answers to questions

1. Combination of plantar flexion and inversion.
2. Anterior talofibular ligament.
3. Rest, Ice, Compression, Elevation.
4. Traction injury resulting from being lifted or pulled by the hand or arm.
5. Supination or hyperpronation of the forearm at the elbow.
6. Anterior drawer test assesses ACL laxity. Physician should assess for other structural abnormalities in the affected knee, as multiple ligaments and/or menisci may be injured.
7. Axillary nerve injury. Injury to the axillary nerve can result in transient loss of sensation, tingling and numbness to the lateral aspect of the deltoid.
8. Stimson technique or external rotation method. See text.

Chapter XIX.8. Sports Injuries
Brent K. Ogawa, MD

Osgood-Schlatter Disease

This is a 12 year old male soccer player who comes into the office with a chief complaint of pain to both knees. He reports a gradual onset of knee pain in the front of both of his knees that started about one year ago. The pain seems to be in the same spots and is worse after a hard practice or game and with running up and down hills. He noticed a "bump" on both of his knees recently that is tender if he falls or accidentally bangs them. The patient does not remember an initial history of trauma or injury. He is otherwise healthy with normal birth and development.

Examination is unremarkable with the exception of his knees. He is comfortable, in no significant acute pain. His right and left knee findings are identical. A mild prominence over the tibial tuberosity is visible. No erythema, edema or effusions are noted. No patellar grind is noted. The patella is normally placed and there is no tenderness over the patella. He has localized tenderness over the tibial tuberosity. His knee range of motion is good, but he experiences pain over the tibial tuberosity when he is asked to extend his knee against force (such as against gravity, or against resistance from the examiner). Motor strength is good. Varus and valgus stress tests are negative. McMurray, anterior drawer, Lachman, and posterior drawer tests are all negative.

Radiographs demonstrate moderate prominence of the tibial tuberosities bilaterally. There is mild soft tissue swelling. No evidence of fracture.

He is instructed to rest and apply ice massages to the area, focus on stretching his hamstrings, and to take acetaminophen. He is permitted to ambulate normally and jog briefly, but he must stop if any pain occurs. After 5 weeks, the pain subsides and after about one year, he is symptom free. There remains mild, nontender prominences over both knees as he becomes older.

Traction apophysitis of the tibial tuberosity was first described independently by both Osgood and Schlatter in 1903 (1). This disease is usually seen in adolescents or older children 11-15 years of age, with a male to female predominance of 3:2 (2). Girls present earlier because the secondary ossification center of the tibial tuberosity appears 2 years earlier. Osgood-Schlatter is seen in children/teens who are very active in sports requiring strenuous quadriceps muscles such as basketball and volleyball. Jumping puts the most force on the quadriceps and the insertion of the patella tendon into the tibial tuberosity. Osgood-Schlatter is also common in running sports such as soccer, baseball and football, but less so than with the jumping sports. This disease is seen more often on the left side and 25% of patients have a bilateral appearance.

The exact etiology remains controversial, although repetitive trauma is the most widely accepted theory. Other less likely theories include avascular necrosis of the tibial tuberosity (although blood supply is abundant), infection (although patients are afebrile and without leukocytosis), and degeneration of the patella with heterotopic ossification (although histological studies show no tendon necrosis and normal tendon insertion) (2,3).

Growth of the proximal tibia is unique because it involves two growth centers in close proximity: the proximal tibial physis and the tibial tuberosity apophysis. An apophysis is a growth plate, which does not contribute to the length of the bone. It is common for a tendon to insert over an apophysis, such as in the tibial tuberosity (patella tendon), calcaneus (Achilles tendon), etc. The cartilage growth plate of the apophysis is a weak spot which is susceptible to microseparation with trauma or overuse (pulling, traction). Anatomy of the tibial tuberosity starts at 12-15 weeks of fetal growth; however, there isn't a recognizable tibial tuberosity growth plate until after birth. Southwick and Ogden described the development of the tibial tuberosity in 7 stages; 3 prenatal and 4 postnatal. Stages 1-3 involve fibrovascular ingrowth and vascularization of the area with anterior outgrowth. Postnatal stages include a separate and distinct tibial tuberosity growth plate (stage 4) that later joins with the tibial growth plate (stage 7). There is a distinct secondary ossification center in the distal portion of the tuberosity (stage 5). During maturation (stage 6) there is a coalescence of the proximal tibial epiphyseal ossification center with the tuberosity ossification center. In the final stage (stage 7), there is fusion to form a contiguous structure. The vascular anatomy of the tuberosity is plentiful even until age 10-12. Therefore, because of its unique anatomy and vascular supply, combined with excessive pulling forces of the extensor mechanism, there is a failure of the secondary ossification center, ultimately leading to the disease.

The pain is localized to the anterior aspect of the proximal tibia over the tibial tuberosity. There is a local prominence and tenderness on exam. Although patients may complain of pain with full extension of the knee (especially against force), they have full range of motion. They may describe a dull ache exacerbated by jumping or stair climbing. Walking on flat surfaces does not cause pain. Patients may often have symptoms for 6-12 months prior to seeking medical attention. Although the tibial prominence may be highly indicative of Osgood-Schlatter in many cases, a full knee exam should be performed to rule out other intra-articular pathology.

Unless other pathology is suspected, radiographs of the knee are usually unnecessary, since this is largely a clinical diagnosis. In more severe cases, lateral radiographs of the knee will often show a decrease in homogeneity of the infrapatellar fat pad, soft tissue swelling, and a prominence/fragmentation of the tibial tuberosity.

The differential diagnosis includes acute stress fracture, contusion of the tibial tuberosity, prepatellar bursitis, and patellar tendonitis. Some have termed Osgood-Schlatter as a "tendonitis" of the patellar tendon insertion. Some consider the two terms, tendonitis and apophysitis to often be interchangeable. Other pathology may also be considered including osteomyelitis or tumor.

Despite the ominous sounding name, the end result is often the same with or without treatment; therefore, alleviating parental fear is important (2). Treatment is mainly symptomatic and involves reducing forceful use of the quadriceps, which equates to playing less, resting more during games and practices, and less jumping. Hamstring stretching, ice, and NSAIDs may be useful as needed. Corticosteroids are not used because subcutaneous atrophy and fat pad necrosis may occur. If the pain is severe, a knee immobilizer may be used to allow for both decreased tension over the patellar tendon by limiting extension. A cylinder cast was used in the past; however, a knee immobilizer is better because it allows for removal to prevent atrophy and stiffness, and allows the patient to shower. Surgery is rarely indicated. Being skeletally immature, these patients are at risk for subluxation of the patella, patella alta (high riding patella), nonunion of the bony fragment of the tibia, and premature fusion of the anterior part of the epiphysis leading to genu recurvatum (hyperextension of the knee). If patients remain symptomatic, surgery may be performed (rarely), usually after reaching skeletal maturity.

After acute symptoms resolve, gradual strengthening exercises of the extensor mechanism using isometric or short-arc terminal extension techniques should be performed. The use of knee pads to prevent reaggravation of contusions should be stressed to both patients and parents.

The prognosis for this disease is good with spontaneous healing usually occurring. As the disorganized ossification fuses with the beaklike portion of the epiphysis, symptoms diminish (4). Often patients decrease their activity voluntarily secondary to pain. Although the symptoms may decrease with activity reduction, local tenderness may persist. In the adult, a local prominence of the tibial tuberosity may remain; however, this is usually painless.

Sever's Disease

This is a 13 year old boy who presents to the office with a chief complaint of right heel pain. The patient states he has gradually noticed this pain since the beginning of basketball season 2 weeks ago. The pain is a dull, 5/10 ache over his right heel that is worse with running, especially when running on the hardwood floor. He has tried ice, which provides only temporary relief until the next practice. He is not taking any pain medications. There is no history of trauma or known injury and he is otherwise healthy. Birth and developmental history are unremarkable.

Examination is unremarkable except for his right lower extremity. He is comfortable in no acute pain. There is no visible deformity, muscle atrophy, or erythema. There is minimal soft tissue swelling and moderate tenderness to palpation over the back of the right calcaneus. Ankle range of motion is normal. He ambulates normally and he is even able to jump up and down.

Radiographs of his right heel are obtained, which demonstrate no specific abnormality. He does have an open growth plate (apophysis) over the Achilles tendon insertion region, but this is noted to be normal for his chronologic and bone age.

He is diagnosed with Sever's disease. He is instructed to rest from athletic activity for 4 weeks, but he is permitted to ambulate normally. He is also instructed to apply ice and take NSAIDs if the pain continues. A heel wedge is placed in his right shoe, which he later reports helps to alleviate the pain. After 4 weeks, he focusses on stretching and strengthening exercises for his calves and hamstrings. He subsequently recovers and returns to his normal athletic function.

Sever's disease (calcaneal apophysitis), first described in 1912 by JW Sever, is inflammation of the open calcaneal growth plate (Achilles tendon insertion) secondary to traction on the apophysis of the os calcis by the Achilles tendon (5). This disease is commonly seen in children 8-13 years old and is more prevalent in runners, especially soccer and basketball players who play on hard or artificial surfaces, or football/baseball players who play with cleats which permit them to gain excess traction into the ground. The mechanics of this injury are similar to Osgood-Schlatter disease except that the major stress is running and pushing forward in Sever's, compared to jumping in Osgood-Schlatter's. Tension is placed on the calcaneus by the strong shearing forces caused by the plantar fascia and triceps surae. Associated pathology thought to predispose to this disease includes internal tibial torsion, forefoot varus, and tight heel cords (6,7).

Clinically these patients present with heel pain over the posterior calcaneus near the Achilles tendon insertion. Soft tissue swelling and induration may be present, although less often. They may have an antalgic gait secondary to pain, but in most instances, their gait is normal during medical evaluation. Most of their pain and discomfort is sustained during athletic activity when stress on the Achilles tendon insertion is maximal. After a period of rest, symptoms commonly subside. Radiographs are not necessary, but if done, three views should be included: AP, lateral, axial (Harris views). Radiographs may show a sclerotic and fragmented calcaneal apophysis in severe cases, but most often, radiographs are normal. An open growth plate is present in Sever's patients, and symptoms usually subside as the growth plate achieves fusion/closure. Oblique views and CT may be necessary to identify occult fractures. Bone scanning may be useful to rule out a stress fracture (8).

The differential includes stress fracture, avulsion fracture of the calcaneus, Brodie's abscess, simple bone cyst, plantar fasciitis, or Achilles tendon rupture.

Treatment for this disease is mainly symptomatic. This includes rest from activity, ice, and NSAIDs as needed. Most patients with mild Sever's disease can still play, but they should be told to rest when pain occurs. A posterior heel wedge 0.5 to 1.0 cm in height is recommended. By raising only the heel, tension is reduced on the Achilles tendon insertion site on the calcaneus. Shock absorbing insoles may also be used. Once acute symptoms have resolved, patients should begin stretching and strengthening exercises of the hamstring and calf muscles. Athletic activity can be gradually resumed. The exact time frame for resolution of symptoms varies. If conservative measurements fail after 6-8 weeks, a bone scan or other studies to seek more occult sources of pain should be considered.

Little League Elbow

This is a 13 year old right handed boy who presents to the clinic with a chief complaint of right elbow pain. The patient has noticed a gradual onset of pain over the past two months since baseball season started. He is the star pitcher for his little league team and pitches full games twice per week. He also practices a lot during the week. He has complained of pain during practices, but has been told to continue practicing; "no pain, no gain." The pain is most severe over the medial aspect of his right elbow and does not radiate. He is able to do normal activities of daily living. His wrist and shoulder are unremarkable. His parents are concerned about him missing the All-Star game if he doesn't continue to perform at a high level.

Exam: His is exam is normal with the exception of his right elbow. No visible deformity, edema, or erythema. He is tender to palpation over the medial epicondyle. An elbow contracture of 15 degrees to full flexion is noted. He has full ROM about the shoulder and wrist. Sensation is intact. Upper extremity strength is good and sensation is intact. Perfusion, pulses and reflexes are all normal. Radiographs of his right elbow are obtained and show a minimally displaced right medial epicondyle fracture.

Despite initial apprehension, the patient and his parents decide to cease activity. Because there is minimally displacement (<2mm), a posterior splint is applied for 2 weeks. On return to the clinic, the patient reports improvement of his symptoms. The splint is removed and active range of motion exercises are taught. The patient continues these diligently. Six weeks later, after radiographic evidence of union, the patient is allowed to start a specific throwing program. He is back to pitch in the championships the following season. The league commissioner decides that each team must keep an accurate pitching record of the number of pitches thrown per game. The community sports medicine physician is also asked to educate coaches and parents about the importance of identifying little league elbow early.

The term "Little League elbow" is used to describe a group of pathologic entities in and around the elbow joint in young throwers. The mechanism includes pitching, tennis serving, volleyball spiking/serving, football and javelin throwing. The syndrome is a result of a repetitive valgus stress during overhead throwing. This valgus stress results in lateral compression and medial traction on the elbow. The injury has expanded to include (9): 1) Medial epicondylar fragmentation and avulsion. 2) Delayed or accelerated apophyseal growth of the medial epicondyle. 3) Delayed closure of the medial epicondylar growth plate. 4) Osteochondrosis and osteochondritis of the

capitellum. 5) Deformation and osteochondritis of the radial head. 6) Hypertrophy of the ulna. 7) Olecranon apophysitis with or without delayed closure of the olecranon apophysis.

The biomechanics of throwing are complex. The physical stresses associated with throwing produce exceptional forces in and about the elbow in the throwing athlete of any age. These forces include tension, compression, and shear localized to the medial, lateral, and posterior aspects of the elbow (10).

1. Tension overload of the medial elbow restraints: early and late cocking phases.
2. Compression overload on the lateral articular surface: early and late cocking phases.
3. Posterior medial shear forces on the posterior articular surface: late cocking and follow through phases.
4. Extension overload on the lateral restraints: acceleration phase.

A comprehensive history is important and should include age, handedness, activity level, sport played, and history of trauma. The age of the thrower can be helpful in the differential and is divided into three groups: 1) childhood (terminates with appearance of all secondary centers of ossification), 2) adolescence (terminates with fusion of all secondary centers of ossification to their respective long bones), and 3) young adulthood (terminates with completion of all bone growth and achievement of final muscular development) (9).

During childhood, pain to the medial epicondyle secondary to microinjuries at the apophysis and ossification center is common. In adolescence, muscle strength, muscle mass, and throwing forces increase. Valgus stress of the elbow results in an avulsion fracture of the entire medial epicondyle. Some athletes develop enough chronic stresses to cause delayed union/malunion of the medial epicondyle. By young adulthood, the medial epicondyle is fused and injuries tend to occur to muscular attachments and ligaments. The flexor muscles and ulnar collateral ligaments are often injured.

Examination should include both elbows looking for atrophy/hypertrophy, ROM, bony deformity, flexion contractures, and carrying angle. Also neurological and vascular exams with attention to the ulnar nerve should be performed.

Radiographs (AP, lateral, oblique) and comparison views are essential. Common findings include an immature elbow with elbow enlargement, fragmentation, and beaking or avulsion of the medial epicondyle. Lateral lesions usually involve the subchondral bone and manifest as osteochondrosis or osteochondritis dissecans (OCD) of the capitellum or radial head. Posterior lesions present with hypertrophy of the ulna causing chronic impingements of the olecranon tip into the olecranon fossa. CT and MRI are also useful modalities.

The American Academy of Pediatrics and youth baseball organizations have made recommendations to reduce the risk of overuse elbow injuries in young athletes by providing leagues and coaches with guidelines limiting the number of pitches per day or per game, a young athlete can throw. It is far preferable to prevent these injuries, than it is to recover from these injuries. The onset of pain or swelling suggests the earliest onset of an injury. Playing through such pain worsens the injury, so this practice should be discouraged. A basic strategy to reduce the risk of these injuries is to restrict further elbow throwing stress for the remainder of the day once the onset of pain occurs.

Medial tension overload injuries are the most common and usually resolve within 4-6 weeks of rest, ice, and NSAIDs. After symptoms resolve, gradual return to throwing is allowed. If disability continues for an extended period of time, throwing should be disallowed until the next season.

Medial epicondylar fractures occur with substantially more acute valgus stresses applied through violent muscle contraction causing an avulsion fracture of the medial epicondyle. This causes a painful elbow with tenderness over the medial epicondyle and elbow flexion contracture that may exceed 15 degrees. In minimally displaced (<2mm) or non-displaced fractures, a single posterior splint for 1-2 weeks then progression to active ROM exercises is commonly used. When radiographic evidence of union is noted, a specific progressive throwing program is started. In moderately displaced fractures (>2mm) open reduction with internal fixation hardware is performed with early ROM exercises at 1-2 weeks to regain flexion and extension.

Medial ligament rupture to the ulnar collateral ligament is not common in young athletes and is seen more in adults. Patients may have medial tenderness for months to years before the ligament is injured, usually in a sudden catastrophic event. If the patient desires to continue throwing, surgical repair is needed. If the injury is detected early, conservative treatment including rest and alternating heat/ice is recommended.

Lateral compression injuries, such as Panner's disease (osteochondrosis), is a malady of the growth degeneration or necrosis of the capitellum and is followed by regeneration and recalcification. Panner's is a focal, localized lesion of the subchondral capitellum and its articular cartilage. It is a self-limiting condition where the capitellum epiphysis essentially assumes a normal appearance as growth progresses. Panner's usually affects a younger population and onset is acute with fragmentation of the entire capitellar ossific nucleus. There are no loose bodies and no late sequelae unlike osteochondritis dissecans. These patients are also younger. Initial treatment of Panner's includes rest, avoidance of throwing, and sometimes a posterior splint until acute symptoms resolve. Radiographic follow up is essential to ensure adequate healing. Late deformity and collapse of the articular surface of the capitellum are rare.

Osteochondritis dissecans (OCD) is a focal lesion of the capitellum occurring in 13-16 year olds. They present with elbow pain and a flexion contracture of greater than or equal to 15 degrees. OCD of the capitellum is secondary to the compressive forces occurring between the radial head and capitellum during throwing. Again, these patients are older than Panner's disease. The etiology of OCD in the elbow is unclear. Theories include ischemia, trauma, and genetic factors. These patients present with poorly localized, dull pain with decreased range of motion during extension with "locking and catching," also unlike Panner's disease. CT and arthroscopy are beneficial in determining the extent and size of the lesion. OCD lesions can be divided into three types: Type I) Intact with no displacement or fracture of the articular cartilage. Treatment includes rest, splinting 3-4 weeks if the pain is severe, followed by ROM exercises. Type II) Shows evidence of fracture or fissure of the articular cartilage. Determining the size and stability of the fragment is important. If the fragment is small, arthroscopic removal may be performed. If the fragment is large, arthroscopic pinning is necessary. Type III) Complete detachment with the fragment lying freely. Treatment includes either trying to reattach the loose fragment or removal. Pain may be relieved; however, there may be little improvement in ROM. These patients should be seriously counseled about the dangers of continued throwing and are urged to abstain.

Posterior extension and shear injuries are uncommon in young throwers but the incidence increases with age. These types of injuries can be divided by age. 1) Childhood: Osteochondrosis of the olecranon. Treatment includes rest and gentle ROM exercises. Flexibility and strengthening are initiated once acute symptoms subside. 2) Adolescents: Avulsion fragments and lack of apophyseal fusion. For avulsion fragments, treatment usually requires arthroscopic removal. If there is lack of apophyseal fusion, rest and immobilization can produce good results. 3) Young adults: Partial avulsion of the olecranon and osteophyte formation at the tip of the

medial border of the olecranon. Partial avulsion of the olecranon requires surgical reattachment of the olecranon and triceps. Osteophytes should be removed to decrease pain and increase ROM.

In summary, overuse injuries to the elbow of young throwing athletes occur often. They can be seen not just in baseball pitchers but also in quarterbacks, tennis players, volleyball players and javelin throwers. Because the biomechanics of throwing are complex, the physical stresses can cause a group of pathologic entities to include the medial, lateral, and posterior aspects of the elbow. Preventing these types of injuries involves teaching proper throwing mechanics, keeping an accurate pitching count, predetermining a stopping point based on number of pitches thrown, and recognizing early warning signs and stopping once the pain starts. Although many of these injuries have been blamed on throwing curve balls, some studies have shown that a properly thrown curve ball causes no more injuries than the traditional fastball (11,12,13).

Orbital fracture/Hyphema

This is a 10 year old boy who presents to the ED with a chief complaint of a "black eye". He was playing in a roller hockey game when a hockey stick was swung high and struck him in the face. Although he was wearing a helmet, he was not wearing protective eyewear. He complains of severe eye pain and tenderness around his right eye. He states he is able to see out of his left eye, but not his right eye. There was no loss of consciousness or other associated injuries. He is able to walk in to the ED with his parents.

Exam: He is alert and cooperative in moderate discomfort. He has his right eye closed during most of the examination. A large area of ecchymosis is noted over the right periorbital region. The skin is intact with no active bleeding. He has severe tenderness over the inferior orbital region. There is moderate soft tissue swelling of the eyelids. He opens his eye with difficulty and apprehension. It is still difficult to see his eye because of the periorbital swelling. A small amount of blood is visible in the anterior chamber. He is able to sense light from the right eye, but his vision is blurry. Visual acuity is 20/50 in the right eye and 20/20 in the left eye. His EOMs are probably conjugate, but it is difficult to be certain because of the periorbital swelling. He does complain of some eye pain with EOM. Pupils are equal and reactive to light. Normal sensation to light touch over his right cheek is noted. Fluorescein examination shows no evidence of corneal abrasion. His left eye exam is unremarkable. The remainder of his face and head are without signs of injury.

It is decided not to order any plain film radiographs. A CT scan of the head with special views of the orbit is ordered, which shows a normal brain and skull. Coronal CT cuts show a fracture of the floor of the orbit with no muscle entrapment.

He is diagnosed with an orbital floor fracture and hyphema. Ophthalmology is consulted and further evaluation for the hyphema includes an intraocular pressure measurement, which is found to be normal. The patient and parents are told to limit his activity for the first 72 hours without television or video games. His immunization records are current and the patient is sent home with a narcotic analgesic and follow-up in 3 days. He recovers well with no diplopia or glaucoma complications. The next season, he is sporting a new pair of safety goggles to every game and practice. The community league also implements a new rule requiring protective eyewear.

Orbital injuries are common injuries in athletes, especially those in high-risk sports with high-speed objects such as sticks, bats, balls, pucks, or aggressive body contact. Eye injuries can almost always be prevented with protective eyewear. Males are at higher risk for orbital fractures because of their increased incidence of trauma.

The aperture of the bony architecture surrounding the eye does not allow an object with a radius of greater than 5 cm to penetrate the globe (14). Fractures of the inferior rim are the most common. The thin orbital floor (maxilla) and the medial wall (ethmoid) are the weakest portions of the orbit. Internal wall fractures with or without bony rim fractures can occur. A direct blow to the bony rim may not cause a bony rim fracture, but can be enough to increase intraorbital pressures (as the globe is compressed) resulting in a "blowout fracture" of the weakest point of the orbital wall, which is usually the floor of the orbit.

Anatomically the orbit consists of 6 facial bones (14,15):

1. Frontal bone: superior orbital ridge and upper medial orbital ridge
2. Zygoma: lateral orbital rim
3. Maxilla: inferior and lower medial rims
4. Lacrimal: medial rim separating orbital from nares
5. Ethmoid: medial wall and part of posterior wall
6. Sphenoid: posterior orbit

Related anatomical structures that can be injured during an orbital fracture include the optic nerve, periorbital fat, extraocular muscles, and the inferior orbital nerve.

The principle morbidity associated with orbital fractures is eye injury. These injuries are multiple and can include corneal abrasion, lens dislocation, iris disruption, choroid tear, scleral tear, ciliary body tear, retinal detachment, hyphema, ocular muscle entrapment, and globe rupture. The patient should be questioned regarding epistaxis or clear fluid from nares or ears, loss of consciousness, visual problems, hearing problems, malocclusion, and facial numbness or tingling. Other specific questions regarding the eye include the presence of diplopia, painful eye motion (entrapment or periorbital edema), photophobia, flashes of light (retinal detachment), or blurred vision (hyphema, vitreous hemorrhage, retinal detachment) (14,16,17).

When an injury near the eye occurs, a thorough exam should be performed. This includes visual acuity, inspection for abrasions, laceration, foreign bodies, changes in pupillary dimension or reactivity to light. Any change in visual acuity, blood in the anterior chamber, or change in the shape of the iris should warrant a consult with an ophthalmologist. The patient should also be inspected for asymmetry (proptosis or enophthalmos), corneal abrasions (fluorescein), nasal septum swelling/deviation, or clear rhinorrhea, which might be CSF. They should have their supraorbital ridge and frontal bone palpated for step-off fractures, and their hard palate and teeth palpated for stability. Evaluate the supraorbital, infraorbital, inferior alveolar, and mental nerve distributions for anesthesia.

These patients may present with ecchymoses, enophthalmos of the globe (sunken eye), vertical dystopia (a change in vertical position of the pupil in relation to the unaffected side), or numbness in the area on the ipsilateral cheek supplied by the infraorbital nerve. Although a "black eye" was once felt to be a relatively benign injury for which medical attention was often not sought, many instances of periorbital ecchymoses are due to orbit fractures.

Radiographically, routine facial views include Waters, Caldwell, and lateral projections (14,15,16). The Waters view is used for identifying inferior orbital rims, nasoethmoidal bones, and maxillary sinuses. The Caldwell projection provides the best view of the lateral rim and ethmoid bone. Lateral views may show air-fluid levels in the posterior maxillary sinus if the patient is lying supine. C-spine films are indicated if the patient complains of neck pain or if a suspected cervical injury cannot be ruled out.

Plain film radiographs have been largely replaced by CT scans. A CT scan with coronal views (done by tilting the patient's head in the CT ring, or angling the CT ring) is the most useful for evaluating inferior and medial walls of the orbit to diagnose a blowout fracture. In patients without ocular injury or entrapment, a CT scan is not necessary, however it is still more useful and diagnostically superior to plain film radiographs. CT may be helpful in identifying direct optic nerve involvement and the presence of retroocular edema or hematoma compressing the nerve.

A forced duction test can determine if limitation of ocular movements is due to entrapped soft tissues or to edema or contusion of a motor nerve or muscle. This is performed by anesthetizing the affected eye with topical anesthesia, grasping the sclera with a fine toothed forceps at the level of the inferior rectus muscle and moving the eye in a superior/inferior direction. If the globe moves easily, entrapment is unlikely (14). In clinical practice, this test is only rarely performed, since it is more convenient to merely wait to see if diplopia subsides with time. If the EOM function normalizes, then the EOM dysfunction is non-surgical (i.e., probably due to edema), while persistence of EOM dysfunction indicates the presence of muscle entrapment requiring surgical release.

Depending on the extent of injury, consultation with ophthalmology, ENT, oromaxillofacial surgery, or plastic surgery may be warranted. Acetaminophen or narcotic analgesics can be used for pain. NSAIDs are sometimes used, but these may cause bleeding, so it is preferable to avoid these especially if a hyphema is present. Tetanus prophylaxis may be indicated. Blowout fractures without associated injuries do not require hospitalization. Even patients with signs of entrapment may be discharged home because most entrapment resolves as the swelling goes down. They should; however, return if there is a change in visual acuity, increased pain, or flashing lights. If entrapment continues for 2 weeks, surgical intervention may be needed.

A hyphema is a collection of red blood cells in the anterior chamber of the eye. In the United States the incidence of hyphema occurs in 20/100,000 per year. Hyphema occurs more often in males (3:1) and is usually seen in a younger population, less than 30 years old (18). Trauma is the most common cause of hyphema, often seen in baseball or hockey athletes where a blunt compressive force hits the globe causing tears in the ciliary body, iris, and other structures in the anterior segment. Other non-sports related causes of hyphema include microvascular disease such as diabetes causing neovascularization, retinal ischemia, carotid stenosis, or iatrogenic (post-intraocular surgery), sickle cell disease, pupillary microhemangiomas, iritis, or intraocular tumors.

Hyphemas can be divided into microhyphema (RBCs detectable by microscopy only) or macrohyphema (visible even without the aid of a slit lamp). Corneal bloodstaining results from blood being forced into corneal endothelial cells. It is an ominous sign and signifies the need for surgical evacuation of the hyphema. Intraocular pressure increases secondary to RBCs and their blood products clogging the trabecular outflow meshwork. Secondary angle-closure glaucoma resulting from pupillary block can occur. This occurs when the clot completely occludes the pupil/lens interface, blocking the flow of aqueous from the posterior to anterior chamber. People of African or Mediterranean descent are prone to sickle cell hemoglobinopathy and thus have a higher incidence of developing glaucoma due to the rigidity of RBCs causing slower passage through the trabecular meshwork and elevated intraocular pressure (18).

Historical data important to illicit include the mechanism of injury, type of assaulting object, whether protective eye wear was used, ethnic origin, and past ocular history. The ocular examination should be certain to rule out a coexisting ruptured globe. Visual acuity, pupillary reaction, extraocular movement, signs of corneal staining, and intraocular pressure are also important aspects of the examination. An exophthalmometer can be used to look for exophthalmos related to ocular trauma.

Treatment includes both operative and nonoperative measures. In patients without an increase in intraocular pressure, behavioral modifications begin with limiting activities such as reading, which cause rapid shifts in the globe. Within the first 72 hours, rebleed is most common, therefore, this is the crucial time when children may have to be bedrested. It is especially important to limit activities in infants and children who watch television or play video games. Watching television from a distance greater than 10 feet limits the amount of extraocular movement. In hyperactive children, bilateral patching may be required to minimize activity level. Patching of the affected eye only, is not beneficial because movement of the contralateral eye will cause movement of the affected eye (18). In general, patients should keep activity to a minimum for at least the first 5 days to prevent a rebleed.

Patients with concurrent elevation in intraocular pressure (IOP) may require both topical and oral ocular hypotensive medications. Persistent elevated IOP can cause optic nerve damage. Topical beta blockers decrease aqueous production and IOP. Osmotic diuretics decrease IOP by reducing vitreous volume. In general, patients with an IOP higher than 30mm Hg (or 24mm Hg in sickle cell patients) should receive IOP lowering medication. Cycloplegics and topical steroids, which treat associated iritis may also be used. Cycloplegics are anticholinergic agents that block the response of the iris sphincter muscle and ciliary body to cholinergic stimulation, causing paralysis of accommodation (cycloplegia) and pupillary dilation (mydriasis). Antifibrinolytics such as aminocaproic acid may be used to prevent recurrent hyphemas, but this medication may cause serious adverse effects. Carbonic anhydrase inhibitors decrease aqueous production and IOP.

Supportive treatment including wearing a metal shield or glasses is recommended. Head elevation keeps the central cornea and pupillary aperture free of blood. Patients should also avoid aspirin to prevent further bleeding.

The most severe complication is a rebleed (usually seen in the first 72 hours). Hyphema resulting from a rebleed is usually more extensive than the initial trauma. Rebleeding may present as a total hyphema with blood filling the entire anterior chamber. This is called an "8-ball" hyphema (18). Such a significant hemorrhage leads to elevated IOPs and corneal blood staining. Hemosiderin collects in the stroma causing a yellow appearance in the cornea. This usually resolves spontaneously in a few years. Glaucoma may lead to optic nerve atrophy. This is especially seen in sickle cell patients.

Prognosis depends on the size of the hyphema. Patients with a small-sized hyphema can be treated with simple management and have a good prognosis. Total hyphema is difficult to treat and visual outcome is poor. Promoting public awareness in parents regarding eye safety for their children is important but often difficult, especially in adolescents when image is important. Just as wearing a helmet in football is mandatory, wearing goggles in high-risk sports should become obligatory.

Prevention of orbital and ophthalmic injuries includes wearing safety glasses or goggles in those who participate in high-risk sports in which balls, bats, or pucks are used.

Questions

1. What is the definition of Osgood-Schlatter's disease?
2. Who is Osgood Schlatter disease and Sever's disease commonly seen in?
3. Is it common to have Osgood-Schlatter disease in both knees?
4. What is the definition of Little League elbow?
5. What types of athletes are subject to Little League elbow besides baseball pitchers?
6. What is a blowout fracture of the orbit?

7. What is the best imaging technique to identify a blowout fracture?
8. How can you reduce elevated intraocular pressure?
9. What is the most severe complication of a hyphema and how can you prevent this?

