Patients with a large to medium sized systemic vasculitis (i.e., Takayasu's arteritis or GCA) generally have an initial inflammatory phase for which corticosteroid treatment should be initiated. Alternative immunosuppressive and immunomodulating agents such as cyclophosphamide, methotrexate, and azathioprine also can be used. These patients benefit from well coordinated multidisciplinary care. Invasive intervention should be avoided during the active inflammatory phase because of the high risk for recurrence and failure.

Revascularization for chronic occlusive disease is limited to limb salvage situations for patients with critical ischemia (tissue loss or rest pain) or debilitating symptoms of effort fatigue secondary to large or medium vessel occlusive disease. Acute arterial occlusions resulting from arterial emboli or trauma generally should be addressed when diagnosed, as operative intervention is easiest in the acute setting, and ischemic symptoms frequently develop once the patient recovers from the acute event.

Regardless of the indication, great care is necessary when operating on the UE vasculature. The proximal UE arteries lack the thick muscular layer of the femoral artery and are torn easily if handled roughly. The forearm arteries are also problematic because of their extreme tortuosity. Avoidance of excessive manipulation is critical. Operative intervention is most useful for treating atherosclerotic occlusive disease of the proximal arteries. Intrathoracic procedures to treat innominate and subclavian artery occlusive disease are discussed in the chapter on brachiocephalic reconstruction.

Endovascular Therapy

Endovascular technique is most commonly used to treat short segment occlusive lesions found in the proximal vessels of the UE, specifically in the proximal left subclavian artery. Standard endovascular techniques typically are used with an antegrade approach via femoral access or, if necessary, a retrograde approach via the brachial artery. Typically long sheaths are used to give adequate support. Because of the larger sheaths that are required (6Fr and larger), open exposure of the brachial artery is preferred to limit access site complications when a retrograde approach is used. Prior studies have reported good outcomes following endovascular stenting and angioplasty for proximal lesions. However, the evidence is lacking for the more distal lesions. Common complications included stent fracture, restenosis, and thrombosis. Angioplasty alone is inferior to combined stenting and angioplasty, especially for occlusive subclavian lesions.

Subclavian Angioplasty/Stenting

Common indications of subclavian angioplasty and/or stenting of subclavian artery stenosis or occlusion include subclavian steal syndrome, vertebrobasilar symptoms, upper limb ischemia, and protection of left internal mammary artery coronary axillofemoral, and axillobrachial bypass. Excellent technical success rates have been reported, though success rates are somewhat lower in cases of chronic total occlusions compared with stenotic lesions. This procedure is associated with low morbidity and mortality. Short- and midterm patency rates are comparable with open surgical reconstruction. Longer term, open repairs have superior patency compared with endovascular interventions. However, given the low complication rates,

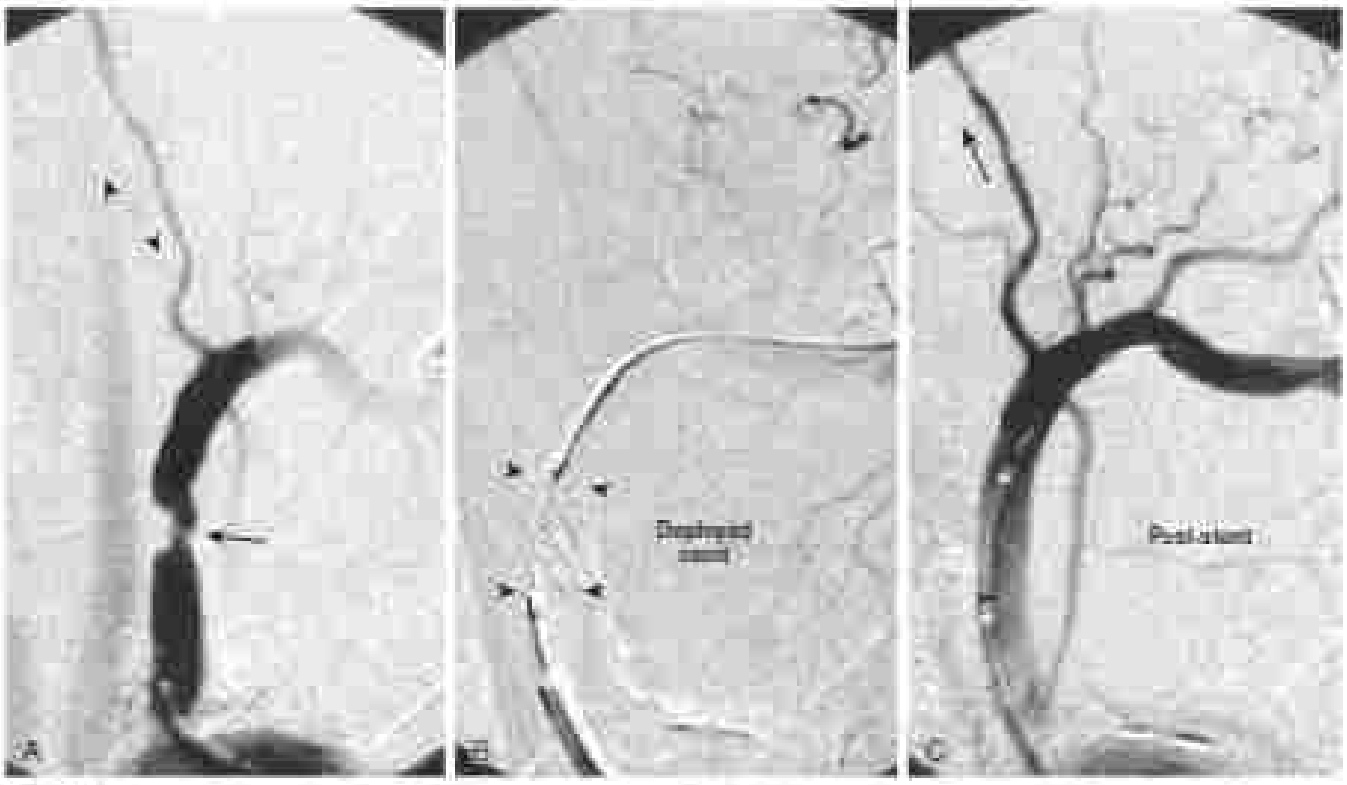

FIG. 4 Endovascular angioplasty and stenting of subclavian artery stenosis. (A) Stenotic lesion in a patient with severe subclavian artery stenosis (arrow). Arrowhead demonstrates perfusion of the arm through reversal of flow in the vertebral artery. (B) Deployment of the stent (arrowheads). (C) Completion angiography poststenting.

the minimally invasive nature, and the often frail patient population that requires such interventions, endovascular therapy is assuming its place as first line therapy for many of these lesions.

Endovascular management of subclavian artery stenosis is performed as follows (Fig. 4). Prior to the procedure, all patients should receive a low to medium dose of aspirin therapy. Clopidogrel can be considered in patients with aspirin sensitivity. Aortic arch aortogram and arteriography of the affected vessels is needed specially to show the location of the lesion with respect to ostium of subclavian artery and origin of its branches. Ultrasound guided micropuncture technique is used for access of the femoral artery. A 6Fr sheath is then placed to allow for easy positioning of the delivery system. Intravenous heparin is used (80 U/kg). After arch angiogram and road mapping of the lesion, 5Fr diagnostic catheter, such as vertebral catheter, is advanced over the wire through the sheath to engage the ostium and select the vessel. Then 0.014-inch, 0.018-inch or 0.035-inch wire is advanced to pass the stenotic lesion through the diagnostic catheter. A long guiding sheath (90-cm Cook select) is then positioned proximal to the lesion. Balloon angioplasty is commonly used prior to stenting. A 5 to 6 mm × 20 to 40 mm balloon is adequate for predilation of most subclavian stenotic lesions. Balloon-expanded stents are recommended to provide adequate radial force in orificial calcified lesions. Stent sizes can vary between 6 and 8 mm in diameter and 20 and 40 mm in length. The stent is delivered through the sheath over the wire and deployed to cover the entire lesion. A completion angiography is performed to rule out any complications (dissection or perforation). A key point to consider is not to oversize the stent in calcified lesions to avoid vessel rupture and bleeding. Also, since the vertebral artery is close to these lesions, care must be taken to avoid dissection and embolization to this vessel.

Endovascular management of subclavian occlusion is better performed through retrograde brachial approach. A 6Fr sheath is placed in the brachial artery distal to the subclavian occlusion. This approach can increase the risk of retrograde dissection into the aortic arch. A 0.035-inch glide wire supported with a curved catheter is used to cross the occlusion. Remaining steps involving angiography to confirm true lumen selection, predilation and stent placement are similar to the antegrade subclavian stenotic lesion as described previously. Angiography of the aortic arch can be performed using femoral access to aid in the proper placement of the stent.

Dual antiplatelet therapy (aspirin and clopidogrel) is required for at least 3 weeks following stenting.

Other Lesions

The use of endovascular techniques for other lesions of the UE is not well defined. Traumatic disruptions of the subclavian axillary artery, which can be difficult to approach surgically, have been treated successfully with cover stent grafts (Fig. 5). Catheter directed thrombolysis has been used for thrombotic occlusions of the UE. Technically successful balloon angioplasty of arterial occlusive lesions in the arm, forearm, and hand has been described. The infrequency of the UE pathology and the lack of long term follow up make it difficult to establish the role of these interventions.

Open Surgical Revascularization

Subclavian

Provided that the ipsilateral common carotid artery is disease free, both carotid subclavian bypass and subclavian transposition can be considered for the treatment of proximal subclavian artery occlusive disease. Although bypass is technically simpler, transposition has superior long term patency. Although endovascular techniques have reduced our reliance on these operations for the treatment of occlusive disease, these operations have in fact become more commonly performed as part of debranching the aortic arch in preparation for endovascular repair of thoracic aortic pathology.

The procedure is performed as follows. The patient is placed on the operating table in a semi Fowler's position, with the head of the table elevated 30 to 50 degrees. A roll is placed under the shoulders to allow for moderate extension of the neck, and the head is rotated

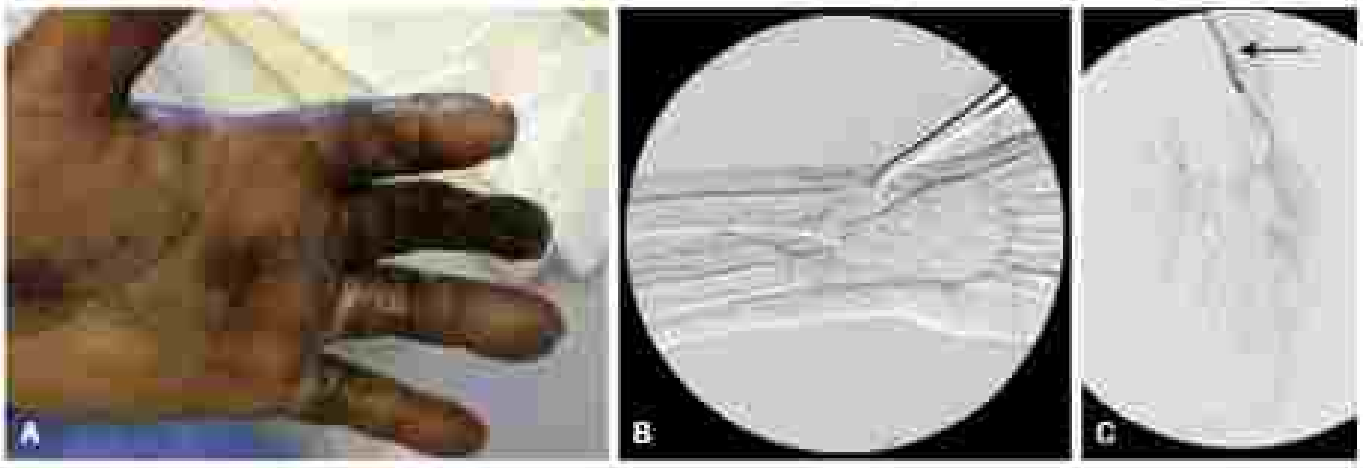

FIG. 3 (A) Ischemic left hand with gangrene of the middle finger in a patient with end-stage renal disease and neglected thromboembolization of the fistula after percutaneous dialysis access graft thrombectomy. (B) Angiography demonstrating occlusion of the ulnar and radial arteries with reconstitution of the radial artery at the wrist. (C) Angiogram demonstrating distal anastomosis and runoff of brachial artery to radial artery bypass with reversed great saphenous vein (arrow).

slightly toward the contralateral side. The ipsilateral arm is placed at the side with the shoulder depressed as much as possible. A transverse incision is made approximately one fingerbreadth (2 cm) above the clavicle, extending from the edge of the sternocleidomastoid muscle to the midportion of the clavicle. Subcutaneous tissues and platysma are divided, and the clavicular head of the sternomastoid muscle is transected. The omohyoid is identified and divided. The underlying scalene fat pad is mobilized along its medial and inferior aspects and retracted superiorly and laterally. During this dissection one must be alert for lymphatic structures, which are carefully ligated before division. However, the thoracic duct or right lymphatic duct is not routinely ligated if encountered unless it is injured. After retraction of the scalene fat pad, the anterior scalene muscle is exposed. The phrenic nerve is identified (coursing lateral to medial along the surface of the anterior scalene) and carefully mobilized and retracted to allow division of the anterior scalene from its tubercle on the first rib. Care is taken not to injure the underlying subclavian artery and adjacent brachial plexus. The subclavian artery is gently dissected free. Exposure of the carotid artery is accomplished through the medial portion of the incision. Injury to the vagus nerve and internal jugular vein is avoided by retracting them laterally. If exposure of the carotid bifurcation is necessary (e.g., for concomitant endarterectomy), a separate incision can be made along the medial border of the sternocleidomastoid. For both bypass and transposition, we create a tunnel posterior to the internal jugular vein, and systemic heparin is administered.

Transposition of the subclavian artery to the carotid artery is suitable only when plaque extends no more than a few centimeters beyond the subclavian artery origin. Transposition requires mobilization of the subclavian artery as proximally as possible. Small branches are divided, but an effort should be made to preserve the vertebral and internal mammary arteries. However, if additional mobilization of the subclavian artery is required to avoid kinking, it may be necessary to divide the internal mammary branch. To minimize the risk of embolization, the distal subclavian, vertebral, and internal mammary arteries are clamped before ligating the proximal subclavian artery. The subclavian is transected proximally with very careful ligation of the proximal stump. A 4- to 5-cm segment of the common carotid artery is clamped proximally and distally, and a short vertical arteriotomy is made along the lateral wall of the carotid, approximately sized to accept the diameter of the subclavian artery. An end-to-side anastomosis is fashioned with running Prolene sutures. Flow is restored after appropriate venting. We do not routinely monitor cerebral perfusion with an electroencephalogram during this procedure.

If a bypass is planned, only a short segment (1–2 cm) of the subclavian artery just distal to the thyrocervical trunk must be exposed. Small branches can and should be ligated to improve exposure. As outlined previously, care should be taken when retracting the subclavian artery to avoid inadvertent injury. A 7- to 8-mm prosthetic graft or a large-caliber saphenous vein graft typically is chosen as the conduit. It is technically easier to perform the subclavian artery anastomosis first. After systemic heparinization, the subclavian artery is clamped proximally and distally, and a short longitudinal arteriotomy is made along the superior surface of the artery at the highest point of its arc above the clavicle. The graft should be beveled to promote a slightly downward course of the graft. An end-to-side anastomosis then is constructed with 5-0 Prolene sutures. Then the graft to the carotid artery anastomosis is performed in an end-to-side fashion with running Prolene sutures as described for the transposition. We routinely leave a small closed suction drain in place; this is removed only after the patient has resumed normal oral intake.

Both carotid subclavian bypass and subclavian transposition have low morbidity and excellent long-term patency (75% to 80% at 5 years for bypass and almost 100% for transposition). Complications include injury to adjacent nerves (brachial plexus, phrenic nerve, and sympathetic chain) and lymphatic structures (thoracic and accessory thoracic ducts). Nerve injuries are usually self-limited. Lymphatic injuries can be problematic, and if drainage is significant or persistent, early reexploration and thoracic duct ligation is advised. Alternatively, therapeutic lymphangiography can be attempted with or without computed tomographic–guided sclerotherapy. This approach has up to 70% success rate in sclerosing the duct.

Axillary Artery

Occlusive lesions of the axillary artery are extremely unusual. Trauma or iatrogenic emboli are the most common causes. Bypass procedures originating from or terminating on the axillary artery also are relatively rare. In the past, axillaxillary bypass was advocated as an alternative procedure for dealing with subclavian disease when the ipsilateral carotid was an unsuitable inflow site. This bypass largely has been abandoned, however, because of its superficial location and reduced patency. Carotid axillary bypass has been used to manage extensive subclavian disease, whereas axillobrachial bypass has been implemented for distal axillary or proximal brachial occlusions. To expose the first and second portions of the axillary artery, the arm should be positioned at the patient's side (a narrow arm board is helpful). Significant abduction must be avoided because this position stretches the axillary artery. A transverse incision is made one

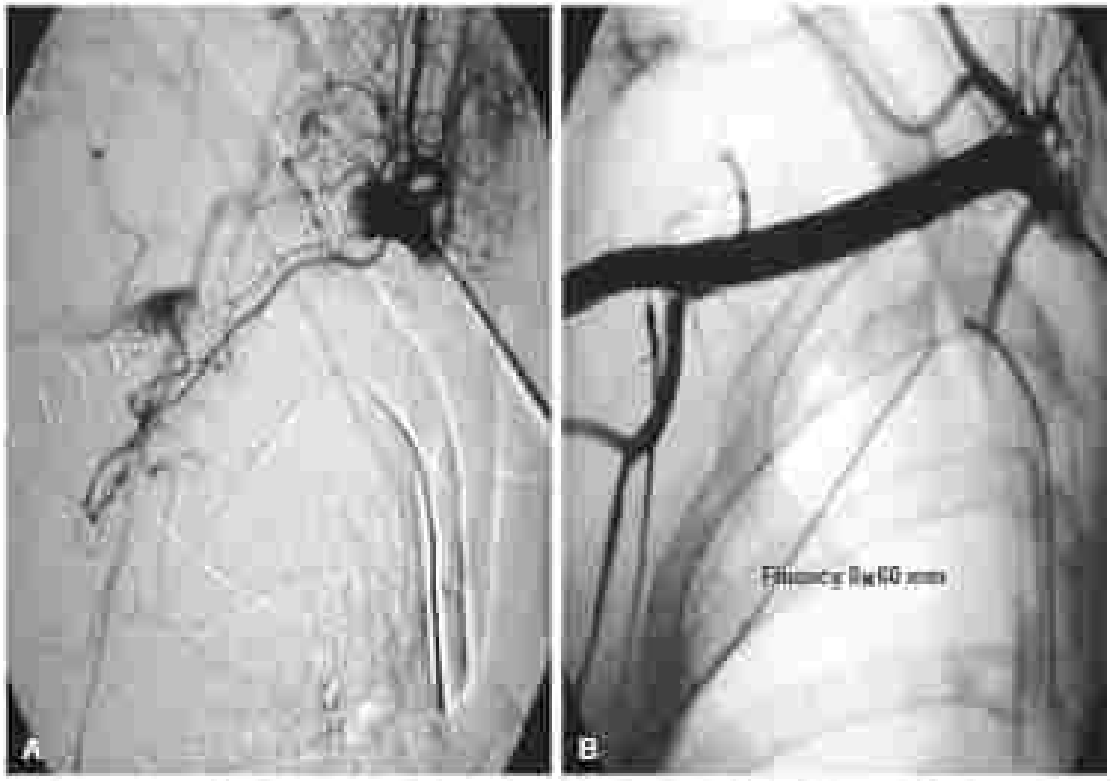

FIG. 8 A 19-year-old woman presented to the emergency with a gunshot wound to the right shoulder with absent radial or ulnar pulses. (A) Preoperative angiography showed absent flow distally. (B) The antegrade endovascular stenting and completion angiography demonstrated normal flow.

longitudinally below the clavicle, extending from the midclavicular line to the deltopectoral groove. The fibers of the pectoralis major muscle are split, and the underlying clavipectoral fascia is incised. Tributaries of the axillary vein are divided and ligated to the axillary vein, which lies inferior and slightly anterior to the artery. If encountered, the crossing medial and lateral pectoral nerves should be preserved to avoid postoperative atrophy of the pectoralis muscles. It is usually necessary to divide a branch or two of the thoracoacromial artery to gain exposure. The artery is located just above the vein, with the cords of the brachial plexus lying superiorly and posteriorly. As with the subclavian artery, care should be taken when mobilizing this thin-walled artery, which frequently has small posterior branches. The head of the pectoralis minor can be divided to facilitate exposure laterally (second portion of the axillary artery). Saphenous vein is the conduit of choice for bypasses originating from or terminating on the axillary artery.

Brachial Artery

Brachial artery lesions are rare and most commonly caused by catheterization and trauma. CEA is a rare cause of proximal brachial occlusive disease. For brachial artery exposure, the arm is abducted and the hand supinated on an arm board. The proximal brachial artery is exposed through a longitudinal incision along the medial aspect of the upper arm to the bicipital groove. Dissection along the posterior aspect of the muscle belly reveals the artery, accompanied by the median and ulnar nerves. The proximal brachial–distal axillary artery can be exposed through a hockey stick–shaped extension of this incision along the lateral border of the pectoralis major. Brachial exposure immediately proximal to the elbow is achieved through an incision along the bicipital groove extended laterally across to the antecubital fossa. The median nerve lies immediately medial to the artery at this level. Alternatively, the distal brachial artery and its bifurcation into the radial and ulnar arteries can be exposed by making a longitudinal incision in the antecubital fossa just distal to the elbow crease and dividing the bicipital aponeurosis. If more distal exposure is required, the incision can be carried inferiorly along the volar aspect of the forearm. If the entire brachial artery at the elbow requires exposure, a lazy S incision is used to avoid scar contracture across the elbow crease. Saphenous vein is the only conduit suitable for bypasses involving the brachial and more distal arteries.

Radial and Ulnar Arteries

Repair to the forearm arteries is rarely necessary and is most often used for trauma and neglected embolic occlusions (Fig. 8). In diabetic patients, these arteries can be affected by a particularly aggressive form of atherosclerosis (isolated arteriopathy) that is rarely amenable to revascularization. Buerger's disease is another cause of forearm occlusive disease that usually is not reconstructable. Exposure of these arteries at the wrist is relatively straightforward, but more proximal exposure requires a thorough understanding of forearm anatomy. Topical papaverine or nitroglycerin is helpful to combat dissection-induced vasospasm. Hypothenar hammer syndrome can be treated by an interposition vein graft of the involved segment of ulnar artery in the proximal hand. A distal limb vein provides the best size match.

Embolism

The management of large artery embolism is discussed in more detail in the chapter on peripheral arterial embolism. Because of increased vascularity and the inevitable resulting vasospasm, multiple passages with balloon embolectomy catheters should be avoided with UE emboli. For this reason, we have a lower threshold for obtaining preoperative imaging when dealing with acute arterial occlusions of the UE, even with a good clinical story for embolism. Imaging can confirm the diagnosis and allows a more directed approach, a particularly important concept when dealing with emboli in the axillary and subclavian arteries.

Although retrograde removal of such proximal clots usually can be performed through a brachial approach, we sometimes prefer to expose the occluded segment directly if there is significant clot burden. This approach minimizes the number of catheter passages necessary to extract the embolus and avoids stripping off clot into patent branches of the segment between the arteriotomy and the occlusion. Although most macroemboli originate from the heart, an arterial source sometimes can be responsible and, if identified, must be addressed. Treatment of arterial thoracic outlet syndrome requires not only excision of the compressive thoracic outlet elements but also some type of arterial reconstruction (discussed in more detail in the chapter on thoracic outlet syndrome).

Trauma

As outlined previously, most traumatic occlusions should be fixed at the time of diagnosis. Isolated radial or ulnar artery occlusions are an exception because they are usually well tolerated. Iatrogenic occlusions usually can be relieved with local exploration, thrombectomy, and repair of associated vessel wall injury. For more significant injuries, formal arterial reconstruction is required. Resection with end-to-end anastomosis can be performed rarely, but in the vast majority of cases interposition grafting with saphenous vein of appropriate caliber is required. A more detailed description of how to manage traumatic occlusions is provided in the chapter on management of vascular injuries.

SMALL ARTERY OCCLUSIVE DISEASE

Treatment of occlusive disease affecting the small arteries of the digits and hands can be challenging. After a proximal embolic source has been ruled out, attention is focused on identification and treatment of any underlying causative diseases. Patients with Buerger's disease frequently experience significant improvement with successful tobacco abstinence. Vibration induced injury will respond to avoidance of the causative vibratory machinery. The rare patient with cryoglobulinemia or hepatitis associated vasculitis will respond to appropriate therapy. Unfortunately, in the majority of cases, no specific therapy is available. In our practice, there are patients with an associated connective tissue disorder, hypersensitivity angiitis, or renal failure. For these individuals, care is focused on supportive measures. Abstinence from tobacco and avoidance of cold are routinely advised. Antiplatelet therapy (aspirin or clopidogrel) and hemorheologic agents (cilostazol) usually are prescribed. Vasodilators, primarily calcium-channel blockers, can be used to treat associated vasospasm with variable success. Areas of tissue loss are treated with local wound care and debridement as indicated. Sympathectomy, both cervicothoracic and digital, can lead to a temporary improvement in skin blood flow but has such limited durability (approximately 6 months) that most authorities have abandoned it except in highly selected patients with residual ischemia after revascularization.

CONCLUSIONS

UE arterial occlusive disease is an uncommon problem with diverse causes. Accurate diagnosis depends on a thorough history and physical examination supported by noninvasive vascular testing. Angiography remains the primary modality of diagnosis. Treatment depends on the nature of the disease process and the severity of the ischemia. Patients with embolic or traumatic occlusions and significantly symptomatic proximal large artery disease usually can undergo vascular intervention with good results. On the other hand, revascularization options for patients with distal small artery occlusive disease are extremely limited. In this setting, after a careful search for treatable causes, management is primarily supportive. Fortunately, progression to limb loss is rare.

Aortoiliac Occlusive Disease

Joseph-Vincent V. Rizo, MD, and Spencer M. Taylor, MD

Peripheral arterial occlusive disease (PAOD) is highly prevalent and affects an estimated 3% of the population of the United States. The incidence and prevalence of PAOD is directly related to risk factors associated with the development of atherosclerosis, by far the most common cause of aortoiliac occlusive. These include age, tobacco use, gender, ethnicity, diabetes, hypertension, dyslipidemia, a family history of PAOD, renal disease, and hyperhomocysteinemia. Of these, cigarette smoking is the single most powerful risk factor associated with the development of PAOD. In fact, there is a dose related association with development and severity of PAOD in tobacco users. The prevalence of PAOD increases with age over 40 years, with increasing prevalence in 15% of patients older than 70 and almost 25% of patients older than 80. PAOD generally affects men more than women, although some studies have shown higher disease prevalence in women. Other, nonatherosclerotic, causes of aortoiliac occlusive disease include trauma or radiation-induced arteritis, occlusive disease, cystic adventitial disease, fibromuscular dysplasia, and a congenital persistent sciatic artery. While these pathologies usually present with similar symptoms, their detailed management is beyond the scope of this chapter and will not be discussed.

The presenting symptoms of PAOD depend on the location(s) and anatomic severity of the distribution. Most commonly, PAOD is asymptomatic and discovered incidentally. Ankle brachial indices are a reliable screening modality for the presence of PAOD (normal >0.9). Symptoms may range from claudication (i.e., activity-induced pain) to critical limb ischemia (CLI) defined as ischemic rest pain, and/or ulceration or gangrene. The limb-specific natural history of PAOD depends on the severity of disease at presentation. Furthermore, PAOD is a strong predictor of future adverse

Although retrograde removal of such proximal clots usually can be performed through a brachial approach, we sometimes prefer to expose the occluded segment directly if there is significant clot burden. This approach minimizes the number of catheter passages necessary to extract the embolus and avoids stripping off clot into patent branches of the segment between the arteriotomy and the occlusion. Although most macroemboli originate from the heart, an arterial source sometimes can be responsible and, if identified, must be addressed. Treatment of arterial thoracic outlet syndrome requires not only excision of the compressive thoracic outlet elements but also some type of arterial reconstruction (discussed in more detail in the chapter on thoracic outlet syndrome).

Trauma

As outlined previously, most traumatic occlusions should be fixed at the time of diagnosis. Isolated radial or ulnar artery occlusions are an exception because they are usually well tolerated. Iatrogenic occlusions usually can be relieved with local exploration, thrombectomy, and repair of associated vessel wall injury. For more significant injuries, formal arterial reconstruction is required. Resection with end-to-end anastomosis can be performed rarely, but in the vast majority of cases interposition grafting with saphenous vein of appropriate caliber is required. A more detailed description of how to manage traumatic occlusions is provided in the chapter on management of vascular injuries.

SMALL ARTERY OCCLUSIVE DISEASE

Treatment of occlusive disease affecting the small arteries of the digits and hands can be challenging. After a proximal embolic source has been ruled out, attention is focused on identification and treatment of any underlying causative diseases. Patients with Buerger's disease frequently experience significant improvement with successful tobacco abstinence. Vibration induced injury will respond to avoidance of the causative vibratory machinery. The rare patient with cryoglobulinemia or hepatitis associated vasculitis will respond to appropriate therapy. Unfortunately, in the majority of cases, no specific therapy is available. In our practice, there are patients with an associated connective tissue disorder, hypersensitivity angiitis, or renal failure. For these individuals, care is focused on supportive measures. Abstinence from tobacco and avoidance of cold are routinely advised. Antiplatelet therapy (aspirin or clopidogrel) and hemorheologic agents (cilostazol) usually are prescribed. Vasodilators, primarily calcium-channel blockers, can be used to treat associated vasospasm with variable success. Areas of tissue loss are treated with local wound care and debridement as indicated. Sympathectomy, both cervicothoracic and digital, can lead to a temporary improvement in skin blood flow but has such limited durability (approximately 6 months) that most authorities have abandoned it except in highly selected patients with residual ischemia after revascularization.

CONCLUSIONS

UE arterial occlusive disease is an uncommon problem with diverse causes. Accurate diagnosis depends on a thorough history and physical examination supported by noninvasive vascular testing. Angiography remains the primary modality of diagnosis. Treatment depends on the nature of the disease process and the severity of the ischemia. Patients with embolic or traumatic occlusions and significantly symptomatic proximal large artery disease usually can undergo vascular intervention with good results. On the other hand, revascularization options for patients with distal small artery occlusive disease are extremely limited. In this setting, after a careful search for treatable causes, management is primarily supportive. Fortunately, progression to limb loss is rare.

Aortoiliac Occlusive Disease

Joseph-Vincent V. Rizo, MD, and Spencer M. Taylor, MD

Peripheral arterial occlusive disease (PAOD) is highly prevalent and affects an estimated 3% of the population of the United States. The incidence and prevalence of PAOD is directly related to risk factors associated with the development of atherosclerosis, by far the most common cause of aortoiliac occlusive. These include age, tobacco use, gender, ethnicity, diabetes, hypertension, dyslipidemia, a family history of PAOD, renal disease, and hyperhomocysteinemia. Of these, cigarette smoking is the single most powerful risk factor associated with the development of PAOD. In fact, there is a dose related association with development and severity of PAOD in tobacco users. The prevalence of PAOD increases with age over 40 years, with increasing prevalence in 15% of patients older than 70 and almost 25% of patients older than 80. PAOD generally affects men more than women, although some studies have shown higher disease prevalence in women. Other, nonatherosclerotic, causes of aortoiliac occlusive disease include trauma or radiation-induced arteritis, occlusive disease, cystic adventitial disease, fibromuscular dysplasia, and a congenital persistent sciatic artery. While these pathologies usually present with similar symptoms, their detailed management is beyond the scope of this chapter and will not be discussed.

The presenting symptoms of PAOD depend on the location(s) and anatomic severity of the distribution. Most commonly, PAOD is asymptomatic and discovered incidentally. Ankle brachial indices are a reliable screening modality for the presence of PAOD (normal >0.9). Symptoms may range from claudication (i.e., activity-induced pain) to critical limb ischemia (CLI) defined as ischemic rest pain, and/or ulceration or gangrene. The limb-specific natural history of PAOD depends on the severity of disease at presentation. Furthermore, PAOD is a strong predictor of future adverse

cardiovascular outcomes (e.g., stroke and myocardial infarction) and death. All-cause mortality and cardiovascular mortality in patients with PAOD is higher in symptomatic patients (5-year risk of 24% and 7.3%, respectively) than asymptomatic patients (5-year risk of 10% and 2.3%, respectively). In general, only a minority of patients with symptomatic PAOD or intermittent claudication worsens over time (~20%) and only 1% to 3% of all claudicants can be expected to develop critical limb ischemia. In the absence of progression, the estimated risk of major amputation in patients with claudication is 12% over a 10-year period (~1% per year). In patients with critical limb ischemia, 25% die of a cardiovascular event or require limb amputation within 1 year of diagnosis. Although aortoiliac occlusive lesions usually begin at the aortic bifurcation and progress proximally and distally, the disease may progress to cause iliac occlusion and aortic occlusion to the renal arteries. In this chapter, we will focus attention on PAOD affecting the aortoiliac distribution.

DIAGNOSTIC EVALUATION

A thorough history with identification of atherosclerotic risk factors is paramount as risk factor modification is a cornerstone of treatment for PAOD. Symptoms of aortoiliac disease are typified by hip, thigh, and/or buttock claudication, leg muscle atrophy, erectile dysfunction, and absent or diminished femoral pulses. When the constellation of proximal claudication, leg muscle atrophy, erectile dysfunction, and absent femoral pulses is present, the patient has Leriche syndrome, described in 1948 by René Leriche. *Pseudoclaudication* is how to pain that is position dependent, not stereotypically associated with activity, and can occur in the absence of activity. It is important to differentiate pseudoclaudication from true occlusive disease symptoms. Causes of pseudoclaudication include musculoskeletal issues (e.g., spinal stenosis, radiculopathy) or neurogenic issues (e.g., sciatic nerve impingement or diabetic neuropathy).

In many cases, a clinical history and thorough physical examination is sufficient for diagnosis of aortoiliac occlusive disease. The ankle-brachial index (ABI) serves as the best initial test for evaluation of PAOD. With a compatible history, ABIs less than 0.9 are diagnostic of PAOD and can correlate with the severity of disease. In general, with progressively more levels of occlusive disease (e.g., aortoiliac plus femoropopliteal plus tibial occlusive disease), the severity is increased and, consequently, the ABI will be lower. Duplex ultrasonography or segmental limb pressures combined with ABIs give a more complete assessment of the extent and severity of PAOD. In our experience, the presence/absence and quality of the ipsilateral femoral pulse is pivotal to the diagnosis of aortoiliac occlusive disease. An absent or weak femoral pulse associated with a segmental pressure difference of 20 mm Hg or higher between the brachial pressure and the thigh suggests an aortoiliac occlusive lesion. In addition, an asymmetric thigh segmental pressure of 15 to 20 mm Hg or higher suggests a unilateral occlusive lesion. Aortoiliac disease alone, per se, is rarely the cause of ischemic rest pain or tissue loss, except in the setting of acute or subacute ischemia such as embolization. This is due to a rich collateral network robust enough to supply the lower extremities with sufficient resting tissue perfusion. In these cases, an exercise arterial duplex with ABI could elicit symptoms of occlusive disease and corroborate it with a decreased ABI.

Computed tomography angiography (CTA), magnetic resonance angiography (MRA), and/or conventional arteriography can be used to delineate the extent and severity of the aortoiliac segment disease. Although conventional contrast angiography is considered the gold standard for PAOD, CTA is rapidly becoming the diagnostic modality of choice. Compared to conventional angiography, CTA gives better contrast resolution and provides three-dimensional views of the aortoiliac segment, albeit at the expense of being able to assess flow through the segment, which conventional angiography is able to provide. Our approach is to obtain an arterial duplex/ABI and cross-sectional imaging with CTA.

MEDICAL TREATMENT

Medical management is the cornerstone of treatment of PAOD, including aortoiliac occlusive disease, to reduce cardiovascular morbidity and mortality. Risk factor modification includes cessation of tobacco use, initiation of antiplatelet therapy (e.g., aspirin and/or clopidogrel), initiation of HMG-CoA reductase inhibitors (i.e., statins), as well as management of other cardiovascular equivalent diseases (diabetes, hypertension, renal disease, etc.) in accordance with guidelines from the American Heart Association. Further medical therapy can include cilostazol, a phosphodiesterase inhibitor, to provide symptomatic improvement in claudicants' exercise tolerance and walking distance. The CLEVER (Claudication: Exercise Versus Endoluminal Revascularization) trial, a randomized controlled trial comparing supervised exercise therapy with endovascular treatment of aortoiliac disease, showed that supervised exercise therapy group had improved short-term walking performance than the group undergoing endovascular intervention. In general, walking exercise is performed at least three times a week for duration of 30 to 45 minutes. That said, in our experience, as few as 30% of patients are either physically able or motivated to engage in meaningful exercise therapy as a sole means of the therapy. However, medical management is imperative for all patients with PAOD, if for no other reason than to improve overall cardiovascular health. Intervention with medical management is best assessed on a case by case basis, taking into account the severity of occlusive disease, the overall condition of the patient and the severity of symptoms.

As will be discussed, the addition of endovascular intervention is safe and effective and, in our practice, offered more liberally for claudication than patients with other patterns of PAOD. In most cases, patients with critical limb ischemia present with multisegmental disease and undergo aortoiliac intervention first to prevent limb loss. Intervention can be divided into an endovascular approach, an open surgical strategy, or a combined (endovascular and open) or hybrid approach.

ENDOVASCULAR TREATMENT

The 2007 Inter-Society Consensus for the Management of Peripheral Artery Disease guidelines (TASC II) provided a framework to aid in choosing an endovascular or open surgical approach for specific anatomic aortoiliac occlusive lesions (Fig. 1). The guidelines recommend endovascular therapy preferably for short, simple type A and type B lesions. Surgery is preferred for more extensive and complex type C and type D lesions, though an endovascular first strategy may be considered. Modern endovascular techniques allow all TASC lesions to be approached percutaneously and, in fact, the number of endovascular interventions for aortoiliac occlusive disease has risen markedly for all aortoiliac lesions. In our practice, open repair is only rarely offered to patients with claudication who have anatomy amenable to a percutaneous approach.

Our method of endovascular intervention involves the following steps:

- Establishing arterial access
- Diagnostic arteriogram and identification of the culprit lesion(s)
- Traversal of the lesion(s)
- Balloon angioplasty with or without the adjunctive use of stents
- Completion arteriogram to assess result
- Successful closure of the arterial access site

Establishing Arterial Access

Anatomic site for access is dictated by the anticipated site(s) of intervention and can be assessed with noninvasive imaging for the most favorable site(s). Aortoiliac lesions can be approached via a percutaneous or open exposure of the ipsilateral and/or contralateral common femoral artery (e.g., subclavian or brachial access) or the brachial artery. Again, the distribution and extent of disease will dictate the access site(s). Our preferred access is with a "micropuncture" small caliber access needle. Once arterial access is secured with an

Type A lesions

- Unilateral or bilateral stenoses of CIA
- Unilateral or bilateral single short (<3 cm) stenosis of EIA

Type B lesions

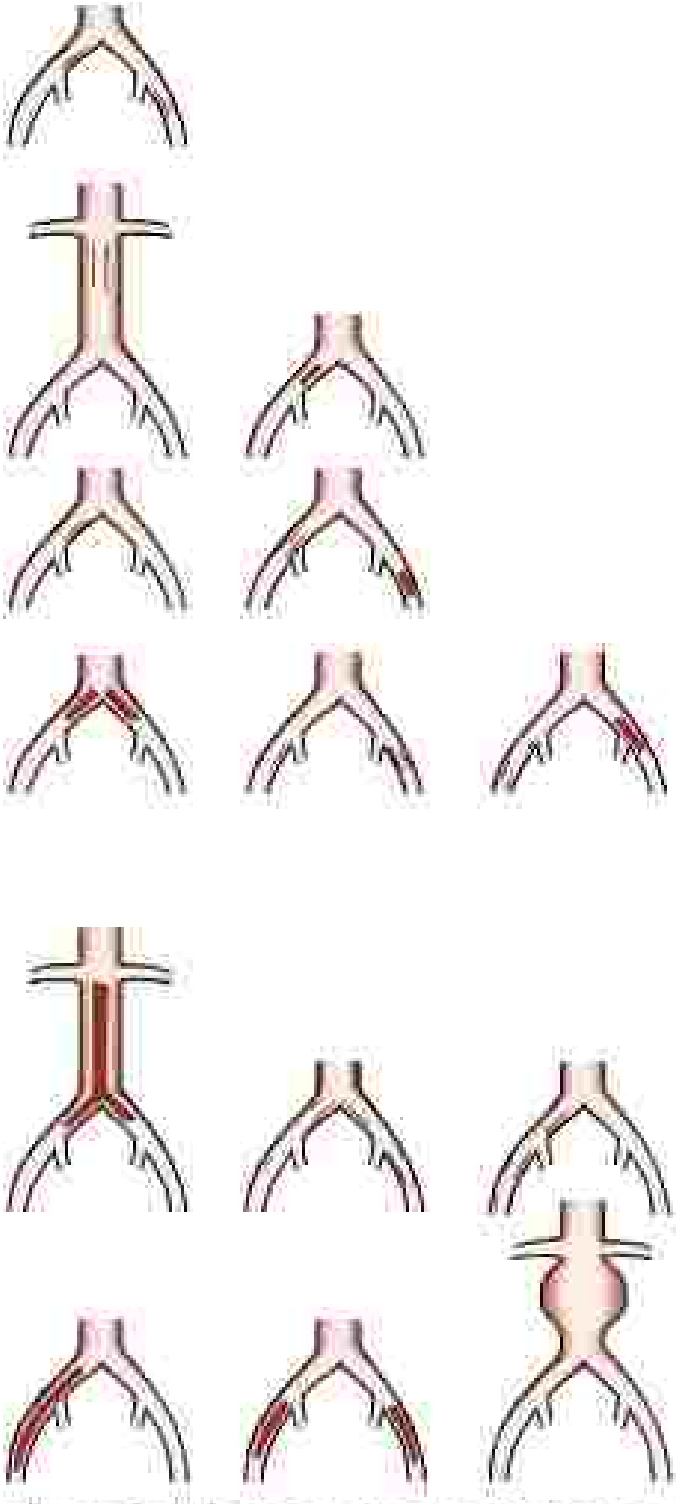
- Short (<3 cm) stenosis of infrarenal aorta
- Unilateral CIA occlusion
- Single or multiple stenosis totaling 3–10 cm involving the EIA not extending into the CFA
- Unilateral EIA occlusion not involving the origins of internal iliac or CFA

Type C lesions

- Bilateral CIA occlusions
- Bilateral EIA stenoses 3–10 cm long not extending into the CFA
- Unilateral EIA stenosis extending into the CFA
- Unilateral EIA occlusion that involves the origins of internal iliac and/or CFA
- Heavily calcified unilateral EIA occlusion with or without involvement of origins of internal iliac and/or CFA

Type D lesions

- Infrarenal aortoiliac occlusion
- Diffuse disease involving the aorta and both iliac arteries requiring treatment
- Diffuse multiple stenoses involving the unilateral CIA, EIA, and CFA
- Unilateral occlusions of both CIA and EIA
- Bilateral occlusion of EIA
- Iliac stenoses in patients with AAA requiring treatment and not amenable to endograft placement or other lesions requiring open aortic or iliac surgery



0.035-inch guidewire, a 5 French sheath and a flush catheter is used for diagnostic arteriography (Fig. 2).

Diagnostic Arteriogram and Identification of the Culprit Lesion(s)

Anteroposterior and oblique images are obtained of the aortoiliac and common femoral bifurcations. Arteriographs of the lower extremities is obtained using a "bolus chase" technique. In cases of trunk occlusions, the flush catheter should be positioned to fill the collateral network to exactly the distal extent of occlusion. Careful review of the diagnostic arteriogram identifies the culprit lesion(s). An occlusion or 50% or more diameter reduction or a pressure drop of 15 to 20 mm Hg across the stenosis defines a hemodynamically significant lesion. The patient should then receive 50 to 80 U/kg of systemic heparin.

disease devices is that it allows the patient to ambulate sooner after a procedure, reducing the length of stay in the hospital or outpatient interventional suite.

Results of Endovascular Interventions for Aortoiliac Disease

Balloon angioplasty remains an option for isolated, short segment iliac disease. The initial technical success rate of iliac angioplasty is greater than 9.%, with 5-year primary patency rates of .5%, and assisted primary and secondary patency rates over ~%. Primary stenting, however, has become the most common approach for most lesions due to the improved long-term primary patency. The prospective, randomized Control versus Balloon Expandable Stent Trial (CREST) concluded that covered balloon expandable stents have less incidence of restenosis, less incidence of stent occlusion, and therefore better long-term patency rates than bare metal balloon-expandable stents in aortoiliac occlusive disease, particularly in TASC C and TASC D lesions (Fig. 4). Perioperative mortality is less than 1% and morbidity ranges from 5% to 20%.

URGICAL TREATMENT

Open surgical revascularization is broadly categorized into a ... [illegible] ... revascularization procedures, or the aortoiliac segment, anatomic revascularization refers to aortobifemoral, axillofemoral bypass or aortoiliac endarterectomy. Extraanatomic revascularization procedures include femorofemoral bypass, cross-iliofemoral or iliofemoral bypass, axillofemoral bypass, or thoracofemoral bypass. Extraanatomic bypasses are generally reserved for patients considered high risk for a major open abdominal surgery. A comprehensive review of all the listed procedures is beyond the scope of this chapter; however, the most common procedures will be discussed.

Aortofemoral Bypass

Aortofemoral (or aortobifemoral) bypass is still considered the gold standard for aortoiliac revascularization. Several important anatomic factors dictate the operative approach and procedure. These factors should be coherently assessed with high-quality cross-sectional imaging (e.g., CTA). Assessment of concomitant renal or visceral artery disease is critically important. The proposed proximal aortic clamp site should be free of large atheromatous burden or calcium. The left renal vein typically will serve as the anatomic landmark for the renal arteries and the proximal aorta clamp site. A retroaortic left renal vein is present in approximately .% of patients, and a circumaortic left renal vein is present in approximately .% of patients. These left renal vein variants are vulnerable to injury and occur in about 40% of patients.

The status of a patient's pelvic circulation may influence the proximal anastomotic configuration (end-to-end vs end-to-side). ...ost favor an end-to-end configuration, which allows for direct aortic thrombectomy/endarterectomy, more favorable blood flow dynamics, and theoretically less risk of development of an aortoduodenal fistula. However, the end-to-side configuration should be strongly considered in patients whose pelvic perfusion or inferior mesenteric artery perfusion would be unlikely sacrificed with an end-to-end configuration. One example is a patient with severe external iliac artery disease or bilateral external iliac occlusives. An end-to-side proximal anastomosis would confer continued antegrade pelvic flow through the existing patent common iliac and hypogastric arteries (Fig. 5). Another example is a patient with a large, patent inferior mesenteric artery with concomitant proximal visceral disease (e.g., celiac or superior mesenteric artery stenosis). Based perfusion would be maintained with an end-to-side proximal anastomotic configuration in this scenario (Fig. ...). A final example is a patient with a sizeable accessory renal artery arising from the infrarenal aorta that would lose substantial kidney function with sacrifice of antegrade renal artery flow in an end-to-end configuration.

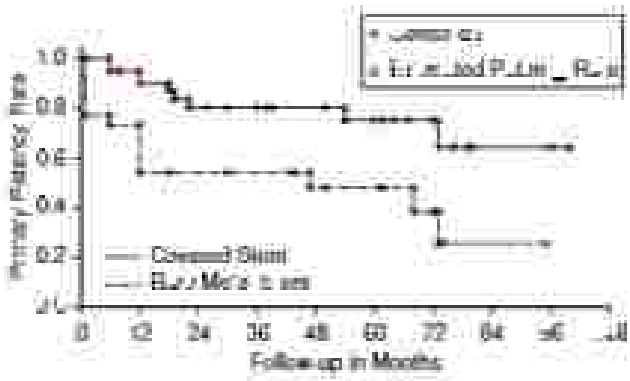

FIG. 4 Primary patency in Iliac Stenting: Comparison of the Management of Peripheral Arterial Disease (C.D) trials after balloon-expandable covered versus bare metal stents.

The patient is widely prepped and draped from the level of the nipples to the feet bilaterally. The procedure begins with bilateral groin incisions to expose the common femoral, profunda femoral, and superficial femoral vessels. Groin incisions prior to the abdominal incision limit the fluid loss through an open abdomen. In unique situations where the external iliac arteries and femoral arteries are spared of disease, an axillofemoral bypass may be performed to the distal external iliac arteries via a retroabdominal approach. Assessment of the femoral vessels is important to determine the need for a common femoral or profunda femoris endarterectomy and or angioplasty. In general, a distal anastomosis incorporating the origin of the profunda femoris artery is critical for achieving durable long-term patency of the graft. ...ith chronic occlusive disease, the inferior epigastric and circumflex iliac arteries can develop into large collateral vessels and should be meticulously protected and maintained. The aorta is exposed through either a midline laparotomy incision or retroperitoneal incision. ...some surgeons primarily favor a retroperitoneal approach. The retroperitoneal approach may be attractive to patients with multiple previous abdominal operations. After entering the peritoneum through a midline laparotomy, the abdominal cavity is inspected for unanticipated concomitant pathology (e.g., malignancy). A nasogastric tube is placed to decompress the stomach and to aid in identifying the esophagus in cases where suprarenal aortic control is anticipated. The transverse colon is retracted cephalad and the small bowel retracted to the right upper quadrant. A final retractor system (i.e., Omni Tract) is placed. The retroperitoneal tissue overlying the aorta and the ligament of Treitz is incised to expose the underlying aorta from the renal arteries to the aortic bifurcation. If necessary, the inferior mesenteric vein is ligated to provide better exposure. Care is taken to protect the left renal vein, the inferior mesenteric artery, and the autonomic nerve plexus located near the bifurcation and left common iliac origin.

Construction of the tunnels for the bypass graft limbs is done by gentle, blunt dissection simultaneously from the groin posterior to the inguinal ligament and from the abdomen. The tunnel must be constructed to run posterior to the ureters to prevent the development of hydronephrosis. Umbilical tape or red rubber catheters are inserted through the tunnel to facilitate passage of the graft limbs.

The patient is systemically treated with 50 to 100 U/kg of intravenous heparin to achieve an activated clotting time greater than 250 seconds. The aorta is clamped distally and then proximally just inferior to the renal arteries to minimize the chance for embolization. ...cases with posterior calcific plaque, clamping the aorta in an anterior to posterior fashion may limit the potential for aortic clamp injury and embolization. Other proximal aortic clamp sites include the suprarenal or supraceliac aorta. Percutaneous insertion of an occlusion balloon is another option for proximal control. If suprarenal or supraceliac control is performed, the clamp should be moved caudal to the renal arteries as soon as the proximal anastomosis is performed successfully to limit visceral and renal ischemia time.

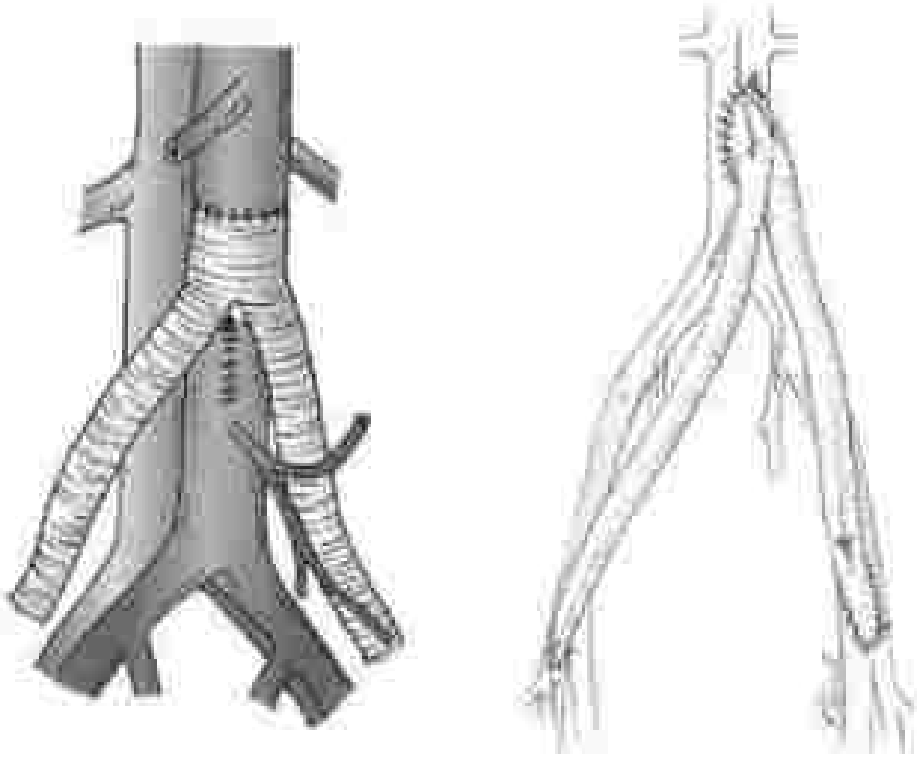

FIG. 5 Proximal anastomosis [illegible] not be aligned so [illegible] [illegible] Surgery in Vascular Disease. 2005.]

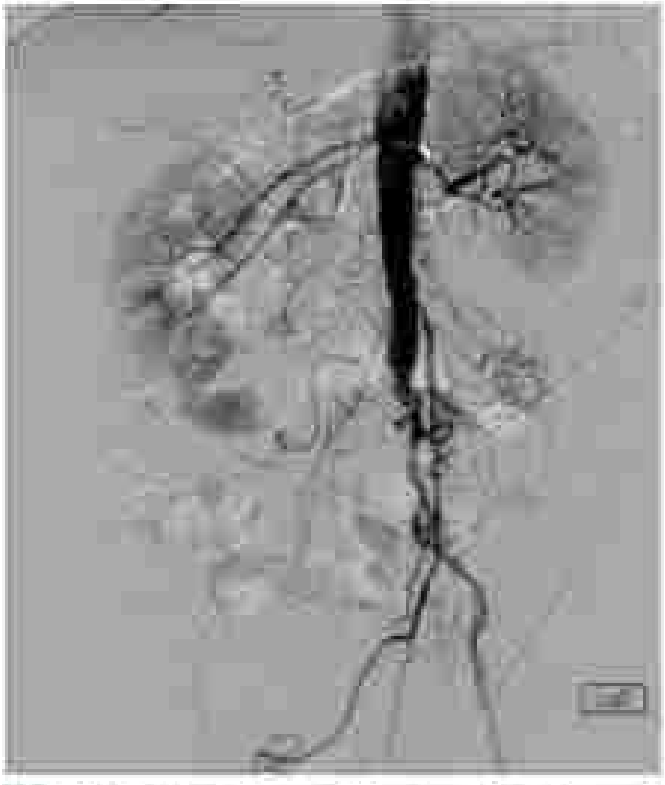

FIG. 6 Aortofemoral occlusive disease with a large patent inferior mesenteric artery.

If an end-to-end configuration is chosen, the aorta at the proximal anastomotic site is transected. The distal stump is oversewn with permanent, monofilament suture (e.g., polypropylene). Pledgeted sutures may be needed for a highly diseased distal aortic stump. An appropriately sized knitted polyester (Dacron) graft is chosen. Typically used bifurcated grafts include 18 mm × 9 mm grafts for 16 mm × 8 mm grafts for men and 14 mm × 7 mm grafts or 12 mm × 6 mm grafts for women. The main body of the graft is trimmed 3 to 4 cm from the bifurcation. The proximal anastomosis is performed using a running 2-0 polypropylene suture. If the aorta wall is thin or fragile, a 3-0 polypropylene interrupted mattress pledgeted suture technique is advisable.

In the end-to-side proximal anastomotic configuration, the aorta is clamped as described above. A longitudinal arteriotomy is done and the edges of the aorta are trimmed to form an ellipse for the anastomosis. The graft is trimmed and beveled to achieve as low a profile as possible. This limits the risk of kinking and limits the amount the graft extends into the abdomen so, theoretically, limits the risk of aortoduodenal fistula formation. The anastomosis should start close to the renal arteries and extend distally to facilitate a low profile anastomosis. In either proximal anastomotic configuration, after the completion of the anastomosis, the proximal clamp is released to examine the anastomosis integrity and hemostasis. Pledgeted sutures may be used to reinforce the anastomosis.

The graft limbs are passed through the prefemoral tunnels with care to avoid twisting. The femoral anastomosis is performed in an end-to-side configuration using running 5-0 polypropylene. As stated previously, outflow through the profunda femoris is crucial for long-term graft patency. In cases requiring a profunda femoris artery endarterectomy or profundaplasty, the distal end of the aortofemoral graft can be used as a profunda femoris artery patch angioplasty. Alternatively, an autogenous vein patch or prosthetic patch can be used for the patch angioplasty with the anastomosis subsequently performed to the patch. In cases of chronic superficial femoral artery

occlusion, the primary outflow vessel is the profunda femoris artery. Adequate outflow through the profunda femoris is assessed on the preoperative cross-sectional imaging and/or angiography. In addition, at the time of operation, the profunda femoris can be assessed with a deflated embolectomy balloon catheter to interrogate the length of the profunda femoris artery. A profunda femoris origin that accepts a 4 mm diameter probe and measures of 20 to 25 cm in length is adequate in nature as autofemoral graft. Concomitant distal revascularization (e.g., femoropopliteal or femoretibial bypass) is necessary in about 15% to 25% of patients and is indicated in cases of compromised outflow. Prior to completion of the anastomosis, the distal vessels are allowed to backbleed and the graft is flushed of debris. In general, with the chronic occlusive nature of disease, reestablishment of leg perfusion results in only small hemodynamic changes. Collaboration with the anesthesia team is paramount, however, prior to reestablishment of distal perfusion to limit the potential for hemodynamic lability. The distal leg is assessed for perfusion prior to beginning closure of the incisions. Lack of distal perfusion with adequate inflow (i.e., systolic flow through the graft) should prompt evaluation of the distal anastomosis for a technical error or raise the concern for a distal embolism. Redo anastomosis is indicated for an anastomotic technical error. Distal embolization is treated with balloon catheter embolectomy.

After satisfactory perfusion is assessed and hemostasis is achieved, we reverse the effects of heparin with protamine. Abdominal closure begins with reapproximation of the retroperitoneal tissue to cover the graft, if possible. An alternative coverage option is to mobilize an omental pedicle placed via a transverse colon mesenteric window. The abdomen is closed in standard fashion. Meticulous groin incision closure is important to limit the risk of infection and wound breakdown.

Results of Aortofemoral Bypass

Perioperative mortality is less than 5%. Primary graft patency approximates 100% initially, with 5 year and 10 year primary patency ranging from 90% to 100% and 75% to 80%, respectively. Cumulative secondary graft patency for 2-, 5-, and 10 years was 97.7%, 95.9%, and 94.4%, respectively. Inferior patency results are documented for patients with ulceration or tissue loss compared to patients with claudication or ischemic rest pain. In addition, age and native aortic diameter have been shown to influence patency after aortofemoral bypass. In fact, patients younger than 50 and those with aortic diameters 18 mm or less have much lower primary patency rates after aortofemoral bypass (50%–65% 5 year primary patency). Infection occurs in 0.3% to 0.7% of cases and anastomotic pseudoaneurysm formation occurs in 1.4% of cases.

Aortoiliac Endarterectomy

Aortoiliac endarterectomy is an option for patients with well localized aortoiliac disease limited to the distal aorta and proximal common iliac arteries. With the increased use of endovascular interventions and the long-term durability and success of aortofemoral bypass, aortoiliac endarterectomy is uncommonly chosen as a primary procedure. The limited disease amenable to aortoiliac endarterectomy is commonly found in young or middle aged women with a history of tobacco use. Operative exposure is done through a standard midline laparotomy, similar to the abdominal portion of an aortofemoral bypass procedure. Complete mobilization of the distal aorta, inferior mesenteric artery, aortic bifurcation and proximal bilateral common iliac arteries is achieved with care to protect the autonomic nerve plexus (nerve sparing). A longitudinal aortic incision is made and may be carried into one of the common iliac arteries. A contralateral common iliac artery can be made to the case of bilateral common iliac disease. Endarterectomy is performed in the subintimal plane with care to taper or feather the distal end of the endarterectomy. Tacking sutures at the distal edge of the endarterectomy can be used to prevent distal dissection. The proximal plaque is transected to a smooth edge. The aorta and iliac arteries are flushed of debris and assessment of the proximal and distal ends of the endarterectomy are performed prior to closure. The arteriotomies are closed with 4-0 or 5-0 polypropylene suture.

Results of Aortoiliac Endarterectomy

Perioperative mortality rates are similar to aortofemoral bypass grafting (2.7% perioperative mortality). Patency rates also appear similar to aortofemoral bypass, 89% 5 year patency and 89% 10 year patency.

Unilateral Iliofemoral Bypass

Unilateral iliofemoral bypass is indicated in cases with limited distal aortic disease and limited ipsilateral proximal common iliac disease. Otherwise, aortofemoral bypass would be preferred. Poor risk patients for open abdominal surgery (e.g., severe cardiopulmonary dysfunction) may also be candidates for this procedure as this is typically performed through a limited retroperitoneal exposure. The patient is positioned supine. Added retroperitoneal exposure is facilitated by a "hump" placed under the ipsilateral flank and/or flexing the table to expand the space between the ribs and the anterior superior iliac spine. A retroperitoneal curvilinear incision is extended from the anterior axillary line to the midline inferior to the umbilicus along the line of the 10th rib. The anterior rectus sheath is incised and the rectus abdominus muscle is grasped and retracted medially. The posterior rectus sheath is incised. The internal and external oblique muscles are incised with electrocautery to expose the transversus abdominis muscle. Beginning laterally, the transversus abdominis muscle and the underlying transversalis fascia are opened to enter the retroperitoneal space. The peritoneum is stripped from the lateral pelvic wall and retracted medially with the intraabdominal contents to expose the underlying psoas muscle. The ureter is identified, protected, and retracted medially. The external iliac artery is readily identified in the distal aspect of the wound and can be followed proximally to the common iliac artery and aortic bifurcation. Proximal clamp site can be done at the proximal ipsilateral common iliac artery or, alternatively, with clamping of the distal aorta and contralateral proximal common iliac artery. A standard exposure of the common femoral artery, similar to that for an aortofemoral bypass, is performed. A tunnel is created anterior to the external iliac artery and posterior to the inguinal ligament. The patient is systemically heparinized. An 8 mm polyester graft is the typical conduit of choice. Proximal anastomosis is performed to the ipsilateral common iliac artery using 4-0 or 5-0 polypropylene suture. The graft is tunneled distally and a distal anastomosis is performed similar to an aortofemoral bypass described above. After satisfactory reperfusion and hemostasis, the retroperitoneal incision and groin incision is closed in the standard fashion.

Results of Iliofemoral Bypass

Perioperative mortality mirrors aortoiliac endarterectomy at 2.7%. Our group published a contemporary review of iliofemoral bypass showing primary patency rates of 87.5%, 76.8%, and 53.9% at 1-, 2-, and 5 years, respectively. Secondary patency rates were 92.5% and 93.3% at 1 and 5 years, respectively. Limb salvage was achieved in 88% to 95% of patients with critical limb ischemia and no amputations were necessary in claudication patients undergoing iliofemoral bypass.

Axillofemoral Bypass

In severely high risk or elderly patients with critical limb ischemia, an axillofemoral (or axillobifemoral) bypass is an alternative to direct aortoiliac revascularization. In addition, it is a reasonable alternative for patients with a "hostile" abdomen, previous radiation therapy, intestinal stomas, infected prosthetic arterial grafts, or aortoenteric fistulae. The axillary artery serves as the inflow for both lower extremities. Blood pressures are obtained in both arms

to determine the optimal side for inflow. Although previous studies have shown improved patency of axillobifemoral bypasses over axillounifemoral bypasses, more recent studies show no significant difference. The patient is positioned supine with the arm(s) abducted to 90 degrees. The patient is propped from the neck and chest down to the knees or bilateral legs. A transverse infraclavicular incision is made along the midportion of the clavicle. The underlying pectoralis major is split along its fibers to expose its underlying clavipectoral fascia. The clavipectoral fascia is incised to expose the underlying neurovascular bundle and axillary sheath with its contents. The axillary anastomosis is generally performed in the first part of the axillary artery due to its relationship with the brachial plexus. At this site, the brachial plexus runs posterior to the axillary artery conferring less risk for injury. In the lateral wound, the pectoralis minor is identified and retracted laterally or transected. The lateral pectoral nerve runs just posterior to the medial border of the pectoralis minor and should be protected. The axillary sheath is incised. The axillary vein is anterior to the sheath and is encircled and retracted inferiorly to expose the axillary artery. Proximal and distal control and control of branches are obtained with elastic vessel loops. The bilateral femoral arteries are exposed, as previously described. An externally supported 8-mm diameter prosthetic graft is chosen. Tunneling is performed with a blunt hemostat created parallel and anterior to the axillary artery, posterior (under) the pectoralis minor muscle and down the anterior axillary line to the subcutaneous space anterior to the iliac crest down to the ipsilateral groin. A subcutaneous tunnel is created between each groin in an inverted U configuration. The graft(s) are passed through the tunnels. The patient is systemically heparinized. The proximal anastomosis is created with running 5-0 or 6-0 polypropylene suture and is oriented parallel to the axillary artery. Placement of the axillary anastomosis in the first portion of the axillary artery and tunneling parallel to the artery and posterior to the pectoralis minor allows some redundancy in the graft to prevent anastomotic disruption with arm abduction. The ipsilateral femoral anastomosis is created with 5-0 polypropylene suture. The femorofemoral component is created onto the hood of the axillofemoral bypass graft using 5-0 polypropylene suture. The contralateral luminal anastomosis is created in standard fashion, as described above. Prefabricated externally supported expanded polytetrafluoroethylene (ePTFE) axillobifemoral grafts are also available.

Results of Axillofemoral Bypass

Historically, the patency rates for axillofemoral bypasses varied widely (20%–80%). Perioperative mortality remains less than 5%; however, published long-term survival rates are reported to be approximately 50%, confirming the high-risk status of these patients. More contemporary studies have shown improved primary 1-year and 5-year patency rates of 75% to 90% and 50% to 80%, respectively. No significant difference in patency is evident between unilateral or bilateral distal configurations.

Femorofemoral Bypass

Femorofemoral bypass is used as an alternative revascularization strategy to axillofemoral or iliofemoral bypass in high-risk patients with unilateral iliac artery occlusive disease or in patients with a hostile abdomen. The bypass is dependent on one iliac artery to provide blood supply to both legs. Thus, the status of the donor artery must be assessed. The presence of a pressure gradient greater than 5 to 10 mm Hg down the proposed donor iliac artery necessitates intervention to prevent arterial steal phenomenon. The patient is positioned supine. This procedure can be done with locoregional or spinal anesthesia in high-risk patients for general anesthesia. The bilateral femoral arteries are exposed, as previously described. A subcutaneous tunnel between incisions is made to achieve an inverted U configuration. This configuration reduces the acute angle of the anastomosis and reduces the risk of kinking. Tunneling in the subcutaneous space, as opposed to the preperitoneal, iliofemoral plane, prevents bowel or bladder injury. We prefer prosthetic grafts as our primary conduit (6 mm or 8 mm externally supported ePTFE); however, there is no current evidence to suggest superiority of one prosthetic conduit choice over another. Standard end-to-side anastomoses to the femoral arteries and groin closure complete the operation.

Results of Femorofemoral Bypass

Perioperative mortality is less than 5%. The primary patency rate at 5 and 10 years are 71.8% and 55.6%, respectively, in a contemporary study. Primary assisted patency rates at 5 and 10 years are 84.3% and 74.8%, respectively. Secondary patency rates at 5 and 10 years are 89.8% and 82.9%, respectively. Overall, these rates remain lower compared to "anatomic" methods of revascularization.