Answers to questions

1. Traction apophysitis of the tibial tuberosity.
2. Osgood-Schlatter: Usually older children or adolescents with male: female of 3:2. Those who do forceful contraction of the quadriceps (jumping sports such as basketball and volleyball). Sever's: Athletes who play with cleats (excess grip in the ground) who push hard while running; also soccer and basketball players.
3. It is more common on the left, however, about 25% have it bilaterally.
4. The term "little league elbow" is used to describe a group of pathologic entities in and around the elbow joint in young throwers secondary to overhead throwing. Valgus stress results in lateral compression and medial traction on the elbow leading to the many types of injuries described in the text.
5. Tennis serving, football quarterbacks, javelin throwers, volleyball spikers.
6. A direct blow to the bony rim causing enough of an increase in intraorbital pressures to fracture the thin interior bones (usually the orbital floor).
7. CT scan, with special coronal views.
8. Topical beta blockers, cycloplegics, osmotic diuretics, carbonic anhydrase inhibitors.
9. The most severe complication is a rebleed. Limiting physical activity in children within the first 72 hours is important. This includes bedrest, no television or videogames, and bilateral eye patching.

Chapter XX.1. Puberty
Sherrel L. Hammar, MD

This is a 15 year old boy who is seen by his primary care physician for short stature and delayed sexual development. His past medical history is unremarkable except for asthma during early childhood, which has been well controlled. He is currently on no medications. He is an average student currently in the 9th grade and is the smallest in his class. He has been harassed by older classmates because of his size. His parents are concerned because Jim is becoming withdrawn and a "loner".

PMH: Pregnancy and delivery were uncomplicated. Birth weight and length were 3.86 kg (8.5 pounds) and 51 cm (20"), respectively. His HC was 35 cm. His immunizations are current.

Family History: His mother is 48 years old and in good health. Her height is 167 cm (50th %tile). Her menarche began at age 13.0 years. His father is 51 years old, also in good health. His height is 184.0 cm (75th %tile). His father's onset of puberty is not known but he was shaving regularly by age 15. There is one older male sibling age 18 who is in good health. His puberty began at age 11 years. There is no history of smoking, alcoholism, mental illness, drug abuse or learning problems in the family.

Exam: VS T 37.1, P 110, R 32, BP 100/60. Ht. 158 cm (3rd %tile), Wt. 42.0 kg. (10th %tile). He is pale and anxious but cooperative. His HEENT exam is normal. His chest is clear. Heart regular, no murmurs. His pulses are symmetrical and equal. There are no masses or areas of tenderness in his abdomen. Genitalia: Normal circumcised phallus, SMR (Tanner) pubic hair stage 1, genital stage 2. His testes are firm, 2.5 cm in length and 4 ml in volume. His scrotum is reddened and stippled. The remainder of his physical exam is unremarkable.

Lab: CBC: Hgb 13, WBC 9.5, normal differential, platelets 350,000. UA is normal. Bone Age: (left hand and wrist) 12.0 years. LH and FSH are decreased but normal for SMR stage 1-2.

Impression: Constitutional Short Stature, Delayed Puberty

Clinical Course: Over the next 6 months, pubic hair growth is noted. His testes enlarge to 3-4 cm in length and his height increases by 5 cm.

Puberty refers to the biological changes that lead to reproductive capability while adolescence generally refers to the psychosocial changes that occur. The sequence of events that occur during puberty are generally fairly predictable. The timing of these events, however may be highly variable.

Sexual Maturity Ratings (SMR), also known as Tanner stages, utilize pubic hair stages and breast development stages for females, and pubic hair stages and male genital development stages for males. Table 1 categorizes the pubic hair SMR stages for males and females. Table 2 categorizes female breast development SMR stages. Table 3 categorizes male genital development SMR stages, which are based on testicular size.

Table 1. SMR Pubic Hair Stages: Mean chronologic age (CA) and bone age (BA) in males and females (in years)

	Male CA	Male BA	Female CA	Female BA
I. None				
II. Sparse	12.2	13.5	10.4	11.5
III. Coarse, easily visible	13.5	14.2	12.2	12.2
IV. Confined to suprapubic area	14.2	14.2	13.0	13.2
V. Adult type on medial thighs	14.9	14.0		

Stage II-V = 2.7 yrs avg.

Table 2. SMR Female Breast Stages: Mean chronologic age (CA) and bone age (BA) in females (in years)

	CA	BA
I. No development		
II. Bud	10.9 (8.5-13.3)	10.5
III. Breast tissue beyond areola	12.2	12.0
IV. Secondary mound	13.2	13.5
V. Adult	14.0	15.0
Peak height velocity	12.2 (10.2-14.2)	12.5
Menarche	12.7 (10.5-15.5)	

Stage II to Stage III = 1.3 yrs avg.
Stage III to Stage V = 2.4 yrs avg.

Table 3. SMR Male Genital Stages. Mean chronologic age (CA) and bone age (BA) in males (in years)

	Testicular Length	Testicular Volume	CA	BA
I.	<2.5cm	<4mL		
II.	>2.5 cm	4-6 mL	11.2 (9.2-14.2)	11.5 (9.0-13.5)
III.	>3.0cm	6-10 mL	12.9	13.2
IV.	>4.0cm	10-15 mL	13.8	14.5
V.	>5.0cm	>15 mL	14.7	
Peak height velocity			13.9 (12.3-15.5)	14.5

Females initially show a deposition of adipose tissue and widening of the pelvis and changes in the contour of the hips. The first clinical sign is thelarche (the appearance of breast buds) and adrenarche (the appearance of dark straight pubic hair over the mons veneris, also called the mons pubis). These changes identify a SMR stage (or Tanner stage) II (see tables 1 and 2). Breast development over the next 4 years will proceed from breast stage II (secondary mound of breast tissue to adult breast stage V). Development of pubic hair starts about 1 year after breast budding and may take place over a 1.5 to 3.5 year period. During SMR stage 3, girls experience a very rapid increase in their height. The peak of their height growth (PHV=peak height velocity) should take place before the onset of menarche in most girls. Menarche occurs six months after the PHV and just prior to stage IV of breast development. Most western girls achieve their menarche around 12.4 to 12.8 years of age. African-American girls are maturing earlier.

Puberty in boys also follows a regular sequence of events, but lacks the clear cut landmarks such as breast development and menarche. In the male, the pubertal growth spurt is a late event starting about two years later than in females. The onset of pubertal changes however, are only about 6 months later than in females (see tables 2 and 3). Enlargement of the testes indicates the transition from genital stage I to Stage II, beginning at an average age of 11.5 years. Penile growth occurs about one year later. This is usually preceded by the appearance of pubic hair at the base of the phallus progressing through pubic hair stages II to V. Pubic hair stage III is followed by the appearance of axillary and facial hair growth. Testicular growth is completed anytime between 13.5 and 17 years of age. Growth of the penis reaches a SMR (Tanner) stage V between 12.5 and 16.5 years of age. Nocturnal emissions (wet dreams) may first appear during SMR stage III.

There is a common misconception that the difference between the onset of puberty in males and females is 2 years. This applies only to the growth spurt and not to pubertal (SMR) changes.

The patient described above is not only short statured but is delayed in his pubertal development. On the basis of the physical findings described, he would fit a presumptive diagnosis of constitutional delay of growth and maturation.

Boys with a constitutional delay of growth and maturation, usually have a normal birth weight and length, and progress along their normal growth centile for the first several years of life, following which, they begin to deviate and grow at or below the 3rd percentile throughout childhood. At the time when normal puberty should begin, there is often a marked fall off in growth (pre-adolescent dip) due to a diminished secretion of growth hormone. This transient fall in growth hormone is probably due to failure of sex hormone production and stimulation.

Skeletal maturation is usually delayed. When the bone age eventually reaches the skeletal age when puberty is expected, it is likely that early signs of sexual maturation will also appear, which is the stage of testicular enlargement (SMR genital stage II).

Often a familial pattern of pubertal delay is reported. The incidence of affected males is about 10%. Patients with constitutional delay in growth and maturation usually do not reach their "mid parent" or predicted height. Catch up growth is largely dependent upon the delay of bone maturation at the time of diagnosis, indicating that there may be a genetic or familial component to their short stature.

In most males, a watch and wait approach is indicated for six to twelve months. The patient presented could have been prescribed a short term course of testosterone or gonadotropins in order to stimulate sexual maturation and growth hormone production. In general, such treatment has been reserved for teenagers with significant behavior or psychological (self image) problems due to their delayed puberty.

In most cases, the evaluation of a patient suspected of delayed sexual maturity can be conservative. A thorough family history, physical examination, and assessment of sexual maturity stage will often show signs of early pubertal changes. The bone age is usually delayed and reflects the physical delays and the height age of the patient (the age corresponding to the 50%ile of the patient's actual height). Gonadotropins usually reflect the sexual maturity status of the patient. A chromosomal karyotype is indicated for all short statured girls who are delayed (for possible Turner syndrome) and for boys who are tall with small soft testes with or without delayed sexual maturity (Klinefelter's syndrome).

Questions

1. What is the first objective physical sign of puberty in the male? In the female?
2. The difference in age between the initiation of pubertal (sexual) changes in the male and female is how many months?
3. What is the definition of delayed puberty? Precocious puberty?
4. What is the height age?
5. The best indicator of the biological age of the individual is?

References

2. Kreipe R E, McAnarney ER. Adolescent Medicine. In: Behrman RE, Kliegman RB (eds). Essentials of Pediatrics, 2nd edition. 1994, Philadelphia: W.B. Saunders & Co., pp. 215-229.

Answers to questions

1. Enlargement of the testes measuring greater than 2.5 cm in length and scrotal changes are the first signs of puberty in the male. The appearance of breast buds in the female indicate the onset of puberty.

2. There is approximately 6 months difference in the age of onset of sexual maturation in the female vs. the male.

3. Puberty is delayed when there is no sign of pubertal development by age 13 years in girls and 14 years in boys. Precocious puberty is secondary sexual development occurring before age 9 years in boys or 8 years in girls.

4. Height age is the age at which the height of the individual is equal to the height of 50 percent of a reference standard population by age and gender. This is done by taking the patient's height and finding the age, at which this height is the 50th percentile on an appropriate height grid.

5. The best indicator of the biological age of the individual is the skeletal age (bone age).

Chapter XX.2. Anabolic Steroids
Robert J. Bidwell, MD

This is a 17 year old male who has come to see you for his annual well-teen sports health evaluation. As with all your patients, you meet with him alone and discuss his physical and psychosocial health and development over the past year. He acknowledges no significant physical illness and feels he is developing appropriately. He reports getting along well with his parents and he is generally a "B" student at school. He is involved in his school's track team and also belongs to a paddling club. He denies any substance use. He is sexually active with his 16 year old girlfriend and reports using condoms consistently. He denies any major mood changes or suicidal ideation. His physical exam was completely normal.

Although he is unaware, you recently received a call from his father who had found pills in his son's room. He believes they may be steroids since he had overhead his son talking with other teammates about someone dealing in steroids at school. He asks you to bring this up with his son. When you specifically address steroid use, he admits that he and several of his friends on the track team have been using steroids regularly for the past 4 months. He believes it has increased his muscle mass and improved his appearance but admits he knows little about the potential side effects of steroid use.

Anabolic steroids, which are synthetic derivatives of testosterone, have legitimate uses in the treatment of male hypogonadism, chronic illness and other starvation or catabolic states. However, they also belong to a group of drugs known as "performance enhancers" (1). Their first use among athletes was in the early 1950s, most notably among male and female Soviet athletes competing internationally. The anabolic (tissue-building) effects of these steroids come from their binding to specific cellular receptors resulting in increased protein synthesis. In addition, they have an anti-catabolic effect by competitively binding to glucocorticoid receptors. The result is increased lean body mass (muscle) as well as increased muscle strength, especially if accompanied by a rigorous exercise regimen and adequate diet. These, in turn, can result in enhanced athletic performance. Their use is most common in football, wrestling, basketball, track and field, swimming, weight training and bodybuilding. Performance also may be enhanced through increased aggressiveness and endurance resulting from steroid use. Anabolic steroids do not improve and may actually limit aerobic capacity, agility and athletic skill. Other "performance enhancers" include human growth hormone (hGH), stimulants, diuretics and a variety of protein, vitamin and mineral supplements. Blood-doping (intravenous infusion of blood) is another technique used by athletes to improve performance. Some male adolescents take anabolic steroids not to enhance athletic performance but to improve their physical appearance through increased muscle mass and definition.

Studies of anabolic steroid use among high school students show a prevalence rate of 5-11 percent for males and 1.4-2.5 percent for females (2). A 1998 survey of junior high school students revealed that nearly four percent had used anabolic steroids (3). During the decade of the 1990s, anabolic steroid use among both males and females has increased (4).

Anabolic steroids can be taken orally or injected intramuscularly. Often both routes are employed simultaneously, a process known as stacking. Another pattern of use is megadosing, with doses up to forty times greater than therapeutic doses. Pyramiding is a third technique in which doses are increased then decreased on a cyclic basis.

Anabolic steroids are not difficult to obtain, even for high school students. Sources of the drug include friends, coaches, veterinarians and physicians. Anabolic steroids can be purchased over-the-counter in many foreign countries and brought back into the U.S. for distribution.

The use of anabolic steroids can result in increased muscle mass and strength. These attributes are highly desired by the adolescent user. However, many negative effects of chronic anabolic steroid use have been documented (Table 1 below). These primarily relate to its effects on growth and the hepatic, cardiovascular, and reproductive systems. Anabolic steroids can also have serious effects on a patient's psychological state, typified by violent mood swings ("roid rage"). Oral preparations are more hepatotoxic than injected forms, but with injection comes the risk of Hepatitis B and HIV (if contaminated or shared needles are used). Studies have shown that as many as 25 percent of users who inject steroids have shared needles (5). Anabolic steroid users are also more likely to use other drugs and experience their attendant risks. Most side effects of steroid use disappear on discontinuation of use. However, premature epiphyseal closure is irreversible and peliosis (purpura), hepatoma, baldness, clitoromegaly and voice changes will likely persist.

Because anabolic steroid use can have multisystemic effects as described above, the differential diagnosis would at first appear to be a lengthy one. However, a history of athletic involvement in sports where muscle mass is important coupled with an unusual degree of muscle development should place anabolic steroid use at the top of the differential diagnosis list. Testosterone-producing tumors may have masculinizing effects on both males and females, but usually result in muscle-wasting and other signs of chronic illness.

Once an adolescent who is using anabolic steroids has been identified, the pediatrician assumes the role of educator and counselor. Traditional drug treatment programs do not treat youths using anabolic steroids unless this use is part of a broader spectrum of substance use. Guidelines for the approach to the adolescent using anabolic steroids have been established by the American Academy of Pediatrics (2). In general, counseling should be provided in a confidential and non-judgmental manner. It is appropriate to acknowledge to the patient that anabolic steroids may, in fact, lead to increased muscle mass and strength. It is also appropriate to express an understanding of why athletes and others might want to increase muscle mass, strength and definition. This honest discussion of the "benefits" of steroid use must then be balanced with an honest review of the risks of use. Simply citing the negative effects is both dishonest and diminishes the physician's credibility in the adolescent's eyes. There is no evidence that scare tactics work in diminishing steroid use since the drive to excel athletically is so strong.

Pediatricians also have a role in prevention. At the individual patient level, screening questions and anticipatory guidance regarding anabolic steroid use should be a part of each well-teen visit. Adolescents who present with signs or symptoms suggestive of steroid use, even if not related to the presenting complaint, should be asked specifically about the possibility of anabolic steroid use at acute care visits. Adolescents can be counseled about alternatives for improving their strength and appearance through healthier diets and appropriate physical training. Discussions about the concept of "fair play" and the satisfaction coming from relying on one's natural abilities and hard work are reasonable, but will be counterproductive if they sound like lecturing.

At a community level, pediatricians can educate parents, schools and coaches about the prevalence and risks of anabolic steroid use among students. Drug screening programs at a school or team level are impractical and expensive.

Table 1. Negative effects of anabolic steroid use (2).

Musculoskeletal: premature epiphyseal closure, short stature, ligament and tendon injuries.
Hepatic: benign and malignant tumors, toxic hepatitis, peliosis hepatis, decreased HDL, increased LDL and cholesterol.
Cardiovascular: hypertension, stroke, thrombosis.
Male reproductive: decreased testosterone production, decreased testicular size, impotence, enlarged prostate.
Female reproductive: breast atrophy, clitoromegaly, menstrual changes, teratogenicity.
Other: deepened voice, acne, alopecia.
Psychological: severe anger outbursts, hallucinations, paranoia, anxiety, addiction.

Questions

1. True/False: Anabolic steroid use is usually effective in enhancing athletic performance.
2. Name the two most common routes of anabolic steroid administration. Which is the more hepatotoxic route?
3. In an adolescent using anabolic steroids who is at Sexual Maturity Rating (Tanner Stage) II, what is a major danger involving the musculoskeletal system?
4. In which patients should pediatricians consider the possibility of anabolic steroid use?
5. What is the role of the pediatrician in addressing anabolic steroid use?

Answers to questions

1. True. One of the reasons it is difficult to dissuade competitive athletes from using anabolic steroids is that it can, in fact, result in increased lean body mass, muscle strength, and aggressiveness. These may, in fact, contribute to enhanced athletic performance.
2. Anabolic steroids may be taken orally or injected intramuscularly. Oral steroids are more hepatotoxic.
3. An adolescent in early puberty who uses steroids risks premature epiphyseal closure with resultant shorter stature than otherwise would be predicted.
4. Anabolic steroid use should be considered and addressed with all adolescent patients, male or female, athlete or non-athlete. Particular attention should be paid to those adolescents who have greater than expected muscle-mass development or in females with signs of masculinization.
5. On an individual level, pediatricians should, without lecturing, initiate an honest discussion of the risks and benefits of steroid use. They should ask all adolescents, and especially those with signs and symptoms of steroid use, about the possibility of using steroids. They also have a role in educating parents, teachers and coaches about the prevalence and dangers of anabolic steroid use.

Chapter XX.3. Substance Abuse
Anthony P. S. Guerrero, MD

This is a 16 year old female brought to the emergency room by her father, with the chief complaint that he thinks his daughter is using drugs and wants her to get treatment. The father reports that she has often been acting "high," with sleeplessness for several days in a row, unusual euphoria, pressured speech, increased activity (e.g., cleaning the bathroom), suspiciousness, and some aggressive behaviors. The pediatric resident begins to advise him that this behavior is typical of cocaine intoxication. However, with encouragement from the supervising emergency room physician, the resident gathers further history. She uses "ice," or "batu", roughly 2-3 times per week, smoking it by pipe. She obtains the drug from her friends. She admits to occasional marijuana use and weekend drinking of alcohol, without any history of blackouts, hallucinations, or incapacitating withdrawal symptoms. Although previously an above average student, she has, for the past year, been truant from school and is failing most of her classes. She has also run away from home on several occasions. She gives vague answers when asked about sexual history.

Her past medical history is otherwise negative. Family history is significant for a history of alcoholism and a possible psychotic illness. Her parents are divorced. There is no history of abuse or domestic violence.

Exam: VS T37.5, P 110, R18, BP 130/80. She is somewhat restless and guarded, with poor eye contact and brief answers. HEENT significant for slightly dilated pupils. Heart shows regular rhythm and elevated rate. Pelvic examination is refused. The remainder of physical examination is normal.

Labs: Urine toxicology positive for methamphetamine, negative for others, including alcohol. Electrocardiogram is significant for sinus tachycardia, otherwise normal.

Clinical course: Psychiatric consultation is obtained, and patient is briefly admitted involuntarily for psychiatric inpatient care. Diagnoses: Methamphetamine dependence and (via pelvic examination eventually performed by the consulting pediatrician) Chlamydia cervicitis. She is discharged to an adolescent substance abuse treatment program.

Substance use is common among adolescents in the United States (1). By the end of high school, 90% of adolescents have tried alcohol and 40% have tried an illicit substance. Among 17 to 19 year olds, the lifetime prevalence of alcohol abuse and dependence (beyond just experimentation) is 32%, while the lifetime prevalence of drug abuse and dependence is 10%. Consequently, pediatricians will often need to be involved in the evaluation and management of: substance use disorders, medical problems related to substance use, and/or other medical problems which may go under recognized or under managed in this high risk population.

Substance abuse is defined as a maladaptive pattern of substance use with clinically significant levels of impairment or distress, while substance dependence requires a substantial degree of substance use involving withdrawal, tolerance, and loss of control over use (2). Risk factors for these substance use disorders include genetic/family predisposition (e.g., with positive family history); exposure to substance use via family or peers; childhood psychiatric conditions; and poor academic performance. The dopamine reward pathway has been implicated in the pathophysiology of substance addiction (3). Contrary to what some may believe, there is no evidence that stimulant treatment of Attention Deficit Hyperactivity Disorder increases risk for substance abuse. In fact, a recent study suggests otherwise, possibly because of the benefits of treatment on behavior and academic performance (4).

Alcohol and sedatives (benzodiazepines, barbiturates, and related compounds) are grouped together because they facilitate binding of gamma amino butyric acid (GABA), an inhibitory neurotransmitter, to neurons. Benzodiazepines and barbiturates may sometimes be referred to as "downers," and are often available in pill form.

Cocaine and methamphetamine both work via an increase of catecholamines, leading to the psychiatric and general physical symptoms as described in the case above. Of interest, chronic use of methamphetamine, via toxic effects on the brain, may also result in a chronic psychotic disorder, even beyond cessation of its use. Patients who present with this syndrome may, on functional brain imaging, show a "Swiss cheese" pattern, with significant areas of hypo-functioning. These drugs may be inhaled, smoked, or (less commonly) taken intravenously.

Hallucinogens, including D-lysergic acid diethylamide (LSD) and various others (mostly from plants) exert their hallucinogenic effects via serotonin receptors. These may be administered via various routes. Of interest, "ecstasy", or 3,4-methylenedioxymethamphetamine, works via the catecholamine and serotonin systems and may produce amphetamine-like effects as well as feelings of closeness to people and sensory sensitivity. Symptoms of catecholamine excess as well as dehydration are possible complications of its acute use. This drug may be taken orally, inhaled, or injected intravenously.

Inhalants, including glue, paint thinner, and other solvents, likely cause disruption of neuronal and other cell membranes, leading to potential complications of encephalopathy and cardiac arrhythmias. These agents, being relatively accessible, may be abused by younger adolescents.

Marijuana exerts its intoxicating effects via tetrahydrocannabinoid receptors in the brain. It is most commonly smoked.

Opioids, including heroin and controlled prescription medications, working via the opioid receptors in the brain, may result in respiratory depression, miosis, analgesia, and constipation during intoxication and autonomic hyperactivity, gastrointestinal hyperactivity, and significant discomfort during withdrawal. Heroin use may be associated with any of the medical complications (e.g., HIV disease, endocarditis, localized skin infections) associated with intravenous drug use and injections using contaminated needles.

Phencyclidine, or PCP, exerts its effects via the receptor of N-methyl-D-aspartate (NMDA), an excitatory neurotransmitter, and other receptors. Intoxication may result in diminished responsiveness to pain, severe muscle rigidity, and hyperthermia. It is most commonly smoked, but may be administered via other routes as well. Because it is more rapidly excreted in acidic urine, acidifying agents may be considered in detoxification.

Other drugs: Gamma-hydroxy-butyrate, or GHB, can have the extremely serious side effects of seizures and coma. It exerts its effects via the dopamine and opioid receptors. It is often available in liquid form.

The pediatrician must always consider substance use as a possibility, and must be prepared to manage any life threatening effects of either intoxication or withdrawal. All substances can potentially cause acute allergic and/or other serious idiosyncratic reactions, which should be managed accordingly, with priority attention always given to airway, breathing, and circulation.

Intoxication with alcohol, especially in a relatively alcohol naive adolescent, may result in a life threatening respiratory depression. Hence, medical admission with close monitoring of respiratory status may be indicated. Likewise, withdrawal from alcohol or other sedatives (e.g., benzodiazepines, barbiturates) may also be life threatening, although delirium tremens is fortunately not as common in adolescents as it is in older adults. Careful monitoring of vital signs, prescription of thiamine and multivitamins, and implementation of

benzodiazepine-based protocols for management of withdrawal (5) are indicated. To assess withdrawal risk, the clinician should take a careful history to include pattern/regularity of use, timing of last use, severity of past withdrawal symptoms, etc.

The autonomic hyperactivity resulting from cocaine or methamphetamine intoxication may lead to life threatening arrhythmias or ischemia of the brain, heart, or intestines. Close cardiorespiratory monitoring and an electrocardiogram may be indicated.

Acute agitation, delirium, and/or psychosis resulting from cocaine, methamphetamine, hallucinogen, or marijuana intoxication may be managed using a quiet, supportive setting and frequent reorientation to person, place, and time. Although substance use may result in altered mental status, general medical conditions (e.g., intracranial bleed) must always be ruled out, as they unfortunately do occur in youth who use substances. Benzodiazepines may be used for agitation. High potency antipsychotics (e.g., haloperidol) may be used for symptoms of delirium or psychosis with agitation. However, antipsychotics should be avoided in cases of alcohol or sedative withdrawal, as these medications may lower the seizure threshold (in such cases, benzodiazepines should be used). Low potency antipsychotics (e.g., chlorpromazine) should not be used in cases of PCP intoxication, as the additive anticholinergic effects may worsen the delirium.

Because youth with substance use disorders are often at risk for poor health, the physician should perform a careful history, physical examination, and laboratory evaluation and thoroughly address any other concerns that may be detected. In addition to addressing physical health concerns, the physician should employ the bio-psycho-social approach (discussed in the chapter on suicide and violence) to comprehensively care for the adolescent with a substance use disorder, and should have a low threshold for consulting a child and adolescent psychiatrist.

Often, the primary care physician can be a credible source of information about the long-term side effects of substance abuse, such as liver damage from alcohol use, serious "brain damage" from inhalant use, and lung cancer from tobacco or marijuana use. Also, the primary care physician may have significant familiarity with the family history, and can be helpful in "personalizing" the information for the adolescent (e.g., discussing relatives who died of medical sequelae of substance abuse or whose lives were destroyed by addiction).

One substance abuse problem commonly encountered and managed by the primary care physician is cigarette smoking and nicotine dependence. The physician should become comfortable with assessing stages of motivation (e.g., contemplation versus pre-contemplation) and practicing the 5 A's of asking (about tobacco use), advising (quitting), assessing (willingness and possible barriers), assisting (e.g., setting a quit date), and arranging (follow-up) (6).

Above all, physicians should be compassionate and professionally responsible towards adolescents with substance use disorders. They should recognize substance abuse as a medical condition and should respect the seriousness of its complications and co-morbidities.

Questions

1. The prevalence of alcohol abuse and dependence among 17 to 19 year olds in the United States is closest to: a) 1%, b) 10%, c) 30%, d) 50%, e) 90%
2. True/False: Stimulant treatment of Attention Deficit Hyperactivity Disorder increases risk for future substance abuse.
3. True/False: Death may occur during intoxication with alcohol or an illicit substance.
4. True/False: Death may occur during withdrawal from alcohol or an illicit substance.
5. Match the following substances with their associated syndromes:

a. Barbiturates	i. Severe encephalopathy
b. "Ecstasy"	ii. Lung cancer
c. Inhalants	iii. Rhabdomyolysis during intoxication
d. Marijuana	iv. Wanting to touch/be touched during intoxication.
e. Methamphetamine	v. Seizures during withdrawal
f. PCP	vi. "Swiss cheese" appearance on functional brain imaging

Chapter XX.4. Adolescent Suicide and Violence
Anthony P. S. Guerrero, MD

This is a 17 year old male who is brought to the emergency room by his family. Earlier, he got into an argument with his girlfriend and began to ingest several ibuprofen tablets in front of her. He says he didn't really premeditate the act, and he denies having written a note. He has been feeling very depressed and upset for the past several months. Family members also note that he has been moody and explosive. In fact, one week ago, he was referred to the school based police officer because he threatened to go on a shooting rampage using his family's hunting rifle. He has been doing worse in school for the past semester and is at risk of not graduating. Reportedly, his teachers have complained that he is disruptive with his non-stop talking and "giggliness". His family suspects that he may be using marijuana. Apparently, he had been referred for a mental health evaluation at the school, but his family decided not to keep the appointment.

His past history is otherwise negative. Family history is significant for alcohol abuse in the biological father, who tended to use corporal punishment on the children.

Exam: His vital signs, including blood pressure, are normal. He is superficially cooperative, though restless and fidgety. His eye contact is poor, and he frequently looks to the side during the conversation. Speech is mumbled and rapid. Affect is angry. He thinks that what he did (with the ibuprofen) was "stupid" but does not elaborate very much. Even though he recognizes his difficulties in school, some of his plans seem a bit unrealistic (e.g., becoming a decorated fighter pilot in the military). Physical examination is otherwise unremarkable.

Laboratory studies: Urine toxicology screen positive for cannabis only. Other screening labs, including tests of thyroid function, are normal.

Psychiatric consult obtained. Provisional diagnoses: Bipolar disorder (not otherwise specified), marijuana abuse. A decision is made to admit the patient for psychiatric care. After discharge, it is discovered that his school is very nervous about accepting him back, for fear that he might become violent again.

In the United States, homicide and suicide are the second and third leading causes of death among teenagers (1). Consequently, all health professionals caring for children and adolescents must give high priority to the prevention, early identification, and early referral for these significant causes of morbidity and mortality. For the purposes of this chapter, suicide and violence will be considered together, as violence to others is often a risk factor for violence to self.

Major risk factors for completed suicide in adolescents include previous suicide attempts, mood disorders, and substance abuse (2). Hence, primary care physicians should be attentive to signs of substance abuse (discussed in another chapter) and possible symptoms of depression, which include a persistently sad mood, lack of enjoyment, sleep/appetite/energy level disturbances, and/or difficulties concentrating and performing adequately in school. Youth who present with a major depressive episode have about a 30% risk (3) of going on to develop a bipolar disorder, which often has a "mixed" (e.g., depressive and hypomanic/manic symptoms coexisting) and/or "rapid cycling" presentation in this age group. Hence, other symptoms which should lead the physician to suspect a mood disorder include irritability, "mood swings," angry outbursts, grandiosity, rapid speech, increased motor activity, and impulsive behavior (which the patient described above seems to have). Often, these youth present in juvenile correctional and other legal settings and would otherwise be diagnosed as having a "conduct disorder". Biederman et al's findings (4) of significant co-morbidity (i.e., correlation) between "conduct disorder" and treatable mood disorders should prompt the primary care physician to carefully consider mood disorders in any "delinquent" adolescent, and to appropriately refer for psychiatric care.

All physicians should be familiar with screening for suicidality and assessment of the suicidal patient. Suicidality is often assessed in the context of routine health maintenance examinations for teenagers. One may enhance the sensitivity of inquiry about suicidality by "leading into" the topic and then definitively asking the questions: e.g., "How do you feel most of the time? Are there ever any times when you would say you feel depressed? How intense does it get? Does it ever get to the point when you think that life isn't worth living anymore? Did you ever make a plan to end your life? Do you have thoughts about ending your life right now?" In the patient who is acutely suicidal, the following items are important to assess: previous attempts, command auditory hallucinations (voices encouraging suicide leading to the attempt), intoxication during the attempt, stressors, and symptoms of mood disorders.

In the patient who has attempted suicide (such as the patient described above), additional items of value are: premeditation, note writing, giving away of objects, setting/context of suicide attempt, how discovered (e.g., in front of others versus all alone, with no expected chance of discovery), appreciation of lethality (e.g., might have thought that ibuprofen could kill instantly; or might have thought that iron pills were harmless), how one feels now, and what has changed since the suicide attempt.

The history and physical should include a thorough psychosocial history (including exposure to violence and abuse) and should be complete enough to rule out any medical conditions which could manifest as a mood disorder (e.g., thyroid disorders, EBV infections, etc.)

The risk factors for, and the assessment of violence, are similar to what is described above (e.g., past violence, intoxication during violence, etc.). There is also a significant emphasis, nationally, on the prevention of violence. The Commission for the Prevention of Youth Violence (5) identifies prevention of youth violence as a high priority, and lists several objectives: 1) to support the development of healthy families; 2) to promote healthy communities; 3) to enhance services for early identification and intervention for children, youth, and families at risk for or involved in violence; 4) to increase access to health and mental health care services (which the family described above had difficulty with); 5) to reduce access to and risk from firearms for children and youth (a priority for the patient described above); 6) to reduce exposure to media violence; and 7) to ensure national support and advocacy for solutions to violence through research, public policy, legislation, and funding. The American Academy of Pediatrics (1) also emphasizes avoidance of corporal punishment (which could have been important for this case).