Thoracofemoral Bypass

The descending thoracic aorta is an excellent inflow source for revascularization in patients with a hostile abdomen, multiple failed anatomic abdominal aortic operations (e.g., failed axillofemoral bypasses), multiple failed extraanatomic revascularization attempts due to compromised inflow, or in the case of aortic graft infection. The patient is positioned in a modified right lateral decubitus position with a double-lumen endotracheal tube to allow deflation of the left lung. The thorax is elevated 30 to 45 degrees and the pelvis is maintained as flat as possible to allow access to the right groin. A left thoracotomy incision is made, typically as high as the sixth intercostal space or as low as the ninth intercostal space. The exact location of the thoracotomy is dictated by the proposed site for proximal anastomosis that is free of disease. Bilateral groin incisions are made, as previously described. A 10-mm externally supported prosthetic graft is the usual conduit. A retroperitoneal counter incision is made in the left flank to facilitate tunneling from the posterior diaphragmatic recess to the left groin. A standard femorofemoral tunnel is created. After systemic anticoagulation, an end-to-side proximal anastomosis is created using 3-0 polypropylene suture. Proximal control for the anastomosis is obtained using partial occlusion clamps or standard proximal and distal clamps. Distal anastomoses are fashioned to penetrating grafts or to the femoral arteries, as previously outlined. Chest tube drainage and closure of the incisions completes the procedure.

Results of Thoracofemoral Bypass

Perioperative mortality remains around 5% to 8%. Primary patency rates range from 63% to 100% at 4 to 5 years, with secondary patency rates of about 83% with longer follow-up.

Hybrid Revascularization Procedures

In unilateral or bilateral aortoiliac disease extending into the common femoral arteries, a hybrid open surgical technique to treat the common femoral arteries combined with endovascular angioplasty and stenting to treat the iliac or inflow vessels is an alternative to axillofemoral or iliofemoral bypass grafting. Perioperative mortality is around 2% to 15%, reflecting the overall patient health undergoing these procedures. Initial technical success with this approach is reported to be 99% to 100% with 2-year to 5-year primary patency rates between 90% and 100% and secondary patency rates of 98% to 100%.

SUMMARY

Aortoiliac occlusive disease can be a debilitating disease. A structured approach to diagnosis and treatment is crucial for successful results. Management is dictated by the severity of disease and the health of the patient. Many options for revascularization exist and the prudent interventionalist or surgeon should tailor their approach on a case-by-case basis.

Femoropopliteal Occlusive Disease

Ali F. AbuRahma, MD, and Zachary T. AbuRahma, DO

Peripheral artery disease (PAD) is a global epidemic that affected over 200 million patients worldwide in 2010. Most of these patients are asymptomatic; however, patients with intermittent claudication usually experience a limb loss rate of less than 5% over 5 years, while patients with critical limb ischemia (CLI) have a 1-year major amputation rate of 25% and death rates of 25%.

Femoropopliteal disease has been treated traditionally with open surgery (femoropopliteal bypass [FPBP]) with favorable 5-year patency rate when saphenous vein (ASV) grafts are used. Several meta-analyses have shown that CLI did not occur for up to 5 years in 50% to 70% of patients who underwent ASV grafting to tibial or pedal targets, with perioperative mortality and limb salvage rates of 3% and 80%, respectively.

A recent study of 667 bypass grafts compared outcomes for ASV and polytetrafluoroethylene (PTFE) grafts and showed the patency rate with ASV was better than PTFE grafts at 5 years (62% vs 36%, $P < .05$); however, good quality vein may not be available (20%–30%). Bypass with PTFE should therefore be limited to select patients.

Open surgical bypass has certain limitations, for example perioperative morbidity/wound complication rate of 10% to 20%, prolonged hospital stay/outpatient care, and patient discomfort. De novo stenosis in vein grafts may also occur in 30% to 40% of patients in the first 2 years, which may necessitate graft surveillance or reintervention. Other systemic complications may occur (e.g., cardiac, pulmonary and renal).

Recently, endovascular therapy has been advocated as an alternative to open bypass. Several studies analyzing outcomes of patients with CLI treated with endovascular therapy have largely been retrospective single center with significant heterogeneity. The OLIVE registry, a multicenter prospective study, analyzed the outcomes of endovascular therapy for infrainguinal disease in 314 patients with CLI and showed a 12-month amputation-free survival of 74%, whereas 34% of patients required reinterventions (endovascular, 31.7% and bypass surgery, 2.6%). These results were satisfactory in

Femoropopliteal Occlusive Disease

Ali F. AbuRahma, MD, and Zachary T. AbuRahma, DO

Peripheral artery disease (PAD) is a global epidemic that affected over 200 million patients worldwide in 2010. Most of these patients are asymptomatic; however, patients with intermittent claudication usually experience a limb loss rate of less than 5% over 5 years, while patients with critical limb ischemia (CLI) have a 1-year major amputation rate of 25% and death rates of 25%.

Femoropopliteal disease has been treated traditionally with open surgery (femoropopliteal bypass [FPBP]) with favorable 5-year patency rate when saphenous vein (ASV) grafts are used. Several meta-analyses have shown that CLI did not occur for up to 5 years in 50% to 70% of patients who underwent ASV grafting to tibial or pedal targets, with perioperative mortality and limb salvage rates of 3% and 80%, respectively.

A recent study of 647 bypass grafts compared outcomes for ASV and polytetrafluoroethylene (PTFE) grafts and showed the patency rate with ASV was better than PTFE grafts at 5 years (62% vs 26%, $P < .05$); however, good quality vein may not be available (20%–30%). Bypass with PTFE should therefore be limited to select patients.

Open surgical bypass has certain limitations, for example postoperative morbidity/wound complication rate of 10% to 20%, prolonged hospital stay/outpatient care, and patient discomfort. De novo stenosis in vein grafts may also occur in 30% to 40% of patients in the first 2 years, which may necessitate graft surveillance or reintervention. Other systemic complications may occur (e.g., cardiac, pulmonary and renal).

Recently, endovascular therapy has been advocated as an alternative to open bypass. Several studies analyzing outcomes of patients with CLI treated with endovascular therapy have largely been retrospective single-center with significant heterogeneity. The GLOVE registry, a multicenter prospective study, analyzed the outcomes of endovascular therapy for infrapatellar disease in 314 patients with CLI and showed a 12-month amputation-free survival of 71%, whereas 34% of patients required reintervention (endovascular, 31.7% and bypass surgery, 2.6%). These results were satisfactory in

those high risk patients (71% diabetics and 22% on hemodialysis) and with severe anatomic disease (42% below knee lesions and ~50% Trans Atlantic Inter Society Consensus [TASC] type C and D).

CLINICAL EVALUATION/IMAGING

A thorough history and physical examination is important. Cardiovascular risk factor identification is critical and includes history of cigarette smoking, hypertension, diabetes, and dyslipidemia. In general, a patient's clinical symptoms and a thorough pulse examination should facilitate in diagnosing PAD. Hemodynamically significant disease can be asymptomatic or present with intermittent claudication or limb-threatening ischemia (rest pain and/or trophic changes, e.g., ulceration or gangrene). Claudication (from the Latin word *claudicare*, means limping) generally manifests as cramping pain in the calf, which is precipitated by walking that occurs at a reproducible distance. It is relieved with rest, and the location of pain is almost always one joint distal to the occlusion. Once the clinical diagnosis is made, noninvasive vascular laboratory can be helpful in confirming the diagnosis and localizing the disease. The most common testing is the ankle brachial index (ABI), which can be combined with color duplex scanning of the lower extremity. The ABI is generally calculated as the ratio of the higher systolic pressures in the arm divided by the highest systolic pressure at the ankle whether the dorsalis pedis or the posterior tibial artery. A normal ABI is generally around 1 ± 10%; an ABI of less than 0.9 is diagnostic of PAD. It is generally believed that an ABI between 0.4 and 0.9 is present in patients with claudications, while an ABI below 0.4 is compatible with rest pain or tissue loss. An ABI greater than 1.2 may be indicative of arterial calcification, which is seen in diabetics and mid stage renal disease (chronic kidney disease (CKD)). Some believe that in these patients an ABI can be greater than 1.3 to 1.4. Patients with vasculogenic claudications will also show an ABI drop when the patients walk to the point of calf claudications using treadmill testing. If an ABI is greater than 1.3 to 1.5, particularly in diabetics or in patients with CKD, obtaining Doppler toe pressures and/or pulse volume recordings might be helpful. A toe brachial index (TBI) of less than 0.7 is indicative of significant disease. Color duplex ultrasound is also available in many of the vascular laboratories where B Mode imaging and color flow Doppler sampling will determine the location and severity of the disease, including occlusion, which will facilitate proper treatment of open or endovascular therapy. For patients who need invasive therapy, further imaging is obtained to show both inflow and outflow arteries, for example contrast computed tomographic angiography (CTA), or magnetic resonance angiography (CCTA to contraindicated). However, if endovascular therapy is anticipated, contrast arteriography may be all that is needed to minimize cost.

TREATMENT

Conservative Medical Therapy

Conservative medical therapy is offered to patients with claudicating claudication, or even as initial step for patients with disabling symptoms. This therapy includes risk factor modifications, such as smoking cessation, dietary and pharmacologic therapy to include statin to lower dentite lipoprotein cholesterol and triglyceride, treatment of hypertension, and diabetes. Patients should also be given aspirin to reduce the risk of cardiovascular morbidity and mortality. Cilostazol (a phosphodiesterase inhibitor) may provide symptomatic improvement in certain patients with claudication. Exercise programs have been advised to improve walking distance. Supervised exercise programs being more effective than unsupervised. However, if an unsupervised program is initiated it should be performed at least 3 times a week for 30 to 45 minutes, and patients should be encouraged to do it to a point where the claudication symptoms appear. Medical treatment is not the first line of therapy for patients with critical limb ischemia.

Open Surgical Versus Endovascular Therapy

The decision to perform open surgical therapy versus endovascular therapy should be based on several factors including patient's age, severity of ischemia, long term prognosis, and anatomic complexity. To many, open surgical therapy is still considered the gold standard for patients with ischemic rest pain or tissue loss. However, for many others endovascular therapy has been advocated as initial therapy. The classification of arterial lesions, which was established by the Trans Atlantic Inter Society Consensus for the Management of PAD (TASC II) may be helpful in choosing the appropriate therapy (Fig. 1). It is agreed upon that endovascular therapy is preferable for type A, B, and C lesions; however, type D lesions are treated mainly by an open surgical bypass. However, some authorities recommend endovascular therapy even for type D lesions as initial therapy, with open bypass if it fails.

Open Surgical Therapy

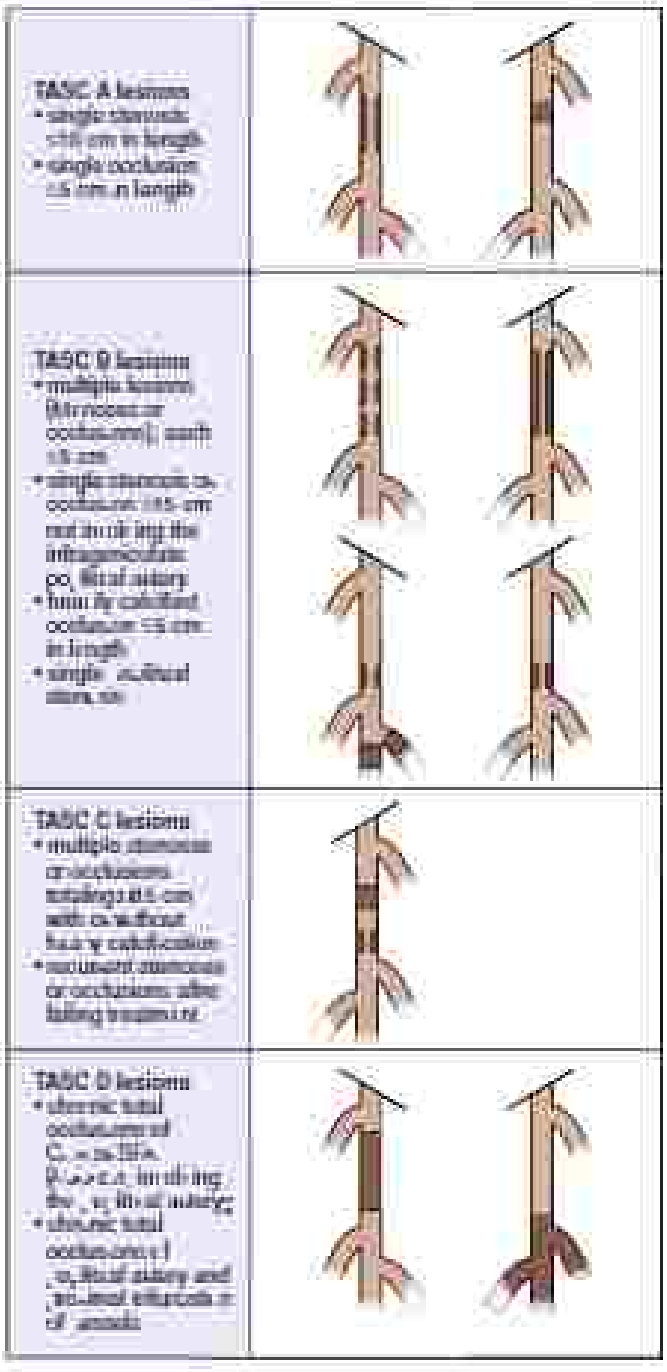
FPBP is the procedure of choice, which involves a bypass of the occlusive disease with or without endarterectomy of the common femoral artery (CFA), if needed. For successful bypass, adequate inflow vessel (arterial), outflow vessels, and conduit are needed. The proximal target should be the CFA; however, the superficial femoral artery (SFA) or the proximal profunda can be used with caution. The distal target site can be above- or below-knee popliteal segment or the tibial vessels. The groin incision can be done either as vertical or oblique just above the crease (Fig. 2). Vertical incision is preferable if common femoral endarterectomy or profundoplasty is needed. A good outflow vessel should be the least diseased with continuous flow to the foot. Every effort should be made to revascularize the target artery that supplies the area of ulceration is present (Fig. 3) based on the angiosome concept.

Exposure of Above- and Below-Knee Popliteal Artery

The above knee popliteal artery is exposed with a longitudinal incision placed along the anterior border of the sartorius muscle in the distal thigh (Fig. 4). Incision is deepened through subcutaneous tissue to the muscular fascia between the vastus medialis anteriorly and sartorius posteriorly. The adductor hiatus is identified to expose the popliteal artery emerging from the distal SFA. The artery lies medial to its accompanying vein upon entering the vascular sheath. Small branches of the popliteal artery should be handled carefully and not divided to minimize compromising leg circulation if the graft failed. To expose below-knee popliteal artery, the incision is positioned below the knee along the medial aspect (Fig. 4). If this was anticipated before vein harvest, the same below knee incision for vein harvest can be used. This incision is generally placed one fingerbreadth posterior to the tibia and carried through the fascia. The gastrocnemius muscle is identified and retracted posteriorly to expose the popliteal space. Further proximal exposure of the popliteal artery/space may be obtained by dividing the tendinous attachment of the sartorius, gracilis, and semitendinosus muscles. For distal grafting to individual tibial vessels, the dissection should continue by detaching some of the soleus muscle fibers, which will expose the tibioperoneal trunk, posterior tibial and peroneal arteries. The anterior tibial artery is generally identified once this process is done.

Conduit of Choice

Autogenous vein has been the first choice for all infrainguinal bypasses. The greater saphenous vein is the preferred choice and should be evaluated with preoperative duplex vein mapping. If this vein is inadequate, a mapping of alternative veins including a lesser saphenous, contralateral greater saphenous vein, and upper arm veins (basilic and cephalic vein) is done. The vein should be sonographed and at least 3 mm in diameter. Vein bypasses can be placed in a reversed, nonreversed, or in-situ configuration. Both reversed and nonreversed vein bypasses have similar patency, particularly for above knee positions. The in-situ configuration is reserved for distal popliteal artery or tibial vessels because of better matching between



[illegible]

the arteries and the vein. Other conduits have been used (e.g., PTFE or Dacron), with or without heparin bonding, with no clear superiority of one over the other. Cryopreserved and human umbilical vein might be used with a similar patency as prosthetic graft; however, they are expensive and used only in exceptional cases.

Vein Harvest/Bypass Technique

Vein harvest is generally done with several long anterior incisions with skip incisions, which I prefer. (A.F.A.) versus continuous long incision. Endoscopic vein harvest can also be done; however, comparative results with open vein harvest have been unsatisfactory. The incision is extended distally along the path that is marked at the time of preoperative vein mapping or using a bedside ultrasound machine. Vein harvest must be meticulous to minimize damage to the vein. A vessel loop can be used to retract the vein from side to side and help identify all side branches, which should be tied 1 to 2 mm away from the vein to minimize kinking or narrowing of the vein. Once the vein is removed, gentle dilation with heparinized saline solution is done. Every effort should be made to minimize the amount of time the harvested vein is not being perfused with the patient's blood. We generally prepare the vein just after exposing both proximal and distal inflow and outflow arteries, so once the vein is harvested it is ready to be used. Due to size mismatch, the vein is spatulated, and if anastomosis to the most proximal valve is excised with direct vision. The end-to-side anastomosis is created with 5-0 or 6-0 polypropylene suture. Flow in the vein is then reversed into the bypass. Valvulotome (Leonhartt) is then used and inserted from the distal end where the remaining valves are gently cut. If the bypass is done to reverse failure, a tunneler is used, which is inserted just deep to the sartorius muscle and superficial to the SFA, and for below-knee popliteal artery bypass, the graft is inserted from above to below knee, with the index finger creating a tunnel between the heads of the gastrocnemius muscle to prevent compression.

Once the tunnels and the conduit are prepared, the patient should receive 80 to 100 U/kg heparin intravenously. A few minutes later, the procedure starts by occluding the CFA, profunda femoris and SFA, and any other branches. A longitudinal incision is made in the CFA with a No. 11 blade and extended using angled Potts scissors. Using double-armed 5-0 or 6-0 polypropylene sutures, the proximal anastomosis is done ballistically. The vein is allowed to distend with blood after loosening the vascular loops. It is then marked along one side to maintain orientation and prevent vein twisting. Once the vein is tunneled distally, the distal anastomosis is performed in a similar fashion using 5-0 or 6-0 polypropylene sutures (Fig. 5).

It is generally recommended to have completion duplex imaging to assess both proximal and distal suture line including the conduit. However, completion contrast angiography can be used if there is any question concerning the technical results. It is critical to evaluate the distal pulses by palpation and the use of continuous wave Doppler. The groin is then closed with multiple layers of absorbable sutures. The skin is closed as usual.

FIG. 3 Groin incision can be done either as vertical (A) or oblique (B) just above the inguinal [illegible]

FIG. 3 Angiosome concept. Six angiosomes of the lower extremity are supplied by the three main arteries (anterior tibial artery, posterior tibial artery, and peroneal artery). Each angiosome is supplied by a distinct source artery and is the tissue territory supplied by that artery. The angiosomes are separated by watershed zones. Direct cutaneous perforators are present in the skin overlying the angiosomes. Indirect perforators supply the skin through the underlying muscle.

Perioperative Management

Medications are started including statins and β-blockers. All patients are given one aspirin daily, which continues indefinitely. Sequential compression devices (SCDs) are applied on postoperative day 1 and continued until the patient is ambulating. Intravenous heparin is generally started in select patients at admission and discharged on warfarin, aiming for an INR of 2–3 for 3 months.

Postoperative Graft Surveillance

Duplex surveillance of the graft is performed at 1, 3, 6, 12, 18, and 24 months postoperatively. Patients are generally instructed to check their pulses daily and to call the vascular clinic immediately if they notice any decrease in pulses. Duplex surveillance is performed every 3 months for the first 2 years and then every 6 months thereafter. Approximately one third of vein grafts will develop lesions within the first 36 days after bypass surgery. Most lesions in graft patency within the first 30 days implies

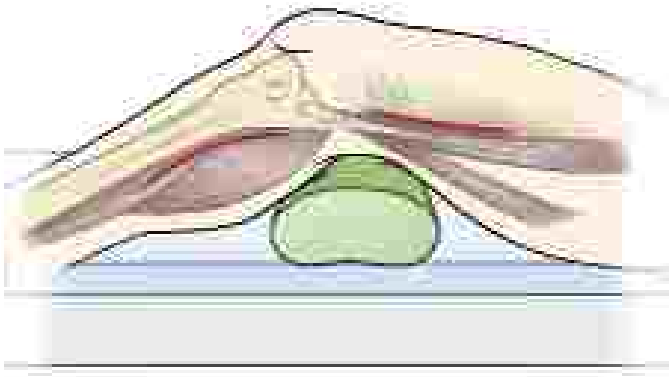


FIG. 4 Exposure of above- and below-knee popliteal artery

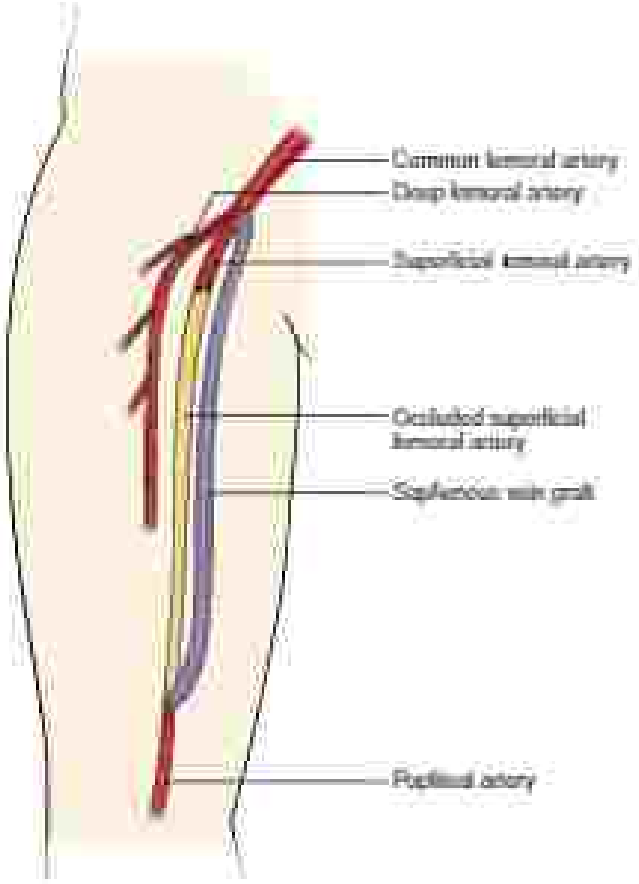

FIG. 5 Bypass done in reverse fashion.

a technical factor. Graft failure is impending [illegible] [illegible] of hyperplasia [illegible] [illegible] [illegible] of 3 to [illegible] [illegible] [illegible] [illegible] [illegible] endovascular [illegible].

Femoropopliteal Bypass Using Prosthetic Conduit

Both PT[illegible] [illegible] have been utilized to [illegible] particularly for above knee [illegible] similar [illegible] described earlier [illegible] diameter [illegible] generally [illegible] for above knee locations [illegible] below knee using prosthetic grafts [illegible] because [illegible] reserved as a last option.

We [illegible] conducted a prospective [illegible] of [illegible] saphenous veins [illegible] patients with bilateral above knee (AK) [illegible] patients [illegible] [illegible] with [illegible] [illegible] with PTFE [illegible] with saphenous vein graft [illegible] SVG [illegible] PTFE. All patients were followed [illegible] [illegible] The perioperative complication rates were [illegible]% for PTFE and 12% for SVG. There were no operative deaths or perioperative amputations [illegible]. The Kaplan-Meier estimate of primary, secondary [illegible] patency rates at 72 months were [illegible]% and 77% [illegible] 76%, 83% [illegible] for SVG. There were no statistically significant differences between primary and secondary patency rates, but [illegible] grafts, however, the assisted primary patency rates were higher for SVG ($P < .05$). The crude limb salvage rate at 72 months was 98% for PTFE and 98% for SVG. We concluded that PTFE and SVG for above knee bypasses have comparable patency and limb salvage rates in claudicant patients with bilateral SF[illegible] occlusion and 2 to 3 vessel runoff. This may justify the use of PTFE for above knee locations in these selected patients.

Results of Vein Surgical Bypass

Several studies compared the results of autogenous with various prosthetic FPBP in both above- and below-knee locations. A recent meta-analysis showed that SVGs were superior to prosthetic bypasses in both above- and below-knee locations. However, as indicated earlier by our experience, some authorities believe patients who are claudicant and needed only AK FPBP who had good runoff (2 to 3 vessels) might be better off served by the use of PTFE or a prosthesis, with the understanding the vein can be saved for future use for below-knee or distal vessels. If autogenous veins were not available for below-knee locations, a PTFE graft with distal anastomotic vein cuff has been suggested to be superior to prosthetic distal anastomosis alone (Table 1).

ENDOVASCULAR THERAPY FOR FEMOROPOPLITEAL DISEASE

Current endovascular therapy includes percutaneous transluminal angioplasty (PTA)/stenting, cutting PTA, atherectomy, covered stents, drug-coated balloons/stents, and cryoplasty. Commonly used modalities are discussed below.

Angioplasty/Stenting

The principle of angioplasty is balloon dilation of the reference lesion by inflating the balloon (several atmospheric pressures) and cracking

TABLE 1 Graft Patency, Aggregate of Multiple Studies

	Suprageniculate Femoropopliteal Bypass			Infrageniculate Femoropopliteal Bypass			Femorotibial Bypass		
Type of bypass	1 y	3 y	5 y	1 y	3 y	5 y	1 y	3 y	5 y

Survival	87%	77%	77%	86%		60%			

PTFE, Polytetrafluoroethylene.
[illegible]

the plaque. PTA is considered by many to be a controlled dissection. PTA has a favorable outcome in larger caliber arteries, in stenosis rather than occlusion, short and focal rather than multiple with good runoff. PTA has a better result when the indication is claudication rather than CLI.

Technical Consideration

Technical consideration starts by obtaining arterial access then identifying the lesion with diagnostic arteriography, followed by crossing the lesion with a guidewire, balloon angioplasty with or without stenting, and completion angiography to evaluate the result. The contralateral CFA is preferable arterial access, however, in certain thin patients the ipsilateral CFA may be used for antegrade access. The brachial artery may be used occasionally, particularly in patients with prior iliac artery/femoral artery bypass graft. The access is either obtained by conventional standard 18 gauge puncture needle or a micropuncture small catheter access needle. Once an access is obtained, 0.035 inch guidewire can be advanced into the iliac system then the aorta using contralateral catheter, access is obtained of the ipsilateral iliac, CFA, then SFA/popliteal artery through the lesion. To facilitate the intervention exchanging the access (6Fr 10 cm sheath) for a longer 45 to 55 cm (8Fr or 6Fr) sheath, which is positioned at the level of the external iliac or CFA on the side of the intervention, which facilitate for wire and catheter support. Spot angiography is used to delineate the lesion. The size and the length of the balloon are tailored to the size and length of the artery. Every effort should be made to avoid ballooning a healthy native artery. After completion angiography if more than 30% residual stenosis exists or if angioplasty has created a dissection (with significant impairment of the flow) then a self expanded stent should be placed across the lesion. We prefer giving 3000 to 5000 U heparin, which is administered intravenously at the start of the procedure once access is achieved. All patients should already be on aspirin regimen for intervention, which is continued afterward in addition to clopidogrel (Plavix), which is prescribed for 4 weeks after PTA. PTA after stent placement is usually necessary for complete expansion of the stent.

Crossing an occlusion can be accomplished with several techniques. An angle support catheter in combination with a straight, stiff hydrophilic wire is generally used initially to traverse a total occlusion. A combination of the support catheter and hydrophilic guidewire allow crossing many of these total occlusions. However, if that was not successful, other maneuvers might be utilized, including subintimal (external), if necessary. This can be achieved by pushing a hydrophilic angle guidewire into the subintimal plane with a loop orientation. ...sing catheter support, the loop is shortened to provide a smaller profile to reenter the luminal space. If that was not successful, reentry into the lumen may be done using reentry catheters (e.g., Pioneer (Volcano) or Outback (Cordis,).

It is generally not recommended to stent the popliteal artery since it is highly mobile and because of its location across the joint, which may lead to stent fracture and higher restenosis rate. Therefore, stenting to this location should be done only in select patients. ... se of the Supera stent (Abbott) has been associated with favorable results in this location.

...hese the procedure is done, the arterial access site can be closed using a variety of closure devices based on the size of the access sheath and the state of the access vessel (particularly calcification). Manual pressure may be appropriate for smaller access sheath and certain calcific lesions.

PTA for CLI can achieve a 5 year limb salvage rate of 89%, similar to earlier reported values with surgical revascularization, which ranged from 70% to 80%. Although the primary patency after PTA for CLI may be low, the limb salvage rate is quite high. The Society of Cardiovascular & Interventional Radiology Transluminal Angioplasty and Revascularization (STAR) registry analyzed 205 patients (79% with stenosis and 21% with occlusions were treated) with mean lesion length of 3.8 cm for stenotic lesions and 8.7 cm for occlusions. The technical success rate was 95%. The primary patency rates were 87%, 80%, and 69% at 1, 2, and 3 years, respectively. Diabetes and poor runoff scores were associated with decreased patency rates.

The use of stents was initially advanced to improve long term patency rates from PTA, especially to longer segment disease. Stenting may reduce elastic recoil and provide a scaffold in the setting of dissection. Initial study results were disappointing, with several randomized trials failing to show any benefit of stent placement over PTA alone. These findings led to the recommendation for stenting only in the setting of a suboptimal technical result following PTA. However, these studies were done using balloon expandable stainless steel stents, and more recent studies using self expanding nitinol stents have shown significantly better results. Three major randomized trials comparing primary nitinol stent placement with stent assisted angioplasty have been reported and show differing results.

The Femoral Artery Stenting Trial (FAST) analyzed outcomes with stent alone PTA versus primary stenting with a single self-expanding nitinol stent. Only single short segment lesions of less than 10 cm were included, with a mean lesion of 45 mm for both groups. A total of 123 patients were assigned to primary stenting and 121 were randomized to PTA alone. Technical success was achieved in 79% of the PTA group versus 93% of the stenting group. Restenosis rates at 1 year, as determined by ultrasound, were not significant (39% in PTA, 32% in stent). Maximal walking distance was slightly improved in the stenting group, but there was no difference in resting ABI or change in rutherford class. Stent fractures were found in 12% of patients, with no significant increase in restenosis with the presence of fractures.

The SUPERA JENT trial is a prospective multicenter trial of 234 patients that compared bare nitinol stents (Lifestent, C.R. Bard) to patients with a mean lesion length of 7.1 cm to PTA patients with a mean lesion length of 6.4 cm. Forty percent of patients with PTA had balloon stent for greater than 30% residual stenosis or dissection. This study suggested a statistical advantage of improved patency with stent over PTA alone. The technical success rate was better with stenting (96% vs 84%). Freedom from target lesion revascularization was better in the stent group than the PTA group at 6 and 12 months: 94% and 81% versus 67% and 57%, respectively. The stent fracture rate was 3% at 12 months and was not associated with any adverse clinical sequelae. The study showed continued advantages of bare metal stents versus PTA at 3 year follow up. The study authors concluded that for moderate length lesions, primary stent placement is superior to PTA alone.

The A SCAFFOLD trial (Balloon Angioplasty versus Stenting with Nitinol Stents in the SFA) included 104 patients with severe intermittent claudication and/or tissue loss (Rutherford classes 3–5) with lesions longer than 30 mm. Patients were randomized to PTA plus optional stenting or primary stenting. Mean target lesion length was 112 mm for the stent group and 93 mm for the PTA group. Restenosis rates were significantly lower in the primary stenting group at 2 years (46% vs 69%). There was no difference between the two groups with respect to Rutherford class at follow up, but there was a trend toward improved walking capacity and resting ABI in the stent group. Overall, reintervention rates were lower in the primary stent group.

Challenges in Stenting Superficial Femoral Artery/Popliteal Lesions

The SFA and popliteal arteries, unlike other arteries, are subject to triplanar intermittent mechanical stresses, including contraction, extension, torsion, flexion, and compression. The efficacy of stents in this location is limited by the fact that they can only deform to a limited extent to stresses exerted on the artery. The lack of flexibility and resistance to stent may reduce stent fractures and promote poorer patency.

Cutting Balloon Angioplasty

Cutting balloon angioplasty uses low pressure balloon catheters mounted with microsurgical blades or microtomes that cut into

luminal vessel during inflation. The mechanism of action is controlled disruption of the vessel wall, resulting in more controlled dilatation at lower balloon inflation pressures.

A prospective randomized controlled trial of de novo SFA lesions of 43 patients (19% had CLI) compared cutting balloon PTA versus conventional PTA and showed a restenosis rate of 32% in PTA and 42% in the cutting balloon PTA group at 6 months ($P = .048$). Therefore, cutting balloon PTA is not routinely used, due to higher costs and inferior results, but can be used for in-stent restenosis and diseased arteries in diversion points (CIA or popliteal artery stent fracture risk).

Atherectomy

Atherectomy involves debulking or atherosclerotic plaque removal. Current devices for this modality include rotational, directional, orbital, and laser atherectomy. Atherectomy for PAD patients is currently used as adjunctive/alternative therapy to traditional PTA or stenting. Plaque debulking leads to an immediate increase in lumen size, which should result in reduced stretch injury of the arterial walls. One potential complication is embolization, although the TALON registry reports a very low embolization rate (0.1%).

The DEFINITIVE LE[illegible] study included 133 patients with calcified femoropopliteal lesions treated with the Silverhawk or Turbohawk (Covidien) and distal embolic protection. They reported a 93% freedom from major adverse events, which included clinically significant embolization. However, the definitive clinical benefit of atherectomy over PTA was not clear. Larger prospective multicenter trials are needed to highlight the role of atherectomy in femoropopliteal arterial disease.

Covered Stents

Stent grafts using endovascular techniques attempt to duplicate open prosthetic femoropopliteal bypass. The Viabahn stent graft (W. L. Gore) consists of a self-expanding nitinol stent bonded to a graft made of expanded PTFE. They perform well in long segment occlusions and SFA restenosis; however, appropriate sizing and adequate runoff are required for optimal outcome and also dual antiplatelet therapy for at least 1 month.

The VIASTAR trial (Viabahn Endoprosthesis with Propaten Bioactive Surface versus Bare Nitinol Stent in the Treatment of Long Lesions in SFA Occlusion) studied 181 patients randomized to Viabahn or bare metal stents. The 1-year patency rate was higher with long lesions (>20 cm) with covered stents versus bare metal stents (71% vs 37%, $P = .01$). The Viabahn stent was then modified and heparin was bonded to the stent. This was examined in the VIPER trial for the treatment of SFA occlusion where the primary and secondary patency rates were improved to 79% and 92%, respectively. Laurinec et al. reported that PAD patients with long femoropopliteal lesions had significantly improved primary patency rates with covered versus bare metal stents at 24 months; however, there was no significant impact on clinical outcomes and target lesion revascularizations.

Drug Eluting Balloons and Stents

Drug-coated angioplasty balloons (DCBs) and drug-eluting stents (DES) are designed to limit the proliferative, reactionary process of neointimal hyperplasia. DCBs were developed to improve the durability of PTA, without the potential drawbacks of stents. It has been hypothesized that stents may actually increase neointimal hyperplasia by causing repetitive trauma and an increased inflammatory reaction. DCBs are designed to curb neointimal hyperplasia by delivering large doses of antiproliferation agents directly to the site of vessel injury.

Paclitaxel is a potent antiproliferative drug that stops cell division and induces apoptosis. The IN.PACT Admiral DCB coating consists of paclitaxel and urea, a carrier molecule. When exposed to blood during inflation, the urea hydrates and releases paclitaxel. Subsequently, the drug transfers into the wall of the artery and migrates through the vessel wall into the media. The IN.PACT Admiral DCB delivers paclitaxel in solid phase, thus establishing reservoirs of drug within the vessel wall. These reservoirs permit sustained drug availability (up to 6 months) and release with subsequent long-term antiproliferative effect.

There are several ongoing studies of paclitaxel DCBs in de novo and restenotic femoropopliteal lesions. Using DCBs to treat in-stent restenosis is preferred over placing additional stents because additional overlapping stents are associated with a higher rate of stent fracture and restenosis. Currently, there are two DCBs approved for use in the United States, Lutonix 035 (Bard) and IN.PACT Admiral (Medtronic). The majority of clinical trial data on DCBs has predominantly included patients with claudication and lower Rutherford classifications, as opposed to CLI patients. Late lumen loss, target lesion revascularization, and angiographic restenosis significantly favored DCBs in these trials.

The LEVANT trial randomized 101 patients to Lutonix DCBs or uncoated balloons. There was a significant increase in primary patency at 12 months with the Lutonix 035 DCB versus plain balloon angioplasty (74% vs 57%, $P = .03$). At 24 months, the major adverse events (death, amputation, target lesion thrombosis/hemorrhage) were 39% for DCB and 46% for uncoated balloon patients ($P = .45$). It should be noted that the results of DCBs have not been encouraging for below-knee vessels. The IN.PACT DEEP study identified a potential safety signal with a trend towards an increased rate of major amputations in the DCB study arm.

Medtronic's IN.PACT SFA trial is a prospective, multicenter, randomized trial in which 331 patients with intermittent claudication and CLI, secondary to femoropopliteal PAD, were randomly assigned in a 2:1 ratio to treat with DCB (Paclitaxel) or PTA. Over 90% of lesions were de novo, with a mean lesion length of 8 cm or greater in both groups. A higher primary patency at 12 months in the IN.PACT Admiral DCB group was noted, compared with the PTA group (83% vs 52%, $P < .001$). The rate of clinically driven target lesion revascularization was 2.8% in the DCB group versus 20.6% in the PTA group ($P < .001$). There was no device/procedure related death or major amputation.

The THUNDER trial followed 154 patients who were treated with DCBs, angioplasty with paclitaxel in contrast medium, or no paclitaxel (control group) for 5 years. The target lesion revascularization was significantly lower in the DCB versus the control group (23% vs 56%, $P = .0005$). DCBs also had lower binary restenosis (17% vs 54%, $P = .04$). DCBs had reduced target lesion revascularization over 5 years.

Limitations of DCBs

The use of cytostatic agents, such as paclitaxel, may have an adverse impact on wound healing. Furthermore, patients with PAD, especially those with CLI, often present with calcified plaque, which is difficult to treat and is often associated with poor procedural and long-term success. Preparing the vessel with atherectomy prior to using DCBs is a strategy that may hold some promise in improving the therapeutic effect of DCBs in calcified lesions.

Drug-Coated Stents

ZEPHYR I and II trials (zotarolimus-eluting stents (Cordis Smart nitinol self-expanding stent) were compared to bare metal stents. There was no difference in in-stent restenosis at 6 months and 2 years. However, the Absolute PTX (paclitaxel) stents (Cook Medical) proved safety and efficacy, and it was superior to PTA with provisional stent placement. In a study by Duke et al. with the Absolute PTX stent, 474 patients were randomized to primary DES or PTA with provisional stents, with subsequent secondary randomization to bare metal stents or DES for patients requiring provisional stents. The event-free survival at 1 year was 90% for primary DES versus 83% for the control arm ($P = .004$). The primary patency rate at 1 year was 83% for DES versus 73% for PTA alone.

Later studies with Zilver PTX stents reported a primary patency rate of 83% for DES and 65% for PTA, excluding acute PTA failure ($P < .001$). The data still supported safety and efficacy of DCS at 5 years. In a larger prospective registry of 787 patients, the 2-year freedom from target lesion revascularization with primary DES placement was 80.5% in the single-arm study. The Zilver PTX stent was also examined for the treatment of in-stent restenosis. In patients with a mean lesion length of 13 cm (91% total occlusions), procedural success was 98%, primary patency rate at 1 year was 79%, and freedom from target lesion revascularization at 2 years was 81%. Dual antiplatelet therapy is recommended for 6 months with the use of the Zilver PTX. Later 5-year data showed that DCS (paclitaxel) had better patency rates than standard PTA (66.4% for lesion 65 ± 40 mm in length) and better freedom from target lesion revascularization (85%).

Drug-Coated Angioplasty Balloon Versus Drug-Eluting Stents for Superficial Femoral Artery Interventions

Lesion length, type of revascularization (subintimal vs intraluminal), degree of calcification, and lesion site (distal, popliteal) should all be considered when choosing the primary strategy. As a general rule, one must avoid stenting when unnecessary due to the possibility of a worse behavior of stent restenosis. It is generally recommended to use a DCB for a TASC II, C, or D lesion upon first presentation and also for restenotic lesions, as well as for in-stent restenosis in the femoropopliteal area. If significant flow-limiting dissection remains, use of a DES as a kind of bailout stent is appropriate.

Primary Amputation

Some authorities feel primary amputation may be appropriate in select patients; for example, a patient with significant tissue loss, who is not likely to return to ambulation and who has a long-standing functional impairment, is best served with primary amputation. Patients who are also paralyzed with contractures, short life expectancy, severe sepsis, end-stage renal disease, or other systemic illness would be better served with primary amputation.

CONCLUSION

Based on a nearly universal procedure success rate, low morbidity and mortality, and improving patency rates with new devices, endovascular therapy is the recommended treatment of choice for TASC A to C lesions, although open surgical bypass with ASV grafts is a durable choice in low-risk patients. Two new studies, BASIL 2 and 3 and BEST CLI, are enrolling patients to further compare open versus endovascular therapy for selected patients with CLI. Until more well-designed randomized trials are completed, physicians should rely on their best clinical judgment.

MANAGEMENT OF TIBIOPERONEAL ARTERIAL OCCLUSIVE DISEASE

Robert J. Rosenfield, [illegible] and [illegible] Mark Hamilton, MD

A generation ago, vascular disease isolated to the tibioperoneal arteries was uncommonly encountered. At that time, the typical vascular patient was a long-term smoker with ischemic and/or [illegible] disease, and distal involvement represented the distal extension of the disease. Since endovascular therapies were nonexistent or in their infancy, distal disease came into play when a leg bypass had to be extended into the tibial vessels and was not commonly the primary indication for operation. Currently, with the high prevalence of diabetes mellitus, peripheral artery disease (PAD) isolated to the tibioperoneal arteries has become a common pattern. Additionally, PAD has increased in prevalence in every type of country regardless of socioeconomic status. This is due in large part to the explosive growth in the number of diabetics. This rise in prevalence has had a significant economic impact, which will undoubtedly worsen with time. Annual healthcare expenditures in patients with PAD are over three times that of age-matched, comorbid-matched cohorts due to

Later studies with Zilver PTX stents reported a primary patency rate of 83% for DES and 65% for PTA, excluding acute PTA failure ($P < .001$). The data still supported safety and efficacy of DCS at 5 years. MANAGEMENT OF TIBIOPERONEAL ARTERIAL OCCLUSIVE DISEASE

Robert J. Beaulieu, MD, and Thomas Reifsnyder, MD

A generation ago, vascular disease isolated to the tibioperoneal arteries was uncommonly encountered. At that time, the typical vascular patient was a long-term smoker with occlusive and/or stenotic disease of the aortoiliac segments, and limb involvement represented the distal extension of the disease. Since endovascular therapies were nonexistent or in their infancy, tibial disease came into play when a leg bypass had to be extended into the tibial vessels and was not commonly the primary indication for operation. Currently, with the high prevalence of diabetes mellitus, peripheral artery disease (PAD) isolated to the tibioperoneal arteries has become a common pattern. Additionally, PAD has increased in prevalence in every type of country regardless of socioeconomic status. This is due in large part to the explosive growth in the number of diabetics. This rise in prevalence has had a significant economic impact, which will undoubtedly worsen with time. Annual healthcare expenditures in patients with PAD are over three times that of age-matched, comorbid-matched cohorts due to

increased costs of interventions and hospitalizations. Therefore, knowledge of the risks, diagnosis, and management of this patient population is of paramount importance, especially to mitigate the morbidity associated with this condition and drive improved high-value care.

ASSESSMENT AND DIAGNOSIS

Assessment of patients with suspected or confirmed chronic limb-threatening PAD should begin with a complete history and physical, aiming to not only define the symptomatology and severity of the disease but also the functionality of the patient. A majority of patients with chronic limb-threatening PAD will be asymptomatic and warrant no vascular intervention. Most patients who need invasive treatment will present with rest pain and/or tissue loss on the foot or a diabetic foot infection. Comorbid conditions that may impact the treatment strategy in particular, a history of major adverse cardiovascular events, such as stroke or MI, as well as the presence of diabetes, hypertension, chronic kidney disease and tobacco abuse should be elicited. However, in ambulatory patients with a limb-threatening problem the work up of the patient revolves around maximizing their current physiologic state since limb salvage is always preferable and less stressful than limb loss.

Noninvasive evaluation of the limb is the next step. An ankle-brachial index (ABI) should be obtained in all patients with suspected PAD. Patients with chronic limb-threatening PAD who are typically diabetic or have chronic renal failure often have incompressible arteries, so the ABI will be falsely elevated or cannot be calculated. However, the addition of digital pressures and pulse volume recordings should allow an accurate assessment of the degree of ischemia. A first toe pressure less than 50 mm Hg is concerning and pressures less than 30 mm Hg in a patient with a foot wound indicate that healing without intervention is unlikely.

In patients with critical limb ischemia (CLI), additional diagnostic imaging will be required to delineate the affected anatomy. Catheter-based angiography is the gold standard to evaluate the extent and location of disease (Figs. 1 and 2). Additionally, it allows for the possibility of simultaneous intervention, the role of which will be discussed in detail later in this chapter. However, the near ubiquity and ease of obtaining magnetic resonance angiography and multidetector computed tomography have increased the use of these modalities. In particular, both of these methods obviate the risks of vascular injury associated with traditional angiography while maintaining greater than 90% sensitivity for diagnosing a stenosis greater than 50%. Since all methods involve the administration of contrast, they are not risk free.

MANAGEMENT

Medical Therapy

Cardiovascular optimization is the cornerstone of medical therapy for limb-threatening PAD. In particular, a healthy diet, smoking cessation, and good glucose control in diabetics are a must. Smoking cessation has been shown to significantly reduce the risk of both amputation and mortality in patients with PAD. Pharmacologic smoking cessation aids, including bupropion and varenicline, should be explored in all patients with a willingness to quit. Additionally, patients who are not in a limb-threatening situation should be encouraged to start an aerobic exercise regimen such as a walking program and enroll in a supervised walking program when possible.

FIG. 1 Digital subtraction angiogram of a patient with dysplastic left common, external, and internal iliac arteries. Atherosclerotic plaque is also noted throughout the abdominal aorta, bilateral common iliac arteries, and left external iliac artery. Collateral vessels are noted in the pelvis, providing retrograde flow to the left common femoral artery (arrow).

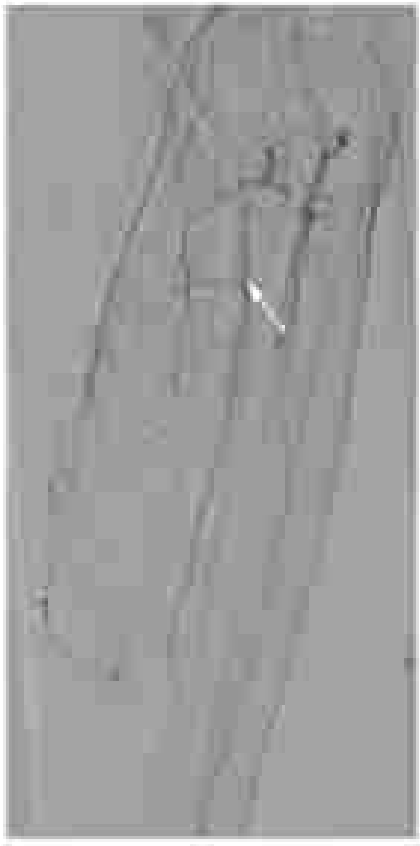

FIG. 2 Digital subtraction angiogram of a patient with dry gangrene of the left fifth toe. Occlusion and stenosis of tibioperoneal arteries with reconstitution of the peroneal artery (arrow) are noted.

Patients with infrapopliteal PAD should also be placed on aspirin or an alternative antiplatelet agent if aspirin intolerant. In addition, statin therapy is a must. Statin therapy has been shown to multiple trials to improve amputation free survival and lower mortality rates in patients with PAD and particularly in those with CLI.

Surgical Intervention

Deciding between the endovascular versus open surgical management of infrapopliteal PAD depends on multiple factors including symptoms, patient anatomy, severity of disease, patient comorbidities, and, importantly, the specialty and skill set of the treating physician. Clearly, both bypass surgery and infrapopliteal angioplasty should be part of the treating physician's armamentarium. No randomized control trials regarding the treatment of infrapopliteal disease have been conducted, but retrospective reviews have yielded consensus guidelines that can be used to direct management (Fig. 3).

Retrospective data include a large meta-analysis of infrapopliteal surgical bypass, which demonstrated an impressive 5 year primary patency rate of 73% and a nearly 80% rate of limb salvage at 5 years. Although it is generally accepted that the patency rates of tibial vessel angioplasty are not as good as surgical bypass (50% 1 year primary patency and 30% limb salvage at 5 years), the physiologic impact of the intervention is clearly less. There are a couple of considerations in choosing between surgical bypass versus tibial angioplasty. First off, tibial angioplasty works best on focal lesions less than 10 cm in length. Long lengths of occluded tibial vessels can be opened with angioplasty resulting in impressive final angiographic results; however, the patency of an endovascular intervention is generally measured in terms of months not years. Next, if the intervention is being undertaken for wound healing then long term patency may not be necessary and tibial angioplasty would be an appropriate choice. An example would be a previously asymptomatic diabetic patient with undiagnosed tibial artery occlusive disease who presents with a diabetic foot infection. After debridement of the infection, the patient has a large defect in their forefoot that will require a modified transmetatarsal amputation to close. Tibial vessel angioplasty can restore normal circulation to the foot, and even if the angioplasty fails after several months, the foot should remain healed since it was asymptomatic prior to the infection. Less often, the patient with infrapopliteal disease presents with ischemic rest pain and tissue loss of the foot. In this patient population, the vascular reconstruction must be durable because if it fails the rest pain will return and the patient's limb will once again be threatened. In these patients, the superior patency of autogenous surgical bypass outweighs the increased risk of the procedure. The bottom line is that the intervention should be customized to the patient, and if the treating physician can skillfully perform tibial angioplasty or a popliteal to distal pedal bypass then the optimal procedure will be chosen for that particular patient.

FIG. 3 Schema for bypass or endovascular treatment. ENDO, GSV great saphenous vein; TASC, transatlantic Inter-Society Consensus.

TECHNIQUES

Overview

The concept of a leg bypass for infrapopliteal PAD is simple and is predicated on dissection of adequate inflow and outflow arteries and harvesting an appropriate conduit. The word *harvesting* was purposely used since removing a prosthetic graft from a box is not harvesting. Autogenous vein should always be used. Since the distance that needs to be traversed is relatively short, there is no reason that enough autogenous vein cannot be found. If the surgeon is uncomfortable harvesting small saphenous, cephalic, or basilic veins then the patient should be referred to a surgeon adept at these techniques. While recent evidence suggests no difference in primary or secondary patency rates and limb salvage rates between arm and leg vein, data are clear regarding the superiority of either vein conduit, even upper arm vein, compared to infrapopliteal prosthetic graft use. While the great saphenous vein is typically used, it is not uncommon to preferentially harvest arm vein in the obese diabetic patient who needs a popliteal to pedal bypass thereby avoiding the thigh incision. The vein harvest is the most important part of the operation. This phase should be done by the most experienced person, as there is no room for error.

Procedure

Generally, the patient is placed supine on the operating room (OR) table, although in an occasional redo bypass utilizing small saphenous vein, a prone technique is used, particularly for the vein harvest and ankle below knee popliteal artery dissection. If ipsilateral great saphenous vein is being used and the operation will be continued to the leg distal to the mid thigh, in high risk patients we use a femoral sciatic nerve block for anesthesia. If the patient is not particularly high risk or if the vein is not coming for the ipsilateral limb then a general anesthetic is used. A Foley catheter is only placed if the expected OR time is going to exceed 3 hours and the patient does not have end stage renal disease. With practice, most of the bypass operations involving the infrapopliteal arteries can be accomplished in the 2- to 2.5-hour range. Next the extremities are prepped in the usual fashion. If arm vein is being used then the attending harvests that while the resident/fellow assistant surgeon circumferentially dissects out the popliteal or distal superficial femoral artery and then dissects out the distal target on its anterior surface only. The vein harvest is best accomplished through a continuous incision uncovering the entire length of necessary vein. An elastic vessel loop is placed around the vein at one end and the dissection proceeds toward the opposite end. All side branches, no matter how small, are ligated with a 4-0 braided, absorbable synthetic suture (polyglactin) on the conduit side, with the other side occluded with a small or medium vessel clip.

If ipsilateral calf great saphenous vein is going to be used then the team jointly harvests the vein and, once mobilized, that same incision is used to obtain control of the inflow popliteal artery. The other main variant in conduit occurs when the outflow distal pedal or plantar artery is very small or difficult to identify by preoperative angiography. In these cases, we identify the outflow vessel first, and make a small arteriotomy in the vessel to confirm a lumen before harvesting the vein.

At the last of the dissection is completed the patient is given 5000 units of intravenous heparin, and started on Dextran 40 at 25 ml/hr to continue for 20 hours. Dextran is not used in the end stage renal failure patients since it acts as a volume expander. In an experience of well over 1000 bypasses involving the infrapopliteal arteries this combination has worked well, and we have never found the need to check activated clotting times or other costly and time consuming confirmations of anticoagulation.

The proximal anastomosis is done first. We make the decision on conduit orientation depending on how the vein tapers. If the vein is uniform in size throughout its length, then we place it reversed. If it tapers, then the big end goes to the large or inflow artery and the smaller end goes to the distal vessel. We utilize an open arteriotomy technique with a 7-0 stitch in the heel, which is then run up

both sides to the midpoint followed by another U stitch in the vein, which is run down both sides to meet the first suture. Either 5-0 or 6-0 polypropylene is used for the proximal anastomosis, generally 7-0 is used for a distal tibial or pedal vessel. The valves are then cut if necessary and the vein tunnelled. There are many options for tunnelling, but in general we try to tunnel as much of the graft subfascially as possible, although it is not uncommon for the majority of the graft to be tunnelled subcutaneously. Once tunnelled, the distal end of the vein is marked, and a tourniquet is placed around the leg. Any kinks or twists in the conduit during tunnelling will result in limited flow, so confirm good continuous flow from the distal end of the bypass prior to inflating the tourniquet. The leg is exsanguinated, and the tourniquet inflated, and the distal anastomosis completed in the same manner as the proximal. This technique avoids crush injury or intimal damage due to externally clamping small calcified distal target vessels.

Once the bypass is in place, the incisions are closed with 2-0 absorbable suture in the fascia and 3-0 nylon interrupted vertical mattress sutures. We have tried every type of skin closure and have found that the number and severity of incisional problems is minimized with this closure. However, if there is an arm incision it may be closed in the most expeditious fashion, as it will eventually heal regardless of technique.

The patient is then taken to the recovery room, and then to a regular surgical floor bed. Unless the patient cannot be extubated or there is an unstable cardiac rhythm, there is no indication for the expense of the surgical intensive care unit for routine recovery. If the operation is appropriately conducted and autogenous vein used as the conduit then the bypass will be working the next day and there will rarely be a need to have a pulse check every 1 or 2 hours that first night.

On the first postoperative day a compressive dressing is placed from the ball of the foot to just below the knee. Our preference is a soft cast consisting of soft cotton padding (such as Covidien Webril Undercast Padding or BSN Medical Artiflex padding) over the surgical dressing (surgical dressing is sterilely changed if soiled) covered with Coban self adhesive wrap at medium stretch. Once that is in place the patient may be out of bed and may be full weight bearing regardless of where the incisions are located. If the patient is able to ambulate and is stable they can be discharged as early as that first postoperative day. Particularly in patients with strong family support, discharge on postoperative day 1 is not uncommon so long as this expectation is stated preoperatively.

Follow up is weekly to change the soft cast and check the incisions. On the third postoperative week, the sutures are removed, and duplex imaging of the bypass and physiologic testing is performed to confirm what has been obvious clinically and to make sure there is no stenosis in the bypass.

Surgical Approaches

Anterior Tibial Artery

Throughout its length the anterior tibial artery is fairly easy to find. A longitudinal incision slightly anterior to the midpoint between the shin and the fibula is made and carried down through the fascia. Since the vessel bundle sits on or near the interosseous membrane the muscle is preferably split between bundles, although if some of the muscle has to be cut it will not affect the patient's functionality. Once the vessel bundle is identified the anterior 50% of the vessel is freed from the surrounding veins and soft tissue. Circumferential dissection is somewhat difficult and unnecessary, as any sidebranches to a tibial vessel should be done under tourniquet control, and ligation/clamping of the vessel and control of any side branches is unnecessary.

Posterior Tibial and Proximal Two-Thirds of the Peroneal Artery

The approach is nearly identical. A medial calf incision is made approximately 2 cm posterior to the posterior edge of the tibia (if saphenous vein has been harvested use the vein harvest incision) (Fig. 4A). Once the superficial fascia has been opened the gastrocnemius muscle is retracted posteriorly and the soleus muscle is seen. The soleus muscle is attached to the deep posterior compartment fascia. This muscle is taken off the deep fascia by gently applying traction to the muscle and cauterizing the muscle attachments off the fascia. This should be done for the entire length of the incision or about 10 cm of length. For the posterior tibial artery the dissection should be about 2 cm in depth, while for the peroneal artery, more like 3 cm of muscle must be cleared off of the fascia. The deep fascia is then opened longitudinally. The posterior tibial vessel bundle runs with the large and easily identifiable tibial nerve (Fig. 4B). Generally, this bundle is just deep to the deep fascia. Once the posterior tibial artery is identified then 2 to 3 cm of the artery are dissected out on its anterior surface. The peroneal artery is usually in the same plane as the posterior tibial artery but deeper. The only landmarks for the peroneal artery are the accompanying paired veins. If the peroneal artery does not seem like it is in a deep hole through this approach then you are probably dissecting out the posterior tibial artery.

Distal Third of the Peroneal Artery

It is difficult to find and dissect out the distal peroneal artery through a medial approach. The distal artery should be approached from the lateral side of the distal calf. A longitudinal incision is made along the distal fibula with the distal end of the incision ending just proximal to the lateral malleolus. The incision is carried down to the fibula using the cautery and all of the soft tissue is cauterized off of the fibula being careful to stay right on the bone. Bending the tip of the cautery can help dissect the tissue off the deep side of the fibula. An alternative technique is to use a key periosteal elevator although it tends to create a bloodier operative field. Once about 8 to 10 cm of fibular are dissected out the bone is divided at the both ends. Although this can be done with a large bone cutter or Gigli saw I have found that it is much easier to accomplish using a micro sagittal or a micro oscillating saw. Once the bone is out the peroneal artery is usually just deep to the bone. Again, dissection is limited to the anterior 50% of the vessel for several centimeters.

Dorsal Pedal Artery

A 2- to 3-cm-long incision is made on the dorsum of the foot just lateral to the easily palpable extensor hallucis longus tendon. The cautery is used to open the fascia. Frequently the vessel will be more medial or lateral than expected and it is acceptable to lengthen the incision if you are having difficulties finding it. Two things help find the vessel: the first is it is generally a thickened and/or calcified vessel so it is frequently easy to palpate once the dissection is deep to the fascia. The second is that there are usually one or two dorsal venae comitantes veins that are easy to see. Again, dissect out the anterior 50% of the vessel for a couple of centimeters.

Plantar Arteries

Although the mid to distal plantar artery can be found through an incision on the plantar aspect of the instep, in the great majority of cases the more proximal medial or lateral plantar arteries are patent and clearly easier to find. The easiest approach is with a longitudinal incision about a finger-width posterior to the medial malleolus. There is a thick fascia deep to the skin that is opened, and usually the distal posterior tibial veins are obvious once that fascia is opened. Between the veins lurks the included and thickened posterior tibial artery. Follow that distally until the vessel bifurcates and that is your medial and lateral plantar arteries. Choose whichever one was patent on preoperative angiography and dissect out a couple of centimeters on its anterior surface. Of note, there is nothing you can harm that lies between the artery and the skin, so cautery dissection is easy and quick. However, all crossing venous branches should be ligated with 4-0 or smaller suture and divided. Despite the ischemia, these veins can cause annoying bleeding, and even small clips used on the veins end up getting in your way later on when sewing the anastomosis.

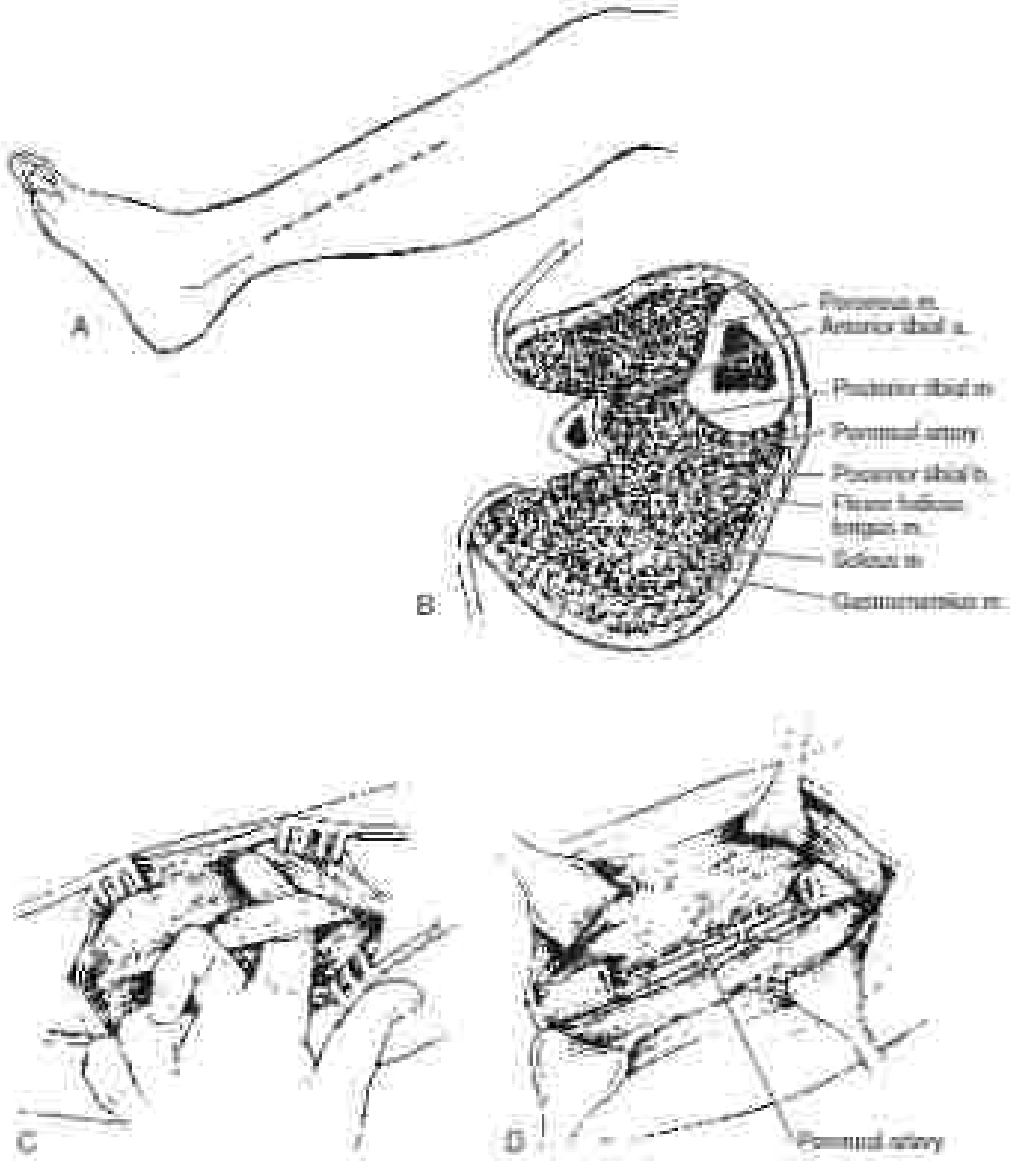

FIG. 4 Lateral exposure of the peroneal artery. (A) The incision is made longitudinally over the fibula. (B) Cross-section view of the lower leg, illustrating the lateral approach with fibula resection. (C) The muscle and fascia are stripped from the fibula, and an 8-cm section is removed. (D) The peroneal artery is exposed and rests to lie on the surface of the tibialis longus muscle. (C-D, pages 1406-1407.)

Tourniquet

A below knee or above knee tourniquet should be used when accessing tibial or pedal vessels. It makes the dissections easier, and damage to the vessels from clamps is avoided. Place a moist lap pad over any incision that the tourniquet is going to cover then place the sterile tourniquet around the leg. I choose the level by using my best guess as to where the calcification is least. Exsanguinate the leg with an Esmarch bandage and inflate the tourniquet to 250 or 300 mm Hg. Proceed with the arteriotomy and the anastomosis.

ENDOVASCULAR TECHNIQUE

All patients should be on aspirin and clopidogrel preprocedure and given full heparin anticoagulation prior to the angiography. Standard multivascular techniques are used; however, bear in mind that working distances tend to be long. Arterial access points include retrograde contralateral common femoral, antegrade ipsilateral common femoral, and retrograde access from the dorsal pedal or tibial anterior or posterior tibial arteries. Standard micropuncture access is obtained from the common femoral artery followed by placement of a 5Fr or 6Fr sheath, preferably with the tip positioned in the proximal superficial femoral artery. For selection of the tibial artery, use an angled glide wire and catheter. Once the catheter is positioned in the appropriate tibial then the glide wire is exchanged for a 300 cm long 0.018 or 0.014 wire. A Quick Cross Support Catheter (Spectranetics, Colorado Springs, CO) helps to pass the wire through occluded vessels, but frequently the wire will pass on its own. Once the wire is beyond the obstruction then a suitably sized balloon (2.5 to 3 mm larger than the measured luminal diameter) is placed over the wire and inflated for 2 to 4 minutes. The results on completion angiography tend to be quite rewarding (Fig. 5). If unable to cross the lesion in an antegrade fashion then the options are surgical bypass or retrograde pedal access. There are several commercially available pedal access kits that may be used or if unavailable a standard micropuncture kit. Under ultrasound guidance, the micropuncture needle is placed into the dorsal pedal artery followed by a 0.018 wire. Only the inner dilator of the micropuncture sheath is placed over the wire and the starter wire exchanged for the 300 cm long 0.018 wire. If the wire

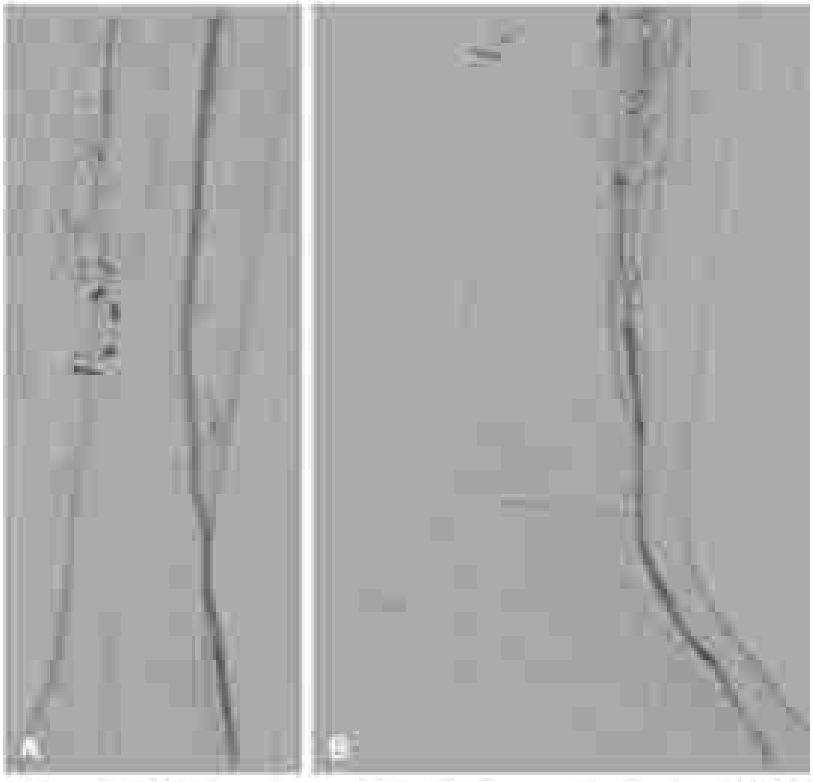

FIG. 5 Digital subtraction imaging of anterior tibial endovascular recanalization. (B) Lateral projection of successful recanalization following angioplasty.

patient easily on further pedal access is necessary. If a microcatheter or Quick Cross Support Catheter will be needed, then a low profile 6Fr sheath is placed. Once the wire is maneuvered into the popliteal artery, s/e femoral access is obtained and the floppy end of the wire in the popliteal artery is snared and pulled out of the femoral sheath. The wire is pulled out far enough until the opposite end nearly disappears. Next, a microcatheter is placed over the wire from the groin to beyond the site of future angioplasty. With the catheter in place the wire is removed and replaced such that the floppy end is in the distal tibial or pedal artery. Now proceed with angioplasty as described above. Once the angioplasty is completed then all catheters and wires are removed. Standard femoral closure is performed, but if there was pedal access we prefer to hold pressure on that site. As a principle, interventions are limited to balloon angioplasty as the available stents are quite short and have an unproven patency rate when used in the tibial vessels. The use of drug coated balloons is becoming an area of increased interest, but experience is limited, and they significantly increase the cost of the procedure.

CONCLUSION

Tibial artery disease with severe ischemia is readily treatable, and every effort should be made to prevent a major amputation. Whether to repair endovascularly or with a surgical bypass depends on the patient's presenting symptoms, location and extent of the disease, and the skill set of the treating physician.

The profunda femoris artery (PFA)—also called the deep femoral artery or deep artery of the thigh—serves critical functions in the perfusion of the lower extremity. It provides the majority of blood flow to the thigh muscles, supplemented by the obturator artery and descending branches of the superior and inferior gluteal arteries. In addition, it provides rich collateral flow to the tibial arteries in the setting of significant arterial occlusive disease of the superficial femoral artery (SFA) or popliteal artery and collateral flow to the pelvis in the setting of iliac arterial occlusive disease (Fig. 1). The PFA plays an important role in lower extremity revascularization procedures. It frequently is relatively spared of significant atherosclerosis disease compared with the common femoral and superficial femoral arteries. Thus, it can serve as a bypass target for outflow or as a source vessel for inflow in infrainguinal arterial bypass procedures.

PROFUNDA FEMORIS RECONSTRUCTION

Luke X. Zhao, MD, PhD, and Addi Z. Rizvi, MD

The profunda femoris artery (PFA)—also called the deep femoral artery or deep artery of the thigh—serves critical functions in the perfusion of the lower extremity. It provides the majority of blood flow to the thigh muscles, supplemented by the obturator artery and descending branches of the superior and inferior gluteal arteries. In addition, it provides rich collateral flow to the tibial arteries in the setting of significant arterial occlusive disease of the superficial femoral artery (SFA) or popliteal artery and collateral flow to the pelvis in the setting of iliac arterial occlusive disease (Fig. 1). The PFA plays an important role in lower extremity revascularization procedures. It frequently is relatively spared of significant atherosclerosis disease compared with the common femoral and superficial femoral arteries. Thus, it can serve as a bypass target for outflow or as a source vessel for inflow in infrainguinal arterial bypass procedures.

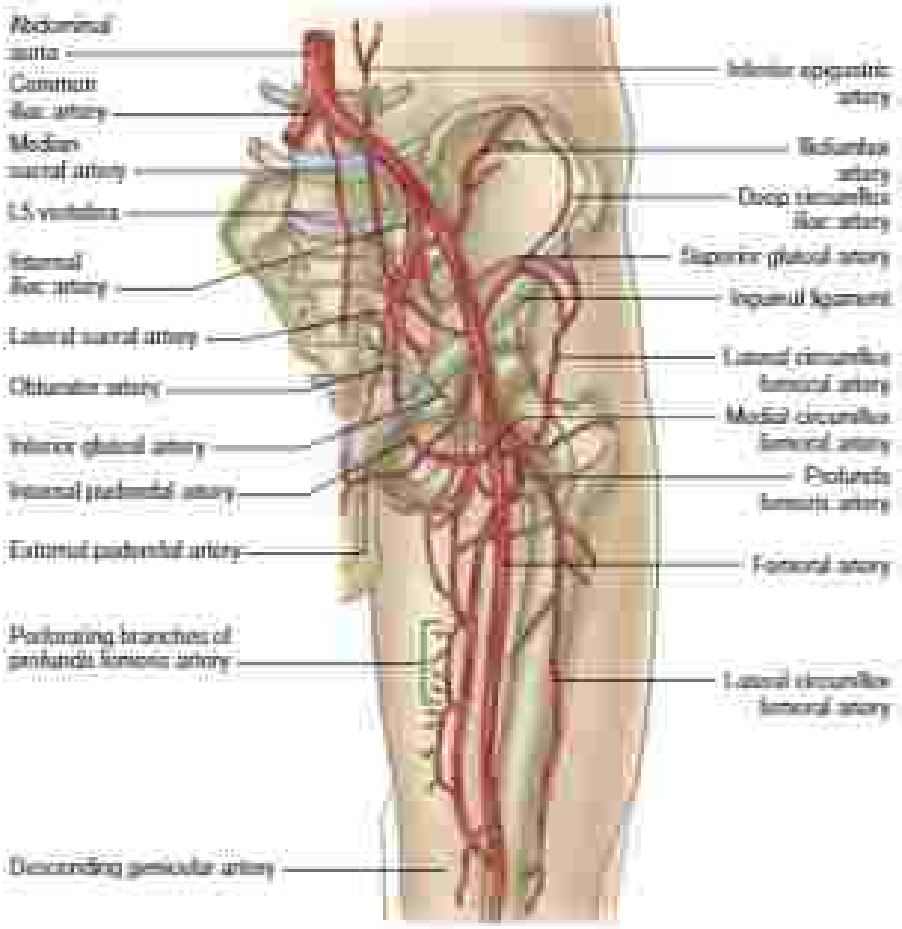

FIG. 1 Vascular anatomy of the thigh depicting the rich collateral network between the internal iliac artery profunda femoris artery and popliteal artery.

A stand-alone profunda artery with open endarterectomy or endovascular angioplasty can also be a main source of leg perfusion in selected patients (Fig. 2).

SURGICAL ANATOMY

Basic Anatomy

The common femoral artery (CFA) bifurcates into the PFA and the SFA 3 to 5 cm inferior to the inguinal ligament. The PFA usually arises from the posterolateral aspect of the CFA and travels in a posterior direction deep to the SFA. A visible change in caliber in the CFA usually marks the femoral bifurcation. An important anatomic relationship in surgical exposure is that the lateral circumflex femoral vein travels between the SFA and PFA. The PFA travels down the thigh close to the femur, running between the pectineus and the adductor longus muscles and on the posterior surface of adductor longus muscle. The PFA typically gives off three branches. The lateral circumflex femoral artery arises from the lateral side of the PFA, passing horizontally between the division of the femoral nerve and posteriorly to the sartorius and rectus femoris muscles. It divides into ascending, transverse, and descending branches. The medial circumflex femoral artery arises from the medial and posterior aspect and winds around the medial side of the femur. The lateral and medial circumflex femoral arteries can originate directly from the CFA 14% to 20% of the time. They can provide collateral branches to pelvic and gluteal vessels. The PFA continues as the perforating arteries, so named because they perforate the tendon of the adductor magnus muscle to reach the posterior and medial compartments of the thigh. The perforating arteries usually have three branches. The first perforating artery passes posteriorly between the pectineus and adductor brevis muscles. The second branch, usually the largest branch, perforates the tendon of the adductor brevis and magnus muscles. The third branch arises below the adductor brevis and pierces the adductor magnus to supply the posterior compartment. These three branches have rich anastomoses with each other.

The PFA is divided into three zones. *Zone 1* (proximal) begins at the origin of the artery and extends to the lateral circumflex femoral artery. *Zone 2* (middle) begins at the lateral circumflex artery and extends to the second perforating branch. *Zone 3* (distal) continues beyond the secondary perforating branch to the inguinal posterior to the adductor longus muscles. The sartorius muscle serves as an important landmark to aid the surgical exposure of zones 1 to 3 of the PFA (Figs. 1, 3, and 4).

Surgical Exposure of the Profunda Femoris Artery

Proximal Zone Exposure

The most common surgical exposure of the PFA is via an upper anterior thigh incision. It allows access to the CFA and the proximal PFA and SFA. The patient is placed in the supine position. Arms may be tucked to facilitate intraoperative angiography. A longitudinal incision that starts approximately two fingerbreadths lateral to the pubic tubercle, directly over the course of the CFA, is created. Palpation of the inguinal ligament and the femoral pulse or direct visualization with duplex ultrasound can demonstrate the course of the CFA and its bifurcation and can be used as an additional guide for incision placement. Even when the CFA is pulseless because of extensive calcification or occlusive disease, it can be localized by anatomic landmarks and is usually palpable as a firm tubular structure when rolled beneath the examiner's fingers. Incision usually begins just proximal

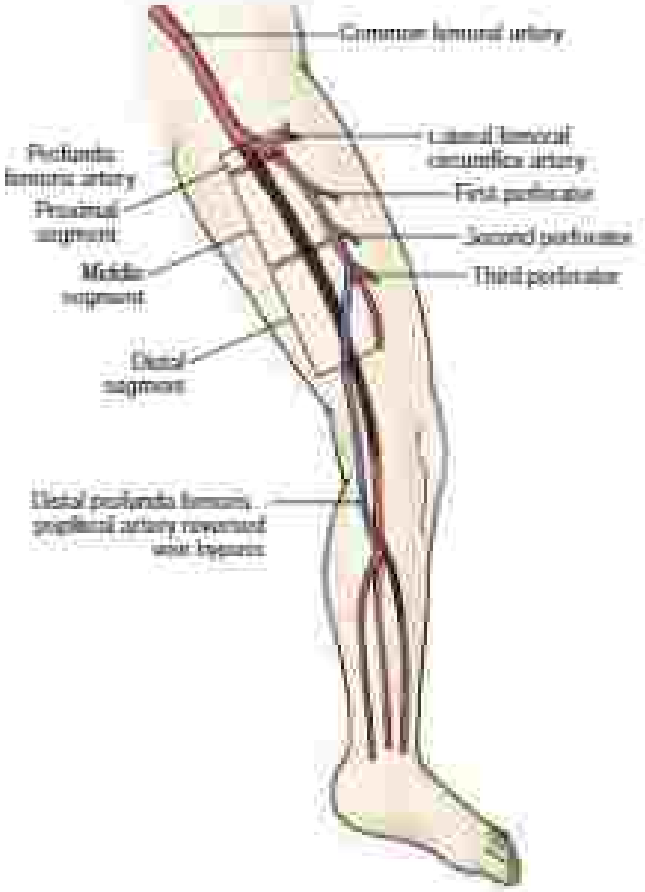

FIG. 2 Schematic of the profunda femoris artery used as an inflow source for an infrainguinal bypass.

to the inguinal crease and is carried distally, inclining slightly toward the medial aspect of the knee. The incision can be extended superiorly or inferiorly to expose the distal external iliac, proximal superficial femoral, or PFA. Alternatively, especially in the obese, a curvilinear incision can be made 1 cm below and parallel to the inguinal ligament, distal to the abdominal pannicular, so as to avoid potential skin maceration and wound complications associated with vertical incisions. Although the proximal superficial femoral and profunda femoris arteries can be exposed via this incision, such a curvilinear or oblique incision limits further distal arterial exposure. It therefore would not be selected if an extensive common and PFA endarterectomy was planned. The dissection is extended more deeply in vertical fashion (even when the initial incision is oblique). It is important to remain directly over the arteries as dissection is carried down deep to the femoral sheath. Encountering muscle structures indicates that one is too medial, whereas encountering underlying iliopsoas muscle, femoral nerve fibers, or lymphatics suggests that dissection is too lateral. Dissection is carried directly along the CIA both superiorly and distally. Proximal dissection along the artery allows exposure of the entire CIA, with the cephalad extent being the inguinal ligament. Caution is necessary when dissecting the CFA segment at or beneath the inguinal ligament. There is usually a vein beneath the inguinal ligament that crosses directly anteriorly over the CFA, making the site of entry or exit of sheaths at the inadvertent transection produces troublesome bleeding. The medial and lateral femoral circumflex arteries are often near the level of the inguinal ligament and should be identified, spared, and controlled with small Silastic vessel loops. As the dissection proceeds distally, an abrupt change in caliber marks the femoral bifurcation and indicates the origin of the

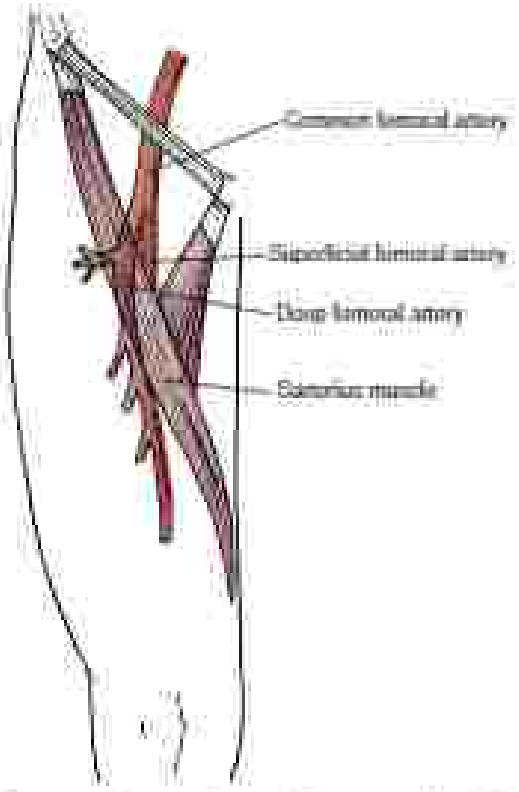

FIG. 3 The course of the circumflex vessels is represented in relation to the profunda femoris artery.

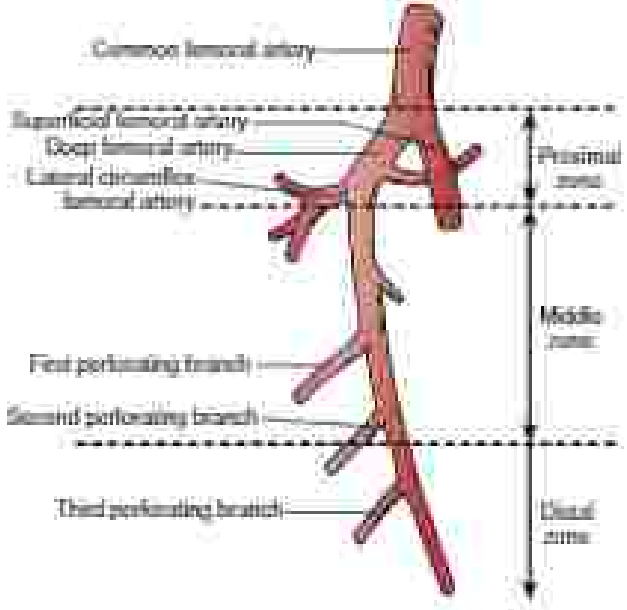

FIG. 4 The branches and zones of the profunda femoris artery.

PFA, usually oriented more deeply and posteriorly. After encircling the common and superficial femoral arteries with Silastic vessel loops, gentle upward traction on either of these loops can help to bring the PFA into view. The lateral circumflex femoral vein may cross under the SFA and course over the PFA near its origin. Division of this vein allows one to mobilize and further expose the first segment of the PFA, which is typically necessary when performing a profunda endarterectomy (see 4, Fig. 5).

Middle and Distal Segments of Profunda Femoris Artery Exposure

The middle (zone 2) and distal (zone 3) segments of the PFA can be exposed with either anterolateral or anteromedial incisions. This exposure for the PFA is useful regardless of whether the PFA is an inflow vessel or outflow target vessel, and the sole goal is to expose the PFA in virgin territory. These two exposures are common in the setting of multiple prior proximal groin exposures, infection in the groin region, or prior irradiation to the groin region. The skin incision is placed along either the medial border (anteromedial approach) or the lateral border (anterolateral approach) of the sartorius muscle. Carry the dissection deeply through the subcutaneous tissue and fascia, passing alongside the lateral or medial edge of the sartorius muscle to the deep layer, respectively. Once you are deep behind the sartorius muscle, mobilize and retract the sartorius muscle laterally or medially, depending on approach. Continue the dissection deeply, passing lateral to the superficial femoral vessels and accompanying nerve, in the valley formed between the adductor longus muscle (medially) and vastus medialis (laterally). The PFA and the profunda femoris vein reside directly underneath. Next, one dissects between the adductor longus and vastus medialis muscles to expose the PFA. It may be necessary to ligate and divide the coming venous tributaries to isolate and control the middle and distal segments of the artery. Alternatively, an incision can be made between the adductor longus (anteriorly) and gracilis muscle (posteromedially). Dissect between the adductor longus and adductor magnus muscles to approach the PFA medially from the distal thigh (Figs. 6, 7, and 8).

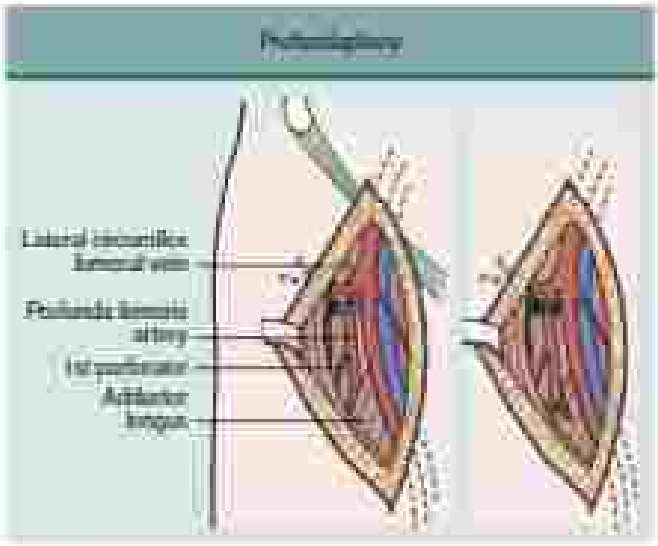

FIG. 5 Standard anterior approach to the profunda femoris artery.

Posterior Medial Approach

The posterior medial approach is also used in the setting of prior groin surgery, groin infection, or a previously irradiated groin. The middle and distal zones of the PFA can be exposed via this incision, and it is a useful exposure in the setting of an ilio-femoral-distal bypass if the PFA is the outflow target vessel. With the knee flexed and the hip rotated externally, a medial thigh incision is placed. The fascia is incised, and the dissection is continued along the posterior surface of the adductor longus muscle and anterior to the adductor brevis muscle. At the deep aspect of this exposure before encountering the femur, the PFA should be identified and isolated (Figs. 6 and 8).

PROFUNDA FEMORIS ARTERY RECONSTRUCTION

Bypass

Often the PFA is used as a source of inflow, particularly in the setting of a distal bypass if there is inadequate vein length or if exposure of the CFA is challenging (i.e., multiple prior groin dissections, infection, or prior irradiation; Fig. 7). The PFA is an excellent inflow target vessel and is often used in the setting of an aortofemoral, axillofemoral, or femorofemoral bypass. Often, when utilizing the PFA as an inflow target, the CFA and PFA will require an endarterectomy, and the hood of the bypass is sewn to both the CFA and the proximal PFA. Once the PFA is exposed, proximal and distal vessels and branches are occluded with small vascular clamps or Silastic vessel loops, the patient is systemically heparinized, and a longitudinal arteriotomy is created extending into the PFA. Regardless of whether the PFA is the inflow or outflow vessel, the hood of the graft can be anastomosed to the profunda in a standard end-to-side fashion using fine polypropylene sutures. If there is significant atherosclerotic disease involving the PFA, it may be necessary to perform a concomitant extended profunda endarterectomy. After an extended endarterectomy, particularly if the PFA is the inflow vessel, it may be necessary to close the arteriotomy with a patch, and the graft then can be sewn onto the patch.

Isolated Profundaplasty

The PFA is essential for maintaining limb viability when severe occlusive arterial disease affects the extremity. It provides the primary blood supply to the tissues of the thigh and is also the most important collateral vessel for bypassing an obstructed or occluded SFA. Historically, significant occlusive disease of the CFA bifurcation and PFA has been treated surgically with low risk and sustained patency and clinical benefit. However, atherosclerosis of the PFA is usually focal, preferentially involving the origin and the very proximal portion of the artery in the majority of limbs; this is essential to consider during strategic planning of an initial or proximal SFA intervention. An isolated profundaplasty is indicated when the PFA is the only vessel perfusing the thigh directly and the distal leg via genicular collaterals. The PFA also can prove useful in removal of an infected prosthetic graft from the groin, in salvage of a nonhealing above-knee or below-knee amputation, and as primary treatment for critical limb ischemia when other surgical or endovascular options are limited.

The success of an isolated profundaplasty in improvement of distal flow can be estimated with the profunda popliteal collateral index (PPCI).

$$PPCI = \frac{(AKSP - BKSP)}{BKSP}$$

where AKSP is above-knee segment pressure and BKSP is below-knee segment pressure. A PPCI greater than 0.5 indicates poor collateral development and likely failure of a stand-alone profundaplasty. A PPCI less than 0.19 indicates significant collateral formation and likely a good response to stand-alone profundaplasty. However, it is generally accepted that profundaplasty alone without concomitant distal bypass is not sufficient to provide palpable in-line flow to the limb with significant tissue loss.

A profundaplasty typically is performed with a CFA endarterectomy. After systemic anticoagulation, the femoral vessels are occluded. A longitudinal arteriotomy is initiated in the mid-CFA and extends proximally toward the external iliac artery and distally moving toward the profunda. A deep medial plane is entered with a plaque elevator proximally in the CFA. The plaque is divided, and the endarterectomy is continued into the PFA to the distal extent of the case. Sometimes, eversion is necessary to terminate the PFA plaque with a thin, feathered endpoint in the PFA. Any loose flap is trimmed sharply or tacked down with 7-0 tacking sutures. The arteriotomy is closed with a patch fashioned from bovine pericardium, Dacron, autogenous vein, or a piece of endarterectomized occluded SFA segment. The latter two are the preferred patch materials in the setting of an infected field (Fig. 9).

ENDOVASCULAR INTERVENTION

The PFA disease also can be treated with endovascular interventions. This serves as a viable option for patients who are poor surgical candidates because of severe systemic comorbidities or prohibitive

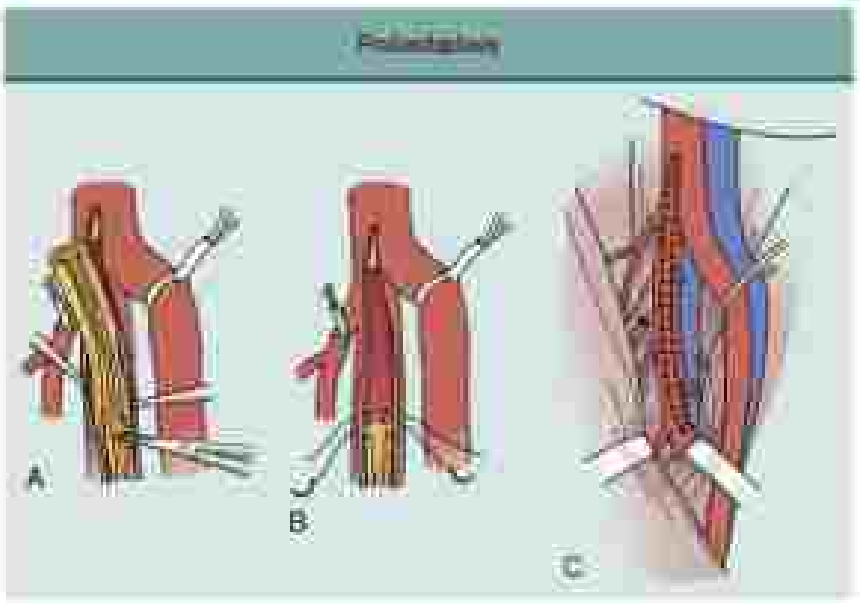

FIG. 9 (A) Endarterectomy of the profunda femoris artery. (B) Patch sutured in place. (C) With patch angioplasty.

challenges to open surgical reconstruction resulting from a hostile groin. It is also indicated as a secondary intervention to maintain the assisted patency of a bypass graft when the PFA was used either as a bypass target or as an inflow source. The access of the PFA for endovascular intervention can be approached from a contralateral retrograde common femoral access in an "up and over" the aortic bifurcation fashion. Alternatively, it can be approached via a retrograde brachial access. The indication for brachial access includes contralateral iliofemoral occlusion, history of aortobifemoral bypass, or presence of a modular bifurcated endograft, as crossing in an up and over technique may be challenging in the latter two settings. The left brachial artery access generally is preferred because it allows access to either lower extremity without crossing the aortic arch. The PFA is best visualized with the imaging intensifier set at an angle of 30 degrees to the ipsilateral oblique view. This offers the best splaying of PFA from the CFA and SFA on angiography. Once the PFA is accessed with a guidewire, balloon angioplasty with or without stenting can be performed. Caution should be used when performing balloon angioplasty at the PFA ostium if the proximal SFA is still open. There is risk of embolization or occlusion of the SFA from the balloon angioplasty. Sometimes, it is worthwhile to place a "buddy wire" into the SFA to maintain access to the SFA for rescue interventions if any of these events occur. The value of PFA angioplasty was demonstrated in a small case series in which PFA angioplasty was the primary treatment in patients with critical limb ischemia and technically demanding open profunda reconstructions, and in patients with expectation strong ischemia at risk of limb disarticulation (Fig. 10).

CONCLUSIONS

The PFA plays a crucial role in maintaining the viability of the lower extremity. It is a versatile vessel that can serve as an outflow target for supragenicular bypass and as an inflow source for infrainguinal bypass. Dedicated profunda angioplasty by either an open surgical or an endovascular approach also may be useful in improving lower extremity perfusion. For vascular specialists involved in lower extremity revascularization, it is a critical skill to possess to preserving the patency of the PFA and to utilize in lower extremity vascular reconstruction procedures.

Popliteal and Femoral Artery Aneurysm

Dawn [illegible] Sang, MD, MHS, and Elliot L. Chaikof, MD, PhD

Although less common than aneurysm of the aorta, femoral and popliteal aneurysms are a diverse and challenging clinical entity with the potential for substantial morbidity and mortality resulting from limb-threatening complications. To deliver optimal care to the patient, the surgeon must consider the etiology, anatomy, distal perfusion, and array of therapeutic options available for treatment of these aneurysms. This chapter discusses both open and endovascular approaches to femoral and popliteal aneurysms, as well as important considerations for the selection of the most appropriate option for an individual patient.

FEMORAL ANEURYSM

True aneurysms and pseudoaneurysms of the femoral artery are the most common type of peripheral aneurysm encountered. Femoral artery aneurysms can be further classified into true degenerative aneurysms, pseudoaneurysms, including iatrogenic, traumatic, or paranastomotic, and infected or mycotic aneurysms. Treatment options vary significantly depending on etiology, presence of infection, and location of the aneurysm and thus the diagnosis, management, and procedural concerns for each subtype will be discussed separately.

Degenerative Femoral Artery Aneurysm

True degenerative aneurysms of the femoral artery are rare. The common femoral artery is the most likely location while isolated aneurysms in the distal superficial femoral artery or profunda femoris artery are less frequent. Population based studies in 1990s estimated a prevalence of femoral aneurysm of 5 per 100,000 in the United States with a heavy male predominance. An important consideration in the patient with a femoral aneurysm is the synchronous presence of a contralateral femoral aneurysm (24%–30%), abdominal aortic aneurysm (50%–90%), or popliteal aneurysm (27%–40%). A large aortic aneurysm should be addressed before, or in conjunction with, an asymptomatic peripheral aneurysm. Approximately one half of patients are asymptomatic at time of the diagnosis of a peripheral aneurysm with symptomatic patients presenting with a palpable mass, pain, or distal ischemia. Ultrasonography cross sectional imaging such as computed tomography (CT) or magnetic resonance imaging can be used to define the size of the aneurysm and to screen for the presence of other aneurysms.

Indication for Repair

Patients presenting with symptoms from local compression or distal ischemia should undergo repair. In the presence of an asymptomatic aneurysm, the goal is to prevent distal ischemia resulting from thrombosis or embolization or, rarely, rupture. Historical series suggested that a femoral aneurysm larger than 2.5 cm should be repaired but more recent retrospective series suggest that a femoral aneurysm smaller than 3.5 cm without intraluminal thrombus is unlikely to present with rupture or embolism. Current consensus guidelines recommend that 3.0 cm be adopted as a threshold for repair. While perioperative mortality for open femoral aneurysm repair is 1%, morbidity may be observed in 10% to 20% of patients.

Approach

Most graft repair of femoral aneurysm is not a preferred approach because of the risk of graft fracture resulting from hip flexion and the preference to avoid occluding the orifice of the profunda femoris artery. In the setting of distal embolization, thromboembolectomy or pharmacomechanical thrombolysis may be used initially to restore distal perfusion.

Open surgical repair of a femoral artery aneurysm requires reconstruction with an interpositional vascular graft (Fig 1). A longitudinal incision is made over the femoral artery with dissection to the retroperitoneal proximal common femoral or distal external iliac artery. Exposure of the distal external iliac artery will require division of the inguinal ligament or a retroperitoneal approach via an oblique incision two to three fingers breadths above the inguinal ligament. Exposure of the superficial femoral and profunda femoris arteries should also be obtained. If dissection of the profunda femoris artery proves difficult because of the size or location of the aneurysm, control of the profunda femoris can be obtained by balloon occlusion using a 3Fr Fogarty catheter positioned 1 cm distal to the orifice after the aneurysm is opened (Fig 2).

Once proximal and distal control has been obtained, the patient is heparinized, vessels are occluded, the sac is opened, and thrombus removed. If the aneurysm is confined to the common femoral artery without involvement of the superficial femoral or profunda femoris artery, the vessel can be reconstructed using an 8- or 10-mm interposition polytetrafluoroethylene (PTFE) or Dacron graft. If the aneurysm is more extensive and involves the superficial femoral or profunda femoris artery, interposition grafting should be performed with either reimplantation or use of a bump graft to the profunda femoris artery. If the profunda femoris artery cannot be revascularized, distal perfusion should be ensured. In the setting of concomitant occlusive disease, femoral-popliteal or femoral-tibial bypass may be required.

Traumatic Femoral Artery Pseudoaneurysm

The incidence of femoral artery pseudoaneurysm following catheterization varies from 0.2% to 1.8%. Risk factors include large sheath size, anticoagulation, obesity, and a high arterial puncture site. Prevention of a pseudoaneurysm is best achieved by routine use of ultrasound-guided vascular access. A femoral pseudoaneurysm may present as a palpable mass, although physical exam can be limited by body habitus

Popliteal and Femoral Artery Aneurysm

Daniel J. Wittig, MD, MHS, and Elliot L. Chaikof, MD, PhD

Although less common than aneurysm of the aorta, femoral and popliteal aneurysms are a diverse and challenging clinical entity with the potential for substantial morbidity and mortality resulting from limb-threatening complications. To deliver optimal care to the patient, the surgeon must consider the etiology, anatomy, distal perfusion, and array of therapeutic options available for treatment of these aneurysms. This chapter discusses both open and endovascular approaches to femoral and popliteal aneurysms, as well as important considerations for the selection of the most appropriate option for an individual patient.

FEMORAL ANEURYSM

True aneurysms and pseudoaneurysms of the femoral artery are the most common type of peripheral aneurysm encountered. Femoral artery aneurysms can be further classified into true degenerative aneurysms, pseudoaneurysms, including iatrogenic, traumatic, or paravascular, and infected or mycotic aneurysms. Treatment options vary significantly depending on etiology, presence of infection, and location of the aneurysm and thus the diagnosis, management, and procedural concerns for each subtype will be discussed separately.

Degenerative Femoral Artery Aneurysm

True degenerative aneurysms of the femoral artery are rare. The common femoral artery is the most likely location while isolated aneurysms in the distal superficial femoral artery or profunda femoris artery are less frequent. Population-based studies in 1990s estimated a prevalence of femoral aneurysm of 5 per 100,000 in the United States with a heavy male predominance. An important consideration in the patient with a femoral aneurysm is the synchronous presence of a contralateral femoral aneurysm (24%–30%), abdominal aortic aneurysm (50%–90%), or popliteal aneurysm (27%–40%). A large aortic aneurysm should be addressed before, or in conjunction with, an asymptomatic peripheral aneurysm. Approximately one half of patients are asymptomatic at time of the diagnosis of a peripheral aneurysm with symptomatic patients presenting with a palpable mass, pain, or distal ischemia. Ultrasonography cross-sectional imaging such as computed tomography (CT) or magnetic resonance imaging can be used to define the size of the aneurysm and to screen for the presence of other aneurysms.

Indication for Repair

Patients presenting with symptoms from local compression or distal ischemia should undergo repair. In the presence of an asymptomatic aneurysm, the goal is to prevent distal ischemia resulting from thrombosis or embolization or, rarely, rupture. Historical series suggested that a femoral aneurysm larger than 2.5 cm should be repaired but more recent retrospective series suggest that a femoral aneurysm smaller than 3.5 cm without intraluminal thrombus is unlikely to present with rupture or embolism. Current consensus guidelines recommend that 3.0 cm be adopted as a threshold for repair. While perioperative mortality for open femoral aneurysm repair is 1%, morbidity may be observed in 10% to 20% of patients.

Approach

Most graft repair of femoral aneurysm is not a preferred approach because of the risk of graft fracture resulting from hip flexion and the preference to avoid occluding the orifice of the profunda femoris artery. In the setting of distal embolization, thromboembolectomy or pharmacomechanical thrombolysis may be used initially to restore distal perfusion.

Open surgical repair of a femoral artery aneurysm requires reconstruction with an interpositional vascular graft (Fig 1). A longitudinal incision is made over the femoral artery with dissection to the retroperitoneal proximal common femoral or distal external iliac artery. Exposure of the distal external iliac artery will require division of the inguinal ligament or a retroperitoneal approach via an oblique incision two to three fingers breadths above the inguinal ligament. Exposure of the superficial femoral and profunda femoris arteries should also be obtained. If dissection of the profunda femoris artery proves difficult because of the size or location of the aneurysm, control of the profunda femoris can be obtained by balloon occlusion using a 3Fr Fogarty catheter positioned 1 cm distal to the orifice after the aneurysm is opened (Fig 2).

Once proximal and distal control has been obtained, the patient is heparinized, vessels are occluded, the sac is opened, and thrombus removed. If the aneurysm is confined to the common femoral artery without involvement of the superficial femoral or profunda femoris artery, the vessel can be reconstructed using an 8- or 10-mm interposition polytetrafluoroethylene (PTFE) or Dacron graft. If the aneurysm is more extensive and involves the superficial femoral or profunda femoris artery, interposition grafting should be performed with either reimplantation or use of a jump graft to the profunda femoris artery. If the profunda femoris artery cannot be revascularized, distal perfusion should be ensured. In the setting of concomitant occlusive disease, femoral-popliteal or femoral-tibial bypass may be required.

Traumatic Femoral Artery Pseudoaneurysm

The incidence of femoral artery pseudoaneurysm following catheterization varies from 0.2% to 1.8%. Risk factors include large sheath size, anticoagulation, obesity, and a high arterial puncture site. Prevention of a pseudoaneurysm is best achieved by routine use of ultrasound-guided vascular access. A femoral pseudoaneurysm may present as a palpable mass, although physical exam can be limited by body habitus

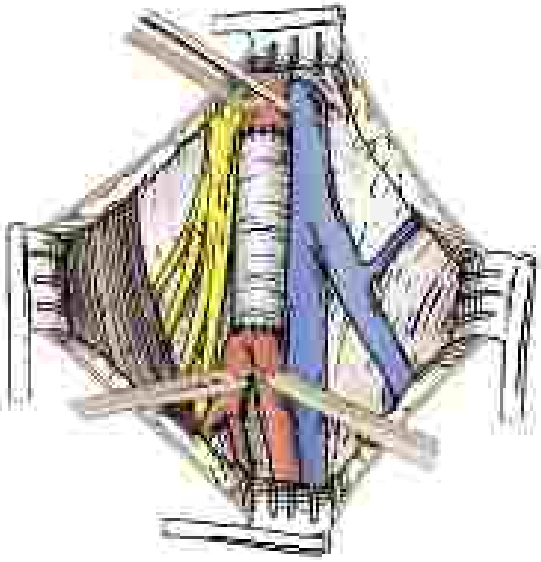

FIG. 9 Interposition graft repair of a femoral artery anastomotic pseudoaneurysm. (From Cronenwett JL, Johnston KW, eds. Rutherford's Vascular Surgery. 7th ed. Philadelphia, PA: Saunders; 2007.)

or hematoma. Duplex ultrasound is the primary means of diagnosis, which allows evaluation of pseudoaneurysm size, neck dimension, and evaluation for the presence of a concomitant arteriovenous fistula.

Indication for Intervention

In the absence of compressive symptoms, including pain, skin blisters, or symptoms of femoral nerve entrapment, small pseudoaneurysms (<1 cm) will often thrombose spontaneously or with ultrasound guided compression, if the patient is not systemically anticoagulated. Follow up ultrasound should be conducted within 2 weeks to confirm thrombosis. A pseudoaneurysm that is larger than 2 cm, symptomatic, or persistent should be treated.

Approach

Ultrasound guided thrombin injection into the pseudoaneurysm sac has become the preferred method of treatment, provided there is a narrow, long neck between the pseudoaneurysm and the femoral artery to minimize the risk of thrombin injection reflux into the artery. Ultrasound guided compression alone, in the absence of thrombin injection, results in option, but is often less well tolerated because of patient discomfort. Therapy typically consists of three successive 20 minute compressions and has a lower success rate than thrombin injection. For thrombin injections, a two-syringe method can be used with one syringe containing 3 mL of saline and the other containing a thrombin solution (1000 U/mL saline) connected using a three-way stop-cock (Fig. 7). Visualization of the tip of the needle can be improved with the use of an echogenic needle. The pseudoaneurysm is punctured and a test injection with saline is visualized on ultrasound. This serves a dual purpose to both confirm needle placement within the pseudoaneurysm, as well as to minimize the risk of accidental injection of thrombin into the native artery, which can result in thrombosis or distal emboli. Small amounts of thrombin are then injected until cessation of flow within the sac is confirmed. If there is a wide neck and the patient is a prohibitive risk for open repair, an intraarterial balloon may be inserted from the contralateral femoral artery and inflated to occlude the pseudoaneurysm during thrombin injection. A follow up ultrasound is performed 24 hours after injection to confirm thrombosis.

Open surgical repair is indicated for a pseudoaneurysm that is expanding, fails nonoperative treatment, displays unsuitable anatomy for thrombin injection, or associated with a painful hematoma, skin breakdown, or symptoms suggestive of femoral nerve entrapment.

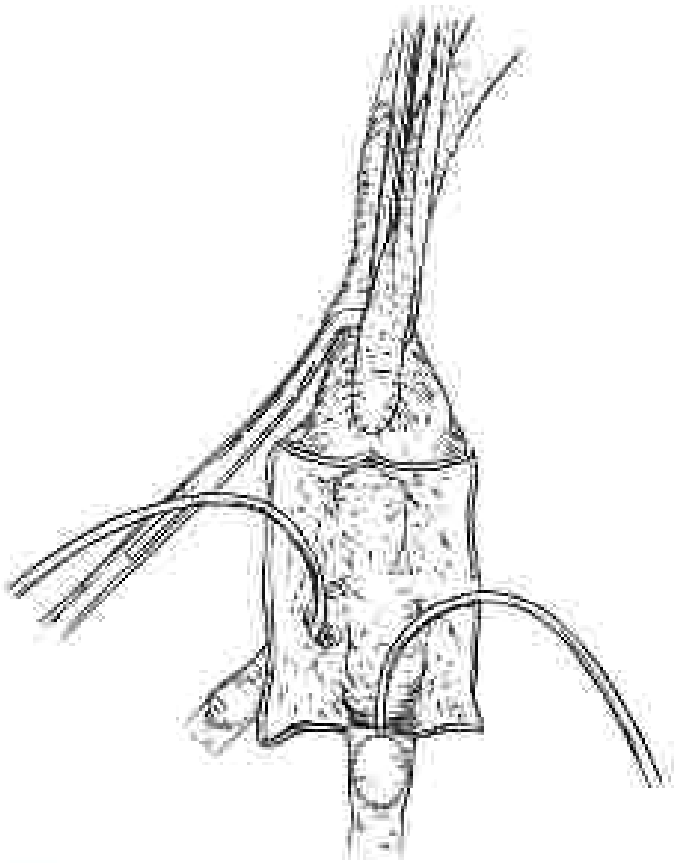

FIG. 8 Distal control of the profunda and superficial femoral arteries can be achieved from within the aneurysm using occluding balloon catheters after the aneurysm is opened. (From Cronenwett JL, Johnston KW, eds. Rutherford's Vascular Surgery and Endovascular Therapy. 8th ed. Philadelphia, PA: Saunders; 2014.)

A longitudinal groin incision over the aneurysm is performed and proximal and distal control achieved. If the sac is inadvertently entered, bleeding is controlled by digital pressure until proximal control is gained, and the puncture site repaired with a 5-0 Prolene suture. The hematoma is evacuated and a 7 mm Jackson Pratt drain placed in the wound.

Anastomotic Femoral Artery Aneurysm

The femoral artery is the most common location of an anastomotic aneurysm associated with an autogenous bypass graft, commonly presenting years after the initial operation as a pulsatile groin mass. An anastomotic pseudoaneurysm may occur from the suture line disruption, infection, or arterial wall degeneration.

Indication for Repair

Operative repair of an anastomotic femoral pseudoaneurysm is recommended if greater than 2.0 cm in diameter or if infection is suspected by the presence of a draining sinus, erythema, or perigraft fluid. CT imaging can assess for the presence of an additional anastomotic pseudoaneurysm at the aortic anastomosis or in contralateral groin. Graft infection should be suspected if exploration reveals a poorly incorporated graft or perigraft fluid. Bacterial cultures should be sent and consideration given to extraanatomic reconstruction or use of an autologous femoral vein or a cryopreserved allograft.

Approach

No Infected Anastomotic Pseudoaneurysm

In the absence of infection, exposure of the nonfemoral graft limb, common femoral, superficial femoral, and profunda femoris arteries

FIG. 3 Duplex ultrasound demonstrating femoral pseudoaneurysm with neck indicated by the arrow. Two syringes with saline and thrombin connected with three-way stopcock used for injection of pseudoaneurysm. [illegible]

should be performed. An ancillary proximal control of the graft limb can be achieved by dividing the inguinal ligament or retroperitoneally via an oblique suprainguinal incision. In a heavily scarred operative field, control of the superficial femoral and profunda femoris arteries can be achieved using Fogarty balloon catheters from within the aneurysm (Fig. 2). Following heparinization, the aneurysm sac is opened, thrombus removed, distal graft resected, and reconstruction performed using an 8-mm interposition PTFE graft, with revascularization of the superficial femoral and profunda femoris arteries.

Infected Femoral Anastomotic Pseudoaneurysm

Graft infection requires removal of the infected graft with restoration of distal perfusion. If infection is suspected, blood cultures should be obtained and empiric antibiotics initiated. CT imaging can help to determine whether infection is limited to the groin or involves the proximal graft or contralateral limb. If infection is confined to the distal limb, the clean portion of the procedure is conducted initially. Proximal control of the uninfected portion of the limb is achieved through a retroperitoneal approach via an oblique incision, extending lateral to the rectus 2 cm above the inguinal ligament, in a point halfway between the distal margin and iliac crest to the midaxillary line. The proximal uninfected graft limb is exposed, avoiding injury to the ureter, and divided with a small margin sent for culture. The distal end of the graft is oversewn, mobilized from surrounding tissues, and displaced distally. Extraanatomic options for revascularization include an iliorenal bypass, an axillofemoral bypass to the superficial femoral artery, or an axillopopliteal bypass. An iliorenal bypass requires creating a tunnel through the medial aspect of the obturator foramen avoiding injury to the obturator artery and nerve, to the superficial femoral artery in the mid-thigh. An end-to-end anastomosis is created using an externally supported PTFE interposition graft between the end of the uninfected graft limb and an end-to-side anastomosis to the superficial femoral artery. Incisions are closed in occlusive sheets using plastic, and the contaminated portion of the procedure performed. A groin incision is made, vascular control obtained, the infected graft removed, and intraoperative cultures sent. Infected tissues should be debrided and the femoral artery defect closed with a vein patch to preserve flow in the profunda femoris artery. A sartorius muscle flap should be mobilized to cover the femoral vessel.

Primary Infected Femoral Artery Aneurysm

A primary infection of the femoral artery must often occur because of a contaminated percutaneous closure system or intravenous drug use. Patients may present with an enlarging pulsatile mass, sepsis, distal emboli, or hemorrhage. Blood cultures are obtained and empiric antibiotics initiated. Goals of the operation include removal of infected tissue, repair of the femoral artery, and restoration of distal perfusion. Options for repair depend upon the extent of local arterial destruction. If limited, a vein patch angioplasty may be feasible, but more extensive arterial destruction may require reconstruction with autologous femoral vein, cryopreserved vein, or an extraanatomic bypass. An obturator bypass may be preferable when the aneurysm is secondary to intravenous drug injection to minimize the likelihood of future needle sticks. Cultures should be obtained and antibiotics continued at least 6 weeks postoperatively. A sartorius muscle flap should be used to provide direct coverage of the arterial repair.

POPLITEAL ANEURYSM

The majority of popliteal aneurysms are true degenerative aneurysms, occur predominantly in men with an estimated incidence of 7 per 100,000 men and only 1 per 100,000 among women. Approximately one-half of patients have bilateral popliteal aneurysms and 30% to 40% have synchronous abdominal aortic aneurysms, which occur in a higher proportion of patients if bilateral popliteal aneurysms are present. Rupture is rare, whereas distal ischemia from thrombosis or embolization is the most common cause of morbidity. Duplex ultrasound, CT, and magnetic resonance imaging are effective methods for diagnosis and establishing size. In contrast to a femoral aneurysm, endovascular treatment of a popliteal aneurysm with a self-expanding covered stent graft may be feasible in many patients. Important considerations to determine whether an endovascular or surgical approach is most appropriate include size of the aneurysm, presence of intraluminal thrombus, compressive symptoms, patency of runoff vessels, and presence of distal ischemia.

Indication for Repair

Asymptomatic aneurysms that are 2 cm or larger in size should be repaired in the healthy adult. All symptomatic popliteal aneurysms should be repaired.

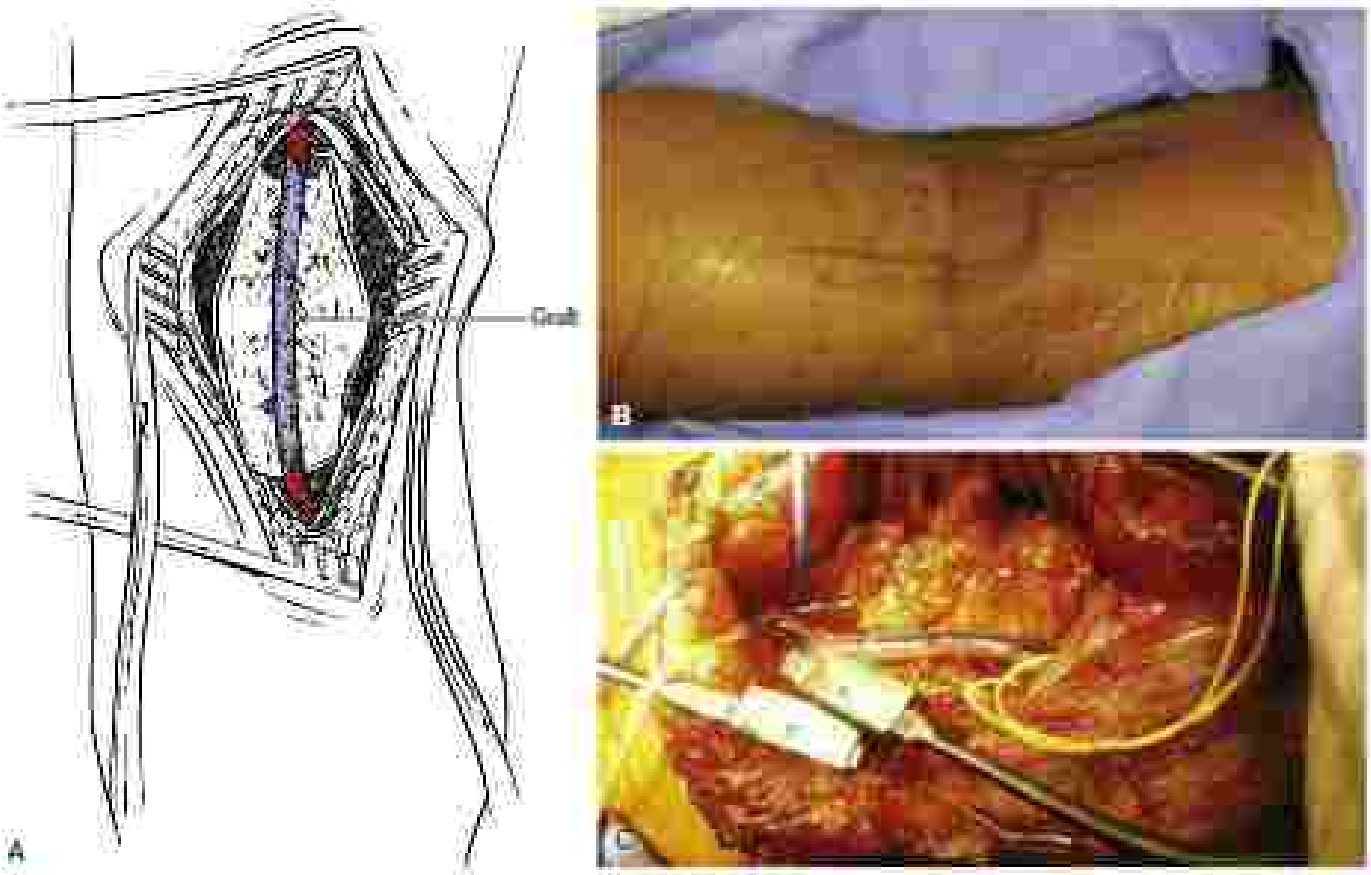

FIG. 4 Posterior approach to popliteal aneurysm repair. (A) Saphenous vein interposition graft. (B) Lazy S incision is used with superior portion beginning medially and extending laterally over fibular crease. (C) Completed saphenous bypass interposition graft. (From Chaikof EL, Lumsden A, Veith FJ. Vascular Surgery and Endovascular Therapy. Anatomy and Technique. Philadelphia: Elsevier; 2014.)

Open Surgical or Endovascular Repair

Open repair consists of revascularization from the distal superficial femoral or proximal popliteal artery to the below knee popliteal or tibioperoneal trunk using a reversed saphenous vein or synthetic bypass graft. A medial surgical approach is common, but a posterior approach is suitable for a localized aneurysm without significant proximal extent. The extent of dissection of a popliteal aneurysm should be minimized to avoid injury of adjacent popliteal veins. Ideally a popliteal aneurysm should be opened and particulate collateral vessels oversewn from within the aneurysm sac. Exclusion of an aneurysm sac alone may be appropriate to select patients without compressive symptoms, but subsequent aneurysm expansion may occur due to collateral vessels. Perioperative mortality associated with open surgical repair is 1% and primary graft patency approximately 90% and 80% at 1 and 5 years, respectively. Endovascular treatment is most suitable for more proximal popliteal or distal superficial femoral artery aneurysms that do not cross the knee or in the patient at high risk for surgical repair because of medical comorbidities. Anatomic criteria dictate proximal and distal landing zones of at least 15 mm in length to achieve an adequate seal for the stent graft. Utilizing antiplatelet treatment is recommended with primary stent graft patency of 80% and 70% at 1 and 5 years, respectively. A recent meta-analysis of surgical and endovascular repair noted that an endovascular approach was associated with a shorter hospital length of stay, fewer wound complications, but led to a greater need for subsequent reintervention.

Approach: Repair in the Absence of Acute Thrombosis

Preoperative vein mapping and a lower extremity CT angiogram or conventional arteriogram are conducted in preparation for repair. Two anatomic approaches are commonly used for surgical repair. The medial approach is preferred for those aneurysms extending beyond the popliteal fossa. The knee is bent and the leg externally rotated. The saphenous vein is harvested and proximal and distal control obtained. A tunnel is created from the above to below the knee popliteal fossa. After heparinization, the aneurysm is opened, arterial branches ligated from within the aneurysm sac, and bypass performed with saphenous vein or a prosthetic graft. If the aneurysm is occluded to avoid extensive dissection and division of the medial musculotendinous attachments of the knee, the artery is suture ligated or divided above and below the aneurysm, prior to revascularization. Following operation, graft surveillance includes quarterly Duplex ultrasound during the first 2 years with annual Duplex imaging thereafter.

The posterior approach is advantageous for an aneurysm confined to the popliteal space. The patient is positioned prone and a lazy S incision is performed with the lateral portion across the posterior fossa crease (Fig. 4). Access to the artery is direct and the popliteal vein can be retracted laterally. Proximal and distal control is established with care to preserve the tibial and peroneal nerves, which usually course lateral to the aneurysm. Following heparinization the sac is opened, collateral vessels suture ligated, and an interposition graft performed. Patients should be maintained on 81 mg of aspirin.

Endovascular repair of a popliteal aneurysm is performed with a flexible nitinol self-expanding covered stent, such as the Viabahn (gore prosthetic (WL Gore, Inc). Characteristically, ipsilateral antegrade femoral artery access is obtained. Angiographic views with the knee in a flexed position is helpful to avoid overlapping stents in the region of maximum flexure. Stent grafts should be oversized by 10% to 20% and if multiple stents are required, 2 cm of overlap is recommended (Fig. 5). Stent graft surveillance includes quarterly Duplex ultrasound during the first 2 years with annual Duplex imaging thereafter.

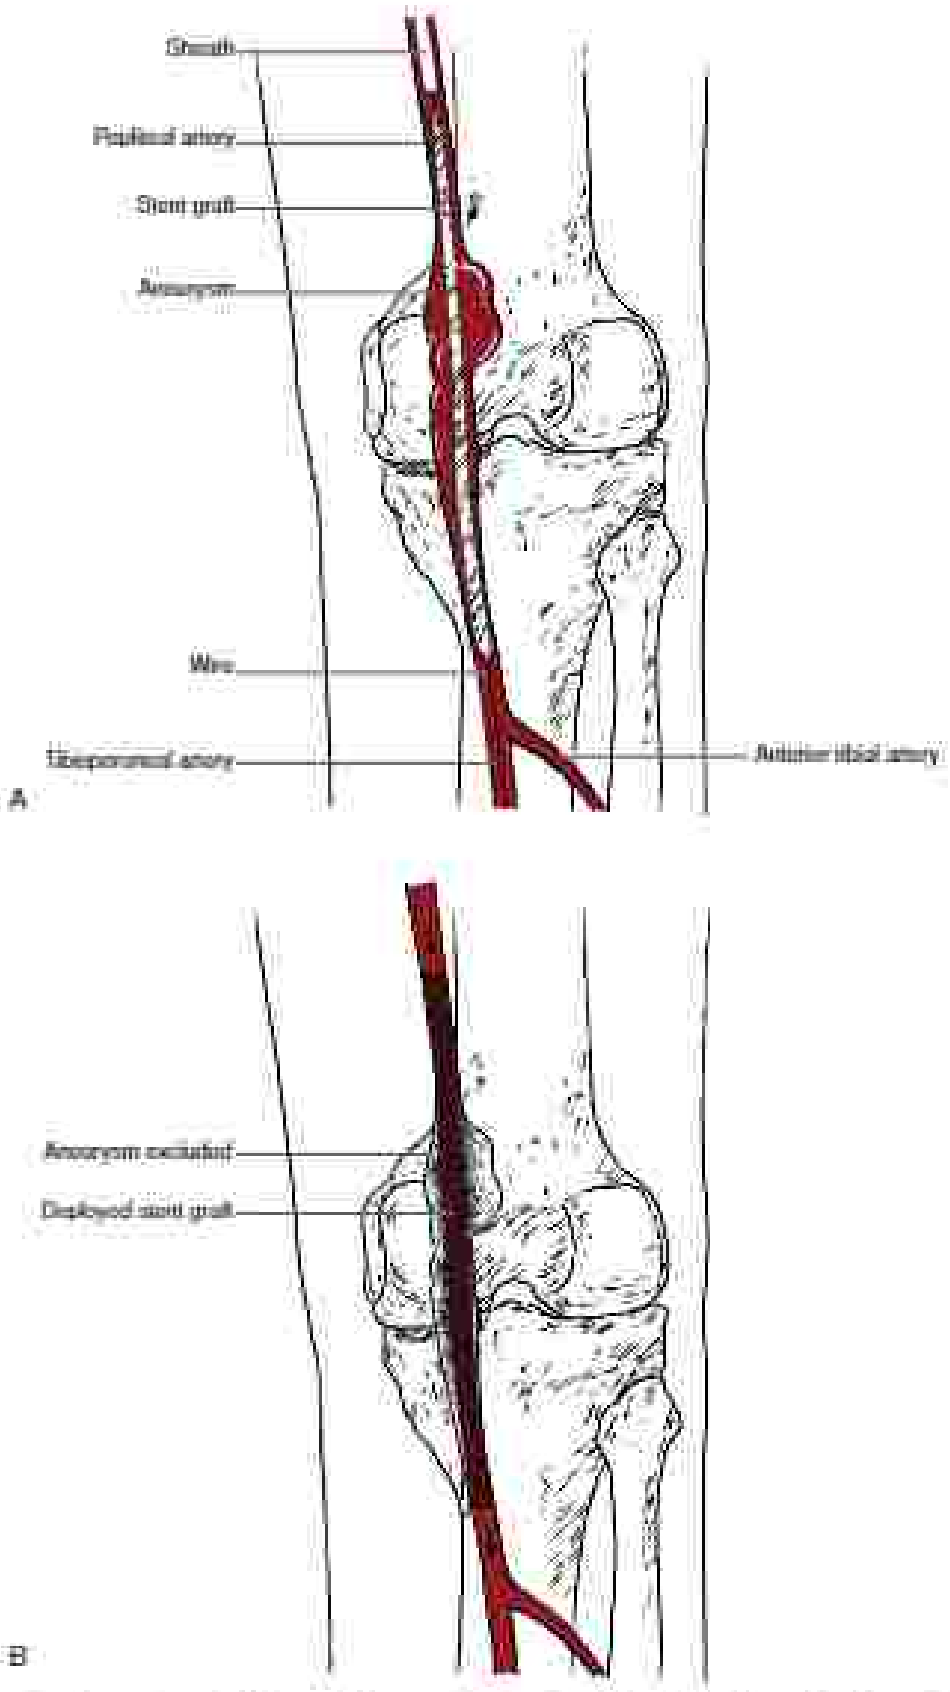

FIG. 5 Covered stent placement excluding popliteal aneurysm. Adequate proximal and distal seal zones are achieved without compromising runoff. (From Chaikof EL, Lumsden E. Atlas of Vascular Surgery and Endovascular Therapy. Anatomy and Technique. Philadelphia: No. Elsevier 2014.)

Approach: Repair in the Presence of Acute Thrombosis

Patients presenting with a popliteal aneurysm and acute limb ischemia, as evident by diminished or absent pedal signals along with pain or motor or sensory findings, have a significantly increased risk for amputation. Anticoagulation is initiated and a CT angiogram or conventional angiography performed to determine if the aneurysm is occluded, the presence and extent of distal embolization, and patency of the infrapopliteal arterial system. If motor and sensory function is intact or symptoms are mild, pharmacomechanical thrombectomy and thrombolysis can be performed followed by definitive endovascular or surgical repair. Should there be evidence of profound motor and sensory dysfunction, the patient should proceed directly to an operating room with imaging capability. Thromboctomy of the popliteal artery and distal tibial vessels can be conducted, the aneurysm excluded, and a bypass performed. A concern for compartment syndrome would necessitate four compartment fasciotomy.

Treatment of Claudication

Courtenay M. Holscher, MD, and Maggie Arnold, MD, FACS

The prevalence of peripheral arterial disease (PAD) increases with age and affects nearly 1 in 6 people age 70 years and older in the United States. Intermittent claudication is often the first symptom of PAD. It is defined as reproducible pain in a specific muscle group that is induced by exercise and relieved by rest. The National Health and Nutrition Examination Survey, a population screening study, found that up to one-half of participants with claudication had never consulted a physician for their symptoms. Most patients (70%–80%) with intermittent claudication will have stable claudication at 5 years after diagnosis without further progression. An additional 20% to 30% will have worsening claudication, and only 1% to 3% will develop critical limb ischemia; however, intermittent claudication must be considered a marker of severe atherosclerotic disease as 10% to 15% of patients will die within 5 years of diagnosis of claudication and another 20% will have a myocardial infarction or stroke. Several risk factors for PAD cannot be modified: older age, African American race, and male gender. Some of the biggest risk factors such as smoking, comorbid diabetes, hypertension, and hyperlipidemia can and should be addressed to decrease the morbidity and mortality associated with intermittent claudication.

CLINICAL PRESENTATION

In normal exercise physiology, there is an increase in blood flow to the active muscle groups to meet the metabolic demands of the activity. Claudication occurs because an arterial obstruction proximal to the affected muscle group limits the exercise-induced increase in blood flow, thereby causing muscle ischemia. This ischemia resolves quickly with rest, when the metabolic demands of the muscle decrease. Although the calf is the most commonly affected muscle group, the buttock or thigh muscles can also be involved. It is important to note that the difference between asymptomatic PAD and intermittent claudication is the activity level of the patient. If patients are sedentary or claudicate, they can develop critical limb ischemia without ever having symptoms of claudication as their PAD progresses.

INITIAL EVALUATION

A thorough history is the key to diagnosing intermittent claudication and should include the distance walked before symptoms develop and how quickly the pain resolves. Claudication tends to be highly reproducible: the symptoms occur every time the patient walks a certain distance, the pain occurs in the same muscle group each time, and the pain is relieved quickly with rest. Although nerve compression, venous congestion, and arthritis are other causes of lower extremity pain, a careful history is typically sufficient to diagnose intermittent claudication. Any history of rest pain, nonhealing wounds, or tissue loss suggests more advanced PAD.

Comorbid coronary artery disease, cerebrovascular disease, and other atherosclerotic risk factors including smoking history, diabetes, hypertension, hyperlipidemia, and chronic kidney disease should be noted. About one half of patients with PAD have coexisting coronary artery disease or cerebrovascular disease. Not only can management of these comorbid diseases slow progression of PAD, the presence of these diseases might also limit the treatment options available to a given patient. For example, a patient with cerebrovascular dementia might require direct supervision for a walking program, making it a caregiver-intensive treatment plan.

A physical examination should assess signs of PAD including weakened or absent distal pulses, absent distal hair growth, and dry skin resulting from sparse gland dysfunction. Wounds and areas of skin breakdown are signs of critical limb ischemia and indicate more advanced PAD. Fontaine's stages and Rutherford's categories provide classification systems for PAD and help to differentiate claudication from critical limb ischemia using the history and physical examination (Table 1).

A critical component of the physical examination and the primary assessment for PAD is the ankle brachial index (ABI), determined for each side as the ratio of the higher of the posterior tibial or dorsalis pedis systolic pressures to the higher of the right or left arm systolic pressures. An ABI of 0.90 or less has high sensitivity and specificity for PAD. A resting ABI of 0.5 to 0.7 predicts claudication. ABIs can be falsely elevated from arterial calcifications, particularly in diabetic patients or those with end-stage renal disease on hemodialysis. In the

Approach: Repair in the Presence of Acute Thrombosis

Patients presenting with a popliteal aneurysm and acute limb ischemia, as evident by diminished or absent pedal signals along with pain or motor or sensory findings, have a significantly increased risk for amputation. Anticoagulation is initiated and a CT angiogram or conventional angiography performed to determine if the aneurysm is occluded, the presence and extent of distal embolization, and patency of the infrapopliteal arterial system. If motor and sensory function is intact or symptoms are mild, pharmacomechanical thrombectomy and thrombolysis can be performed followed by definitive endovascular or surgical repair. Should there be evidence of profound motor and sensory dysfunction, the patient should proceed directly to an operating room with imaging capability. Thromboctomy of the popliteal artery and distal bed vessels can be conducted, the aneurysm excluded, and a bypass performed. A concern for compartment syndrome would necessitate four compartment fasciotomy.

Treatment of Claudication

Courtenay M. Holscher, MD, and Maggie Arnold, MD, FACS

The prevalence of peripheral arterial disease (PAD) increases with age and affects nearly 1 in 6 people age 70 years and older in the United States. Intermittent claudication is often the first symptom of PAD. It is defined as reproducible pain in a specific muscle group that is induced by exercise and relieved by rest. The National Health and Nutrition Examination Survey, a population screening study, found that up to one-half of participants with claudication had never consulted a physician for their symptoms. Most patients (70%–80%) with intermittent claudication will have stable claudication at 5 years after diagnosis without further progression. An additional 20% to 30% will have worsening claudication, and only 1% to 3% will develop critical limb ischemia; however, intermittent claudication must be considered a marker of severe atherosclerotic disease as 10% to 15% of patients will die within 5 years of diagnosis of claudication and another 20% will have a myocardial infarction or stroke. Several risk factors for PAD cannot be modified: older age, African American race, and male gender. Some of the biggest risk factors such as smoking, comorbid diabetes, hypertension, and hyperlipidemia can and should be addressed to decrease the morbidity and mortality associated with intermittent claudication.

CLINICAL PRESENTATION

In normal exercise physiology, there is an increase in blood flow to the active muscle groups to meet the metabolic demands of the activity. Claudication occurs because an arterial obstruction proximal to the affected muscle group limits the exercise-induced increase in blood flow, thereby causing muscle ischemia. This ischemia resolves quickly with rest, when the metabolic demands of the muscle decrease. Although the calf is the most commonly affected muscle group, the buttock or thigh muscles can also be involved. It is important to note that the difference between asymptomatic PAD and intermittent claudication is the activity level of the patient. If patients are sedentary or claudicate, they can develop critical limb ischemia without ever having symptoms of claudication as their PAD progresses.

INITIAL EVALUATION

A thorough history is the key to diagnosing intermittent claudication and should include the distance walked before symptoms develop and how quickly the pain resolves. Claudication tends to be highly reproducible: the symptoms occur every time the patient walks a certain distance, the pain occurs in the same muscle group each time, and the pain is relieved quickly with rest. Although nerve compression, venous congestion, and arthritis are other causes of lower extremity pain, a careful history is typically sufficient to diagnose intermittent claudication. Any history of rest pain, nonhealing wounds, or tissue loss suggests more advanced PAD.

Comorbid coronary artery disease, cerebrovascular disease, and other atherosclerotic risk factors including smoking history, diabetes, hypertension, hyperlipidemia, and chronic kidney disease should be noted. About one half of patients with PAD have coexisting coronary artery disease or cerebrovascular disease. Not only can management of these comorbid diseases slow progression of PAD, the presence of these diseases might also limit the treatment options available to a given patient. For example, a patient with cerebrovascular dementia might require direct supervision for a walking program, making it a caregiver-intensive treatment plan.

A physical examination should assess signs of PAD including weakened or absent distal pulses, absent distal hair growth, and dry skin resulting from sparse sweat gland dysfunction. Wounds and areas of skin breakdown are signs of critical limb ischemia and indicate more advanced PAD. Fontaine's stages and Rutherford's categories provide classification systems for PAD and help to differentiate claudication from critical limb ischemia using the history and physical examination (Table 1).

A critical component of the physical examination and the primary assessment for PAD is the ankle brachial index (ABI), determined for each side as the ratio of the higher of the posterior tibial or dorsalis pedis systolic pressures to the higher of the right or left arm systolic pressures. An ABI of 0.90 or less has high sensitivity and specificity for PAD. A resting ABI of 0.5 to 0.7 predicts claudication. ABIs can be falsely elevated from arterial calcifications, particularly in diabetic patients or those with end-stage renal disease on hemodialysis. In the

TABLE 1 Fontaine's Stages and Rutherford's Categories of Peripheral Arterial Disease

Fontaine Stage	Clinical	Rutherford Grade	Category	Clinical
I	Asymptomatic	0	0	Asymptomatic
IIa	Mild claudication, symptoms at distances >200 m	I	1	Mild claudication
IIb	Moderate to severe claudication, symptoms at distances <200 m	I	2	Moderate claudication
		I	3	Severe claudication
III	Ischemic rest pain	II	4	Ischemic rest pain
IV	Ulceration or gangrene	III	5	Minor tissue loss
		III	6	Major tissue loss

setting of a convincing history and a normal resting ABI, an exercise ABI can demonstrate PAD. This is an ABI measured after walking on a treadmill until symptoms force stopping or for a maximum of 5 minutes.