Management of a case such as the one described above, mandates a comprehensive bio-psycho-social approach. From a biological perspective, the patient may have a genetic predisposition to a mood disorder amenable to a mood stabilizer medication. However, the patient also uses substances which could affect mood; therefore, maintenance of a drug free state is also important for treatment. Other medical conditions should be ruled out. From a psychological perspective, recent stressors may include academic difficulties and difficulties in his relationship. Furthermore, poor coping skills and exposure to family violence may increase his risk of committing a violent act. He may therefore benefit from: an educational evaluation to identify and address any possible learning difficulties; supportive psychotherapy; and training in anger management. From a social/cultural perspective, dysfunction in the home may have led him to seek support from substance abusing peers. Culturally sensitive services for the family would also be key to effective treatment, keeping in

mind the possible language and cultural barriers to timely mental health intervention. The family and school should be educated on community resources for violence (e.g., suicide and crisis hotline). Finally, firearms and other potential agents of violence should be removed from the home.

Understandably, even with optimal, comprehensive management, this will be a significant challenge for families, schools, and communities. Prevention is therefore an important task for all healthcare professionals.

Questions

1. True/False: Mood disorders should be seriously considered in all teenagers with disruptive behaviors and decline in academic performance.
2. True/False: Otitis media, meningitis, and pneumonia are the top leading causes of death in children and adolescents.
3. True/False: The comprehensive bio-psycho-social approach to suicide/violence prevention is a potentially life saving skill that all physicians should practice.
4. True/False: Physicians should liberally use antidepressants to treat any child or adolescent who appears depressed.
5. True/False: A teenager who intentionally ingests a large yet non-toxic dose of a non-toxic medication may still be at significant risk for suicide.
6. True/False: Physicians caring for teenagers with disruptive behaviors should attempt to minimize contact with the teenagers' families.
7. True/False: In the future, pediatricians will likely have little role in violence prevention, because there are projected to be enough child and adolescent psychiatrists to fulfill this role.

Answers to questions

1. T
2. F
3. T
4. F. Compared with adults, children and adolescents presenting with a major depressive episode are at relatively higher risk of actually having a bipolar disorder. Significant caution must therefore be exercised in prescribing an antidepressant, which may precipitate mania or hypomania. The author advises that child and adolescent psychiatric consultation be sought.
5. T.
6. F. Often, working with the family is a key component of treatment.
7. F. Currently, there are only 6300 child and adolescent psychiatrists in the United States, where the estimated need is for up to 30,000. The population of children is expected to grow 40% in the next 50 years (6). Pediatricians will likely play a very significant role in insuring the psychosocial health of children.

Chapter XX.5. Eating Disorders
Robert J. Bidwell, MD

This is a 16 year old female who is brought to your clinic for her annual well teen exam. She denies any physical complaints, except for an occasional cold. Specifically, she denies any history of fatigue, fever, appetite or weight change. She is active and a review of symptoms is completely negative. A psychosocial (HEADSS) screening interview reveals no significant disagreements with her parents. She is a nearly straight "A" student at a public secondary school. She smokes an occasional cigarette but acknowledges no other substance use. She denies sexual activity with others and denies any history of abuse or suicidal ideation.

On physical exam, you note that she has lost 9 kg (20 lbs) since her last well teen exam a year ago. Her height is at the 50th percentile for age and her weight is now at the 10th percentile for age. Other than being very thin, the only other abnormality in her physical exam is a heart rate of 44 beats per minute. She had normal dentition, no lanugo hair, and a Sexual Maturity (Tanner) Rating of V. She denies any feeling of being too thin or too fat.

On a separate interview with her parents, you discover that they have been concerned about her losing weight since she began "eating healthier" over the past several months. She also seems "almost obsessive" in her physical activity, taking part in paddling, track, tennis and aerobic exercises at home. They believe she is no longer having menstrual periods. There has been no evidence of any binging or purging behaviors.

Eating disorders include anorexia nervosa, bulimia nervosa, binge-eating disorders and a number of disordered eating variants. The Diagnostic and Statistical Manual IV (DSM-IV) criteria for anorexia nervosa include an excessive concern with body weight and shape, an intense fear of gaining weight and an obsessional preoccupation with food and eating (1). Additional criteria include either excessive weight loss or failure to gain weight as expected in a pubertal child, accompanied by secondary amenorrhea or a failure to achieve menarche. Bulimia nervosa involves repeated episodes of binge eating, often accompanied by purging (self-induced vomiting, and laxative or diuretic use). Binge eating disorder consists of repeated consumption of very large amounts of calorie dense foods in a short period of time without subsequent purging. Variant eating disorders would include those in which an individual does not express dissatisfaction with weight or body shape or in which menstrual periods remain unaffected by weight loss. Anorexia nervosa and bulimia nervosa appear to represent a spectrum of disordered eating. At least half of the patients with anorexia nervosa engage in binge eating/purging and many patients with bulimia nervosa experience periods of significant caloric restriction.

It is believed that anorexia nervosa and bulimia nervosa have existed in Western societies for centuries. However, there has been an apparent increase in both since the late 1960's. They appear to be more prevalent in modern industrialized societies throughout the world. In the U.S., they occur in all socioeconomic classes and ethnic groups. Anorexia nervosa typically has an onset in adolescence or in early adulthood and is more common in females, with a prevalence rate of about 0.5% among 15 to 19 year old adolescent girls (2). The prevalence among adolescent males is much lower, although males make up as much as 40 percent of individuals with binge eating disorders. The prevalence of bulimia nervosa is less certain, but surveys indicate that 10 to 50 percent of young females engage in periodic self induced vomiting or binge eating. While about 3 percent of females have anorexia nervosa, bulimia nervosa or binge eating disorder based on strict DSM-IV criteria, at least 20 percent are considered to have some degree of disordered eating. This fact is important because the clinician should be prepared to intervene early, before all DSM-IV criteria are met.

The cause of eating disorders is multifactorial (3). Genetic predisposition, neurochemical factors, psychological factors and sociocultural influences all have been implicated in the onset of disordered eating.

It is also important to recognize the high incidence of psychiatric comorbidities among patients with eating disorders. These include mood disorders, obsessive-compulsive traits, perfectionist traits, social isolation, and impulsive tendencies (e.g., related to sex and drugs).

Signs and symptoms related to anorexia nervosa are primarily those resulting from starvation and malnutrition, and can affect nearly every organ system. For patients engaged in bulimic as well as restrictive eating behaviors, additional signs and symptoms related to binge eating and purging may be present. The most frequent and obvious physical sign of anorexia nervosa is significant weight loss leading eventually to profound cachexia. Other frequent signs include bradycardia, cardiac arrhythmia, hypotension, hypothermia and dehydration. Dry skin, brittle hair, and lanugo hair are also frequently noted. While many patients may deny any symptoms, despite significant cachexia, some will acknowledge weakness, fatigue, lightheadedness, headaches, palpitations, abdominal pain, constipation, cold intolerance and amenorrhea. Some patients will not express a distorted body image early in treatment, saying their weight loss is due to forgetting or being too busy to eat. However, as treatment begins and weight gain occurs, the underlying fear of gaining weight often becomes very evident. Pubertal delay and bone fractures due to osteopenia are possible, although infrequent sequelae to prolonged starvation. Laboratory studies, which are frequently normal, may reveal anemia, leukopenia, thrombocytopenia, hypercholesterolemia and mild elevation of hepatic enzymes. Hyponatremia secondary to water-loading is not uncommon.

Patients with bulimia nervosa are frequently normal weight for height or may be overweight. Those with periodic restriction may experience dramatic fluctuation in weight. Many patients with binge eating and purging behaviors may have a completely normal physical exam. Those signs and symptoms generally associated with these behaviors include dental erosions, parotid swelling, pharyngitis, chest pain (esophagitis), abdominal pain, hematemesis, and calluses or abrasions on the dorsum of the hand from self-induced vomiting. With significant purging behavior (vomiting, laxative, or diuretic use) electrolyte abnormalities, usually reflecting a hypochloremic hypokalemic metabolic alkalosis, and dehydration are common.

The differential diagnosis of weight loss in an adolescent is long (4). It includes malignancy and a variety of chronic illnesses including diabetes mellitus, hyperthyroidism, malabsorption syndromes, systemic lupus erythematosus, inflammatory bowel disease, and psychiatric disorders such as major depression and substance abuse. However, in most cases, information gathered from the history, physical examination and evaluative studies makes the diagnosis of anorexia nervosa relatively easy. For example, a patient (or patient's parents) who gives a history of a daily diet of only lettuce, tomatoes and rice cakes and who, despite a 10 kg (25 lb) weight loss, reports running 10 miles three times a week, is unlikely to have cancer or any of the other disorders listed above. On the other hand, it is important to remember that a patient with disordered eating may also develop diabetes or hyperthyroidism.

The differential diagnosis of binge eating with purging is much shorter, but may include other psychiatric conditions. If a patient denies willfully induced vomiting, the differential diagnosis includes a variety of gastrointestinal and metabolic disorders. Nevertheless, these latter conditions do not usually involve binge eating or lead to the kind of surreptitious vomiting engaged in by adolescents with bulimia nervosa.

In approaching the differential diagnosis it is important not to rely only on the adolescent patient's history. Many patients with anorexia nervosa will not report feelings of being fat or desiring to lose weight. Similarly, most patients with bulimia nervosa initially deny any bulimic behaviors. Parental observations of the patient's eating and purging behaviors or expressions of dissatisfaction with weight or body shape are invaluable on these cases.

Having made the diagnosis of an eating disorder, the first decision in treatment is whether the patient is in a life-threatening situation that requires either medical or psychiatric hospitalization. Medical hospitalization is generally indicated if there is evidence of significant cardiac compromise reflected in significant bradycardia, arrhythmia or hypotension. Electrolyte abnormalities such as hypokalemia or hyponatremia also place the patient at significant risk. Electrolyte disturbance and dehydration are relatively easy to correct through intravenous fluid and electrolyte supplementation. Continuous cardiac monitoring is also available in the hospital setting. Whether treatment begins in an ambulatory or an inpatient setting, an immediate goal is to increase nutrient intake. This can be done orally with a carefully devised meal plan or, if this is refused, through nasogastric feedings or hyperalimentation in the hospital setting. Treatment usually involves institution of an "Eating Disorder Protocol" in which normalized eating and weight gain is rewarded with increased privileges and non-compliance results in removal of privileges or hospitalization. The protocol also provides incentives for decreasing bulimic behaviors.

The treatment team often includes a psychiatrist, a pediatrician, a dietitian as well as the patient and her or his family. Because eating disorders are chronic in nature, the eating disorder team has a long term commitment to work with the adolescent patient and her/his family. The role of the pediatrician is to regularly monitor the patient's physical status during the stage of refeeding and weight gain. The dietitian provides counseling on appropriate nutrition and structural goals and guidelines to assure this occurs. The psychiatrist provides supportive care during the early stages of refeeding, and later begins the important work of facilitating increased self understanding as to the origins of the patient's disordered eating and provide therapy aimed at addressing those issues (5).

The long term prognosis for adolescent patients with anorexia nervosa is guarded at best (6). A recent review of follow-up studies of patients with this disorder found that only 44 percent had a good outcome (normalized weight for height and return of menstrual periods). Twenty-four percent had a poor outcome (failure to achieve normal weight for height and continued menstrual irregularities). Twenty-eight percent had an intermediate prognosis between "good" and "poor." Mortality was 5 percent overall. Suicide is the most frequent cause of death in patients with anorexia nervosa, followed by cardiac arrest and other medical complications related to starvation and/or binging or purging. The best prognosis occurs in patients with early onset of the disorder, less weight loss, no purging behavior, and healthy family functioning prior to onset of the disorder. Anorexia nervosa is often accompanied by other psychiatric conditions, and studies have found that patients responding well to treatment for their eating disorder may continue to experience depression, anxiety, obsessive-compulsive traits, social phobia and substance abuse.

Prognosis related to bulimia nervosa is less certain since many individuals with this disorder do not enter treatment. There is some evidence that even without treatment the rate of spontaneous remission may be as high as 30 to 40 percent over a one to two year period. With treatment, a positive outcome may be as high as 50 to 70 percent, although the relapse rate may also be high. One study of patients with bulimia nervosa who had successful results from intensive treatment showed that 60 percent continued to have good results at 6 years following treatment (7). Mortality was only 1 percent. Death is generally related to cardiac effects of hypokalemia due to purging behavior. Prognosis may be poor for patients with more frequent vomiting prior to entering treatment.

Questions

1. What is the leading cause of death in patients diagnosed with anorexia nervosa?
2. What is the most likely electrolyte abnormally in patients with bulimia nervosa who engage in self induced vomiting?
3. Name three indications for medical hospitalization of a patient with an eating disorder.
4. A teenaged female reports feeling healthy, denies feeling fat, and has normal menstrual periods. However, she has evidenced a 20 lb. weight loss. What is the most likely diagnosis?
5. Name six possible conditions or disorders on the differential diagnosis of excessive weight loss in an adolescent.
6. Which disorder is most likely to present with a normal physical exam, anorexia nervosa or bulimia nervosa?

Answers to questions

1. Suicide is the leading cause of death in anorexia nervosa. The second highest cause of death is cardiac arrest.
2. Patients who self induce vomiting are most likely to develop a hypochloremic hypokalemic metabolic alkalosis.
3. Three indications for hospitalization of a patient with anorexia nervosa include: a) electrolyte abnormalities (hypokalemia, hyponatremia), b) cardiovascular abnormality (bradycardia, arrhythmia, hypotension), c) inability or refusal to engage in outpatient treatment.
4. The most likely diagnosis is anorexia nervosa. The point is that the most likely cause of significant weight loss in an adolescent female is an eating disorder, even if DSM-IV criteria are not completely met.
5. Disorders other than anorexia nervosa in the differential diagnosis of excessive weight loss in an adolescent include malignancy, diabetes mellitus, hyperthyroidism, malabsorption syndromes, systemic lupus erythematosus, inflammatory bowel disease, depression and substance use.

6. Bulimia nervosa is more likely to present with a normal physical exam. By definition, anorexia nervosa must show weight loss or a failure to gain weight appropriately during puberty.

Chapter XX.6. Adolescent Sexuality
Robert J. Bidwell, MD

Case 1: This is a 17 year old male who has been in a year-long relationship with his 16 year old girlfriend. Their relationship includes sexual activity, including both vaginal intercourse and oral sex. They use condoms consistently, citing a wish to avoid pregnancy and sexually transmitted infections (STIs). They both say their relationship is mutually consensual and fulfilling. They are doing well at school, have good relationships with their family and peers, and have plans to attend college next year. Marriage has not been discussed although they see their relationship as a long-term commitment.

Case 2: This is a 14 year old female who was sexually assaulted by her uncle between ages 8 and 11. At age 12 she began to skip classes at school and "cruise" with friends at the beach. A year later she was introduced to "ice" (methamphetamines) and also used cocaine, alcohol and marijuana on a weekly basis at "hotel parties." She has met many of her sexual partners, usually older males, at these parties. She rarely uses condoms and has had chlamydia cervicitis once. She is not sure if she has ever been pregnant; but admits she would like to become a mother. She is not interested in learning more about contraception or STI prevention at this visit.

Case 3: This is a 16 year old female who is seeing you for her annual well-teen evaluation. In interviewing her about sexuality, she says she has never been sexually active. Although she has dated boys, she acknowledges a growing awareness of her sexual attraction to other girls and believes she may be a lesbian. She is hoping you can provide more information to help her better understand her feelings.

Sexuality is one of the most fundamental aspects of who we are as human beings. It is directly related both to an individual's physical as well as psychosocial well-being. It also is multidimensional in nature, referring not only to sexual behaviors but also to attractions, fantasies, affiliations, sexual orientation, and gender identity. Issues related to sexuality, particularly adolescent sexuality, are often controversial. In our pluralistic society, attitudes about adolescent sexuality differ not only by ethnicity, socioeconomic status, religion, and geographic region, but also can vary widely within individual families and communities. It is always a "hot topic" and one that health care providers will be required to address in their daily practice with adolescents and their families.

Human sexuality begins in infancy and continues through old age. However, with the beginning of puberty, there clearly is a quantitative change in the experience of sexuality by the developing child. The process has been described as a "sexual unfolding", that is the evolving expression of sexual feelings and experiences whose strongest roots are established in early infancy and childhood. This sexual "unfolding" is influenced by hormonal and physical changes, as well as psychosocial changes shaped by individual experiences and societal influences. Sexual development includes an adolescent's increasingly better understanding of who he/she is as a sexual being. This is accomplished in part through the acceleration of sexual exploration both with self and others. In general, pediatrics in the Western world feels that such experimentation is a normal and healthy part of adolescent development. However, there still remains some controversy, even within pediatrics, around what specific feelings and behaviors are developmentally appropriate.

Sexual development is intimately connected to the stages of adolescent development. In early adolescence (approximately 10 to13 years old) there is a significant increase in sexual feelings and preoccupations. These may be directed toward the same or opposite sex. There is often an increase in sexual self-exploration, including masturbation, which is considered a normal sexual behavior. Nocturnal emissions ("wet-dreams") occur in males and menarche in females, signifying the onset of reproductive capacity. Some early adolescents may engage in same or opposite-sex exploration. These do not necessarily reflect eventual sexual orientation. These sexual experiences are usually more experimental and self-focused than those of older adolescents.

Middle adolescence (approximately 14-16 years old) is often the hallmark of adolescent sexuality. Pubertal changes are nearly complete and there is significant increase in both same and opposite sex preoccupation and activity. With an increased understanding of their sexual selves, middle adolescents are more able to establish longer-term relationships and understand that intimacy involves more than simply sexual activity.

In late adolescence (approximately 17 to 19 years old), preoccupation with sexuality and the percentage of teenagers who are sexually active continue to increase but the older adolescent is, in general, able to bring a greater commitment and mutuality to his/her relationships. The late adolescent is also more future-oriented and often begins to consider what sorts of qualities, sexual and otherwise, he/she considers desirable in a potential spouse or life-partner. The "sexual unfolding" outlined above is a lifelong process and does not, of course, end at age 19. It is, in fact, a lifelong process.

While all adolescents address issues of sexual development, more than half abstain from sexual intercourse until age 17. However, research has demonstrated that some of these "abstinent" teenagers may engage in a variety of potentially risky sexual behaviors with others. These include mutual masturbation, fellatio, cunnilingus and anal intercourse. The Centers for Disease Control's (CDC) 2001 Youth Risk Behavior Survey, an anonymous survey of 9th to 12th graders in all 50 states, indicates that within this grade range, 46 percent acknowledge sexual intercourse, 14 percent have had four or more sexual partners, and 33 percent have had intercourse during the three months prior to the survey. Among those students who reported sexual intercourse, 33% had not used a condom and 82% of females had not used birth control pills during their most recent sexual intercourse. Despite this evidence of significant adolescent sexual activity, positive trends have appeared in the CDC data over the past decade. For example, the percentage of students reporting sexual intercourse has dropped from 54% to 46% between 1991 and 2001. The percentage reporting four or more partners has decreased from 19% to 14% and the use of condoms at most recent intercourse has increased from 46% to 58% during that ten-year period.

One of the reasons that health professionals are concerned about the high percentage of adolescents engaged in sexual behaviors is that these behaviors often entail significant risks to physical and psychosocial health. Early pregnancy and sexually transmitted infections are two of the primary risks inherent in adolescent sexual activity. Pregnancy occurs at a rate of 80 per 1,000 females aged 15 to 19. For the same age range, the birth rate is 50 per 1,000 and the abortion rate (intentional termination of pregnancy only) is 28 per 1,000 females.

Adolescent pregnancy and birth rates have remained stable over the past decade. The rate of chlamydia infection is 1,132 per 100,000 adolescents aged 15 to 19. For the same age group, the rates for gonorrhea and syphilis infections are, respectively, 572 and 6 per 100,000 persons. The fact that these rates are far greater than those of Western European countries with similar rates of adolescent sexual activity most likely reflects U.S. adolescents' lower use of condoms and contraceptives. This may be due, in part, to cultural factors as well as health and educational policies at the federal and local levels that limit adolescents' access to information and services related to sexual and reproductive health.

Adolescent sexual decision-making is a very complex phenomenon. Research has demonstrated that the early onset of sexual activity with others is usually accompanied by other risk behaviors, such as substance use, school problems, and parent-teen conflict. It is also highly associated with a history of physical and sexual abuse, both inside and outside the family. In short, biological, social, familial, and experiential factors all play a part in each adolescent's decision to be sexually abstinent or become sexually active. If an adolescent does become sexually active, these factors also influence the ability to engage in "safer sex" practices. In general, the earlier the age of sexual initiation the more likely there are associated risk factors and a history of significant childhood abuse. The initiation of sexual activity during later adolescence is more likely to represent a normative process with fewer associated risks. The multitude of factors influencing an adolescent's decision to be abstinent or sexually active, likely is one of the reasons that "abstinence-only" sexuality curricula have been less effective in preventing adolescent sexual risk-taking than "comprehensive" sexuality curricula. The latter interventions encourage abstinence as the safest choice but recognize that some adolescents will choose to be sexually active and should be provided the information and skills they need to make that activity as safe as possible.

One of the most neglected areas related to adolescent sexuality has been that of sexual orientation. During puberty, approximately 3 to 10 percent of adolescents begin to recognize their lesbian or gay (homosexual) sexual orientation. An even greater percentage may be bisexual while a small minority is transgender, feeling as if they are one gender trapped in the body of the other gender. Sexual orientation and gender identity are not a choice and appear to be established by early childhood. They likely are shaped by both biological and environmental influences. Pediatrics now regards homosexuality and bisexuality as normal and healthy developmental outcomes. Transgenderism continues to be listed in the Diagnostic and Statistical Manual, 4th edition (DSM-IV) under the designation "Gender Identity Disorder," although the appropriateness of this continues to be debated. It is important to recognize that there are significant risks to growing up lesbian, gay, bisexual or transgender (LGBT) in American society. Certain segments of society regard a minority sexual orientation or transgender identity as pathologic or sinful. Many LGBT youth experience violence at school and in their own homes. Growing up with a stigmatized identity, or forced to hide one of the most important part of who they are, LGBT adolescents often encounter problems at home, at school, and in their communities. A small percentage run away from home, drop out of school, and turn to drugs, street-life, prostitution, or suicide as a means of escape. A larger percentage choose to postpone their sexual development or lead secret sexual lives that distort their sexual development and place them at high risk for depression, exploitation, violence, HIV/AIDS, and other sexually transmitted infections. Health providers have a special responsibility to these disenfranchised youths to make sure that they have access to accurate information, appropriate health care, and supportive community services so they may develop into healthy and productive adults. It is important to note that the American Academy of Pediatrics has taken a strong stand against "reparative therapies' and "transformational ministries" that seek to change sexual orientation from homosexual to heterosexual. These interventions are regarded as harmful and unethical.

A health provider has multiple roles in addressing issues of sexuality with adolescent patients, including those of screener, educator, counselor, and advocate. Research indicates, however, that many providers feel uncomfortable and unskilled in discussing sexuality with their adolescent patients. Therefore, providers must first examine their own comfort and attitudes about sexuality, particularly as these relate to adolescents, and reflect on how these attitudes affect their work with teenagers.

In their role as screeners, health providers should monitor their patients' sexual development by routinely asking questions related to sexual feelings and behaviors, preferably well before the onset of sexual activity. As educators, providers are in an excellent position to provide accurate information and anticipatory guidance to teenagers and their families, not only about pubertal development but also about normative sexual development during the adolescent years. It is especially important that they inform teenagers and their families about pediatrics' position on such controversial issues as contraception, masturbation and sexual orientation. As counselor, the provider should encourage postponement of sexual activity with others until the adolescent has the physical, emotional and cognitive maturity to enter into relationships that are consensual and non-exploitative. The provider should counsel adolescent patients that healthy sexual relationships should be both honest and pleasurable, and that steps should be taken to prevent sexually transmitted infections and unintended pregnancy. At a community level, health providers are in an excellent position to participate in the development and delivery of comprehensive sexuality curricula in the schools and other community forums. They also can be strong advocates for the development of confidential, accessible and affordable reproductive services for teenagers and for policies that nurture and support the healthy sexual development of all adolescents.

Questions

1. True/False: The incidence of U.S. adolescent sexual activity has increased over the past decade.

2. A 16-year-old boy reveals to you that he has become increasingly aware of his sexual attraction to other boys. Which is the most appropriate first response as a pediatrician to this revelation?
   a. Reassure the boy that such feelings are normal and may or may not be indicative of a homosexual or bisexual orientation.
   b. Report this revelation to the patient's parents.
   c. Refer the patient to a therapist trained in "reparative therapy."
   d. Discuss the dangers of anal intercourse, including HIV infection and other STIs.
   e. Suggest the boy spend more time with appropriate male role models and activities.

3. True/False: The onset of sexual activity in older adolescents may have different antecedents, predictors and consequences than that in younger adolescents.

4. True/False: Sexual experimentation is a normal part of adolescent development.

5. In the field of pediatrics which of the following is considered abnormal in adolescent sexual development.
   a. Masturbation
   b. Sexual coercion
   c. Homosexual orientation
   d. Sexual fantasies
   e. Sexual experimentation

Answers to questions

1. False. The incidence of adolescent sexual activity, at least among in-school youth, appears to be declining. In addition, sexually active adolescents report fewer sexual partners and are more likely to use condoms than teenagers in the early 1990s.

2. a. Same-sex attraction is considered a normal part of adolescent and adult sexual experience. It may or may not reflect a bisexual or homosexual orientation, either of which, like heterosexuality, is believed to be established in early childhood and represents a normal developmental outcome.

3. True. The onset of sexual activity in younger adolescents is more likely to be associated with a history of negative life experiences and high-risk behaviors such as sexual abuse, substance use, parent-teen conflict and school problems. In older adolescents, the onset of sexual activity is often a more normative process.

4. True. Pediatrics as a discipline recognizes that sexual experimentation, with oneself and others, is a normal part of adolescent development. More controversial are the issues of age of initiation of sexual activity and the nature of those activities. There is a wide spectrum of viewpoints within pediatrics, reflecting broader societal views, on these latter issues.

5. b. Sexual coercion is a form of violence and, therefore, pathologic. Masturbation, homosexual orientation, and sexual fantasies and experimentation are considered a part of the spectrum of normal adolescent sexual development.

Chapter XX.7. Adolescent Gynecology

Renee L. Sato, MD

This is a 14 year old female who is brought to the Teen Health Clinic by her mother with a chief complaint of "missed periods" for 2 months. She experienced menarche at age 13. She believes her menses have been "more or less" regular but she has never kept track. She cannot remember the exact date of her last menstrual period. She states that when she has her menses, she has pain that is occasionally bad enough that she misses school. Her mother reports that her daughter has not had a period in at least two months and she wants you to test her for pregnancy and screen her for any sexually transmitted diseases (STD). She vehemently denies any sexual activity. She states that she feels perfectly fine and refuses to have a pelvic exam performed.

PMH: Unremarkable. No history of bleeding disorders. No current medications.

FH: Mother experienced menarche at age 13. No FH of bleeding disorders, gynecological tumors or other gynecological problems.

ROS: Unremarkable

Exam: VS are normal. Height and weight are 75th percentile for age. She is a well developed, adolescent female, in no acute distress. Non-hirsute. HEENT exam is normal. You ask her mother to step outside for the pelvic exam. While she is outside, you continue your questioning. She admits that she is sexually active. She uses condoms "sometimes" but her boyfriend doesn't like them. She states that she couldn't possibly have an STD because her boyfriend is "not that kind of person." She asks if you could give her some type of birth control and keep the conversation a secret from her mother. You explain carefully the need for a thorough gynecological exam and how the exam will be done. After talking with you a while, she agrees to have the pelvic and STD screen. She declines an HIV test.

Breasts: Tanner stage 4. Pelvis: Pubic hair tanner stage 3. Genitalia: Normal outward appearance. No malodor or discharge at the introitus. No vesicles, ulcers, or other lesions. Speculum/Pelvic Exam: Normal-appearing, nulliparous cervix. A Pap smear is performed and cervical swabs are obtained. No cervical motion tenderness is present. Non-gravid sized uterus palpable, without masses. Bilateral ovaries non-enlarged. No adnexal tenderness. The rest of her exam is normal.

Labs: UCG (-), WBC 7.0, Hg 13.8, Hct 40%, Plt 200, serum iron 100ug/dL, ferritin 80 ng/mL, RPR (-). A wet mount and KOH test are negative for yeast infection, bacterial vaginosis, or trichomonas. The GC and chlamydia assays are negative.

Clinical Course: After discussing contraceptive options with the patient, she decides on the combined oral contraceptive pill. She is counseled on monitoring her menses. Before she leaves, you warn her about HIV and STDs, and encourage condom use.

One month later, you get a call from her mother who is upset when she sees her medical insurance statement which shows an itemized expense list which contains a pregnancy test, a gonorrhea culture, and a prescription claim for birth control pills. She demands an explanation.

When dealing with the adolescent patient, it is important to remember that the adolescent is the patient, even if she is accompanied by a parent, usually the mother. At this stage of development, many adolescents are struggling to assume an adult identity and the patient

may resent being talked about in her presence as though she wasn't there. She may have concerns that are different from an adult. An adolescent will likely be anxious about the gynecological exam. She may be afraid that it will be painful, and will likely be embarrassed about undressing (1). In allaying such fears, it would be helpful to direct the majority of the initial discussion toward the adolescent and to explain the exam completely. Speaking to the mother alone is useful for obtaining family history that may be pertinent and for uncovering any concerns that she may have. The patient may be suspicious of your private conversations with her mother. Often, the patient can be reassured by telling her what was discussed. Patients in this age range are often modest about the changes taking place in their bodies, and it is often best to leave it up to the girl whether she wants her mother present during the exam. It is important to speak to the patient alone at some point because she may have information that she is reluctant to reveal in the presence of her mother.

When attempting to solicit information about her menstrual cycles, it is best to ask specific questions regarding the frequency of menstrual flow, length of menses, and the amount of blood lost. Do not accept without question the patient's assurance that her periods are "normal" or "regular". When assessing the amount of blood lost, the patient should be asked how long it takes to soak through a tampon or pad, if she ever has to awaken in the night to change a pad, or if she has to use both methods at once. It is not enough to simply note how many pads or tampons the patient uses in a day because she may change pads as soon as one is soiled, wait until it is soaked, or change it according to her class schedule which dictates when she can make it to the restroom.

Menarche is the onset of menstruation in girls. As the hypothalamic-pituitary-gonadal (HPG) axis matures during puberty, the hypothalamus begins pulsatile secretion of gonadotropin releasing hormone (GnRH). GnRH stimulates the pulsatile secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the pituitary, approximately every 90-120 minutes. In turn, LH stimulates the theca cells of the ovary to secrete androstenedione, testosterone, and estradiol. FSH increases the number of granulosa cells in the ovarian follicle and promotes the conversion of androstenedione to estradiol in the granulosa cells. Estradiol promotes the formation of uterine endometrial glandular cells and stroma. Menarche occurs when estrogen levels are sufficient to stimulate proliferation of the uterine endometrium. Estradiol also stimulates the development of the follicle and its levels increase in puberty until ovulatory cycles are established. The rising estradiol levels positively feedback to stimulate an LH surge, prompting ovulation. Following menarche, plasma estradiol levels range from 50-200 pg/ml during the follicular phase, while progesterone levels range from 200-2500 ng/dl (average 750) during the luteal phase (2).

Menarche in North American girls occurs at a mean age of 12.7 years, with a range of 10-16 years, and occurs an average of 2 years after the onset of breast development (2,3). The majority of cycles within the first 2 years after menarche are anovulatory, and there tends to be great variance in cycle interval, duration of flow, and amount of blood loss. Cycle intervals may be as long as 6 months and continue to be irregular for the first 15 cycles (2,4,5,6).

Dysfunctional Uterine Bleeding

In a normal cycle, an average of approximately 35 mL blood is lost (range 20-60 mL) (7). The amount of blood loss is difficult to estimate by sight. A good guideline may be to consider 8 pads or 12 tampons, well soaked, as the upper limit of normal; however even these estimates are user-dependent and may not correlate well with actual blood loss. The normal duration of flow is 3-7 days, with >7 days considered prolonged. A normal cycle interval ranges from 21-35 days, with less than 21 or more than 35 days considered abnormal (8).

Until ovulatory cycles are established in the adolescent, endometrial proliferation occurs without progesterone regulation. The endometrium grows until the level of estrogen cannot sustain it, resulting in endometrial sloughing. In the adolescent, this results in cycles that are irregularly regular until regular ovulation is established. Although cycle lengths will vary, they tend to stay within the normal range. The time to develop ovulatory cycles is dependent on the age at which menarche occurs. When the ages of menarche were <12.0 years, 12.0-12.9, and 13.0 years or greater, it took, respectively, 1, 3, and 4.5 years to attain 50% ovulatory cycles (9). The same study demonstrated that it may take 6-7 years to attain 90% or greater ovulatory cycles. Most importantly, although most menstrual cycles in early adolescence are anovulatory, truly abnormal bleeding is rare.