Vascular laboratory studies including duplex ultrasound, volume plethysmography, and segmental limb pressures including the toes can be useful tools in initial evaluation as well as to identify progression of PAD. Doppler waveforms can identify the level of stenosis and provide a visualization of progressive arterial waveform deterioration (Fig. 1). Volume plethysmography measures changes in limb volume across the cardiac cycle, thereby describing the limb perfusion. Additional imaging such as computed tomographic angiography or digital subtraction angiography is not indicated unless revascularization is being considered.

TREATMENT

The treatment of PAD should include management of comorbid diseases that contribute to PAD progression, pharmacologic management of PAD to include an antiplatelet agent, and a walking program for all patients who can participate. For those who cannot participate or who fail to improve despite a walking program, revascularization can be considered after localization of the causative lesion(s) (Fig. 2).

Management of Comorbid Disease

Smoking Cessation

The association between smoking and PAD has been recognized for more than 100 years. In 1911, Erb reported that claudication was 3 times more likely in smokers compared to nonsmokers. The severity of PAD correlates with the number of cigarettes smoked. Continued smoking with PAD increases risk of amputation, myocardial infarction, and death. For patients with PAD who have undergone bypass grafting, graft failure is 2 to 3 times more likely in those who continue to smoke.

Smoking cessation is a challenging task best addressed through a multidisciplinary approach including behavioral modification, nicotine replacement, and often other pharmacologic management. Behavioral modifications can be taught and supported through group programs. Nicotine replacement through patches, gum, lozenges, inhalers, and nasal sprays can be helpful in addressing nicotine cravings. Little is known about the risks of PAD specifically associated with electronic cigarettes, or vaping, but these should not be considered a method of smoking cessation. Bupropion and varenicline are pharmacologic treatments shown to improve rates of persistent abstinence.

Diabetes

Nearly 1 in 3 patients with diabetes has PAD, and amputation rates in patients with diabetes are as much as 10 times higher than in those without diabetes. Although aggressive glucose control can help decrease risk of cardiovascular events, patients with diabetes and PAD warrant close limb follow-up as well because they have a higher risk for peripheral neuropathy and infectious complications.

Hypertension

All antihypertensive drugs are reasonable approaches to decrease risk of cardiovascular events in patients with hypertension and PAD. Previously β-adrenergic blocking drugs were thought to worsen claudication symptoms, but this was not seen in randomized trials, and often patients with PAD have concomitant coronary artery disease with an indication for β-blockade.

Hyperlipidemia

Dietary modification and statins are important interventions to decrease risk of cardiovascular events in patients with claudication. Although most patients should have a low-density lipoprotein level below 100 mg/dL, those with concomitant coronary artery disease should have more aggressive treatment to decrease low-density lipoprotein to below 70 mg/dL.

Hyperhomocysteinemia

Nearly 1 in 3 patients with PAD have elevated serum homocysteine levels. Although folic acid and vitamin B12 can reduce serum homocysteine levels, there is no evidence that lowering homocysteine levels decreases risk of cardiovascular events. In fact, in a randomized trial of 5522 patients with vascular disease or diabetes randomized to take folate, vitamin B12, and vitamin B6 or placebo, there was a higher rate of hospitalization for unstable angina in the treatment group.

Pharmacologic Treatment for Claudication

Antiplatelet Therapy

Antiplatelet therapy with aspirin at 81 to 325 mg daily has the dual purpose of decreasing risk of limb events and cardiovascular events in patients with claudication. There is no evidence to argue for a particular dose of aspirin. Clopidogrel is an effective alternative in patients with an aspirin allergy or intolerance. Dual antiplatelet therapy with aspirin and clopidogrel has a higher risk of major or life-threatening bleeding without evidence for better limb outcomes.

Symptom Management

Cilostazol is a phosphodiesterase III inhibitor which improves symptoms of claudication through several mechanisms: vasodilator, metabolic, and antiplatelet activity. Cilostazol, compared with placebo treatment, was associated with a longer treadmill walking distance and improved quality of life in several randomized trials. Congestive heart failure is a contraindication for cilostazol use.

Walking Programs for Claudication

The cornerstone of management of intermittent claudication is a walking program (Box 1). Walking should be of sufficient intensity

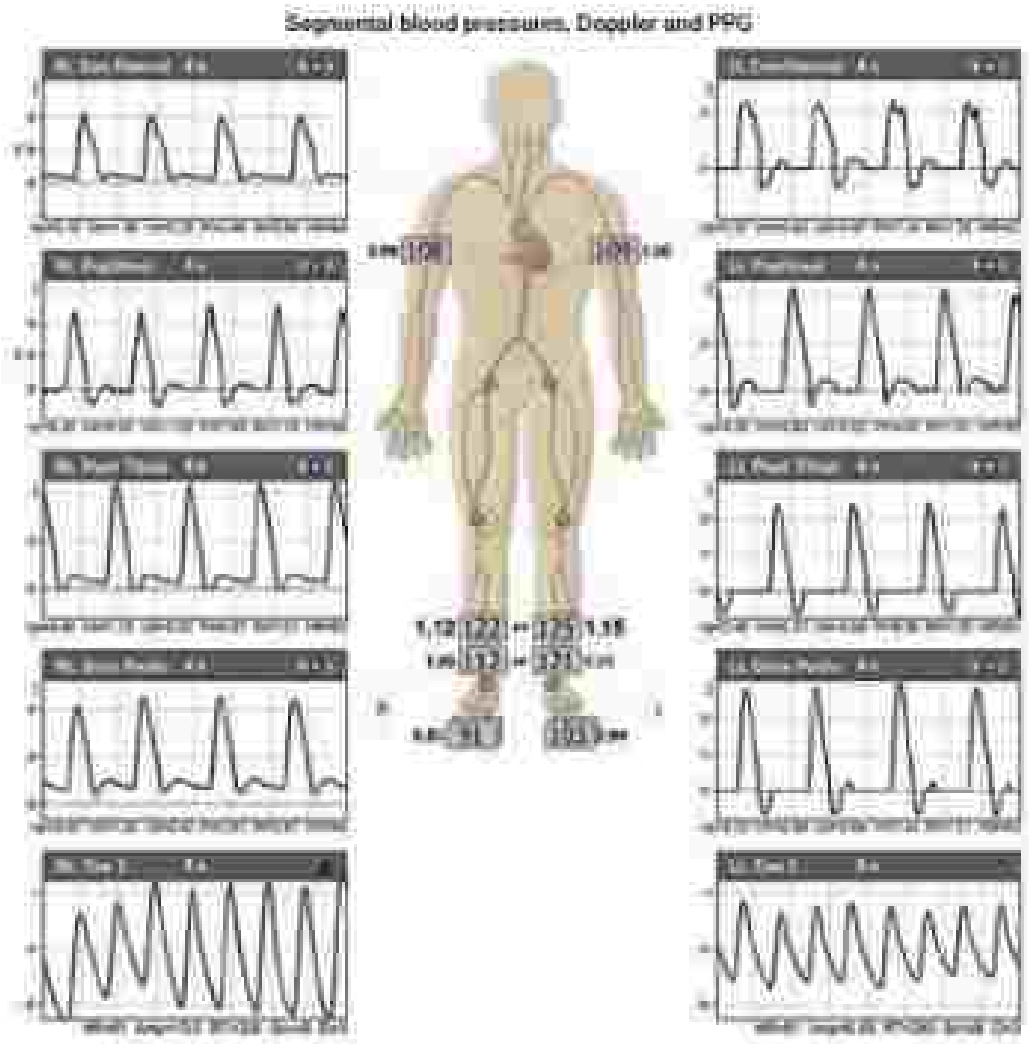

FIG. 1 Lower extremity Doppler waveforms demonstrating right iliac artery obstruction distal with flowing of the proximal waveforms mostly PPG. Photoplethysmography

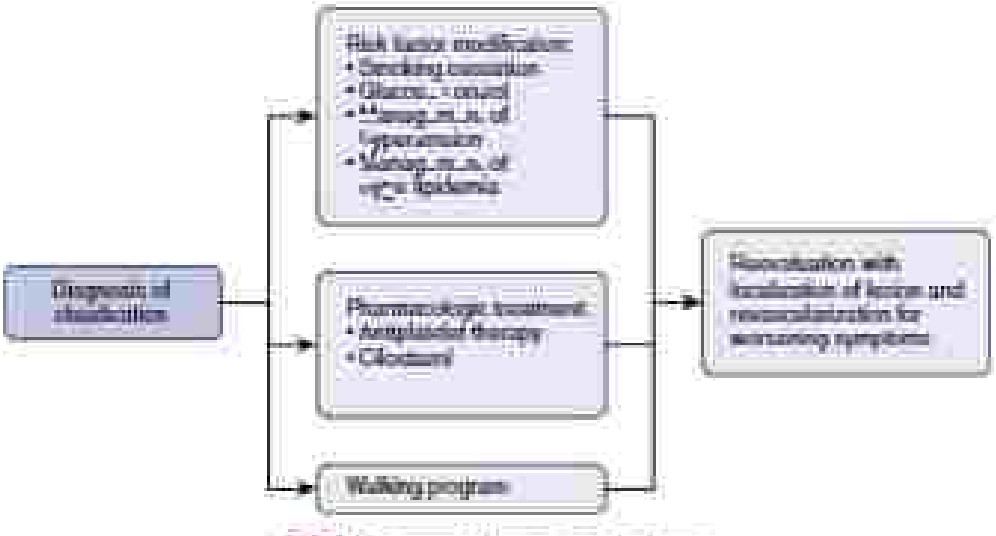

FIG. 2 Management of intermittent claudication.

BOX 1 Sample Walking Program Handout for Patient Use

Benefits of a Walking Program

Using a walking program to treat claudication has many benefits. It not only enables you to walk farther and faster but it also helps with weight reduction and improves your outlook on life (as any exercise program will). The reason that walking is the appropriate exercise for people with claudication (pain in calves or thighs with walking) is that walking is the activity that is limiting you.

Rules of a Walking Program

1. Walk 6 days a week. Take the same day off each week. For example, if you take Sunday off the first week, it is the day you take off each week.
2. Walk at about the same time each day. This enables your walking program to become part of your daily routine. After a week or two, your spouse, family, and friends will know that you will not be available at that time of the day unless they want to walk with you.
3. Start by walking a half hour a day. The time you take to rest (before the pain subsides) counts as part of your one half hour of exercise. Eventually you will be walking intervals for the entire half an hour. After 2 months, increase your time to three-quarters of an hour and only increase it further if you want.
4. A slow, steady walk is the best if you want to walk a maximum distance. Shorter, faster walks with more frequent rests will increase your endurance quicker; our recommendation is to start out with slow, steady walks for the first month or two. After that, try fast, shorter walks several times each week with slow walks on the other days.
5. Remember, the pain that you feel in your legs is not an indication of any damage. It may be annoying and it may make you stop but you are not damaging your muscles. If you can walk with the pain a while, it will help to increase your endurance. Good luck. You will enjoy your walks. Caution: smoking is not permitted while walking.

to induce claudication, followed by a brief period of rest, then continued walking, for a 30- to 60-minute session. Walking programs increase both the total distance walked on treadmill testing as well as the distance walked prior to claudication. The Claudication: Exercise Versus Endoluminal Revascularization trial randomized 111 patients to optimal medical therapy, which included antiplatelet therapy and cholesterol, or to optimal medical therapy plus supervised exercise or optimal medical therapy plus stent revascularization. At 6 months, they found that those managed with optimal medical therapy plus supervised exercise had the best improvement in treadmill walking performance. Although stent revascularization was also associated with an improvement in treadmill walking performance, it carried an additional cost of about $5000 per patient.

Revascularization

A minority of patients who are managed with antiplatelet therapy, cholesterol, a walking program, and comorbid disease management will have progression of symptoms or worsening PAD that requires revascularization. As such, patients with claudication should be evaluated at least yearly by a vascular surgeon or specialist. Discussion of revascularization for claudication should give particular consideration to complications, long term patency, and the patient's individual operative risk. A detailed discussion of revascularization techniques is included elsewhere in this text.

Pseudoaneurysms and Arteriovenous Fistulas

Amani D. Politano, MD, MS, and Erica L. Mitchell, MD, MEd

A pseudoaneurysm (PSA), or false aneurysm, is a focal outpouching of an artery that does not include all layers of the arterial wall. This outpouching may be contained by the adventitia or may consist only of a rim of fibrous tissue containing thrombus and arterial flow to communicate with a defect in an artery. In other words, it is a contained bleed from a focal site of the arterial wall. PSAs most commonly result from iatrogenic injury to the arterial wall but can be attributed to other etiologies as well (Box 1). Injury to the arterial wall results in pulsatile flow into the perivascular space, dissection into surrounding tissues, and hematoma formation. A persistent passage from the injury site results in a flow channel, or neck, leading into a false lumen, or sac, with to-and-fro arterial flow between the artery and the sac (Fig. 1). PSAs, unlike true aneurysms, lack all three normal elements of the arterial wall and are therefore at increased risk of rupture with potentially catastrophic bleeding. Postcatheterization femoral artery PSAs are the focus of this chapter.

RISK FACTORS

PSAs are most frequently seen as a complication related to percutaneous arterial access. The common femoral artery (CFA) is the most common access site for catheter based interventions for cardiologists, interventional radiologists, and vascular surgeons alike. Technique for accessing the common femoral artery vary and include direct palpation of the pulse, fluoroscopic guidance, and ultrasound guided access. The latter has become more prevalent because it results in fewer access related complications and is considered the standard of care. Nonetheless, the incidence of femoral artery PSAs is increased when the puncture site is not in the CFA, but rather in the external iliac artery, superficial femoral artery (SFA), or profunda femoral artery (PFA).

Risk factors for the development of iatrogenic PSAs associated with arterial access procedures are listed in Box 2. These can be divided into procedure related and patient related factors. Increased complexity of intraarterial intervention has been shown to increase the risk of vascular complications. Therapeutic interventions such as arterial angioplasty and stenting, atherectomy, and thrombolytic therapy have a higher rate of PSA formation (2%–8%) than diagnostic procedures (0.05%–2%). Related to both the therapeutic nature and complexity of interventions, larger diameter catheter or sheath use is also correlated with higher rates of PSA

Pseudoaneurysms and Arteriovenous Fistulas

Amani D. Politano, MD, MS, and Erica L. Mitchell, MD, MEd

A pseudoaneurysm (PSA), or false aneurysm, is a focal outpouching of an artery that does not include all layers of the arterial wall. This outpouching may be contained by the adventitia or may consist only of a rim of fibrous tissue containing thrombus and arterial flow to communicate with a defect in an artery. In other words, it is a contained bleed from a focal site of the arterial wall. PSAs most commonly result from iatrogenic injury to the arterial wall but can be attributed to other etiologies as well (Box 1). Injury to the arterial wall results in pulsatile flow into the perivascular space, dissection into surrounding tissues, and hematoma formation. A persistent passage from the injury site results in a flow channel, or neck, leading into a false lumen, or sac, with to-and-fro arterial flow between the artery and the sac (Fig. 1). PSAs, unlike true aneurysms, lack all three normal elements of the arterial wall and are therefore at increased risk of rupture with potentially catastrophic bleeding. Postcatheterization femoral artery PSAs are the focus of this chapter.

RISK FACTORS

PSAs are most frequently seen as a complication related to percutaneous arterial access. The common femoral artery (CFA) is the most common access site for catheter-based interventions for cardiologists, interventional radiologists, and vascular surgeons alike. Techniques for accessing the common femoral artery vary and include direct palpation of the pulse, fluoroscopic guidance, and ultrasound-guided access. The latter has become more prevalent because it results in fewer access-related complications and is considered the standard of care. Nonetheless, the incidence of femoral artery PSAs is increased when the puncture site is not in the CFA, but rather in the external iliac artery, superficial femoral artery (SFA), or profunda femoral artery (PFA).

Risk factors for the development of iatrogenic PSAs associated with arterial access procedures are listed in Box 2. These can be divided into procedure-related and patient-related factors. Increased complexity of intraarterial intervention has been shown to increase the risk of vascular complications. Therapeutic interventions such as arterial angioplasty and stenting, atherectomy, and thrombolytic therapy have a higher rate of PSA formation (2%–8%) than diagnostic procedures (0.05%–2%). Related to both the therapeutic nature and complexity of interventions, larger diameter catheter or sheath use is also correlated with higher rates of PSA

BOX 1 Etiologies of Pseudoaneurysm Formation

Acquired

Trauma
Penetrating
Gunshot wound
Stab wound
Blunt or stretch
Proximity injury

Infection
Drug abuse
Contamination
Bacterial seeding

Iatrogenic

Anastomotic
- Patch
- [illegible]

Vascular access

Spontaneous

Vasculitis
Behçet's disease
Polyarteritis nodosa

BOX 2 Risk Factors for Pseudoaneurysm Formation

Procedural Factors

Therapeutic vs Diagnostic Procedure
Complex procedures
Larger sheath size (>8Fr)
Prolonged procedure
Simultaneous artery and vein cannulation
Use of closure device

Puncture site
Low (CFA or PFA) or high (EIA) puncture sites
Inadequate compression of puncture site

Patient Factors

Advanced age
Female gender
Obesity
Hypertension
Hemodialysis dependent end stage renal disease
Concurrent anticoagulation
Calcified vessels
Steroid use

EIA, external iliac artery; PFA, profunda femoral artery; SFA, superficial femoral artery.

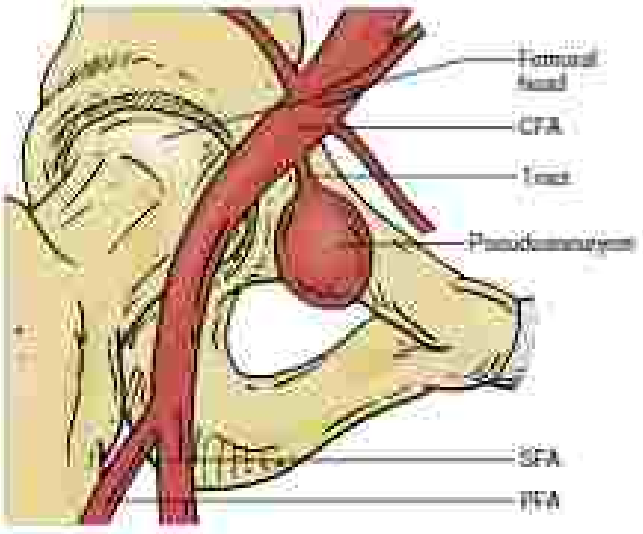

FIG. 1 Common femoral artery (CFA) pseudoaneurysm and neck (necks). PFA, Profunda femoral artery; SFA, superficial femoral artery.

FIG. 2 Mass effect of a pseudoaneurysm causing pressure necrosis of the overlying skin.

formation. Other procedural related factors include simultaneous arterial and venous puncture, urgent versus elective procedures, the use of arterial closure devices, and insufficient duration of puncture site compression after the sheath is removed. PSA formation is less common when ultrasound guidance or fluoroscopic localization of the medial one third of the femoral head is used for femoral artery puncture. Patient related risk factors contributing to PSA formation include advanced age, female gender, obesity, preprocedural thrombocytopenia, and postprocedural antiplatelet or anticoagulation use.

Diagnosis

PSAs may be asymptomatic or may present with mild tenderness to palpation or swelling in the groin after catheterization. Although this is the most common presentation of a PSA, more severe symptoms can be more related to the mass effect of a PSA and associated hematoma. Large PSAs with associated hematoma may result in skin necrosis (Fig. 2) and/or compression of nerves and vessels in the groin. Lower extremity swelling, deep venous thrombosis, and/or ischemia secondary to vessel compression are rare but serious findings. Ruptured PSAs may present with hemodynamic collapse and significant groin or thigh swelling.

Any patient who experiences pain disproportionate to that expected after a percutaneous procedure should undergo evaluation to exclude PSA. Examination should include a thorough peripheral pulse examination, documentation of the ankle brachial index, and limited ultrasonography of the vasculature in the affected groin. Laboratory assessments such as decreased platelet count (<150,000/L) or elevated D dimer values have been shown to correlate with diagnosis of a PSA or duplex.

The diagnostic examination of choice is duplex ultrasound (DUS, 5- to 7-MHz linear transducer). Because B-mode imaging alone is unable to differentiate a PSA from a hematoma, color Doppler should be used to enhance the diagnostic accuracy of ultrasound (sensitivity, 94%; specificity, 97%) as it allows for identification of pulsatile flow within the sac. The typical appearance of a PSA on DUS is demonstrated in Figs. and 4. Active flow within the PSA sac is often referred to as to and fro flow or a yin yang pattern. The PSA sac size (maximal diameter) and the length and width of the neck should be measured with DUS because they are important for guiding treatment options. If an arterial duplex examination cannot be performed or if the results are equivocal, computed tomography imaging (with intravenous contrast) can be used to make the diagnosis of PSA (Fig. 5) or to obtain more detailed anatomic information to plan a surgical repair. In addition to assessing the PSA, DUS or computed tomography angiography should assess for secondary injuries, including posterior arterial injury and presence of an arteriovenous fistula.

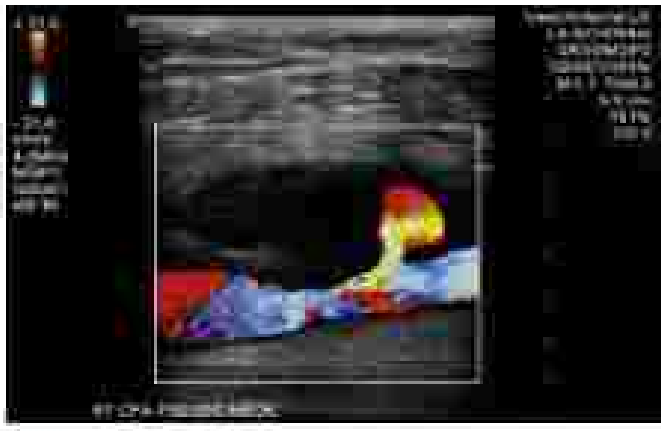

FIG. 3 Duplex ultrasound findings of a pseudoaneurysm include a fluid collection adjacent to the femoral artery a high-velocity jet through the arterial wall and a neck or communication with the artery.

Treatment

A number of treatment options for iatrogenic femoral PSAs exist. The therapeutic choice depends on the PSA size, neck characteristics, and the patient's symptoms. Treatment options include observation, ultrasound guided compression (USGC), percutaneous ultrasound-guided thrombin injection (USTI), and open surgical repair. More recently, creative therapeutic approaches have been described, including more advanced endovascular options and endoluminal interventional techniques.

Observation

Studies have shown that the majority of small PSAs (<2–3 cm) thrombose spontaneously within 4 weeks for patients not on anticoagulants. Conservative management, or a watch and wait policy, has been advocated for small and asymptomatic PSAs. Spontaneous

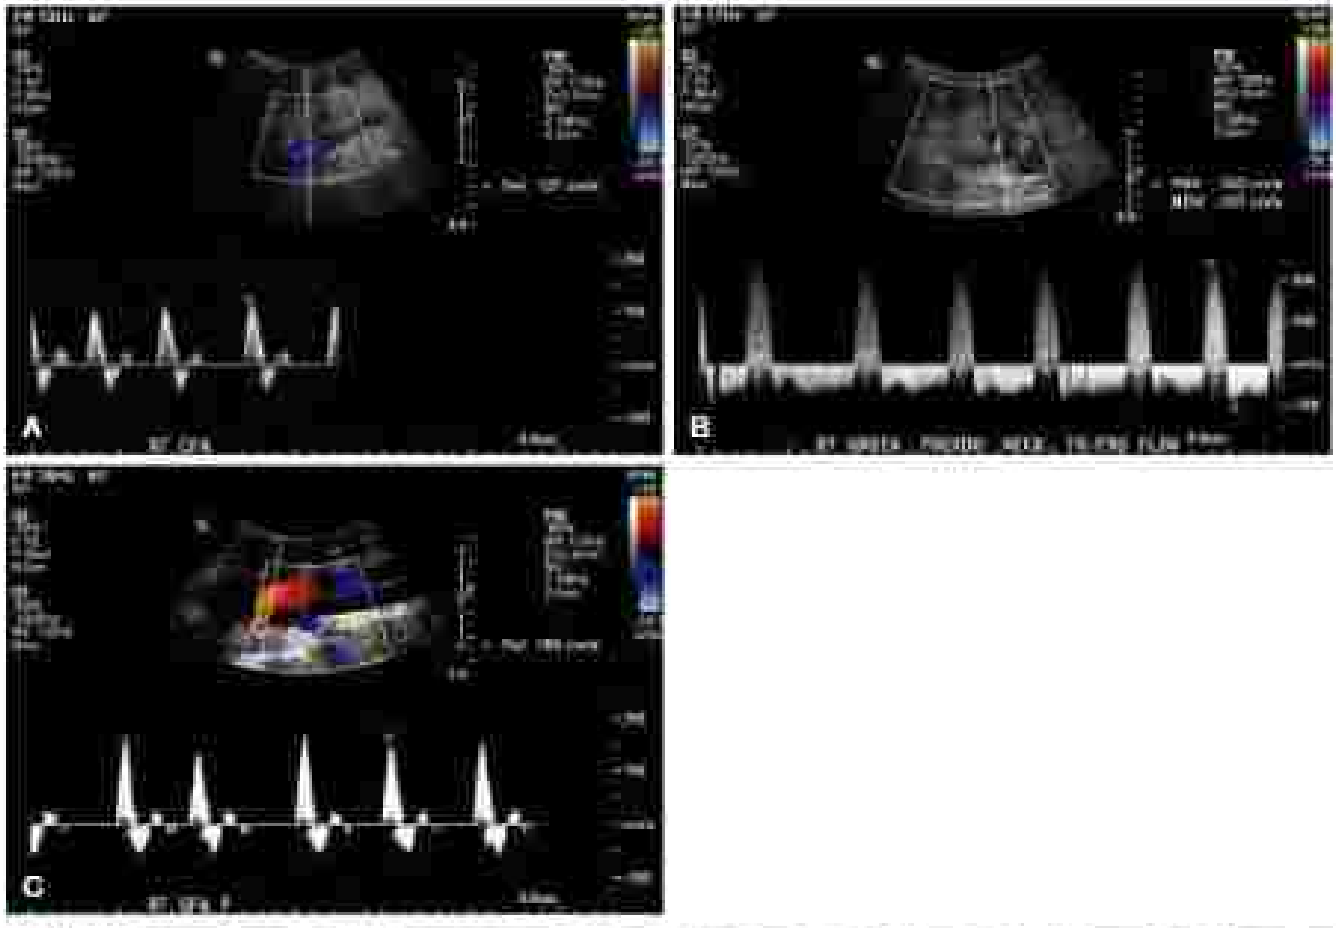

FIG. 4 Duplex ultrasound examination of a (B) pseudoaneurysm as well as the (A) proximal and (C) distal vessels. Duplex ultrasound shows a patent common femoral artery and superficial femoral artery. The pseudoaneurysm arises from the common femoral artery with classical peak systolic velocities and to-and-fro flow representing systolic flow entering the common femoral artery and retrograde diastolic flow exiting the pseudoaneurysm.

resolution can be unpredictable; therefore patients with small PSAs require periodic surveillance with DUS. The disadvantage of this watch and wait policy is that patients undergoing surveillance may have activity restrictions, discomfort with serial DUS, and prolonged hospital stays. PSAs that do not thrombose risk enlargement and additional complications, thus adhering to a scheduled follow up is critical. Patients considered at risk for being lost to follow up should undergo definitive treatment initially.

USGC

USGC therapy has been shown to be a safe and noninvasive method for treatment of PSAs with success rates ranging between 73% and 93%. Ultrasound is used to identify the PSA sac and neck. The ultrasound transducer is positioned over the PSA neck, and pressure is applied until there is obstruction of flow within the neck and sac. During compression of the PSA, cessation of flow within the PSA is verified with continual duplex imaging, whereas flow in the native artery is preserved. Blind manual compression has also been described but lacks continual monitoring to ensure complete occlusion of flow into the PSA, and therefore risks inadequate treatment, especially when even small position changes by the patient can require the operator to make similar adjustments to maintain complete occlusion. Compression is usually held for increments of 10 to 15 minutes. This is repeated until successful PSA sac thrombosis is achieved, or until a discretionary failure time is met. Compression times average 35 minutes for acute PSAs and 51 minutes for more chronic PSAs (>10 days).

Limitations of USGC include both patient specific and operator dependent factors. Patient specific concerns include the location of the PSA, body habitus, and ability to be compliant with or tolerate compression. Supratarsal PSA compression is generally not recommended because it may result in PSA rupture and inability to quickly control bleeding. Brachial artery PSAs usually require open decompression because of symptomatic nerve compression. It is more technically challenging to both achieve and maintain compression in an obese patient without operator fatigue. Compression is also time consuming and may not be well tolerated by patients. Conscious sedation can be administered with improved tolerance but requires increased resources (such as advanced nursing care and appropriate bed/unit placement during the procedure and recovery) and may increase overall risk to the patient. Operator-dependent factors include variable or inadequate compression, fatigue, and the time-dependent nature of the task.

Predictors of poor outcome with USGC include concomitant anticoagulation, large PSA size (>4 cm), and patient obesity. Patients with these negative predictors generally have lower technical success rates (55%–75%), higher recurrence rates (20%), and greater complication rates (3.6%) than patients without these factors. Complications and contraindications to USGC are listed in Box 3.

UGTI

UGTI has become the treatment of choice for midsize mid-post catheterization PSAs (2–5 cm). Thrombin is injected into the PSA sac for immediate thrombosis of the PSA (Fig. 6 and Box 4). This is an off-label use of thrombin; it is US Food and Drug Administration–approved for topical use only. UGTI is contraindicated in the setting of lower extremity ischemia, infection, arteriovenous fistula, and pregnancy.

UGTI has several advantages compared with USGC for the treatment of PSAs. The procedural time is shorter, the procedure is better tolerated by patients, and the technical success rate is greater (>96%). In addition, UGTI can be used effectively in the setting of concomitant anticoagulation or for supratarsal PSAs. The ability to perform this procedure in the outpatient setting or at the bedside also reduces the relative cost. Complications of UGTI include arterial thrombosis (<2%), PSA rupture, treatment failure, or allergic response to bovine thrombin. Arterial thrombosis has been associated with the treatment of small PSAs (<2.5 cm). Complications related to neck length are more variably reported; arterial thrombosis has been shown not to be related to short neck length (<5 mm) although necks shorter

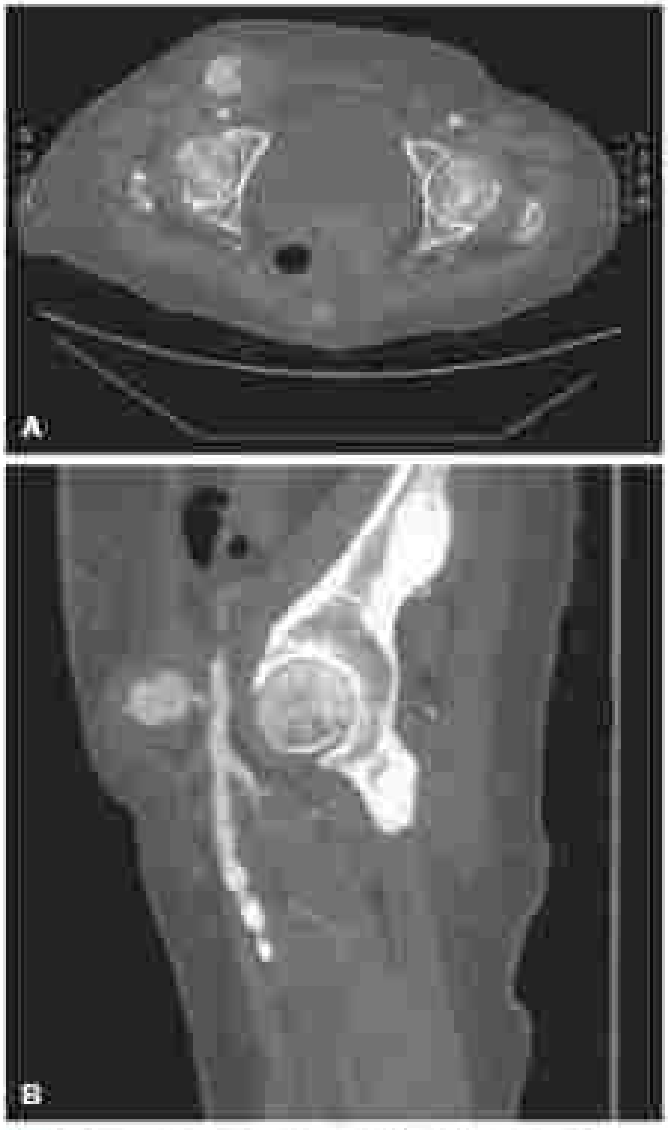

FIG. 5 Computed tomography angiographic axial (A) and sagittal (B) images of a right femoral pseudoaneurysm and neck.

BOX 3 Complications and Contraindications of Ultrasound-Guided Pseudoaneurysm Compression

Complications

Rapid enlargement of the PSA sac
Skin necrosis
Distal embolization
Venous thrombosis
Rupture

Contraindications

Peripheral ischemia
Cutaneous ischemia
Infection
Surgical graft
Supratarsal PSA

PSA, pseudoaneurysm.

FIG. 6 Ultrasound-guided thrombin injection. A 1-mL syringe containing bovine thrombin (1000 units/mL) and a 5-mL syringe with sterile normal saline flush are connected to a three-way stopcock fitted with a 22-gauge needle (40 mm or 1.6 mm). If the pseudoaneurysm (PSA) is deeper than 1.75 cm, then a 22-gauge × 4-cm Echotip needle (Cook Medical) can be used. The PSA sac is visualized in transverse and longitudinal views on duplex ultrasound. The thrombin port is placed in the "off" position and the saline port is placed in the "on" position. The needle and transducer are kept parallel as the needle is advanced under ultrasound guidance. Punctures into the sac at least superficial and far from the PSA tract. Proper needle placement is confirmed by aspiration of blood and a small injection of saline will produce a flash of color on duplex ultrasound. The thrombin port is placed in the "on" position and the saline port is placed in the "off" position. Thrombin is then injected into the PSA sac in 0.2-mL aliquots until there is cessation of blood flow in the PSA sac and tract. This can usually be achieved in seconds. The tract should never be directly injected because of the risk of thrombosis of the native artery. An average of 500 units (0.5 mL) of thrombin (range, 50–1000 units) is required to thrombose the PSA sac. An arterial duplex is repeated 24 hours postprocedure to check for recurrence (0.a., 9.) and to rule out postprocedure complications.

BOX 4 Three-Way Stopcock Technique of Ultrasound-Guided Thrombin Injection

1. The patient's groin is prepped and draped in the usual sterile fashion.
2. The distances from the skin to the most superficial portion of the PSA sac and the distance to the PSA tract are measured.
3. The skin and subcutaneous tissue are infiltrated with 1%–2% lidocaine.
4. A three-way stopcock is prepared as described in Fig. 6.
5. The needle is advanced under DUS guidance to the depth measured in step 2 and the PSA sac is entered superficially. Entry into the PSA sac is confirmed by aspiration of blood and proper placement of the needle tip is confirmed by saline injection on DUS. The needle must be in the PSA sac and not in the tract, artery, or vein.
6. The thrombin port is turned on and the saline port is turned off. Thrombin is injected gently in 0.2-mL aliquots until the PSA sac and tract are thrombosed or until 1.0 mL (1000 units) of thrombin is used.
7. If there are >2 PSA sacs, then the most superficial sac is injected first.
8. If the tract persists, do not inject directly into the tract. Follow the patient as the tract normally thromboses within 24 hours.
9. A DUS is repeated 24 hours postprocedure to check for recurrence (0%–9%) and rule out postprocedure complications such as arterial or venous thrombosis.
10. The procedure may be performed on an outpatient basis with the patient discharged immediately after injection.
11. A PSA that recanalizes after thrombin injection may be reinjected on follow-up visit.

DUS, duplex ultrasound; PSA, pseudoaneurysm.

than 2 mm have demonstrated increased risks of embolic complications. Exposure to bovine factor V may cause some patients to form antibodies that cross react with human factor V and induce coagulopathy. Patients who undergo UGTI should have a follow-up duplex in 24 to 48 hours to ensure continued thrombosis of the PSA.

Endovascular Repair

Covered stents have been widely used in the treatment of aneurysm, but their use in femoral PSAs is limited. Current barriers include high cost, lower patency rates, the need for larger delivery systems, and the lack of long-term data. Endovascular repair is not recommended if treatment of the PSA requires placing a stent across the groin crease or across the origin of the PFA. Covered stent use can be considered for treatment of suprainguinal PSAs where the distal endpoint of the stent does not cross beneath the inguinal ligament. Complications unique to covered stents include infection, migration, and thrombosis. Long-term duplex surveillance is required postprocedure to monitor for in-stent restenosis and stent patency.

The use of covered stents for treatment of infected PSAs is not recommended. In the setting of advanced cancer, definitive treatment of a PSA via covered stent placement with or without coiling and covering of the PFA may have a role. Covered stent use has also been described in intravenous drug abusers who present with ruptured PSAs or acute sepsis associated with an infected PSA. In these settings, the stent provides a bridge to arterial reconstruction by obtaining hemostasis or allowing for surgical debridement of the infected tissue before reconstruction. When definitive arterial reconstruction is anticipated, preservation of the profunda is recommended.

Some authors have described using endovascular balloon occlusion of the origin of the PSA at the time of thrombin injection to reduce the risk of intra-arterial thrombosis, especially if there are concerns for a wide or short neck. This risks across the complications as the contralateral femoral access site but has been performed successfully. Case reports have also described the use of various arterial closure devices (e.g., Angio-Seal and Star-Close, Perclose ProGlide, Amplatzer plug) to treat iatrogenic PSAs.

Open Surgical Repair

Noninfected Pseudoaneurysms

Patients with contraindications to compression therapy or thrombin injection should be considered for open surgical repair. These include peripheral or cutaneous ischemia, infection, surgical graft, large suprainguinal PSAs, or those who present with complicated PSAs (i.e., rapid enlargement, distal embolization, rupture) (Fig. 7). Repair of suprainguinal PSAs requires retroperitoneal access to achieve proximal control of the iliac vessels. Hybrid open and endovascular techniques, in which endovascular balloon occlusion is used to provide proximal and/or distal control through either the PSA itself or via contralateral femoral access, have been described.

Once proximal and distal control are obtained, the pseudoaneurysm can be opened and the defect repaired. Often, the actual arterial injury is small and can be repaired with a simple, interrupted polypropylene suture. The back wall of the artery should be inspected to ensure no posterior arterial injury. Patch angioplasty may be required if the arterial wall is significantly damaged or if there is luminal narrowing of the artery with primary repair. Any hematoma should be evacuated, and in the setting of a large tissue defect or hematoma, drain placement may be necessary. Complications associated with open surgical repair include wound infection, bleeding, lymphocele, radiculopathy, perioperative myocardial infarction, and death.

FIG. 7 Noninfected femoral pseudoaneurysm requiring open surgical repair because of its large size and overlying skin necrosis.

Infected Pseudoaneurysms

Compression or injection of infected PSAs is contraindicated, and they must be treated promptly and aggressively. Management includes appropriate antibiotic coverage, debridement of infected tissue, and arterial repair or replacement with autogenous vein graft. Arterial ligation without revascularization is reserved for aggressive bacterial infection and may be associated with intermittent claudication or limb loss. Muscle flap coverage of the tissue defect may be required to further protect the repair. Except for rare circumstances, such as providing immediate hemostasis of an acute rupture with planned definitive management including dose removal once the patient is stabilized, endovascular occlusion with covered stents should be avoided.

Alternate Percutaneous Methods

Perianeurysmal saline injection has been described as an alternate method to either US-C or US-T for PSAs. This technique uses ultrasound guidance to position a needle outside of the artery along the PSA neck and injects normal saline (30–80 mL) into the extravascular tissue to cause external compression of the PSA neck and obliteration of flow within the PSA. A second injection on the opposite side of the PSA neck is sometimes required, and the injection is followed with five minutes of manual compression.

Cyanoacrylate glue has also been used for percutaneous treatment of PSAs. Various reports describe intrasac injection, much like thrombin, or injection into the collapsed PSA walls. This second method uses ultrasound guided compression of the PSA before injection, with subsequent injection of small aliquots of the glue directly into the opposed walls of the PSA. Compression is continued for 5 minutes, and injection and compression are repeated if signs of separation are seen with gradual release of compression. Administration of cyanoacrylate glue has also been described using contralateral arterial access to provide balloon occlusion across the pseudoaneurysm neck during injection.

Although studies have demonstrated initial success with each of these techniques, further investigation is warranted.

Anastomotic Pseudoaneurysms

Anastomotic PSAs are an infrequent but important late complication of prosthetic arterial reconstruction (Fig. 8). The femoral arterial anastomosis is the most common site for an anastomotic PSA (12.6%). The presence of an anastomotic PSA should raise suspicion of a graft infection, and treatment should be planned with this in mind. An anastomotic PSA is typically composed of a fibrous pseudocapsule surrounding an occult graft infection or arterial degeneration to a previously endarterectomized artery. Because anastomotic PSAs are unpredictable and are associated with a high incidence of rupture, they should be treated early and aggressively.

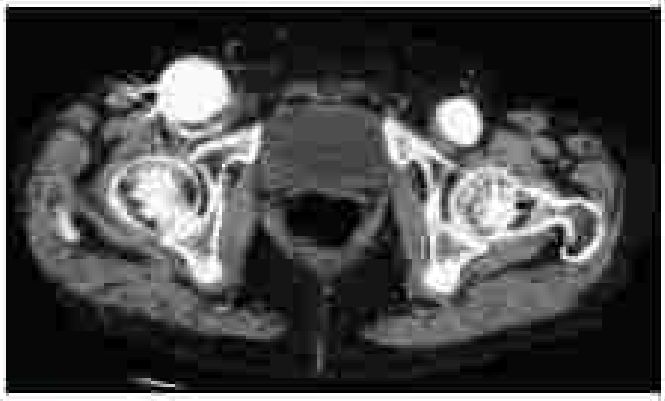

FIG. 8 Ruptured femoral anastomotic pseudoaneurysm. This patient underwent bilateral common femoral endarterectomies and an aortobifemoral bypass for aortoiliac occlusive disease 15 years before presentation. There are no fluid collections or abnormal tissues within the tissue surrounding the pseudoaneurysm, which suggests no evidence of infection. On physical examination and laboratory testing, no clinical evidence of infection was found.

Observation can only be recommended for patients with very small PSAs, prohibitive operative risk, or short life expectancy. Operative repair is generally recommended for all groin anastomotic PSAs greater than 3 to 4 cm in diameter. If there is no evidence of infection and a well-incorporated graft, interposition graft replacement of the degenerative aneurysmal portion of the existing graft can be performed safely. If the graft is infected, removal and replacement of all infected graft and tissue is necessary. Revascularization may require extra-anatomic bypass grafting through a noninfected field or replacement of the infected conduit with autogenous femoral vein. Grossly infected arterial beds may require coverage with sartorius or rectus femoris muscle flaps. Endovascular repair of femoral artery anastomotic PSAs has been reported, however, it is generally not recommended in the setting of infection or when stenting would result in occlusion of the PFA origin.

ARTERIOVENOUS FISTULA

An arteriovenous fistula (AVF) is an abnormal communication between an artery and vein. Although AVFs can be congenital, they are more frequently iatrogenic or traumatic. Femoral AVFs almost always develop secondary to penetrating injuries or percutaneous vascular interventions. The incidence of postcatheterization femoral AVF is 0.2% to 2%. Patient related risk factors include female gender, hypertension, and ongoing anticoagulation. Age and morbid obesity have not been identified as risk factors. Procedural related risk factors include left sided groin punctures and high levels of anticoagulation (>12,500 units of perioperative heparin). Postcatheterization femoral AVFs will be the focus of this section.

Diagnosis

The diagnosis of an AVF in the extremities can be made with history and physical examination. Physical examination may reveal a bruit or thrill on auscultation and a thrill on palpation. A tic and/or holosystolic/diastolic bruit at the puncture site is pathognomonic for an AVF, and the intensity of the sound on auscultation typically correlates with the size of the fistula. Large AVFs may also present with unilateral limb swelling, mild to severe limb ischemia (claudication or tissue loss), or heart failure. If physical examination findings are not diagnostic but an AVF is suspected, DUS can be a useful diagnostic tool. AVFs are characterized by high arterial peak systolic velocities proximal to the fistula resulting from low resistance at the fistula site. Reduced arterial flow distal to the fistula is secondary to shunting, and

bidirectional or turbulent flow is seen at the fistula site. The venous side of the AVF demonstrates pulsatile flow with elevated peak systolic velocities that result from mixing of arterial and venous flows.

Treatment

Iatrogenic AVFs, unlike traumatic AVFs, may close spontaneously. Studies have shown that 20% to 50% of iatrogenic postcatheterization femoral AVFs resolve spontaneously. Iatrogenic AVFs are more likely to persist in patients with chronic renal insufficiency or concomitant steroid use. Patients with small or low flow AVFs may never develop symptoms and can be safely managed conservatively. Repair is indicated for all symptomatic patients.

Open Surgical Repair

Surgical repair is the traditional method for treating femoral AVFs and is associated with morbidity and mortality rates of 27% and 8%, respectively. The principle of surgical repair is obliteration of the connection between the artery and vein with restoration of vessel patency. Proximal and distal control of both the artery and vein is required. Because AVFs can result in significant enlargement of venous structures, operative repair can be associated with significant blood loss. Preoperative placement of arterial or venous balloons for intraoperative occlusion may help decrease blood loss during the repair, and cell saver and rapid infusion devices can be used when large volumes of blood loss are anticipated. Repair can be achieved with primary closure of the fistula tract, vein patch angioplasty, or interposition bypass graft.

Endovascular Repair

Endovascular treatment of iatrogenic or traumatic femoral AVFs is becoming more commonplace. Catheter based interventions are indicated for high risk surgical patients, or those who present with "hostile" anatomy such as morbid obesity, previous femoral interventions, or groin surgery and those with aneurysmal enlargement of venous collaterals. The most common endovascular method of treating AVFs is placement of a covered stent to the arterial system to occlude the connection between artery and vein. Contraindications to endovascular repair include patients in whom endovascular stenting will obliterate the IVA or cross the groin crease. The placement of common femoral artery stents also precludes use of that site for future endovascular access. Venous stents are usually reserved for iliac vein or inferior vena cava AVF occlusion after unsuccessful intraarterial stent placement. Superficial femoral artery stent grafts for iatrogenic femoral AVFs have a reported 1- and 4-year primary patency of 76% and 57%, respectively, and a 4-year secondary patency rate of 80%.

Alternative endovascular methods for treatment of AVFs include embolization with coils, cyanoacrylate glue, collagen or gelatin, and others. During embolization, percutaneous venous access with balloon inflation may be required to occlude the venous outflow if there is a short tract connecting the artery and vein. Using detachable coils and packing smaller coils after larger coils can reduce inadvertent placement. Amplatzer plug occlusion of a femoral PSA with concomitant AVF has also been described.

Axillofemoral Bypass Grafting in the Twenty-First Century

John Fatchen, MD, and Evan C. Lipsitz, MD, MTM, FACS

Treatment of atherosclerotic and other occlusive disease of the abdominal aorta and iliac arteries remains a common challenge to vascular surgeons practicing today, despite continued advances in surgical and endovascular technology. Aortoiliac disease affects 8 to 10 million people in the United States annually. Currently, there remains no official consensus on the natural history of aortoiliac occlusive disease. Although some suggest that about one third of patients will progress to occlusive aortic disease involving the renal and mesenteric aorta within 5 to 10 years of diagnosis, others suggest that such estimates is rare. Over time, as the disease progresses to complete occlusion resulting from the accumulation of plaque and vessel wall calcification, patients may experience a wide range of symptoms including thigh and/or buttock claudication as well as impotence in male patients, the constellation of symptoms known as Leriche's syndrome. Anatomic characteristics and disease progression notwithstanding, the symptoms experienced by the patient guides treatment, as in other areas of occlusive vascular disease. Patients presenting with concurrent infrainguinal arterial disease will likely experience more severe claudication and possibly rest pain or tissue loss.

Absent lower extremity pulses, including femoral, are the hallmark of the disease. The diagnosis can be confirmed with a number of additional diagnostic tests. Pulse volume recordings will show decreased waveforms throughout all segments of the lower extremities. Arterial duplex of the aortoiliac segments estimates the degree of stenosis or occlusion and may be combined with infrainguinal duplex to assess the overall circulation to the extremity. Traditional angiography provides detailed anatomic information of the abdominal aorta, pelvis, and lower extremity arterial tree and identifies patterns of collateral flow around obstructions. In the setting of aortoiliac occlusive disease, femoral artery access may be difficult or impossible, and the use of alternative access sites, such as the brachial artery may be required. Computed tomography angiography is a very useful imaging modality for defining aortoiliac anatomy and planning intervention. Computed tomography angiography delineates the degree and extent of vessel calcification and identifies the course of any previous bypass procedures. Magnetic resonance angiography can also be useful although it is not as robust as computed tomography angiography for this application.

Treatment algorithms for aortoiliac disease have gone through several iterations over the past half-century. Initial attempts at surgical reconstruction before the development of synthetic grafting involved femoral and aortoiliac endarterectomy. Although effective, such extensive surgical repair was fraught with high rates of morbidity

bidirectional or turbulent flow is seen at the fistula site. The venous side of the AVF demonstrates pulsatile flow with elevated peak systolic velocities that result from mixing of arterial and venous flows.

Treatment

Iatrogenic AVFs, unlike traumatic AVFs, may close spontaneously. Studies have shown that 20% to 50% of iatrogenic postcatheterization femoral AVFs resolve spontaneously. Axillofemoral Bypass Grafting in the Twenty-First Century

John Fatchen, MD, and Evan C. Lipsitz, MD, MBA, FACS

Treatment of atherosclerotic and other occlusive disease of the abdominal aorta and iliac arteries remains a common challenge to vascular surgeons practicing today, despite continued advances in surgical and endovascular technology. Aortoiliac disease affects 8 to 10 million people in the United States annually. Currently, there remains no official consensus on the natural history of aortoiliac occlusive disease. Although some suggest that about one third of patients will progress to occlusive aortic disease involving the renal and mesenteric aorta within 5 to 10 years of diagnosis, others suggest that such estimates is rare. Over time, as the disease progresses to complete occlusion resulting from the accumulation of plaque and mural wall calcification, patients may experience a wide range of symptoms including thigh and/or buttock claudication as well as impotence in male patients, the constellation of symptoms known as Leriche's syndrome. Anatomic characteristics and disease progression notwithstanding, the symptoms experienced by the patient guides treatment, as in other areas of occlusive vascular disease. Patients presenting with concurrent infrainguinal arterial disease will likely experience more severe claudication and possibly rest pain or tissue loss.

Absent lower extremity pulses, including femoral, are the hallmark of the disease. The diagnosis can be confirmed with a number of additional diagnostic tests. Pulse volume recordings will show decreased waveforms throughout all segments of the lower extremities. Arterial duplex of the aortoiliac segments estimates the degree of stenosis or occlusion and may be combined with infrainguinal duplex to assess the overall circulation to the extremity. Traditional angiography provides detailed anatomic information of the abdominal aorta, pelvis, and lower extremity arterial tree and identifies patterns of collateral flow around obstructions. In the setting of aortoiliac occlusive disease, femoral artery access may be difficult or impossible, and the use of alternative access sites, such as the brachial artery may be required. Computed tomography angiography is a very useful imaging modality for defining aortoiliac anatomy and planning intervention. Computed tomography angiography delineates the degree and extent of vessel calcification and identifies the course of any previous bypass procedures. Magnetic resonance angiography can also be useful although it is not as robust as computed tomography angiography for this application.

Treatment algorithms for aortoiliac disease have gone through several iterations over the past half-century. Initial attempts at surgical reconstruction before the development of synthetic grafting involved femoral and aortoiliac endarterectomy. Although effective, such extensive surgical repair was fraught with high rates of morbidity

and mortality, especially in high risk populations. By the 1970s, the use of Dacron as aortoiliac and aortobifemoral replacement grafts in open abdominal procedures had completely supplanted aortoiliac endarterectomy. With 5 year patency rates of aortobifemoral grafts reaching and exceeding 90% throughout the contemporary literature, it remains the gold standard for aortoiliac occlusive disease for good risk patients. During this same era of surgical advancement, the first extraanatomic axillofemoral bypass was performed by Blaisdell and Hall for several high risk patients with iliac occlusive disease. This technique was quickly adopted by Sauvage in the 1980s for bilateral occlusive disease, with bifurcated grafts of varying configurations allowing for anastomosis to both femoral arteries. Axillofemoral bypass is an extraanatomic bypass as it does not course along the normal anatomic path of the vessels being bypassed. Grafts are tunneled subcutaneously, avoiding a midline laparotomy and aortic cross clamping, significantly reducing operative stress, making this a favorable choice in high risk patients. Early patency rates were good, plagued by graft compression and unequal flow rates, with reported three year patency as low as 39%; however, the introduction of externally supported prostheses, including polytetrafluoroethylene grafts with external ring reinforcement dramatically improved the durability of the axillofemoral bypass.

INDICATIONS

There are a number of indications for axillofemoral bypass. Axillofemoral bypass is typically performed in patients with chronic arterial insufficiency and symptoms of critical limb ischemia such as disabling claudication, rest pain, ischemic ulceration, or gangrene. The most common etiology of this insufficiency is atherosclerotic, although it may also result from radiation damage to vessels. There are other applications for the procedure including acute occlusion or aortic dissection resulting in acute lower limb ischemia or the presence of an infected aortic graft that is to be removed. Additional indications include those where axillofemoral bypass may be deemed unfavorable because anatomic considerations such as a heavily calcified aorta, a hostile abdomen or the need for peritoneal dialysis, or medical comorbidities such as severe cardiopulmonary, renal or hepatic disease, active sepsis, fistula, or the presence of intraabdominal infection (Box 1). The timing of intervention depends on the indication for the operation as well as the overall health status of the patient.

The recent and rapid advancement of endovascular therapy has had a significant effect on the treatment of aortoiliac disease. Younger, otherwise healthier patients with aortoiliac disease who might otherwise have undergone open revascularization in the past have been treated successfully with endovascular interventions. As a result, many of the patients who ultimately require surgical repair are older and have more significant comorbidities, and are not considered candidates for direct aortic reconstruction, leaving axillofemoral bypass as the best option.

With the ongoing incorporation of advancing endovascular techniques in the standard practice of the vascular surgeon, the rates of direct aortoiliofemoral or extraanatomic revascularization has decreased substantially over the past decade, traded instead for transluminal angioplasty and stenting of diseased aortic iliac segments. Now, such open revascularization techniques appear to be reserved for patients with either extensive aortoiliac occlusive disease or those who have already failed catheter based intervention. The debate between endovascular versus open intervention has been ongoing in the vascular literature for the past two decades. The Trans Atlantic Inter Society Consensus for the Management of Peripheral Arterial Disease (TASC) guidelines and subsequent updated guidelines (TASC II) were published in the early 2000s by an international consortium of vascular, cardiovascular, and radiologic societies to bring together evidence based data to provide recommendations on treatment modalities for lower extremity peripheral arterial disease. Atherosclerotic lesions of the aortoiliac and femoropopliteal systems were classified based on degree and length of occlusion. And although initial guidelines suggested that endovascular techniques were more suited for short segment (TASC type A or B) iliac and femoral lesions, percutaneous technology has now advanced and being successfully applied to long segment (TASC type C or D) lesions.

Another indication for axillofemoral bypass is the use as a temporary bypass or shunt, either to decrease lower extremity ischemia time during placement of a fenestrated aortic endograft or to allow for continued limb, visceral, and renal perfusion during thoracic aortic clamping for thoracoabdominal aortic reconstruction. Axillofemoral bypass has also been described as a temporary extraanatomic shunt in patients with blunt infrarenal aortic injury. And although its use as temporary adjunct may be appropriate in patients with aneurysmal disease, especially in patients with prior kidney transplant, axillofemoral bypass is not definitive repair in this patient population. Rather, these patients require either open or endovascular repair of the diseased aortic segment to prevent risk of future aneurysmal degeneration and rupture.

In patients with combined aortoiliac and infrainguinal occlusive disease, establishment of inflow to the femoral level via axillofemoral bypass may be enough to relieve symptoms, and the infrainguinal disease treated subsequently as needed. For patients with common femoral artery occlusion, patients undergoing axillofemoral bypass may require outflow to either the superficial femoral, profunda femoris, or popliteal artery. In the cases of severe limb threatening ischemia, concomitant axillofemoral and infrainguinal reconstruction may be required.

BOX 1 Indications for Axillofemoral Bypass

Anatomic
- Heavy aortic calcification

Hostile abdomen
- Previous surgery
- Excess fat or scarring
- Pelvic irradiation

Peritoneal dialysis

Comorbid conditions

Severe cardiopulmonary disease

Severe renal or hepatic disease

Otherwise unfit for major surgery

Infection
- Infected intraabdominal graft
- Infected aortoiliac graft

Mycotic aneurysm

Aortoenteric fistula

Temporary
- Bypass for temporary visceral and renal ischemia during endovascular aortic reconstruction

PREOPERATIVE EVALUATION

Patients selected for axillofemoral bypass require the same thorough preoperative evaluation as patients undergoing any major vascular procedure. Because these patients tend to be older and have more advanced comorbid conditions, a complete medical evaluation should be obtained, and the patients medically optimized before surgery.

The choice of inflow axillary artery is based on several physical examination and diagnostic imaging findings. Blood pressure measurements should be performed and compared between both upper extremities. If there is a significant difference (>10 mm Hg) between both sides, the arm with the higher pressure is chosen for inflow. If such a difference exists at baseline, this may prompt further evaluation with upper extremity pulse volume recordings or Doppler waveform analysis to help identify possible proximal occlusive disease and guide further therapy. Patients with abnormal noninvasive testing

may benefit from subsequent imaging with either computed tomographic angiography or magnetic resonance angiography. Digital subtraction angiography of the upper extremity, aortic arch, and great vessels allows for both diagnostic imaging and possible intervention for any lesions identified before bypass. In cases with no notable disease on either side, the right axillary artery is typically selected for inflow because of the higher incidence of atherosclerotic vascular disease to develop in the left subclavian artery. If axillary inflow is adequate and equal in both extremities, some surgeons will advocate the placement of the axillary limb on the side ipsilateral to the more symptomatic leg. Grafts should not be based off limbs where there is evidence of distal arm ischemia or a functioning dialysis access. Additional anatomic considerations include the presence of thoracic outlet syndrome, breast cancer, the presence of an ostomy or abdominal hernia, or other previous surgery. Finally, in patients undergoing intervention in the setting of intraabdominal sepsis, who in the future may be candidates for subsequent aortic reconstruction via a left retroperitoneal approach, the right axillary artery should be used for inflow to avoid interference of a left sided graft with a retroperitoneal approach.

OPERATIVE TECHNIQUES

Axillofemoral bypass is nearly always performed under general anesthesia in the supine position. Although the procedure can be performed under local anesthesia with sedation for patients with prohibitive surgical risks, this requires a large volume of local anesthetic to cover the extensive areas encompassed by the incisions and subcutaneous tunnels. The room should be kept warm to prevent hypothermia, and body warming adjuncts should be considered given the large surface area that is exposed. The donor arm is abducted to 90 degrees. A rolled towel is placed between the scapulae to facilitate exposure of the medial most portion of the axillary artery, and exposure of the lateral body wall that will be the site of the subcutaneous tunnel. The donor artery arm is prepped circumferentially to facilitate passive movement of the arm and direct inspection of the axillary anastomosis during the procedure, ensuring that undue tension is not placed on the anastomosis. The chest, abdomen, pubis, and upper thighs are prepped and covered with iodophor-coated clear plastic drapes, permitting for wide exposure. Perioperative antibiotics are always administered, and care is taken to avoid direct contact of prosthetic graft to skin.

A transverse infraclavicular incision is made approximately one fingerbreadth below the lateral one third of the clavicle and carried through the clavipectoral fascia, exposing the pectoralis major muscle. The pectoralis major muscle fibers are split in the horizontal plane and pushed superiorly and inferiorly, exposing the deep fascia and, beneath it, the investing fascia of the axillary artery, vein, and brachial plexus elements. The pectoralis minor muscle may be retracted slightly laterally to enhance exposure of the first portion of the axillary artery; however, in most cases, it is preferable to divide the muscle to prevent excessive graft tension or kinking. The axillary vein is first identified and retracted caudally. Frequently, this requires the identification and ligation of crossing venous tributaries. The axillary artery is then exposed from the clavicle medially to the pectoralis minor muscle laterally and encircled with silicone vessel loops, taking care to isolate and preserve smaller branches. Given the proximity of the brachial plexus, it is best to avoid excessive use of electrocautery when exposing the axillary artery through the length of the incision.

The femoral arteries are exposed in the standard fashion with longitudinal or oblique groin incisions. This allows for the isolation and control of the superficial and profunda femoris arteries and gives the operator flexibility in the placement of the femoral anastomoses. Longitudinal incisions will facilitate adjunctive procedures such as femoral endarterectomy and/or patching when required. The femoral anastomoses are generally placed in the distal common femoral artery over the takeoff of the profunda femoris artery. Variation of the site of anastomosis is dependent on the location and degree of disease in the iliofemoral system and, if necessary, direct anastomosis to the superficial femoral or profunda femoris artery is possible. If the common, superficial, and deep femoral arteries are all occluded, direct reconstruction to the popliteal artery may be required.

Once the vessels are exposed, a long, standard tunneling device is used to create a subcutaneous tunnel between the axilla and groin. The graft should be tunneled in the midaxillary line to prevent kinking and should initially take a lateral course under the pectoralis minor that follows a gentle curve in the lateral chest wall. A countercincision can be made just below the inferior aspect of the pectoralis major on the lateral chest wall to facilitate tunneling. For patients undergoing bilateral grafts, a second suprapubic tunnel is created between the subcutaneous space over the inguinal ligaments into the exposed femoral incision using either a tunneling device or large aortic clamp.

Systemic heparin is given after graft tunneling. An externally supported polytetrafluoroethylene or Dacron graft is used as the conduit. All anastomoses are performed in an end to side fashion and are typically constructed using 5‐0 or 6‐0 polypropylene suture. The axillary anastomosis is generally performed first. It is very important to place the axillary graft anastomosis along the anterior surface of the axillary artery as medially as possible to avoid tension on the anastomosis site when the arm is abducted. It should also be performed anterior to the axillary vein to prevent compression and allow for easier access to this region should a second operation become necessary. The graft is cut in a beveled fashion and the anastomosis created at a somewhat acute angle (Fig. 1). Leaving a slight excess length of graft in the axilla has been advocated to reduce the likelihood of tension on the anastomosis. This can also be accomplished by modifying the distal course of the graft such that it travels adjacent and nearly parallel to the axillary artery for 8 to 10 cm into the axilla, and then directed to a redundant curve into the chest wall (Fig. 2). Thus, tension along the graft is concentrated along the length of the curve in the axilla instead of the anastomosis. The axillary anastomosis can be constructed with a single suture begun at the mid posterior point of the anastomosis or with two sutures beginning at the heel and toe. Femoral anastomoses initially at the heel and toe and are sutured on each side of the artery toward the center of the arteriotomy.

The distal anastomosis is conventionally performed in an end to side fashion to the appropriate artery in the groin. Confirmation of the patient's pulse status in both upper and lower extremities should be performed prior to closure. This can be done with continuous wave Doppler. In the case of axillofemoral bypass, multiple graft configurations are possible. Typically, the femorofemoral graft may be placed with the distal anastomotic limb of the axillofemoral graft. Conversely, the femorofemoral graft may be placed first and the distal anastomosis of the axillofemoral graft may be attached to the ipsilateral femorofemoral graft anastomotic limb. In obese patients, tension on the femoral anastomosis can be alleviated by adopting a ripple knee configuration (Fig. 3). The anastomosis is created with the heel caudal to the toe, thus the graft initially takes a caudal course before heading cephalad and crossing the midline. In this configuration the tension is transferred from the anastomosis to the fingertip point of the graft, reducing the risk of anastomotic disruption. There are no objective data that suggest superiority of any bypass configuration. Prefabricated grafts are also available that mitigate the need for a graft to graft anastomosis altogether.

RESULTS

Reported patency rates with axillofemoral bypass have varied widely over the past several decades, from as low as 59% to as high as 85% at 3 years. This variability was due in part to changing patient selection and indications over the past several decades, as well as status of the patient's arterial outflow. Patients undergoing axillofemoral bypass for emergent acute lower extremity ischemia tended to suffer more perioperative complications and poorer outcomes on the basis of their presenting pathology and comorbidities. Patients undergoing bypass

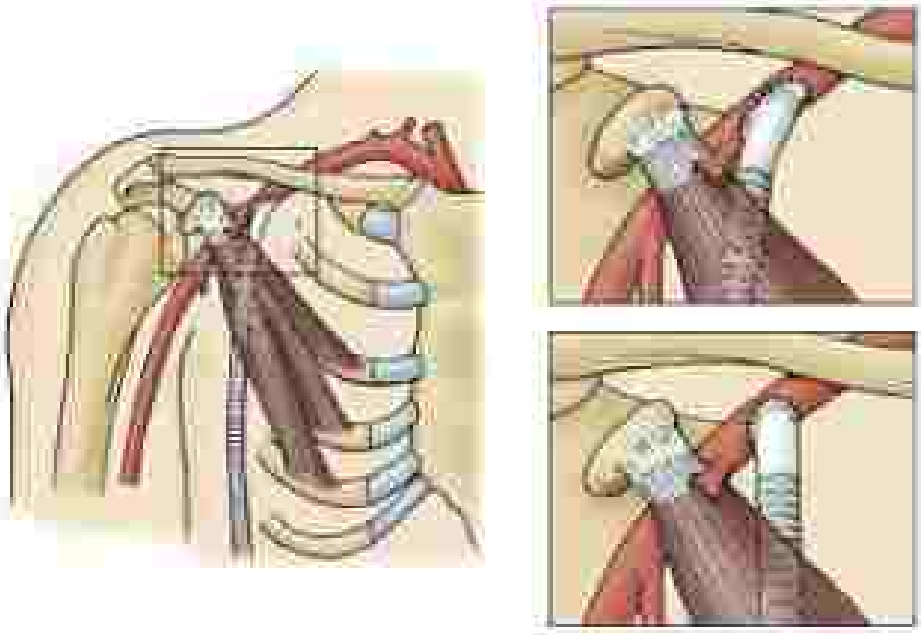

FIG. 1 Operative findings in cases of graft disruption. Femur-producing disruptions occurs with arm abduction/extension as illustrated. Top inset, Common disruption with "hood" of graft scar and scarce pulling out of "cone" of graft. Bottom inset, Complete circumferential graft disruption adjacent to anastomosis. Blaisdell and [illegible] in their initial description of the procedure, carefully recommend placing the axillary anastomosis on the first portion of the axillary artery to avoid undue tension with arm movement. (From Dyke I M, Porth H, [illegible] of Acute Disruption of Polytetrafluoroethylene Grafts Used for Axillo-[illegible] Anastomosis: A Complication of Axillofemoral Grafting. J Vasc Surg. 1994;20(1):120.)

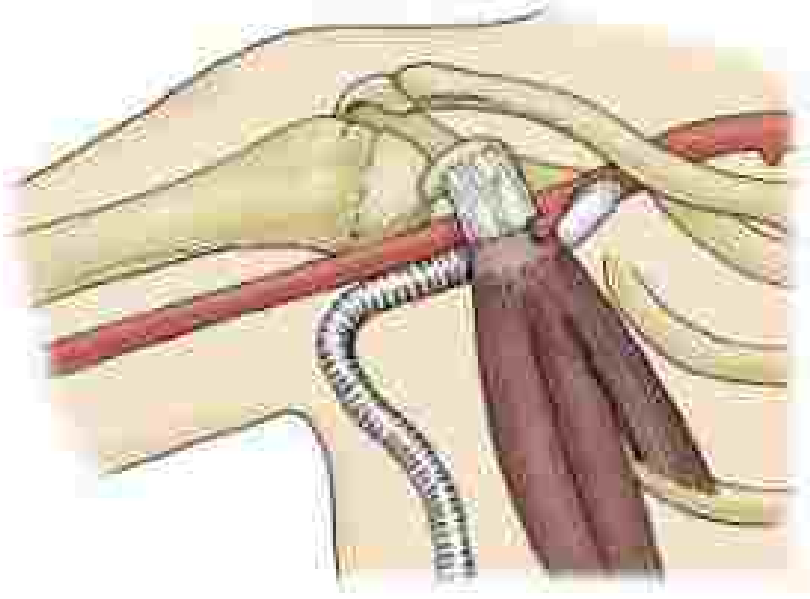

FIG. 2 Modified technique of axillofemoral graft proximal anastomosis. Graft is anastomosed to end-to-side fashion to first portion of axillary artery and evasion parallel and adjacent to artery beneath pectoralis minor for 8–10 cm before being directed in gentle and redundant curve to axilla to lie against chest wall in subcutaneous position. (From Dyke I M, Porth H, [illegible] of Acute Disruption of Polytetrafluoroethylene Grafts Used for Axillo-[illegible] Anastomosis: A Complication of Axillofemoral Grafting. J Vasc Surg. 1994;20(1):120.)

for claudication tended to have superior results, both in symptomatic improvement and patency compared to patients with critical limb ischemia likely due to significantly worse outflow disease in the latter group. However, axillofemoral bypass offers fair to excellent limb salvage rates in those presenting with CLI, with 3 year limb salvage estimates ranging from 69% to 80%. The overall perioperative mortality of axillofemoral bypass ranges from 3% to 12%, and estimated survival following axillofemoral bypass may be as low as 63% at 28 months and 35% at 3 years, although rates may be rising because of improved medical management of cardiopulmonary comorbidities.

Axillofemoral bypass is generally performed in lieu of axillofemoral bypass for reasons noted previously. Although there are no randomized comparisons of axillofemoral and axillofemoral bypass, there have been several retrospective case control studies comparing the two procedures. A recent study by Passman et al. reported a 5-year estimated patency of 74% for axillofemoral bypass versus

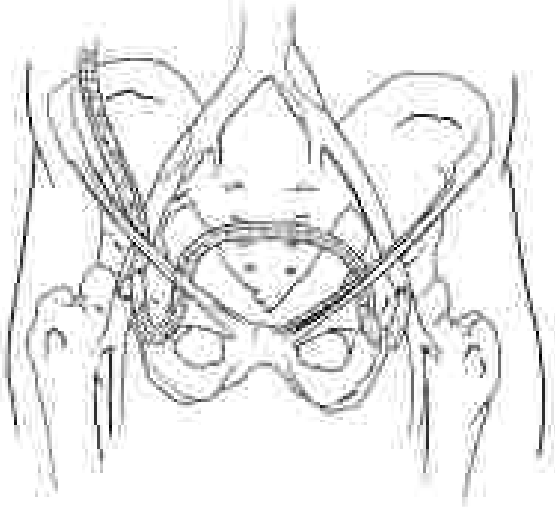

FIG. 3 Saint Mary configuration of femoral anastomosis: vessel is displaced from the anastomosis to the inferior bend of the supportive graft, which acts as a ridge, reducing the risk of disruption.

80% for aortobifemoral bypass, a difference that was not statistically significant. Although these data remain under scrutiny for patient selection, many surgeons use it as justification for offering high-risk patients extraanatomic revascularization. Not surprisingly, patients who underwent axillobifemoral bypass tended to be older, underwent surgery for limb salvage, and had higher rates of heart disease, renal failure, and prior abdominal or aortic surgery compared to those who underwent aortobifemoral bypass. Although there was no significant difference in operative mortality between the two groups, patients undergoing axillobifemoral bypass had fewer rates of postoperative complications compared to aortobifemoral bypass (9.2% vs 19.4%, respectively; $P < .05$). Although there was no difference in myocardial infarction, graft occlusion, or bleeding rates, patients who underwent aortobifemoral bypass had higher rates of pulmonary failure, acute renal failure, and stroke. There was no significant difference in patency and limb salvage rates at 5 years, although patients who underwent axillobifemoral bypass had lower overall survival.

Although much as been theorized about the potential difference in a bifemoral versus bifemoral configuration may place on graft flow rates and thus, long term patency, there has been no significant difference in a retrospective study seen between axillobifemoral and axillobifemoral grafts. There have been no significant differences associated with graft diameter nor or the presence of external graft support, however anecdotally, many vascular surgeons opt for an 8 mm polytetrafluoroethylene graft with external support.

When comparing reports in the literature regarding axillofemoral bypass grafts, there is considerable variability in the techniques used and the outcome measures defined, for example, primary versus secondary patency. In addition, it must be noted whether graft components are considered separately in patency calculations, as some authors may consider the axillofemoral and the femorofemoral components as distinct grafts.

COMPLICATIONS

Despite issues of graft patency, axillofemoral bypasses are generally well tolerated in patients with relatively infrequent reported complications. Axillary anastomosis disruption, while rare, is the most serious and life-threatening of all complications. Most cases can be attributed to excessive tension, and strategies to avoid such graft problems have been alluded to earlier in this chapter. A typical clinical scenario will involve the sudden onset of infraclavicular pain, swelling, or upper extremity neurologic symptoms following the extension or abduction of the ipsilateral arm. In such emergent situations, the single most important aspect of surgical intervention is obtaining proximal control before entering the disrupted region. This can be done either via supraclavicular approach to gain control of the subclavian artery, or with proximal and distal balloon occlusion under an endovascular fluoroscopic guided approach. Once proximal control is obtained, the treatment of choice is to disconnect the graft and place a patch over the anastomotic site (Dacron salvage is not possible).

Acute thrombosis of the axillary artery is often associated with a technical problem such as clamp injury or kinking of the native axillary artery and can be remedied with thrombectomy with patch angioplasty. Graft thrombosis is typically a result of low flow, typically because of increased resistance from progression of outflow disease rather than proximal inflow atherosclerosis. Graft salvage can be performed either with immediate operative thrombectomy or catheter based thrombolytic therapy. In either case, the underlying outflow problem should be diagnosed and addressed following initial treatment. In the event of graft thrombosis, patency can frequently be reestablished with thrombectomy performed under local anesthesia. We prefer to perform these procedures under direct fluoroscopic guidance for several reasons. First, the chance of injury to the native vessel is reduced by preventing overdistention of the balloon thrombectomy catheters. Second, it allows the surgeon to identify and possibly treat any underlying inflow or outflow lesions with and endovascular approach. Finally, should a revision be required, and angiogram defining the patient's anatomy can be obtained. In patients suffering from thromboembolism of the brachial artery resulting from steno syndrome with graft occlusion, open thrombectomy of the brachial artery with flush ligation of the axillofemoral graft at the anastomosis or occlusion of the occluded graft using a stent is the recommended approach.

Upper extremity steal syndromes is rare, but often associated with proximal subclavian disease, which can be treated with transfemoral or transbrachial balloon angioplasty with or without stent. Although the presence of inflow disease should have been evident in preoperative testing, atherosclerotic disease progression can lead to significant proximal stenosis years after initial bypass.

Fortunately, the incidence of graft infection for axillofemoral bypass is low, despite the higher risk patient population. However, when performed in situations of intraabdominal graft infection, rates of graft contamination have been reported as high as 27%. The treatment is removal of infected graft and establishment of inflow from the contralateral axillary artery. Secondary tunneling of the femorofemoral segment requires avoiding the previously infected field, and in some cases necessitates tunneling underneath the anterior abdominal musculature fascia. In rare cases of severe bilateral groin infections, bilateral axillofemoral bypass grafting should be considered. For those patients with noninfected asymptomatic perigraft seroma, the standard approach is to allow such collections to resolve spontaneously without intervention. If the seroma does not resolve after several months, it should be drained in the operating room under sterile conditions.

POSTOPERATIVE MANAGEMENT

Patients are placed on single or dual antiplatelet therapy with formal anticoagulation reserved largely for patients with a known hypercoagulable state, or in whom a secondary procedure was required to reestablish patency. As in all patients with peripheral artery disease the use of a statin is recommended. Graft surveillance is performed according to standard protocols generally every three months for the first year, every 6 months for the second year, and yearly thereafter. The need for a subsequent intervention or other abnormal findings on duplex may necessitate more frequent surveillance.

CONCLUSIONS

Axillofemoral bypass is an important and valuable option in the treatment of patients with aortoiliac occlusive disease. For many reasons, it is the preferred or only viable option for patients with significant anatomic or medical comorbidities, which preclude standard bypass options. Axillofemoral bypass can be performed with

acceptable morbidity, mortality, and long-term results, even in high-risk patients. For these reasons, surgeons should be familiar with the indications and application of these techniques.

Management of Peripheral Arterial Thromboembolism

Colby J. Swayngim, DO, and Thomas H. Cogbill, MD, FACS

The incidence of noncerebral systemic embolic events has decreased significantly with earlier diagnosis of atrial fibrillation and use of oral anticoagulation. However, embolism to the extremities may still result in severe morbidity and mortality if not diagnosed early and managed expeditiously. Various sources of emboli have been described; cardiac causes are most common, including atrial fibrillation (AF), acute myocardial infarction, left ventricular dysfunction, and prosthetic heart valves with inadequate anticoagulation. Anatomically, arterial emboli to the extremities often lodge at bifurcations; lower extremities are affected more frequently than upper extremities (Table 1).

The overall incidence of lower extremity thromboembolism in an adult referral population decreased from 7.9 per 100,000 in 2000 to 3.5 per 100,000 in 2014. Approximately 0.5% of patients with AF will experience clinically significant noncerebral systemic embolic events, with an incidence in contemporary reviews of 0.24 per 100 patient-years. Approximately two thirds of these events affect the extremities and one third affect the visceral mesenteric circulation. Risks are significantly higher among patients with permanent rather than paroxysmal AF and with AF of longer duration (>2 years). In these patients, anticoagulation use has been associated with a lower incidence of systemic emboli, with direct oral anticoagulants being at least as effective as vitamin K antagonists. Over the past decade, the use of antiplatelet or antithrombotic medication has remained 2.3% per year. Thirty-day mortality in this patient population after a systemic embolic event is 12% to 25% and has changed little over the past 3 decades. Major adverse cardiac events within 1 year of a lower extremity thromboembolic event is about 18%. In patients with prosthetic valves the risk of a thromboembolic event is between 0.6% and 2.3% per patient-year. Thromboemboli originate from mitral prosthetic valves two to three times more frequently than from aortic prosthetic valves. Other cardiac sources of emboli include atrial myxomas and valvular heart disease due to rheumatic fever or endocarditis.

CLINICAL PRESENTATION

Symptoms and signs of acute peripheral artery embolism are often characterized by the "six Ps" associated with acute limb ischemia (ALI): pain, pulselessness, poikilothermia, paresthesia, pallor, and paralysis. History and physical examination help to differentiate between patients with peripheral arterial disease, and those with an acute embolic event. Symptoms that are chronic (months to years), progressive, associated with claudication, or rest pain and nonhealing wounds are most likely to be associated with peripheral arterial disease. Patients with ALI caused by embolism are more likely to have an arrhythmia or recent cardiac event. Other differential diagnoses to consider are acute aortic dissection, tubular disease, aneurysmal disease, arterial injury from recent vascular intervention, or thrombophilia.

Careful physical examination is critical in determining the severity of ALI and the level of occlusion, which then may indicate the most appropriate management pathway. The color and temperature of the skin should be noted with level of demarcation documented. Both sensory and motor neurologic examination should be performed with location of areas of diminished sensation or complete anesthesia and muscle weakness or paralysis. One should compare the ipsilateral vascular exam to the contralateral side, checking for presence and character of all pulses, Doppler signals, and segmental pressures. Absence of the femoral pulse or a "water hammer" femoral pulse on one side suggests a unilateral embolus lodged at or near the femoral bifurcation. Absence of both femoral pulses suggests an aortic or aortoiliac embolus. Presence of a strong, normal, femoral pulse with inaudible Doppler flow or absence of pulses to the ipsilateral pedal arteries usually indicates thromboembolism to more distal vessels in the leg. Based on physical findings, the severity of ALI can be stratified into four classes (Table 1).

PREINTERVENTION IMAGING

Patients with a classic history (acute onset of ischemic symptoms, presence of atrial fibrillation, and no previous arterial disease) and physical findings (signs of ischemia, ipsilateral loss of pulses and Doppler flow compared with normal vascular exam on contralateral limb) require no imaging to confirm the diagnosis. Delaying therapy may exacerbate the muscle and nerve damage associated with prolonged ischemia. Additionally, the cost and morbidity of imaging can be avoided.

Preintervention imaging is helpful if the diagnosis is not clear or if there is a history of preexisting atherosclerotic disease or vascular interventions. Ultrasound may be used to identify arterial emboli, aneurysmal disease, or to exclude deep vein thrombosis as a cause for symptoms. Computed tomographic angiography (CTA) of the chest, abdomen, pelvis, and lower extremity runoffs may establish or exclude differential diagnoses such as arterial dissections, tumor-based aneurysms, and atherosclerotic disease. In cases in which an embolism is identified by ultrasound or CTA, these images may assist in operative planning. Finally, conventional angiography in a hybrid operating room or interventional radiology suite may be performed as a prelude to open or endovascular procedures in patients with a previous history of atherosclerotic vessel disease, previous vascular

acceptable morbidity, mortality, and long-term results, even in high-risk patients. For these reasons, surgeons should be familiar with the indications and application of these techniques.

Management of Peripheral Arterial Thromboembolism

Colby J. Seagmiller, DO, and Thomas H. Cogbill, MD, FACS

The incidence of noncerebral systemic embolic events has decreased significantly with earlier diagnosis of atrial fibrillation and use of oral anticoagulation. However, embolism to the extremities may still result in severe morbidity and mortality if not diagnosed early and managed expeditiously. Various sources of emboli have been described; cardiac causes are most common, including atrial fibrillation (AF), acute myocardial infarction, left ventricular dysfunction, and prosthetic heart valves with inadequate anticoagulation. Anatomically, arterial emboli to the extremities often lodge at bifurcations; lower extremities are affected more frequently than upper extremities (Table 1).

The overall incidence of lower extremity thromboembolism in an adult referral population decreased from 7.9 per 100,000 in 2000 to 3.5 per 100,000 in 2014. Approximately 0.5% of patients with AF will experience clinically significant noncerebral systemic embolic events, with an incidence in contemporary reviews of 0.24 per 100 patient-years. Approximately two thirds of these events affect the extremities and one third affect the visceral mesenteric circulation. Risks are significantly higher among patients with permanent rather than paroxysmal AF and with AF of longer duration (>2 years). In these patients, anticoagulation use has been associated with a lower incidence of systemic emboli, with direct oral anticoagulants being at least as effective as vitamin K antagonists. Over the past decade, the use of antiplatelet or antithrombotic medication has remained 2.3% per year. Thirty-day mortality in this patient population after a systemic embolic event is 17% to 25% and has changed little over the past 3 decades. Major adverse cardiac events within 1 year of a lower extremity thromboembolic event is about 18%. In patients with prosthetic valves the risk of a thromboembolic event is between 0.6% and 2.3% per patient-year. Thromboemboli originate from mitral prosthetic valves two to three times more frequently than from aortic prosthetic valves. Other cardiac sources of emboli include atrial myxomas and valvular heart disease due to rheumatic fever or endocarditis.

CLINICAL PRESENTATION

Symptoms and signs of acute peripheral artery embolism are often characterized by the "six Ps" associated with acute limb ischemia (ALI): pain, pulselessness, poikilothermia, paresthesia, pallor, and paralysis. History and physical examination help to differentiate between patients with peripheral arterial disease, and those with an acute embolic event. Symptoms that are chronic (months to years), progressive, associated with claudication, or rest pain and nonhealing wounds are most likely to be associated with peripheral arterial disease. Patients with ALI caused by embolism are more likely to have an arrhythmia or recent cardiac event. Other differential diagnoses to consider are acute aortic dissection, valvular disease, aneurysmal disease, arterial injury from recent vascular intervention, or thrombophilia.

Careful physical examination is critical in determining the severity of ALI and the level of occlusion, which then may indicate the most appropriate management pathway. The color and temperature of the skin should be noted with level of demarcation documented. Both sensory and motor neurologic examination should be performed with location of areas of diminished sensation or complete anesthesia and muscle weakness or paralysis. One should compare the ipsilateral vascular exam to the contralateral side, checking for presence and character of all pulses, Doppler signals, and segmental pressures. Absence of the femoral pulse or a "water hammer" femoral pulse on one side suggests a unilateral embolus lodged at or near the femoral bifurcation. Absence of both femoral pulses suggests an aortic or aortoiliac embolus. Presence of a strong, normal, femoral pulse with inaudible Doppler flow or absence of pulses to the ipsilateral pedal arteries usually indicates thromboembolism to more distal vessels in the leg. Based on physical findings, the severity of ALI can be stratified into four classes (Table 1).

PREINTERVENTION IMAGING

Patients with a classic history (acute onset of ischemic symptoms, presence of atrial fibrillation, and no previous arterial disease) and physical findings (signs of ischemia, ipsilateral loss of pulses and Doppler flow compared with normal vascular exam on contralateral limb) require no imaging to confirm the diagnosis. Delaying therapy may exacerbate the muscle and nerve damage associated with prolonged ischemia. Additionally, the cost and morbidity of imaging can be avoided.

Preintervention imaging is helpful if the diagnosis is not clear or if there is a history of preexisting atherosclerotic disease or vascular interventions. Ultrasound may be used to identify arterial emboli, aneurysmal disease, or to exclude deep vein thrombosis as a cause for symptoms. Computed tomographic angiography (CTA) of the chest, abdomen, pelvis, and lower extremity runoffs may establish or exclude differential diagnoses such as arterial dissections, thrombosed aneurysms, and atherosclerotic disease. In cases in which an embolism is identified by ultrasound or CTA, these images may assist in operative planning. Finally, conventional angiography in a hybrid operating room or interventional radiology suite may be performed as a prelude to open or endovascular procedures in patients with a previous history of atherosclerotic vessel disease, previous vascular

interventions, or thromboembolism with a distal distribution of occlusions in the presence of intact proximal (femoral or brachial) pulses but loss of distal pulses and/or Doppler flow.

THROMBOEMBOLISM MANAGEMENT STRATEGY

The goals of therapy are to prevent further propagation of thrombus and to reestablish perfusion to the affected limb(s) as quickly as possible. When a peripheral artery embolism is suspected, initial management includes intravenous limb resuscitation with normal saline and anticoagulation with intravenous heparin using a loading bolus of 75 to 100 U/kg followed by a 15 U/kg per hour infusion to achieve an activated partial thromboplastin time (aPTT) goal of 60 to 80 seconds. Patients who are intolerant to heparin should receive a direct thrombin inhibitor such as lepirudin or argatroban with a similar aPTT goal. A 12-lead electrocardiogram should be obtained. Baseline laboratory tests should include complete blood count, serum creatinine, glucose, electrolytes, creatine phosphokinase (CPK), lactate, and a blood bank sample for type and screen. Anticoagulation and serial evaluation are sufficient for the small number of arterial embolism patients with class I ALI because the limb is not immediately threatened in these situations.

The two primary approaches for treatment of class II ALI resulting from peripheral artery embolism are open surgical thromboembolectomy and endovascular therapy consisting of percutaneous mechanical thrombectomy and/or catheter directed thrombolysis. There was a 4% increase per year in the number of endovascular procedures used for peripheral artery thromboembolism from 2003 to 2014. A Cochrane meta-analysis of five prospective, randomized controlled trials of patients with ALI compared catheter directed thrombolysis with tissue plasminogen activator (tPA) or urokinase to surgical thromboembolectomy. Death and amputation rates within 1 year were similar for each treatment modality; however, the rates of stroke (1.3% vs 0%), major bleeding (0.8% vs 3.3%), and distal embolization (12.3% vs 0%) were significantly higher following thrombolysis. Current methods of percutaneous mechanical thrombectomy were not evaluated in this meta-analysis. A recent single-center study found similar technical success and amputation rates for open thromboembolectomy versus endovascular techniques, including percutaneous mechanical thrombectomy. Open surgical and endovascular techniques are not mutually exclusive options. Increasingly, these two approaches are utilized in tandem (hybrid approach) to achieve optimal extremity reperfusion. In a small number of cases, extremity perfusion remains insufficient after open and/or endovascular interventions. Completion angiography may demonstrate persistent acute or chronic occlusive disease that requires vascular bypass grafting for limb salvage.

Factors to be considered in making therapeutic decisions include equivalence of clinical outcomes, comparative costs, length of time to reperfusion, procedural risks, and speed of recovery. Contraindications to pharmacologic thrombolysis include active hemorrhage, stroke, recent trauma, severe hypertension, intracranial tumor, or a recent surgical procedure. Risk of contrast induced nephropathy must also be evaluated whenever angiographic imaging is one component of a therapeutic modality. Regardless of the therapeutic modality selected, patients and their families should be counseled on the procedure related complications as well as the advantages and disadvantages when compared with alternative approaches.

In an effort to balance the previously mentioned considerations, we developed a treatment algorithm that can be used as a guide for management of lower extremity artery embolism with class II ALI (Fig. 1). In patients with an absent or "water hammer" ipsilateral femoral pulse and normal pulses on the contralateral limb, open femoral thromboembolectomy is favored based on ease and speed of establishing reperfusion and fewer procedure related complications. A single bolus of thrombolytic solution such as tPA can be flushed into the distal vasculature just before closure of the arteriotomy.

Patients with acute ischemia and absence of both femoral pulses in whom an aortic or aortoiliac embolus is suspected are best managed by bilateral femoral thromboembolectomies based on speed of reestablishing perfusion and effective removal of significant clot burden. These procedures should be performed in a hybrid operating room because completion angiography and adjunctive endovascular or open procedures may be necessary in these patients.

Patients with acute ischemia and a normal ipsilateral femoral pulse but absent ipsilateral distal pulses and normal contralateral pulses should undergo initial angiography with a plan for percutaneous mechanical thrombectomy and/or catheter-directed thrombolysis (Fig. 1). This approach is much more likely to achieve effective reperfusion of the smaller distal vessels involved with this distribution of thromboembolism. Angiography can better identify the site

TABLE 1 Distribution of Extremity Arterial Emboli

Site of Embolism	Approximate Frequency
Lower Extremity	84.0%
Aortoiliac	29.7%
Common Femoral	34.0%
Superficial Femoral	4.5%
Popliteal	10.5%
Tibial	5.0%
Upper Extremity	16.0%
Brachial	8.1%
Axillary	4.5%
Radial and ulnar	2.4%

TABLE 2 Classification of Acute Limb Ischemia

Class	Sensory Loss	Muscle Weakness	Arterial Doppler
I. Viable limb	None	None	Audible
IIA. Marginally threatened limb	Toes or none	None	Often inaudible
IIB. Immediately threatened limb	More than toes; Rest pain	Mild or moderate	Usually inaudible
III. Irreversible	Profound; anesthetic	Profound; paralysis	Inaudible

From Rutherford RB, Baker JD, Ernst C, et al. Recommended standards for reports dealing with lower extremity ischemia: revised version. J Vasc Surg 1997;26(3):517–538.

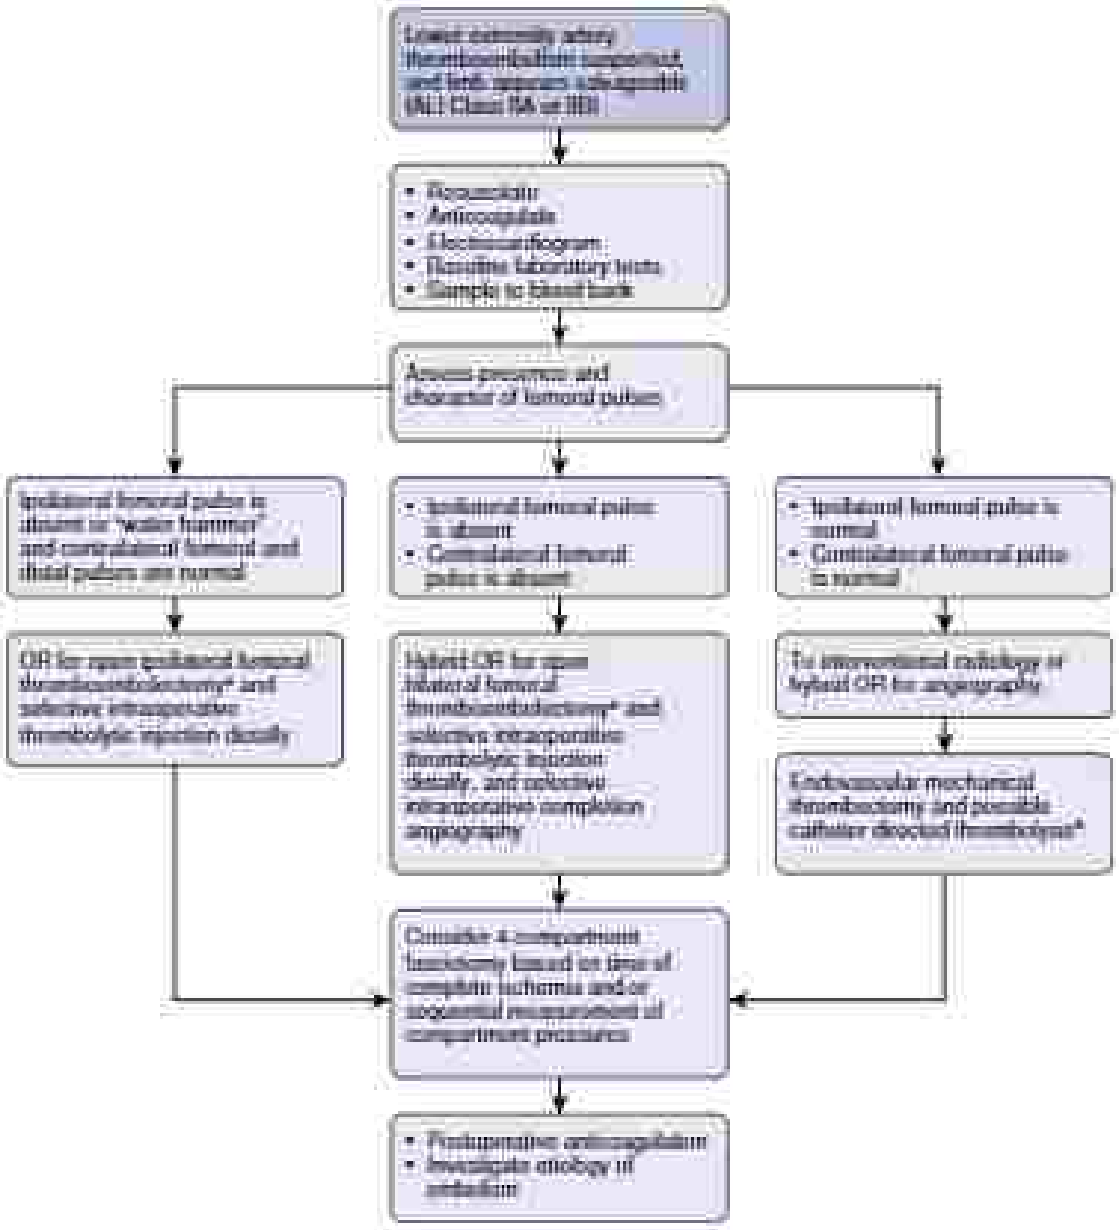

FIG. 1 Treatment algorithm for patients with class IIA and IIB acute lower extremity ischemia due to arterial thromboembolism. OR, operating room. *Open surgical and endovascular techniques may be used in tandem (hybrid approach) to achieve adequate extremity perfusion. Vascular surgical bypass may occasionally be necessary for limb salvage in the presence of a persistent acute or chronic arterial occlusion.

of embolization and thrombolysis therapy can be delivered by catheter directly into the thromboembolus. Additionally, identification of concomitant arteriosclerotic lesions may dictate the best method for revascularization.

For upper extremity emboli, we favor open brachial thromboembolectomy based on small vessel size, ease and speed of reestablishing perfusion, and fewer procedure related complications.

In the rare patient who presents with prolonged (>12 hours) class III A1I with complete loss of motor and sensory neurologic function as well as changes of livedo reticularis, revascularization of a nonviable limb may cause life threatening physiologic changes with little chance of limb salvage. A primary amputation in this setting is preferable to avoid multiple system organ failure and death.

OPEN SURGICAL TREATMENT

Femoral Thromboembolectomy

This procedure can often be performed with a local anesthetic and maintained anesthesia care. The common femoral, superficial femoral, and profunda femoris arteries are dissected and surrounded with vessel loops. A transverse arteriotomy is placed on the distal common femoral artery if there is no evidence of atherosclerotic disease so that the artery is not narrowed during closure. In patients with atherosclerotic plaque a longitudinal arteriotomy can be performed allowing for endarterectomy if necessary and closure with a patch to prevent arterial narrowing. A balloon tipped catheter is passed proximally and distally beyond the occlusion, with subsequent balloon inflation and

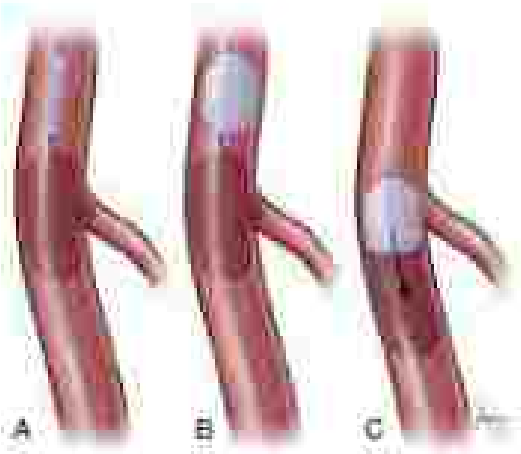

FIG. 2. Technique of balloon thromboembolectomy. (A) Pass a balloon-tipped catheter via arteriotomy through the embolus into the vessel distal to the area of occlusion. (B) Inflate the balloon while slowly withdrawing the catheter to prevent damage to the arterial wall. (C) Withdraw the inflated balloon catheter and remove thromboembolic material through the arteriotomy. (Courtesy Cleveland Clinic Center for Medical Art & Photography. Copyright 2009. All rights reserved.)

withdrawal leading to removal of the thromboembolus (Fig. 2). We recommend balloon inflation while slowly withdrawing the catheter to prevent arterial injury. Although resistance to balloon withdrawal may be related to the presence of an embolus, it also may be related to the presence of an atherosclerotic plaque, and a degree of balloon deflation may be required to avoid arterial injury. Likewise, overinflation of an inappropriately large balloon or inadvertent passage of the catheter into a branch vessel can cause arterial dissection or rupture. Two to three additional passes of an embolectomy catheter without retrieval of additional embolic material is usually sufficient. Qualitative assessment of adequate inflow can be performed by loosening the proximal vessel loop or releasing the proximal clamp. Submission of the thrombus for pathologic examination may be considered should myxoma or tumor thrombus be a possibility. The availability of over-the-wire Fogarty catheters allows the catheter to be passed into all major runoff vessels of an extremity under fluoroscopic guidance. If a standard Fogarty catheter has been used, an intraoperative completion angiogram may be considered, as the presence of backbleeding alone may not confirm complete thrombus retrieval. Should there be concern for residual thrombus, a single bolus of thrombolytic solution such as tPA can be flushed into the distal arterial bed prior to arterial closure. Intraoperative angiography is mandatory should audible Doppler signals at the dorsalis pedis or posterior tibial arteries not be restored.

AORTIC THROMBOEMBOLECTOMY

When an aortic bifurcation embolus is suspected, open surgery in a hybrid operating room is preferred. Bilateral groin cutdowns should be performed and the common, superficial, and deep femoral arteries exposed in order to obtain proximal and distal control. After systemic heparinization, a 4Fr or 5Fr embolectomy catheter is passed cranially, approximately 25 cm into the infrarenal aorta through transverse arteriotomies in each common femoral artery. The contralateral femoral artery should be occluded during each passage of the balloon catheter to minimize inadvertent embolization from the aorta down the opposite limb. After achieving appropriate prograde flow, distal thromboembolectomy of the superficial femoral and popliteal arteries is performed using a 3Fr or 4Fr catheter, followed by thromboembolectomy of the profunda femoris artery with a 3Fr catheter. If attempts to clear the distal circulation are unsuccessful, arteriography is recommended to guide endovascular thrombectomy or thrombolytic therapy. We do not recommend surgical embolectomy below the popliteal artery.

BRACHIAL THROMBOEMBOLECTOMY

Surgical thromboembolectomy is recommended over endovascular therapies for upper extremity emboli due to small vessel size and ease of surgical exposure. Upper extremity thromboembolectomy is typically performed through a transverse arteriotomy to the brachial artery. The distal brachial artery may be exposed through a transverse incision just above the elbow or, if needed, an S-shaped incision may be extended across the antecubital fossa to expose the proximal radial and ulnar arteries. Once proximal and distal control is obtained, a 4Fr catheter can be passed proximally into the subclavian artery and a 3Fr catheter subsequently passed distally through the radial and ulnar arteries. Some caution is required, as loosened subclavian thrombus may be embolized inadvertently into the cerebral circulation if the catheter is passed into the aortic arch. The Fogarty catheter can be measured externally against the patient's chest and arm and marked to help estimate the position of the subclavian artery to prevent passage of the catheter proximal to the subclavian artery origin. Should there be concern for residual distal thrombus, a single bolus of thrombolytic solution such as tPA can be flushed into the distal arterial bed prior to arterial closure.

PERCUTANEOUS ENDOVASCULAR THERAPY

Catheter-Directed Pharmacologic Thrombolysis

Ultrasound-guided access to the contralateral femoral artery is obtained initially, and a diagnostic angiogram is performed as a guide for further therapy. In addition to providing a more complete view of the arterial inflow, obtaining access remote from the embolus decreases the risk of bleeding complications because of the proximity of the puncture site to the delivery of the thrombolytic agent. Once the embolic occlusion is identified on arteriography, a sheath of appropriate length is inserted, and a hydrophilic-coated angled guidewire is passed through the thromboembolus. If the guidewire is unable to traverse the occlusion, diagnosis of acute thrombosis at the site of preexisting atherosclerotic plaque should be considered. Once the thromboembolus has been traversed by the guidewire, a multiple sidehole catheter is advanced over the guidewire and thrombolytic agent is delivered directly into the thromboembolus. Although streptokinase and urokinase continue to be used worldwide, the current lytic agent of choice in the United States is tPA. A pulse-spray bolus of 10 mg of thrombolytic agent is delivered into the thromboembolus, followed by continuous infusion at approximately 0.5 mg/hr. Heparin is administered through the side port of the sheath at 500 units/hr to prevent catheter-associated thrombosis. Every 4 to 8 hours aPTT and fibrinogen levels are checked to monitor for systemic thrombolysis. Infusion is held if fibrinogen level drops below 100 mg/dL or by more than 50% from baseline. Because low-dose heparin is administered to prevent catheter-associated thrombotic complications, the aPTT is titrated to 30 to 50 seconds. Reimaging is performed in 12 to 24 hours to assess thromboembolus dissolution. Close monitoring of the access site is imperative; this is best done in a critical care unit. Patients may report increase in distal extremity pain because of embolization of thrombus that has been lysed by tPA. Continued thrombolytic infusion and analgesia are recommended with close monitoring; these symptoms should eventually improve.

PERCUTANEOUS MECHANICAL THROMBECTOMY

Percutaneous mechanical thrombectomy was introduced to decrease the need for prolonged infusion times and reduce the number of procedures required for successful catheter-directed thrombolysis.

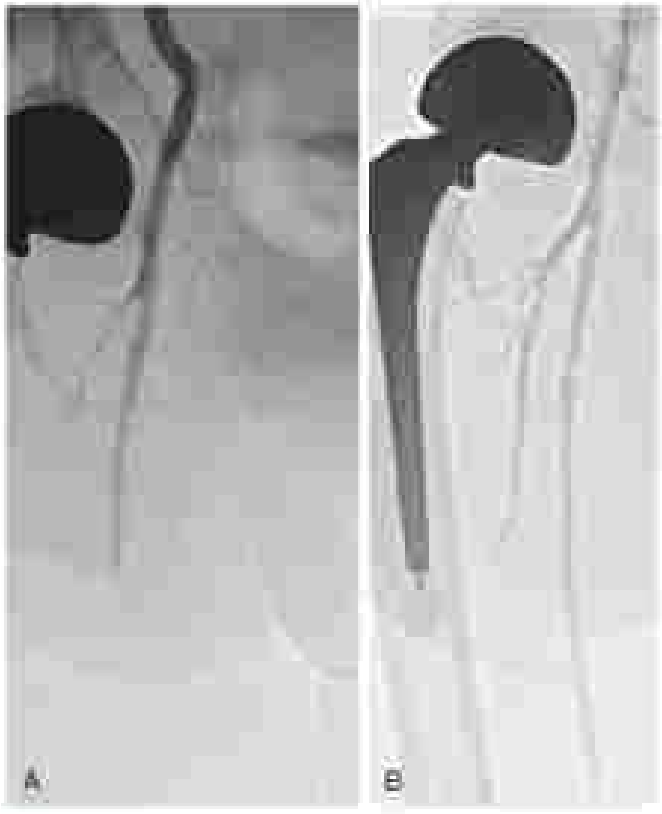

FIG 3. (A) Right femoral arteriogram obtained in a patient with atrial fibrillation, normal right femoral pulse, and cool, pale limb. Ischemia demonstrating thromboembolic occlusion of the superficial femoral artery. (B) Repeat right femoral arteriogram following pulse spray of tissue plasminogen activator and Angiojet percutaneous arterial thrombectomy demonstrating dissolution of the thromboembolism and free flow of contrast throughout superficial femoral artery.

Under ideal circumstances, percutaneous mechanical thrombectomy expeditiously reduces overall clot burden and increases the surface area of exposed clot to enable more effective pharmacologic lysis. Various devices have been designed to use suction, rotational infusion, ultrasound, or a high velocity thrombolytic jet to achieve mechanical thrombectomy. Femoral artery access is obtained in a similar manner to that described above for catheter-directed thrombolysis. Pharmacomechanical thrombolysis refers to using the percutaneous device to first face the thrombus with a pulse spray bolus of thrombolytic agent, which after a brief dwell time is followed by mechanical thrombectomy. The Angiojet Thrombectomy System (Boston Scientific) is a popular rheolytic device that works on the premise of Bernoulli's principle. Circumferentially oriented pressurized saline jets fragment the thrombus with creation of a low pressure zone, which facilitates the removal of the resultant thrombotic debris through catheter side holes. In a large multicenter registry, successful outcome was obtained in 83% of patients without adjunctive catheter-directed thrombolysis needed in 52% of patients.

POSTPROCEDURE MANAGEMENT

Hemodynamic monitoring, routine laboratory analysis with correction of acidosis or electrolyte imbalance, and serial neuromuscular examinations are necessary. Despite successful revascularization, limb loss may occur from development of acute compartment syndrome. In patients with a history of prolonged ischemia (>6 hours), a prophylactic fasciotomy should be considered. Fasciotomy is performed through medial and lateral lower extremity incisions or dorsal and volar upper extremity incisions. For patients who have not undergone prophylactic fasciotomy, the diagnosis of compartment syndrome should be considered in the presence of a tensely swollen extremity with pain on passive motion. Elevated CPK levels and myoglobinuria are late markers of tissue destruction and should not be used to establish the diagnosis. Direct compartment pressure measurements can be obtained, and fasciotomy considered if pressures are elevated (>30 mm Hg), but even in the presence of normal compartment pressures, fasciotomies should be performed if there is clinical suspicion. The wound should be left open and a vacuum assisted closure device applied in the postoperative period to reduce muscle edema. Systemic effects of muscle ischemia include rhabdomyolysis, which may cause acute tubular necrosis and renal failure. Aggressive resuscitation with intravenous fluids is the main treatment modality. This may require 1 to 2 L of normal saline per hour until diuresis is provoked and then titrating to urine output greater than 300 to 500 mL/hr until CPK drops below 5000 U/L.

Nearly all patients will require long term systemic anticoagulation to decrease the chance of a recurrent thromboembolic event. In the initial postoperative period, this is achieved with heparin or a direct thrombin inhibitor, such as lepirudin or argatroban, until bridging to an oral vitamin K antagonist is complete. Once the acute ischemic episode and its sequelae have been managed, the underlying embolic etiology should be investigated. For patients without atrial fibrillation, this approach includes transesophageal echocardiogram to evaluate the heart for vegetations, thrombus, or the presence of right to left shunt, CTA of the chest, abdomen, and pelvis with bilateral lower extremity runoff to evaluate for the presence of an aneurysm, atherosclerotic lesion or ulcer, a hypercoagulable workup, and bilateral lower extremity ultrasonography to assess for deep venous thrombosis if paradoxical embolism is suspected.

CONCLUSIONS

The incidence of acute limb ischemia secondary to arterial embolism has decreased over the past 15 years, in part from improved treatment of atrial fibrillation. However, emboli to the extremities are still responsible for limb-threatening ischemia, which requires prompt recognition and expeditious intervention. Optimal management of peripheral arterial emboli depends on the location of the embolus, the severity of ischemia, and the duration of symptoms. Contemporary treatment relies on both open surgical thromboembolectomy and endovascular techniques including percutaneous mechanical thrombectomy and catheter-directed thrombolysis. A hybrid approach to using these techniques to increasingly used to achieve limb salvage. Early limb salvage rates following treatment for peripheral arterial thromboembolism approach 90%; the amputation rate is 25% within 1 year. The 1 year overall survival rate in these patients ranges from 80% to 85% and the 5 year survival rate is less than 50%.

Acute Peripheral Arterial and Bypass Graft Occlusion: Thrombolytic Therapy

Kelvin Hong, MD, and Robert P. Liddell, MD

Acute limb ischemia (ALI) is a vascular emergency caused by arterial embolism or thrombosis of native vessels or bypass grafts. Timely management of ALI requires expedited clinical evaluation, diagnostic workup, and initiation of appropriate treatment. Today, advances in thrombolytic agents, infusion catheters and endovascular techniques have led to catheter directed thrombolysis (CDT) becoming the treatment of choice for patients with relatively mild ALI. Patients with severe ALI need emergent surgical revascularization; however, CDT should be considered if the relative risks compared with primary operation are favorable. This chapter describes how to select the appropriate therapy for ALI, with an emphasis on the role of CDT.

PATIENT PRESENTATION AND WORKUP

Clinical Assessment

The clinical assessment of a patient with ALI should begin with a thorough history, focusing on the patient's presenting symptoms and current overall health. A history of rest pain, claudication, myocardial infarction, stroke, hypertension, diabetes mellitus, atrial fibrillation, aneurysmal disease, smoking, high cholesterol, vasculitis, and prior vascular or endovascular surgery is important to obtain. The initial physical examination should assess for the dominant clinical signs and symptoms of ALI, which traditionally include the six P's: pain, pulselessness, pallor, poikilothermy, paresthesias, and paralysis. The presence of one or more of these findings and the abruptness of their onset may also aid in determining the underlying etiology. Obvious neurologic deficits suggest an advanced state of ischemia, with sensory deficits preceding motor deficits. Frank mottling of the skin with muscle necrosis and induration implies irreversible limb ischemia (Fig. 1).

A formal stratification system has been developed to help guide the evaluation and management of ALI, while defining prognosis (Table 1). Acutely ischemic limbs should be described as viable, threatened, or irreversibly ischemic. Threatened limbs are reversibly ischemic and are salvageable with appropriate, timely intervention, whereas irreversibly ischemic limbs require amputation because major myoneuronal damage has occurred and is not reversible with surgical or endovascular revascularization.

The severity of ischemia is determined by a number of factors, including the etiology of the obstruction, the level of obstruction, the adequacy of collateral circulation, the extent of thrombus propagation, the patients underlying peripheral vascular disease and cardiac output. Although variable based on the network of existing collaterals, a period of 6 hours is generally accepted as the window in which revascularization is absolutely necessary for ALI. In practice, the degree of ischemia is more important than the absolute duration of ischemia, therefore patients must be assessed on an individual basis and in a timely fashion.

IMAGING ASSESSMENT

Imaging is done to evaluate the extent of blood flow compromise, localize culprit flow limiting lesions, and identify other sequelae of peripheral vascular disease (dissection, aneurysmal disease, thrombophilia). An acutely ischemic limb may be imaged with Doppler ultrasound (DUS), computed tomography angiography (CTA), magnetic resonance angiography (MRA), or digital subtraction angiography (DSA) before treatment. When choosing an imaging modality for native vessel disease, clinicians should take into account whether the patient has underlying renal insufficiency, diabetes, or implanted metal devices. For patients who have *normal* renal function and are not diabetic, initial evaluation with either CTA or MRA is reasonable based on their similar excellent diagnostic capabilities. Overall, DUS is a less sensitive technique for imaging native vessel stenosis than CTA or MRA; however, DUS is more ideally suited for post-lower extremity arterial bypass surgery surveillance. Asymptomatic vein graft stenosis can result in acute thrombosis and ultimately graft failure if not detected early. In contrast, DUS is not well established for evaluating long term patency of synthetic conduit bypass grafts.

DSA remains the gold standard for imaging of patients with acute limb ischemia. The chief benefit of DSA is that endovascular therapies may be initiated in the same setting as diagnostic angiography because arterial access is already achieved. Although DSA is a more invasive technique when compared with MRA and CTA, the risks associated with arterial access are minimal. Moreover, MRA and CTA are limited in assessing smaller tibial arteries and in such cases lower extremity angiography is preferred.

SELECTION OF THERAPY

The clinical and imaging assessment of a patient with ALI should be completed as quickly and efficiently as possible. Once the diagnosis of ALI is made, treatment should be initiated as soon as possible. Regardless of the etiology, all patients without contraindications should receive intravenous (IV) fluids, supplemental oxygen, an IV drip dose of aspirin, and a 100 U/kg bolus of IV heparin followed by a continuous infusion to keep the partial thromboplastin time at 2.0 to 2.5 times normal. As described earlier, the length of time a limb can endure ischemia varies with the cause and severity. The Society of Vascular Surgery/ISCVC classification based on sensory motor and Doppler evaluation, is used to triage initial limb treatments. Level I patients should be treated with heparin and observation, followed by more definitive therapy once comorbidities, functional status, and activity level are determined. Level II patients should be treated soon (Ila) or immediately (IIb) after imaging. Endovascular or operative interventions are equally efficacious in these patients, the choice being contingent on the skill and availability of the interventional radiologist or vascular surgeon. Patients with more severe ischemia (III) had traditionally been sent to surgery, but the recent advent of fast acting lytic drugs, spray pulse infusion techniques, and pharmacomechanical thrombolysis allow endovascular techniques to have a wider application. Level III patients who seek care shortly after symptom onset are candidates for surgical revascularization and fasciotomy; those presenting some time after symptom onset require amputation. Attempts to revascularize ischemic limbs late in the progression of disease are not only likely to fail but frequently result in severe pain, hyperkalemia, renal failure, and sepsis.

Recommended Interventions for Disease in Native Arteries

Catheter directed thrombolysis was first described by Dotter in 1974. When compared with high dose systemic intravenous thrombolysis CDT, resulted in significantly better outcomes with significantly lower adverse bleeding events. During the mid 1990s, a number of randomized, multicenter trials compared CDT with surgery for ALI. The Surgery versus Thrombolysis for Ischemia of the Lower Extremity (STILE) trial showed that CDT produces outcomes similar to surgery when used to treat thrombosed native arteries presenting within 2 weeks of the onset of symptoms. In patients

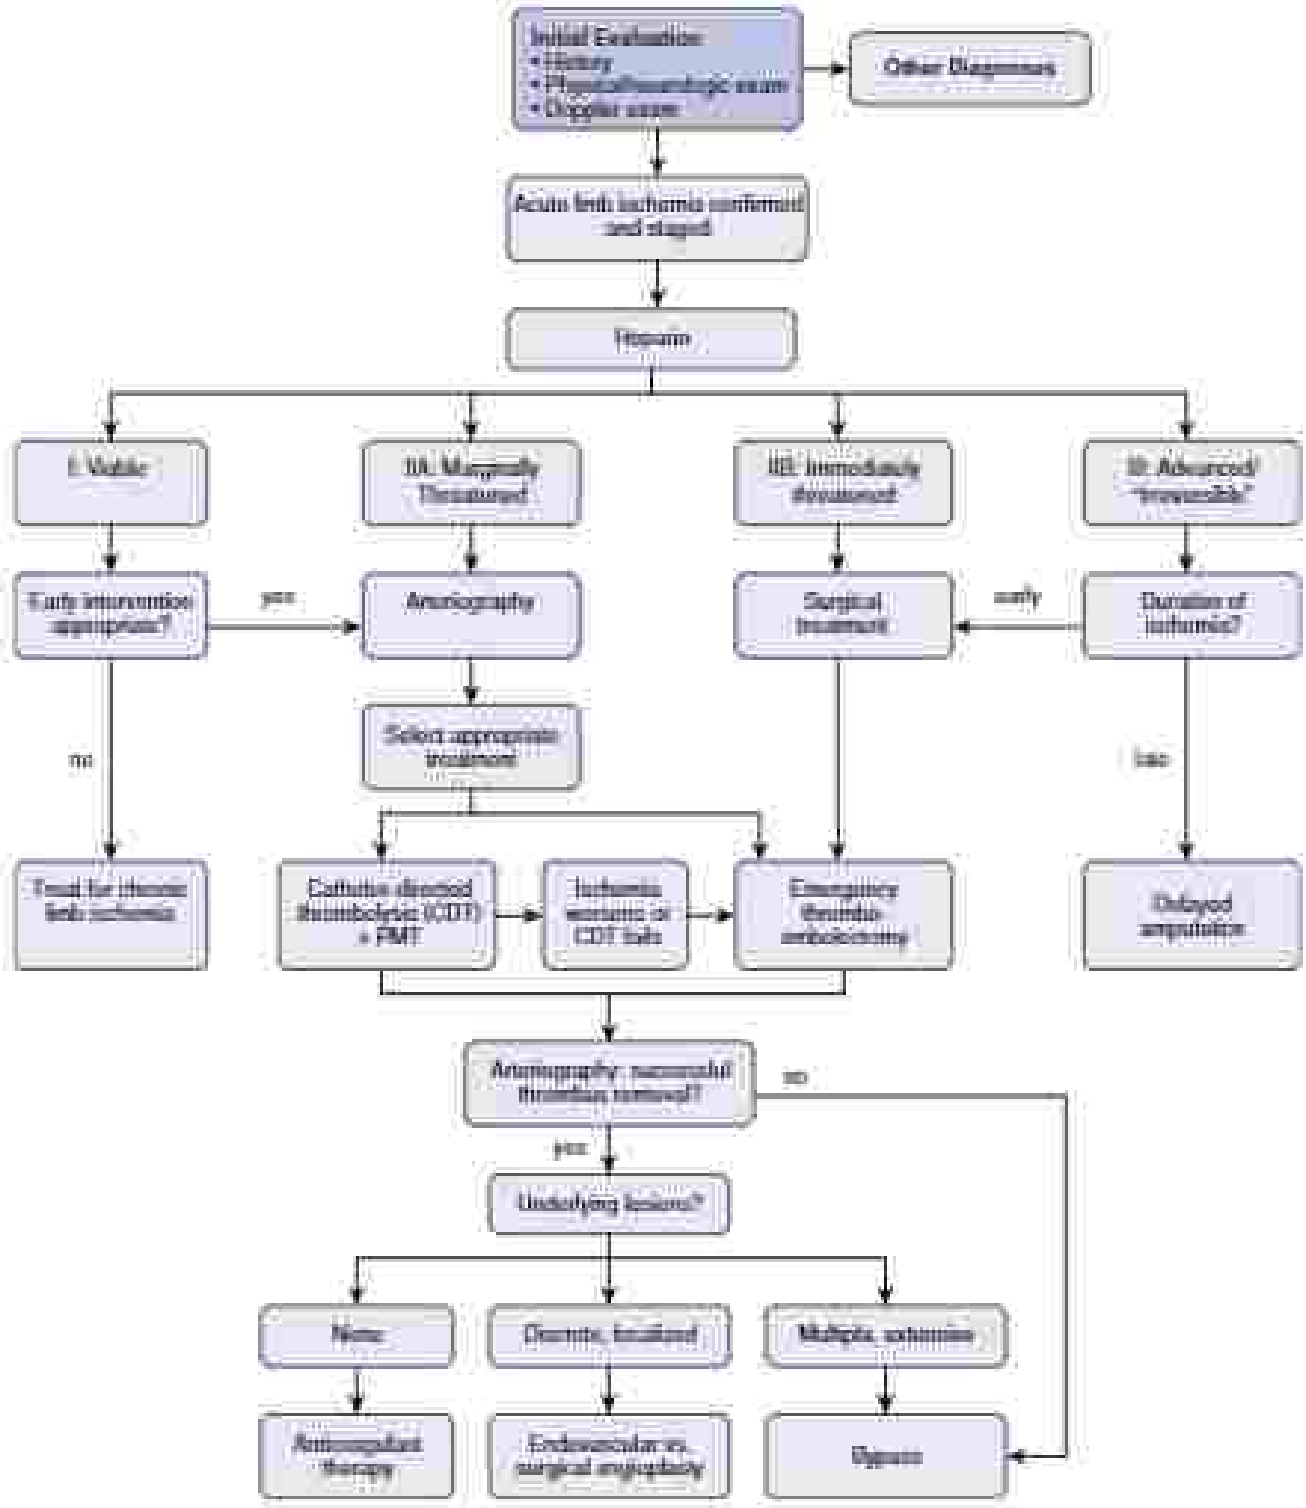

FIG. 1. Algorithm for management of acute limb ischemia. (From Rutherford RB, Acute limb ischemia. In: Rutherford RB, ed. Vascular Surgery. Philadelphia: WB Saunders; 1977. p. 1–21.)

presenting greater than 2 weeks from the onset of symptoms, surgery showed better outcomes. The STILE trial also showed that surgical interventions had better outcomes for native thrombotic or femoropopliteal disease. The Thrombolysis or Peripheral Arterial Surgery trial showed that CDT may be attempted, and then abandoned when unsuccessful in favor of more localized surgery, without increasing mortality or amputation rate. A number of retrospective studies have also demonstrated that performing CDT and angioplasty before attempting surgery can reduce the number of patients who will ultimately require surgical bypass or amputation. Although these studies do not provide definitive answers to a preferred treatment in all cases, they do suggest that CDT may improve outcomes without compromising the efficacy of subsequent surgery. Therefore, if readily available, CDT should be the first line therapy for acute native artery occlusion, with endovascular or surgical intervention to treat underlying disease once unmasked.

TABLE 1 Clinical Categories of Acute Limb Ischemia

Category	Description/Prognosis	Findings		Doppler Signals	
		Sensory Loss	Muscle Weakness	Arterial	Venous
I. Viable	Not immediately threatened	None	None	Audible	Audible
II. Threatened					
a. Marginally	Salvageable if promptly treated	Minimal (toes) or none	None	Inaudible	Audible
b. Immediately	Salvageable with immediate revascularization	More than toes, associated with rest pain	Mild, moderate	Inaudible	Audible
III. Irreversible	Major tissue loss or permanent nerve damage inevitable	Profound, anesthesia	Profound, paralysis (rigor)	Inaudible	Inaudible

Before initiating CDT, one should assess the extent of disease in the affected limb, not only the thrombosed segment, but also in the vasculature proximal and distal to the occlusion. The assessment of distal runoff is sometimes hindered by the fact that outflow distal to an occlusion is often significantly limited. If prior studies are available, their review is often helpful in identifying possible causative underlying stenoses as well as defining distal runoff. If prior studies are not available, it is important to attempt to cross the occlusion and directly assess distal runoff without causing distal embolization. According to the Trans Atlantic Inter Society Consensus Document on Management of Peripheral Vascular Disease II guidelines, focal stenoses are best treated with percutaneous balloon angioplasty (PTA) and stenting once the native artery is opened with CDT. In contrast, long segment stenosis, diffuse disease, or limited runoff limit the affected vessel should dissuade one from initiating CDT. In diffusely diseased vessels, thrombolysis serves to only consume time while exposing the patient to potential bleeding complications. Therefore, these patients often will be triaged directly to surgical bypass.

In patients with native vessel occlusions resulting from embolic disease, lack of well developed collaterals often results in dramatic, poorly tolerated symptoms very early in the course of ischemia. When initial assessments suggest minimal baseline atherosclerotic disease, or when history points to an embolic occlusion, these patients should undergo surgical embolectomy. CDT in combination with mechanical or aspiration embolectomy is also an option. These endovascular techniques are especially efficacious below the knee, where angiographic guidance allows for evaluation and selective interventions in small arteries.

RECOMMENDED INTERVENTIONS FOR DISEASE IN BYPASS GRAFTS

The STILE trial demonstrated lower amputation rates with CDT compared with surgery for thrombotic occlusions of bypass grafts. In patients with thrombosed bypass grafts, timing of the graft failure determines the appropriate treatment. If the patient presents within the first 30 days after bypass, graft failure is most often a result of technical problems with the graft; assuming the patient is not hypercoagulable. If the bypass is partially open, imaging usually reveals the causative lesion; the most common finding is a distal anastomosis stenosis. In native vessel conduits, one will occasionally see a stenosis that results from the use of too small a caliber venous conduit, or even more uncommonly, a perivascular hematoma, resulting from improper vein preparation. Patients with early bypass failure should undergo surgical revision. An endovascular approach is only recommended in the rare case of an isolated unfavorable lesion that appears amenable to PTA. More often, thrombolysis alone serves only to open the bypass temporarily. The underlying technical problem quickly reasserts itself, and the limb once again becomes ischemic.

If the bypass goes down beyond the 30-day perioperative period, one should first consider the severity of the ischemia and the indications for the original surgery. If the ischemia does not threaten the viability of the limb, as it did in 30% of the patients in the STILE trial, and the original bypass was performed to treat life-threatening ischemia, a watch and wait approach may be warranted. It is unlikely that any revision of the graft will provide long term improvement in limb perfusion, but it is possible that further surgery could make things worse. In these cases, noninvasive imaging and DSA are appropriate to assess whether distal target vessels are available for the secondary bypass and to assess whether endovascular treatments could improve outflow from the poorly functioning bypass.

In cases of life threatening ischemia occurring beyond the 30 day perioperative window, the most common causative lesion is focal intimal hyperplasia, typically at a valve or anastomosis. CDT is the treatment of choice in these instances because it allows for identification of the treatable lesion. CDT also restores flow through the thrombosed collaterals, thus reperfusing the threatened limb. Thrombolysis should be followed by PTA once the focal lesion is identified. If a causative lesion can be identified and treated, the 1 year patency is more favorable than if there had been no lesion. Grafts maintained exclusively by CDT and PTA have been found to have excellent long-term patency rates, especially if ABIs immediately after treatment are high. There are, however, two caveats: first, the outcomes (particularly the rate of amputation free survival) of thrombolysis are generally much better in venous grafts than in synthetic grafts; second, the beneficial effect of CDT is short lived in diabetic patients, with 1 year patencies being very low. In these patients, if imaging reveals suitable distal target vessel, secondary bypasses are a superior treatment choice because of their higher patency rates.

Patients with vein grafts more than 1 year old are excellent candidates for CDT because the mature conduit has proven itself once time. The failure is usually a result of progressive atherosclerotic disease in the inflow or outflow vessels. CDT will often unmask a stenosis supporting graft with poor inflow or outflow vessels, which themselves can be treated via endovascular means to maintain graft function.

CATHETER-DIRECTED THROMBOLYSIS

Over the past 20 years, CDT has completely supplanted systemic intravenous thrombolysis. The role of CDT is to (1) restore flow, (2) reveal and underlying causative lesion, and (3) improve perfusion of the outflow vessels. The unmasked lesion should then be treated via endovascular or open surgery.

Preoperative Planning

If CDT is to be used as part of the ischemic limb treatment plan, the preprocedural consent should describe the risk of hemorrhage, limb loss, renal failure, anaphylaxis, stroke, and death. Bleeding is the most frequent significant complication associated with CDT. Intracranial hemorrhage can often be devastating, but is fortunately rare, having been reported in 1.2% (STILE) to 2.1% (Thrombolysis or Peripheral

Arterial Surgery 1) of patients undergoing CDT. Absolute contraindications to CDT include active/life-threatening bleeding, aortic dissection, recent intracranial or intraspinal surgery or trauma, and intracranial arteriovenous malformations or aneurysms. Relative contraindications include major surgery within the past 4 weeks, uncontrolled hypertension, gastric ulcers, recent eye surgery, recent stroke, recent neurosurgery, ongoing bleeding diathesis, pregnancy or the first 10 days postpartum, and intracranial neoplasms.

Technique

Patients should be given aspirin and heparin as they are being worked up for CDT. Any previous noninvasive imaging should be made available and reviewed. Pulses in both limbs should be documented, and an operating room suite should be available in the event of that conversion to open surgery be necessary. Iso-osmolar contrast should be used throughout, and the procedure should be performed under conscious sedation.

Retrograde contralateral access should be obtained with arterial puncture occurring over the femoral head. Ultrasound guided 21-gauge micropuncture access is recommended to minimize the risk of hematoma and dissection. A 5Fr vascular sheath should then be placed. A 5Fr Omni flush (AngioDynamics) or pigtail catheter should then be advanced to the level of the renal arteries. An aortogram and bilateral lower extremity runoff should then be performed.

Once the thrombosed vascular segment is identified, the wire-catheter combination should be advanced up and over the iliac bifurcation to the levels of the contralateral (affected side) external iliac artery. After a wire is placed in the contralateral external iliac artery the access catheter and 5Fr sheath should be exchanged for a 6–7Fr up-and-over sheath such as a Flexor Ballvin (Cook Medical) into the contralateral common iliac or external iliac artery. A heparin bolus is then usually administered (100 U/kg) and an activated clotting time is checked (goal activated clotting time >250 seconds).

An attempt should then be made to cross the thrombosed segment. I prefer a combination of a 45° straight or 30° angle taper Glide catheter (Terumo) and a hydrophilic guidewire (e.g., Glidewire [Terumo], Roadrunner [Cook]). This combination imparts excellent maneuverability and easily crosses most occlusions. In cases with significant underlying atherosclerotic disease, a combination of a 45° straight Glide catheter and a Bowen wire (Cook) can be used to traverse the thrombus. This combination ensures that the bent tip of the wire leads as the lumen of the diseased vessel, minimizing the risk of dissection. Use gentle, controlled attempts to cross the thrombus, with injections of dilute contrast whenever the wire-catheter combination does not easily advance. The goal is to carefully advance through the soft thrombus, avoiding embolization while staying intraluminal. Rarely, a microwire (<0.018 inch) and microcatheter (<3 Fr) may be advanced coaxially to aid in successful crossing thrombus in heavily diseased vessels with tight stenoses.

Once the thrombosed segment is crossed, the length of the occlusion should be defined and measured. An appropriate multiple side hole infusion catheter (Pulse Spray Infusion System [AngioDynamics Inc.], Katana Infusion Wire [Boston Scientific]) should then be advanced over the wire through the occlusion. The infusion length should be as close to possible to the length of the occlusion, erring on the side of a shorter infusion length. If some side holes are outside the thrombus, the infused drug will take the path of least resistance and will escape out the holes in the patent artery. After the infusion catheter is in position, the guidewire is removed and the end hole of the infusion catheter is plugged with an occlusion wire (Pulse Spray Infusion System) or infusion wire (Katana Infusion Wire). The sheath and catheter are secured to the skin, whereas the infusion catheter is secured to the sheath with Steri-Strips and sutures to prevent catheter displacement, before the patient leaves the angiography suite. I use a 150–300 U/hr intra-arterial infusion of heparin via the tip and over the sheath to prevent thrombus from forming on the tip of the sheath or along the unobstructed portion of the infusion catheter.

Infusion

Very limited data are available that compares the efficacy of thrombolytic agents for use in CDT. In the United States, streptokinase, anistreplase, alteplase (recombinant tissue plasminogen activator [tPA]), reteplase, and tenecteplase are available. A systematic review suggests that intra-arterial recombinant tPA is more effective than intra-arterial streptokinase in improving vessel patency. Lysis and bleeding rates are comparable among the various agents, with very few direct comparison trials available and no clear-cut evidence of superiority of one agent over another for CDT.

There are a number of different thrombolysis techniques described in the literature. The simplest and most often used technique is continuous infusion. In this technique, thrombolysis is performed via an infusion catheter placed after diagnostic angiography. The patient subsequently returns for follow-up angiography until a procedure endpoint (successful lysis) is reached. The bolus method involves delivery of a single, highly concentrated dose of thrombolytic agent throughout the occlusion and then initiation of continuous infusion. The pulse spray technique refers to repeated forceful injection of small aliquots of thrombolytic, thus distributing the thrombolytic agent rapidly throughout the thrombus as well as mechanically disrupting the thrombus. Pulse spray is initiated and continued in the angiography suite until antegrade flow is restored. In the graded infusion technique, the rate of drug infusion is diminished over time. Step-wise infusion differs from the other methods in that it uses an end hole catheter that is embedded in the proximal portion of the thrombus. There is no evidence of significant differences in amputation-free survival between these methods. Continuous infusion requires the least procedure time and is an appropriate choice for relatively mild ALI. If an infusion is begun late in the day, the infusion rate can be set relatively low for a 12- to 15-hour overnight infusion. However, studies have shown faster thrombolysis times when bolus or pulse spray methods are combined with continuous infusion. Therefore, bolus and pulse spray methods are often used when time is limited for reestablishing antegrade flow, which is often the case in ALI. Some reports, however, show an increased risk of bleeding complications compared with continuous infusion, whereas others do not. There is concern with both bolus and pulse spray infusion techniques that there may be an increase in distal embolization resulting from thrombus fragmentation.

I typically lace the thrombus with an initial 5–10 g bolus of tPA then initiate a 0.5–1.0 mg/hr continuous infusion (10 mg tPA in 1 L of normal saline, infused at a rate of 50–100 ml/hr). A recent study has shown similar positive results using an ultra-high dose infusion CDT protocol. The ultra-high dose technique used an initial pulse spray technique delivering 1 mg/min for 15 minutes, followed by an infusion of 15 mg over 2 hours. An angiogram is then performed and if there was residual thrombus present a further 10 mg of alteplase is infused over an additional 2 hours. Another recent study has shown that accelerated CDT protocol with an initial dose of 10 mg recombinant tPA for 30 minutes followed by a 3 hour course of a continuous intra-arterial 10 mg/hr infusion showed positive outcomes.

Patients should be admitted to a monitored bed where checks of the treated limb, Doppler pulses, groin checks, and neurologic checks should be performed at regularly prescribed intervals (every 2 hours). Fibrinogen, hematocrit, hemoglobin, platelets, and partial thromboplastin time should be checked at baseline and every 8 to 4 hours, with the tPA infusion rate halved for when the fibrinogen level falls below 150 mg/dL. If the fibrinogen level falls below 100 mg/dL infusion should be discontinued because of the increased of bleeding demonstrated in the STILE 1 trial. However, there is no prospective evidence that this practice lowers bleeding risk, and consequently, many other practices do not monitor fibrinogen levels. Alternatively, cryoprecipitate can be given to raise the fibrinogen level and allow for continued infusion of tPA.

Increased pain in the treated limb may indicate successful thrombolysis, with pain occurring as a result of distal emboli showering and washout of cytokines. Other clinical variables such as temperature,

color, pulse, and capillary refill should all point toward improving perfusion. If at any point the treated limb appears to be more ischemic, the infusion setup and catheter position should be checked. If the limb becomes critically ischemic, CDT should be aborted and surgical revascularization should be attempted. If the limb ischemia is stable or improving, revaluation with angiography is indicated every 6 to 24 hours until flow is restored.

A number of devices have been developed in an effort to accelerate the thrombolytic process, therefore decreasing the risk of hemorrhage and other complications. Pulse-spray catheters, mechanical lysis catheters, aspiration catheters, rheolytic catheters, and ultrasound-accelerated devices are all currently available. These devices have been developed to facilitate disruption and penetration of the thrombus by the thrombolytic agent. In theory, this allows less thrombolytic to be used and shortens the infusion time necessary to achieve thrombolysis. A recent study showed that there was a significant improvement in complete thrombolysis, lower 30-day amputation rate and fewer bleeding complications with ultrasound-accelerated CDT (EKOS [Bothell, WA]) when compared with standard CDT. The study also reported a significant decrease in thrombolysis time and volume of lytic agent required for successful thrombolysis in native arteries and bypass grafts.

Patients requiring more than 3 thrombolysis days are likely to have chronic thrombotic components underlying their acute presentation and could be resistant to fibrinolytic therapy. In these patients, it is possible that despite infusion of fibrinolytics, the thrombus is not lysed and they may be at risk for adverse complications of continuous fibrinolytic therapy.

ADJUNCTIVE PHARMACEUTICALS

The addition of glycoprotein IIb/IIIa platelet receptor inhibitors reduce platelet aggregation and reduce thrombolytic resistance of platelet-bound fibrin. There are several drugs in clinical use that bind glycoprotein IIb/IIIa receptors. These include abciximab (ReoPro; Lantus Biotech), a monoclonal antibody fragment; eptifibatide (Integrilin; Shering Plough); and tirofiban (Aggrastat; Merck). Studies comparing adjunctive use of abciximab during peripheral arterial CDT with CDT alone have shown no difference in technical success (Post Myocardial Infarction Remodeling Prevention Therapy and AIMAT trials). Infusion time was either shorter or equivalent. The frequency of bleeding was either equivalent or higher. Experience with tirofiban and eptifibatide is limited. Use of these agents in peripheral arterial CDT has not been widely adopted given the clinical results so far.