Classification of Abnormal Uterine Bleeding in the adolescent (8):

Menorrhagia (hypermenorrhea): Prolonged (more than 7 days) or excessive (>80 ml) of uterine bleeding occurring at regular intervals.

Polymenorrhea: Regular episodes of uterine bleeding occurring at intervals of <21 days.

Metrorrhagia: Uterine bleeding occurring at irregular intervals with variable amount of flow.

Menometrorrhagia: Irregular and frequent bleeding, which may be excessive in amount and/or prolonged in duration.

Oligomenorrhea: Irregular bleeding episodes occurring at intervals of 35 days to 6 months.

Amenorrhea: No menses for at least 6 months.

Intermenstrual bleeding: Bleeding episodes occurring between regular menstrual periods.

Postcoital bleeding: Bleeding occurring after sexual intercourse.

Hypomenorrhea: Decreased amount of uterine bleeding occurring at regular intervals.

Dysfunctional uterine bleeding: Excessive uterine bleeding with no demonstrable organic cause.

The most common cause of excess irregular bleeding in the adolescent is dysfunctional uterine bleeding (DUB), comprising 50% to 97% of causes (10,11,12). The most common etiology of DUB is anovulatory cycles, but this can only be diagnosed after all organic causes have been ruled out. Included in the differential for an adolescent who presents with excessive uterine bleeding are: Pregnancy, spontaneous abortion, trauma, foreign bodies in the vagina, complications of contraceptive devices or hormones, infection, coagulation defects, platelet abnormalities, leukemia, drugs or medications, polycystic ovary disease, or endocrine disorders such as hypo/hyperthyroidism, Addison's or Cushing's disease. Although polyps, myomas, tumors, or endometriosis may be included in the differential, in contrast to the mature woman, diseases of the uterus are rarely the cause for irregular uterine bleeding in adolescents (10,11,12).

A common clinical problem seen by physicians is the adolescent who presents with irregular intervals of bleeding that is normal in duration and amount of flow. For most of these adolescents, reassurance and observation are usually sufficient. The adolescent should be encouraged to keep a record of duration of menses, cycle interval, and amount of bleeding. Bleeding that is outside of normal parameters requires further evaluation (13). Signs of chronic disease, polycystic ovary disease, endocrine abnormalities, or blood dyscrasias, if present, should be evident in the physical exam with corresponding symptoms obtained in the history. The evaluation of abnormal uterine bleeding in the adolescent also requires a thorough gynecological exam. If the bleeding is active, the site of bleeding should be

determined, as occasionally rectal or urethral bleeding may be mistaken for menstrual spotting. A speculum exam should be performed to inspect for signs of infection, trauma, foreign bodies, or evidence of contraceptive devices. Cervical cultures, a wet mount, and a Pap smear are obtained as necessary. Vaginal irrigation may be used to obtain these samples in the patient who will not tolerate a speculum exam. A bimanual pelvic exam is used to check for cervical motion tenderness, adnexal tenderness, and masses. A single-finger digital palpation is adequate for most adolescents, but if the hymenal orifice is still too small for a single-digit exam, a rectoabdominal bimanual palpation may be done instead. Initial laboratory evaluation should include a CBC, coagulation studies, serum iron and ferritin, and urine or blood HCG. The following studies should be added if clinically indicated: thyroid studies, prolactin level, glucose, STD screen, hormone levels to evaluate for hirsutism or polycystic ovary disease (DHEAS, testosterone, 17-OH progesterone, LH, FSH). A pelvic ultrasound, endometrial biopsy, or pituitary CT may be added if warranted. Surgical interventions, such as a hysteroscopy and D&C are diagnostic methods of last resort (13).

After organic, systemic, and iatrogenic causes are ruled out, the abnormal bleeding may be diagnosed as dysfunctional uterine bleeding (8). Most adolescents with irregular bleeding in the first two years following menarche do not require long term management (10). If the bleeding interferes with the patient's daily activities or is severe enough to cause anemia, treatment is recommended. If anovulation is the suspected etiology, the initial hormonal intervention should be progestin therapy to initiate a secretory change of the endometrium and produce a controlled withdrawal bleed. Progestin stops endometrial growth and organizes endometrial sloughing so that menses will occur following progestin withdrawal, rather than at random times. Failure to bleed with progestin withdrawal warrants further workup. Estrogen treatment causes the regrowth of endometrium over raw, denuded areas where previous bleeding occurred. It is often clinically useful in controlling acute bleeding episodes, but progestin therapy is also required if the etiology of the bleed is anovulation. Combination estrogen/progestin oral contraceptives are the treatment of choice in adolescents, and also serve the dual benefit of preventing pregnancy if the adolescent is sexually active (8).

Dysmenorrhea

Dysmenorrhea is defined as cramping pain in the lower abdomen that occurs in conjunction with menstruation. If the pain is due to pelvic pathology or alterations in normal pelvic anatomy, the pain is classified as secondary dysmenorrhea, whereas primary dysmenorrhea occurs in the absence of any known pelvic pathology. Secondary dysmenorrhea is uncommon in adolescents, but primary dysmenorrhea is the most common gynecologic problem in young women, with reported rates as high as 75-90% (14,15,16). The incidence increases with sexual maturity, with one study reporting a 38% incidence at Tanner stage 3, increasing to 66% at Tanner stage 5. Dysmenorrhea also increases with chronological age from 39% in 12 year olds to 72% in 17 year olds. 14% of girls in one study frequently missed school because of menstrual pain, and of those with severe dysmenorrhea, 50% reported missing school (17).

Symptoms of primary dysmenorrhea are usually noted beginning 1-3 years after menarche. It is more commonly seen in girls who have established ovulatory cycles. Pain that begins within 6 months or 3 years after menarche is more indicative of secondary dysmenorrhea. Patients typically report intermittent, cramping suprapubic pain that may radiate to the lower back or thighs. The pain may begin a few days before menstruation and continue for as long as 7 days following the start of flow. More commonly, the pain begins a few hours after the start of menstruation, and lasts 24-48 hours. The pain is often accompanied by systemic symptoms including nausea and vomiting, fatigue, diarrhea, lightheadedness, and headaches. Often, there is a family history of dysmenorrhea, and the physical exam is completely normal (18).

Due to the nature of the symptoms and the timing of the pain coincident with menses, a focused history and physical exam is usually sufficient to rule out non-gynecologic conditions of lower abdominal pain such as appendicitis, urinary tract infections, or inflammatory bowel disease. Secondary causes of pelvic pain must be ruled out. As with all women of child-bearing age, pregnancy must be excluded, along with the possibility of ectopic pregnancy. Premenstrual syndrome (PMS) will also occur cyclically with menses, but is usually associated with breast tenderness and abdominal bloating rather than abdominal cramping. A history of infection or previous abortion or surgery may indicate pelvic inflammatory disease (PID) or adhesions from inflammation and scarring. Any sexually active adolescent should have a speculum exam with cultures taken for Chlamydia trachomatis and Neisseria gonorrhoeae, and have a Pap smear. A pelvic exam should detect any unusual masses, cervical motion tenderness typical of PID, or cervical stenosis. Secondary causes such as endometriosis, polyps, fibroids, or tumors are rare in adolescents, and a workup for these conditions are not usually indicated. In many instances, it is preferable to confirm the diagnosis through a therapeutic trial of NSAIDs (16).

Most of the symptoms of primary dysmenorrhea are now thought to be due to the effects of endogenous prostaglandins, particularly PGF2alpha. The secretory endometrium contains high levels of PGF2alpha which are released when the endometrium is sloughed off during menstruation. These prostaglandins stimulate uterine contractility and painful cramping. The levels of PGF2alpha are highest in the first two days of menses, when symptoms are most severe, and have been shown to be elevated in women who complain of severe dysmenorrhea (16). NSAIDs are the treatment of choice for initial therapy of dysmenorrhea in adolescents. These drugs act to inhibit prostaglandin synthetase, and have reported efficacy rates of 64-100%. In contrast, aspirin and acetaminophen were not shown to be superior to placebo in double-blind studies (19,20). Unfortunately, many adolescents self-treat for dysmenorrhea without consulting an adult. Of those that are self-treating, many take ineffective medications (aspirin or acetaminophen) or use less than the recommended dosages. Therefore, it is important for physicians to inquire about dysmenorrhea during routine visits to ensure that patients are being treated appropriately. Oral contraceptives are a second treatment option for dysmenorrhea that is highly effective (90%) and also serves the dual benefit of birth control for sexually active adolescents. For the roughly 10% of those who do not respond to these options, other alternatives exist ranging from laparoscopic surgery to acupuncture (16).

Contraception

By their 18th birthday, 56% of female adolescents have had intercourse (21). Each year, more than 1 million females 15-19 years old become pregnant, with the vast majority of these pregnancies unintended (22). An effective strategy to reduce unintended pregnancies and sexually transmitted diseases is to provide teens with basic information about reproduction and contraception (21). Contraceptive options for adolescents must be tailored to their specific needs and concerns. Factors to consider in choosing a contraceptive for an adolescent include: ease of use, STD protection, cost, safety, and acceptability.

Combined oral contraceptives (COC): AKA "The Pill". These consist of a daily tablet containing a combination estrogen and progestin taken continuously for 3 weeks, with one week of placebo pills to allow menses. COCs inhibit the midcycle gonadotropin surge, thereby preventing ovulation. They also thicken the cervical mucus, making passage of sperm into the reproductive tract more difficult, and thin the lining of the endometrium, making it less favorable for implantation. They have a perfect use failure rate of 0.1% with a typical failure rate of 3% even when an occasional pill is missed (23). COCs have multiple noncontraceptive benefits which are not

usually appreciated by adolescents, such as the reduction of endometrial and ovarian cancer. One benefit that many young women may appreciate is the recent FDA approval of one COC, OrthoTricyclen, for the treatment of acne. COCs may also be beneficial in young women who experience heavy, prolonged, or painful menses. This method does not require the cooperation of a partner, and does not interfere with spontaneity. Oral contraceptives, however, do not protect against STDs so teens should be encouraged to also use condoms. The patient must be motivated to take a pill every day in order for this method to be successful. Contraindications include: history of breast cancer, thromboembolic disease, pregnancy, undiagnosed abnormal uterine bleeding, smoking, heart disease or heart failure, CVA, or liver tumors. Older formulations of "The Pill" contributed to weight gain, but this is not seen with the newer pills on the market today. Teens who receive reassurance from their doctors that the new oral contraceptives will not cause them to gain weight are more likely to continue taking the pill long term (24).

Progestin only pill (POP): "Mini pill". This is a pill that is taken daily without any breaks. Its mechanism of action is similar to COCs. It thickens the cervical mucus and thins the endometrium to prevent implantation. Ovulation is suppressed only 60% of the time and the requirements for taking the POP are stricter. These pills must be taken at approximately the same time, every day. If a pill is delayed by more than 3 hours, the patient must be counseled to use a backup method of contraception for at least 48 hours. Perfect use failure rate is 0.5%, actual use 3-5%. POPs may cause irregular or breakthrough bleeding that may be stressful for the adolescent. In general, this method is not recommended as a first choice for most teens, but is useful for those with medical conditions where estrogen is contraindicated. It can also be used safely by nursing mothers (23).

DepoProvera: This is depot medroxyprogesterone acetate (DMPA) that is injected intramuscularly every 12 weeks. It works primarily by suppressing ovulation through a mechanism similar to the POPs. Its perfect use and actual use failure rate is 0.3%. Because the patient is required to return for a new injection every 12 weeks, it is still user-dependent, but the teen is freed from daily compliance worries. The major drawback of this method is that irregular bleeding or spotting has been reported in 25-50% of users in the first 6-12 months. However, most users eventually become amenorrheic. The patient should be properly counseled to expect these effects, and if she can get through the initial irregular bleeding, most teens find the lack of monthly menses appealing. This may be a disadvantage to those teens who rely on their periods as an indicator of pregnancy. This method is advantageous to certain handicapped adolescents and their caretakers. It provides both long-term birth control and the eventual freedom from messy menses (23).

Lunelle: This is a once-a-month injection of synthetic estrogen and progesterone (medroxyprogesterone acetate/estradiol cypionate). It provides the convenience of a once-monthly birth control method while minimizing the irregular bleeding that occurs with progestin-only contraceptives. The mechanism of action is similar to the COCs. The failure rate is currently estimated at 0.1 failures per 100 women-years. This method has only recently been approved for use. It requires that the patient return to their health care provider monthly for injections (25).

Ortho Evra, the first contraceptive patch, was introduced in 2002. It is placed on the skin of the buttocks, torso, or abdomen and releases a steady stream of estrogen and progestin (norelgestromin and ethinyl estradiol). A patch should be worn each week for 3 weeks in a row and changed every 7 days. The 4th week is patch-free to allow menses. The mechanism of action and side effect profile are similar to other hormonal contraceptives. Perfect use failure rate is 0.6%. The patch may be less effective in women >198 lbs compared to women with lower body weights. The risk of the patch falling off was <2% in clinical trials (26).

NuvaRing: The first hormonal vaginal contraceptive ring was approved by the FDA in 2001. NuvaRing is a small, flexible, transparent ring containing the hormones etonogestrel and ethinyl estradiol which are similar to the hormones in COCs. The ring is inserted into the vagina and provides a continuous low dose of estrogen and progestin for 3 weeks. It is removed in the fourth week to allow menses. A new ring is used each month. In clinical trials, pregnancy rates were 1-2% in one year of use. Side effects and contraindications are similar to COCs. Like all hormonal contraceptives, it does not protect against STDs or HIV (27).

Male latex condoms are the method of choice for adolescents, as they offer protection against both pregnancy and STDs. The male condom is the most common nonhormonal contraception used by adolescents aged 15-19 (28). Latex condoms have been shown to prevent the transmission of HIV, herpes, chlamydia, gonorrhea, cytomegalovirus, hepatitis B, trichomonas, and probably human papilloma virus (29). Perfect use failure rates range from 1-4%, with typical use failure rates of 10-21%. Teens should be instructed in the proper use of condoms. They should be advised to use spermicide, a water-based lubricant if needed, never a petroleum or oil based lubricant as these compromise the integrity of the condom, and to seek emergency contraception right away if the condom should break or slip. The most common deterrents to use are the interruption of intercourse required to put on the condom, the foresight required to purchase and keep the condom readily available, and the necessary cooperation of the male partner. Actual side effects, such as latex or spermicide allergies are not common (23).

Female condoms work as a barrier to sperm, similar to the male condom. It is a single-use, polyurethane pouch with a ring on one end that is inserted into the vagina to cover the cervix, and another open ring on the other end that remains outside the vagina. Perfect use failure rate is 3%, typical use failure is 15-25%. The advantages of this method are that it is the only female-controlled barrier method that offers protection against STDs comparable to the male condom, it is an alternative to females who have a latex allergy, and does not require male cooperation. Disadvantages include its higher cost ($3.00 per condom) and lesser availability, unusual appearance, and occasional crackling noise during intercourse or walking (23).

The diaphragm is a flexible rubber dome placed over the cervix and is used in conjunction with spermicidal jellies or foam. It may be inserted up to 6 hours prior to intercourse, but must be in place at least 30 minutes prior. It must be left in place for 6 hours after. The perfect use failure rate is 6% with a typical use failure of 20%. The diaphragm must be fitted by a physician and the patient must be able to insert and place it properly. It provides limited protection against some STDs but is not as effective as condoms. The initial cost of several hundred dollars may be discouraging to teens, but can be cost-saving in the long run if the patient is extremely active sexually. Disadvantages: Some teens are not comfortable touching their own genitals during insertion and removal. If positions are changed during sex, the diaphragm must be checked to make sure it is still in place. If the patient has a significant weight change, or becomes pregnant, she must be refitted. The diaphragm must be carefully inspected and cleaned between uses. There is a slight increase in urinary tract infections associated with diaphragm use, and if left in place >24 hours, there is a risk of toxic shock syndrome (23).

The contraceptive sponge was pulled off the market in 1995 for reasons unrelated to either safety or reliability, but it has become available again in 1999. The sponge is a doughnut-shaped polyurethane foam barrier containing a chemical spermicide. The sponge must be moistened with water and inserted into the vagina up to 24 hours prior to intercourse and may be left in place up to 30 hours. Perfect use failure rate is 10%. Typical use failure is 15-20% for nulliparous women, and has been reported as high as 40% in women who have had a child (30).

Spermicides come in a variety of forms (jellies, creams, foam, suppositories, tablets) that may be used alone or in conjunction with other methods. The most common active ingredients in spermicides are nonoxynol 9 or octoxynol, which acts to incapacitate sperm. In

addition, these spermicides may have some bactericidal action. Spermicides must be inserted vaginally 10-30 minutes prior to intercourse and a new application is required for each act of intercourse. The perfect use failure rate is 6% with a typical use failure of 25%. Spermicides are often perceived by adolescents as messy and inconvenient, and continuation rates are low (23).

Contraceptive methods that are not appropriate for adolescents include the cervical cap and intrauterine devices (IUD). Sterilization is not appropriate as it is considered a permanent end to fertility. (31)

Intrauterine devices (IUD) and cervical caps are not recommended for teens so they will not be discussed here.

Physicians should ensure that adolescents are informed of the availability of emergency contraception. Teens need to be made aware of this option ahead of time due to the narrow window of time that treatment can be effectively applied. It should be stressed that postcoital methods should not be relied upon as the primary birth control method, and are primarily intended for emergencies. The most common method is the prescription of a larger than normal dose of oral contraceptive pills usually within 72 hours of intercourse. Depending on the time of the cycle in which it is taken, emergency contraceptive pills may inhibit ovulation, interfere with fertilization, or inhibit implantation of a fertilized egg. They should not be confused with abortifacients such as RU486 which are designed to end established pregnancies.

In general, the male condom is the most appropriate birth control method for adolescents. It is readily available over the counter, inexpensive, and protects against both pregnancy and STDs. Adolescents should be encouraged to use condoms, but a second method may be appropriate if condom use is less than perfect. Hormonal methods do not offer protection against STDs, but have low failure rates. The most common side effect of progestin-only methods is irregular bleeding. Many adolescents are not comfortable touching their own genitals, making internal barrier methods such as the diaphragm, the sponge, or the cervical cap less than ideal methods for many teens.

STD screening

The gold standard for the diagnosis of Neisseria gonorrhoeae and Chlamydia trachomatis has been culture. Endocervical specimens for culture are typically obtained from swabs taken during a speculum exam, with additional pharyngeal and rectal swabs obtained as necessary. Culture for C. trachomatis has sensitivities of 60-80% and specificities close to 100% for endocervical specimens (32). Culture for N. gonorrhoeae is 58-96% sensitive (33). A single endocervical culture will detect 85% of N. gonorrhoeae infections. A second culture will catch an additional 7-10% of infections (34). Culture methods have several limitations. They are slow, generally requiring 3-7 days for results. Only viable organisms can be detected and test results can be affected by storage and transport conditions.

Recently, several alternative tests for the detection of chlamydia or gonorrhea have been made available with acceptable sensitivities and specificities. Newer DNA amplification tests increase diagnosis when used in conjunction with other detection methods, and can be performed on both endocervical specimens and urine samples. Urine based testing provides a unique method of noninvasive screening, and is especially helpful in young adolescents who may be uncooperative with the pelvic exam. Polymerase Chain Reaction (PCR) and Ligase Chain Reaction (LCR) are two DNA amplification methods used today. For the detection of C. trachomatis in endocervical specimens, PCR is comparable to culture (sensitivity 79-99% and specificity 99-100%). In urine samples, the measured sensitivity was 96-100% with a specificity of 99-100% (32). LCR results have outperformed culture (Endocervical: sens 94% and spec 100%); (Urine: sens 96% and spec 100%) (35). For the detection of N. gonorrhoeae, LCR has been proven equally sensitive to culture methods using both endocervical swabs and urine specimens. Most studies have shown a sensitivity of >88% and specificity of 99-100% for LCR (34,36). Another alternative to culture is the DNA Probe assay, which may be performed alone (unamplified) or in conjunction with DNA amplification. DNA amplification is recommended for all urine samples. The unamplified DNA probe has a sensitivity and specificity essentially equivalent to culture for endocervical specimens, but a sensitivity of only 50% in urine that has not undergone amplification (34,37). Enzyme Immunoassay (EIA) and Direct Fluorescent Antibody (DFA) were developed as an alternative to culture. Both these methods are faster than culture and can detect nonviable as well as viable organisms; however, their sensitivities have been shown to be variable with the prevalence of the disease. They are useful screening tools in populations where the prevalence of infection is high (32,34).

Questions

1. Can a physician provide family planning services to a minor without parental knowledge? If an adolescent demands confidentiality, how can a physician prevent the transfer of billing/insurance information to reach parents?
2. What is the normal age range for menarche?
3. What are some common treatments for dysmenorrhea?
4. Name some things that should be discussed with a female adolescent during a physician visit?
5. What is the normal cycle length, amount of blood loss, and duration of flow in menses?
6. What is the most common side effect of progestin-only contraceptive methods?
7. If a speculum exam cannot be performed, or the patient refuses, how can screening for chlamydia and/or gonorrhea be accomplished?

Answers to questions

1. In Hawaii, a minor who is at least 14 years of age may consent to receive contraceptive services, prenatal care, and STD/HIV/AIDS services. The physician may notify parents (with the consent of the patient), but parental consent or notification is not required. In fact, if an adolescent demands confidentiality, it becomes a difficult situation since it might not permissible for the physician to release information, even to parents. The wording of the statute is, "left up to the treating physician's discretion in consultation with the minor who received medical treatment", but the statute later states that the minor, "shall have the same legal capacity to act" as an adult, making their demand for confidentiality no different than that of an adult. Most insurance companies provide itemized claim information to the subscriber of the insurance policy (usually the parent). It is not possible to circumvent this in most instances. Thus, adolescents should be counseled that once they have used their parent's medical insurance, their parents will receive such information. They must consent to this release of information, or they must remove the medical insurance information so that an insurance claim is not submitted. They should also understand that they will receive a bill for all medical services, although their ability to pay it should not impede the delivery of medical services. In most instances, it may be appropriate to counsel the adolescent to share this information with their parents, and in many instances, they will consent once they understand all the issues. This requires provision of factual information to the adolescent and patience.
2. 10 to 16 year old, average 12.7.
3. NSAIDs are the treatment of choice in adolescents. Oral contraceptives may also be used.
4. Adolescents should be provided with information about their diagnosis, contraception, breast self-exam, STDs and AIDS. Instruction should be provided on how to track menses. Condom use should be encouraged in those who are sexually active.
5. 21-35 days between menses, 20-60 mL blood loss (avg 35 mL), 3-7 days of menstruation.
6. Irregular bleeding.
7. PCR or LCR (DNA methods) for chlamydia and gonorrhea assayed from a urine sample or vaginal fluid sample.

Chapter XXI.1. Eczematous Dermatitis (Atopic Dermatitis and Seborrhea)

M. Stanton Michels, MD

This is a 2 year old toddler who has had "bad skin" since soon after he was born. He had "cradle cap" as an infant that became generalized to his face, and from there to his upper torso. Off and on throughout his life, he has had "flare-ups" of erythematous, scaling patches on his cheeks, chest and abdomen. His mother expresses frustration with the doctors' inability to help her son's skin. She has used moisturizers and 1% hydrocortisone cream episodically in the past. Presently his hands are so inflamed, cracked and bleeding that he doesn't move his fingers much. "He never stops scratching!", she declares. She admits however that they are more successful in controlling his asthma that was diagnosed about one year ago.

Atopic dermatitis (AD) largely starts in infancy and early childhood. 85% of cases first present before the fifth birthday. Common manifestations can include pruritus (which is universal), lichenification and linear cracking in those flexural areas, xerosis (dry flakey skin generally prior to the patchy outbreaks), periauricular fissures, cheilitis (inflammation and cracking of lips, particularly at the corners of the mouth), scalp dermatitis (e.g., cradle cap), and susceptibility to cutaneous infections by S. aureus.

Epidemiologically, atopic dermatitis seems to be increasing worldwide. Exact figures are lacking; however since there is not a strict method of defining the disease. There does seem to be some variation in rates from one ethnic or geographic area to another. Reported rates can run from greater than 20% in Scandinavian populations to less than 5% in east Africa.

Some would offer the diagnostic criteria of: itchy skin (mandatory for the diagnosis) plus at least 3 of the following:

1) Involvement of the skin creases.
2) Past medical history of asthma or hay fever.
3) History of generally dry skin.
4) Onset less than age 2 years.
5) Visible flexural dermatitis.

Other objective tests useful in the diagnosis might include total IgG and increased IgE. Genetics seems to play an important factor. Co-twin studies have shown a high concordance for the disease in identical twins over dizygotic twins. In addition, there is a strong relationship between atopic dermatitis and other allergic disease manifestations such as asthma and allergic rhinitis. AD characteristically displays two immune responses: 1) IgE overproduction, and 2) diminished cell mediated immunity. Cytokines, particularly IL-4 produced by T cells, seem to promote IgE production. It is hypothesized that an overwhelming T-cell activity which produces this aberrant lymphokine profile limits cellular immune response. This in turn may increase susceptibility to certain microorganisms. Interestingly, house dust mite, cat dander, and certain pollens have been related to atopic dermatitis exacerbations.

The question of food allergy is often posed by parents, but the connection to food allergies is less clear. The consensus is that food can play a role in certain individuals. Finding the specific food precipitant, however, is usually a time consuming and frustrating process. Although the literature is somewhat conflicting, it is generally held that less than 10% of AD children can be shown to have a specific food as a cause for their dermatitis. Skin testing or RAST blood tests are often not helpful in the diagnosis. Having said this, the most common offending agents, when one is identified, are eggs, milk, seafood, nuts, wheat, and soy. Elimination diets may not in the end alter the natural course of atopic dermatitis. Eczematous reactions may not become apparent until several days after the ingestion.

Differential diagnosis largely depends on the age and distribution of the rash. Although there is some dispute on the nomenclature, many authors would lump atopic dermatitis and seborrhea together in a group of eczematoid dermatitis. They stress that atopic dermatitis often occurs in individuals who had seborrheic dermatitis in infancy. There are some differences however. In early infancy, seborrheic dermatitis usually presents earlier than 2 months of age with AD presenting thereafter. Seborrhea has a much better prognosis, and usually resolves by six months of age, just when atopic dermatitis becomes more prevalent. Pruritus is not customarily a big factor in seborrhea, but is always present in AD. There are patches of erythema which usually start on the scalp and move down over the face and cheeks. These red patches scale and have an oily appearance. The rash itself is difficult to distinguish morphologically from atopic dermatitis. In older children, scabies can cause discrete areas of pruritus with papular erythema, but usually these show a predilection for the hands, feet, and genital areas. One will often find the tiny burrow wounds on close inspection (often in the web spaces between the fingers). Allergic contact dermatitis is more sudden in onset and less relapsing in course. Usually a specific new allergen can be identified by history. Very specific distribution is often helpful.

There are several more severe immune disorders that may be entertained. Hyper IgE syndrome (Job's syndrome) often produces more severe infections of tissues other than the skin, such as pneumonias, sinusitis, or deep soft tissue abscesses. Wiskott-Aldrich syndrome can produce flexural dermatitis which appears clinically as AD, and X-linked Bruton's agammaglobulinemia can also produce similar rashes, but shows low IgE levels. Histiocytosis-X can also present with patchy erythematous, pruritic rash.

As is the case with acne, the level of therapy should be tailored to the severity of the disease. Generally, AD patients are found to have dry skin, which may produce cracking that contributes to antigen stimulation of the deeper tissues. Without a doubt, moisturizers hold a key role in providing a barrier to this drying. Emollients are best, but a very greasy product may not be well tolerated by older patients although they form the best barrier. Systemic antihistamines may help with pruritus, and the more sedating of these, such as hydroxyzine, seem to have the greatest effect, particularly in younger children to avoid bed time scratching.

Corticosteroids form the main line of therapy. These should be started with 1% hydrocortisone, which is the mildest of the group. For more resistant cases, one will probably have to use fluorinated, high potency steroid preparations. Triamcinolone cream 0.1% can be used for flare ups. Very occasionally, particularly severe, body wide exacerbations, may require short bursts of systemic steroids (1-3 mg/kg per day of oral prednisolone), which is often successful in improving the severe exacerbation within a few days. There is a concern of systemic absorption of topical steroids, but many studies have failed to show an actual adverse effect unless there was long term use. However, potent topical corticosteroids, if used repeatedly or over long term, can cause skin thinning and striae. Should these measures fail, some have used tar or ichthammol. PUVA (psoralen + ultraviolet A light) enhances the absorption of UV-A selectively into the affected skin lesions. Cyclosporin has also been used.

Newer medications called non-steroid immunomodulators, tacrolimus (Protopic) and pimecrolimus (Elidel), are approved by the FDA (since 2000) for atopic dermatitis. Unlike corticosteroids, these can be safely used for long periods of time without the corticosteroid side effects of skin thinning and telangiectasia.

Seborrheic dermatitis is usually managed somewhat differently than AD. There is an overproduction of oil on the scalp which combines with superficial exfoliated cells of epidermis to form the scales that are so prevalent. Oils therefore tend to worsen this condition so that moisturizers are actually contraindicated. Indeed, when parents, thinking that the scales indicate dry skin, rub oil into the scalp of their baby, the condition usually worsens. Parents should be instructed to shampoo the scalp with mild baby shampoo and gently try to remove the flakes and scales with their fingers. When the condition creeps down onto the face, however, mild corticosteroid creams can provide great relief as is the case with atopic dermatitis.

Questions

1. True/False: Seborrhea starts in infancy at the same time as atopic dermatitis.

2. True/False: Many infants who have seborrhea will eventually develop atopic dermatitis.

3. True/False: The prevalence of atopic dermatitis is generally higher in more developed societies and may be in part related to diverse environmental stimuli present in these communities.

4. Which of the following is a true statement?
    a. Seborrhea produces dry scales on the scalp of infants.
    b. Both seborrhea and atopic dermatitis benefit from scale removal.
    c. Seborrhea is not pruritic.
    d. Hydrocortisone cream can be used in cradle cap dermatitis.

5. A 5 year old child presents with a red, itchy rash in a 2 cm band across his abdomen below the umbilicus. The most likely diagnosis is:
    a. Contact dermatitis
    b. Scabies
    c. Atopic dermatitis
    d. Shingles

Answers to questions
1.False, 2.True, 3.True, 4.c, 5.a

Chapter XXI.2. Acne
M. Stanton Michels, MD

A 16 year old male presents for a pre-sports physical. His sole complaint is his acne, which he admits, has made him reluctant to ask female classmates out on dates. As his acne has become worse in recent years, he feels that he is becoming more withdrawn and self-conscious. He has tried Clearasil as an OTC medication, but he usually just "pops" the lesions when they appear. He'd like anything that would improve his complexion.

His exam is unremarkable except for moderately severe facial acne with secondary scarring.

Acne is a common skin condition of adolescent males and females. It is estimated that it affects 40% of teenagers at some point. The lesions take several forms:

Comedones come in two types. Closed comedones, also known as "whiteheads" are dilated plugged follicles that have not yet reached the surface. Often they are difficult to see and are 1-2 mm papules. When these reach the surface, the follicle becomes dilated at the orifice and are more visible as open comedones, or "blackheads

Inflammatory lesions that grow from comedones are of two types as well. Pustules are superficial, raised white lesions that are filled with pus. Pustules usually resolve in a matter of days without scar formation. Papules are deeper, dermal inflammatory lesions that are more erythematous, raised and solid. They take a longer time to heal and often result in scaring.

Cysts or nodules are the most severe form of acne lesions. These are really suppurative abscesses. Scarring is to be expected.

Scars take two forms. Ice pick scars are atrophic, broad-based depressions that reflect scarring of the deeper dermal tissues. Hypertrophic or keloidal scars are raised, thick fibrotic plaques that occur more frequently on the chest or shoulders. African-Americans are particularly prone to this form of scarring.

The pathogenesis of acne involves abnormalities in follicular keratinization with the excessive proliferation of Propionibacterium acnes. The excessive keratin produces a horny impaction or microcomedo. As this extends to the surface a comedone is formed. The sebaceous gland hypertrophies and secretes excess sebum. This process is greatly promoted by androgen hormones, and thus becomes most evident in puberty. Dehydroepiandrosterone (DHEA), from the adrenal glands along with testosterone, which is converted in the sebaceous glands to the more active dihydrotestosterone, are important in comedone formation.

P. acnes, which is an anaerobic diphtheroid, colonizes the impacted gland. Interestingly, the number of P. acnes bacteria on the skin surface do not correlate to the severity of the acne. Staphylococcus epidermidis and Pityrosporum ovale also are sometimes found from culture of the follicular material. P. acnes possesses a lipase that can hydrolyze sebum to free fatty acids. Intrafollicular free fatty acids promote inflammatory responses with chemotaxis of polymorphonuclear leukocytes and monocytes.