FOLLOW-UP

The goal of CDT is to provide timely, safe, effective, and durable revascularization of the affected limb. After successful revascularization, the patient should be placed on an 81 mg daily dose of aspirin for life. Underlying vascular risk factors should be addressed with antihypertensives, glycemic control, statins, and smoking cessation. Additional antithrombotic drugs may be administered, depending on the nature of the revascularization procedure. The value of dual antiplatelet therapy comprising aspirin plus clopidogrel or ticlopidine, which is well established in coronary stenting, remains controversial in peripheral revascularizations, and evidence-based guidelines do not recommend routine use. ABIs should be used to monitored patency after revascularization. If the ABI decreases by more than 0.2, angiography or noninvasive imaging is indicated.

MANAGEMENT OF INFECTED GRAFTS

Melanie Nichols, MD, and Matthew R. Smeds, MD, FACS

Graft infection is a constant concern when a prosthetic material is used as a conduit in vascular surgery procedures, and a devastating complication when it occurs. Its occurrence often results in significant morbidity, high rates of limb loss, and portends a significant mortality risk. Infection rates vary depending on the anatomical location of the graft material as well as the pathology being treated as well as presence of intervening systemic infections or contaminated initial procedures. Open aortic graft implantations have infection rates ranging between 1% and 3%, which interestingly mirrors that of endovascular stent grafts, which demonstrate an infection rate of 0.2% to 1% despite the minimally invasive approach to this pathology. Lower extremity grafts have similar infection rates with up to 4.3% to 6% with higher rates associated with those in the groin. As expected, infections in grafts placed for dialysis access occur at higher rates due to the repeated manipulations, occurring in 5% to 20% of the patients. Regardless of the location of the graft or pathology being treated, the key to a good clinical outcome is early diagnosis and treatment with removal of all infected graft material, debridement to healthy tissue, and coverage of any exposed vessels.

DIAGNOSIS

The diagnosis of graft infection can be as obvious as observing exposure of part of the graft in a wound or as subtle as identifying a small amount of fluid around the graft on imaging (Fig. 1). Once there is suspicion for a graft infection, a good history and physical concentrating on fever or chills, malaise, and constitutional symptoms and examining the suspicious area for any erythema, cellulitis, swelling,

color, pulse, and capillary refill should all point toward improving perfusion. If at any point the treated limb appears to be more ischemic, the infusion setup and catheter position should be checked. If the limb becomes critically ischemic, CDT should be aborted and surgical revascularization should be attempted. If the limb ischemia is stable or improving, revaluation with angiography is indicated every 6 to 24 hours until flow is restored.

A number of devices have been developed in an effort to accelerate the thrombolytic process, therefore decreasing the risk of hemorrhage and other complications. Pulse-spray catheters, mechanical lysis catheters, aspiration catheters, rheolytic catheters, and ultrasound-accelerated devices are all currently available. These devices have been developed to facilitate disruption and penetration of the thrombus by the thrombolytic agent. In theory, this allows less thrombolytic to be used and shortens the infusion time necessary to achieve thrombolysis. A recent study showed that there was a significant improvement in complete thrombolysis, lower 30-day amputation rate and fewer bleeding complications with ultrasound-accelerated CDT (EKOS [Bothell, WA]) when compared with standard CDT. The study also reported a significant decrease in thrombolysis time and volume of lytic agent required for successful thrombolysis in native arteries and bypass grafts.

Patients requiring more than 3 thrombolysis days are likely to have chronic thrombotic components underlying their acute presentation and could be resistant to fibrinolytic therapy. In these patients, it is possible that despite infusion of fibrinolytics, the thrombus is not lysed and they may be at risk for adverse complications of continuous fibrinolytic therapy.

ADJUNCTIVE PHARMACEUTICALS

The addition of glycoprotein IIb/IIIa platelet receptor inhibitors reduce platelet aggregation and reduce thrombolytic resistance of platelet-bound fibrin. There are several drugs in clinical use that bind glycoprotein IIb/IIIa receptors. These include abciximab (ReoPro; Lantus Biotech), a monoclonal antibody fragment; eptifibatide (Integrilin; Shering Plough) and tirofiban (Aggrastat; Merck). Studies comparing adjunctive use of abciximab during peripheral arterial CDT with CDT alone have shown no difference in technical success (Post Myocardial Infarction Remodeling Prevention Therapy and AIMRT trials). Infusion time was either shorter or equivalent. The frequency of bleeding was either equivalent or higher. Experience with tirofiban and eptifibatide is limited. Use of these agents in peripheral arterial CDT has not been widely adopted given the clinical results so far.

FOLLOW-UP

The goal of CDT is to provide timely, safe, effective, and durable revascularization of the affected limb. After successful revascularization, the patient should be placed on an 81 mg daily dose of aspirin for life. Underlying vascular risk factors should be addressed with antihypertensives, glycemic control, statins, and smoking cessation. Additional antithrombotic drugs may be administered, depending on the nature of the revascularization procedure. The value of dual antiplatelet therapy comprising aspirin plus clopidogrel or ticlopidine, which is well established in coronary stenting, remains controversial in peripheral revascularizations, and evidence-based guidelines do not recommend routine use. ABIs should be used to monitored patency after revascularization. If the ABI decreases by more than 0.2, angiography or noninvasive imaging is indicated.

MANAGEMENT OF INFECTED GRAFTS

Melanie Niekola, MD, and Matthew R. Smeds, MD, FACS

Graft infection is a constant concern when a prosthetic material is used as a conduit in vascular surgery procedures, and a devastating complication when it occurs. Its occurrence often results in significant morbidity, high rates of limb loss, and portends a significant mortality risk. Infection rates vary depending on the anatomical location of the graft material as well as the pathology being treated as well as presence of intervening systemic infections or contaminated initial procedures. Open aortic graft implantations have infection rates ranging between 0.5 and 3%, which interestingly mirrors that of endovascular stent grafts, which demonstrate an infection rate of 0.2% to 1% despite the minimally invasive approach to this pathology. Lower extremity grafts have similar infection rates with up to 4.3% to 6% with higher rates associated with those in the groin. As expected, infections in grafts placed for dialysis access occur at higher rates due to the repeated manipulations, occurring in 5% to 20% of the patients. Regardless of the location of the graft or pathology being treated, the key to a good clinical outcome is early diagnosis and treatment with removal of all infected graft material, debridement to healthy tissue, and coverage of any exposed vessels.

DIAGNOSIS

The diagnosis of graft infection can be as obvious as observing exposure of part of the graft in a wound or as subtle as identifying a small amount of fluid around the graft on imaging (Fig. 1). Once there is suspicion for a graft infection, a good history and physical concentrating on fever or chills, malaise, and constitutional symptoms and examining the suspicious area for any erythema, cellulitis, swelling,

FIG. 1 Exposed femoral-femoral bypass graft with sartorius muscle flap for coverage. *(From Abramowitz JT, Jimenez JM, editors. Endovascular Surgery. 4th ed. Philadelphia: Elsevier; 2019.)*

or drainage is the first step. When infection is suspected and not obvious, then imaging modalities will be the next step for making the diagnosis. During this time, the patient should be resuscitated, a complete blood count and blood cultures should be obtained from the patient, and the patient should be started on empiric broad-spectrum antibiotics. Markers of inflammation such as the erythrocyte sedimentation rate or C-reactive protein may also be obtained in patients with graft infection and can be obtained with initial labs as well. The surgeon should begin to consider all surgical and medical management options once the diagnosis becomes clear as timely management is crucial to this disease process.

Imaging

Computed tomography (CT) scanning is the current gold standard imaging modality for making the diagnosis of graft infection (Figs. 2 and 3). Key findings on this imaging may include periprosthetic fluid or soft tissue changes, fat stranding or loss of tissue planes, ectopic gas, and pseudoaneurysm. Because these are findings that suggest infection and much greater sensitivity in the later stages of infection, a high index of suspicion is necessary. This should be the modality of choice in all suspected intracavitary graft infections (abdominal and thoracic aortic) unless contraindicated. Findings are best appreciated with intravenous contrast. Use of CT is limited when contrast cannot be used or there is artifact from previous metal implants.

Ultrasound is the initial test of choice for suspected extracavitary graft infections. It is a modality that is usually readily available, is noninvasive, and can be performed at the bedside if necessary. Findings include periprosthetic fluid and color flow can easily eliminate intraluminal extravascular fluid. It is also able to show pseudoaneurysm, hematoma, and soft tissue masses as well as assess graft patency. It is limited by being dependent on the skill of the technician and its use for intracavitary grafts is limited due to anatomic issues.

Magnetic resonance imaging (MRI) is able to distinguish similar features as CT scan for graft infections and it has the added advantage of being able to distinguish periprosthetic fluid from chronic inflammation such as fibrosis or chronic hematoma via T1- and T2-weighted images. There is no radiation exposure and contrast is not required, but gadolinium does help delineate the vasculature. Limitations of MRI include expense, length of time for image acquisition, and nephrogenic systemic fibrosis in renal patients who are given the contrast agent.

Tagged white blood cell scans and positron emission tomography scanning are also used often in diagnosis of graft infection. Tagged white blood cell scanning is a nuclear medicine test that aims to show abnormal accumulation of leukocytes in periprosthetic tissue. This test will not delineate the vasculature but can be used in conjunction with CT or MRI to determine the presumed location of the increased uptake as it correlates to graft location. This is a very sensitive test but is not useful in the early postoperative period given there is increased uptake resulting from the normal healing process during this time. This test also takes some time to complete, often with multiple trips to the nuclear medicine division. Positron emission tomography is a newer diagnostic modality and has good sensitivity due to the increased uptake of fluorodeoxyglucose in the inflammatory cells. As with the tagged white cell scan, this test can have a high false positive rate since normal healing will also increase the uptake.

Finally, endoscopy is a modality used for very specific infections which would result in a graft to enteric fistula. It should be considered in a patient with previous aortic graft placement that presents with an upper GI bleed. Ideally the technician will visualize the entire esophagus, stomach and duodenum to look for any sign of fistulation as well as other causes of bleeding. While it is a limited role, it is not a modality to discount in these situations (Fig. 4).

TREATMENT

The basic considerations for graft infection is to eradicate the infection and preserve perfusion. There are many options for accomplishing this, and the treatment modalities need to be individualized to the patient as well as abiding to basic surgical principles. The basic approach to graft infection falls into essentially one of three categories: (1) graft excision with revascularization, (2) graft excision without revascularization, or (3) graft preservation. Within these broad categories, there are multiple options for repair; however, not all these options are useable in every case and each technique may be suitable for specific circumstances. In all cases, coverage of the repair with autologous tissue (muscle flaps, omentum, etc.) may be used to decrease rates of future reinfection and deep cultures should be done to allow speciation of the infectious agent and better select antimicrobial therapy.

Graft Excision With Revascularization

Graft excision with revascularization is an option that is required if preserved in line arterial flow is necessary for limb or bowel tissue perfusion. This may include infected aortic grafts placed for occlusive or aneurysmal disease or in extracavitary grafts if the initial procedure was performed for critical limb ischemia. The goal is to remove all infected graft material and debride tissue to healthy viable deep tissue and reconstruct the arterial system in a way that is less prone to reinfection.

Extraanatomic Bypass

Extraanatomic bypass with excision of all prosthetic material for infected intracavitary abdominal grafts has traditionally been the gold standard for repair. This ensures all the infected material is

removed and that a new conduit is placed through healthy, uninfected tissue planes. The most common procedure performed is an axillofemoral graft with a femoral femoral bypass or an axillofemoral bypass using expanded polytetrafluoroethylene as conduit (Fig. 5). The inflow anastomosis often lines the axillary artery and the outflow is to the common femoral arteries if there is no groin infection. In the setting of infection to the common femoral region, the anastomosis can be to any distal vessel not affected, usually either the superficial femoral artery or the profunda, depending on patency. If the superficial femoral artery or profunda is used as the outflow vessel, the approach to these vessels should be lateral to the sartorius muscle to avoid contamination from the femoral triangle.

If there is a need for revascularization of the contralateral limb, this can be achieved via femoral femoral bypass with prosthetic if there is no groin infection, or can be done by an iliofiac bypass if the iliac vessels are not in a contaminated field. If a groin infection is present and a femoral-femoral bypass is necessary, then use of a saphenous vein or cryopreserved vein or artery conduit may be considered, or the outflow vessel to the contralateral limb can be distal (profunda femoris or superficial femoral artery). Once the lower extremities are

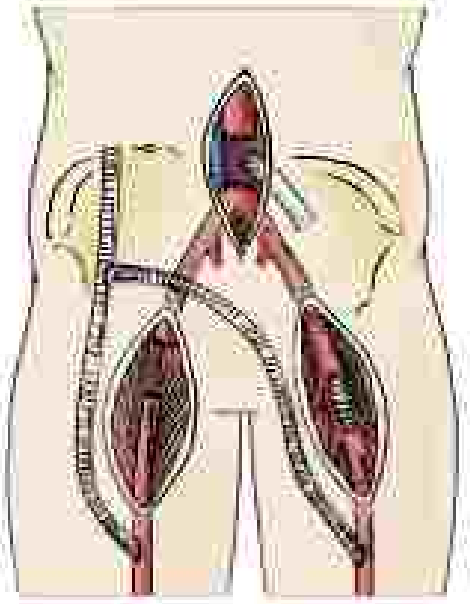

FIG. 3 Axillary artery to bilateral superficial femoral artery with ligation of aorta and excision of infected graft. (From Calligaro KD, Ferraro NA, Veluz AA, Dougherty MJ: Vascular Surgery 19th ed. Chicago: 2013.)

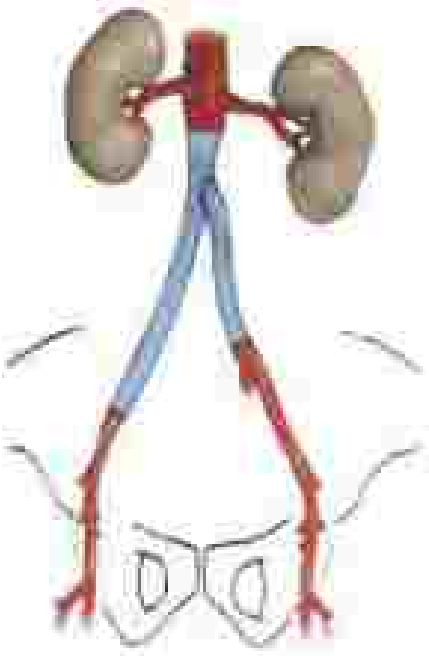

FIG. 4 Neoaortoiliac system procedure with replacement of the aorta with bilateral popliteal vein segments. (From Jackson MR, et al.: Aortic and subaortic revascularization of an infected aortic bifurcation graft treating the aortic duodenal fistulae. Vasc Surg 2002;36:627.)

reconstructed, the infected graft is completely excised, infected tissue is debrided and tissue coverage can be entertained. The approach to the infected graft is either transperitoneal by laparotomy or via a retroperitoneal approach, which can avoid intraabdominal adhesions from previous procedures. The suprarenal aorta is often needed for proximal control depending on the extent of the infected field and inflammation. Distal control of the bilateral iliac arteries should be obtained, and ureters should be identified and protected. The infrarenal aorta should be debrided to healthy tissue and the proximal portion should be oversewn in a double layer fashion with nonabsorbable monofilament suture. The same closure should be done for the distal aorta or iliac arteries. All prosthetic material should be removed and sent for culture and the unhealthy tissue should be debrided along with irrigation. The aorta stump should be covered with omentum and the retroperitoneum should be widely drained.

Complications of extraanatomic bypasses with graft explantation include anastomotic (3%–37%), early mortality, limb loss (3%–17%), and the dreaded aorta stump blow out with life-threatening hemorrhage (3%–29%). Additionally, the procedure often requires a lengthy operative time, frequently over two procedures, and the patency rates of the ultimate revascularization are not as robust as those of anatomic bypasses.

In Situ Antibiotic Impregnated Graft Replacement

In situ prosthetic graft replacement with antibiotic impregnated or antimicrobial grafts is acceptable for many patients, particularly those with low virulence pathogens, antibiotics, fistula, or erosion with impending hemorrhagic catastrophe. The procedure includes gaining proximal and distal control, excision of all graft material, debridement of infected tissue, irrigation with antibiotic solution, and immediate replacement with a new prosthetic graft. When possible, the graft material should be tunneled through a new route and all should be covered with omentum or tissue coverage, including muscle flap coverage with either the sartorius or gracilis muscle to the groin. The prosthetic materials most commonly used are Dacron soaked in rifampin or silver impregnated prosthetic grafts. Post-procedure, the patient will need to be maintained on intravenous antibiotics for 4 to 8 weeks and in some lifelong suppressive oral antibiotics after that. Use of this technique has demonstrated short operating times, excellent patency/durability, and low amputation and mortality rates, and it can be used in emergency settings in which the surgeon does not have adequate time to harvest autologous vein or thaw cryopreserved tissue. Its use in more aggressive microbial infections (drug resistant or *Pseudomonas*) is called in to question, and there is a potential for developing rifampin resistant organisms over time.

In Situ Cryopreserved Allograft Replacement

In situ arterial allograft is another alternative that consists of removing all infected graft material, debridement of tissues, antibiotic irrigation and new conduit placement with cryopreserved aorta. Again, the patient will receive 6 to 8 weeks of antibiotics postoperatively. Similar to the antibiotic impregnated grafts, the advantage of this technique is a one stage procedure, but this technique uses autologous material rather than prosthetic to decrease reinfection rate. The disadvantage of this procedure is lack of availability and cost as well as the time necessary for implantation, which requires thawing the frozen product before use. There is also concern for aneurysmal degeneration over time and need for continued surveillance of the graft and its use in aggressive microbial infections (drug resistant or *Pseudomonas*) is questioned. Long-term patency rates of this graft are less than that of prosthetic material but better than extraanatomic bypasses. Amputation rates are low (less than 8%) and mortality varies widely (9%–34%).

In Situ Venous Autograft

In situ venous autograft is a procedure also known as neo-aortoiliac system (NAIS) and consists of reconstructing the aortoiliac system using femoral popliteal vein as conduit (Fig. 4). Preoperative venous duplex of the bilateral lower extremities is necessary for this procedure because of the long length of saphenous vein that is needed as well as to ensure patency of the veins. It is unlikely that the saphenous vein will be of good caliber for use but in the event that it is (7–8 mm), then one of the deep veins can be preserved in each leg. Longitudinal thigh incisions lateral to the sartorius muscle are made to harvest the deep vein, the adductor hiatus is divided to expose the superficial femoral vein and its branches. The branches are ligated and the vein is

harvested from the level of the profunda femoris to as far proximally on the popliteal as needed for adequate length. Care is taken to preserve the profunda femoris vein and the superficial femoral vein is taken flush at its origin to ensure no deep venous thrombosis occurs. Once the vein is obtained the incisions are closed, preferably over drains. Authors have described staging the NAIS procedure. Vein is harvested with side branches ligated and left in situ and the patient is brought back the next day for the aortic portion of the case. This makes the operation much less arduous on the surgeon and has similar patency rates.

After the clean vein harvest is complete, the procedure continues with exposure of the infected graft. This includes gaining proximal and distal control, excision of all graft material, debridement of infected tissue, and irrigation with antibiotic solution. Once this is done the femoral vein is attached to the proximal aorta in a similar reversed fashion for appropriate size match. If the size mismatch is too great, then other techniques may be necessary. Two segments of superficial femoral vein can be anastomosed to each other, making a pantaloon configuration. The composite ends are then sewn end to end to the aorta (Fig. 7). Alternatively, if the mismatch is too great then the aortic stump can be oversewn and the vein graft can be anastomosed to the anterior surface of the aorta in an end to side fashion. The vein graft can then tunneled through the peritoneal tunnels and constructed to the femoral artery in an anterolateral fashion. The contralateral limb is then revascularized by creating an anastomosis with the second vein segment at the midpoint of the aortofemoral graft and then passing this to the contralateral groin where the distal anastomosis is made. The groin is closed, usually with muscle flap coverage.

The advantages of this procedure are autograft being used, in this case, complete removal of infected endograft, no concerns for immunogenicity of the conduit, and likely eradication of the infection. The disadvantages are procedure length and the complications that come with deep vein harvest, notably leg swelling and potential venous compartment syndrome that may require fasciotomies. Long term reinfection rates are close to 0% and mortality rates following the NAIS procedure range from 0% to 33%.

In situ venous allograft replacement is a procedure with similar construction to the NAIS but using cryopreserved vein. This is done to avoid the deep vein harvest and the complications that go along with it as well as to remove all infected graft material. The CryoVein is anastomosed to the aorta in an end to end fashion and the graft can then be tunneled to the femoral arteries in an anterolateral bypass fashion. As discussed, the original tunnels can be used for this procedure and muscle flaps to close the groins. CryoVein is more readily available than the CryoAorta or arterial grafts in many institutions, making this an easier conduit to obtain. However, the procedure remains lengthy, and although the conduit used is autologous, its use in aggressive microbial infections is still questioned.

Graft Excision Without Revascularization

Graft excision without revascularization can be considered in cases where the initial procedure was done for claudication or in a case where the graft is thrombosed and the patient does not have critical limb ischemia. Although the goal in most infected graft procedures is to remove graft material and maintain flow, this may not be necessary because the location of the graft or reasons for its placement. The technique in this case is to preserve as many branches as possible to maintain collateral flow. The arteriotomy left with the graft removal is repaired, commonly with a vein patch to not narrow the vessel. In some cases, a small cuff of graft is left behind and oversewn. This still not narrow the artery but may pose a future problem with continued graft material in this infected field. The patient is at risk of limb loss even if their initial procedure was not for critical limb ischemia. Their native vessel may have progressed with calcific disease and the nature of the graft removal may disrupt any collateral vessels feeding the outflow, so monitoring of the limb closely postoperatively is crucial.

FIG. 7 Nonanatomic aortic replacement of infected aortic graft with harvested femoral popliteal vein. Patient's head is picture right, vein is anastomosed in end-to-end fashion with aorta on right of picture with end-to-side anastomosis of vein to vein to create bifurcation in the middle of the image. (*Courtesy Kevin Ni, MD.*)

Graft Preservation

A final option for graft infection is graft preservation with wide local wound debridement. Infected prosthetic material is left behind, and this technique should be reserved for limited circumstances. Patent grafts with a short segment involved with low virulent infections are a prime example of one where preservation can be considered. Infections limited to the periprosthetic tissue, nonvirulent species and no systemic signs are criteria necessary before preservation is attempted. Once a patient fit into this category then the next step is debridement of all infected tissue with washout of the area. This may need to be done several times to ensure there is healthy uninfected tissue. Repeat cultures of the area are also necessary to continue to guide treatment. Once there are negative cultures and healthy tissue, the wound can be closed or covered. If the tissue in the surrounding area is healthy, then muscle flap coverage is a good option. The wound may require negative pressure vacuum-assisted closure therapy as well as possible need for skin graft. Authors have described the use of antibiotic beads placed at the site of infected grafts that cannot be explanted or a period of antibiotic instillation and drainage of drains can be placed near the abscessed graft. Conservative management of intracavitary graft infections in these manners can be done, but it is exceedingly more difficult to preserve graft material without persistent or recurrent infection. Partial graft preservation is also sometimes entertained, particularly in patients with isolated infections of a limb of a prosthetic graft. The infected limb is removed, culturally tissue is debrided, and it is replaced with autogenous, autologous, or antibiotic soaked Dacron. This new conduit is often tunneled through clear tissue planes, with some surgeons using the obturator canal. Graft preservation is difficult and may ultimately fail, but the features to increase success are: low virulence organisms, absence of periprosthetic abscess or sepsis, and early appearing infection (Figs. 8 and 9).

INFECTED STENT-GRAFTS

Aortic stent graft infection is a rare problem at this time but clearly poses a large concern for morbidity and mortality in these patients, and given the increasing extent of endovascular management of vascular diseases, this issue promises to become much more prevalent. Additionally, as we have become more adventuresome with repairing large vascular problems with this minimally invasive approach,

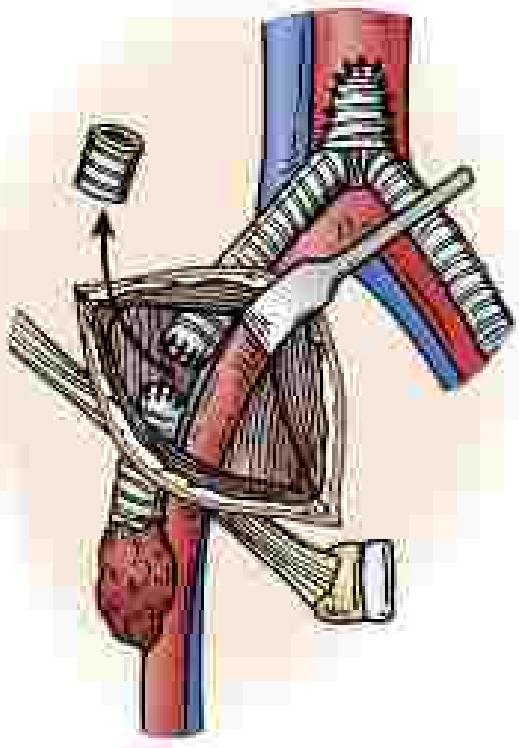

FIG. 8 Retroperitoneal exposure of aortobifemoral graft limb through obturator plane. (From Crawford JL, Johnson WC, Salam AA, Kahaku EK, Hallett JW Jr. Aortic reconstruction through the obturator plane. Surgery. 1985;98:1000–1008.)

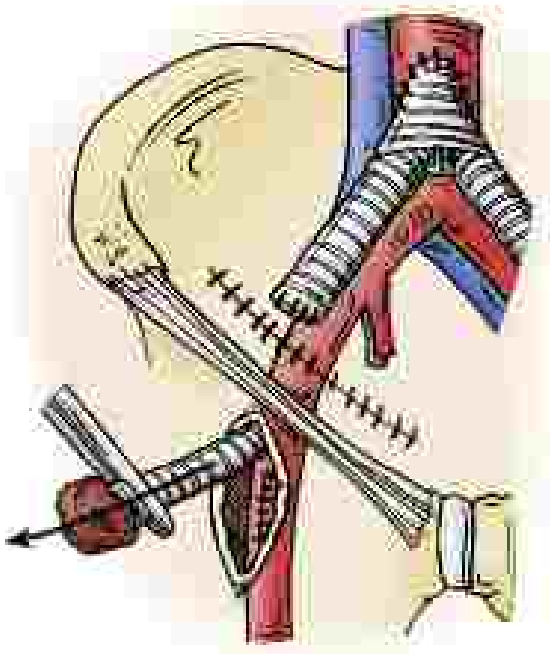

FIG. 9 Removal of infected graft portion from the groin. Replacement with vein, cryopreserved artery or rifampin-soaked Dacron graft is performed for revascularization if needed. (From Crawford JL, Johnson WC, Salam AA, Kahaku EK, Hallett JW Jr. Aortic reconstruction through the obturator plane. Surgery. 1985;98:1000–1008.)

patients are now being offered endovascular repairs while not being candidates for open repairs. Infections in this older and sicker population can thus be challenging. Currently, 0.2% to 5% of abdominal or thoracic stent grafts get infected. The source of infection is thought to be due to systemic bacteremia resulting in seeding of stent graft and every device is equally susceptible. This bacteremia may be the result of internal known systemic infections, chronic infections, placement of the stent graft in an infected field, or in patients who have had repeated interventions performed after their initial procedure. Time to diagnosis is usually within 22 months of surgery.

Patients may be asymptomatic but usually will present with pain, bronchitis, development of an endoleak, fistula, or rupture. Diagnosis is largely made by CT angiogram but can also be made via other modalities discussed earlier (Fig. 10). In patients with presumed infection, blood cultures should be taken and the patient should be started on broad spectrum antibiotics. The determination is then made if the patient will be able to withstand a major procedure to remove the infected stent graft.

If the patient is able to withstand an open operation, then preparation should be the same as for the intracavitary infected grafts. The options for removal of the infected material and maintaining flow are the same as for the infected aortic grafts. After the abdomen is opened and infected tissue debrided, proximal and distal control is obtained on the aorta. The proximal control may need to be supraceliac or even in the thoracic aorta. The aorta is opened and the stent graft is removed. This could pose a challenge particularly in grafts with suprarenal fixation. Once the graft is removed then aortic reconstruction is accomplished by in situ prosthetic graft placement, in situ arterial allograft, in situ venous autograft or in situ venous allograft. The other option would be to do an extra anatomic bypass with removal of all infected material and over sewing of the aorta. These procedures were discussed earlier. Long term, these patients have fairly high morbidity and mortality, with up to 50% having a perioperative complication and an overall 5-year survival of 50%.

FIG. 10 Computed tomography angiogram reveals air and fluid around abdominal aortic graft. Arrow points to duodenum looping over the top of the graft with an accompanying fistula. (Courtesy Michael Williams, MD.)

Patients with infected thoracic endovascular aortic repairs do worse than those with infected endovascular aortic repairs and use of autologous or autogenous material as conduit has been demonstrated to be superior.

INFECTED DIALYSIS ACCESS GRAFTS

Prosthetic arteriovenous access is used for a large number of renal patients on dialysis. These grafts can essentially be anastomosed to any artery and vein that are in close proximity including access in the

area, groin, and chest wall. Because this graft is repeatedly punctured for dialysis as well as the location of some of the access sites, there is a relatively high rate of infection ranging from 9% to 20%.

These graft infections can present like any other graft infection, but with the repeated use, there is a high chance of developing a pseudoaneurysm or hemorrhage in these patients. Patients often present with malaise, fevers, and evidence of erythema or purulent drainage from previous access sites. Once graft infection is suspected, blood cultures should be taken and the patient should be placed on empiric antibiotics. If there is a high enough index of suspicion, then no imaging is necessary; however, some of the infections can take a more indolent course and ultrasound or tagged white blood cell scan can aid in diagnosis.

As described previously, all infected material should be removed. An incision should be made over the area of the anastomosis and control should be both proximal and distal on the artery and the vein. Once this is done, then the graft can be removed. This may require a combination of several depending on how well the graft is incorporated. Once the graft is removed, the venotomy can be closed primarily. A vein patch obtained from either saphenous vein or a nearby vein if able should be used to close the artery to prevent narrowing. Tissue or muscle is then used to close the area over the vein and artery. If there is evidence of significant infection, such as purulent drainage, the skin should be left open to heal by secondary intent or a wound vacuum assisted closure device placed. The patient may then need a temporary dialysis line until the infection is cleared at which time a more permanent access can be entertained.

CONCLUSIONS

Although prosthetic graft infection is a diagnosis no surgeon wants to make, the key to a good outcome is early diagnosis and intervention. The patient will need control of sepsis, broad-spectrum and then targeted antibiotics, debridement of the infected tissue, removal of all graft material when able, and revascularization as needed. With careful patient selection and timely repair, salvage of these patients is possible via a number of surgical options.

ATHEROSCLEROTIC RENAL ARTERY STENOSIS

Joseph S. Giglia, MD

Atherosclerosis is the most common cause of renal artery stenosis (RAS), accounting for 90% of cases. Atherosclerotic RAS has been implicated as a significant contributor to systemic hypertension and impaired renal function. It is important to understand that RAS is rarely the sole cause of hypertension or renal dysfunction. Although the incidence of RAS may be as high as 45% in certain high-risk groups, there are no data to justify prophylactic treatment of asymptomatic patients. The majority of patients with symptomatic RAS should be managed medically with invasive intervention reserved for only a select subset of patients. As in other areas of vascular intervention, the explosion of catheter-based endovascular interventions has increased the number of procedures for RAS often without regard for the natural history or the clinical outcomes. Open surgical reconstruction is still indicated in a limited number of situations with very specific indications.

INCIDENCE

The incidence of atherosclerotic RAS in approximately 5.4% in patients with resistant hypertension, and it may affect as many as 6.8% of adults older than 65 years of age. It is even more prevalent in those with vascular disease, with estimates between 22% and 49%. Risk factors associated with atherosclerotic RAS include advanced age, hypercholesterolemia, peripheral arterial disease (PAD), cerebrovascular disease (CVD), and coronary artery disease (CAD), with the severity of atherosclerotic RAS often paralleling the severity of CCAD.

NATURAL HISTORY

Although RAS often is implicated as a cause of systemic hypertension and worsening renal function, it is most frequently discovered as an incidental finding on abdominal ultrasound, computed tomography angiography, magnetic resonance angiography, or random angiography performed for another reason. In studies using sequential angiography, atherosclerotic RAS lesions progressed in 11% to 44% of subjects. Progression to complete occlusion occurred in only 10% to 16% of patients with more than 60% stenosis. In patients studied by ultrasound, complete occlusion occurred in only 7% of patients with a stenosis greater than 60%. Progression of these lesions may be even less common, as a significant increase in RAS was seen annually in only 0.5% of patients with cardiovascular risk factors. Recently, these observations have led to a shift in the paradigm of RAS treatment.

The underlying pathophysiology is complex but likely related to a combination of renal ischemia and activation of the renin-angiotensin-aldosterone (RAA) system. Activation of the renin-angiotensin-aldosterone system results in the release of the vasopressor angiotensin II and plasma expansion via the effects of aldosterone. In most cases, the resultant hypertension can and should be managed medically. The ultimate endpoint of the disease process is hypertension resistant to medical therapy and progressive renal dysfunction resulting from ischemia, with renal atrophy being documented in 5.5%, 11.7%, and 29.8% of patients with normal renal arteries, renal arteries with less than 60% stenosis, and renal arteries with more than 60% stenosis, respectively. A critical issue is whether the renal parenchyma has already undergone permanent irreversible changes that will not be altered by intervention on a proximal main renal artery.

EVALUATION

Symptomatic RAS patients have resistant hypertension (uncontrolled hypertension on three medications) or progressive renal failure. Current guidelines suggest screening for RAS as part of a secondary hypertension etiology workup for those with resistant hypertension, severe hypertension (systolic blood pressure higher than 180 mm Hg, diastolic blood pressure greater than 110 mm Hg), elevated nighttime blood pressures during 24-hour monitoring, malignant hypertension, onset of hypertension at age younger than 30 years, sudden worsening of previously well-controlled hypertension, or discrepant kidney length on imaging. Patients with sudden worsening of renal function

groin, groins, and chest wall. Because this graft is repeatedly punctured for dialysis as well as the location of some of the access sites, there is a relatively high rate of infection ranging from 9% to 20%.

These graft infections can present like any other graft infection, but with the repeated use, there is a high chance of developing a pseudoaneurysm or hemorrhage in these patients. Patients often present with malaise, fevers, and evidence of erythema or purulent drainage from previous access sites. Once graft infection is suspected, blood cultures should be taken and the patient should be placed on empiric antibiotics. If there is a high enough index of suspicion, then no imaging is necessary; however, some of the infections can take a more indolent course and ultrasound or tagged white blood cell scan can aid in diagnosis.

As described previously, all infected material should be removed. An incision should be made over the area of the anastomosis and control should be both proximal and distal on the artery and the vein. Once this is done, then the graft can be removed. This may require a combination of several depending on how well the graft is incorporated. Once the graft is removed, the venotomy can be closed primarily. A vein patch obtained from either saphenous vein or a nearby vein if able should be used to close the artery to prevent narrowing. Tissue or muscle is then used to close the area over the vein and artery. If there is evidence of significant infection, such as purulent drainage, the skin should be left open to heal by secondary intent or a wound vacuum assisted closure device placed. The patient may then need a temporary dialysis line until the infection is cleared at which time a more permanent access can be entertained.

CONCLUSIONS

Although prosthetic graft infection is a diagnosis no surgeon wants to make, the key to a good outcome is early diagnosis and intervention. The patient will need control of sepsis, broad-spectrum and then targeted antibiotics, debridement of the infected tissue, removal of all graft material when able, and revascularization as needed. With careful patient selection and timely repair, salvage of these patients is possible via a number of surgical options.

Atherosclerotic Renal Artery Stenosis

Joseph S. Giglia, MD

Atherosclerosis is the most common cause of renal artery stenosis (RAS), accounting for 90% of cases. Atherosclerotic RAS has been implicated as a significant contributor to systemic hypertension and impaired renal function. It is important to understand that RAS is rarely the sole cause of hypertension or renal dysfunction. Although the incidence of RAS may be as high as 45% in certain high-risk groups, there are no data to justify prophylactic treatment of asymptomatic patients. The majority of patients with symptomatic RAS should be managed medically with invasive intervention reserved for only a select subset of patients. As in other areas of vascular intervention, the explosion of catheter-based endovascular interventions has increased the number of procedures for RAS often without regard for the natural history or the clinical outcomes. Open surgical reconstruction is still indicated in a limited number of situations with very specific indications.

INCIDENCE

The incidence of atherosclerotic RAS is approximately 5.4% in patients with resistant hypertension, and it may affect as many as 6.8% of adults older than 65 years of age. It is even more prevalent in those with vascular disease, with estimates between 22% and 49%. Risk factors associated with atherosclerotic RAS include advanced age, hypercholesterolemia, peripheral arterial disease (PAD), cerebrovascular disease (CVD), and coronary artery disease (CAD), with the severity of atherosclerotic RAS often paralleling the severity of CCAD.

NATURAL HISTORY

Although RAS often is implicated as a cause of systemic hypertension and worsening renal function, it is most frequently discovered as an incidental finding on abdominal ultrasound, computed tomography angiography, magnetic resonance angiography, or random angiography performed for another reason. In studies using sequential angiography, atherosclerotic RAS lesions progressed in 11% to 44% of subjects. Progression to complete occlusion occurred in only 10% to 16% of patients with more than 60% stenosis. In patients studied by ultrasound, complete occlusion occurred in only 7% of patients with a stenosis greater than 60%. Progression of these lesions may be even less common, as a significant increase in RAS was seen annually in only 0.5% of patients with cardiovascular risk factors. Recently, these observations have led to a shift in the paradigm of RAS treatment.

The underlying pathophysiology is complex but likely related to a combination of renal ischemia and activation of the renin-angiotensin-aldosterone (RAA) system. Activation of the renin-angiotensin-aldosterone system results in the release of the vasopressor angiotensin II and plasma expansion via the effects of aldosterone. In most cases, the resultant hypertension can and should be managed medically. The ultimate endpoint of the disease process is hypertension resistant to medical therapy and progressive renal dysfunction resulting from ischemia, with renal atrophy being documented in 5.5%, 11.7%, and 29.8% of patients with normal renal arteries, renal arteries with less than 60% stenosis, and renal arteries with more than 60% stenosis, respectively. A critical issue is whether the renal parenchyma has already undergone permanent irreversible changes that will not be altered by intervention on a proximal main renal artery.

EVALUATION

Symptomatic RAS patients have resistant hypertension (uncontrolled hypertension on three medications) or progressive renal failure. Current guidelines suggest screening for RAS as part of a secondary hypertension etiology workup for those with resistant hypertension, severe hypertension (systolic blood pressure higher than 180 mm Hg, diastolic blood pressure greater than 110 mm Hg), elevated nighttime blood pressures during 24-hour monitoring, malignant hypertension, onset of hypertension at age younger than 30 years, sudden worsening of previously well-controlled hypertension, or discrepant kidney length on imaging. Patients with sudden worsening of renal function

or recurrent flash pulmonary edema should also undergo evaluation for RAS. Individuals in whom renal function acutely worsens after the initiation of an angiotensin converting enzyme (ACE) inhibitor have an increased incidence of bilateral RAS.

Duplex ultrasound is the initial method of choice for RAS screening. The degree of stenosis is best determined by measurement of each renal artery peak systolic velocity (PSV). Normal renal arteries have a PSV of 60 to 180 cm/s. Renal artery PSV greater than 180 cm/s is indicative of RAS greater than 60%. The ratio of renal artery PSV to aortic PSV, also is calculated, with a value higher than 3.5 being indicative of RAS with luminal stenosis greater than 60%. The ratio of renal artery PSV to aortic PSV is invalid if the aortic PSV is greater than 100 cm/s, suggesting severe aortic disease. The other signs of RAS include intrarenal vascular tardus parvus and renal atrophy. A critical portion of the examination is calculation of the resistive indices within the kidney. Elevated risk indices indicate permanent irreversible renal parenchymal damage that would not be expected to be altered by renal artery intervention.

Computed tomography angiography and magnetic resonance angiography are more sensitive and specific modalities for delineating the precise anatomy and degree of RAS. Conventional arteriography remains highly accurate for identification and quantification of RAS but should only be undertaken if therapeutic intervention is planned.

Patients with RAS often have concomitant CAD, PAD, and CVD and should undergo evaluation as indicated by history and physical examination. Baseline serum creatinine, hemoglobin, lipid panel, and glucose are checked routinely.

TREATMENT

Although atherosclerotic RAS is associated with increased cardiovascular morbidity and mortality, there is no current evidence to support revascularization of asymptomatic patients or patients with well-controlled hypertension. Numerous randomized controlled studies, including the Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) trial comparing the results of endovascular intervention versus medical management, have demonstrated no benefit of stenting in patients with atherosclerotic RAS who are treated with antiplatelet therapy, statins, and blood pressure control with an ACE inhibitor or angiotensin receptor blocker (ARB).

Revascularization of patients with atherosclerotic RAS currently is reserved for refractory hypertension that is not responsive to maximal medical therapy and for patients with worsening coronary renal function. Young patients in whom flash pulmonary edema is caused by atherosclerotic RAS also may benefit from revascularization.

Medical Therapy

All patients with atherosclerotic RAS are at increased risk for cardiovascular morbidity and mortality, therefore hypertension and factors known to be associated with progression of atherosclerosis should be controlled aggressively.

Hypertension Control

Hypertension control should start with an ACE inhibitor or ARB. Calcium channel blockers, β-blockers, chlorothiazide, or hydralazine may be added for better control. There is good evidence that ACE inhibition and ARBs are helpful in patients with underlying cardiac disease and nephropathy. Most patients are able to tolerate ACE inhibitor or ARB therapy. However, ACE inhibition can decrease glomerular filtration rate (GFR) by blocking efferent arteriolar constriction, and therapy must be monitored closely to ensure that the decrease in GFR is minimal.

Lipid-Lowering Agents

Hyperlipidemia should be treated with a statin. Statin therapy decreases rates of myocardial infarction, prevents progression of CAD, PAD, and CVD, and decreases cardiovascular mortality. Although few studies have directly correlated statin use to outcomes in patients with RAS, reduction in angiographic progression of RAS has been demonstrated.

Antiplatelet Therapy

Although no study has focused specifically on patients with atherosclerotic RAS, antiplatelet therapy with aspirin or clopidogrel has been associated with decreased adverse cardiovascular events and mortality in patients with CAD, PAD, and CVD. Antiplatelet therapy is also an important adjunct after endovascular RAS revascularization. Patients who receive renal artery stents are treated with clopidogrel for at least 30 days, followed by low dose aspirin indefinitely. Antiplatelet therapy in these instances is meant to reduce early thrombotic complications as well as to reduce the chance of restenosis.

Smoking Cessation

As in all patients with atherosclerosis, smoking cessation is essential. Smoking has been implicated in arterial endothelial cell damage, increased levels of low density lipoprotein cholesterol, and increased platelet aggregation. Smoking also causes vasoconstriction, increased heart rate, and increased blood pressure. Smoking cessation has been shown to improve survival in patients with CAD and PAD. Patients who are able to quit smoking enjoy a 13% reduction in all cause mortality.

Glycemic Control

Patients with diabetes and concomitant atherosclerosis are at increased risk for progression of vascular disease. Good glycemic control (hemoglobin A_1 <7.0%) should be attained via either oral hypoglycemic agents or insulin therapy to prevent microvascular complications.

Renal Artery Stenosis Surveillance and Follow-Up

Although there are no quality data on RAS surveillance, I recommend duplex ultrasound initially every 6 to 12 months for patients with RAS greater than 60% to assess for progression of stenosis and renal atrophy. Blood pressure must be monitored carefully along with measurement of serum creatinine or estimated GFR. An abrupt change in control of hypertension or renal function may prompt earlier restaging of the renal arteries.

Revascularization

Based on the results of the Angioplasty and Stenting for Renal Artery Lesions and CORAL trials, revascularization for atherosclerotic RAS currently is reserved for patients with recalcitrant hypertension or worsening kidney function despite optimal medical management and young patients with flash pulmonary edema caused by RAS. Entry criteria for these studies excluded patients most likely to benefit from revascularization. For example, during the CORAL trial, enrollment was broadened to include patients with well-controlled hypertension, and patients with a recent history of congestive heart failure were excluded.

Revascularization can be accomplished by endovascular procedures or by open surgery. Endovascular approaches are preferred in most cases because of their minimally invasive nature, excellent early results, and lower perioperative morbidity and mortality when compared with open surgery. Angioplasty alone has lower success rates than angioplasty with stent placement. Open renal artery surgery is reserved for urgent salvage of endovascular technical failures resulting in hemorrhage or renal ischemia, revascularization of renal artery branches that are not amenable to endovascular repairs, and renal artery revascularization in combination with elective aortic reconstructions that require an open approach. Open renal artery

revascularization may also be required in select patients with aortic aneurysms or dissections treated with endovascular techniques.

Endovascular Therapy

The endovascular approach typically begins with standard percutaneous femoral artery access using the Seldinger technique. A diagnostic

FIG. 1 Aortogram displaying a proximal left renal artery stenosis.

catheter is inserted into the aorta, and an aortogram is obtained (Fig. 1). The brachial or radial arteries can be used if the renal artery is steeply angled or the patient has unfavorable aortoiliac anatomy (Fig. 2). A weight-based dose of unfractionated heparin is administered intravenously after the appropriate size sheath is in place. A wire is introduced into the diseased renal artery using an end-hole selective catheter (Fig. 3). Percutaneous balloon angioplasty is then performed with an appropriate size balloon-expandable stent (Fig. 4). It is important to place the stent extending 1 to 3 mm into the aorta, however, as the renal ostium is often composed with aortic wall plaque (Fig. 5). The proximal end of the stent is then flared with a slightly

FIG. 3 Right renal artery has been catheterized and a wire advanced distally.

FIG. 2 A left brachial or radial approach is used if there is unfavorable aortoiliac anatomy.

FIG. 4 Left renal artery stenosis treated with an appropriately sized balloon expandable stent from a femoral artery approach.

larger balloon. Repeat selective renal angiography is performed before removing the guidewire to confirm patency. Completion angiography is then performed after the wire is removed over-the-end hole catheter. Control of the access site may be accomplished with a closure device or simple removal of the sheath followed by manual pressure after the activated clotting time has decreased below 180 seconds. Open femoral artery repair may be selected in patients with small arteries or if there was increased risk for hemorrhage or thrombosis.

Medical Management After Revascularization

Clopidogrel is prescribed for at least 30 days after intervention and low-dose aspirin therapy is continued indefinitely. The patient returns in 2 weeks to assess the access site, renal function and blood pressure.

Complications

Complications include rapid postintervention decline in renal function, which can result from atheromatous embolization or contrast-induced nephropathy. Contrast-induced nephropathy is seldom an issue as the procedure can be performed with minimal dilute dye or carbon dioxide. Pre- and postprocedure hydration is routinely performed for patients not at risk for congestive heart failure.

Renal artery rupture is a rare but serious complication during percutaneous balloon dilation and stent deployment. It is critical to maintain wire access of the vessel until satisfied with post-intervention anatomy. In the event of rupture of the renal artery, a covered stent may be deployed to control the site of perforation. Endovascular access to a ruptured vessel may be exceedingly difficult or impossible if wire selection is lost before repair. An urgent open salvage procedure that is rarely successful secondary to the duration of warm ischemia.

Renal capsule perforation with hemorrhage can occur if a wire extends distally through the kidney. It is critical to maintain control of a hydrophilic wire while it is in the renal artery and to maintain visualization of the tip with fluoroscopy at all times. It may be necessary to use an angled hydrophilic wire to cross a severely stenotic lesion, but it should be exchanged for a braided 3 tip (3 mm) wire before proceeding with the intervention.

FIG. 5 Proximal end of the stent is positioned into the aortic lumen because the renal artery plaque is often continuous with aortic disease.

Renal artery dissection can occur when traversing tight calcified lesions. In addition, branch vessels may be compromised with treatment of a proximal lesion. Occasionally, a dual-wire configuration is needed to maintain access to both branches (Fig. 6).

Access site complications, including femoral pseudoaneurysm, hematoma with potentially significant blood loss, lymphatic leak, and femoral artery dissection, are possible. It is mandatory to use ultrasound guidance to locate appropriate access site in the common femoral artery to minimize access site complications. In addition, fluoroscopy should be used to localize the femoral head to enhance the ability to control hemorrhage with manual compression following femoral sheath removal.

Outcomes

Control of hypertension, measured by number of antihypertensive medications, has been demonstrated to improve in up to 80% of RAS patients treated by angioplasty and stenting. Renal dysfunction, measured by serum creatinine or estimated GFR, has been shown to stabilize or improve in 60% of RAS patients.

Surveillance and Follow-up

Although there are no quality data on RAS surveillance after angioplasty and stenting, we recommend a duplex ultrasound within 1 month after the procedure to document the postprocedural change in renal artery PSV and in the renal artery PSV to aorta PSV ratio. Several additional duplex ultrasounds are performed every 6 to 12 months to assess for recurrent stenosis and renal atrophy. Blood pressure must be monitored carefully along with measurement of serum creatinine or estimated GFR. An abrupt change in control of hypertension or renal function may prompt earlier imaging of the renal vasculature.

Endovascular Management of Restenosis

Restenosis rates are as high as 50% at 12 months and 67% at 18 months. Unfortunately, the impact of restenosis has been addressed poorly in the randomized controlled trials comparing stenting and medical management. Postintervention statins and antiplatelet medications are beneficial for prevention of restenosis. Patients with progressively worsening restenosis on follow-up duplex studies and all symptomatic patients with worsening renal function or blood pressure control who have imaging evidence of restenosis should undergo reintervention if no contraindications exist. Endovascular reintervention had only modest success with a 47% rate of hypertension improvement in several small studies.

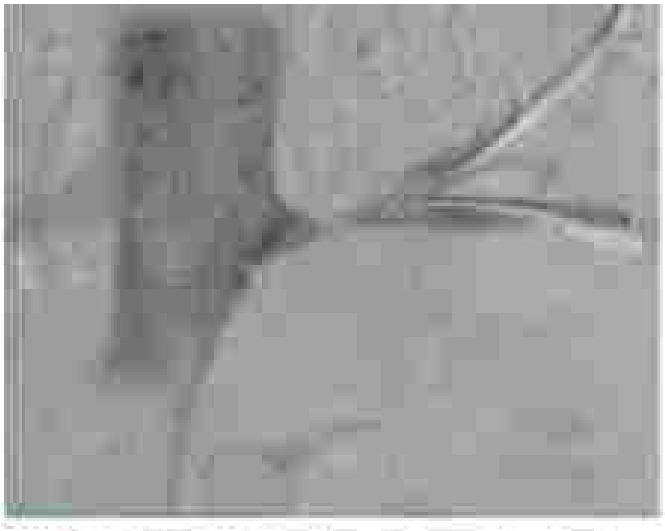

FIG. 6 Dual-wire technique is used to maintain access to both renal artery branches in this situation with a proximal left renal artery stenosis and an early bifurcation.

Open Surgical Repairs

Open surgical repair may be considered in patients with symptomatic atherosclerotic RAS who are undergoing elective open surgery for aortic disease. These individuals with significant renal artery branch disease also should be considered candidates for open repair, as stenting may not be feasible in these patients.

For elective open renal artery revascularization, careful preoperative risk assessment is essential. RAS is a marker for generalized atherosclerosis, and these patients must be screened for CAD, PAD, and CVD. Preoperative cardiac and pulmonary assessments are paramount to assess perioperative risk and initiate therapy to mitigate risk.

Aortorenal Artery Bypass

The patient should be positioned with the umbilicus at the level of the bed break, with the table angled at 15 degrees. The most versatile approach for open repair is the midline incision from xiphoid to pubis in the event that other procedures are indicated. However, a transverse supraumbilical incision provides better exposure of the paraaortal aorta and proximal renal arteries. Traditionally, the small bowel is retracted to the right side of the abdomen, the retroperitoneum is incised to expose the aorta, and the duodenum is subsequently reflected to the patient's right. Alternatively, full mobilization of the left colon and splenic flexure provides the best exposure of the paraaortal aorta and proximal renal arteries. It is easily performed and may be associated with decreased postoperative ileus (Fig. 7). The left renal vein is retracted cephalad to expose the underlying aorta and the left renal artery. Left renal vein branches (gonadal, adrenal, lumbar) may be divided to improve mobilization; it is necessary for the surgeon to decide if division of the left renal vein will be necessary before division of these important renal vein collaterals.

The proximal right renal artery can be accessed through previously mentioned exposure; however, if access to the distal right renal artery is required, it is best accomplished by medial mobilization of the right colon and duodenum. Mannitol (12.5 g) may help to prevent the development of acute renal failure by renal vasodilation, flushing of renal tubules, and scavenging free radicals. The patient is systemically heparinized before clamping the arteries. Consideration should be given to perfusion with cold preservation solution if the renal ischemia time is expected to be more than 1 hour.

Saphenous vein or synthetic grafts are used to create the aortorenal artery bypass. An atraumatic vascular clamp is applied to a suitable soft portion of the aorta. An arteriotomy is made with a No. 11 blade or an aortic punch. An end to side anastomosis is then fashioned using running 5-0 polypropylene sutures. The graft is distended with arterial pressure before being cut to length. Appropriate graft length is important to avoid undue tension or redundancy. The stump of the proximal end of the renal artery is oversewn with running 6-0 polypropylene suture. The distal end of the graft and the distal end of the renal artery are spatulated. An end to end anastomosis is then fashioned using 6-0 polypropylene suture. After completion of the anastomosis flow within the distal renal artery is interrogated with handheld continuous wave Doppler ultrasound and/or an ultrasonic flow probe.

Extraanatomic Renal Artery Bypass

When the aorta is heavily diseased with calcific atherosclerotic plaque and an aortorenal bypass is not feasible, there are several options for an extraanatomic bypass. The left renal artery may be revascularized using the transected distal splenic artery. The retroperitoneal exposure described earlier is carried cephalad, and the pancreas is mobilized anteriorly to expose and mobilize the splenic artery. Intravenous unfractionated heparin is administered, and the splenic artery is controlled proximally with an atraumatic vascular clamp and ligated and divided as distally as possible. The left renal artery is then controlled proximally and distally with vascular clamps and transected close to its aortic origin. The proximal stump is closed with 4-0 polypropylene suture at the aorta. The transected end of the splenic artery is then mobilized and anastomosed to a distal, free portion of the transected left renal artery using 6-0 polypropylene suture (Fig. 8). An extensive endarterectomy of the proximal left renal artery can be performed if additional length of the vessel is required for a tension-free anastomosis. The spleen is left in situ if collateral circulation is intact and there is no evidence of a capsular tear. Splenectomy should be performed if there is any indication of capsular injury secondary to the risk of postoperative hemorrhage.

The right renal artery may be revascularized using the common hepatic artery as the inflow source. The right colon is mobilized and

FIG. 7 Retrorenal exposure instead of the standard intraperitoneal approach provides excellent access to the paraaortal aorta and bilateral renal arteries as seen in this intraoperative image.

FIG. 8 Completed splenorenal bypass. Note the left renal artery is mobilized, cephalad and anastomosed to the transected splenic artery. The left renal vein is being retracted with a Penrose drain to expose the aorta.

FIG. 9 Proximal anastomosis of a right hepatorenal bypass with with the saphenous vein graft is seen to the common hepatic artery at the site of origin of the gastroduodenal artery. Metzenbaum scissor is used to mark the vein to assist with proper orientation.

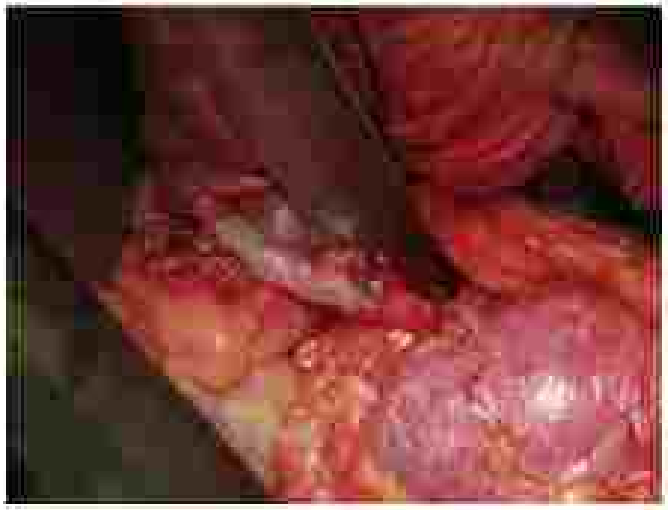

FIG. 10 Distal anastomosis of a right hepatorenal bypass with a saphenous vein graft in this case it was performed in an end-to-end configuration to prevent retrograde flow into the false lumen of an aortic dissection.

the right renal artery is identified as it courses distal to the inferior vena cava. The common hepatic artery is located and dissected until the gastroduodenal artery is exposed. The common hepatic artery is left intact and a saphenous vein interposition graft is anastomosed at the origin of the transected gastroduodenal artery (Fig. 9). The vein graft is then anastomosed to the right renal artery either in an end-to-side or an end-to-end configuration. An end-to-side configuration may be used for proximal stenosis without evidence of distal embolization and an end-to-end configuration is necessary if the proximal renal artery requires ligation (Fig. 10).

The left and right renal arteries also may be revascularized with PTFE or vein interposition grafts originating from the iliac arteries. Whenever a graft is used, appropriate graft length is critical to ensure that there is no tension or redundancy.

Aortorenal Endarterectomy

A midline incision is made and the retroperitoneum is opened overlying the infrarenal aorta, with exposure obtained as outlined previously. The left and right renal arteries are dissected free, and vascular loops are placed around each of the renal arteries. The aorta is circumferentially freed above and below the renal artery origins. Intravenous unfractionated heparin is administered. Vascular loops are used to control the renal arteries. The suprarenal and infrarenal aorta is controlled with atraumatic vascular clamps. Aortorenal endarterectomy can be accomplished via transverse arteriotomy extending onto the renal arteries. Atheromatous plaque is removed carefully with a vascular knife to achieve tapered endpoints. Occasionally, a small distal shelf will require placement of a 7-0 polypropylene tacking suture. The aortotomy is closed with a patch angioplasty.

Complications

Cardiovascular and pulmonary complications are common after open renal artery revascularization. Dialysis-dependent renal failure occurs in only 1% of patients. The perioperative mortality rate is between 2% and 4%. Thirty-day mortality has been associated with increasing age, chronic renal failure, and history of congestive heart failure.

Results

Approximately 80% of patients experience blood pressure improvement or cure postoperatively. Renal function improves or stabilizes in approximately 60% of patients who undergo open repair. As many as 70% of selected patients who recently started dialysis may no longer require dialysis after open renal artery revascularization. Early postoperative thrombosis occurs in only 1% to 2% of patients.

Surveillance and Follow-up

Although there are no quality data on RAS surveillance after bypass or endarterectomy, I recommend a duplex ultrasound 30 days after the procedure to interrogate the graft and flow to the renal arteries. Several additional duplex ultrasounds are performed every 6 to 12 months to assess for recurrent stenosis and renal atrophy. Blood pressure must be monitored carefully along with measurement of serum creatinine or estimated GFR. An abrupt change in control of hypertension or renal function may prompt earlier restaging of the renal vasculature.

SUMMARY

Atherosclerotic RAS may cause systemic hypertension or impaired renal function. The vast majority of patients with symptomatic RAS are managed successfully by careful control of hypertension and risk factors associated with the progression of atherosclerosis. Revascularization is recommended for RAS patients with renovascular hypertension that is not responsive to maximal medical therapy, those with worsening excretory renal function, and young individuals in whom flash pulmonary edema is caused by RAS. Revascularization by renal artery angioplasty and stenting has largely supplanted open renal artery surgery because of its minimally invasive nature, excellent early renal artery patency, and decreased periprocedural morbidity and mortality. Open renal artery bypass and endarterectomy currently are reserved for urgent salvage after technical endovascular failures and procedures in combination with elective aortic reconstructions that require an open approach. Open extraanatomic renal artery bypass operations may be helpful when treating patients with aortic aneurysm or dissections when using aortic endografts.

Raynaud's Phenomenon

Nasim Nasiri, MD, and Alan Dardik, MD, PhD

First described by Maurice Raynaud in 1862, Raynaud's phenomenon (RP) has been characterized by pathologic, paroxysmal, reversible vasoconstriction of acral arteries and arterioles in response to sympathomimetic stimuli (cold, provocative emotional or pharmacologic stimuli, etc.). The classic triphasic presentation involves progression from a period of pallor secondary to intense vasospasm, to cyanosis related to pooling of deoxygenated blood, and finally to rebound hyperemia due to gradual vasodilatation. The overall prevalence in the general population has been estimated to be 3% to 5%. The nomenclature used to describe this condition, including Raynaud's syndrome, Raynaud's disease, Raynaud's phenomenon, primary Raynaud's, and secondary Raynaud's, has been confusing, misleading, and often erroneously applied. Coined by Hutchinson, RP was a term designed to suggest the variable etiologic mechanisms underlying this condition.

In 1992, Leflon and Medsger addressed the issue and proposed the following solution, primary RP refers to the characteristic findings without evidence of an underlying medical or surgical condition (but to an idiopathic condition). Secondary RP describes the characteristic findings related to an underlying medical or surgical condition. This chapter follows the language suggested by Leflon and Medsger.

PRIMARY

Primary RP is seen worldwide, with higher incidence in colder climates. The median age at onset of primary RP is 14 years; only 27% of cases begin at the age of 40 or later. Symmetric events involving both hands or feet are common. Tissue loss or gangrene is not associated with primary RP. Given the idiopathic nature of this subtype, diagnostic tests aimed at identifying underlying contributory causes, such as nail fold capillaroscopy, erythrocyte sedimentation rate, and serologic markers, are, by definition, normal (Fig. 1 and Table 1). A positive family history in first-degree relatives is not uncommon, suggesting a yet to be identified genetic correlation of unknown penetrance.

SECONDARY

Secondary RP is more commonly seen after the age of 30 years. Unlike primary RP, secondary RP is associated with severe attacks that may be isolated to one extremity. Gangrene and ischemic ulceration are possible. Common systemic diseases associated with secondary RP include certain connective tissue, rheumatologic, autoimmune, endocrine, and hematologic disorders. The disorder most commonly associated with secondary RP is scleroderma. Given the asymmetrical patterns of distribution, a thorough workup evaluating for thromboembolic, atherosclerotic, degenerative, and/or compressive arterial etiologies is advisable (Box 1).

PATHOGENESIS

The pathogenesis of RP involves a highly localized process with unimpeded, augmented sympathomimetic tone and subsequent vasoconstrictive mechanisms affecting acral arteries, arterioles, and thermoregulatory arteriovenous connections. This has been attributed to overexpression or hyperactivity of postsynaptic alpha-2 receptors, decreased endothelial nitric oxide and prostacyclin production, and altered metabolism of endothelin-1 and angiotensin II. Disrupted capillary flow caused by endothelial dysfunction occurs in severe cases of secondary RP leading to tissue loss and/or gangrene. A chronic inflammatory state from recurring episodes can lead to vascular structural changes such as intimal fibrosis. In addition, imbalances between coagulation and fibrinolysis have been observed in both primary and secondary RP.

DIAGNOSIS

The diagnosis of RP remains primarily clinical. It is critical to differentiate between primary and secondary RP to correctly manage and treat patients as management is considerably different for the two conditions. A detailed clinical history with special emphasis on the location, severity, and frequency of symptoms is required. Seasonal variation and association with stressful situations are important to elicit. A detailed social history focusing on past or present tobacco and/or illicit drug use as well as a thorough review of active medications and supplements is critical. The physical examination should include a thorough pulse examination.

A screening diagnostic test is usually a noninvasive arterial study to rule out obstructive pathology (Fig. 2). The study should include evaluation of bilateral extremities with segmental pressures, Doppler waveforms, and wrist/ankle brachial indices. Plain radiographs are of limited utility, but they may demonstrate heterotopic calcification or cervical ribs suggesting upstream etiologies for secondary RP. Digital plethysmography can be performed. Obstructive lesions will demonstrate blunted, dampened waveforms on pulse volume analysis, whereas vasoconstrictive processes have a pathognomonic peaked dome at the apex of the waveform. Cold immersion testing is a highly sensitive but nonspecific adjunctive diagnostic measure. Computed tomography angiography or magnetic resonance angiography are helpful in screening for upstream or thromboembolic arterial disease. Selective, catheter-directed, digital subtraction angiography is reserved for those cases in which noninvasive testing has been inconclusive or has suggested the presence of disease amenable to endovascular therapy.

Serologic tests are appropriate when secondary RP is suspected. This is especially true when systemic symptoms such as myalgias, arthralgias, fever, weakness, and rash are present. A complete blood count, routine blood chemistry panel, antinuclear antibodies test, rheumatoid factor, and complement levels should be drawn (Box 1).

MANAGEMENT

Nonpharmacologic

Conservative, nonoperative, nonpharmacologic measurements aimed at avoidance of triggers are the cornerstone of therapy for most patients with RP. Cold exposure should be minimized and hands' first warming measures, such as mittens, applied as often as necessary. Caffeine, cigarette smoking, and other culprit agents should be avoided. The severity and frequency of symptoms determines how drastic the lifestyle modification is required.

Pharmacologic

Patients whose symptoms remain refractory to conservative measures are considered for vasodilatory pharmacotherapy with a number of agents available for off-label use. These medications are prescribed at the lowest possible dose that allows a satisfactory decrease in the frequency and severity of the vasospastic episodes.

The typical first-line pharmacologic agent for RP is a dihydropyridine class, long-acting calcium channel blocker such as nifedipine, nicardipine, or amlodipine. Sustained-release nifedipine, for example, is titrated at a dose of 10 to 30 mg daily to three times daily. Side effects include hypotension, headaches, weight gain, dizziness, or lightheadedness. Other doses and types of calcium channel blockers are available and have been used with variable success rates. Phosphodiesterase inhibitors (e.g., sildenafil, tadalafil) may be tried if calcium channel blockers are ineffective. There are multiple

FIG. 1 Raynaud's phenomenon in a patient with Ehlers-Danlos syndrome as illustrates the color changes associated with cerebral stimuli. (A) Normal-appearing hand. (B) After cold stimuli, the pallor from vasoconstriction can be seen. (C) After 30 seconds the hypothenar eminence appears in digital with blood hyperfusion. (D) Hand after 3 minutes exposure to normal.