Therapy in acne is usually staged and relates to:

1. The type of lesion.
2. The acne severity.
3. The psychological impact of the disease.

Mild acne can usually be handled with a topical preparation antimicrobial such as benzoyl peroxide. This agent is bactericidal for P. acnes and comes in various strengths from 2.5 to 10% preparations. Higher concentrations are often used with truncal involvement.

Topical antibiotics are also useful in relatively mild cases of acne. Options here include erythromycin and clindamycin. Both have been shown to be equally effective although there are increasing reports of resistance to erythromycin. Pseudomembranous colitis secondary to topical clindamycin is almost unheard of.

For patients with more severe or inflammatory lesions, or those who failed to respond to topical therapy, systemic antibiotics are often added. These drugs can also have an anti-inflammatory effect and may decrease the chances of scar formation in patients predisposed to scarring. Options here include tetracycline BID or doxycycline once a day dosing. Of course these drugs should never be given to pregnant women or children under the age of 12 because of skeletal growth inhibition and discoloration of the teeth. Photosensitivity can also occur.

Topical Retin-A (tretinoin) and Differin (adapalene) normalize follicular keratinization by increasing turnover of cells lining the sebaceous gland. This invariably leads to irritation, erythema and desquamation of the skin that many patients find intolerable. The patient must be counseled prior to treatment about these effects and encouraged to give the drug a 3 month trial before deciding against its use.

Since hormones play a role in the pathogenesis of acne, hormonal manipulation is sometimes useful. The goal here is to reduce androgen production or inhibit androgen metabolism at the follicular level. Estrogen can be added to female patients in the form of oral contraceptives. This is unacceptable in male patients, due to the feminizing side effects. In a similar way, this option should not be used in patients younger than 16 years because of its adverse effect on growth in height.

Finally, systemic (oral) isotretinoin (Accutane) approaches the problem of comedone formation by decreasing sebum secretion. This depletes follicular P. acnes concentrations and then neutrophil chemotaxis. Hyperkeratosis is diminished. Accutane is an oral systemic analog of vitamin A and is indicated in patients with the most severe nodular or cystic forms of acne that have the highest propensity towards scar formation. Side effects are similar to hypervitaminosis A syndrome and include mucocutaneous inflammation, cheilitis (inflammation affecting the lips), conjunctivitis, and xerosis (eye dryness). Patients commonly complain of symptoms such as pruritus, chapped lips, and dry eyes. Moisturizing creams my help the cutaneous symptoms. Pseudotumor cerebri can also result which mandates stopping the drug. 25% of patients show an elevation of serum triglycerides, often with a rise in low-density lipoprotein levels. Liver enzymes may be elevated. The best-known side effect however is teratogenicity which has been shown to cause severe malformations in CNS, cardiac and craniofacial development. All female patients administered this drug should have a negative pregnancy test and advised not to become pregnant while taking the drug.

Questions

1. Organisms associated with the inflammatory process of acne include all of the following except:
    a. Pityrosporum ovale
    b. Propionibacterium acnes
    c. Strep pyogenes
    d. Staphylococcus epidermidis

2. All of the following are true statements are true of isotretinoin except:
    a. Cheilitis and xerosis necessitate discontinuing the drug
    b. Pseudotumor cerebri is sometimes irreversible
    c. The drug can be used in fertile women
    d. Increased levels of low density lipoproteins are sometimes seen

3. True/False: Comedones can be thought of as small pustules that can eventually develop into cystic acne.

4. True/False: Closed comedones are composed of small pus collections.

5. True/False: Retin-A (tretinoin) and Accutane (isotretinoin) both act to decrease hyperkeratosis.

Answers to questions
1.c, 2.a, 3.False, 4.False, 5.True

Chapter XXI.3. Hemangiomas, Vascular Malformations and Nevi

M. Stanton Michels, MD

A 12 month female is brought in by her mother because she afraid that her daughter has a skin tumor. What started as a small red spot on her cheek has recently grown to almost the size of a dime. It now "sticks out" and can be palpated with a bulging appearance. Mom is also concerned because other people have remarked about the lesion, but the child seems unconcerned as it seems to cause no pain.

The child's exam is normal except for a 1 cm bright red strawberry colored mass on her cheek which is elevated approximately 4 mm higher than the surface of her skin. You advise her parents that this is a strawberry hemangioma which should resolve on its own. Surgical removal is not advised since this will result in more scarring than letting it involute on its own.

Various methods of categorizing congenital vascular lesions have arisen. One common grouping is to separate these entities into: 1) Hemangiomas, sometimes termed vascular nevi, and 2) Vascular Malformations.

Hemangiomas are defined as benign neoplasms with proliferating vascular endothelium. This endothelium enlarges, stabilizes, and finally undergoes involution. Vascular malformations on the other hand, are hamartomas of mature endothelium that do not proliferate. Hemangiomas are also more common in females with at 3:1 or even 5:1 ratio. This may be related to the common finding of high levels of estrogen receptors in the proliferating lesions. Hemangiomas are usually single lesions, but multiple lesions occur in less than 25% of cases. If one measures H-thymidine uptake in these lesions, one finds increased proliferation. Another interesting feature is the number of mast cells in these lesions on microscopy is up to 10 times the number in otherwise normal tissue.

There are well-defined stages of hemangiomas: proliferate, stationary, and involutional phases. Characteristically the lesions grow and become more protuberant over a period of time and adopt the typical raised configuration of the "strawberry" hemangioma. Then they slowly regress and in about 75% of cases, they completely disappear by age 7 years. Overall spontaneous resolution occurs in greater than 90%. Treatment is usually discouraged because a variety of techniques including surgery, cryotherapy, laser therapy, injection of sclerosing agents, and photocoagulation have all caused scarring that is unacceptable compared to the typical spontaneous resolution.

One particular type of hemangioma should be mentioned, Kasabach-Merritt syndrome. In this condition, the hemangioma is very large and extends to deep structures. Complications can include disfigurement; high output cardiac failure, infection and thrombocytopenia with acute or chronic consumptive coagulopathy as in DIC.

Vascular malformations make up about two thirds of all lesions in the newborn. Common vascular malformations include the "salmon patch" which are extremely common and usually fade spontaneously, and the "port wine stain" or nevus flammeus, which is permanent. Port wine stains occur in 0.3% to 0.6% of children. When this occurs on the posterior neck, it is termed the "stork bite", or on the eyelids, the "angel's kiss". Most of the lesions on the face fade with time. Some of the occipital patches persist.

Unlike the hemangioma group, the port wine stains are composed of mature capillaries that are limited to the dermis alone. As the number of vessels increases and age, the color can change from bright pink to dark purple. As facial port wine stains age, the vessels undergo progressive ectasia, developing a dark violet hue and often a roughening skin texture. The can lead to considerable emotional impact on the part of the child and the parents as well. Laser treatment is available for this condition. Certain parts of the skin act as targets that absorb specific wavelengths of light. The light is converted to heat, which destroys the target. Careful selection of the wavelength administered can direct precise treatment with minimal peripheral destruction. This tends to decrease scaring, although some degree of scar formation is always possible.

There are several syndromes that can be associated with vascular malformations. The most common of these is Sturge-Weber Syndrome. Externally, this presents with a port wine stain over areas of the face innervated by the first division of the trigeminal nerve (V1). The significant hidden finding is the ipsilateral leptomeningeal angiomatosis. Classically this produces railroad track calcifications of cortical vessels seen on plain skull films. CT may show these cortical calcifications earlier in life than routine X-ray. Other concomitant findings include seizures in 55-97%, mental retardation and various eye findings including glaucoma, visual defects, optic atrophy, cataracts, retinal detachment and heterochromia of the iris. For this reason, CT is advised for the infant with a port wine stain in the first division of the trigeminal nerve distribution. Serial ophthalmologic examination is necessary to screen for glaucoma.

Nevi are collections of normal melanocytes. The lay public terms these moles. The greatest concern about them comes from the fact that some undergo malignant transformation to melanoma. Nevi fall into several classes.

Giant congenital nevi are defined as being greater than 20 cm in diameter. 6% of these will turn malignant within the individual's lifetime. Therefore, most authorities feel that they should be removed if at all possible. Sometimes the location or extent makes removal very difficult. Some practitioners advocate the removal of all congenital nevi, regardless of size because of this theoretic danger.

Acquired melanocytic nevi, or common moles can appear at any time after birth. They are often divided into 3 common types: 1) Junctional nevi have melanocytes that are limited to the epidermis. 2) Compound nevi have nevus cells both at the dermal-epidermal junction and lower inside the dermis. They frequently are raised but smooth bordered. 3.) Intradermal nevi have nevus cells completely within the dermis. These are raised, dome shaped, and smooth bordered. There is the theoretic possibility of malignant transformation in these nevi as well, but the rate is so low that these nevi do not need to be removed.

Lentigines are small, (less than 1 cm), hyperpigmented macules which unlike freckles, can develop on sun exposed skin but also on unexposed areas of the body. Several syndromes may be associated with lentigines. The most well known of these is Peutz-Jeghers syndrome. This entity also includes characteristic pigmented lesions on the lips and oral cavity. It is dominantly inherited, but what is most problematic is the associated intestinal polyps which may cause cramping or bleeding.

Café au lait spots are another type light brown hyperpigmented lesions, which if more than 5 or 6 in number can herald neurofibromatosis or von Recklinghausen's disease.

Questions

1. True/False: Proliferating vascular endothelium can be arrested with laser treatment.

2. True/False: The concerned parent whose child has a protuberant, growing vascular lesion in early childhood can often be reassured that the lesion will involute with time.

3. Common manifestations of Sturge-Webber Syndrome include all of the following except:
   a. Meningeal vascular malformations
   b. Choanal atresia
   c. Homonymous hemianopia
   d. Mental retardation

4. True/False: Like most hemangiomas, Kasabach-Merritt Syndrome lesions tend to involute with time, but do not disappear.

5. True/False: Lentigines are "age spots" that crop up in sun exposed areas.

6. True/False: Peutz-Jeghers syndrome often is picked up when hyperpigmented macules are found on the lips of children with chronic abdominal pain.

Answers to questions

1.False, 2.True, 3.b, 4.False, 5.False, 6.True

Chapter XXI.4. Burns
Annemarie Uliasz

This is a 3 year old male who is brought to the emergency room after suffering burns to the right arm when a hot cup of coffee spilled on him. His family applied gel from an Aloe plant to the burn before coming to the ER. He is otherwise healthy and his immunizations are up to date.

Exam: VS T 37.5, P120, R20, BP (unobtainable, crying), oxygen saturation 100% in room air. Weight 15 kg. He is alert and active, in moderate distress. His right forearm appears mostly red, and is painful upon palpation. Blanching is apparent on palpation. One smaller intact blister and one large ruptured blister are present on the dorsal aspect of the right forearm. The blistered surface area is estimated to be 2% and the non-blistered red area is estimated to be 2% for a total body surface area (TBSA) of 4%.

The physician recommends an IM dose of morphine, but his parents decline this, so acetaminophen with codeine is given instead. Cool, sterile, saline-soaked gauze is applied to the wound surface and the open areas are gently cleansed with saline. Tissue from the ruptured blister is removed and the intact blister is flimsy so it is drained and removed. Silver sulfadiazine cream is applied to areas of partial thickness burns and the burns are dressed. He is discharged with instructions for the parents to gently cleanse the burns with mild soap and water, reapply the antibacterial cream, and change the dressing each day. His burn healed completely without complications in five weeks.

Fires are second only to motor vehicle crashes as a leading cause of death in children. In the US, approximately 1.2 million people seek medical treatment for burns. Approximately 50,000 are hospitalized. One third to one half of these are under 18 years old. Children from birth to age 4 account for nearly 50% of all pediatric burns (1). After age 4, the incidence of burn injuries declines only to rise again in adolescence as individuals enter the work force.

Skin is the largest organ in the body. It consists of three main layers: the epidermis, the dermis, and the subcutaneous tissue. The epidermis is the outermost layer of the skin. It is composed of viable cells that mature and differentiate into cornified cells as they reach the skin surface. The superficial layer of anuclear cornified cells is called the stratum corneum. The stratum corneum prevents water and electrolyte loss, as well as acting as barrier to the entrance of microorganisms.

Deep to the epidermis is the dermis. The dermis is made up of stroma, a dense fibroelastic connective tissue containing collagen and elastic fibers, and ground substance, an extracellular gel. The dermis contains an extensive neurovascular network, special glands and appendages that communicate with overlying epidermis. The innermost layer of skin is subcutaneous tissue. It consists of fatty connective tissue, skin appendages, glands, and hair follicles.

Burns are classified according to the depth of injury. First degree burns are limited to the epidermis. A sunburn is an example of a first degree burn. These burns are red, dry and painful with no epidermal sloughing or blistering. Blanching is visible when pressure is applied to the wound. First degree burns do not lead to scarring, and require only local wound care. Second degree (partial thickness) burns extend into the dermis, with some residual dermis remaining viable. These burns are pink to pale pink, moist, and painful. They blanch on application of pressure. Epidermal sloughing and blisters are present. In third degree (full thickness) burns, the entire dermis is destroyed leaving subcutaneous tissue exposed. These burns appear white, mottled, or charred. They are dry and may be firm or leathery. Third degree burns do not blanch and are not painful. Fourth degree (transmural) burns extend through the subcutaneous tissue, exposing muscle and bone. They are usually associated with a lethal injury.

Most pediatric burn injuries occur at home and are largely preventable. In children younger than 4 years old, the most frequent burns are scalds. These injuries are the result of exposure to hot liquids (pulling pots off the stove, spilling hot beverages, or hot tap water). The second most frequent cause of burn injuries is contact with hot objects (the stovetop, a hot oven door, clothes irons, or curling irons). Furthermore, infants, toddlers, and small children may not be able to escape the burning object as well as an older child. Prolonged duration of contact may increase the severity of the injury. In older children, the majority of burns are due to fires and environmental causes such as hot barbecue grills, hot mufflers or engines.

Although the majority of pediatric burns are accidental, approximately 20% of burn injuries occur as a result of child abuse (2). If a non-accidental burn is suspected, the family should be questioned carefully. Any inconsistencies in the history of the injury suggest the possibility of child abuse and should be reported to the child protective authorities as required by law. Chronically abused children may have a depressed affect. Furthermore, the pattern of the burn may be suspicious of intentional injury. Scalding burns of the extremities in which the entire foot or hand is burned, with a glove or stocking pattern and lack of splash marks, suggest forced immersion into hot water. Additionally, burns on the back, buttock, or both soles of the feet are highly suspicious for child abuse. The depth of the burn is another factor to keep in mind when abuse is being considered. Partial thickness burns commonly result from accidental scalding. Full thickness burns caused by scalding suggest sustained contact with hot water. Small area, full thickness burns suggest injury from a cigarette. Evidence of other trauma, such as bruising or numerous healed wounds, should be documented.

The first step in management of a burn injury is assessment of life-threatening conditions. The airway must be evaluated immediately for compromise in the case of burns caused by flame or history of smoke exposure. Smoke inhalation can result in severe inflammation of the airways and lungs. Classic signs associated with significant smoke inhalation are burns to the face or nasal hairs and/or carbonaceous sputum. Because the airway can swell rapidly, this condition must be treated aggressively and quickly to prevent airway obstruction. Immediate tracheal intubation is indicated if the patient shows signs of laryngeal edema, such as hoarseness, stridor, or a brassy cough. Endotracheal intubation and mechanical ventilation are required in the case of respiratory failure. Signs of respiratory failure include the development of tachypnea, use of accessory respiratory muscles, and hypoxemia (3).

All patients exposed to smoke in an enclosed space should be screened for carbon monoxide poisoning by measuring a CO level or co-oximetry since an arterial blood gas and pulse oximetry will not adequately identify CO poisoning.

To accurately estimate the depth of skin injury, devitalized tissue must be debrided, and large blisters must be removed. This procedure is usually painful and requires potent analgesics. Burn depth is estimated by careful observation of the wound surface.

The extent of total body surface area (TBSA) covered by second or third degree burns has a great impact on the morbidity and mortality, and must be estimated. Areas of first degree burns are associated with negligible mortality, so the important components of the TBSA are the areas of second and third degree burns. Although time-consuming, the Lund and Browder chart is the most accurate method of determining TBSA. It consists of an anterior and posterior diagram of a patient that is divided into sections which can be colored in according to the distribution of the patient's burns. The TBSA of burn is the sum of the colored areas. Different charts are available for different age groups. An alternative to the Lund and Browder chart is the rule of nines. In this method, the body is divided into eleven

areas of nine percent each. Each upper extremity is 9%, the anterior and posterior portions of each lower extremity are 9%, the anterior upper and lower portions of torso are 9% each, the posterior upper and lower portions of the torso are 9% each, and the neck and head together is 9% to give a total of 99%. The perineum makes up the remaining 1%. However, it must be taken into account that the head is relatively larger and the legs relatively smaller in surface area for children compared with adults. A palm of the hand on one side including the area of the digits, is approximately 1% of the body surface area and can be used to estimate the TBSA of burn.

A burn covering 10% or more of the TBSA of a child is considered a serious burn and should be managed as an inpatient, preferably in a burn unit where specialized expertise is available. Significant burns of face, hands, genitalia, feet, or across the joints are categorized as serious. Transfer to or consultation with a burn center should be considered for these patients.

Management: Any clothing and jewelry should be removed from the area of the burn. If clothing has adhered to the skin, it should be left for removal during the cleansing of the wound (4). Non-adherent material may be cut away. To decrease pain, the burn may be cooled with the application of cooled, sterile, saline-soaked gauze.

Prior to cleaning the burn, analgesia is desirable (4). Burns should be cleansed to remove contaminating debris. Tar or asphalt may be removed with a mixture of cool water and mineral oil (4). Embedded clothing and debris can be removed by irrigation.

Necrotic tissue must be debrided to minimize infection. Removal of necrotic tissue can be accelerated with the use of enzymatic debriding preparations such as collagenase and papain-urea preparations. These preparations may be less painful and may hasten epithelialization. Blisters which have already lysed should be debrided so that the excess skin does not harbor infection. Flimsy intact large blisters are likely to lyse on their own soon, so these can be debrided as well. Small firm blisters can be left alone. The appearance of the burn on the second day almost always looks worse with enlarging blisters. This should be anticipated in counseling.

Patients suffering wounds deeper than a superficial partial-thickness burn should have their tetanus immunization updated. Bacitracin ointment or silver sulfadiazine cream are not necessary in the treatment of superficial burns, but should be used to prevent infection in all other burns.

Once cleansed, the wound should be dressed daily until epithelialization occurs. This will provide some pain relief, protect the wound from infection, and absorb drainage from the wound.

Superficial partial thickness burns heal in approximately 1-3 weeks. Most deep partial-thickness burns eventually heal by epithelialization in 3-9 weeks. Epithelialization begins in the dermis in the remaining hair follicles. As buds of epithelium grow, they eventually merge to close the wound. Hair follicles are destroyed in full-thickness wounds preventing epithelialization. Full thickness burns require surgical treatment consisting of eschar excision and skin grafting.

Severely injured patients are better served at a designated burn center specifically trained in analgesia and wound care for patients with burns. Transfer to a burn center should be considered in more severe burns, major burns to the hands, face, feet, perineum, or complex electrical burns.

If an extremity is involved, immobilization and elevation may be helpful to reduce edema. Edema may increase ischemia and tissue necrosis. Furthermore, compartment syndrome may develop in an extremity that has sustained a circumferential burn. Patients with circumferential burns of an extremity should be admitted to the hospital for observation of the development of this potentially limb and life threatening condition.

Patients with burns covering 10-15% of the TBSA or more, usually require parenteral fluids. Ingestion of fluids may be inadequate in children due to pain, anxiety, and the effects of narcotics. Extravasation of fluid into unburned tissue as well as increased evaporation from the surface of the wound results in hypovolemia. Fluids must be administered to prevent hypovolemia-induced ischemia, lactic acidosis, and shock. Fluid resuscitation with Ringer's lactate or normal saline solution should be administered according to the Parkland formula (7). This formula estimates the fluid requirements of the pediatric patient for the first 24 hours (4 cc/kg for each TBSA percentage point infused over 24 hours in addition to the maintenance calculation), but urinary output is the best indicator of satisfactory hydration. Although adequate fluid administration is essential, it is important to avoid over-hydration. Increased hydrostatic pressure and decreased oncotic pressure from protein loss contributes to the fluid shift, and over-hydration may result in increased wound and whole-body edema (including pulmonary edema and respiratory compromise).

When administering fluid to infants, it is important to appreciate the lack of maturity of their kidneys. Adult glomerular filtration rate levels are not achieved until age 9-12 months. The infant handles fluid overload very inefficiently. Because of an imbalance of maturation of tubular and glomerular functions, the osmolar concentrating ability is estimated to be one half of that seen in adults (6).

Loss of water by evaporation leads to heat loss. Small pediatric burn patients are especially at risk for hypothermia. In order to minimize radiant and evaporative heat loss, the ambient temperature should be kept sufficiently high. IV fluids should be warmed during large fluid infusions. Special care should be taken in patients younger than 6 months old. Children in this age group do not have the ability to shiver. Thermiogenesis is accomplished by catabolism of fat stores requiring large amounts of oxygen. Excessive lactate production and metabolic acidosis may result from prolonged thermiogenesis.

The basal metabolic rate may double after a major burn injury. The increase in metabolic expenditure is roughly proportionate to the surface area burned. For example, a child with a burn covering 50% TBSA requires an increase in the basal level of calories of at least 50%. To decrease the loss of muscle mass, about 20% of the calories administered should be from protein.

Most children sustain electrical burns by the insertion of a metal object into a wall outlet or by exposure to frayed electric cords. Intense heat and deep injuries are produced when the current passes through the tissues. If a child puts a live electric cord into the oral cavity, the lips may be burned. Additionally, the burn may extend completely through the lips and oral mucosa to the labial artery. This can be potentially catastrophic if this artery erodes due to sloughing of necrotic tissue. Sudden hemorrhage can occur as late as one week after injury (1).

Burn injuries may result in scarring and contracture. There is a high risk of scar formation associated with burn wounds that take more than 3 weeks to heal. Furthermore, scars may develop in wounds that heal spontaneously without skin grafting. Children tend to scar worse than adults, and patients with dark skin color, scar worse than patients with light skin. Pressure garments worn 24 hours a day, continuously for one year after healing, may limit the progression of scarring. Joint contractures are characteristic of scarring.

Physical and occupational therapy should begin on the day of admission in order to maximize the cosmetic and functional outcome. If necessary, therapy may continue after discharge for several months as the scar tissue forms and contractures develop. Rehabilitation involves joint positioning, active and passive range of motion exercises, limitation of pressure necrosis, ambulation, and assistance in daily activity. Rehabilitation programs for burn patients consist not only of physical support, but emotional support as well. As the pediatric burn patient matures and enters into new social situations, psychological support may be beneficial.

Questions

1. When is antibacterial ointment indicated?
2. When treating an infant, what are some special considerations that must be acknowledged?
3. When should a patient be sent to a burn unit?
4. How is the %TBSA calculated?
5. What formula is used to determine the amount of fluid administered to the pediatric burn patient within the first 24 hrs?
6. Despite following the above fluid formula, a burn patient has a continuous urine output via urinary catheter of only 0.2 cc/kg/hr (ideally, this should be about 1 cc/kg/hr). The child appears to be moderately edematous. Should the fluid rate be increased or continued at the same rate?

Answers to questions

1. Antibiotic ointments such as silver sulfadiazine and bacitracin are indicated for all burns except superficial burns.
2. Infants 6 months old or younger are more prone to fluid overload because of their reduced glomerular filtration rates. Additionally, they are more susceptible to hypothermia because they are unable to generate heat by shivering.
3. A patient should be sent to a burn unit if they have serious burns that are beyond the scope of care in the local institution. Examples of this include, second degree burns of 20% TBSA, third-degree burns of 5% TBSA, major burns to the hands, face, feet, perineum, or electrical burns.
4. % TBSA can be estimated by using the rule of nines, the Lund and Browder chart, or by designating the child's palm as 1% of the TBSA. The most accurate method is the Lund and Browder chart.
5. The Parkland formula is used to estimate the amount of fluid appropriate for administration in the first 24 hours.
6. The slow urine output indicates hypovolemia. The fluid infusion rate should be increased to improve the urine output.

Chapter XXI.5. Bites and Stings

Todd T. Kuwaye, MD, MS

A 6 year old female was playing in the yard when she suddenly felt pain in her left ankle. Her ankle became swollen, red and painful, so her mother took her to the pediatrician's office. Upon close examination there is a central puncture lesion with a small amount of serosanguineous drainage. Her vital signs are normal. No other examination findings are present

What are the potential causes for this lesion? What current treatment is needed? What advice should be given to the child and parents?

In Hawaii, we are fortunate to have only a few arthropod bites and stings that are of a medical concern. An arthropod may bite with the use of mandibles or inflict a wound from a stinger. In Hawaii, arthropod bites can occur from mosquitoes, flies, fleas, ants, lice, centipedes, beetles, roaches, and spiders. These arthropod bites are rarely serious except for a few notable arthropods such as the brown violin spider and the black widow spider because of the toxicity contained in their venomous bite. Although bites from these spiders can be serious, they are not as frequent as the bites that occur from mosquitoes, ants, fleas and flies. All bites have the potential to cause local skin irritation, pruritus, swelling, erythema and pain. If not treated well with local skin care, a lesion can also become infected. Local allergic reactions are common from insect bites. Insect bites rarely cause systemic allergic reactions in children when compared to insect stings (1). Although uncommon, if a patient has enough of a repeated allergen load from proteins contained in the saliva of the biting arthropod, systemic allergic reactions could occur (1). Anaphylaxis has been reported from bites of the mosquito, horsefly, and the tick (2).

Another health problem associated with insect bites is the potential to transmit disease. An outbreak of dengue fever in Hawaii (2001) by mosquitoes demonstrated the disease carrying ability of insects as vectors. Another noteworthy vector in Hawaii is the flea and its ability to transmit the plague. Fortunately Hawaii does not have ticks and fleas that carry Lyme disease and Rocky Mountain spotted fever.

Envenomation occurs from such arthropods such as spiders and centipedes in Hawaii. A centipede's bites cause intense localized pain, swelling, and occasionally infection and local tissue necrosis. A few of the spiders in Hawaii contain venom in their bite that can lead to serious complications. Two of the more dangerous spiders are discussed in greater detail below.

The Southern Black Widow Spider (Latrodectus mactans), as well as its cousins, the brown widow (Latrodectus geometricus), and the Western Black Widow (Latrodectus Hesperus), are found in Hawaii (3). The black widow lives in warm, dark, dry places outdoors or in sheds, basements and garages. The Black Widow is a non-aggressive spider, which bites in self-defense. Its venom causes severe muscle cramping which is mediated by a neurotoxin that acts on the presynaptic membrane causing the release and decreased uptake of acetylcholine (4). The victim usually experiences a pinprick sensation, followed by regional lymph node tenderness (30-120 minutes later), a target lesion (at the bite site), and muscle cramping near the bite site (4). Dysautonomia manifested with nausea, emesis, sweating,

hypertension, tachycardia, and malaise can occur (3,8). Symptoms may last 36-72 hours (4). Treatment is analgesia, while supportive care is given to hypertensive and tachycardic patients (4). Antivenom derived from horse serum is available but reserved for the severe cases due to the adverse effects from horse serum administration (4).

The brown violin spider (Loxosceles rufescens) is a cousin of the brown recluse spider (Loxosceles reclusa), which is responsible for most of the clinically significant necrotic spider bites in the United States (5). The Brown recluse spider is not found in Hawaii but the brown Violin spider is found locally (3). All Loxosceles spiders are venomous and produce the clinical condition called loxoscelism, also known as necrotic arachnidism (5). The brown violin spiders are non-aggressive, nocturnal and found under boards and loosened bark (3). The brown violin spider's venom is used to digest its prey, but has both a local and systemic effect in humans, causing dermonecrosis and hemolysis (5). Bites usually are seen in children and can be asymptomatic or it can cause a mild to sharp stinging pain followed by potential development of a central blister to dermonecrosis (5). Systemic reactions include fever, chills, arthralgias, malaise, nausea, emesis, leukocytosis, hemolytic anemia, jaundice, renal failure, shock, DIC and death (5). Systemic reactions are infrequent. Loxosceles envenomation can usually be treated as an outpatient unless there are systemic symptoms, serious infection, or extensive necrosis (5). There is no effective treatment for the dermonecrosis. An antivenom is currently experimental and appears promising (5).

Fortunately, most arthropod bites are more of an annoyance rather than a potential life-threatening situation. Keys to management include prevention of arthropod bites by eradication, avoidance of arthropod's habitats and use of protective clothing. Immediate management may include: local wound care, topical corticosteroids, antibiotics if infected, antihistamines if the lesion is pruritic for comfort and prevention of infection by excoriation, tetanus toxoid booster if not current, and analgesics.

In Hawaii, arthropod stings can occur from bees, wasp, ants and scorpions. All of these arthropods contain mild venoms. However, systemic allergic reactions occur more frequently from insect stings compared to insect bites in children (1). Stinging insects belonging to the order Hymenoptera (bees, wasp, and ants) are responsible for 40-50 deaths a year in the United States (2,7). Reactions to arthropod sting can be classified as usual, large local, anaphylactic and toxic reactions (2). The usual arthropod sting causes the local pain, swelling, and erythema, which resolves in a few hours (2). Large local reactions involve more extensive symptoms, which last 24-48 hours (2). Anaphylaxis is the most serious response (see chapter on anaphylaxis). A toxic reaction occurs from envenomation from multiple stings.

Immediate management is to ensure the removal of the stinger. The stinger of the bee is barbed and detaches after being imbedded into the victim's skin. Since wasps can sting repeatedly, one may find grouped lesions without any visible stinger. The bee stinger contains venom sacs which if pinched can increase the level of envenomation. It is recommended to brush the stinger out of the skin. The usual and local reactions of insect stings require control of pain, pruritus, and swelling, as well as local wound care to prevent infections. Localized hypersensitivity reactions can be treated with topical corticosteroids, urticaria can be treated with antihistamines and anaphylactic reactions are treated more intensively with epinephrine, antihistamines and corticosteroids.

Repeat anaphylactic reactions to insect stings are more common in adults than in children (2). Children under 16 years old, who have isolated allergic reactions (urticaria and angioedema) after stings have a 10% incidence of subsequent systemic reactions and only a less than 0.1% incidence of a life threatening respiratory or cardiovascular allergic reaction (2,7,9). Children's sensitivity to insect venom is expected to diminish over time (2). An allergist should evaluate any child with an anaphylactic reaction to insect stings. Immunotherapy for insects can be used on children depending on the severity of the allergic reaction. However, any child with a history of anaphylaxis and positive skin test or in vitro assay for venom specific IgE should receive immunotherapy for 4-5 years (2). In children with large localized reactions and who are at risk for future frequent or multiple stings, immunotherapy is an option (2). These children should also be given a self-administered epinephrine kit with instructions and a demonstration of its use. Patients should also obtain a medical alert bracelet.

Scorpions are found in Hawai'i, but their stinger contains a venom, which is not significantly toxic. Scorpions from other parts of the world do contain venoms, which can be substantially toxic.

Avoidance of stinging arthropods becomes an important part of management and includes: identification and elimination of stinging insect nests, avoiding brightly colored clothing or strongly scented lotions, wearing shoes or protective footwear outdoors, exercising caution around sites frequented by stinging insects (eaves, attics, and areas where food is present outside), and wearing protective clothing when outside (long shirt, pants, hat, gloves, socks and shoes) (6).

Marine envenomations common in Hawaii occur from box jellyfish, Portuguese man-of-war, and venomous fish. These animals produce protein-based venoms that are used in self-defense or to capture prey. Unfortunately the unwary beach goers may interact adversely with these animals and sustain intensely painful wounds. As a general rule, these venoms tend to be heat labile and can be denatured with heat.

Venomous snakes are not found in Hawaii. A discussion of snakebites is beyond the scope of this chapter.