TABLE 1 Characteristics of Primary and Secondary Raynaud's Phenomenon

	Primary	Secondary
Age	Younger (<30 years)	Older (>30 years)
Gender preference	Female	Male (depending on secondary cause)
Incidence	Most common	Less common
Familial predisposition	Yes	Yes
Combination with other disease	No, idiopathic	Associated with systemic disease
Vascular defect	Functional dysregulation of autonomic nervous system	Structural changes to connective tissue or vessels
Associated signs	None	Arthritis, sclerodactyly, cardiopulmonary abnormality, rash
Frequency	Precipitated by stimuli	Periodic and stimuli trigger
Severity of symptoms	Long history of mild attacks	Severe and disabling pain
Distribution	Symmetric	Asymmetric
Duration	Self-limited	Need for additional treatment (pharmacologic, surgery)
Critical complications	None	Ischemia and ulcers
Capillaroscopy	Normal (symmetric, slim, and uniform)	Abnormal (dilated, irregular, elongated, and tortuous vessel)
Vascular examination	Normal pulses	Abnormal pulses
Erythrocyte sedimentation rate	Normal	Elevated
Serologic studies	Negative	Autoantibody antibody, autoantibodies
C-reactive protein	Normal	Elevated

BOX 1 Secondary Causes of Raynaud's Phenomenon

Rheumatologic
- Systemic sclerosis (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia syndrome)
- Sjögren's syndrome
- Systemic lupus erythematosus
- Ehlers-Danlos syndrome
- Rheumatoid arthritis
- Dermatomyositis
- Polymyositis
- Mixed connective tissue disease

Autoimmune
- Raynaud's syndrome
- Vasculitis (polyarteritis nodosa, Henoch-Schönlein purpura)
- Antiphospholipid syndrome
- Primary pulmonary hypertension

Endocrine
- Hypothyroidism
- Pheochromocytoma
- Carcinoid

Infections
- Hepatitis B and C infection
- *Mycoplasma pneumoniae*

Medications
- Cyclosporine
- Ergotamine
- β-blockers
- Cytotoxic chemotherapeutic agents (bleomycin)
- Bromocriptine
- Nicotine
- Cocaine
- Sulfonylureas
- Interferon-α and interferon-β
- Clonidine
- Sympathomimetics
- Estrogen in oral contraceptives
- Caffeine

Occlusive Vascular
- Atherosclerosis
- Vascular trauma (hypothenar hammer syndrome)
- Buerger's disease
- Thoracic outlet syndrome
- Thromboembolism

Hematologic Proliferative
- Leukemia
- Lymphoma
- Polycythemia vera
- Multiple myeloma
- Dysproteinemia (intravascular coagulation)
- Cryoglobulinemia
- Cold agglutinin disease

Neurologic
- Migraines
- Carpal tunnel syndrome
- Polyneuropathy

Environmental
- Emotional stress
- Tobacco
- Repetitive trauma or injuries to hand

Malignancy
- Lung, stomach, small bowel
- Paraneoplastic syndrome
- Neurofibromatosis

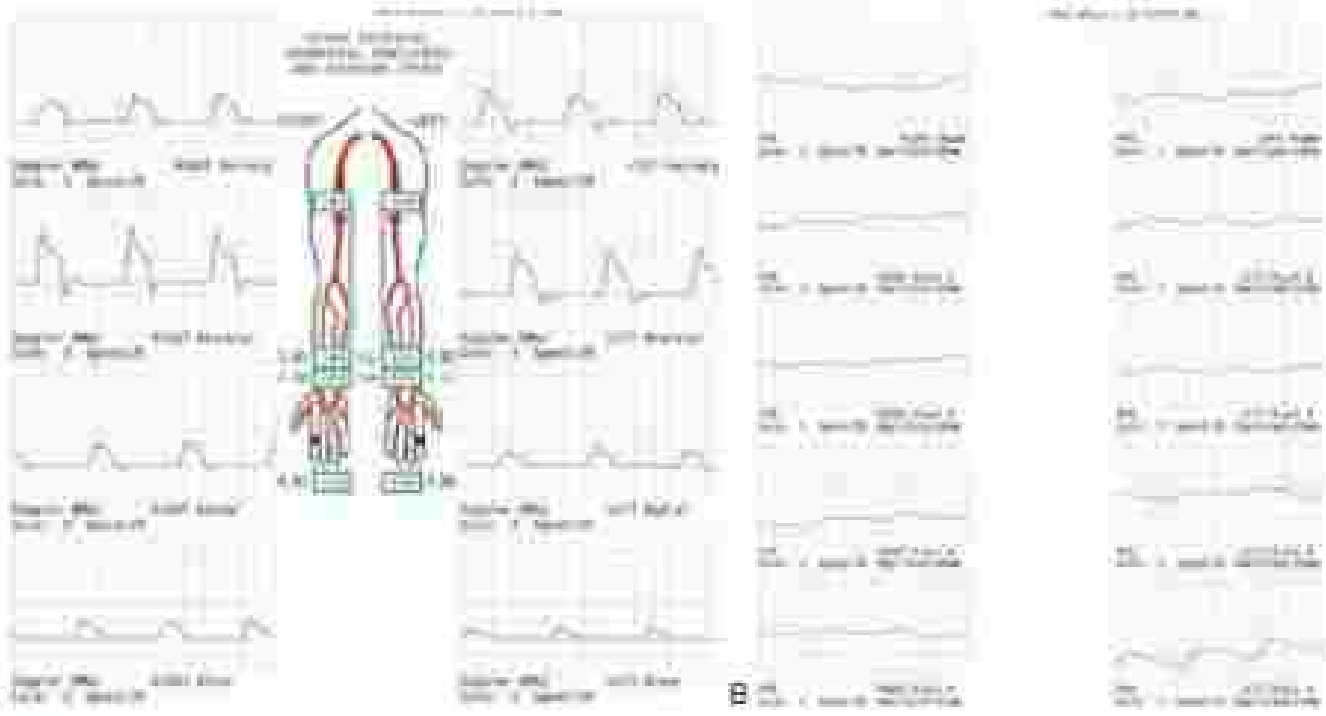

FIG. 1 (A, B) Example of an abnormal upper extremity noninvasive arterial study focus the thumb waveforms proximally and the the digital brachial

second-line agents for the treatment of RP, including prazosin, losartan, and prostaglandins. These drugs are reserved for recalcitrant cases and usually are used by subspecialists in the field. Topical nitroglycerin at 0.1 mg of gel up to 4 times a day can be used alone or in combination with oral agents. Close monitoring of side effects and vital signs is important in cases of polypharmacy.

Surgical Treatment

Surgical treatment for secondary RP is indicated to treat any identified underlying obstructive pathology (Box 1). Local wound care is initiated with serial debridement of necrotic tissue and dressing changes. Limited digital amputation may be required with the treatment goal of alleviating pain and preserving function. Cervical or lumbar sympathectomy (chemical or surgical) can provide temporary relief of pain and ulcer healing but long-term results are variable. A thoracoscopic approach has nearly replaced open procedures for cervical sympathectomy. Other proposed techniques are characterized by anecdotal results, variable success and complication rates, significant placebo effect, and limited long-term data; these techniques include adventitial stripping of digital arteries, regional sympathetic blocks, digital botulinum toxin injections, and spinal cord stimulation.

SUMMARY

RP encompasses two broad categories of disease depending on the etiology, location, and severity of symptoms. Primary RP is a more benign, idiopathic condition with a more symmetric distribution affecting the bilateral hands and/or feet. Its diagnosis is mainly clinical with adjunctive noninvasive studies that can help rule out upstream pathology and/or rule in provoked vasospasm. Lifestyle modifications and avoidance of provocative stimuli remain the cornerstone of therapy. Refractory cases can be treated with a variety of off-label pharmacologic agents, most commonly long-acting calcium channel blockers. Secondary RP is a more severe form of disease most commonly associated with scleroderma. Other contributing causes include upstream obstructive pathologies, compression-related syndromes, thromboembolic phenomena, and systemic inflammatory conditions. Treatment is aimed at addressing the underlying cause and attenuating symptoms. Less responsive to pharmacotherapy, Secondary RP has also been treated with a variety of adjunctive surgical/interventional maneuvers that have yielded equivocal short- to mid-term outcomes. Further research into the behavioral and alternative therapeutic modalities is ongoing.

THORACIC OUTLET SYNDROME

Timothy R. Williams, MD, and Julie A. Freischlag, MD

Thoracic outlet syndrome (TOS) represents several distinct entities with a constellation of signs and symptoms depending on the anatomic structures involved. The underlying pathophysiology of these disorders is compression of the neurovascular structures of the upper extremity where they emerge from the chest, the region known as the thoracic outlet. Estimates of incidence range from 3 to 80 per 1000 in the population. In general, there are three forms of TOS described, namely neurogenic, venous, and arterial. Neurogenic TOS (nTOS) is by far the most common form, accounting for 95% of all cases. This occurs from compression of the brachial plexus within the interscalene triangle, which is bordered by the first rib, the anterior scalene muscle, and the middle scalene muscle (Fig. 1). The second most common is venous TOS (vTOS), which accounts for approximately 4%. vTOS arises from compression of the axillosubclavian vein within the costoclavicular space, which is bound by the first rib, clavicle, and anterior scalene muscle. The subclavius muscle and tendon, which connects the first rib and the clavicle, frequently contributes the vein in this region (Fig. 1). Finally, arterial TOS (aTOS) occurs in about 1% of all cases and develops from compression of the axillosubclavian artery within the interscalene triangle. This disorder commonly occurs in association with a cervical rib. Aside from being rare, arterial TOS is frequently insidious in its evolution, making it a challenge to diagnose. It frequently manifests with evidence of limb ischemia resulting from distal embolization from aneurysmal degeneration or from vessel occlusion. Although these three disorders are all defined as thoracic outlet syndrome, the presentation, diagnosis, and management vary significantly.

DIAGNOSIS AND TREATMENT

nTOS

TOS is largely a clinical diagnosis that is established based on a careful history and physical examination. Unfortunately, there exists no gold standard diagnostic modality to either confirm or exclude the diagnosis; however, select tests can be used that influence the strength of the diagnosis. TOS can develop from acquired factors such as trauma to the shoulder and chest wall, from repetitive overhead activity, or from certain congenital anatomic predispositions such as a cervical rib or anomalous fibrous bands. Common presenting symptoms include upper extremity paresthesias and pain within the C8-T1 dermatome, as well as arm weakness. These symptoms are typically exacerbated by arm abduction (raising the arms overhead) and are alleviated by adduction (arm at the side). nTOS occurs most commonly in women, with a ratio of nearly 3:1. Additional symptoms include anterior neck, back, and shoulder pain of varying degrees, making this disorder difficult to distinguish from other pathologic conditions.

Several physical examination maneuvers can be used to support the diagnosis. Many patients will experience tenderness to palpation over the anterior scalene muscle to the low anterior neck. Classically, Adson's maneuver has been used to assess for TOS, with ablation of pulses at the wrist representing a positive test; however, this and other

second-line agents for the treatment of RP, including prazosin, losartan, and prostaglandins. These drugs are reserved for recalcitrant cases and usually are used by subspecialists in the field. Topical nitroglycerin at 0.1 mg of gel up to 4 times a day can be used alone or in combination with oral agents. Close monitoring of side effects and vital signs is important in cases of polypharmacy.

Surgical Treatment

Surgical treatment for secondary RP is indicated to treat any identified underlying obstructive pathology (Box 1). Local wound care is initiated with serial debridement of necrotic tissue and dressing changes. Limited digital amputation may be required with the treatment goal of alleviating pain and preserving function. Cervical or lumbar sympathectomy (chemical or surgical) can provide temporary relief of pain and ulcer healing but long-term results are variable. A thoracoscopic approach has nearly replaced open procedures for cervical sympathectomy. Thoracic Outlet Syndrome

Timothy R. Williams, MD, and Julie A. Freischlag, MD

Thoracic outlet syndrome (TOS) represents several distinct entities with a constellation of signs and symptoms depending on the anatomic structures involved. The underlying pathophysiology of these disorders is compression of the neurovascular structures of the upper extremity where they emerge from the chest, the region known as the thoracic outlet. Estimates of incidence range from 3 to 80 per 1000 in the population. In general, there are three forms of TOS described, namely neurogenic, venous, and arterial. Neurogenic TOS (nTOS) is by far the most common form, accounting for 95% of all cases. This occurs from compression of the brachial plexus within the interscalene triangle, which is bordered by the first rib, the anterior scalene muscle, and the middle scalene muscle (Fig. 1). The second most common is venous TOS (vTOS), which accounts for approximately 4%. vTOS arises from compression of the axillosubclavian vein within the costoclavicular space, which is bound by the first rib, clavicle, and anterior scalene muscle. The subclavius muscle and tendon, which connects the first rib and the clavicle, frequently compresses the vein in this region (Fig. 1). Finally, arterial TOS (aTOS) occurs in about 1% of all cases and develops from compression of the axillosubclavian artery within the interscalene triangle. This disorder commonly occurs in association with a cervical rib. Aside from being rare, arterial TOS is frequently insidious in its evolution, making it a challenge to diagnose. It frequently manifests with evidence of limb ischemia resulting from distal embolization from aneurysmal degeneration or from vessel occlusion. Although these three disorders are all defined as thoracic outlet syndrome, the presentation, diagnosis, and management vary significantly.

DIAGNOSIS AND TREATMENT

nTOS

TOS is largely a clinical diagnosis that is established based on a careful history and physical examination. Unfortunately, there exists no gold standard diagnostic modality to either confirm or exclude the diagnosis; however, select tests can be used that influence the strength of the diagnosis. TOS can develop from acquired factors such as trauma to the shoulder and chest wall, from repetitive overhead activity, or from certain congenital anatomic predispositions such as a cervical rib or anomalous fibrous bands. Common presenting symptoms include upper extremity paresthesias and pain within the C8-T1 dermatome, as well as arm weakness. These symptoms are typically exacerbated by arm abduction (raising the arms overhead) and are alleviated by adduction (arm at the side). nTOS occurs most commonly in women, with a ratio of nearly 3:1. Additional symptoms include anterior neck, back, and shoulder pain of varying degrees, making this disorder difficult to distinguish from other pathologic conditions.

Several physical examination maneuvers can be used to support the diagnosis. Many patients will experience tenderness to palpation over the anterior scalene muscle to the low anterior neck. Classically, Adson's maneuver has been used to assess for TOS, with ablation of pulses at the wrist representing a positive test; however, this and other

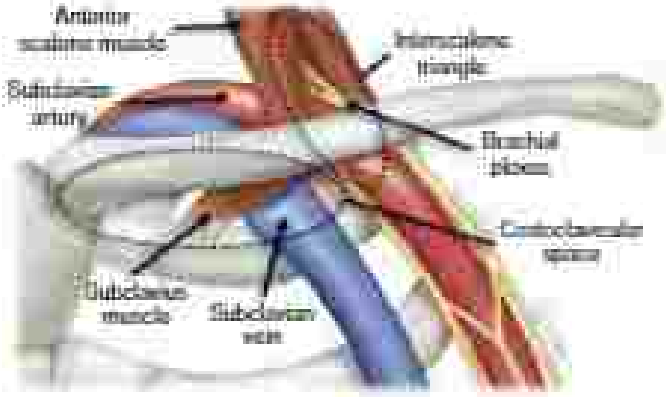

FIG. 1 Anatomy of the thoracic outlet. Key structures within the thoracic outlet, from left to right: the costoclavicular ligament, subclavius muscle, subclavian vein, anterior scalene muscle, subclavian artery, and the brachial plexus. The two key anatomic spaces exposed across the costoclavicular space and the interscalene triangle. (Courtesy I.A. Crim.)

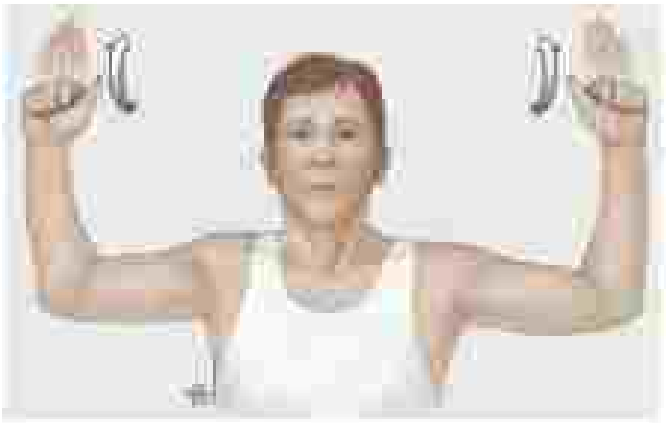

FIG. 2 The elevated arm stress test. The arms are held at 90 degrees of abduction and external rotation with the elbows at 90 degrees of flexion to narrow the costoclavicular triangle. Hands are rapidly opened and closed to elicit the patient's symptoms, which is suggestive of neurogenic thoracic outlet syndrome. (Courtesy Mayo Foundation for Medical Education and Research.)

similar arm abduction tests can be positive in upwards of 20% of healthy, asymptomatic individuals and should therefore not be used to support the diagnosis. The clinical test that has proven most beneficial is the elevated arm stress test, where the arms are positioned in the hold up position (90 degrees of shoulder abduction, external rotation, and elbow flexion) (Fig. 2). Patients are instructed to continuously open and close their hands for 3 minutes, with reproduction of their symptoms defined as a positive test. A chest radiograph should be performed to assess for evidence of a cervical rib (Fig. 3A) or rudimentary first rib (Fig. 3B), as well as other bony abnormalities including previous clavicular fractures. Duplex ultrasonography is commonly performed to assess for arterial and venous compression, which can serve as indirect evidence of compression within the thoracic outlet. Other diagnostic modalities such as computed tomography (CT), magnetic resonance imaging, and electromyography are costly and add little to the diagnosis of nTOS and therefore should not be routinely performed. Select centers have used magnetic resonance imaging with provocative maneuvers to evaluate for nerve compression within the interscalene triangle; however, this test requires local expertise that may not be present at all institutions. Additionally, maximal positioning required for these studies may result in significant

FIG. 3 Bony abnormalities in thoracic outlet syndrome. (A) Chest radiograph demonstrating bilateral cervical ribs. (B) Chest radiograph demonstrating a rudimentary first rib. Such bony abnormalities can predispose individuals to neurogenic and arterial thoracic outlet syndrome. (A, Modified from Kliewer MA, Hertzberg BS, Dubose-Ellis J, et al. Cervical rib: radiographic prevalence and significance. Radiology. 1998;208:645–648.)

symptom exacerbation, so should be used with caution. In select patient populations with atypical symptoms or suspicion for alternate pathologies, these tests may play an important role.

When the diagnosis remains equivocal, an anterior scalene muscle block can be performed, which is widely accepted as a useful diagnostic adjunct for suspected nTOS. This involves the injection of a short acting local anesthetic directly into the anterior scalene muscle using ultrasound or CT guidance. The block is meant to induce muscle relaxation, thereby simulating decompression of the thoracic outlet. A positive block is one that effectively reduces the patient's symptoms

and has been shown to correlate with symptomatic improvement following surgery. Beyond serving as a diagnostic modality, anterior scalene muscle block will frequently provide short-term symptom relief. When botulinum toxin (Botox) is used, longer-term symptom relief can be achieved, with reported durations of up to 3 months. This can be used as a bridge to surgical decompression but should not be used as primary therapy because repeated injections can increase the risk of scar formation, thereby complicating future surgery.

Although the presentation of nTOS may vary across patients, consensus-based diagnostic criteria have been developed by experts in the field (Consortium for Outcomes Research and Education on Thoracic Outlet Syndrome) in an effort to standardize the approach to this challenging patient population. The symptoms and physical examination findings felt to most strongly correlate with the diagnosis of nTOS include the following: local tenderness with palpation over the scalene triangle, reproduction of hand/digit paresthesias with palpation over the scalene triangle, symptom exacerbation with overhead arm use, thenar/hypothenar muscle atrophy, a positive supraclavicular Tinel's sign, weakness of handgrip, paresthesias in the supraclavicular space, paresthesias in digits 4 and 5, and a positive 1-minute elevated arm stress test, among others. Additionally, the following diagnostic tests have been deemed to most strongly correlate with the diagnosis: symptom improvement with scalene and/or pectoralis minor muscle block, the presence of a cervical rib or prominent C7 transverse process, and improvement following first rib resection and scalenectomy (FRSS) for contralateral disease.

Preoperative management centers around physical and/or occupational therapy, activity modification/restrictions, and pharmacotherapy. In general, a minimum of 2 to 3 months of physical therapy should be performed because many patients with nTOS will experience significant improvements and may not require surgery when activity modifications or postural changes have proven beneficial. Muscle relaxants, nonsteroidal antiinflammatory drugs and analgesic agents are commonly used as an adjunct to management.

For those patients with history, physical examination, and diagnostic findings to support the diagnosis of nTOS, along with a suboptimal improvement following a reasonable trial of physical therapy, surgical intervention should be strongly considered. In general, a lower threshold for surgical intervention should be considered in those patients with a compelling diagnosis confirmed with focal bony abnormality such as a cervical or rudimentary first rib.

vTOS

vTOS represents the second most common form of TOS and involves compression of the subclavian vein within the costoclavicular space. Most commonly, this stems from acquired anatomic changes such as hypertrophy of the anterior scalene and subclavius muscles or from trauma to the anterior chest, particularly to the context of a clavicular fracture. It is frequently seen in young, otherwise healthy adults or adolescents, in athletes, and those who are exposed to occupational conditions that demand repetitive overhead use of the arms. Over time, this repetitive mechanical injury to the vein can lead to progressive scarring, inflammation, narrowing and ultimately thrombosis (Paget-Schroetter's syndrome). Common presenting signs and symptoms include arm swelling, pressure, fatigue, cyanosis, and a sensation of heaviness. In contrast to nTOS, patients do not typically experience debilitating pain, but may experience discomfort from tense edema. In those with a subacute or late presentation, evidence of venous collaterals along the chest wall may be apparent. Patients with venous compression in the absence of prior thrombosis or occlusion may experience similar symptoms, but these tend to be milder and relieved by arm rest (McElhenny's syndrome).

The diagnosis can be suspected based on history and physical examination findings, however, it is definitively established with duplex ultrasound, CT venography, or conventional venogram. Typically, duplex ultrasound is the standard initial diagnostic modality. Findings supporting the diagnosis of vTOS include loss of flow on color Doppler in the distal subclavian vein and a continuous venous waveform (lack of phasicity) within the axillary vein. In the absence of complete occlusion, venous compression can be elicited with the arm in varying degrees of abduction, resulting in an ablation of flow. Chest radiographs should be routinely performed to assess for bony abnormalities.

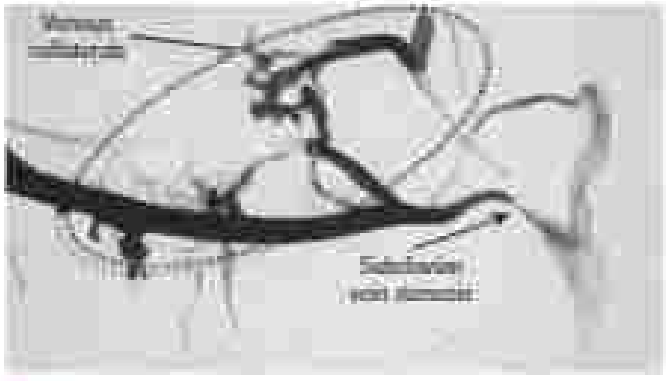

FIG. 4 Venogram in a patient with venous thoracic outlet syndrome. Venogram performed following transaxillary first rib resection and scalenectomy shows the venous stenosis within the costoclavicular space, which resulted in abundant collateral vessels providing venous drainage of the arm.

Perioperative management is centered around anticoagulation. For patients with a severe, acute presentation (onset <14 days), catheter-directed thrombolysis can be considered, although this remains controversial. Venography characteristically demonstrates abundant collateral vessels and stenosis/occlusion of the subclavian vein at the costoclavicular junction (Fig. 4). In general, angioplasty should be avoided before surgical decompression because this seldom rectifies the underlying extrinsic compression of the vessel and results in further injury. For subacute or chronic presentations, thrombolysis plays no role in management.

In patients without secondary causes for venous thrombosis of the subclavian vein (i.e., central venous catheters, documented hypercoagulable state), surgery is typically indicated. The timing of surgery remains an area of controversy, with some advocating for early surgical decompression and others promoting an upfront period of anticoagulation (weeks to months) prior to surgery. It is the author's stance to perform early decompression (within 1 week) for acute presentations in an effort to minimize the inflammatory cascade produced by acute thrombosis, with a more protracted approach for patients with a chronic presentation (≥ 4 weeks).

aTOS

aTOS is the rarest form of TOS, representing approximately 0.5% of patients overall. As with vTOS, it tends to occur in younger patients and most commonly occurs in patients with bony anomalies such as a cervical or rudimentary first rib. The underlying pathology of this disorder is repetitive trauma to the subclavian artery, which leads to progressive vessel stenosis, occlusion, or aneurysmal degeneration with distal embolization. Presenting symptoms commonly include arm or hand claudication. Patients may also experience typical signs or symptoms of acute limb ischemia, including paresthesias, poikilothermia, paralysis, pallor, and pulselessness. Because distal embolization may cause variable degrees of ischemia, patients may experience an insidious progression of the disease and present late, with abrupt episodes of exacerbation punctuated by intervals of improvement. In advanced disease, patients may experience tissue loss or even digit gangrene.

Initial assessment should include duplex ultrasonography along with upper extremity segmental blood pressure measurements. It is important to obtain bilateral upper extremity blood pressure

measurements to assess for a discrepancy. Duplex ultrasound can reliably detect axillosubclavian stenosis and/or aneurysmal degeneration, as well as downstream occlusion of the brachial artery or forearm vessels from distal embolization. As with other forms of TOS, a chest x-ray should be performed to evaluate for bony anomalies. CT angiography should be considered to further delineate the patient's anatomy; however, conventional angiography may be necessary to aid in surgical decision making.

Unlike other forms of TOS, aTOS universally requires surgical intervention and frequently mandates surgery beyond thoracic outlet decompression. Although surgical decompression of the thoracic outlet remains a fundamental tenant of management in these patients, aTOS requires a tailored surgical approach based on the patient's specific anatomic abnormalities. This may include reconstruction of the axillosubclavian artery, thrombolysis, endarterectomy, and/or distal bypass depending on the extent and level of disease.

SURGICAL MANAGEMENT

Although certain aspects of surgical management may vary based on the specific form of TOS, the unifying aspect of all interventions involves surgical decompression of the thoracic outlet. This can be performed using a supraclavicular, transaxillary, infraclavicular, or paraclavicular (infraclavicular and supraclavicular) approach depending the form of TOS and the patient's unique anatomic characteristics. It is our preference to use the transaxillary approach for the majority of neurogenic and venous TOS cases, which represents approximately 80% of all cases. aTOS, because it frequently requires vascular reconstruction to varying degrees, is typically managed from a paraclavicular approach, as it frequently requires vascular reconstruction, either bypass or interposition grafting.

Transaxillary Approach

The transaxillary approach provides excellent surgical exposure of the interscalene triangle and the costoclavicular space, making it ideally suited for the surgical management of both nTOS and vTOS. Because this technique uses a lateral surgical approach rather than anterior, the first rib can be exposed widely. This exposure also provides excellent visualization of the brachial plexus, subclavian vein, and subclavian artery. Additionally, this exposure provides excellent control for comparison to alternative exposures.

Patients undergo general anesthesia routinely, along with a short acting nondepolarizing muscle blockade. Long acting neuromuscular blockade should be avoided to enable nerve stimulation and corresponding muscle contraction during exposure and dissection, thereby minimizing the risk for iatrogenic nerve injury. Following anesthesia induction, the patient is positioned in the lateral decubitus position with support from an axillary roll and a bean bag. The body is further padded with foam at pressure points and pillows are placed between the legs. The arm, axilla and chest wall are widely prepped. The arm is then suspended within the Mathieder retractor, which holds the arm in 90 degrees of abduction and the elbow at 90 degrees of flexion (Fig. 5). Not only does this retractor hold the arm in a stable position, but it facilitates lateral retraction of the arm to open the axillary space and provide adequate visualization during the dissection. The arm is appropriately padded to prevent neurovascular injury during positioning and retraction.

A transverse incision approximately 8 to 10 cm in length is made within the axilla at the lower border of the axillary hair line, between the pectoralis major muscle anteriorly and the latissimus dorsi muscle posteriorly. Following incision, dissection proceeds with electrocautery down to the chest wall, being vigilant to avoid injury to the long thoracic and thoracodorsal nerves. Upon reaching the chest wall, the arm is retracted laterally, and blunt dissection ensues within this avascular plane using finger dissection, Kitner dissectors, and/or peanuts. The first rib can be palpated deep in the dissection bed. Additional blunt dissection is performed to identify the subclavian vein anteriorly, the first rib inferiorly and the subclavian artery and brachial plexus posteriorly (Fig. 6A).

FIG. 5 Positioning for the transaxillary approach. The patient is in the lateral decubitus position with the arm suspended within the Mathieder retractor which affords excellent exposure and maintains stable arm positioning. The joint of the retractor is raised and lowered throughout the procedure to enhance exposure and to minimize traction injury. (Image courtesy of Jeffrey S.A. Carter.)

Next, soft tissue attachments and the intercostal muscle bridging the first and second rib are cleared from the lateral superior border of the first rib using a periosteal elevator or blunt dissection. The subclavian muscle and tendon are identified anteriorly and carefully lysed with Metzenbaum scissors, being mindful to not injure the adjacent subclavian vein. The inner table or surface of the rib is then carefully separated from the underlying parietal pleural of the chest using a spatula or small periosteal elevator. On the lateral and flat outer surface of the rib, fibers of the middle scalenus muscle are pushed posteriorly to create a plane between the brachial plexus and the rib. It is important to not transect this muscle sharply as inadvertent transection of the long thoracic nerve may occur, which passes through the belly of the middle scalene muscle in this region.

A plane is then developed bluntly between the anterior scalene muscle and the subclavian artery using a Kitner to facilitate safe division of the anterior scalene muscle. Division of the anterior scalenus is performed in several steps, using a right angle clamp to spread and laterally retract a portion of muscle followed by meticulous transection using Metzenbaum scissors (Fig. 6B). Additional passes are performed until the entirety of the muscle has been divided. The rib is then divided with a bone cutter anteriorly within the costal cartilage, being mindful to not injure the subclavian vein. The right angle is then passed along the inner border of the first rib to remove any additional fibers of the anterior scalene muscle that remain. Next, the rib is transected posteriorly, while avoiding injury to the brachial plexus (Fig. 6C). In the presence of a cervical rib, removal of both the first and cervical rib is typically required but poses unique challenges. Often, the nerve is anteriorly displaced by the cervical rib, making it difficult to achieve a safe plane for bone transection. Furthermore, the cervical rib or rudimentary rib frequently has a bony attachment to the rib below. Resection frequently requires this bone removed using a rongeur, but ultimately a tailored approach based on the patient's specific anatomic characteristics is required. Following removal of the rib, a rongeur is used to excise any residual bone to avoid sharp edges.

Major complications are rare, with the risk of significant nerve or vascular injury being less than 1%. In the event of an arterial and/or venous injury, it is challenging, if not impossible, to definitively repair from the transaxillary exposure, requiring an urgent anterior approach for vascular control. Assurance for a pneumothorax is achieved by filling the surgical field with saline before closure and

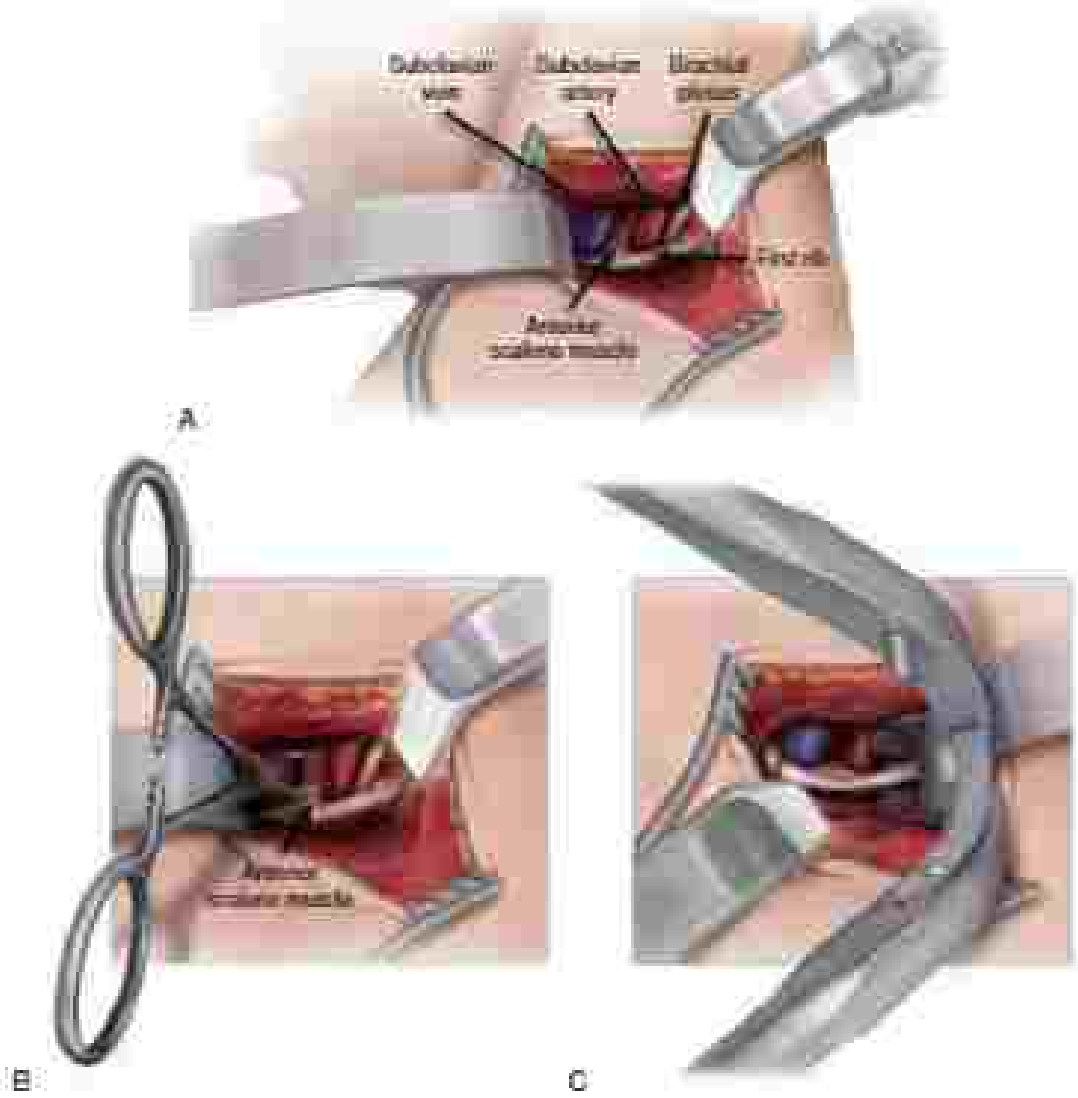

FIG. 6 Infraclavicular approach for first rib resection and scalenectomy. (A) Anatomic relationships as viewed from the infraclavicular approach. A rigid retractor is used to enhance visualization and combined with a Deaver to provide superior and posterior retraction. (B) Division of the anterior scalene muscle is performed with the use of a long right-angle clamp and Metzenbaum scissors. (C) Division of the rib first performed anteriorly then posteriorly (courtesy S.A. Sanders).

performing a Valsalva maneuver, with loss of fluid volume and/or bubbling of air serving as evidence of a pleural defect. This rarely requires placement of a chest tube. Rather, the pneumothorax can be evacuated during closing through application of suction to a red rubber catheter placed within the pleural space, which is removed before final skin closure. The skin and subcutaneous tissue are then closed in standard fashion. A routine postoperative chest x-ray is not required even when a pneumothorax is detected intraoperatively because it does not change management, provided the patient remains asymptomatic.

Supraclavicular Approach

An alternative and widely used exposure is the supraclavicular approach, which is commonly used for all forms of TOS (Fig. 7). This is our preferred exposure for the management of arterial TOS, enabling both arterial reconstruction and first rib resection. This is also our preferred approach for redo operations following prior, non-transaxillary exposure, given the increased potential for vascular complications resulting from scarring. For patients with either aTOS or vTOS, the supraclavicular approach can be combined with an infraclavicular approach (paraclavicular) to better facilitate vessel exposure, lysis, and/or reconstruction.

Patients are positioned supine with a shoulder roll to allow for neck extension. The head is rotated contralateral to the affected side. The chest wall, axilla, and ipsilateral upper extremity are included in the operative field. A skin incision in the supraclavicular fossa is made 1 to 2 cm cephalad and parallel to the clavicle, extending from the clavicular head of the sternocleidomastoid muscle laterally for approximately 10 cm. The scalene fat pad is divided inferiorly and medially between ties or with electrocautery to facilitate superolateral retraction. Care should be taken to avoid injury to the phrenic nerve as it emerges through anterior surface of the anterior scalene muscle. A nerve stimulator can be used to aid in identification. Next, the anterior scalene muscle is divided sharply, being mindful to avoid injuring the subclavian artery found deep to the muscle. Some authors suggest full excision of the muscle from its insertion on the transverse process to provide the greatest decompression of the space, which is an advantage afforded by this anterior approach. However, this places the phrenic nerve at risk and has not been conclusively shown to minimize recurrence.

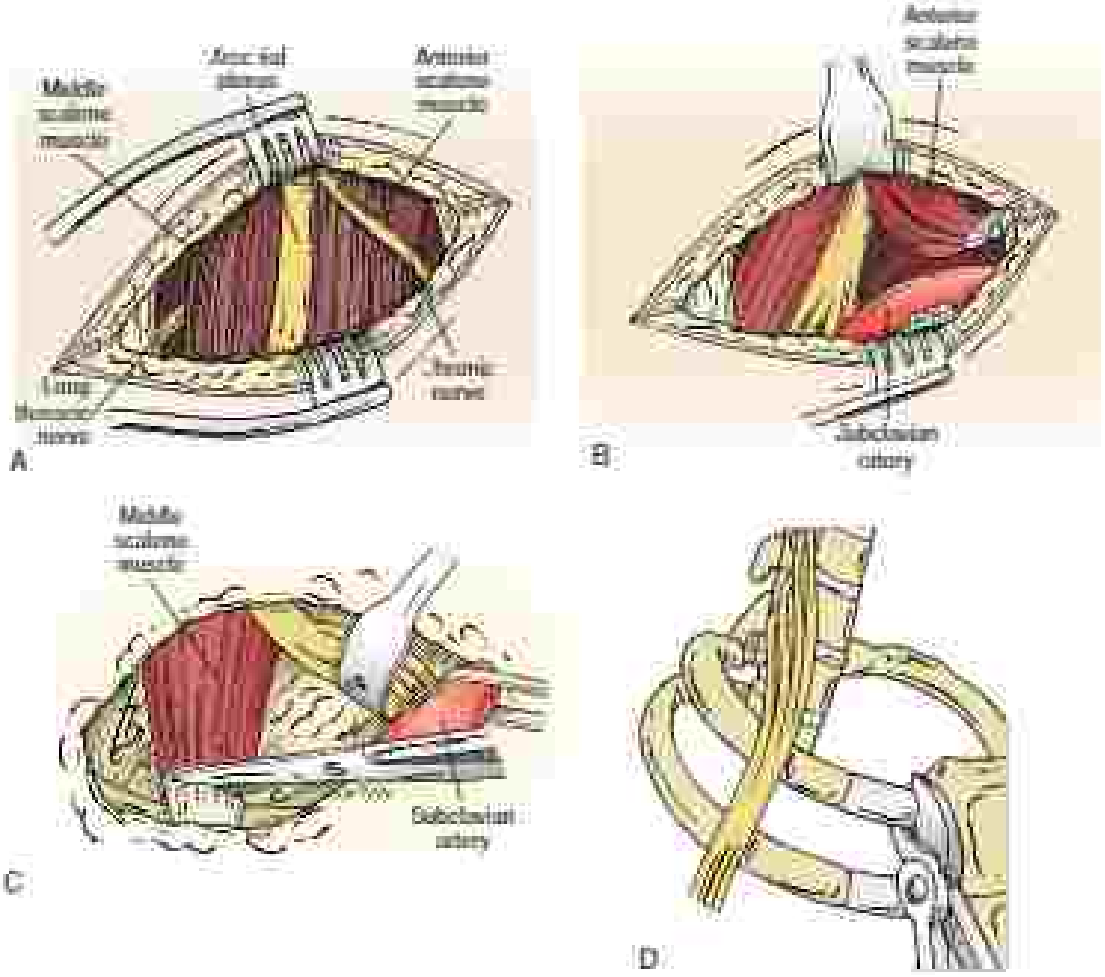

FIG. 1 (A-D) Supraclavicular approach for first rib resection (left side). See text for details.

Posterior to the brachial plexus is the middle scalene muscle, which must be cleared from the first rib to facilitate posterior transection of the rib. The long thoracic nerve can be found exiting the middle scalene muscle along its lateral border and should be protected; injury to this nerve can result in significant disability, causing a winged scapula and impairing anterior arm elevation. The middle scalene muscle is bluntly cleared from the rib using a periosteal elevator. Sharp division of the muscle close to the rib can be entertained, provided the long thoracic nerve has been identified and protected. Anterior slips of the muscle may be found coursing beneath the plexus, which may require epifascial retraction on the nerves to fully detach the muscle from the rib.

Intercostal muscle between the first and second ribs is dissected away anteriorly and posteriorly. The parietal pleura is then bluntly dissected away from the inner surface of the rib above and below, being careful to not enter the pleural space. Small branches of the subclavian artery may require ligation to facilitate elevation of the artery before transection of the rib. Any residual attachments between the rib and the brachial plexus are then cleared. While anteriorly retracting the pleura, a bone cutter is positioned posteriorly around the rib and the rib is divided. Next, the subclavian vein and artery are elevated and retracted posteriorly to facilitate anterior division of the rib, anterior to the insertion of the anterior scalene muscle. Unlike the transaxillary approach, transection of the rib at the costrovertebral junction can seldom be achieved from this exposure, but it should be divided as far anterior as possible. Residual bone can then be excised using a rongeur.

Infraclavicular Approach

The infraclavicular approach is an alternative for patients with venous TOS, providing access to the costoclavicular space and allowing for more complete anterior resection of the first rib. It also provides excellent exposure of the axillosubclavian vein, allowing for venous reconstruction either with patch angioplasty or interposition grafting, a strategy advocated by some surgeons for competitive athletes. However, there is not a uniform consensus on the need to perform venous reconstruction in the majority of vTOS cases and should therefore be performed in a very selective fashion. As mentioned previously, this approach is frequently combined with a supraclavicular exposure, what has been called the panclavicular approach, enabling both venous and arterial reconstruction, as well as sufficient posterior exposure for complete rib resection.

Patients are positioned and prepped as described for the supraclavicular approach. A transverse skin incision should be made 1 to 2 cm caudal to the clavicle approximately 10 cm in length, beginning at the medial one third of the clavicle and extending laterally. The pectoralis major muscle will be encountered and is spread to expose the clavipectoral fascia. The pectoralis minor is retracted laterally or can be divided to enable more distal exposure of the subclavian artery and vein, thereby facilitating vascular reconstruction. The subclavius muscle and tendon medially are divided sharply to provide adequate decompression of the vein. The rib can be divided far anteriorly at the costosternal junction.

SURGICAL OUTCOMES

CONCLUSION

SUGGESTED READINGS

THE DIABETIC FOOT

David W. Schuchhman, MD

The prevalence of diabetes and its associated complications has continued to rise in the United States and worldwide. There are an estimated 30 million people in the United States with diabetes. Of these patients, up to 25% will develop a diabetic foot ulcer during their lifetime. Diabetic foot ulcers and infections are the long-term complication of diabetes responsible for the most hospital admissions and account for nearly one half of all diabetes-related hospital bed days. The financial burden is significant as well with the mean adjusted cost of care for a diabetic foot ulcer at more than $9000 per admission, costing $13 billion per year in the United States.

The primary factors for developing foot ulcers are peripheral neuropathy, peripheral arterial disease, reduced immune function, and altered foot architecture. Although 15% to 40% of diabetic foot ulcers are primarily neuropathic in nature, 50% to 60% are secondary to both neuropathy and ischemia. The cornerstone of care for the diabetic foot ulcer is prevention. This is done with a combination of foot inspections, foot hygiene, offloading shoes, and education on when to seek medical care. If an ulcer does occur, the early identification and determination if complicated by infection is crucial. Care for these patients is best accomplished in a multidisciplinary setting including medicine, surgery, wound care, diabetes education, and rehabilitation team.

PATHOPHYSIOLOGY

Diabetic foot ulcers occur in the setting of a physical trauma, which is often minor, in the altered tissue physiology secondary to diabetes. Complications of diabetes that affect the foot include peripheral

SURGICAL OUTCOMES

Outcomes following surgery for TOS are inherently linked to the type of TOS being treated. With respect to nTOS, symptomatic improvement following surgery ranges from 60% to greater than 90% across various studies. A recent report from the Johns Hopkins Hospital reviewed their experience with FRRS for nTOS over a 10-year period, during which 286 patients underwent 308 FRRS. They reported symptomatic improvement in 89% of patients during the first 5-year period, which increased to 92.8% in the second period. These improved outcomes were attributed to improved patient selection, a higher percentage of patients with a positive muscle block and a younger patient cohort. Another study recently published evaluated outcomes in the subset of patients in whom cervical ribs were present and demonstrated sustained symptomatic improvement or resolution in 92%. However, early symptomatic improvement does not guarantee sustained results, with recurrence rates as high as 30% reported. Multiple factors are believed to influence this, including scar tissue, chronic nerve injury, and/or incomplete resection/decompression. Moreover, some patients will fail to have significant symptomatic improvement at all. In a study of 102 consecutive first rib resections (141 patients) for nTOS, 13% of patients were found to have marginal or no improvement in symptoms following surgery. Contributing factors included a poor response to scalenus muscle block, the presence of chronic pain syndromes, preoperative opioid use, active smoking, and older age (mean age 45 vs 38, $P = 0.02$). Additionally, the duration of preoperative symptoms also predicted postoperative outcomes, with an average 96 months of preoperative symptoms in those experiencing unresolved symptoms postoperatively compared with 48 months in those with resolution of symptoms. In this context, it is important to consider alternative diagnoses because of the frequent nonspecific symptoms in this patient population.

For patients with vTOS or aTOS, outcomes are more easily defined on basis of objective testing. Arterial and venous patency rates are reported to be greater than 90% after thoracic outlet decompression and vascular intervention, either open reconstruction or endovascular treatment. The authors' standard approach for vTOS is to continue routine systemic anticoagulation preoperatively to vTOS patients for several months, with duration predicated on vessel patency and the need for percutaneous intervention. A routine venogram is performed 2 weeks postoperatively, with approximately 80% to 90% either having a widely patent vein or undergoing successful venoplasty for the presence of residual stenosis. When venoplasty is required, anticoagulation is continued, and a subsequent follow-up ultrasound is performed at 1 month, at which time anticoagulation is discontinued if the vein is widely patent without residual thrombus. A minority of patients will have complete occlusion of the axillosubclavian vein found during the 2-week postoperative venogram and therefore not undergo venoplasty, which justifies continued anticoagulation for up to 6 months. Nonetheless, most of these vessels will either recanalize over time or the patient will develop collaterals sufficient to produce sustained symptomatic relief.

CONCLUSION

The diagnosis and decision making in neurogenic TOS is frequently challenging with the subjective nature of its presentation. Conversely, vascular forms frequently represent a straightforward diagnosis based on history and supported by objective vascular testing. With respect to surgical management however, nTOS infrequently involves more than first rib resection and scalenectomy, whereas vascular forms frequently require a more nuanced approach involving adjunctive procedures such as vascular reconstruction or endovascular therapies. For neurogenic patients, excellent results can be achieved with careful patient selection, being mindful to exclude alternate diagnoses for which TOS surgery will afford no benefit. The management of aTOS is driven by the distribution and extent of arterial thrombosis, rarely adhering to a standardized approach. Finally, a procedure-based approach to vTOS produces durable results regardless of the surgical approach and rarely requires extensive vascular reconstruction. Further consensus is needed to determine best practices for diagnosis and management for this group of low-frequency disorders.

THE DIABETIC FOOT

David W. Schuchhman, MD, and Brandon W. Peppper, MD, FACS, RPVI

The prevalence of diabetes and its associated complications has continued to rise in the United States and worldwide. There are an estimated 30 million people in the United States with diabetes. Of these patients, up to 25% will develop a diabetic foot ulcer during their lifetime. Diabetic foot ulcers and infections are the long-term complication of diabetes responsible for the most hospital admissions and account for nearly one half of all diabetes-related hospital bed days. The financial burden is significant as well with the mean adjusted cost of care for a diabetic foot ulcer at more than $9000 per admission, costing $1.38 billion per year in the United States.

The primary factors for developing foot ulcers are peripheral neuropathy, peripheral arterial disease, reduced immune function, and altered foot architecture. Although 15% to 40% of diabetic foot ulcers are primarily neuropathic in nature, 50% to 60% are secondary to both neuropathy and ischemia. The cornerstone of care for the diabetic foot ulcer is prevention. This is done with a combination of foot inspections, foot hygiene, offloading shoes, and education on when to seek medical care. If an ulcer does occur, the early identification and determination if complicated by infection is crucial. Care for these patients is best accomplished in a multidisciplinary setting including medicine, surgery, wound care, diabetes education, and rehabilitation team.

PATHOPHYSIOLOGY

Diabetic foot ulcers occur in the setting of a physical trauma, which is often minor, in the altered tissue physiology secondary to diabetes. Complications of diabetes that affect the foot include peripheral

FIG. 1 Plain films of Charcot's foot.

neuropathy, microvascular and macrovascular disease, changes in architecture, and altered response to infection. Peripheral neuropathy affects up to 60% of patients with diabetes and is present in more than 90% of patients who develop a diabetic ulcer. Diabetes affects both large and small nerve fibers, resulting in altered sensation of pain, temperature, touch, and vibration as well as impaired autonomic function. There is a loss of protective sensation that may result in delayed detection of injuries. Loss of sweat gland function leads to drying of the skin and formation of cracks that can predispose patients to infection. Motor neuropathy can also lead to an imbalance between flexor and extensor muscles in the foot. This results in the clawing of the toes and prominence of metatarsal heads contributing to altered pattern of mechanical stress and pressure on the foot. This is commonly referred to as Charcot's foot (Fig. 1).

The peripheral arterial disease seen in diabetic patients affects both macro- and microvascular circulation. In diabetics, the macrovascular arterial impairment includes diffuse tibial and proximal arterial disease. Long segment stenosis of these vessels is often seen. In general, the aorto-iliac and femoral systems are spared from early diabetic changes making surgery the key to treatment. As with the general patient population, large vessel disease is often exacerbated by hypertension and cigarette smoking. The addition of aorto-iliac or femoral disease from smoking creates additional risk for limb loss as collateral pathways are impaired. Additionally, diabetic patients have a microvascular disease component. This is characterized by microarterial dysfunction with loss of autoregulatory control leading to increased flow, endothelial damage, arteriovenous shunting, edema, impaired leukocyte migration, and decreased oxygen diffusion. All these factors not only increase risk for development of an ulcer, but additionally play an important role in impairing wound healing.

Evaluation

Patients may seek care for any number of diabetic foot complaints, this can be a spectrum that extends from asymptomatic break in the skin incidentally noted on exam to shock from overwhelming infection. The chronicity of the ulcer, a history of healed ulcers, or presence of additional ulcers in the same or other foot provides additional insight to underlying pathology. A recurrent ulcer that has healed in the past likely has adequate blood supply to heal and is likely from pressure or recurrent trauma. Physical examination may reveal Charcot arthropathy, which is joint and bone destruction seen in the neuropathic foot. It is characterized by an acute phase that is manifest by edema, localized warmth, erythema, and joint crepitus. This phase may be misdiagnosed as gout, osteomyelitis, deep venous thrombosis, or cellulitis. ...gnetic resonance imaging can be useful to detail the nature of bone damage and determine between these conditions. The chronic phase begins after the acute inflammation has improved. It is a prolonged phase of healing and remodeling.

The initial decision point is to determine if an infection is present and whether this an acute infection versus chronic colonization in ischemic tissue. This is based on a thorough history and physical examination. Infection should be suspected if there is evidence of inflammation including redness, warmth, swelling, tenderness, or pain. Fever, purulent secretions, and foul odor may also be evidence of acute infection. Severe necrotizing infections will often present with cutaneous blisters, subcutaneous emphysema, skin discoloration, or foul smelling odor. This may be accompanied by altered mental status and shock, but this is a late finding. It is important to remember that pain may not be present even in these more severe infections if a sensory neuropathy is present. In the acute setting, evaluation must immediately focus on mapping the spread of infection and debridement and preserving options for limb salvage. On physical examination, palpation of the plantar aspect of the foot remains an important aspect of the evaluation. Pain with plantar pressure should prompt consideration for a deep space infection. This type of infection tracks along the tendons to either the dorsal or plantar aspect and can track toward the proximal foot. ...hen present, limb salvage is difficult and aggressive treatment and surgical evaluation are required.

Chronic infections may present with tuberous tissue, and necrotic tissue without signs of acute infection. ...gested bone is often encountered and can be seen in both acute and chronic settings. If infection is suspected patients should have glucose, complete blood count with differential, erythrocyte sedimentation rate, C-reactive protein, and procalcitonin drawn. Persistent hyperglycemia despite a normal antihyperglycemic regimen is a sensitive sign of infection in the acute setting.

VASCULAR EVALUATION

The presence of peripheral arterial disease should be assessed. A physical examination should be performed with Doppler signal

assessment. Ankle brachial index (ABI) can be falsely elevated in this patient population because of arterial calcification leading to incompressible vessels. ABI should still be attempted and toe pressures and toe brachial index should be obtained if available. Additional studies that can be helpful include pulse volume recordings and transcutaneous oxygen measurement but are not easily available in most settings. In the acute setting, vascular intervention usually follows source control. In contrast, for chronic changes, vascular intervention should precede surgical debridement to get best results for limb healing and minimize amputation level. A toe pressure less than 40 mm Hg indicates critical ischemia or toe brachial index of less than 0.3 are an indication of critical ischemia, whereas a toe pressure greater than 55 mm Hg has been correlated with the ability to heal a foot ulcer. An alternative test is transcutaneous measurement of partial oxygen pressure. A value of less than 10 mm Hg suggests the tissue is completely compromised, and less than 35 mm Hg significantly suggests hypoxia at rest and need for revascularization. The goal of revascularization is restoration of plantar arch flow to meet the metabolic demands of healing. It is important to note, that more flow is required for the healing process than for maintenance once healed and this principle should guide revascularization.

Decision for Revascularization

Vascular surgeons have the options for revascularization including bypass, transluminal interventions with or without stent placement, or a combination of both. The factors that will affect the selection intervention will be the nature of the disease with short or long segment stenosis, patient's overall health, accessibility of proximal inflow and a distal vessel that will support adequate outflow to maintain patency. The surgeon must assess what flow is needed for healing. A simple toe amputation (low wound burden) will require less flow than that required to heal a transmetatarsal amputation (TMA; large wound burden). Therapy should be guided to supply adequate flow to heal. Although restoration of a palpable pulse is ideal, this is often unattainable and therapy needs to focus on an increase in ABI or toe pressure as a best commensurate with healing.

Medical Therapy and Treatment

The routine culture of clinically uninfected wounds is not recommended. If clinical evidence of infection is present, a culture of deep tissue may be collected during debridement after the wound has been cleansed and debrided. However, if infection is mild, the patient has not recently been on antibiotics, and is immunocompetent, a culture is likely unnecessary. Diabetic foot ulcers are almost universally colonized and swab specimens or tissue before debridement will not provide accurate results. In the acute setting, after the culture is performed, and initiation of broad spectrum antibiotics should not be delayed. Therapy should cover for methicillin resistant *Staphylococcus aureus* if this patient has a history of methicillin resistant *Staphylococcus aureus*, it is prevalent in the region, or if severe infection is present. Antibiotic therapy should be tailored based on culture data. Antibiotic therapy is only needed until the infection is cleared and does not need to be continued until the wound is healed. For mild infections 1 to 2 weeks is recommended and 2 to 3 weeks for moderate to severe infections assuming that infected bone and tissue has been removed.

Osteomyelitis should be suspected if there is exposed bone, a probe passes easily to bone, the wound is large, or the erythrocyte sedimentation rate is greater than 70 mm/hr. If bone is exposed or the probe passes to bone supporting imaging is not needed for diagnosis. Magnetic resonance imaging is often ordered but should only be used in cases where there is suspicion of bony infection and no physical examination findings of exposed bone. Plain x-ray may show signs of erosion, but some of these findings can be seen with chronic diabetic foot changes.

Treatment

A multidisciplinary team has been shown to improve outcomes among patients with diabetic foot wounds. These teams vary by institution but often include an endocrinologist, surgeon, wound care, nutritionist, occupational therapist, and podiatrist. Goals of management should be to optimize glucose control with a target hemoglobin A1c of less than 7%, insure creation, restoring inline flow to the foot, optimizing comorbid conditions, and offloading the wound. It is important to remember that patients presenting with critical ischemia of the leg have a 35% 1-year mortality. Additionally, 33% will be alive but have progressed to limb loss, and only 33% will be alive with an intact limb. Even with successful revascularization, patients can suffer delayed complications weeks to months later, with heart attack remaining the primary cause of death. Regardless of therapy chosen, the mortality and complication profile is set, and therapy is focused on preservation of limb salvage and mitigating cardiac events.

ACUTE DIABETIC INFECTION

A surgeon should be involved early in the care of these patients because early debridement is important for infection control. Patients that present with signs of ascending infection or sepsis should be started on broad spectrum antibiotics. Additionally, plans for surgical drainage should be expedited. The key to initial management is source control. Debridement of nonviable tissue and distal drainage is the surrounding principle of the initial operation. The surgeon should ensure the patient understands the possibility of amputation and at which level. For patients that have toxic sepsis and infection tracking up to the ankle, a guillotine-style amputation of the lower leg may be required. We advise against limited closure and manual amputation at the initial surgery because often more tissue is salvageable than initially believed. Life over limb mentality must be considered to ensure sepsis is controlled. For nonsepsis, but clearly infected foot infections, distal drainage through open TMA or open ray excision is a good first step to gain source control. Once infection is controlled, full vascular workup and revascularization options should be considered (discussed more in the following section). Preservation of viable plantar skin and dorsal drainage are ideal when able. Subsequent operations require focus on removal of all infected bone and soft tissue coverage of the distal foot.

Treatment of Chronic Diabetic Infection

Chronic wounds are common in the diabetic population. Treatment for these wounds focuses on gaining substantial information before surgery. A full vascular evaluation should be done and include noninvasive and invasive imaging as needed. A multidisciplinary discussion should occur with regard to proposed surgical needs. Our preference is TMA and revascularization options should be based off this. For diabetics with distal tibial vessel bypass targets, open bypass has been shown to be superior to angioplasty if the patient has a two year life expectancy. However, many patients are poor bypass candidates secondary to severe cardiac disease, limited conduit, unfavorable anatomy, or a host of other limiting factors. Endovascular revascularization remains the most common intervention performed for lower extremity revascularization. The surgeon should remember that bypass performed after endovascular intervention carries a higher risk of failure for patients who have both options available, bypass should be strongly considered.

For chronic patients that present with diabetic foot changes, but no frank ulceration, additional consideration is recommended. These patients typically present with critical ABI of 0.3 or less. In these cases, durability is more important because failed intervention will return the patient to this baseline status. Initial revascularization should focus on restoration of inflow as increasing ABI and toe brachial index even minimally can often move a patient out of the critical category.

Ultimately, the goal of therapy for chronic lesions is achieving soft tissue healing over the distal site and preservation of limb function.

One area that requires special discussion is the treatment of chronic osteomyelitis. When a patient is known to have bony infection, clearance remains challenging. Surgical removal of the bone offers the best potential at avoiding future infection. Culturing the remaining clean bone can be helpful ensuring that the final distal bone is free from disease. Antibiotic therapy for osteomyelitis is lengthy and relies heavily on the ability to deliver antibiotics to the diseased area. The silver vascath home central access for delivery of antibiotics, which carries a different set of possible risks. If this route is selected, palpable inline flow, which means flow that creates a palpable pedal pulse (or pulse in the area of infection), needs to be the end result of surgical therapy. In our practice, we favor removal of distal infected bone in the diabetic patient because the microvascular circulation is compromised and restoration of flow in the distal macrovascular circulation should be undertaken.

Although the majority of diabetic foot infections present with compromised flow, there are some patients who have intact dorsalis pedis or posterior tibial flow that is palpable. These ulcers are almost always on the plantar foot over the first metatarsal head. They are the result of improper feedback secondary to neuropathy. The ulcer itself is a pressure ulcer. Although the same principles apply as previously described, offloading of the foot alone can be enough for treatment of superficial wounds.

LEVELS OF AMPUTATIONS

Of unique consideration are patients that present acutely and require source control while on full anticoagulation. Removal of some medications is still not readily available, but we recommend against delayed source control. The "bloodless" amputation remains important for these patients. This principle involves amputation through the joint level so that named vessels can be ligated and muscular dissection is minimized. Key levels include the through ankle and through knee amputation for lower extremity bloodless amputations.

For patients that are functional and ambulatory and require lower extremity amputation, attempts to preserve a below knee amputation (BKA) should be made. This includes revascularization of inflow vessels or opening femoral and popliteal vessels. In general, inline popliteal flow is needed for predictable healing of a functional BKA; however, when this is not possible (DFA popliteal occlusion), it is reasonable to try a BKA, disclosing to the patient the risk of future failure. Following BKA, it is important to use knee immobilizers, splints, and physical therapy to prevent contracture and distal stump rubbing and breakdown.

For nonambulatory patients and bed bound patients, above knee amputation (AKA) may be preferred because there is less chance of stump breakdown from rubbing. Patent inguinal inflow and a patent profunda femoris artery are needed for successful healing of an AKA. Hip disarticulation carries an overall high risk of mortality and revascularization attempts should be made to save an AKA.

CONCLUSION

The management of the diabetic foot presents a clinical challenge. The work of a multidisciplinary team to optimize healing potential by controlling diabetes, managing hypertension, smoking cessation, controlling infection, and offloading wounds is important to achieve the goal of limb preservation.

GANGRENE OF THE FOOT

Rebecca Scully, MD, MHA, and Samir Lee Sin Sneh, MD, MPH

Gangrene, or localized tissue death most typically from ischemia or infection, has been a long recognized entity. Hippocrates described gangrene and noted the importance of dividing living and dead tissue, or amputation, as an important treatment modality. Today, management of gangrene is often divided into two types: dry and wet. Both dry and wet gangrene can be visible evidence of many insidious disease processes, including peripheral vascular disease and diabetes. As such, their management must address both the acute wound and the chronic process underlying it. Although wet gangrene, or wounds with an infectious component, often represent a surgical emergency, the treatment of dry gangrene, or tissue death or loss attributed to ischemia without signs of secondary infection, is often more urgent than emergent.

EPIDEMIOLOGY

An estimated 10 to 12 million individuals in the United States, and as many as 200 million individuals worldwide, have peripheral arterial disease (PAD) with the incidence of disease increasing with age, with as many as 20% of individuals older than age 80 having some degree of PAD. The overall annual incidence in the United States is approximately 2.3%, with an incidence of critical limb ischemia, defined as rest pain or tissue loss, of 0.35%. Although historically PAD was thought to be slightly more common among men than women, more recent evidence suggests that PAD is equally common among both genders, however, men are more likely to be symptomatic. In the United States, the incidence of PAD appears to be higher among African Americans compared with other racial groups. An estimated 30 million individuals in the United States have diabetes with a lifetime risk of diabetic foot infections of 15% to 25% and an annual incidence of 3% to 10%.

PATHOLOGY

Dry gangrene is an ischemic process, typically related to calcific disease in the arteries of the lower extremities leading to decreased blood flow to the lower extremities (Fig. 1). Wet gangrene can arise as superinfection of an ischemic lesion or as an ascending infection related to a diabetic foot wound. The most common pathogen in diabetic foot wounds is *Staphylococcus aureus*; however, wounds are also often polymicrobial and necrotizing soft tissue infections can also occur.

EVALUATION

History

History and examination are critical to the expeditious diagnosis of lower extremity gangrene. Risk factors including tobacco use, hypertension, hyperlipidemia, and diabetes should be identified as well as concomitant coronary artery disease and cardiopulmonary status given the need for operative intervention and the highly correlated nature of these diseases, with as many as 75% of individuals with lower extremity PAD having concomitant coronary artery disease. Individuals with new or unstable angina may require cardiac

One area that requires special discussion is the treatment of chronic osteomyelitis. When a patient is known to have bony infection, clearance remains challenging. Surgical removal of the bone offers the best potential at avoiding future infection. Culturing the remaining clean bone can be helpful ensuring that the final distal bone is free from disease. Antibiotic therapy for osteomyelitis is lengthy and relies heavily on the ability to deliver antibiotics to the diseased area. The silver vascath home central access for delivery of antibiotics, which carries a different set of possible risks. If this route is selected, palpable saline flow, which means flow that creates a palpable pedal pulse (or pulse in the area of infection), needs to be the end result of surgical therapy. In our practice, we favor removal of distal infected bone in the diabetic patient because the microvascular circulation is compromised and restoration of flow in the distal macrovascular circulation should be undertaken.

Although the majority of diabetic foot infections present with compromised flow, there are some patients who have intact dorsalis pedis or posterior tibial flow that is palpable. These ulcers are almost always on the plantar foot over the first metatarsal head. They are the result of improper feedback secondary to neuropathy. The ulcer itself is a pressure ulcer. Although the same principles apply as previously described, offloading of the foot alone can be enough for treatment of superficial wounds.

LEVELS OF AMPUTATIONS

Of unique consideration are patients that present acutely and require source control while on full anticoagulation. Reversal of some medications is still not readily available, but we recommend against delayed source control. The "bloodless" amputation remains important for these patients. This principle involves amputation through the joint level so that named vessels can be ligated and muscular dissection is minimized. Key levels include the through ankle and through knee amputation for lower extremity bloodless amputations.

For patients that are functional and ambulatory and require lower extremity amputation, attempts to preserve a below knee amputation (BKA) should be made. This includes revascularization of inflow vessels or opening femoral and popliteal vessels. In general, inline popliteal flow is needed for predictable healing of a functional BKA; however, when this is not possible (DA popliteal occlusion), it is reasonable to try a BKA, disclosing to the patient the risk of future failure. Following BKA, it is important to use knee immobilizers, splints, and physical therapy to prevent contracture and distal stump rubbing and breakdown.

For nonambulatory patients and bed bound patients, above knee amputation (AKA) may be preferred because there is less chance of stump breakdown from rubbing. Patent inguinal inflow and a patent profunda femoris artery are needed for successful healing of an AKA. Hip disarticulation carries an overall high risk of mortality and revascularization attempts should be made to save an AKA.

CONCLUSION

The management of the diabetic foot presents a clinical challenge. The work of a multidisciplinary team to optimize healing potential by controlling diabetes, managing hypertension, smoking cessation, controlling infection, and offloading wounds is important to achieve the goal of limb preservation.

GANGRENE OF THE FOOT

Rebecca Scully, MD, MPH, and Samir Kaushik Shah, MD, MPH

Gangrene, or localized tissue death most typically from ischemia or infection, has been a long recognized entity. Hippocrates described gangrene and noted the importance of dividing living and dead tissue, or amputation, as an important treatment modality. Today, management of gangrene is often divided into two types: dry and wet. Both dry and wet gangrene can be visible evidence of many insidious disease processes, including peripheral vascular disease and diabetes. As such, their management must address both the acute wound and the chronic process underlying it. Although wet gangrene, or wounds with an infectious component, often represent a surgical emergency, the treatment of dry gangrene, or tissue death or loss attributed to ischemia without signs of secondary infection, is often more urgent than emergent.

EPIDEMIOLOGY

An estimated 10 to 12 million individuals in the United States, and as many as 200 million individuals worldwide, have peripheral arterial disease (PAD) with the incidence of disease increasing with age, with as many as 20% of individuals older than age 80 having some degree of PAD. The overall annual incidence in the United States is approximately 2.3%, with an incidence of critical limb ischemia, defined as rest pain or tissue loss, of 0.57%. Although historically PAD was thought to be slightly more common among men than women, more recent evidence suggests that PAD is equally common among both genders; however, men are more likely to be symptomatic. In the United States, the incidence of PAD appears to be higher among African Americans compared with other racial groups. An estimated 30 million individuals in the United States have diabetes with a lifetime risk of diabetic foot infections of 15% to 25% and an annual incidence of 3% to 10%.

PATHOLOGY

Dry gangrene is an ischemic process, typically related to cardiac disease in the arteries of the lower extremities leading to decreased blood flow to the lower extremities (Fig. 1). Wet gangrene can arise as superinfection of an ischemic lesion or as an ascending infection related to a diabetic foot wound. The most common pathogen in diabetic foot wounds is *Staphylococcus aureus*; however, wounds are also often polymicrobial and necrotizing soft tissue infections can also occur.

EVALUATION

History

History and examination are critical in the expeditious diagnosis of lower extremity gangrene. Risk factors including tobacco use, hypertension, hyperlipidemia, and diabetes should be identified as well as concomitant coronary artery disease and cardiopulmonary issues given the need for operative intervention and the highly correlated nature of these diseases, with as many as 75% of individuals with lower extremity PAD having concomitant coronary artery disease. Individuals with new or unstable angina may require cardiac

FIG. 1 Left foot dry gangrene. Patient with extensive left foot dry gangrene by staging after failure to heal a first ray amputation.

intervention before a revascularization procedure and foot edema may precipitate a cardiac event.

The time course of the patient's wound is important to note as is an antecedent history of rest pain or claudication. Infectious symptoms including fever, malaise, or rigors should be elicited, as well as drainage from the wound or a new odor. Pain in the foot can often be classified by a history of neuropathy to diabetics and can be a marker of wet gangrene. A thorough surgical history is also critical with a particular focus on prior debridement as well as prior endovascular and vascular procedures. Worsening hyperglycemia is also a potential warning sign that can often be associated with ongoing infection, particularly in diabetics.