Questions

1. A ten year old male is stung by a bee. Upon examination of the sting site, a stinger is still embedded in the skin. What should you do?
   a. Pinch it off
   b. Brush it off
   c. Wait till you seek medical attention

2. A twelve year old male moving boxes in the basement experienced a pinprick sensation on his right hand followed by muscle cramps and swelling in his right axilla. On presentation to the ER a target lesion is noted on his right hand. The patient is noted to be nauseated, sweating, hypertensive, and tachycardic. What is the probably culprit?
   a. Centipede
   b. Scorpion
   c. Yellow jacket
   d. Black widow
   e. Brown violin spider

3. True/False: Ticks, flies and mosquitoes can cause anaphylaxis.

4. True/False: Snakes and scorpions are some of the most venomous animals in Hawaii.

5. What two spiders are found in Hawaii that can inflict a serious and potentially deadly envenomation?

6. True/False: Repeat anaphylactic reactions to insect stings are more common in adults than in children.

7. A teenage boy fishing is accidentally poked by a spiny fish. The site becomes red and painful. What are reasonable management steps.
   a. Local wound care
   b. Epinephrine
   c. Application of heat to sting site
   d. Antibiotic ointment
   e. Tetanus toxoid
   f. Contact a poison information center

Answers to questions

1. b
2. d
3. True, anaphylaxis can occur from any repeated insect bite or sting in which re-exposure to an antigen occurs.
4. false
5. Southern black widow and Brown violin spider.
6. true
7. All except b.

Chapter XXI.6. Common Skin Conditions
Annemarie Uliasz

This is a 6 month old female who is brought to the office with her mother with a chief complaint of a diaper rash for one week. Mother has been using baby powder to keep the area dry, but the rash is worsening.

Upon examination, the buttocks, perianal region, and tops of the thighs appear erythematous with no ulcerations or erosions. Areas of flexure are involved and there are some beefy red areas with a few satellite lesions. The rest of the exam is normal.

Her mother is given instructions to change her infant's diapers frequently, at least every three hours. Baby powder does not keep the area dry once the child urinates, so its value is minimal. Special attention should be made to keep the skin under the diapers dry. Hydrocortisone ointment or cream can be used to suppress the inflammation. Petrolatum or zinc oxide applied to the diaper region is suggested as prophylaxis against irritation. Topical clotrimazole cream is also recommended to eliminate any yeast infection that may be present.

The skin is composed of three different layers. The outer most layer, the epidermis, is made predominantly of keratinocytes. The most superficial layer of the epidermis, the stratum corneum, serves as a protective barrier against the environment, and prevents desiccation. The epidermis also plays a role in immune surveillance (1). Damage to the epidermis increases skin permeability, thereby increasing the risk of infection. The epidermis also contains melanocytes (which gives the skin its color), Merkel cells (which are pressure receptors), and Langerhans cells (which participate in the skin's immune response).

The dermis lies beneath the basement membrane of the epidermis. The dermis consists of collagen, elastin, and proteoglycans, which lend support and durability to the skin. Blood vessels, lymphatics, sweat glands, hair follicles, smooth muscle, and neuroreceptors are all found in the dermis. Fibroblasts in the dermis are responsible for collagen production and are the predominant cell in this layer of the skin. Other cells common in the dermis include mast cells, leukocytes, and histiocytes.

Subcutaneous tissue resides beneath the dermis. This layer serves as insulation, a fat depot, and a cushion against trauma. Blood vessels and lymphatics are found in the subcutaneous tissue as well as the base of hair follicles and sweat glands.

In order to describe a skin lesion, one must have a basic understanding of the language of dermatology. A primary lesion is a lesion that has not been altered by trauma, infection, scratching, therapy, or regression over time. Primary lesions are described as macules, patches, papules, nodules, tumors, vesicles, bullae, pustules, plaques, cysts, and wheals. A macule is a flat, circumscribed skin discoloration that is neither raised nor depressed. It cannot be felt. Once it reaches 1cm or greater in size, it is termed a patch. A papule is an elevated, solid lesion that is less than 0.5cm in diameter. If the diameter is greater than 0.5cm, it is known as a nodule. A nodule is basically a larger, deeper papule. Tumors are usually larger in diameter than nodules, and tend to be variable in consistency and mobility. Vesicles (blisters) are raised, fluid-filled lesions less than 0.5cm in diameter. A bulla is a larger fluid-filled lesion that is greater than 0.5cm in diameter. A pustule is a papule that contains purulent material. A plaque is an aggregation of papules, vesicles, or pustules that is greater than 0.5cm in diameter. Wheals are palpable, firm, edematous lesions that may vary in configuration and size. They tend to be pruritic and evanescent (existing briefly before disappearing). A cyst is a lesion that contains fluid or semi-solid material. Its walls are circumscribed and thick, and it is located deep in the skin.

Primary lesions may develop or turn into secondary lesions. Secondary lesions include crusts, scales, excoriations, fissures, erosions, ulcers, and scars. Crusts (scabs) are dried collections of blood, serum, or pus. They usually arise from a primary lesion such as a vesicle, bulla, or pustule. Scales consist of compressed layers of keratinocytes on the skin surface. An excoriation is a linear erosion caused by scratching. A fissure is a crack in the skin. An erosion is a focal loss of epidermis that heals without scarring. An ulcer is a focal loss of epidermis extending into the dermis that heals with scarring. A scar is an end-stage lesion composed of connective tissue, which may be atrophic or hypertrophic.

Once the definitions of primary and secondary lesions are learned, a skin lesion may be described. The description should include the lesion's size, color, shape, arrangement, distribution, and whether it is a primary or secondary lesion. The following chapter discusses common dermatologic conditions in the pediatric patient.

Contact dermatitis can result from injury to the skin, as in irritant dermatitis, or from a hypersensitivity response, as in allergic dermatitis. The distribution of the rash is determined by the points of contacts. Common hypersensitivity contact dermatitis allergens include latex (rubber), nickel (jewelry, buckles, snaps), hair dye and leather (tanning chemicals). If a particular substance is suspected, a simple test to confirm hypersensitivity is to tape a small piece of it on the medial portion of the upper arm and observe for a reaction 12 hours later.

In the pediatric population, irritant dermatitis is more commonly seen than allergic dermatitis. Irritant dermatitis is an inflammation of the skin caused by exposure to irritants such as soaps, saliva, citrus juice, bubble baths, or detergents (1). The appearance of the skin may range from mild redness, edema, or vesicles to oozing bullae. The face and hands may be affected by saliva from a drooling infant. Bubble baths may be the source of an intense pruritus. Restrictive shoes that trap sweat and moisture may cause irritant dermatitis of the feet. Treatment of contact dermatitis may be as simple as removing the irritant. Hydrocortisone cream will provide additional relief.

Diaper dermatitis (diaper rash) is a common ailment of infants. Diaper rash occurs in approximately 50% of infants. The peak of incidence occurs between the ages of nine and twelve months (2). The main source of irritation is urine and feces on the skin. Diaper dermatitis may occur if diapers are not changed frequently enough, or if the infant has diarrhea. However, it may occur even if diapers are changed regularly. The buttocks, perineal area, lower abdomen and top of the thighs are the areas that are most frequently involved. Characteristically, areas of flexure are spared. The rash appears erythematous, and the skin may look scalded. Ulcers and erosions may be seen in severe cases. Diaper rash may be treated by frequent changes of diapers, at least every three hours, and close attention to keeping the skin dry. Most cases are self-limited and resolve in 3 days (3). Petrolatum or zinc oxide may be used as a protective barrier. Severe cases may be treated with low potency topical corticosteroids. Diaper rashes may be complicated with a secondary Candida infection. Candida albicans can complicate any diaper rash that has been present for three or more days (4). In these cases, the rash involves the skin flexures with satellite lesions. These rashes may be treated with anti-candidal agents (e.g., clotrimazole, miconazole and nystatin).

Erythema toxicum, a skin eruption which occurs in roughly half of all newborns, usually within the first two days of life (5). It is self-limited, lasting approximately three days. The etiology is unknown. Erythema toxicum presents as papules, macules, and sometimes pustules surrounded by an irregular halo of erythema. The lesions are distributed on the arms, legs and trunk. A Wright stain of a smear (by pricking the skin and doing a touch prep on a slide) reveals eosinophils with no organisms present (3).

Nevi (moles) are clusters of melanocytes that appear at the epidermal-dermal junction. The number of acquired nevi increases with age, reaching a plateau in the 30s or 40s (1). An adult will have on average 25-30 nevi. The amount of nevi that develop is related to the amount of sun exposure sustained in childhood. Although most nevi are benign, a small percentage may undergo malignant transformation into melanoma. Risk of melanoma increases as the number of nevi increases and as the amount of sun exposure increases. Malignant change may be suspected if the nevi display irregular borders, large size (5-15mm), multiple colors, or become ulcerated, scaled, or indurated. If any of these suspicious characteristics are observed, the nevus can easily be excised. A complete skin examination is recommended for children with atypical nevi. These children should be counseled regarding limiting sun exposure.

Paronychia is inflammation of the nail folds of the fingers. Acute paronychia may occur spontaneously, or after trauma, removal of a hangnail, or nail-biting (6). Staphylococci or streptococci infections are often responsible for acute paronychia. The patient presents with warmth, edema, erythema and proximal nail fold tenderness. Treatment includes warm soaks (to soften the skin), oral antibiotics, and drainage of an abscess if one is present. The chronic form is more commonly seen in children and is often caused by finger sucking, which creates a desirable environment for yeast, such as Candida, and bacteria to thrive (7). In chronic paronychia, the nail fold (eponychium) will swell and then separate from the underlying nail plate. Foreign material present under the nail leads to inflammation and infection. Treatment includes reducing predisposing factors, careful attention to hand drying, incision and drainage of the pus, and topical anti-inflammatory agents. Antibiotics may be employed empirically or until the cultures come back (most likely Staph aureus) (7).

Varicella zoster (chickenpox) is spread via respiratory secretions and direct contact with cutaneous lesions. Routine varicella immunization has drastically reduced the incidence of this infection. The incubation period is approximately 2 weeks (10 to 21 days). Subsequently, a pruritic, vesicular rash originates on the scalp or trunk and spreads to the rest of the body. Macular or papular lesions appear which develop into vesicles. The lesions of varicella zoster are sometimes described as "dew drops on a rose petal" (8). The vesicles then dry up and become crusts, which persist for three weeks before disappearing. Typically, there are lesions in various stages of healing. Children are contagious from two days before to five days after the onset of the rash. A Tzanck smear may be helpful in confirming the diagnosis (reveals multinucleated giant cells) (6), but this is usually unnecessary. Complications include secondary infection with staphylococci or streptococci. Varicella encephalitis may occur shortly after the appearance of the rash, most commonly presenting with mild ataxia. However, the prognosis is usually good, unlike the encephalitis caused by herpes simplex virus. Immunocompromised patients with varicella zoster infections may experience persistent vesicular eruptions that may become hemorrhagic or they may experience disseminated varicella. It is recommended that high-risk individuals (immunocompromised) receive human varicella zoster immunoglobulin (VZIG) following exposure to chickenpox. Additionally, neonates whose mothers develop chickenpox within five days prior to or two days following delivery should receive VZIG as well as premature neonates born less than 30 weeks gestation who have been exposed to chickenpox. Acyclovir may be administered in cases of severe varicella, but some advocate routine use of acyclovir for varicella or zoster, especially for adolescents due to their propensity to develop severe disease. Because of the risk of Reye syndrome, aspirin should be avoided.

Once chickenpox subsides, the virus becomes latent. Latent varicella may reactivate causing herpes zoster. Herpes zoster, or shingles, is characterized by groups of vesicles distributed along a cutaneous nerve (a dermatome). The thorax is most commonly involved, but lesions may appear along any dermatome. Involvement of the face, neck, and eye can be serious. New crops of vesicles may appear for three to five days. As in chickenpox, the vesicles dry up into crusts and disappear within three weeks.

Five to ten percent of children develop cutaneous warts (1). Common warts, typically found on the hands, are caused by HPV (human papilloma virus) types 1, 2, 4, and 7 (9). Common warts are flesh-colored, rough, and hyperkeratotic. When the superficial surface is excised, many black dots may be visible. These black dots are actually loops of capillaries. Plantar warts are found on the soles of the foot. They are often compressed against the surface of the foot due to continual weight bearing pressure and may be painful. Plantar warts are caused by HPV types 1and 2. Flat warts, or verrucae planae, are caused by HPV types 3 and 11. They are slightly raised, typically less than 3mm in diameter, and appear in crops of 10-30 or more. Their color ranges from pink to brown, and may occur on the forehead and dorsum of the hand. Condyloma acuminata are warts that are found in the anogenital region. They are most commonly seen in the sexually active adolescents. In a young child, these warts may have been transmitted through the birth canal, through spread from cutaneous warts, or they may signify child abuse. Condyloma acuminata are caused by HPV types 6, 11, 16, 18, and 31. Types 16, 18, and 31 are associated with cervical cancer. Condyloma acuminata are moist, soft, papillomatous lesions that may occur as single or multiple lesions. If untreated, they may grow to cauliflower-like masses. Genital warts are covered in the chapter on sexually transmitted infections.

Over fifty percent of warts regress spontaneously within two years. However, untreated warts have the potential to spread and progress. When treating warts, it is imperative to protect the surrounding skin from irritation. Prior to treatment, plantar, palmar, and common warts should be pared down until the capillaries are revealed. This makes the warts more responsive to treatment. It is recommended that therapy be administered every two weeks. Liquid nitrogen or cantharidin may be used to treat common warts as well as light electrodesiccation and curettage. Common warts and plantar warts may respond to lactic acid or salicylic acid treatments (over the counter topical wart medication). These warts may also be soaked in warm water and reduced with a pumice stone. Successful treatment with duct tape has also been reported. Condyloma may be treated with podophyllin applications every two weeks. However, if the warts are refractory, liquid nitrogen or CO2 laser treatment may be necessary.

Molluscum contagiosum is a viral infection of the skin caused by a DNA containing pox virus. It is most commonly seen in children. Boys are more commonly affected than girls are. The peak incidence is at age ten years (2). The lesions are small, firm, skin-colored papules that are centrally umbilicated. They may appear as one or multiple lesions, and tend to be approximately 1-5 mm in diameter. The papules may occur anywhere on the body, but are usually found on the trunk, face, arms, and genital region. Molluscum contagiosum may be spread by direct contact, or by autoinoculation. This infection typically spontaneously resolves within six to nine months, however, treatment may prevent autoinoculation and person to person spread (1). Treatment includes curettement, electrosurgery, cryosurgery, or other standard wart medications. Instructions on washing it well (to prevent spread) may be all that is necessary.

Pediculosis, commonly known as lice, affects people of all ages. There are three types of lice: body or clothing lice (Pediculus humanus corporis), head lice (Pediculus humanus capitis), and pubic or crab lice (Phthirus pubis). Pruritus is the hallmark of all types of pediculosis. Lice bite the skin and live on the blood. They cannot survive without human contact. The female louse lays eggs, which may be seen attached to hair follicles or clothing fibers. Once the eggs hatch, the newly born lice mature in 30 days (1). The female louse lives another thirty days and deposits a few eggs each day. The diagnosis is made by identifying lice or eggs (nits) on the hair shaft or clothing fibers. The nits are small white oval-shaped capsules.

Body lice is rare in children. It may be seen in conditions of poor hygiene, especially in colder environments when the opportunity to change clothes regularly is lacking. The lice are transmitted on contaminated clothing or bedding. They are found on the skin only

transiently when they are feeding. At other times, the nits are firmly attached to the seams of clothing. The primary lesion found on the shoulders, trunk or buttocks, is a small, red macule or papule with a central hemorrhagic punctum. Treatment consists of improved hygiene and washing all infested clothing and bedding in hot water. Alternatively, the lice will starve if clothing is stored at 75-85 degrees F for two weeks. For those unable to change clothes, clothes may be dusted with 10% lindane powder. Lindane lotion or permethrin cream may be applied for 8-12 hours to eradicate eggs and lice on body hair.

Head lice infest the scalp hair. It is especially bothersome among school children. Patients often present with scalp itching. If the eyelashes are involved, conjunctivitis may result. Transmission occurs by head-to-head contact, and shared combs, brushes, or towels. Translucent eggs are laid near the proximal portion of the hair shaft. Treatment involves application of 0.5% malathion (Ovide) to the hair for 12 hours (although application for much shorter periods may be sufficient). The hair is then washed, and the dead nits are then removed from the hair shafts by a fine toothed comb. Clothes must be laundered or dry-cleaned. Other shampoo treatments include permethrin 1% creme rinse (Nix or Elimite), pyrethrin shampoo, or 1% lindane shampoo (Kwell). Lindane is potentially neurotoxic so it is not recommended for infants and young children. These shampoos are applied and rinsed after 10 minutes, with a repeat application 7-10 days later. There are presently no published trials assessing the safety or efficacy of alternative treatments such as herbal remedies, kerosene, or battery-powered combs. Occlusive dressings are sometimes recommended using mayonnaise or petroleum jelly, but their efficacy is not thoroughly studied.

Pubic lice (crabs) is transmitted by skin-to-skin or sexual contact with an infested individual. The infestation is usually encountered in adolescents, although small children may occasionally acquire pubic lice on the eyelashes. Pubic lice are only 1-2 mm in length (body and head lice are 2-4 mm in length), and are greater in width than length, giving them a crab-like appearance. Treatment includes a 10 minute application of a pyrethrin preparation. Retreatment may be necessary in 7-10 days. Lindane shampoo, which requires a 10 minute application time, is an alternative choice. Eyelash involvement may be treated by petrolatum applied three to five times per day for 8-10 days. Clothing, bedding, and towels should be thoroughly washed or dry-cleaned.

Scabies is caused by the female Sarcoptes scabiei mite. A papular and vesicular rash is seen as a result of the mite burrowing into the stratum corneum. The mites burrow approximately 2mm (1). Itching occurs two to six weeks after infestation, and may be more intense at night when the mites are more active. Lesions are most commonly seen between the fingers and toes, axillae, flexor surfaces of the wrists, belt line, and areas surrounding the nipples, genitals, and buttocks. A diagnosis of scabies is made based on a history of itching and the characteristic lesions. A definitive diagnosis is made upon identification of the adult mite, ova, or larvae upon microscopic examination of skin scrapings from the lesions, but this is rarely done in general pediatric practice. The patient should bathe thoroughly and the involved areas should be scrubbed with a brush. Permethrin cream (Elimite), lindane lotion (Kwell), or crotamiton (Eurax) lotion may be applied, and the patient should be dressed in clean clothing. Bedding should be cleaned and other family members should be questioned and inspected to determine if they are infested as well. Scabies may persist for months in patients who are untreated.

Mosquito bites and flea bites are common sources of skin irritation in children. Fleas tend to bite multiple times in one area, whereas mosquitoes usually bite in random widely dispersed areas that are not covered by clothes. The irritation that stems from an insect bite is due to a localized hypersensitivity reaction. Treatment of mosquito and flea bites consists of cool compresses, calamine lotion, topical hydrocortisone and oral antihistamines to provide relief from the pruritus. Insect repellants may be used on exposed skin as prophylaxis. DEET containing mosquito repellants are effective, but DEET is potentially neurotoxic so it should be applied judiciously. Using clothes to completely cover the skin may be safer. Fleas may be eradicated by treating pets and decontaminating the house.

Questions

1. Name the three layers of skin. Name three functions of skin.
2. What organism is responsible for the development of warts?
3. What are the two organisms responsible for infection in acute paronychia?
4. What is the treatment for lice?
5. Who should receive varicella zoster immunoglobulin?
6. What characteristics of a mole are suspicious for malignant melanoma?

Answers to questions

1. The three layers of skin are the epidermis, dermis, and subcutaneous tissue. The skin serves as a barrier against the environment, protection against desiccation, and plays a role in immune surveillance.
2. Human papilloma virus is organism responsible for the development of warts.
3. Staph aureus is responsible for most infections in acute paronychia.

4. Pediculosis is treated with a shampoo such as 0.5% malathion rinse, permethrin 1% creme rinse, 1% lindane shampoo, or pyrethrin. After the shampoo is rinsed, the hair is combed with a fine toothed comb to remove dead nits. Clothes and bedding must be washed in hot water.

5. Varicella immunoglobulin should be given to immunocompromised individuals, neonates whose mothers develop chickenpox within five days prior to or two days following delivery, and premature neonates born less than 30 weeks gestation who have been exposed to chickenpox.

6. Suspicion of malignant transformation of nevi should arise upon observation of irregular borders, variegated color (multiple colors), size greater than 5-15 mm, and any change in texture including crusting, ulceration, or induration.

Chapter XXII.1. Statistics
Loren G. Yamamoto, MD, MPH, MBA

The mother of a 15 month old boy is brought to the clinic because of fever. His temperature has been up to 40 degrees (104 degrees F). He has a slight cough, but no vomiting or diarrhea. His urine output is normal without urinary complaints. Mother has given him acetaminophen which results in some improvement. His past medical history is unremarkable. He is generally healthy.

Exam: VS T 39.8 (103.6), P120, R 35, BP 90/60, oxygen saturation 99% in room air. Height and weight are at the 50th percentile. His examination is normal except for mild nasal congestion. His tympanic membranes are normal.

You believe that he most likely has a viral infection, but you are told that occult bacteremia is a possibility. Since this is a clinically occult phenomenon, you decide to do a study to determine if a CBC is useful in predicting whether occult bacteremia is present. You put together an institutional review board (IRB) study proposal which is approved. 400 febrile patients are enrolled in the study. They all have CBCs and blood cultures drawn. Out of the 400 patients, 20 have positive blood cultures. The mean white blood count (WBC) in these 20 bacteremic patients is 16.8 (standard deviation=7.3). The mean WBC in the other 380 patients is 13.9 (standard deviation=6.2). p=0.04 which means that the probability that this difference is due to chance is only 4% (0.04). Thus, there is a 96% chance that this difference is real, which means that the WBC in bacteremic patients is significantly higher than in non-bacteremic patients. Believing that your study results are astounding, you decide to present this information to the hospital chief of staff summarized as follows:

	ALL	<10.0	10.0-14.9	15.0-20.0	>20.0
Positive BC patients:	20	4	5	6	5
Negative BC patients:	380	120	110	90	60

All of a sudden, the results do not appear to be as astounding as initially thought. If a child has a WBC >20.0, most of the patients still have negative blood cultures. Additionally, 9 out of the 20 bacteremic patients had WBC counts less than 15.0.

There are two basic types of data: 1) continuous variables which can take on any value within a reasonable range (e.g., age, weight, blood pressure, peak flow, oxygen saturation, cholesterol, etc.), and 2) discrete (or categorical) variables (e.g., sex, ethnicity, socioeconomic status, medical insurance, etc.) which can only take on values of discrete categories. Data types are important because this determines which type of statistical test(s) to run.

Notice that most continuous variables can be converted into discrete variables by grouping them in ranges. For example, age groups can be formed: 1) 0-1 yr, 2) 2-5 yrs, 3) 6-10 yrs, 4) 11 yrs and above. Cholesterol values can be categorized into high cholesterol versus low cholesterol. Discrete variables cannot usually be converted into continuous variables. However, some discrete variables have rank order while others do not. For example, medical insurance has a particular rank order: 1) no insurance, 2) medicaid insurance, 3) private insurance. Military rank order is another discrete variable that has rank. Socioeconomic status could have rank as well: 1) unemployed, 2) blue collar, 3) white collar. Discrete variables such as race, hair color, political party, etc., have no inherent rank order.

Statistics are basically either descriptive or inferential. Descriptive statistics are summary numbers use to describe a set of data. If 1000 data measurements are obtained, it would be impractical to list all 1000 measurements in your publication. It would be more efficient to present a few summary numbers which describe the 1000 data measurements. These are descriptive statistics. Descriptive statistics for continuous variables include: mean, standard deviation, range, mode, median, etc. The mean, mode and median describe the central tendency of the group of observations. The range, standard deviation and confidence interval describe the spread of the observation measurements. For example, for a set of 1000 cholesterol measurements, the mean is 100, the range is 40 to 310, and the standard deviation is 45. Descriptive statistics for discrete variables include rates and frequencies (numerator/denominator). For example, 30% of the group has black hair.

These descriptive statistics can be graphically compared to determine if two sets of observations are different. The means represent the center of two bell shaped curves. A small standard deviation means that the shape of the bell is very narrow. A large standard deviation means that the shape of the bell is very wide. One standard deviation from the mean estimates the point of inflection (where the curve changes from convex down to convex up) of the bell shaped curve. The mean plus or minus two standard deviations should contain approximately 95% of the observations (or area under the curve). If the two bells have substantial overlap, then the two groups are most likely, NOT significantly different. If the two bell shaped curves have almost no overlap, then the two groups are most likely, significantly different.

The 95% confidence interval can be calculated to determine the likely range of the true mean. The mean of a sample estimates the true mean. The 95% confidence interval calculates the range of possible values for the mean with 95% confidence (i.e., there is a 95% chance that the true mean lies within the 95% confidence interval). A wide range or interval means that there is great uncertainty about what the true mean is (large variance), while a narrow 95% confidence interval means that there is great certainty about what the true mean is. The 95% confidence interval is similar to graphing two distributions because if the 95% confidence intervals of two groups exclude each other, then the two groups are significantly difference. For example, group A has a mean of 25 and group B has a mean of 30. The 95%CI for A is 23 to 27, while the 95%CI for B is 28 to 32. The two groups are significantly different because the two 95%CIs exclude each other. But if the 95%CIs were 20 to 30 and 27 to 33, then they overlap, so the two groups are probably not significantly different.

Inferential statistics compare two or more groups of observations to determine if the groups are significantly different (or related) or NOT different, in a more mathematically precise way. Nowadays, these tests are all done by computer software. It is not really useful to know the formulas for calculating the test results. The concepts of which test to use and how to interpret the results are more important. The selection of a statistical test seems perplexing, but in its basic form, it is rather simple. Since there are only two types of data (continuous and categorical), comparing variables can only take on a limited number of combinations. A basic guide is as follows:

Comparing a continuous variable between two groups: T-test.

Comparing a continuous variable between more than two groups: Analysis of variance.

Comparing a discrete variable between more two groups or more: Chi-square.

Determining the relationship between one continuous variable and one or more continuous variables: Regression (linear regression for two variables, multiple regression for more than two variables).

Although we often use inferential statistics to determine if two groups of observations are different, statisticians utilize a non-intuitive concept called the null hypothesis, which hypothesizes that the two groups are the same. If we are trying to determine if something is different (which is the usual case), you can think of the null hypothesis as the opposite of what we are trying to show. For the example of the study of WBCs and bacteremia, the null hypothesis is that the WBCs in bacteremic and non-bacteremic febrile children are the same.

The commonly cited p value is the probability that the difference demonstrated is due to chance alone. Statisticians have selected p=0.05 (or 5%) as an arbitrary cut off value. If p<0.05, then the difference is said to be statistically significant because the probability that this difference is due to chance alone is less than 5%. If this probability is greater than 5%, then this probability is too high for the difference to be statistically significant.

If p<0.05, the statistical terminology is that we reject the null hypothesis. Recall that the null hypothesis was that the WBC counts in bacteremic and non-bacteremic febrile children are the same. So by rejecting the null hypothesis, we are concluding that the WBCs in bacteremic and non-bacteremic children are different (i.e., significantly different such that we can reject the null hypothesis).

The null hypothesis is non-intuitive (seemingly backward thinking) to most non-statisticians. It might be easier to think of the p value as the significance level. If p is <0.05 (or 5%), then this difference is said to be significant. If p is >0.05, then this probability is not small enough, so the result is said to be non-significant.

These statistical tests are best understood by example. A study is undertake to determine which alien species is smarter: Jupitrons or Zoobies. IQ tests are performed on 1000 Jupitrons and 800 Zoobies. The mean IQ for the Jupitrons is 110 (standard deviation 30), and the mean IQ for the Zoobies is 120 (standard deviation is 75). A T-test is done which determines the p value to be non-significant. Although the Zoobies have a higher IQ, their standard deviation is large which means that there are a lot of smart Zoobies and a lot of not-so-smart Zoobies. The standard deviation for the Jupitrons is smaller, so the spread of Jupitron IQs is narrower. Since p is larger than 0.05, we must accept the null hypothesis and conclude that the IQs of Jupitrons and Zoobies are not different (i.e., they are the same). If p were 0.02 instead, then we would reject the hypothesis and conclude that the IQ levels of Jupitrons and Zoobies are significantly different.

Another alien group, the Dimbos, are added to the comparison. 1000 Dimbos are studied and their mean IQ is 68 (standard deviation 22). The three groups, Jupitrons, Zoobies and Dimbos are compared using analysis of variance (ANOVA): p=0.01, which means that at least one of these groups is different from the others. In this case, it is quite obvious that the Dimbos are less intelligent than the Jupitrons and Zoobies, but in some other instances, it may not be that obvious. If 10 different groups are tested and p is significant, this could mean that the lowest group is different from the highest group, but other groups may be different from the others as well.

Compare the T-test to ANOVA. The only difference is that the T-test tests two different groups and ANOVA tests three or more groups. What if we did an ANOVA test, but only used two groups? It turns out that this is mathematically identical to the T-test. So whether you select a T-test or ANOVA for the comparison of two groups, the statistical calculation and the p value will be the same.

Jupitrons have hearts too, so a study is done to compare heart attack (acute myocardial infarction) rates in Jupitrons and Humans. Out of the 1500 Jupitrons residing on the planet colony Vlazer, 15 have sustained myocardial infarcts (MI) (1%). This compares to the 3000 Humans residing on Vlazer of whom, 90 have sustained MIs (3%). A chi-square test is done to determine if the 3% MI rate in Humans is significantly higher than the 1% MI rate in Jupitrons. These results form a 2 by 2 table which looks like this:

Species	MI	No MI	Total	MI rate
Humans	90	2910	3000	90/3000 = 3%
Jupitrons	15	1485	1500	15/1500 = 1%
Total	105	4395	4500	

The clinical question is: Do MIs occur more frequently in Humans? The 2 by 2 table above can be related to an "expected values" table. If the species (Human versus Jupitron) is unrelated to MI (in other words, there is no relationship between MI and species, or the MI rates are the same in both species), the numbers in each of the cells of the 2 by 2 table should distribute randomly. The expected value in each cell should be the row total multiplied by the column total, divided by the grand total. The expected values table should look like this:

Species	MI	No MI	Total
Humans	70	2930	3000
Jupitrons	35	1465	1500
Total	105	4395	4500

The expected value for the Human MI cell is calculated by multiplying the row total (3000) by the column total (105), all divided by the grand total (4500).

3000 X 105 / 4500 = 70

The actual value in this cell is 90. So this deviates from the expected value by 20. The differences between the true values and the expected values in each cell are squared and added together. This forms the numerator for the chi-square value. The larger the chi-square value, the smaller the p value. The 2 by 2 table is a reasonably simple calculation by hand, but nowadays, all of these calculations are done by computer. The p value for this particular set of data is <1% (p<0.01), which is significant, so we conclude that the MI rates in Humans is significantly different from that of Jupitrons (i.e., we reject the null hypothesis that the MI rates in Humans and Jupitrons are the same).

A similar methodology can be used if there are more than two groups and more than two possible outcomes. For example, comparing MI rates in Humans, Jupitrons and Zoobies would result in a 2 by 3 table. Comparing hair color in Humans, Jupitrons and Zoobies would result in a 4 by 3 table assuming that there are 4 possible hair color types.

Note that so far, we have compared a continuous variable by a categorical variable (IQ by alien species using a T-test or ANOVA), then a categorical variable by a categorical variable (MI by alien species using the Chi-square method). The only other possible combination is to compare a continuous variable by a continuous variable. The method used here is regression. In the selection of a statistical test, there are only three possibilities: 1) continuous by categorical, 2) categorical by categorical, and 3) continuous by continuous. The selection of a statistical test is not that hard after all.

Regression analysis determines the degree of correlation that one continuous variable has with another. An example would be age and weight. Of course these have some degree of correlation, so such a study would show statistically significant correlation. Regression analysis generates a correlation coefficient (called r). The correlation coefficient (r) can range from -1 to 1. If r is positive, this means that as one variable goes up, the other variable goes up. Age and weight would be an example of this. If r is negative, this means that as one variable goes up, the other variable goes down. Birth weight and hospital length of stay is an example of this because low birth weight tends to result in longer hospitals lengths of stay. An r value of 1 or -1 implies perfect positive or perfect negative correlation, respectively. An r value of 0 indicates that there is no correlation between the two variables tested. Regression analysis also calculates a p value. The p value is the probability that the r value is 0.

For example, if the r value is 0.1 and p=0.01, then there is significant correlation, because p is <0.05, which means that the r value is significantly different from zero. If the r value is 0.5 and p=0.4, then there is no significant correlation even though the r value is larger, because p is too high, which means that there is a 40% probability that r could be zero. A large r value with a large p value is often seen with regression analysis with only a few observations (an inadequate sample size).

If the regression analysis involves only two variables, this is called linear regression. If the regression analysis involves more than two variables, then this is called multiple regression, in which case, one variable must be considered a dependent variable and the other variables must be independent variables, such that:

$$D = Q + aX + bY + cZ$$

In the above equation, D is the dependent variable, Q is a constant, XYZ are independent variables, and abc are factors which determine the effect of XYZ on D. An example of this is a study which attempts to determine the environmental factors that result in wheezing. D=the number of children wheezing on a given day. X=the amount of viral infections in the community on that day, Y=the bad weather index as measured by that day's barometric pressure, and Z=the amount of air pollution (dust, pollutants and volcanic dust present) that day. All three of these factors affect the amount of wheezing in the community. Terms a, b, and c can be thought of slope terms for the model, but they are not the correlation coefficients. Separate correlation coefficients and p values would be determined for each independent variable X, Y and Z to determine the degree of correlation (the r value) and whether the correlation is significant (p value) for each of X, Y and Z.

All the statistical tests that have been described so far, have a few assumptions. A basic assumption is that the data is distributed in a "normal distribution" (resembling a bell shaped curve). This assumption is usually not true. However, the central limit theorem (no need to describe this here) usually allows us to use these tests if the distribution is "somewhat normal" and there are enough observations (data points). If a normal distribution is clearly not present, then, we must use "non-parametric" tests (e.g., Wilcoxon rank-sum test, Mann-Whitney U test, etc.). So the selection of a statistical test is not quite as simple as what was described earlier.

There are two types of statistical errors knows as type 1 and type 2. The type 1 error is the probably of incorrectly concluding that a true difference exists. The probability of a type 1 error is known, measured by the p value. In the case example, the probability of incorrectly concluding that, the WBC counts in bacteremic versus non-bacteremic patients is different, is 4% (p=0.04).

The type 2 error is the probability of incorrectly concluding that the two groups are the same (i.e., no difference exists). Unfortunately, there is no foolproof way to measure this type of error accurately. If one concludes that no difference exists because p>0.05, then there are two possible realities. One reality is that the two groups are the same and the conclusion that no difference exists, is correct. The other possible reality is that the two groups are different, but because of an inadequate sample size, the study was unable to show that p<0.05. For example, if we undertook a study to determine if males were taller than females, and we took a random sample of 6 adults (3 male and 3 female), the mean male height is 173 cm and the mean female height is 163 cm. In this case p=0.15. We conclude that there is no significant difference in male and female heights. A type 2 error has occurred here. We know that there should be a difference. Yet the p value has not achieved statistical significance (p is not less than 0.05). This is due to an inadequate sample size. With only three data points in each group, it is intuitively obvious that more subjects in each group would be necessary.

Whenever an inferential statistical test concludes that no significant difference exists, it is customary to perform a "power calculation" which approximates the probability that the conclusion of "no significant difference" is correct. A large sample size has greater statistical power adding to the strength of the conclusion that no significant difference exists. How many subjects or observations does one need to avoid type 2 errors? This gets into the discussion of sample size determination. This is a rather complex subject, but suffice it to say that it requires several assumptions.

a) How do we know if a true difference exists? If one truly does NOT exist, it would take an infinite number of data observations to achieve statistical significance. Since we don't really know if a true difference exists (that's why we're doing a study), how can we really determine the sample size?

b) What is the true variance (std. deviation, etc.) or scatter of the real life data? If the scatter is wide, we need a large sample size. If the scatter is narrow, then we can get by with a smaller sample size. But we often do not know what the actual variance is. Then how can we determine a sample size before the study?

So to estimate a sample size before a study is done, we must guess that if a difference exists, it must be approximately as large as our assumption guess. Also, we must guess at what the spread (variance) of the data must be. If we make these two assumptions, we can estimate the sample size.

Just because something is statistically significant, does not necessarily mean that this is clinically important. In the WBC/bacteremia example in the case, bacteremic patients were shown to have significantly higher WBC counts compared to non-bacteremic patients. Look at the actual numbers again:

	ALL	<10.0	10.0-14.9	15.0-20.0	>20.0
Positive BC patients:	20	4	5	6	5
Negative BC patients:	380	120	110	90	60

As we know, in any single case, the WBC is not very predictive because there is too much overlap. Note that MOST of the patients with WBC>20.0 have negative BCs. Also, nearly half of the bacteremic patients had WBCs lower than 15,000. Statistical significance does not always indicate clinical importance.

Most studies perform multiple statistical tests. Using $p<0.05$ as a cutoff value for statistical significance, means that each "statistically significant" result has a 5% chance of being due to chance alone (i.e., wrongly concluding that a difference actually exists). The more tests that are run, the more like it is that one will, by chance, wrongly find a "statistically significant" result. When multiple tests are performed, this phenomenon should be acknowledged. Prior to running the statistical tests, it may be more optimal to set statistical cutoff values at something less than 5% (e.g., 1%). The means to correct for the phenomenon of multiple tests has been supported by some editorials in the literature. Just realize that the problem exists and perhaps acknowledge it, form a crude means to correct it, or get a statistical expert to find an acceptable way of correcting it.

Optional paragraph (feel free to skip this entire paragraph, because the concept discussed in this paragraph is somewhat difficult to grasp): Note that the conclusion in the case example, is that the WBCs in the two groups are different. "Different" means greater than or less than. Although we know that the mean WBC in bacteremic patients is higher than the mean WBC in non-bacteremic patients, the probability of 4% ($p=0.04$ in the case example) means that the probability that the difference is due to chance is 4%. If we knew ahead of time, that if a difference exists, then we would expect the WBC in bacteremic patients to be higher and not lower, then we are actually only interested in checking one side of the "they are different" relationship (i.e., that the WBC count is higher in bacteremic patients). We are NOT interested in investigating the possibility that the WBC count is lower in bacteremic patients. This is a rather subtle difference and this concept is difficult to understand. This refers to the concept of the single sided test versus the two-sided test (also know as two tailed). Computer generated p values are always two-sided probabilities since the assumption is that we are performing a two tailed test. The two tailed probability is for the conclusion that the WBC is different in bacteremic patients. The single sided probability is that the WBC is greater in bacteremic patients. So the probability that the different WBC in bacteremic patients is due to chance is 4% ($p=0.04$). The probability that higher WBC in bacteremic patients is due to chance is 2% (half of the two tailed probability). This concept can be very important if your p value is for example 8% ($p=0.08$) which is not considered statistically significant. However, if you appropriately use a single sided probability, then $p=0.04$ which is statistically significant. The major issue here is that the null hypothesis must be stated properly prior to determining the probabilities. This is somewhat complex and beyond the scope of this chapter.

Questions

1. You have interviewed 50 children who have been hospitalized for bicycle related head injuries and found that 14 of them were wearing a bicycle helmet at the time of the accident. In a control group (children without injuries riding their bicycle on a community bicycle path), you observe the first 100 children and note that 92 of them are wearing bicycle helmets. What descriptive statistics should be described here? What inferential statistical test should be done?

2. If the result of the inferential statistical test for the example above is $p=0.001$, what conclusion can be drawn?

3. What would the null hypothesis be for the example above?

4. Indicate whether the following are categorical variables or continuous variables?
    a. Type of health insurance.
    b. Cholesterol.
    c. Oxygen saturation.
    d. Respiratory rate.
    e. Subdural hematoma.
    f. Lumbar puncture result.
    g. Cervical spine fracture.

5. You are doing a study on oxygen saturation values in asthmatics presenting to an emergency room. You find that asthmatics who are eventually discharged home had a mean oxygen saturation of 95.6% at initial presentation, but the asthmatics who require hospitalizations presented with a mean oxygen saturation of 94.5%. What are the descriptive statistics that should be presented? What inferential statistical test should be used here?

6. In the example above the p value is found to be 0.001. This is considered highly significant since the p value is so small. Comment on whether this highly significant result is clinically important?

7. Is the oxygen saturation measurement distributed in a normal fashion? In other words, if you plotted a value of oxygen saturation for 10,000 patients, would the shape of the distribution be bell shaped? Explain why or why not.

8. Without doing a statistical test, indicate whether you think the following examples show groups that are significantly different or not and justify your answer:
    a. Mean IQ in two groups are 90 and 120. The standard deviation is 45 for both groups.
    b. Mean weight in two groups are 45 and 55 kilograms. The standard deviation is 3 for the first group and 2 for the second group.
    c. Mean oxygen saturations in two groups are 94% and 97%. The standard deviation is 2% for both groups.

Answers to questions

1. Descriptive statistics are the rates of bicycle helmet use in the injured group and in the control group. The proper inferential statistical test to use is a chi-square test.

2. The rate of bicycle helmet use in the injured group is significantly different from that in the control group. It might be tempting to say that bicycle helmets prevent significant head injuries from this study, but such a study is not good enough to conclude this.

3. Bicycle helmet use rates in the two groups are the same.

4a. Categorical.

4b. Continuous.

4c. Continuous.

4d. Continuous.

4e. Categorical. The patient either has it or they don't.

4f. This could be both depending on what we mean by this. This would be a continuous variable if we are referring to the CSF WBC count, the RBC count, the CSF glucose, or the CSF protein. This would be a categorical variable if we are considering the CSF to be normal or abnormal, or if we are considering the gram stain result (organisms versus no organisms).

4g. Categorical. The patient either has it or they don't.

5. The basic descriptive statistic is the mean oxygen saturations in each group. Other commonly cited descriptive statistics are the standard deviations and the ranges for each group, which would describe the spread of the data. The inferential statistical test would be a T-test or ANOVA.

6. This difference is statistically significant, but it is not very clinically important because the difference between 95.6% and 94.5% is only about 1%. Continuous pulse oximetry readings will frequently fluctuate by 2 to 4 percentage points on the same patient without any clinical changes occurring.

7. The oxygen saturation (like most biomedical measurements) is not normally distributed. Most biomedical measurements have a theoretical limit on their values. Oxygen saturation values cannot exceed 100%. Thus, if one creates a distribution of oxygen saturation measurements, it will show a few points below 80%, a few more points between 80% and 90%, a fair number of points between 90% and 95%, a large number of points between 95% and 100%, and no points about 100%. This is not bell shaped. Other examples of theoretical limits are: glucose values cannot go below zero, respiratory rates will not go below 10, etc.

8a. These groups are not significantly different. The mean plus or minus two standard deviations should contain approximately 95% of the area under the bell shaped curve. Thus, the shapes of these curves are wide with substantial overlap. It is not likely that these groups will be shown to be significantly different.

8b. These standard deviations are small, so the bell shaped curves are very narrow and they do not overlap each other. Thus, it is likely that these groups will be shown to be significantly different from each other.

8c. This one is not easily determined. A T-test would have to be run to calculate the p value. The two means are fairly close to each other, but the standard deviation is also small.

Chapter XXII.2. Evidence-Based Medicine
Claudine Kimura, MD

A 3 year old boy presents to the clinic with a cough for 2 days and a temperature of 99 degrees. He is noted to have a barking cough and other clinical findings consistent with a diagnostic impression of laryngotracheobronchitis or croup. After a discussion with the clinic attending, she mentions that dexamethasone may be a good treatment for this patient. You perform a literature search on PubMed and find an article entitled, "A prospective randomized double-blind study to evaluate the effect of dexamethasone in acute laryngotracheitis" (1).

One of the most exciting aspects of the practice of medicine is that it is continually evolving and changing. Every physician maintains the perpetual title of "Student of Medicine" as we are all constantly learning and absorbing new information. This, however, is also one of the most challenging and daunting aspects of the practice of medicine. Faced with thousands of articles every year, a practitioner can't help but feel overwhelmed at times. This is why the practice of evidence-based medicine is so important.

Evidence-based medicine (EBM) has been described as "a process of life-long, self-directed learning in which caring for our own patients creates the need for clinically important information about diagnosis, prognosis, [and] therapy" (2). It has also been described as "the process of systematically finding, appraising, and using contemporaneous research findings as the basis for clinical decisions" (3). The goals of evidence-based medicine are fourfold, and include: 1) improving the uniformity and standardization of care so that all patients receive optimal care; 2) helping providers make better use of limited resources by seeking the most effective treatments; 3) preventing harmful side effects or outcomes; and 4) making the literature accessible to all, thereby helping clinicians make the most informed decisions possible (3). Everyone, from the medical student to the most senior physician, can use the principles of evidence-based medicine. But, like any other worthwhile endeavor, it takes practice to become comfortable with and proficient in using these guidelines.

The basic tenets of evidence-based medicine are laid out in a series of articles published in JAMA, collectively entitled "Users' Guides to the Medical Literature" (4). There are over 25 different guides to EBM. The first two basic guidelines regarding articles on therapeutics (5, 6) and articles on diagnostic tests (7, 8) will be discussed here.

The basic process of evidence-based medicine involves seven steps (Table 1) (4). The first step occurs at the bedside, when a clinical question arises during the care of a patient. The question could be whether a test that was ordered will be likely to help make a diagnosis or if the present medication is the most efficacious for the patient's condition. The second step involves searching for sources of information. This might be as simple as asking a knowledgeable physician or looking in a textbook, but for the most comprehensive and up-to-date source of information, physicians turn to the medical literature. The simplest means of accessing the medical literature involves conducting a Medline or PubMed search using the internet. The third step is to identify the sources that are found, (i.e., identifying studies relating to the clinical question). The fourth step is to determine whether the results of the study being examined are valid. The specific guidelines for this will be outlined in the following paragraphs. The fifth step is to determine what the actual results are, for instance whether a test was able to accurately diagnose a particular condition. The sixth step is to determine whether the results are applicable to your patient, and thus helpful to you in caring for your patient. The last step is to the resolve the clinical question.

Table 1. Evidence-Based Medicine Approach to Clinical Problems
1. Identify the clinical question.
2. Search for sources of information.
3. Identify the source(s) found (relevant articles).
4. Determine whether the results are valid.
5. Determine what the results are.
6. Determine whether the results will help you in caring for your patients.
7. Resolve the clinical question.

The steps involved in evaluating an article on therapy are outlined in Table 2 (5,6). The first steps involve determining whether the results of the study are valid. Toward this end the article should first be scrutinized for randomization of patients. Many factors (e.g., age, sex, ethnicity, etc.), the least of which may be the therapy being studied, affect patient outcome. If the study population is large enough, randomization ensures that both known and unknown factors are evenly distributed between the treatment and control groups, making it more likely that any difference in outcome between the two groups is due to the treatment effect alone. In the croup article, the patients were randomized, as is noted in the title.

Table 2. Guide to an Article About Therapy
I. Are the results of the study valid?
  A. Primary guides
    1. Was the assignment of patients to treatments randomized?
    2. Were all patients who entered the trial properly accounted for and attributed at its conclusion? a) Was follow-up complete? b) Were patients analyzed in the groups to which they were randomized? ("intention-to-treat analysis).
  B. Secondary guides
    1. Were patients, health workers, and study personnel "blind" to treatment?
    2. Were the groups similar at the start of the trial?
    3. Aside from the experimental intervention, were the groups treated equally? Co-interventions (see below)?
II. What were the results?
  A. How large was the treatment effect? (see Table 3)
  B. How precise was the estimate of the treatment effect? (95% confidence interval)
III. Will the results help me in caring for my patient?
  A. Can the results be applied to my patient care?
  B. Were all clinically important outcomes considered?
  C. Are the likely treatment benefits worth the potential harms and costs?

Next, it is important to ensure that all patients enrolled in the study were properly accounted for at the end of the study. If there were a large number of patients "lost to follow-up," the results of the study may be skewed. To avoid having a therapy appear more effective than it is, assume that any "lost" patients from the treatment group had a "bad" outcome and those lost from the control group had a "good" outcome. It is also important to then evaluate whether the authors preserved randomization by using an "intention-to-treat analysis." This means that during the analysis of the study results, patients remain in the groups to which they were randomized in the beginning of the study, even if they are unable or unwilling to complete the treatment. If patients from the treatment group who were unable to complete the treatment because they got sicker are transferred to the placebo (control) group, the treatment may show more effect than is truly present, just because the placebo group has sicker patients. In the croup article, of the 29 patients randomized to the study, 28 were assessed at the 12 hour post-treatment mark, and 25 patients were assessed at the 24 hour mark. The reasons for the loss of the patients were given in the article. An intention-to-treat analysis appears to have been carried out by the simple design of the study, although this fact was not spelled out as such in the text of the article.

The next step is to determine whether patients and study personnel were "blinded" to treatment. It is well known that if a patient or worker knows that a patient is receiving the study medication, this will bias their assessment of the patient's outcome. It is then important to determine whether the two groups were similar at the start of the trial. If they were significantly different in any aspect other than the therapy (e.g., age, gender, ethnicity), this difference, and not the therapy, may account for any outcomes difference between the two groups. Next, it is important to ensure that both the treatment and control groups were treated equally in regards to any "co-interventions." Again, if one group received more of a co-intervention than the other, the outcome may be due to the co-intervention and not the therapy of interest. In the croup article, the patients and study personnel were both blinded. The groups did appear similar at the start of the study. In this study the rate of co-intervention use was one of the secondary outcomes measured, and the use of racemic epinephrine was found to be lower in the treatment group, but there was no difference between the two groups in rate of supplemental oxygen use.

The next set of steps involves evaluating the results of the study. This includes the computation of several formulas, listed in Table 3. Most trials evaluating therapy consider whether the therapy had a beneficial effect on some adverse outcome or event, such as hospitalization. One of the ways to express the difference in outcome is to calculate the absolute difference between the treatment and control groups: the absolute risk reduction (ARR). If "X" is the number (or percentage rate) of patients in the control group who were hospitalized, and "Y" is the number (or percentage rate) of patients in the treatment group who were hospitalized, then the ARR for hospitalization is "X-Y".

Table 3. Measurements of treatment effect
X = outcome in control group
Y = outcome in treatment group
Relative risk (RR) = Y/X
Relative risk reduction (RRR) = 1- Y/X
Absolute risk reduction (ARR) = X-Y
Number needed to treat (NNT) = 1/ARR

In the croup article, the primary endpoint was improvement in total croup score at 12-hour intervals after treatment. The severity of illness was measured using a "croup score," which was based on retractions, stridor, air entry, cyanosis, and level of consciousness. It was determined prior to the start of the study that an improvement in the total croup score of at least 2 points (out of a possible total of 17 points) would be clinically significant. At 12 hours after treatment, 13 of 16 patients (81%) in the treatment group had at least a 2 point improvement in their croup score, while only 4 of 12 patients (33%) in the placebo group had a similar improvement. A secondary endpoint was the need for racemic epinephrine aerosols, and whether there was a decreased need in the treatment versus the placebo group. In the placebo group 8/13 or 62% (X) of patients required an aerosol, while in the dexamethasone group 3/16 or 19% (Y) required similar co-intervention. The ARR for racemic epinephrine aerosol was (62%-19%) or 43% with respect to racemic epinephrine utilization as the comparison variable.

Another way to express the difference between the two groups is to calculate the relative risk (RR). The relative risk is the proportion of patients who experienced the adverse outcome in the treatment group as compared to the control group and is expressed as "Y/X". But the more common usage of RR is as the relative risk reduction (RRR). This is presented as a percentage and is calculated as [1-(Y/X)]. The larger the RRR, or the ARR, the more effective the treatment. However, it is important to understand the difference between the two values. If the results of a trial showed that 10 patients who received a placebo were hospitalized and only 5 patients who received a medication were hospitalized, the ARR would be (10-5) or 5. But the RRR would be [1-(5/10)], or 50%. A 50% reduction sounds better to most people than a reduction of 5, but in this scenario, the two results represent the same information. In the croup article, the RR for the requirement of racemic epinephrine aerosols would be calculated as 0.19/0.62, or 30%. The RRR would then be calculated as [1-0.30] or 70%.

The next step in evaluating the validity of a study's results is to determine how precise they are. This involves calculation of the confidence interval (CI). The CI is usually calculated as the "95% CI," which means that the true RRR lies within the range of the confidence interval 95% of the time. The CI speaks to the power of a study, and the factor which has the most impact on a study's power is its sample size. A study with 100 participants may have the same RRR as a study with 1000 participants, but the latter will invariably have a narrower CI and thus be more precise and the results more powerful. The 95% CI can be applied to absolute and relative values. Since a treatment would be deemed to be beneficial if the RRR (relative risk reduction) was greater than zero, the 95% CI would have to exclude zero in its range if the treatment is beneficial. For example, for a RRR study, a 95% CI of -0.1 to 0.4 cannot be statistically concluded to be beneficial since the value zero is contained within its confidence limits. However a 95% CI of 0.1 to 0.2, describes a statistically beneficial treatment, since zero is not included in the range (i.e., there is a less than a 5% chance that the treatment has no benefit).

The last set of steps involves determining whether the study you have just reviewed will help you to care for your patient. It is important to determine whether your patient is similar to the patients who were in the study you are investigating. If your patient would have met all the inclusion and exclusion criteria for the study, the results are likely applicable to your individual patient. It is also important to evaluate whether all significant outcomes were measured. The endpoint of decreased mortality as a result of treatment is always significant, but other outcomes, such as rate of hospitalization or subsequent morbidity, can also impact your patient's care. And lastly, the benefits and risks of the proposed treatment must be weighed for the individual patient. For the article on croup, you've decided that the results of the study are valid based on the study design, and you've evaluated the results of the study. You now determine that your patient is similar to those enrolled in the study, so the results can be applied to him. The study did not discuss any side effects or risks to the treatment, so the benefits of the treatment seem to outweigh the risks. You decide to treat your patient with a dose of dexamethasone.

The second set of guidelines entails the appraisal of articles on diagnostic tests. Table 4 outlines the steps involved (7,8). Again the first of these involves determining the validity of the study results. This includes evaluating whether there was a blind comparison of the test in question with a reference standard. This is important to determine how a new test measures up to the current "gold standard." Next it is important to determine whether the study included a sample of patients that is representative of the type of patients the test would be performed on in clinical practice. If the patients in the study differ from the type of patient who would require the test, the study may not be useful.

Table 4. Guide to an Article About a Diagnostic Test

I. Are the results of the study valid?
- A. Primary guides
  1. Was there an independent, blind comparison with a reference standard?
  2. Did the patient sample include an appropriate spectrum of patients to whom the diagnostic test will be applied in clinical practice?
- B. Secondary guides
  1. Did the results of the test being evaluated influence the decision to perform the reference standard?
  2. Were the methods for performing the test described in sufficient detail to permit replication?

II. What were the results?
- A. Are likelihood ratios for the test results presented or data necessary for their calculation provided? (see Table 5)

III. Will the results help me in caring for my patient?
- A. Will the reproducibility of the test result and its interpretation be satisfactory in my setting?
- B. Are the results applicable to my patient?
- C. Will the results change my management?
- D. Will patients be better off as a result of the test?

The next step is to ensure that all patients in the study underwent both the test in question and the reference standard. If only patients with abnormal results on the test being evaluated then underwent the reference standard, this would unfairly bias the results of the study, which is known as a "work-up bias." It is also vital to determine whether the methods used to perform the test were described with enough detail so that the results could be confirmed with a second study if necessary. If the test cannot be duplicated, it may be difficult to use in clinical practice.

The second set of steps involves evaluating the results of the study. The traditional method of defining the strength of a test is to determine its sensitivity and specificity. These are calculated using a "2x2 table" of the study results (Table 5). Sensitivity indicates the

probability that a patient with a particular disease (as defined by an established reference method*, commonly called a "gold standard") will have a positive test. Specificity indicates the probability that a patient without a disease will have a negative test (think of this as the true negative rate). The "2x2 table" can also be used to calculate positive and negative predictive values. Positive predictive value indicates the likelihood that a positive test will indicate the presence of a disease in a patient. Negative predictive value indicates the likelihood that a negative test will indicate the absence of a disease in a patient.

Table 5. Formulas for sensitivity, specificity, predictive value, likelihood ratios
For the given 2x2 table of results:

Test Result	Disease Present*	Disease Absent*
Positive	True Positive (a)	False Positive (b)
Negative	False Negative (c)	True Negative (d)

Sensitivity = a/(a+c)
Specificity = d/(b+d)
Positive predictive value (PPV) = a/(a+b)
Negative predictive value (NPV) = d/(c+d)
Positive likelihood ratio (+LR) = [a/(a+c)]/[b/(b+d)] = sensitivity/(1-specificity)
Negative likelihood ratio (-LR) = [c/(a+c)]/[d/(b+d)] = (1-sensitivity)/specificity

Another method of evaluating a diagnostic test is the likelihood ratio (LR). LRs indicate the accuracy with which the test in question confirms the diagnosis of a particular condition. The first step in using the LRs requires the determination of a pretest probability, which is the clinician's "gestalt" about the chances that a patient has a particular condition based on clinical information such as symptoms, risk factors, and physical examination. The LR then determines how a diagnostic test will affect the pretest probability, making a disease more or less likely, the outcome of which is called the posttest probability. This can be calculated using Bayes' theorem (rather difficult), but an easier way to determine the posttest probability by applying the LR is via a nomogram described by Fagan (9). Although this concept is a very useful and clinically important concept for clinicians, it is mathematically (even with the nomogram) difficult to determine. This concept is best understood with an example. If a patient with worsening right lower quadrant (RLQ) abdominal pain and classic symptoms/signs of appendicitis undergoes an ultrasound which is "negative for appendicitis", a clinician would be wise to ignore the ultrasound result and still suspect appendicitis as an etiology. If the clinical risk is low; however, such as in a fully ambulatory patient with minimal abdominal pain, appendicitis is very unlikely. Essentially, the diagnostic certainty is improved when the clinical impression is confirmed by the diagnostic test. In other words, if there is a high clinical probability and a positive test, then the patient most likely has that diagnosis. If there is a low clinical probability and a negative test, then the patient is not likely to have that diagnosis. If the clinical probability and the diagnostic test do not agree, then the diagnostic certainty is intermediate. In most situations, clinicians have an appreciation of these probabilities, but the numerical values can be difficult to measure. Bayes' theorem and Fagan's nomogram which are used to calculate a posttest probability, can be difficult concepts to grasp and cumbersome to use for those not familiar with them, but their advantage over the more widely used "sensitivity" and "specificity" are that they allow the clinician to apply the results from a research study to his or her individual patient.

An LR of 1 means the test offers no help is making the diagnosis since this means that the pretest and posttest probabilities are the same. The magnitude of the LRs affects their power to influence the posttest probability, i.e. the larger a positive LR the greater the likelihood the disease is present, and the smaller the negative LR the less likely a disease is present. See Table 6 for relative strengths of different LRs. LRs can be calculated via different means, including from the sensitivity and specificity of a test, as in Table 5. LRs are different from sensitivity and specificity because they take into account each individual patient, using the pretest and posttest probabilities.

The last set of steps again involves determining whether the results of the study will help you care for your individual patient. It is important to determine whether the test in question is feasible to perform and interpret in your setting. If a test requires special expertise to perform or interpret, the test may be less useful to you and your patient. It is also important to determine whether the results are applicable to your particular patient. If your patient has different co-morbidities or a different severity of disease, the results of the study may be less applicable, and the diagnostic test less useful.

It is also important to determine whether the results of the test will change your management. If you will not use the test to initiate treatment or determine prognosis, depending on the test's risk:benefit ratio, cost, and complexity, you may decide against performing it. Ultimately you must determine if performing the test will benefit the patient and whether the patient will be better off as a result.

Evidence-based medicine is a method for critically appraising and applying the medical literature. It is a tool, just like a stethoscope or history-taking skills, and can be immensely helpful in the day-to-day care of patients. No one can ever master all there is know in medicine, but the principles of evidence-based medicine can get you one step closer, one article at a time.

Table 6. Relative strength of Likelihood Ratios

LR >10 or <0.1	Large change from pretest to posttest probability.
LR 5 to 10 or 0.1 to 0.2	Moderate change from pretest to posttest probability.
LR 2 to 5 or 0.2 to 0.5	Small, but sometimes important, changes in probability.
LR 1 to 2 or 0.5 to 1	Small, rarely significant, changes in probability.
LR = 1	Pretest probability = posttest probability.

Questions

1. What are the 7 basic steps outlining the evidence-based medicine approach to clinical problems?
2. Why is randomization important?
3. What is an "intention-to-treat analysis?"
4. How do you calculate relative risk, relative risk reduction (RRR), absolute risk reduction (ARR), and number needed to treat (NNT), and what do these values mean?
5. What is the "95% confidence interval?"
6. Why is "blinding" important?

7. What are sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) and how do you calculate these values?
8. What are positive and negative likelihood ratios, and how do they differ from sensitivity and specificity?
9. How are pretest and posttest probabilities calculated and applied?
10. How can evidence-based medicine help you in your practice of medicine?

Answers to questions

1. I) Identify the clinical question. II) Search for sources of information. III) Identify the source(s) found. IV) Determine whether the results are valid. V) Determine what the results are. VI) Determine whether the results will help you in caring for your patients. VII) Resolve the clinical question.
2. Randomization ensures that both known and unknown factors are evenly distributed between the treatment and control groups, making it more likely that any difference in outcome between the two groups is due to the treatment effect alone.
3. This means that during the analysis of the study results, patients remain in the groups to which they were randomized in the beginning of the study, even if they are unable or unwilling to complete the treatment.
4. Relative risk reduction (RRR) = 1- Y/X. Absolute risk reduction (ARR) = X-Y. Number needed to treat (NNT) = 1/ARR. See Table 3.
5. The "95% CI," which means that the exact RRR lies within the range of the confidence interval 95% of the time. The CI speaks to the power of a study, and the factor that has the most impact on a study's power is its sample size.
6. It is well known that if a patient or worker knows that a patient is receiving the study medication, this will bias their assessment of the patient's outcome.
7. Sensitivity = a/(a+c). Specificity = d/(b+d). Positive predictive value (PPV) = a/(a+b). Negative predictive value (NPV) = d/(c+d). See Table 5.
8. LR for a positive test result (+LR) = [a/(a+c)]/[b/(b+d)] = sensitivity/(1-specificity). LR for a negative test result (-LR) = [c/(a+c)]/[d/(b+d)] = (1-sensitivity)/specificity. LRs are different from sensitivity and specificity because they take into account each individual patient, using the pretest and posttest probabilities.
9. The pretest probability is the clinician's "gestalt" about the chances that a patient has a particular condition based on clinical information such as symptoms, risk factors, and physical examination. The LR then determines how a diagnostic test will affect the pretest probability, making a disease more or less likely, the outcome of which is called the posttest probability.
10. a) Improves the uniformity and standardization of care so that all patients receive optimal care; b) Helps providers make better use of limited resources by seeking the most effective treatments; c) Prevents harmful side effects or outcomes; and d) Makes the literature accessible to all, thereby helping clinicians make the most informed decisions possible.

Chapter XXII.3. Epidemiology and Research Methodology
Loren Yamamoto, MD, MPH, MBA

You are seeing an obese 10 year old for a school physical. A history of his overall activity level indicates that he does not participate in sports, he stays indoors all the time and watches TV during the entire weekend. He doesn't know how to ride a bicycle. His only physical exercise is at school during recess and physical education classes. Because he is obese, the other kids make fun of him, so he prefers to just sit in the shade during recess.

His family history is significant for: 1) obesity in both parents; 2) cigarette smoking, coronary artery disease and hypertension in his father; 3) death from acute myocardial infarction in his paternal grandfather at age 45.

Exam: VS are normal except for his blood pressure which is 130/85. He height is at the 50th percentile. His weight is 84 kg (>95th percentile). He is very obese in no distress. His examination is normal except for the findings associated with obesity.

You advise his parents that he is at risk for heart disease in his early adult life if his obesity continues. You recommend a physical exercise program and suggest that his father should not smoke inside the home. However, his mother and father state that they are unable to comply because they live in an apartment. They don't believe that indoor exercises would help. They are skeptical and say that they would like to see some proof that exercise has some benefit. His father shows you a magazine article (from your waiting room) which states that cigarette smoking does not cause lung cancer.

You decide to look up some studies on the effect of exercise on obesity and cardiovascular disease. However, you find that there are many different types of studies and these are hard to compare and it is difficult to determine the quality of these studies. The statement about smoking is puzzling. The article states that although cigarette smoking is associated with lung cancer, it has not been shown to cause lung cancer. You decide to find out how experts determine if an association is truly due to cause and effect.

Epidemiology includes the description of methods which describe the occurrence of disease. Descriptive and inferential statistics are discussed in a separate chapter. Many epidemiology numbers are special descriptive statistics which help to summarize the occurrence of disease within a population. In clinical research, several types of studies exist. Understanding the differences between these study methods enables one to assess how good a study is in contributing to the clinical question at hand. This chapter will cover some basic epidemiology and focus on research methodology to develop an ability to critically appraise the medical literature.

Study design types (method of study) can be categorized into: 1) Experimental design, 2) Clinical trial (placebo controlled, blinded), 3) Cohort study, and 4) Case control study.

Recognizing what "type" of study one is reading is not nearly as important as recognizing the actual weakness of the data and its conclusions. Many studies do not fit neatly into one specific study type.

For the above 4 study types, they can be further classified as prospective, longitudinal, and retrospective based on the time sequence of the data observations. A prospective study generally looks at some time of exposure (a risk factor) and then determines at some future time, if a disease condition develops. Retrospective studies look at those who have developed a disease and then determine if any risk factors were present in the patients at some time in the past. Longitudinal studies make observations in the study group at several points in time moving forward.

Prospective and longitudinal studies are the most difficult to do because they require a long period of time to complete. Retrospective studies are easier to do, however, they are subject to numerous methodological flaws. Prospective and longitudinal studies are less subject to methodological flaws, so the quality of their conclusions is usually superior to that of a retrospective study.

1) The experimental design type of study is not common in clinical medicine using actual patients. This type of study is usually done in a lab using models or study subjects who are subjected to different treatments. It is nearly flawless from a methodological standpoint if it is done correctly. Example: Does 20-minute EMLA cream (a topical anesthetic) reduce the pain of starting an IV? Healthy study subject volunteers are recruited who are willing to have two IV's started on them. EMLA cream is applied to one hand and placebo cream is applied to the other hand with the study subject blindfolded. An IV is started on one hand and then the other hand. The study subject must now rank which hand was more painful. Note that this type of study could not be done on actual patients, because they would not ordinarily require two elective IVs.

2) The clinical trial is a study type that generally appears in the New England Journal of Medicine. Because such studies are very expensive to undertake, they have consumed enormous resources, and they have taken a long time to complete, it is unlikely that anyone else will have the resources to repeat it, and such studies are often fairly definitive in drawing conclusions. Clinical trials of new treatments must be compared to some type of control. The control could be an older treatment or it can be a placebo (placebo controlled). If patients know which treatment they are getting (the new treatment or the control), then the study is not blinded. This is a problem because patients may perceive they have gotten better if they got the new treatment and those who got the control (placebo or older treatment) may be less likely to feel like they have gotten better. The study design should somehow measure the patient's clinical response to treatment. It is best if this measurement is highly objective (e.g., blood sugar at 6:00 a.m.), but often it is a rather subjective measurement such as tympanic membrane abnormality or subjective pain relief. Even a measurement such as blood pressure may be subject to bias to some degree. If the measurement of clinical outcome has any degree of subjectivity, then it may be subject to bias if those making the measurements know whether the patient received the new treatment or the control. If those making the measurement are blinded as to whether the patient received the new treatment or the control, this removes the bias. This is blinding the study investigator. If possible, it is best to blind both the subjects (patients) and the study investigators (double blinded). Double blinding can be accomplished by assigning codes to pre-measured treatment vials. After the clinical outcome measurements are made, the code is revealed to determine which study subjects received the new treatment versus the control. It is not always possible to blind the patient or the investigator. For example, comparing the outcome a jogging program and weight control 2 years later, it would not be possible to blind the patient as to whether they were assigned to the jogging or non-jogging group.

3) In a cohort study, a group (cohort) is identified. Disease outcome and risk factors are assessed within the cohort. This can be done prospectively, longitudinally, or retrospectively. Examples:

Prospective: All patients in the emergency department (ED) arriving with wheezing are treated in an unrestricted fashion by the ED physician on duty. A data sheet is completed during the ED visit which indicates the patient's initial oxygen saturation, the number of bronchodilator treatments received, and whether the patient required hospitalization. This data can be analyzed to see if hospitalized patients have lower initial oxygen saturations compared to patients who were discharged home from the ED.

Longitudinal: The Hawaii Heart and Cancer Study, located at Kuakini Medical Center, enrolled all Japanese males of a certain age group on Oahu using selective service (military draft) registration data. Since the 1960s, this group of men has undergone periodic screening physical examinations, histories, lifestyle surveys, and laboratory studies. Since this cohort has been followed for a long period of time, many of the men have developed heart disease, cancer, etc. Such large longitudinal cohorts have yielded substantial information regarding the role of risk factors for such diseases. Other large cohorts are followed similarly in other research centers in the U.S.

Retrospective: 120 inpatient cases of intussusception were reviewed. Each chart was reviewed (retrospectively) to look for documentation of currant jelly stool and whether the diagnosis of intussusception was missed on the initial medical evaluation. The study concluded that the presence of frank currant jelly stool was associated with a low likelihood of missing the diagnosis of intussusception while there was a higher likelihood of missing the diagnosis in the absence of frank currant jelly stool.

4) A case-control type of study is always retrospective. Patients with a particular disease condition are identified (cases). A set of matched controls without the disease are found. Risk factors (exposure factors) are then compared in the two groups. For example, to examine the relationship of bicycle helmets on brain injuries, we could identify 30 patients hospitalized with brain injuries due to bicycle accidents. We could then go to a different hospital ward and find 30 patients of similar age and sex, but without a brain injury. We could then survey each group for the bicycle helmet use. If the bicycle helmet use frequency is 30% in the head injury group and 75% in the control group, and if $p<0.05$ for this difference, then an association exists to suggest that bicycle helmet use may lower the risk of bicycle related head injuries. However, there are other possible explanations for this so the strength of the conclusion is not as strong.

Clinical trials are the most difficult and expensive to do. Case-control studies are the easiest and least expensive to carry out. Cohort studies are in between. While case-control studies are the easiest to perform, they are the most subject to methodological flaws. In studying rare diseases, case-control studies are the most efficient means of epidemiological research. For example, in the Hanta virus epidemic in New Mexico, the most efficient way to determine risk factors for the deaths due to the unknown cause was to examine the background history of all the patients who died mysteriously compared to a group of matched controls.

Consider the example in the case in which we are trying to determine if lack of childhood exercise is associated with coronary artery disease (CAD) in later adult life. Using the four different study types, this is how it would have to be done:

For an experimental design, we would obtain 1000 young mice, since we could not do this study in humans. 500 mice would be exercised and the other 500 would be forced to be sedentary. When the mice become adults, we would look at their hearts to see how many in each group have CAD.

For a clinical trial, we would obtain 1000 child volunteers. We would then randomize them to childhood exercise or childhood non-exercise groups. Study volunteers would have no choice as to what group they would be in. Those assigned to the exercise group would have to exercise all through childhood. Those assigned to the non-exercise group would be forbidden from exercise throughout childhood. 40 years later as adults, we could survey them for CAD using angiography or a more sophisticated future method of imaging the coronaries. We would not be able to do a double blinded study since the study volunteers would know whether they were randomized to the exercise or non-exercise group. Such a clinical trial would be unethical and impossible.

In a cohort study, we would identify 1000 children who will be observed longitudinally for the next 50 years. There would be no restrictions on their lifestyle. Some will have a lot of exercise, some will have none and some will have intermediate levels of exercise. Somehow, this will have to be quantitated. Other factors associated with CAD must also be monitored, such as blood pressure, cholesterol, diet etc. In late adulthood, the cohort could be evaluated for CAD to determine whether more CAD is present in the groups who had less childhood exercise.

In a case control study, we would go to the coronary care unit (CCU) to find 50 patients hospitalized with ischemic cardiac disease. We would find 50 age and sex matched controls from the general hospital ward (without heart disease). We would then obtain a detailed history of their childhood exercise habits to see if there is less childhood exercise in the CCU patients compared to the controls.

In reviewing the medical literature, there are several common pitfalls in the interpretation of published data. Some of these include:

1. Gold standard.
2. Statistical significance versus clinical importance.
3. "Fishing" for a significant result: Data dredging.
4. Confounding variables.
5. Association versus cause & effect.
6. Case reports.

The gold standard refers to a method that truly identifies a particular condition. Some disease conditions have gold standards and others do not. Examine the following examples. Which of these are good gold standards and which of these are "bronze" standards?

Pregnancy: Positive beta-HCG, rising beta-HCG, baby/fetus/fetal tissue is eventually passed.

Meningitis: Elevated white cell count on CSF analysis.

Pneumonia: Characteristic CXR findings.

Appendicitis: Exploratory laparotomy examination of the appendix confirmed by histopathology.

In the above examples, the only one that is a poor standard (not "gold") is the CXR for pneumonia, since for a mild pneumonia, some radiologists would read the CXR as normal, while others would read it as a slight pneumonia.

Think of gold standards for the following examples that have been studied frequently in the literature: otitis media, strep pharyngitis, periorbital cellulitis, scaphoid fracture, bacteremia. The diagnostic standard for otitis media is, an examiner states that the patient has otitis media. This is a poor standard. The conclusions from many of the studies on otitis media are weak because it is not convincing that all the study subjects actually have otitis media. The diagnosis of strep pharyngitis is based on a throat swab. However, we know that some positive throat cultures are due to tonsillar colonization and not necessarily to strep pharyngitis. Periorbital cellulitis is a clinical diagnosis. Some would call a swollen bug bite on the upper eyelid a cellulitis. Scaphoid fractures are not always radiographically apparent. Bacteremia relies on a positive blood culture, but many blood cultures grow out contaminants and a negative blood culture may occur in bacteremia if the bacteremia is low grade. Thus, none of these diagnostic clinical entities are well defined by gold standards. If a gold standard is lacking, one cannot be certain what clinical entity is being studied.

Statistical significance versus clinical importance has been described in the chapter on statistics. Just because something is statistically significant does not necessarily mean that it is clinically important. For example small differences in white blood counts,

oxygen saturation values, pain scores may be statistically significant, but the differences need to be larger for them to be clinically important.

"Fishing" or "data dredging" for a significant result has been discussed in the statistics chapter. This phenomenon occurs when too many statistical tests are performed, which increases the likelihood that you will find a difference due to chance (which is not a true difference) leading you to an incorrect conclusion. Worded another way, the likelihood of a type 1 statistical error, increases with the number of statistical tests that are performed.

Confounding variables are variables that are related to the study risk factor and the outcome. Such factors must be matched or compensated for in order to compare two groups.

Example: Does watching Japanese language Samurai movies on TV cause GI cancer? We studied 50 men with GI cancer and found that 60% of them frequently watched Samurai movies. We then found a control group of teenagers from a high school who presumably do not have GI cancer. We found that 0% of the controls frequently watched Samurai movies. We thus, conclude that watching Samurai movies puts one at greater risk for GI cancer. What is wrong with this conclusion? Age is a confounding variable. Age is related to GI cancer since GI cancer tends to occur in older adults and not teenagers. Age is also related to the likelihood of watching Japanese language Samurai movies. While older Japanese men are somewhat likely to watch Japanese language Samurai movies, young teenagers are very unlikely to frequently watch these. Thus, to have a better control group, a confounding factor such as age must be matched for (i.e., the age distribution in the GI cancer group must be the same as that of the control group).

Age and sex are almost always confounding variables. Thus, comparison groups must always be matched for age and sex. Other confounding variables are more difficult to identify. Ethnicity is a significant confounding variable in the example above, since non-Japanese men are much less likely to watch Samurai movies.

See if you can think of some potential confounding factors for the following study. The emergency department carried out a study comparing special intraosseous needles with generic bone marrow needles to determine which needle was the easiest to use for an intraosseous (IO) procedure. Thirty Honolulu paramedics were asked to insert the special IO needle into a turkey bone, then to insert the generic bone marrow needle into a turkey bone. The two IO insertion times were recorded and the paramedics were asked to determine which needle they preferred. The following are the results. Mean insert time was 21 seconds for the special IO needle, and 15 seconds for the generic bone marrow needle, (p=0.02). 20% of the paramedics favored the special IO needle, while 80% favored the generic bone marrow needle (p=0.001). Identify some potential confounding variables?

1) These paramedics had previous experience and training with the intraosseous procedure. Which needle were they trained with and which needle have they used more in their experience? If they had previous significant experience with the generic bone marrow needle, then we would expect that they would have an easier time with this needle. Thus, previous intraosseous experience is potentially a confounding variable. This confounding variable could be corrected by matching those with previous generic bone marrow needle experience with others who have more special IO needle experience. Another way of eliminating this confounding variable is to use other study subjects, such as students, who have never performed an intraosseous insertion before.

2) Note that the study described above always started with the special IO needle, followed with the generic bone marrow needle. This gives the special IO needle a disadvantage because it gives the paramedics an opportunity to practice with a different needle prior to using the generic bone marrow needle, but no practice run is allowed prior to the special IO needle. If the turkey bone model is not similar to an actual intraosseous attempt, it may take some getting used to. The turkey femur is cylindrical, while an infant's tibia is flat. Thus, any practice on the unfamiliar cylindrical turkey femur may help to reduce the time of IO needle insertion. Thus, the sequence of which needle is used first is a confounding variable. This confounding variable could be eliminated by alternating or randomizing which needle is tried first.

How can we determine if the association between two variables is a mere association or if one causes the other? We often take this for granted. For example:

1. Measles virus exposure is associated with measles.
2. Asbestos exposure is associated with mesothelioma.
3. Stress is associated with shingles (zoster).
4. Cigarette smoking is associated with lung cancer.

Which of the above are mere associations and which are cause and effect? What objective criteria are you using to come to a decision?

Koch's Postulates are useful in determining cause and effect, but these postulates are applicable to infectious disease only:

1. The microorganism must be present in every case of the disease.
2. The organism can be cultured.
3. This cultured organism must cause the same disease when inoculated into another host.
4. The organism must be recovered and re-cultured from this new diseased host.

Although not as sound as Koch's postulates, the following criteria have been the standard for determining cause and effect. Epidemiologic cause and effect criteria include:

1. Strength and consistency of association (multiple studies show the same relationship).
2. Dose-response relationship (greater risk factor exposure results in greater risk of disease).
3. Correct temporal association (risk factor occurs first, then disease; not vice-versa).
4. Specificity of cause and effect (risk factor is specific for this disease; i.e., it does not cause other diseases).
5. Plausible reason for a cause and effect relationship to exist.

Are the following cause and effect under the above criteria?

1. Measles virus exposure is associated with measles. Yes.
2. Asbestos exposure is associated with mesothelioma. Very close to yes.
3. Stress is associated with shingles (zoster). No.
4. Cigarette smoking is associated with lung cancer. Probably, but not definite.

Stress does not meet the cause and effect criteria for zoster since the strength and consistency of the association is weak and the level of stress is difficult to measure, so a dose-response relationship is lacking. Stress and zoster are not specifically linked, since stress causes ill conditions other than zoster. Cigarette smoking does not meet cause and effect criteria because it does not meet the specificity criterion. Smoking is associated with GI cancer, lung cancer, esophageal cancer, oral cancer, heart disease, etc. If you have ever wondered why the tobacco industry claims that cigarette smoking is not a proven cause of lung cancer, this is the reason (lack of specificity). However, the reason for this is that cigarette smoke is not a homogenous substance and the pathogenesis of cancer is complex and multifactorial.

Single case reports should always be viewed with suspicion. Single case reports are only reported if the phenomenon reported is rare or unheard of. Such cases present a distorted view of reality. One could interpret case reports in the exact OPPOSITE way that they are presented. For example, if I wrote a "case report" about a child who got bit by a mosquito and then began to itch, no journal would ever publish this case report since we know that mosquito bites cause localized pruritus. But if I wrote a case report about a child who got bit by a mosquito and while scratching he invented a warp drive rocket engine, such an unexpected "case report" would be of interest to some journals. It has been said that you may choose to believe the exact opposite of a case report. In this case, getting bit by a mosquito does not cause one to invent an advanced means of interplanetary rocket propulsion. Additionally, if the case reported is so rare and it already occurred, it may not likely occur again.

Case series, on the other hand, are not subject to the same criticism as the single case report. Case series should be taken more seriously.

Screening tests: These terms are frequently misused.

Sensitivity=TP/(TP+FN)=the fraction of all true positives that are caught by the test. A very sensitive test identifies most of the true positives. However, there may still be a substantial number of false positives in a highly sensitive test.

Specificity=TN/(TN+FP)=the fraction of negatives that are true negatives. A very specific test correctly identifies most of the true negatives. However, there may still be a substantial number of false negatives in a highly specific test.

Positive predictive value=TP/(TP+FP)=the likelihood of having a disease if the test is positive.

Negative predictive value=TN/(TN+FN)=the likelihood of not having a disease if the test is negative.

Using tuberculosis (TB) as an example, primary screening tests should be very sensitive (catch most of the positives). TB skin testing is a useful primary screening test because it is positive in those with TB exposure (most of whom do not have pulmonary TB yet).

Secondary (confirmatory) screening tests should be specific. A negative CXR is likely to indicate the absence of pulmonary TB, thus, the positive skin test indicates TB exposure, but not pulmonary TB.

The negative predictive value is always high in rare conditions, regardless of how good or bad a test is. For example, is a serum beta-HCG a good test to rule out TB? Of course not. But did you know that its negative predictive value is 99% in ruling out TB. In a study sample only one in 200 TB skin tests was positive. All of these patients have negative B-HCG's. Thus, a negative B-HCG has a negative predictive value of 199/200=99.5% Wow!

Consider the following statement by Dr. Superstar: My clinical evaluation is 95% accurate in diagnosing appendicitis. What does this mean?

Does this mean that Dr. Superstar correctly identifies 95% of those with appendicitis (i.e., sensitivity=95%)? This may sound impressive at first glance, but I could roll a pair of dice and tell you that if I roll any number less than 13, the patient has appendicitis. Using this method, I will identify 100% of those with appendicitis. Of course there will be many false positives, but no false negatives. Rolling dice identifies 100% of those with appendicitis (i.e., sensitivity=100%).

Does Dr. Superstar mean that if he diagnoses appendicitis, then there is a 95% chance that the patient actually has appendicitis (i.e., positive predicative value=95%)? This may sound impressive at first glance, but consider the following: This could mean that Dr. Superstar evaluated 1000 patients. He made a clinical diagnosis of appendicitis in 100 patients, and of these 100 patients, 95 patients had appendicitis and 5 did not (positive predictive value=95%). Of the 900 patients who received a negative clinical evaluation by Dr. Superstar, 450 had appendicitis. Thus, Dr. Superstar could have a 95% positive predictive value, but this does not necessarily indicate that he is a good clinical diagnostician for appendicitis if he misses 450 cases of appendicitis for every 95 that he diagnoses.

Does Dr. Superstar mean that if he concludes that the patient does NOT have appendicitis, then there is a 95% chance that this is correct (i.e., negative predictive value=95%)? This may sound impressive at first glance, but remember the general statement made earlier about negative predictive value: The negative predictive value for any rare condition is always high regardless of how good or poor the test is. If Dr. Superstar evaluated 1000 patients and only 40 patients actually had appendicitis (4%), then I could use the dice test to predict which patients do not have appendicitis. Rolling any number less than 13 indicates the absence of appendicitis. This test will identify true negatives in 960 out of 1000 instances (i.e., negative predictive value=96%). Again, an obviously useless test, can often be better than a seemingly useful test. You must be careful in accepting some of these numbers.

There is a fallacy in the high percentages such as 95%. We tend to think that 95% and above for any kind of test is good, because all through our lives, we were taught that 95% was an "A grade". We needed these grades to get into college and medical school. The reality of these numbers is that 95% can be good, but it can also be very poor. THINKING is required to sort this out. Whenever sensitivity and specificity values are calculated, the author should ideally calculate all four values (sensitivity, specificity, PPV, NPV). If the author only publishes one or two of these, it is very likely that the unpublished values are very poor and do not support the author's conclusion. Such an omission should be viewed with extreme skepticism.

Special rate calculations are very common in epidemiology. These terms are frequently used incorrectly. Incidence is the number of new cases that occur. An incident rate is the incidence divided by some type of standardization factor such as a one year period (the annual incidence rate) or a clinical occurrence such as the total number of births as in the infant mortality rate (the number of infant deaths divided by the total number of live births). Prevalence is the number of cases that exist at a specific moment in time. A prevalence rate is the prevalence divided by some type of standardization factor (which cannot be a time period because by definition, prevalence refers to a single point in time and not a period of time) such as a population base. Because of these differences, incidence is generally used to describe acute conditions, while prevalence is used to describe chronic conditions. The incidence of a nursemaid's elbow might be 1000's

of cases per year. But the prevalence (how many have the condition now) of nursemaid's elbow at this very instant might be zero (or perhaps 1 or 2), because it is very likely that only 0, 1 or 2 children have this at this moment. The prevalence of childhood diabetes in a community might be 300 cases at this moment. If the number of new cases if childhood diabetes is about 35 per year, then we could say that the incidence of new onset diabetes (the initial onset is the acute event) is 35 per year. Thus, incidence underestimates the magnitude of the problem for chronic diseases since incidence only measures new cases.

Mortality rates are commonly cited to describe survival and the overall health of a community. Similarly, injury rates and other outcome rates can be used to describe the health of a community. Remember that the mortality rate for everyone is 100%. That is, all of us will eventually die. Therefore a mortality rate of 10% is impossible. This would make sense only for a time-limited mortality rate. Such as a 10-year mortality rate for leukemia is 11%. Which means that 10 years after the diagnosis of leukemia, there is a 89% chance of survival. All mortality rates should have a time period attached to them or it should be understood that the time period is short. The mortality rate for bacterial meningitis is 10%. Does this mean that if I have bacterial meningitis, I have a 90% chance of living forever? No, it implies that 10% of children with bacterial meningitis, die shortly after the diagnosis. It should be more accurately called a 1 year or 6 month mortality rate.

Mortality rates can be age adjusted which also permits the rate to be less than 100% because it is a calculated mortality rate corrected by the age distribution of the community's population. This calculation is beyond the scope of this chapter. Some examples of this will be described later. Infant mortality rates are frequently used to assess the health of a community or country. The implication is that a healthy community or country should have a low likelihood of an infant dying.

Consider the following CHALLENGING data interpretation examples:

Patients with angina who have coronary artery imaging studies often reveal the presence of coronary artery disease. Following coronary artery bypass grafting (CABG), patients' angina often resolves. What can be said about the observations in determining the utility of CABG? While these findings suggest that CABG reduces angina pain by improving coronary blood flow, a control group of "sham thoracotomy" patients (their chest was cut open, but no coronary grafts were performed) noted a similar degree of angina pain improvement following the "sham thoracotomy" procedure, suggesting that the thoracotomy itself had at least some role in reducing angina pain and this reduction in pain was not necessarily due to the coronary grafts. CABG recommendations were modified to recommend this procedure only in those with severe coronary disease.

Is phototherapy useful in the management of neonatal hyperbilirubinemia? Is bilirubin toxicity the cause of kernicterus? This is a complicated question, but in a study of ABO incompatibility patients with pre-set exchange transfusion criteria, babies were randomized to phototherapy or no phototherapy to see how many babies in each group reached the pre-set exchange transfusion criteria. There was no significant difference suggesting that phototherapy does not prevent the need for exchange transfusion in ABO incompatibility hyperbilirubinemia. Whether bilirubin is the cause of kernicterus is controversial and unlikely in my opinion since very high bilirubins are only associated with kernicterus if the cause of the hyperbilirubinemia is due to Rh incompatibility or G6PD deficiency. Other causes of high bilirubins are not associated with kernicterus. Bilirubin may be a marker of the actual cause of kernicterus, rather than be the cause of kernicterus itself.

In a study of 100 joggers compared with 100 age matched controls, the mean HDL was significantly lower than in the controls. What can be said about this data? It might be tempting to conclude that jogging improves HDL levels. However, joggers and non-joggers differ from each other in more ways than just jogging. It is likely that joggers have different diets than non-joggers. Multiple confounding factors exist such as diet, smoking, other exercise, work related stress, obesity, hypertension, diabetes, etc. All these factors are related to jogging and potentially to HDL. These confounding variables must be matched for among joggers and non-jogger controls.

Design a study to investigate whether IV magnesium prevents the need for intubation in severe status asthmaticus. When a severe asthmatic in near respiratory failure comes in to the ED, randomize the patient to magnesium or no magnesium and determine which group does better. This is not possible because, we would need to get consent from such patients to participate in such a study. It's not possible to get consent from such severely ill patients. All such patients get treated with multiple meds to prevent respiratory failure. Nothing should be held back. Any study claiming to have ethically randomized severe asthmatics, must not have been enrolling severe asthmatics; they must have enrolled moderately severe asthmatics who were stable for a consent procedure.

In a meta-analysis of ultrasound in the diagnosis of appendicitis, a scan of the literature identified 32 studies. 27 of these studies concluded that ultrasound is highly accurate in the diagnosis of appendicitis while 5 studies concluded that ultrasound is not accurate? The meta-analysis concludes that ultrasound is accurate. Comments? Several points here: 1) The more studies you see in the literature on a topic, the more controversial it must be. If the answer were clear-cut, no further publications on the topic are necessary. However, in controversial subject areas, multiple publications are often present in the literature, attempting to clarify the controversy. Thus, the correct conclusion should be that the accuracy of ultrasound in appendicitis is controversial. 2) There is publication bias towards studies with "positive" results. Thus, although 27 studies conclude positively that ultrasound is accurate and 5 studies conclude negatively, this doesn't mean that the positives outnumber the negatives, therefore the positive conclusion should not necessarily be reached. One negative study should have the weight of multiple positive studies since there is known publication bias favoring the publication of "positive" studies. 3) A study of ultrasound done by the University of XXX's Department of Pediatric Abdominal Ultrasonography Professors (i.e., superspecialists), should not be equated to the practice of general radiologists in community hospitals. A study conducted by superspecialists does not necessarily mean that a group of generalists can match the same results.

Consider the following statement: Trauma is the second leading cause of death. Gee, I didn't know that trauma was such a common cause of death. Trauma is the second leading cause of death only if the leading cause of death could be lumped into "non-trauma". There are ways to make any disease seem to be very important. For example, bicycle injures might be the first or second leading cause "accidental, non-motor vehicle related death in children 5 years of age". Additional phrases qualifying the death rate can be used to make any particular condition seem very important.

The U.S. has a higher infant mortality rate than Country-X (a very poorly developed country). How can this be? The U.S. defines a live birth as any birth with an Apgar score greater than zero. If a 21-week fetus (not compatible with survival) is passed with a heart beat of 10 beats per minute for 15 seconds until it stops, this is considered a live birth and an infant death in the U.S. Other countries do not count this as a birth. Thus, the U.S. infant mortality rate is not comparable to the way that infant mortality rates are measured in other countries. Very poor countries have poor health surveillance methods and probably don't know about most births and most infant deaths in their country, making their published infant mortality rates very inaccurate. Additionally, a very ill infant with complex surgical problems is transferred from another country to the U.S. where specialized surgical care is available. Despite heroic surgical efforts the infant dies.

This infant death is counted in U.S. statistics and not in the infant mortality rate of the country of the infant's birth. There are many things which distort the infant mortality rate making it an inaccurate proxy for the health status of the U.S.

A study is done to determine the most common causes of pneumonia in young adults presenting to a college student health clinic. Blood cultures are drawn from the first 500 patients diagnosed with pneumonia. Of these 500 blood cultures, 15 grow pneumococcus and 4 grow staph epidermidis. The study concludes that only 0.2% (15 out of 500) cases of pneumonia are due to pneumococcus. Comment on this conclusion. A blood culture is a not a gold standard for determining the cause of the pneumonia. Many patients with pneumococcal pneumonia have negative blood cultures. Staph epidermidis is often a contaminant and is very rarely a cause of pneumonia. Other causes of pneumonia such as mycoplasma and viruses will not be recovered from a blood culture.

A study was done to determine if a single IM dose of ceftriaxone (Rocephin) was sufficient to cure otitis media. This study randomized children with OM to receive 10 days of amoxicillin or a single IM dose of ceftriaxone. After 10 days, roughly 67% of children were found to be cured in both groups. The study concludes that single dose ceftriaxone is effective in treating otitis media. What are the problems with this study? In a study comparing amoxicillin with placebo in the treatment of otitis media, cure rates were roughly the same in both groups. Thus, ceftriaxone is similar to placebo in efficacy or similar to amoxicillin in efficacy. If similar to placebo, then one would conclude that ceftriaxone doesn't work, but if similar to amoxicillin, one would conclude that it does work. Unfortunately, we can conclude neither because the definition of OM is poor (no gold standard). It is likely that most cases of OM are minor and don't require treatment, so if the study deliberately enrolled patients with minor OM, then the spontaneous cure rate would make it appear that both groups got better at the same rates. Drug companies might deliberately set up a study to have a favorable conclusion. Notice that they chose to compare ceftriaxone to amoxicillin rather than to placebo because if the cure rates were shown to be similar to amoxicillin, the conclusion would be that ceftriaxone is effective, but if the cure rates were similar to placebo, then the conclusion would be that ceftriaxone is ineffective. When you do a study consisting of 980 cases of minor OM and 20 cases of severe OM, any treatment benefits will be diluted by the 980 minor cases that don't benefit from treatment. The problem here is that there is no gold standard to define the disease condition being studied and the heterogeneity (minor cases mixed with severe cases) of the condition being studied.

Questions

1. At the Acme emergency department, the hospitalization rate for all ED patients is 6%. The emergency physicians at Acme have developed a test to predict the need for hospitalization. When this test is positive, there is a 93% chance that the patient will NOT need hospitalization. Is this a useful test?

2. In a meta-analysis of midazolam (Versed) sedation in children undergoing procedures, a scan of the literature identified 10 studies. 7 of these studies concluded that midazolam was highly efficacious in accomplishing sedation without significant adverse effects. Three studies concluded otherwise. The meta-analysis concludes that midazolam is an effective agent for pediatric sedation. Comments?

3. True/False: Sweden and Norway have lower mortality rates than the U.S.

4. Poor country PP has a border with a wealthy country WW. The age adjusted mortality rate for WW is higher than for PP, suggesting that PP is a healthier country than WW. This is obviously not the case as one can observe by traveling through both countries. How can this discrepancy be explained?

5. You read in a textbook of medicine citing the incidence and prevalence of diabetes mellitus. Which number (incidence or prevalence) is more useful to describe the epidemiology of diabetes? When is one preferred over the other? How accurate are these numbers? Where do these numbers come from?

6. Define sensitivity, specificity, positive predictive value and negative predictive value. Which of these is frequently >90% even if the test is a poor one?

7. Is it possible to have a test that has a nearly 100% sensitivity, specificity, positive predictive value and negative predictive value? If so, give an example of such a test in clinical medicine.

Answers to questions

1. No. Since the Acme emergency department has a hospitalization rate 6%, we know that 94% are not hospitalized. By just stating that all patients do not require hospitalization, I have a 94% chance of predicting this correctly. Therefore, no test at all is better than the 93% predictive value of the Acme physicians' tests. Although 93% sounds like a good number, it is actually a poor number in this case.
2. The more studies you see in the literature on a topic, the more controversial it must be. If the answer were clear-cut, no further publications on the topic are necessary. However, in controversial subject areas, multiple publications are often present in the literature, attempting to clarify the controversy. Thus, the correct conclusion should be that the efficacy of midazolam for pediatric sedation is controversial.
3. No matter what country you live in, we all eventually die. The mortality rate in all countries is 100%.
4. It could be that since PP is so poor, they don't have an organized health department which keeps accurate health statistics. When the World Health Organizations asks PP to submit their age adjusted mortality rate, the health minister in PP just writes down any number and sends it in. This random number just happens to be lower than the accurately determined age adjusted mortality rate submitted by WW. Another explanation is that since PP has such a poor health care system, any patient who is very ill, is illegally smuggled over the border into WW where the patient shows up in an emergency room. The ethical staff in WW hospitals take care of these very ill patients who frequently die. These death statistics are registered in the health statistics of WW. Thus, many deaths that should have been attributed to PP, actually show up in the age adjusted mortality rate of WW instead. Such a phenomenon could make it appear that many people in PP never die.

5. Prevalence is better for diabetes. Chronic diseases are best described with prevalence while acute diseases are best described with incidence. These numbers may not be very accurate. They may come from disease condition registries or from health department statistics. These systems require that hospitals and/or physicians send in report cards diagnosing the patient's condition so that the statistic can be kept. However, such reports are frequently not made even in "reportable" diseases which the law requires to be reported. Diabetes is not a reportable illness. Another source may be health insurance claims information which contain diagnostic codes.

6. Sensitivity=TP/(TP+FN)=the fraction of all true positives that are caught by the test. A very sensitive test identifies most of the true positives. However, there may still be a substantial number of false positives in a highly sensitive test. Specificity=TN/(TN+FP)=the fraction of negatives that are true negatives. A very specific test correctly identifies most of the true negatives. However, there may still be a substantial number of false negatives in a highly specific test. PPV=TP/(TP+FP)=the likelihood of having a disease if the test is positive. NPV=TN/(TN+FN)=the likelihood of not having a disease if the test is negative. The NPV frequently has a deceptively high value, such as >90% if the disease condition is infrequent.

7. It is possible. Most of these tests are gold standards since they are nearly perfect and they actually define the disease entity. But generally if a study publishes only two out of these four values, it is likely that are publishing the two best values and the authors have suppressed the other two values which do not appear as good. A test which is has nearly perfect sensitivity, specificity, PPV and NPV is the pregnancy test. Lumbar puncture for meningitis is also quite good. Radiographic images for certain types of fractures which are obvious (e.g., forearm fractures) are also quite good.