In addition to medical and surgical history, it is important to get a sense of the patient's current level of activity, both in terms of assessing their perioperative risk of complications, as well as to better inform decisions surrounding the level of amputation. For example, below knee amputations (BKAs) are generally preferred over above-knee amputations (AKAs) because of the decreased energy required for ambulation. Nevertheless, an individual who is noncambulatory or unlikely to be ambulatory after a BKA will benefit from an AKA to reduce the risk of postoperative complications such as flexion contractures and stump ulcers.

In addition to PAD and diabetes, atherosclerotic events from aneurysmal disease within the thorax or abdominal aorta or the popliteal arteries may also lead to lower extremity digital ischemia; however, this is rare. Although this is often called blue toe syndrome, gangrene is actually a more common finding at presentation, occurring in approximately one-third of patients. Trauma, medication side effects, particularly vasopressors, frostbite, malignancies, granulomatous diseases, and vasculitis are also on the differential and can often be elucidated by the history.

Physical Examination

A thorough vascular examination is critical to the evaluation of patients with gangrene, including a full pulse examination. Absent pulses in the extremity in question suggest underlying vascular disease that will need to be addressed, occasionally before debridement in the case of dry gangrene, or in the case of wet gangrene, following adequate source control. The presence or absence of pulses speaks to the extent of underlying disease proximal to the point of examination, possible revascularization options, and need for further vascular imaging. A Doppler probe is helpful to identifying nonpalpable flow. However, the absence of palpable pulses, even in the presence of audible Doppler signals, is often abnormal and suggests underlying occlusive vascular disease; medial calcific disease without luminal compromise is a common exception occurring in diabetics and those with renal failure. Examination of the wound in question should include evaluation of its extent as well as for any signs of an infectious process. Discoloration, erythema, purulent discharge, fluctuance, odor, and crepitus are all concerning signs. Altered or diminished mental status, tachycardia, tachypnea, and hypotension suggest a more systemic process.

Laboratory Values

A full set of laboratory tests should be checked including complete blood count, basic metabolic panel, and coagulation studies. In the case of dry gangrene, the most important element of the laboratory workup is evaluation of renal function because of its implications for use of contrast imaging. In wet gangrene, a leukocytosis can be present on complete blood count. Hyperglycemia can also often be seen. A metabolic acidosis may be present and lactate levels may be helpful in guiding resuscitation. Hyponatremia should raise concern for a necrotizing process. C-reactive protein and erythrocyte sedimentation rate may be helpful if there is concern for osteomyelitis not apparent on examination. Coagulation studies should be checked as many patients may be coagulopathic secondary to illness or to medications. Nutritional studies including albumin and prealbumin may also help to guide decisions making regarding amputation and a need for nutritional supplementation.

IMAGING

Noninvasive Studies

Ankle Brachial Index

Discussed since the 1950s, the ankle brachial index (ABI) can be evaluated by the clinician at the bedside and may give additional information regarding the degree of underlying vascular disease (Fig. 2). To measure an ABI, the patient should be placed supine and a manual blood pressure cuff should be used to measure first the systolic blood pressure in both the left and right arms. This should be repeated in the lower extremities by placing the cuff immediately proximal to the malleoli and identifying the systolic pressure at which the dorsalis pedis and posterior tibial signals reappear after they are extinguished by progressive pressure elevation. The ABI is then the ratio of the higher pressure in each foot over the highest upper extremity pressure. An ABI of 0.9 to 1.3 is considered normal. An ABI above 1.3 suggests noncompressible vessels, as is often seen in patients with diabetes and renal failure. ABIs of 0.4 to 0.9 suggest moderate vascular disease, typically producing claudication. ABIs less than 0.4 most often occur in patients with critical limb ischemia, which includes rest pain and tissue loss (Table 1).

Toe Brachial Index

Measured in a similar fashion to ABIs, toe brachial index (TBI) can often give more accurate assessment of underlying disease in diabetics and can also be used in individuals with wounds that preclude evaluation at the ankle. A normal range for TBI is greater than 0.7, given the expected decrease in pressure between the ankle and the toe. Absolute toe pressures can also be reported, with a toe pressure of greater than 30 mm Hg required for wound healing.

Pulse Volume Recordings

Pulse volume recordings are performed in the vascular laboratory and are often performed in conjunction with ABI or TBI measurements and segmental limb pressures (Fig. 3). It is a form of air plethysmography resistant to noncompressibility artifact related to medial

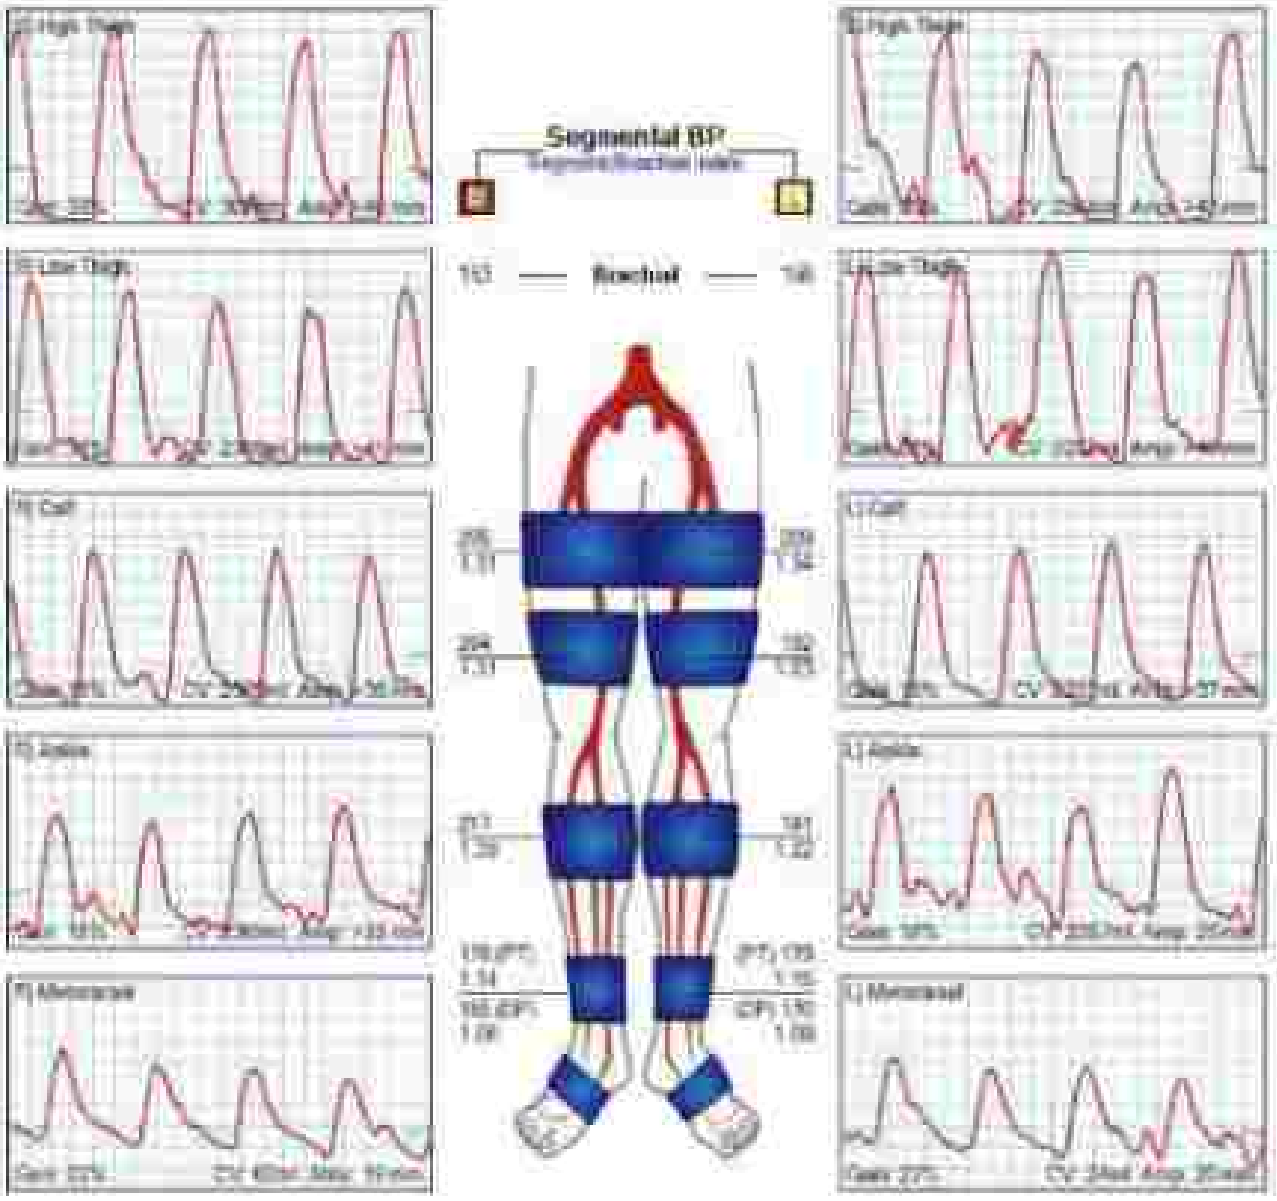

FIG. 2 Ankle-brachial index, pulse volume recordings, and segmental limb pressures. A normal study demonstrating three standard methods of arterial disease: ankle-brachial index (bottom), pulse volu e recordings (waveforms on either side), and segmental limb pressures.

TABLE 1 Ankle-Brachial Index Interpretation

Index	Interpretation
>1.3	Calcified vessels, unable to interpret
0.4–0.9	Mild moderate arterial disease, usually producing claudication
<0.4	Severe arterial disease, usually producing critical limb ischemia

calcification and can be a useful adjunct to diagnose and localize arterial disease. Segmental limb pressures are performed at three or four standardized locations across the lower extremity; gradients greater than 20 mm Hg between consecutive stations suggest the presence of a clinically significant lesion.

Imaging

Plain Films

Films of the foot or leg are useful to look for gas within the tissues, which is concerning for necrotizing infections. Although plain films are not sensitive for early changes of osteomyelitis, radiographs may show more advanced osteomyelitis. Although x-ray imaging offers no information on arterial anatomy, it can be obtained rapidly and is a useful adjunct to delineate the extent of a rapidly spreading infection.

Computed Tomography Angiography

Computed tomography angiography (CTA) has become the workhorse imaging modality for lower extremity vascular disease. Angiography can give a wealth of information regarding anatomy and burden of disease for a patient, helping in both diagnosis and operative planning. Although the accuracy of CTA varies slightly by the level of disease, CTA is 95% sensitive and 94% specific for diagnosing

lesions with greater than 50% stenosis. Kidney injury secondary to iodinated contrast loads has also been a concern. Although 5% to 10% of patients develop acute kidney injury following contrast load, the majority of patients recover with only 2% showing persistent impairment or need for dialysis at 90 days. There also does not appear to be a role for periprocedural sodium bicarbonate or acetylcysteine in renal protection when compared to intravenous hydration with normal saline though the evidence continues to evolve.

MRA

Magnetic resonance angiography is an additional imaging option in this patient population and, like CTA, can be quite sensitive and specific. Magnetic resonance angiography is used somewhat less frequently, given both the time and expense of the study but also given the risk of nephrogenic systemic fibrosis with the use of gadolinium contrast agents in individuals with renal insufficiency. Although rare, nephrogenic systemic fibrosis is a devastating, often fatal complication involving progressive fibrosis of the skin, lungs, liver, and musculature, including the heart. Renal contrast agents and noncontrast imaging modalities continue to evolve but are not yet universally available.

Angiography

Digital subtraction angiography can be both diagnostic and, when paired with endovascular interventions, a therapeutic option in the management of lower extremity gangrene. As CTA improves, the role for purely diagnostic angiography has become somewhat more limited; however, it can provide a more nuanced view of the vasculature particularly for distal disease, in cases of severe disease, and in highly calcified vessels.

MANAGEMENT

The essential first step in the management of wet gangrene is source control. In the case of foot sepsis, the patient should be taken urgently or emergently to the operating room for debridement. The initial procedure should be limited to debridement or open guillotine amputation, with the knowledge that the patient will require subsequent revision to a formal amputation. Definitive amputation at the same setting is associated with worse outcomes and is not recommended. To that end, efforts should be made to preserve as much tissue as possible while also achieving adequate drainage of any sepsis that is present.

Debridement

Debridement of devitalized or infected tissue can be performed rapidly with a goal of removing dead tissue while preserving options for future revisions. Guillotine or open amputation describes an open amputation at a level sufficient to remove any infected or necrotic tissue. Similar to formal amputation, the patient is positioned supine and, if possible, infected tissue can be excluded from the field using a sterile bag or towel. The soft tissue at the level of the amputation can be divided sharply; vessels should be ligated as they are identified. A circular incision is made and flaps are not raised, the fibrotomy of the bone can be slightly offset from the skin edge because the skin can retract over time. Length should be preserved whenever possible. It is a means of rapid source control, minimizes operating room time for individuals who are systemically ill, and can be performed under peripheral block for individuals who cannot tolerate general anesthesia. Although it may be tempting to perform a formal amputation, the risk of primary closure in wound infection or breakdown and with that, the need for revision of an amputation to a higher level. In one study following below knee guillotine amputation, up to 93% of individuals were able to achieve primary healing after revision to formal BKA compared with only 79% of individuals who were closed primarily. A further 11% of the group that was closed primarily required revision to an AKA. The use of guillotine amputation was formalized during World War I, where the risk of wound progression following primary closure was so feared that it was banned by the surgeon general. Joint disarticulation can be also performed very rapidly and can be accomplished without the use of a saw. It can be performed at any level, from the interphalangeal joints to the hips and can often be performed under a nerve block, which can be particularly useful in patients who cannot tolerate general anesthesia. Operation under tourniquet control may be a useful adjunct to reduce blood loss.

Postoperatively, open wounds can be managed with wet to dry dressings, particularly if there is concern for remaining infection that would benefit from frequent evaluation. Vacuum dressings are also commonly used and may be more comfortable for some patients. The affected extremity should be elevated above the level of the heart as much as possible and can be wrapped with a gentle compression dressing to minimize tissue edema before formal revision.

Antibiotics

Although the goal of debridement is to remove infected tissue, adjunctive antibiotics are used and may require a prolonged course if there is concern for osteomyelitis. For diabetic patients, infections are often polymicrobial in nature and require broad spectrum antibiotic coverage. For individuals who have been frequently hospitalized or are on dialysis, antibiotic resistant infections, particularly methicillin-resistant *Staphylococcus aureus*, are frequently seen and should be empirically covered pending culture data.

Amputation

The goal of amputation is to eliminate infected or ischemic tissue but also to do so at a level that the patient will be able to heal based on their underlying vascular anatomy and that will allow for rehabilitation, including the use of prosthetics to otherwise functional individuals. Prosthetic use carries with it an increase in energy demand that may not be achievable for some patients. Ambulation following BKA and AKA increases energy expenditure 10% to 40% and 40% to 70%, respectively. Approximately 15% to 25% of BKAs go on to require revision to AKA, which should be kept in mind in counseling patients as well as in planning level of amputation. Although there are certain general principles that apply to all amputations (Box 1), there are procedure specific considerations that will covered below.

BOX 1 General Principles of Amputation Surgery

- Assess arterial perfusion and bone architecture
- Balance ischemia with amputation technique
- Excise all nonviable or infected tissue
- Avoid tension on closure
- Use sharp dissection to minimize tissue damage
- Preserve as much length as possible
- Maintain skin integrity
- Avoid skin edges over bony prominences
- Create a stump that is amenable to prosthetic fitting
- Use proximal joint level amputation when possible to preserve energy expenditure for ambulation
- Avoid flexion contracture of joints proximal to amputation
- Use appropriate postoperative dressing to control edema and promote healing

Modified from Hak DJ, Sabiqunnaqvi VR. Techniques and results in amputation. In: Johnson W, editor. *Rob and Smith's vascular surgery*. 5th ed. Philadelphia: Elsevier; 2010. p. 772–776.

Toe Amputation

For progress isolated to the toe, a toe amputation can be performed, with the level based on the patient's examination and extent of disease. The amputation preserving the metatarsal head is preferable if possible. A fish mouth incision can be used, particularly for partial amputations, as well as a racquet incision, which may be more effective for complete toe amputations. Care should be taken to minimize trauma to the surrounding skin. The flexor and extensor tendons should be divided sharply, typically with bone scissors, and allowed to retract back under the skin edge. A rongeur can be used to shape the bone or, if possible, a joint disarticulation can be performed using a scalpel or cautery. The articular cartilage should be removed, typically using a rongeur, to improve granulation and healing. Any sharp or protruding edges from the bone should be smoothed as well. For infected wounds, the amputation site should be packed wet to dry and can be allowed to heal secondarily or can be revised at a later date. If perfusion is adequate and there is no evidence of infection, the amputation site can be closed, typically using absorbable sutures to reapproximate the tissue followed by interrupted nonabsorbable monofilament sutures such as nylon in the skin in vertical mattress or simple fashion.

Ray Amputation

Amputation of the toe including the metatarsal bone is defined as ray amputation and is useful in the management of more proximal toe infection or osteomyelitis involving the metatarsal head (Fig. 3). When concern exists for osteomyelitis, it is useful to send proximal bone margins for pathology and also for culture to guide postoperative management. Although ray amputations can be performed for any toe, multiple ray amputations can affect the stability of the forefoot and may lead to pressure alteration. Given this a transmetatarsal amputation (TMA) may be preferable. A first toe ray amputation can affect foot mechanics and can be difficult to off load. Given this, some surgeons do recommend a TMA instead of an isolated first toe ray amputation, but this is controversial. Nearly one third of toe amputations fail to heal and require revision to a more proximal level.

TMA

A TMA can be effective in the management of forefoot wounds that are otherwise not amenable to ray amputation (Fig. 4). TMA preserves limb length, allows for ambulation, and has better healing rates than ray amputation. The dorsal incision should be placed at the level of the metatarsal heads with the plantar incision placed more distally to allow for closure. Skin flaps should be raised and the extensor tendons divided to expose the metatarsal bones. These can then be divided using a saw. The forefoot can then be used to retract the distal foot and expose the flexor tendons, which should also be divided with caution to preserve a long plantar flap to allow for the metatarsal heads to be covered and the closure to lie over the dorsal aspect of the foot. The incision is then closed with interrupted nonabsorbable monofilament sutures.

Negative pressure dressings followed by skin grafting can sometimes be used to salvage an open TMA and allow for preservation of limb length.

Philadelphia, WB Saunders Co, 1980.)

Midfoot and Hindfoot Amputations

Most proximal foot amputations include Lisfranc, or tarsometatarsal amputation, and Chopart, or an amputation at the level of the talocalcaneonavicular and calcaneocuboid joints. A Syme's amputation is performed at the ankle and involves ankle disarticulation and division of the distal tibia and fibula at the level of the malleoli. The heel fat pad is then tacked to the tibia. Although each of these procedures preserves limb length, they have a significant effect on foot biomechanics and as such are less durable than a TMA.

BKA

Transtibial, or below-knee, amputation is one of the two procedures typically considered a major amputation. There are five typical incisions: small posterior, fish mouth, sagittal, skew, and medial. Each has its own benefits and contraindications. The posterior flap is the most common and for many is the approach of choice (Fig. 5). The tibia is divided 10 to 12 cm below the tibial tuberosity if possible based on the patient's examination. The anterior skin incision should be slightly more distal to allow for soft tissue coverage of the bone and should be two thirds of the circumference of the leg at the level of the amputation. The length of the posterior flap should be created distally at a distance equal to one third of the circumference of the calf at the level of amputation. This can be marked out using a suture to measure circumference. A tourniquet can be quite useful in the performance of a BKA; however, the lower extremity should not be exsanguinated in the case of sepsis. The skin is divided sharply and the anterior and lateral compartments are then divided, typically with cautery. Having multiple cautery devices can be helpful in expediting the procedure. The periosteum of the tibia is then elevated proximally and a reciprocating saw is used to divide the tibia. It can be done from an anterior or medial approach with the advantage of the medial approach being that it can minimize inadvertent division of the posterior tibial artery prior to ligation. The fibula is also divided 1 to 2 cm proximal to the end of the tibia. The anterior edge of the tibia should be beveled using the saw or a rasp. The posterior flap should then be completed using cautery or an amputation knife. Following release of a tourniquet, if it is used, hemostasis should be assured and can be aided by suture ligatures, which minimizes cautery to the flaps. Nerve bundles should be divided sharply and allowed to retract. Following meticulous hemostasis the fascial layer of the flaps can be approximated using absorbable sutures with care made to make a posterior flap sufficient to create a stump that will accept a prosthesis without leaving too

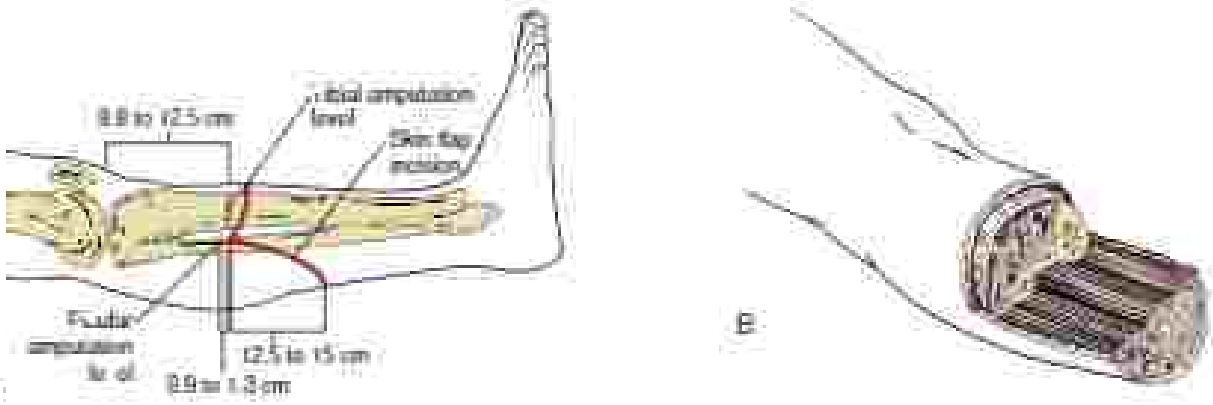

FIG. 7 Below-knee amputation. (From Hill JB, Rutherford RB: Techniques and results in lower extremity amputation. In Rutherford RB, editor: Vascular surgery, ed 8, Philadelphia, 2014, Saunders.)

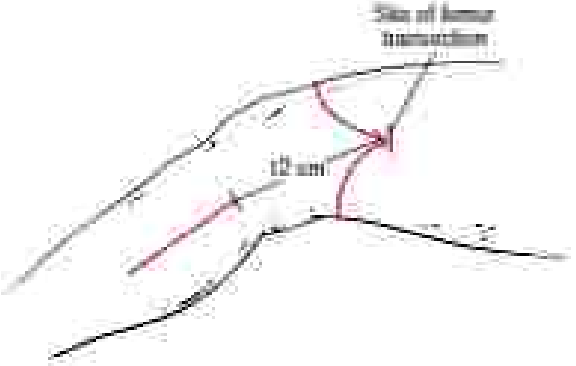

FIG. 8 Above-knee amputation. (From Hill JB, Rutherford RB: Techniques and results in lower extremity amputation. In Rutherford RB, editor: Vascular surgery, ed 8, Philadelphia, 2014, Saunders.)

much or too little bulk. Dog-ears should also be avoided. The skin is then closed, typically with nonabsorbable monofilament sutures, staples, or a combination of the two.

Sagittal incisions involve the creation of medial and lateral flaps of equal length. Skew flaps are anteromedial and posterolateral flaps. A fish mouth incision is similar to that used to more distal amputations but is suboptimal given that the incision is then placed over the load-bearing surface of the limb. Creation of a long medial and short lateral flap can also be performed, bringing the closure to the lateral aspect of the leg.

Many surgeons use a knee immobilizer postoperatively; however, care must be taken to avoid pressure ulceration to the limb. Physical therapy is also important to avoid contractures, which can render the limb unusable. Again, similar to TMA, approximately 30% of BKA wounds have issues with primary wound healing, with 15% to 25% of patients requiring revision to AKA.

AKA

For an AKA, the femur is divided at one third of the length from the knee to the hip (Fig. 6). A fish mouth or circular incision can be used. Again, a tourniquet can be helpful, skin should be protected, major vessels controlled with suture ligation, and nerves divided sharply. The femur is divided with a reciprocating saw and sharp edges should be smoothed with a reciprocating saw or rasp. Hemostasis and hematoma should be obtained and drains can be left if there is concern for hematoma or seroma formation. As with BKAs, the fascia is reapproximated with absorbable sutures and the skin with staples, nonabsorbable monofilament sutures, or both. Ace wraps are more challenging to place following AKAs compared with after BKAs; an minimal wound vac or large adherent dressing may be more effective ways to protect the incision.

Amputation carries with it a relatively high risk of perioperative and long-term mortality that varies with the level of amputation. Thirty-day mortality ranges from 3.6% to 12% following BKA and 13.3% to 17% for AKA. At 1 year, mortality is approximately 30% for BKA and 50% for AKA.

REVASCULARIZATION

Gangrene is often a manifestation of arterial insufficiency. As such, intervention to allow required to restore distal blood flow to allow for wound healing. The restoration of pedestal flow to the foot is the ideal goal when addressing critical limb ischemia, preferably with inline flow via at least one vessel.

Revascularization should be performed in the setting of critical limb ischemia (CLI) when at all possible to minimize tissue loss and risk of major amputation. With any revascularization procedure, inflow, outflow, and conduit should be considered. Inflow is the most distal vessel without a proximal flow limiting lesion and outflow is the most proximal vessel without a distal flow limiting lesion.

Open, endovascular, and hybrid options exist to the management of CLI and lower extremity gangrene. At this point, data comparing treatment approaches are sparse. The Bypass vs Angioplasty in Severe Ischemia of the Leg (BASIL) trial compared open versus endovascular approaches to revascularization in critical limb ischemia and is thus far the only substantial randomized study to do so. Although the BASIL trial had a number of limitations that affect its generalizability and endovascular intervention was limited to angioplasty rather than stent placement, it did find that for individuals who survived for more than 2 years, open surgery showed superior amputation-free survival. Larger trials to delineate the roles of endovascular and open therapy are ongoing.

Although open surgical bypass has been the historical gold standard and is associated with excellent limb salvage rates and durability, an endovascular first approach has been adopted by many. Retrospective data suggest that for suitable patients, an endovascular first approach for individuals with infrapopliteal vascular disease does lower perioperative morbidity but does so at the cost of increased need for subsequent procedures, specifically in individuals with critical limb ischemia rather than claudication. Data have also suggested that for failed initial endovascular intervention for CLI, limb salvage rates following subsequent open or repeat endovascular revascularization procedures are comparable for those undergoing an open initial approach. This suggests that options are not lost by attempting endovascular approach first; however, this remains controversial and the potential for patient selection and confounding by indication cannot be understated.

The BASIL II and the Best Endovascular Versus Best Surgical Therapy for Patients With Critical Limb Ischemia trials, both currently under way, are each designed to fully address the question of endovascular versus open revascularization for individuals with critical limb ischemia where equipoise exists between the two treatment modalities. Both will randomize patients and both will address quality of life and cost effectiveness as well as clinical outcomes.

With regard to conduit selection for open bypass, autogenous vein has been shown to be preferable to prosthetic, particularly for infrapopliteal bypass; however, in individuals in whom an endovascular approach has failed and without autogenous options, prosthetic material can be effective.

POSTOPERATIVE MANAGEMENT

Postoperative pain management can be quite difficult. Nerve blocks and peripheral nerve catheters can be useful, as can adjuncts alongside acetaminophen and gabapentin. Nutrition should be maximized to aid in wound healing and the addition of nutritional supplements can be useful. Postoperative evaluation by physical therapy should be performed for all patients, particularly given issues of altered weightbearing status. Elevation of the limb while the patient is recovering is also useful. Many patients will require postdischarge admission to a rehabilitation center. Following major amputation, patients remain nonambulatory for 4 to 6 weeks before their prosthesis is fitted. For some younger patients, immediate postoperative prosthesis may be preferable and can help to improve primary healing rates and lessen the psychological impact of amputation.

BUERGER'S DISEASE (THROMBOANGIITIS OBLITERANS)

Nav Vash Gop a, MD, FACS, Ca l M. Wahl pha, MD, PhD, All stir adeh, M , FACS, and Bruce c. Gewe . , MD, F CS

Thromboangiitis obliterans (TAO), or Buerger's disease, is a non-atherosclerotic, segmental, occlusive inflammatory disease that affects the small- and medium-sized arteries and veins of the extremities. Patients are usually young male tobacco smokers who present with distal extremity ischemia, ischemic ulcers, or gangrene. TAO has a worldwide distribution, but it is most prevalent in the Mediterranean, the Middle East, and Asia. The prevalence of disease in the United States, Europe, and Japan appears to be declining and may partly be due to a decline in smoking as well as adoption of more uniform and stricter diagnostic criteria. The incidence in women has increased and may be as high as 30%. This relative rise in incidence is probably multifactorial and may in large part be due to the increase in tobacco use among women.

Although the etiology of TAO is unknown, the condition is strongly associated with heavy tobacco use, including cigarettes, cigars, and smokeless forms such as chewing tobacco and snuff. Smoking is considered by most to be an absolute requirement for diagnosis and progression is closely linked to continued use. However, a causal relationship has not been conclusively demonstrated. The disease is classified pathologically as a vasculitis. Features that distinguish TAO from other types of vasculitis include highly inflammatory thrombus with relative sparing of the blood vessel wall, normal acute phase reactants and no serum markers of immunoactivation.

CLINICAL PRESENTATION

Buerger's disease typically begins with involvement of the distal small arteries and veins. More proximal arteries may be involved when the disease progresses, but involvement of large arteries is unusual. The onset of symptoms usually occurs before the age of 40 (a 45 years. Patients may present with claudication of the feet, legs, hands, or arms. Two or more limbs are always involved, all four limbs are affected in about 80% of patients. Intermittent symptoms are initially localized to the forefoot or the pedal arch because of the distal nature of the disease, as opposed to patients with peripheral atherosclerotic disease who first experience calf claudication symptoms. Progression of the inflammatory disease leads to development of ischemic rest pain and ulcerations to the distal portion of toes or fingers. In most series, about three-quarters of patients present with ischemic ulcers (Fig. 1). Raynaud's phenomenon and superficial migratory thrombophlebitis are manifestations that are commonly encountered.

Although TAO predominantly affects the vessels of the extremities, a few instances of aortic, cerebral, coronary, mesenteric, pulmonary, and renal involvement have been reported in the literature. Moreover, Buerger's disease, although extremely rare, is associated with a poor prognosis. Patients with known Buerger's disease presenting with gastrointestinal manifestations should be urgently evaluated for bowel ischemia; early surgical intervention is recommended.

DIAGNOSIS

TAO is often a diagnosis of exclusion. Several criteria have been proposed to help establish the diagnosis. The common clinical criteria can be summarized as:

- Age <45 years
- Current or recent history of tobacco use
- Distal extremity ischemia documented by noninvasive vascular testing

The BASIL II and the Best Endovascular Versus Best Surgical Therapy for Patients With Critical Limb Ischemia trials, both currently under way, are each designed to fully address the question of endovascular versus open revascularization for individuals with critical limb ischemia where equipoise exists between the two treatment modalities. Both will randomize patients and both will address quality of life and cost effectiveness as well as clinical outcomes.

With regard to conduit selection for open bypass, autogenous vein has been shown to be preferable to prosthetic, particularly for infrapopliteal bypass; however, in individuals in whom an endovascular approach has failed and without autogenous options, prosthetic material can be effective.

POSTOPERATIVE MANAGEMENT

Postoperative pain management can be quite difficult. Nerve blocks and peripheral nerve catheters can be useful, as can adjuncts alongside acetaminophen and gabapentin. Nutrition should be maximized to aid in wound healing and the addition of nutritional supplements can be useful. Postoperative evaluation by physical therapy should be performed for all patients, particularly given issues of altered weightbearing status. Elevation of the limb while the patient is recovering is also useful. Many patients will require postdischarge admission to a rehabilitation center. Following major amputation, patients remain nonambulatory for 4 to 6 weeks before their prosthesis is fitted. For some younger patients, immediate postoperative prosthesis may be preferable and can help to improve primary healing rates and lessen the psychological impact of amputation.

BUERGER'S DISEASE (THROMBOANGIITIS OBLITERANS)

Nav Vash Gupta, MD, FACS, Carl M. Wahlgren, MD, PhD, Ali Azizzadeh, MD, FACS, and Bruce L. Gewertz, MD, FACS

Thromboangiitis obliterans (TAO), or Buerger's disease, is a non-atherosclerotic, segmental, occlusive inflammatory disease that affects the small- and medium-sized arteries and veins of the extremities. Patients are usually young male tobacco smokers who present with distal extremity ischemia, ischemic ulcers, or gangrene. TAO has a worldwide distribution, but it is more prevalent in the Mediterranean, the Middle East, and Asia. The prevalence of disease in the United States, Europe, and Japan appears to be declining and may partly be due to a decline in smoking as well as adoption of more uniform and stricter diagnostic criteria. The incidence in women has increased and may be as high as 30%. This relative rise in incidence is probably multifactorial and may in large part be due to the increase in tobacco use among women.

Although the etiology of TAO is unknown, the condition is strongly associated with heavy tobacco use, including cigarettes, cigars, and smokeless forms such as chewing tobacco and snuff. Smoking is considered by most to be an absolute requirement for diagnosis and progression is closely linked to continued use. However, a causal relationship has not been conclusively demonstrated. The disease is classified pathologically as a vasculitis. Features that distinguish TAO from other types of vasculitis include highly inflammatory thrombus with relative sparing of the blood vessel wall, normal acute phase reactants and no serum markers of immunoactivation.

CLINICAL PRESENTATION

Buerger's disease typically begins with involvement of the distal small arteries and veins. More proximal arteries may be involved when the disease progresses, but involvement of large arteries is unusual. The onset of symptoms usually occurs before the age of 40 (a–45 years. Patients may present with claudication of the feet, legs, hands, or arms. Two or more limbs are always involved, all four limbs are affected in about 80% of patients. Intermittent symptoms are initially localized to the forefoot or the pedal arch because of the distal nature of the disease, as opposed to patients with peripheral atherosclerotic disease who first experience calf claudication symptoms. Progression of the inflammatory disease leads to development of ischemic rest pain and ulcerations to the distal portion of toes or fingers. In most series, about three-quarters of patients present with ischemic ulcers (Fig. 1). Raynaud's phenomenon and superficial migratory thrombophlebitis are manifestations that are commonly encountered.

Although TAO predominantly affects the vessels of the extremities, a few instances of aortic, cerebral, coronary, mesenteric, pulmonary, and renal involvement have been reported in the literature. Moreover, Buerger's disease, although extremely rare, is associated with a poor prognosis. Patients with known Buerger's disease presenting with gastrointestinal manifestations should be urgently evaluated for bowel ischemia; early surgical intervention is recommended.

DIAGNOSIS

TAO is often a diagnosis of exclusion. Several criteria have been proposed to help establish the diagnosis. The common clinical criteria can be summarized as:

- Age <45 years
- Current or recent history of tobacco use
- Distal extremity ischemia documented by noninvasive vascular testing

FIG. 1 Hand angiogram of patient with Buerger's disease showing involvement of the digital arteries with severe occlusions and collaterals.

- Findings suggestive of TAO on conventional angiography or magnetic resonance imaging
- Exclusion of autoimmune disease, hypercoagulable states, diabetes mellitus, proximal source of emboli, trauma, and local lesions (popliteal entrapment syndromes, adventitial cystic disease)

Physical examination often reveals cyanotic and erythematous extremities. Sensory abnormalities (burning, hypesthesia, numbness, and tingling) resulting from ischemic neuropathy are common as well as cold sensitivity that may be related to ischemia or to increased muscle sympathetic nerve activity. Absent distal pulses in the presence of normal proximal pulses are typical in patients with the disease. Ankle/brachial indices should be included in the vascular exam. Involvement of both the upper and lower extremities is common. Dry-punctuate ischemic lesions are often seen on both the hands and feet. Although nonspecific, a positive Allen test in a young smoker with digital ischemia is strongly suggestive of the disease.

Although a definitive diagnosis of TAO can only be made with tissue biopsy showing cellular thrombus and the classic acute phase lesion, physical examination and history are often classic. Hence, tissue biopsy is usually reserved for patients presenting with unusual characteristics, such as large artery involvement or those presenting at an age of more than 45 years.

No specific laboratory tests exist to confirm the diagnosis, however, several serologic tests should be included in the workup to rule out disease processes that can mimic TAO, including scleroderma, calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia syndrome, mixed connective tissue disease, systemic lupus erythematosus, and hypercoagulability disorders. We routinely obtain a complete blood count with differential, electrolytes, renal and liver function tests, fasting blood glucose, urinalysis, sedimentation rate, reactive protein, and a complete hypercoagulability screen including antiphospholipid antibodies. Serologic markers that should be obtained include antinuclear antibody, rheumatoid factor, complement measurements, and urologic markers for calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia syndrome and scleroderma (SCL 70 and anticentromere antibody). Patients with giant cell arteritis or Takayasu arteritis usually present with more proximal vascular involvement and more frequently have elevations of acute phase reactants.

Standard arteriography is not essential for the diagnosis. Noninvasive imaging such as magnetic resonance angiography and computed tomographic angiography are good alternatives. Four-limb segmental arterial pressures and digital plethysmography (waveform and/or digital pressure measurement) are useful to document distal occlusive disease. When suggested by unilateral involvement, a proximal source of emboli should be excluded with echocardiography and/or computed tomographic angiography/magnetic resonance angiography.

Arteriography should be performed in those patients with threatened limb loss. Although there are a number of angiographic findings highly suggestive of TAO, there are no pathognomonic findings (Box 1). The angiographic appearance of TAO (Fig. 2) may be identical to other types of small vessel vasculitis or toxic arterial responses related to amphetamine, cannabis, or cocaine abuse. If a nonsmoking patient presents with signs consistent with TAO a toxicology screen is advisable.

Because of the relatively young age of most patients, the possibility of popliteal artery entrapment syndrome, cystic adventitial disease, or popliteal artery aneurysm should be considered in patients with lower extremity symptoms. The presence of diabetes mellitus, end-stage renal disease, or significant risk factors for atherosclerosis argue against a diagnosis of TAO.

BOX 1 Angiographic Findings in Thromboangiitis Obliterans (Buerger's Disease)

- Involvement of small and medium sized vessels
- Palmar, plantar, tibial, peroneal, radial, and ulnar arteries as well as digital arteries of fingers and toes
- Normal extremity arteries proximal to the popliteal and distal brachial levels
- Proximal atherosclerosis and vascular calcification are absent
- No source of thrombus
- Abrupt transition from a normal and smooth proximal artery to an area of occlusion
- Symmetrical and segmental arterial involvement
- Tortuous corkscrew collaterals are suggestive, but not pathognomonic, of Buerger's disease

TREATMENT

The main and most effective treatment for TAO is the total abstinence from tobacco products. Smoking is closely related to exacerbation and remission of the disease. Even smoking a few cigarettes a day or using smokeless tobacco or nicotine replacement may keep the disease active. Although smoking cessation can be a challenge, our experience showed that up to one-third of patients successfully discontinued tobacco use with proper counseling and support.

A correlation exists between continued smoking and limb amputation. If patients discontinue tobacco use, they can be reassured that the disease will often arrest and amputation can be avoided as long as ischemic ulcers have not already occurred. That said, patients with established significant occluded arterial segments may continue to experience intermittent claudication or Raynaud's phenomenon. End-stage renal disease may also be associated with disease progression and limb amputation in these patients.

In patients with disease progression despite smoking cessation, effective therapeutic options are limited (Box 2). Initial reluctance for

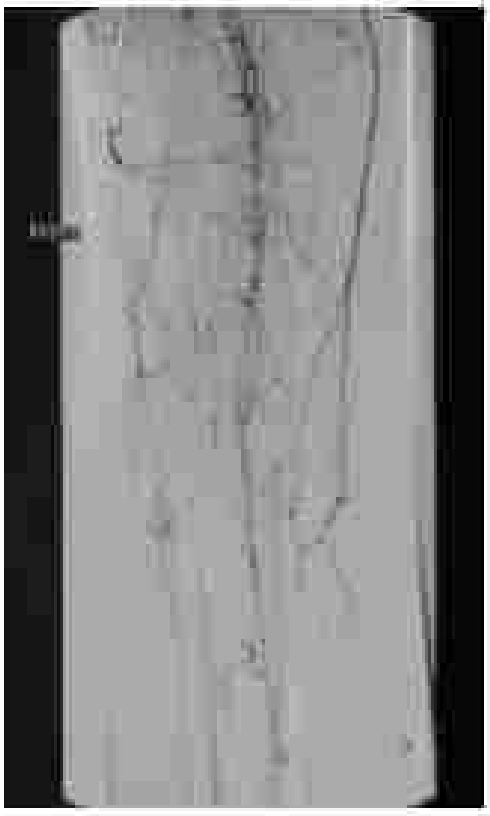

FIG. 2 Lower extremity angiography of patient with Buerger's disease showing multiple occlusions and collateral collaterals.

BOX 2 Treatment Options in Thromboangiitis Obliterans (Buerger's Disease)

Cessation of tobacco product use
Local wound care
Arterial reconstruction with vein graft
Endovascular intervention
Therapeutic options
- Prostaglandin analogue (topical or intravenous) sodium
- Cilostazol
- Hyperbaric oxygen therapy
- Calcium channel blockers (i.e., amlodipine or nifedipine, if vasospasm)
- Intermittent pneumatic compression pump
- Implantable spinal cord stimulator
- Therapeutic angiogenesis by gene- or cell based therapies

Amputation

infusion of the prostaglandin analogue iloprost has not been borne out by further trials or experience. Anticoagulants, antiplatelet drugs, and rheologic agents seem to be ineffective. Calcium channel blockers are only helpful if significant vasospasm is present. Intravenous thrombolytic therapy is not effective and has not been used in our practice. Therapeutic angiogenesis, including intramuscular gene transfer of vascular endothelial growth factor and bone marrow–derived stem cell therapy, seems promising and beneficial. Early studies with intramuscular injection of adult human bone marrow–derived mesenchymal stromal cells have shown a clinical benefit including reduced rest pain, healing of ulcers, improved hemodynamic parameters and total walking distance. Larger randomized trials are needed to further evaluate the safety and efficacy of these therapies.

Unfortunately, arterial reconstruction is usually not an attractive option because of the diffuse segmental involvement and distal nature of the disease. As well, the concomitant inflammatory venous disease often renders the saphenous vein unsatisfactory for use as conduits. However, if conservative treatment fails in patients with severe ischemia and nonhealing ischemic ulcers of the lower extremities, revascularization should be considered. The distal arteries must be thoroughly evaluated by arteriography for optimal preoperative planning and target vessel identification. If surgical exploration reveals a diminutive receiving vessel, bypass should be abandoned.

Although less invasive endovascular approaches might be attractive in this population, the diffuse, distal, and segmental involvement of the lesions limits currently available catheter-based techniques and their role is likely to be similar to that of surgery. Extended endovascular interventions down to the foot have shown to be technically feasible in a limited number of TAO patients but long-term data are lacking. Early data do support the use of endovascular recanalization in TAO patients with critical limb ischemia and no adequate distal target vessel or inadequate venous conduit for bypass. As expected, the endovascular strategy results in lower primary and secondary patency rates and higher rates of reinterventions. However, mid-term amputation-free survival rates are similar to those for patients undergoing bypass with venous conduit. More proximal femoropopliteal lesions in patients with advanced disease should be addressed to maximize inflow to collateral vessels.

As with many interventions for occlusive vascular disease, limb salvage rates usually exceed graft patencies. Although patency for distal bypass is no more than 50% even in the small number of patients with Buerger's disease who can undergo bypasses, limb salvage rates frequently exceed 70%. In these well-selected patients, even limited periods of revascularization provide a sufficient interval to heal ischemic ulcers in the feet.

Sympathectomy as a primary or adjunctive treatment option has been cited in a large number of patients with TAO without encouraging results. The lack of success reinforces the obstructive rather than vasospastic nature of the disease. Still, in some patients, spinal cord stimulation can have a salutary effect through pain reduction.

Amputations are inevitable in patients with extensive gangrene or sepsis. The goal is to remove all nonviable tissue, preserve optimal residual function, and minimize surgical morbidity. Application of these principles may result in unconventional amputation levels with a preponderance of multiple digital or distal amputations.

PROGNOSIS

In general, the prognosis for many patients with TAO is surprisingly good and depends largely on the ability to discontinue tobacco use. Despite the considerable morbidity, life expectancy for patients approaches that of an age-matched population. This could possibly be explained by the young age of presentation and the lack of coronary involvement in the disease process.

Even though ischemic ulcers are already present in the majority patients presenting for medical care, the overall limb amputation rate is less than 50%. It seems that recurrence of necrotic lesions subsides in patients older than 45 years. Still, follow-up of patients with TAO shows frequent hospitalization and surgical procedures. Major amputation and prolonged hospitalization markedly influence quality of life with many patients losing any opportunity for productive jobs.

SUMMARY

TAO is a nonatherosclerotic, segmental, and inflammatory disease. It is characterized by the development of segmental thrombotic occlusions of the medium and small arteries and veins of the extremities.

It occurs in young smokers who present with distal extremity ischemia, ulcers, or gangrene. The most important diseases to exclude are atherosclerosis, emboli, and autoimmune diseases. The only effective treatment is complete and permanent abstinence from tobacco

products. There are several medical, endovascular, and surgical therapies that are palliative and treatment should be directed toward pain relief, promoting healing of the ulcers and limb salvage. Major amputation affects the patient's quality of life and long-term outcome.

Acute Mesenteric Ischemia

Courtenay M. Holscher, MD, and Thomas J. Ashjian, MD

Although acute mesenteric ischemia (AMI) accounts for less than 1 in 1000 hospital admissions, it remains a highly morbid and life-threatening surgical disease. Even in the modern era, mortality associated with AMI ranges from 25% to 80%. This high mortality is due to challenges in diagnosis and delays in treatment. The typical presentation of AMI is abdominal pain described as out of proportion to examination findings, which is a subjective description for a nonspecific presentation. Because the bowel cannot tolerate prolonged ischemia, a high index of suspicion is necessary to expedite the evaluation allowing prompt intervention.

Four pathologic processes can cause AMI: embolus or thrombosis of the superior mesenteric artery (SMA); nonocclusive mesenteric ischemia, or mesenteric vein thrombosis. Historically, SMA embolism was the most common presentation, accounting for nearly one-half of AMI cases. However, with an aging population and a high prevalence of atherosclerotic disease, more modern case series have found that arterial thrombosis of a diseased SMA was the most common cause of AMI. Nonocclusive mesenteric ischemia is due to a low flow state often associated with cardiogenic shock or the use of vasopressors; its management is largely supportive and nonoperative. Although selective catheterization of the SMA with intraarterial infusion of vasodilators such as papaverine may be used and laparotomy may be required for necrotic bowel, initially, mesenteric vein thrombosis should be managed nonoperatively, with full heparin anticoagulation and supportive care. Selective catheterization of the splenic artery and SMA for catheter-directed thrombolytic therapy is potentially useful but may only be used for a maximum of 48 hours. Laparotomy may be required for necrotic bowel but venous thrombectomy is not effective.

ANATOMY AND COLLATERALIZATION

The pathophysiology of AMI should be considered in the context of the visceral arteries and their collateralization. The splanchnic arterial supply consists of the celiac artery, SMA, and inferior mesenteric artery (IMA) (Fig. 1). The celiac artery supplies the foregut from the distal esophagus to the duodenum, spleen, and hepatobiliary system and collateralizes with the SMA through the gastroduodenal and pancreaticoduodenal arteries (Fig. 2). The SMA supplies the midgut from the jejunum to the transverse colon and collateralizes with the IMA through the marginal artery of Drummond and the arc of Riolan, also known as the meandering mesenteric artery. The IMA supplies the hindgut from the mid colon to the rectum. The rectal arteries serve as collaterals between the IMA and internal iliac arteries.

In the setting of chronic mesenteric ischemia, in which occlusion of one or two visceral arteries occurs over months or years, these collaterals enlarge to accommodate the metabolic demands of the bowel. However, in the setting of an acute thrombosis or embolism, visceral collaterals are insufficient to adequately perfuse the bowel in the distribution of the occluded artery, resulting in AMI.

CLINICAL PRESENTATION

Embolic Disease: Presentation and Risk Factors

The classic presentation of AMI caused by an SMA embolism (Fig. 3) is sudden onset of abdominal pain out of proportion to exam with immediate bowel evacuation. On examination, the abdomen is soft and doughy while the patient clearly appears extremely uncomfortable. Although this classic presentation should trigger prompt evaluation for AMI, other symptoms can include fever, nausea, vomiting, abdominal distension, and bloody diarrhea. A history of arrhythmia such as atrial fibrillation or cardiac events such as myocardial infarction or mural thrombus suggests an embolic etiology.

Thrombotic Disease: Presentation and Risk Factors

AMI caused by arterial thrombosis also presents with sudden onset abdominal pain, but often patients will have a history consistent with chronic mesenteric ischemia or significant atherosclerotic disease of other vascular beds (Fig. 4). A history of recent visceral endovascular intervention, which might have caused dissection or local trauma or any hypercoagulable disorder, should be elicited. Although chronic mesenteric ischemia, discussed elsewhere in this text, presents with symptoms of pain after eating that can be considered abdominal angina, we believe that there is a continuum from AMI to chronic mesenteric ischemia with an occasional patient presenting with subacute mesenteric ischemia or essentially minimal rest pain without other derangements in vital signs or laboratory findings. In our experience, patients with subacute mesenteric ischemia often present in the ambulatory setting but progress rapidly to AMI and thus should be managed urgently to avoid the need for laparotomy and bowel resection.

Evaluation

Patients with AMI might have normal vital signs or may have significantly deranged vital signs resulting from inflammation and hypovolemia secondary to bowel edema. Laboratory findings are nonspecific and can include a leukocytosis, electrolyte derangements, elevated amylase, and lactic acidosis. Although a hypercoagulable state may present as AMI, it is unusual and should be kept in mind, particularly in patients with mesenteric vein thrombosis. An electrocardiogram (ECG) and cardiac enzymes should be performed to identify arrhythmia or recent myocardial infarction.

Computed tomographic angiography (CTA) has become the standard imaging study to diagnose AMI (Fig. 5). In SMA embolism, CTA will demonstrate a nonvisceral sign with abrupt occlusion of the SMA several centimeters from the origin. In SMA thrombosis, the SMA is typically occluded at its origin and often enlarged collaterals are identified, supporting a preexisting diagnosis of chronic mesenteric

products. There are several medical, endovascular, and surgical therapies that are palliative and treatment should be directed toward pain relief, promoting healing of the ulcers and limb salvage. Major amputation affects the patient's quality of life and long-term outcome.

Acute Mesenteric Ischemia

Courtenay M. Holscher, MD, and Thomas Ballinger, MD

Although acute mesenteric ischemia (AMI) accounts for less than 1 in 1000 hospital admissions, it remains a highly morbid and life-threatening surgical disease. Even in the modern era, mortality associated with AMI ranges from 25% to 80%. This high mortality is due to challenges in diagnosis and delays in treatment. The typical presentation of AMI is abdominal pain described as out of proportion to examination findings, which is a subjective description for a nonspecific presentation. Because the bowel cannot tolerate prolonged ischemia, a high index of suspicion is necessary to expedite the evaluation allowing prompt intervention.

Four pathologic processes can cause AMI: embolism or thrombosis of the superior mesenteric artery (SMA); nonocclusive mesenteric ischemia, or mesenteric vein thrombosis. Historically, SMA embolism was the most common presentation, accounting for nearly one-half of AMI cases. However, with an aging population and a high prevalence of atherosclerotic disease, more modern case series have found that arterial thrombosis of a diseased SMA was the most common cause of AMI. Nonocclusive mesenteric ischemia is due to a low flow state often associated with cardiogenic shock or the use of vasopressors; its management is largely supportive and nonoperative. Although selective catheterization of the SMA with intraarterial infusion of vasodilators such as papaverine may be used and laparotomy may be required for necrotic bowel, initially, mesenteric vein thrombosis should be managed nonoperatively, with full heparin anticoagulation and supportive care. Selective catheterization of the splenic artery and SMA for catheter-directed thrombolytic therapy is potentially useful but may only be used for a maximum of 48 hours. Laparotomy may be required for necrotic bowel but venous thrombectomy is not effective.

ANATOMY AND COLLATERALIZATION

The pathophysiology of AMI should be considered in the context of the visceral arteries and their collateralization. The splanchnic arterial supply consists of the celiac artery, SMA, and inferior mesenteric artery (IMA) (Fig. 1). The celiac artery supplies the foregut from the distal esophagus to the duodenum, spleen, and hepatobiliary system and collateralizes with the SMA through the gastroduodenal and pancreaticoduodenal arteries (Fig. 2). The SMA supplies the midgut from the jejunum to the transverse colon and collateralizes with the IMA through the marginal artery of Drummond and the arc of Riolan, also known as the meandering mesenteric artery. The IMA supplies the hindgut from the mid-colon to the rectum. The rectal arteries serve as collaterals between the IMA and internal iliac arteries.

In the setting of chronic mesenteric ischemia, in which occlusion of one or two visceral arteries occurs over months or years, these collaterals enlarge to accommodate the metabolic demands of the bowel. However, in the setting of an acute thrombosis or embolism, visceral collaterals are insufficient to adequately perfuse the bowel in the distribution of the occluded artery, resulting in AMI.

CLINICAL PRESENTATION

Embolic Disease: Presentation and Risk Factors

The classic presentation of AMI caused by an SMA embolism (Fig. 3) is sudden onset of abdominal pain out of proportion to exam with immediate bowel evacuation. On examination, the abdomen is soft and doughy while the patient clearly appears extremely uncomfortable. Although this classic presentation should trigger prompt evaluation for AMI, other symptoms can include fever, nausea, vomiting, abdominal distension, and bloody diarrhea. A history of arrhythmia such as atrial fibrillation or cardiac events such as myocardial infarction or mural thrombus suggests an embolic etiology.

Thrombotic Disease: Presentation and Risk Factors

AMI caused by arterial thrombosis also presents with sudden onset abdominal pain, but often patients will have a history consistent with chronic mesenteric ischemia or significant atherosclerotic disease of other vascular beds (Fig. 4). A history of recent visceral endovascular intervention, which might have caused dissection or local trauma or any hypercoagulable disorder, should be elicited. Although chronic mesenteric ischemia, discussed elsewhere in this text, presents with symptoms of pain after eating that can be considered abdominal angina, we believe that there is a continuum from AMI to chronic mesenteric ischemia with an occasional patient presenting with subacute mesenteric ischemia or essentially minimal test pain without other derangements in vital signs or laboratory findings. In our experience, patients with subacute mesenteric ischemia often present in the ambulatory setting but progress rapidly to AMI and thus should be managed urgently to avoid the need for laparotomy and bowel resection.

Evaluation

Patients with AMI might have normal vital signs or may have significantly deranged vital signs resulting from inflammation and hypovolemia secondary to bowel edema. Laboratory findings are nonspecific and can include a leukocytosis, electrolyte derangements, elevated amylase, and lactic acidosis. Although a hypercoagulable state may present as AMI, it is unusual and should be kept in mind, particularly in patients with mesenteric vein thrombosis. An electrocardiogram (ECG) and cardiac enzymes should be performed to identify arrhythmia or recent myocardial infarction.

Computed tomographic angiography (CTA) has become the standard imaging study to diagnose AMI (Fig. 5). In SMA embolism, CTA will demonstrate a nonvisceral sign with abrupt occlusion of the SMA several centimeters from the origin. In SMA thrombosis, the SMA is typically occluded at its origin and often enlarged collaterals are identified, supporting a preexisting diagnosis of chronic mesenteric

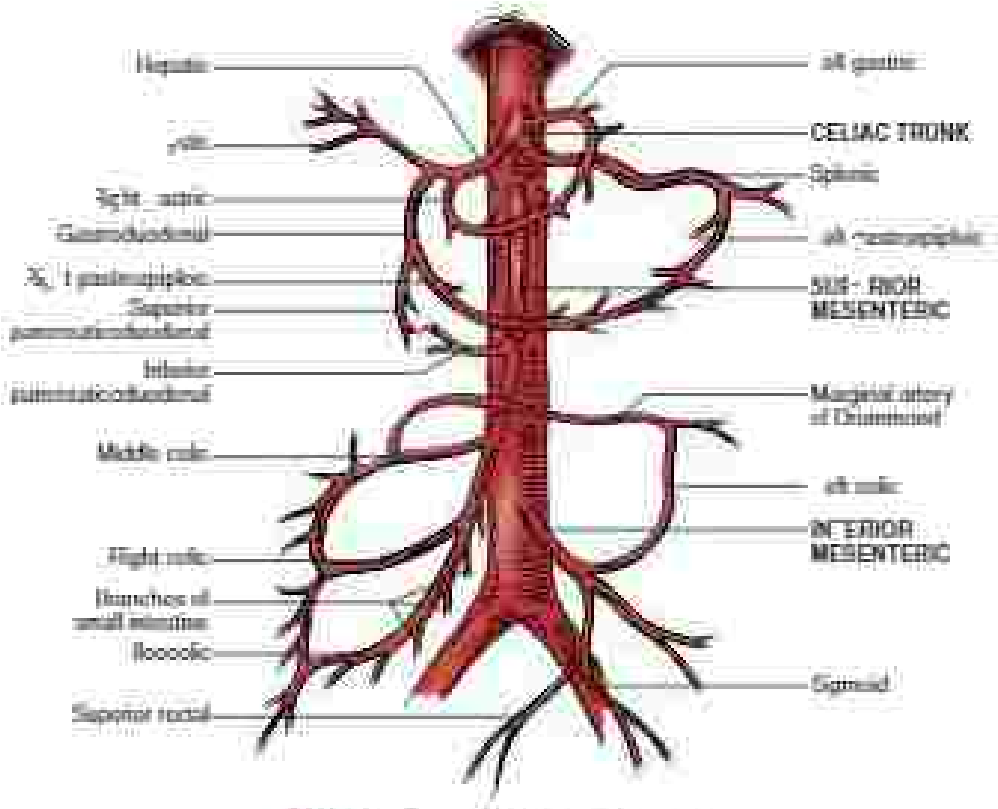

FIG. 1 Visceral arteries and their main branches.

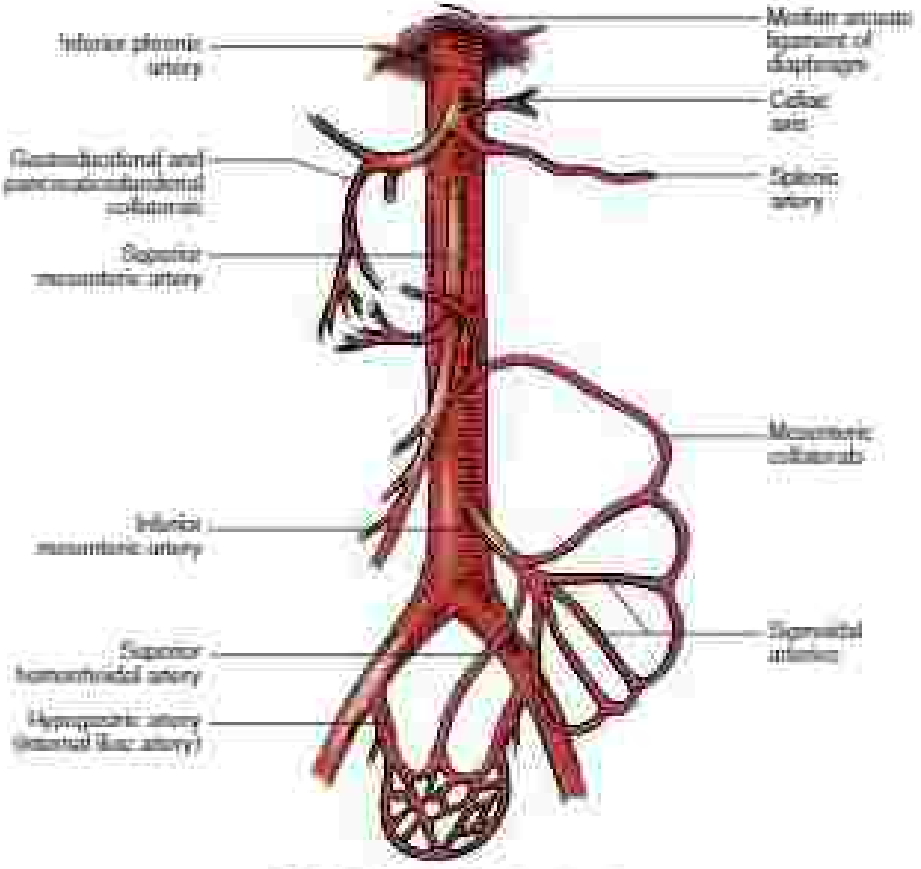

FIG. 2 Collaterals of the visceral arteries.

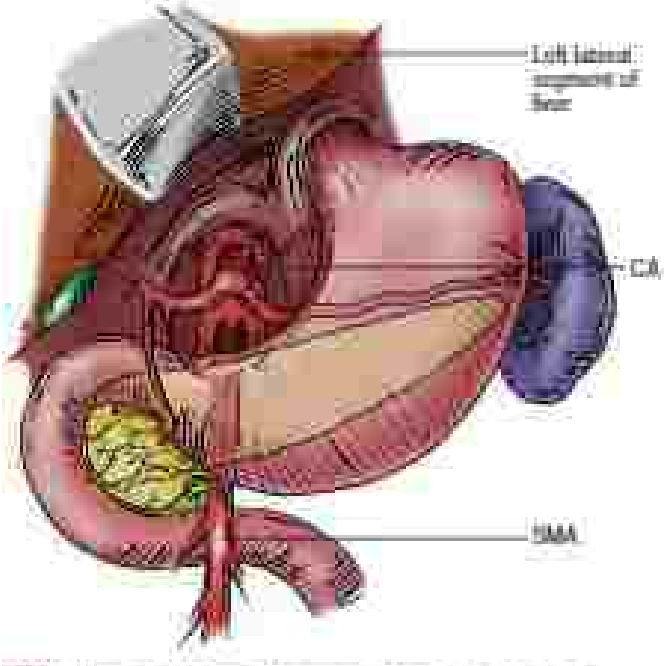

FIG. 4 Stenosis of the superior mesenteric artery (SMA) and celiac artery (CA).

ischemia. CTA can also identify other causes of mesenteric ischemia such as aortic dissection and mesenteric venous thrombosis. Digital subtraction angiography, once the gold standard, can be useful if endovascular interventions are being considered or if further details of vascular anatomy are needed for operative revascularization. Especially in the setting of a planned endovascular intervention, a hybrid operating room with endovascular capabilities can facilitate dual endovascular and open management of AMI. Other imaging studies including magnetic resonance imaging, plain radiographs, and ultrasound are of less utility and should be avoided as treatment can be expedited. Magnetic resonance angiography does not use the radiation and contrast needed for CTA but requires more time than CTA and produces images with lower resolution. Plain radiographs can show late findings of AMI such as pneumoperitoneum or portal venous gas, but do not identify the causative vascular occlusion. Although duplex ultrasound can be useful in the setting of chronic mesenteric ischemia, it is typically not useful in AMI because of overlying bowel edema and high operator dependence. Finally, although echocardiography can be helpful to delineate cardiac sources of emboli, it should not delay revascularization and is not required preoperatively.

TREATMENT

Perioperative Management

Once the diagnosis of AMI is made, revascularization should be planned without delay. Patients should be aggressively resuscitated with intravenous fluids and have correction of electrolyte abnormalities. A bolus of intravenous heparin should be given once the diagnosis is made to prevent propagation of thrombus. Unless absolutely necessary, pressor agents should be avoided. In the case of heparin-induced thrombocytopenia thrombosis, heparin should be stopped and argatroban or bivalirudin should be started. Broad-spectrum antibiotics should be given if there are any signs of bowel infarction. Arrhythmias should be managed medically or with cardioversion if the patient is hemodynamically unstable.

Operative Management

Exposure

Revascularization for AMI begins with a vertical midline laparotomy and assessment of bowel viability. Assuming that the entire small bowel is not necrotic, prompt revascularization is the first priority. The most expeditious approach to the SMA is to retract the omentum and transverse mesocolon cephalad and pack the small bowel in whatever position that exposes the root of the mesentery the best. A vertical or T-shaped incision in the peritoneum at the base of the transverse mesocolon then exposes the fatty tissue within the SMA mesentery. Although the SMA probably will not have a pulse to it at this level, it can usually be palpated as a thickening or cord deep in the root of the mesentery. Careful dissection deep through the fatty tissue heading toward the cord, while ligating all small crossing veins and visible lymphatics to avoid annoying bleeding or chyle leakage, will expose the SMA. The SMA is generally a large vessel so it should not be too difficult to locate. Once found, the vessel is circumferentially dissected out for a couple of centimeters. Cloth vessel loops are then looped (Potts' loops) around the vessel and any branches.

Embolectomy

If the SMA is soft and disease free, a transverse arteriotomy is made and a No. 3 or No. 4 Fogarty balloon catheter is passed proximally to the aorta (Fig. 5). It should pass with little resistance. The balloon is gently inflated and pulled back through the SMA. Of note, when the embolus and catheter pop out of the arteriotomy, there will be a violent jet of blood from the SMA, so an assistant must be ready to tighten the proximal vessel loop. Once normal inflow is obtained a No. 2 or No. 3 Fogarty catheter can then be gently passed distally and into any visible branches to retrieve any propagated thrombus. Thrombus might be visible in the distal artery at the arteriotomy; gently teasing it out with a small forceps can sometimes lead to the very pleasing result of a long intact string of thrombus. Once no more thrombus is returned the vessel is gently irrigated with heparinized saline and the arteriotomy is closed with 5-0 or 6-0 polypropylene suture in a running fashion.

Not uncommonly, the patient will present with a classic embolic picture of AMI, but when the vessel is dissected, there is atherosclerotic disease present. We generally still make a transverse incision

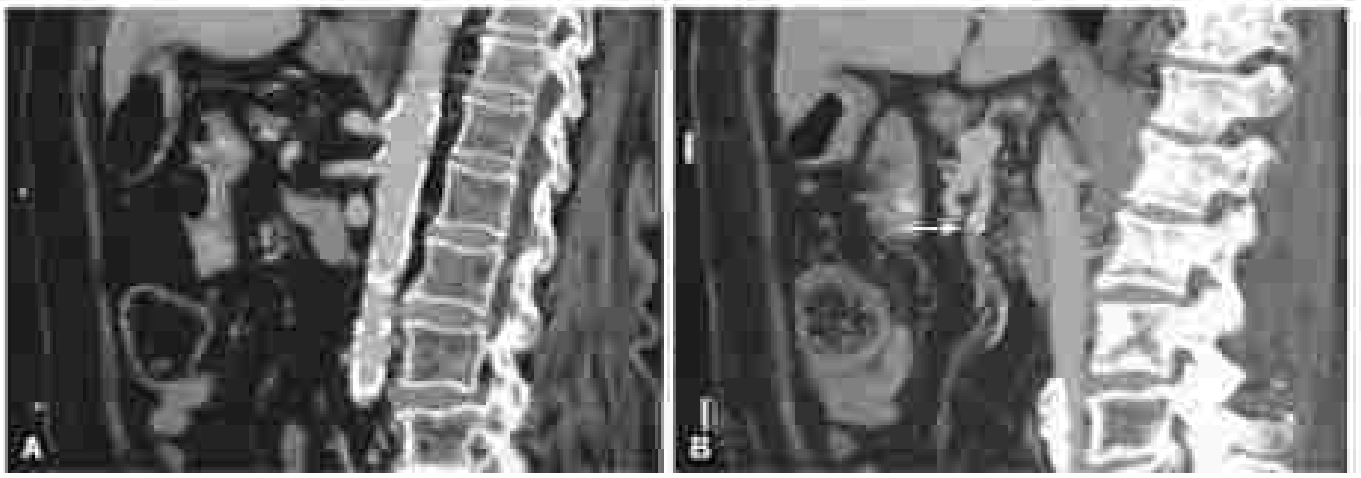

FIG. 5. Thrombus in the superior mesenteric artery (SMA), demonstrated on computed tomography. (A) Patent but diseased aorta and SMA origin. (B) Thrombosed mid-SMA just distal to atherosclerotic plaque (arrow).

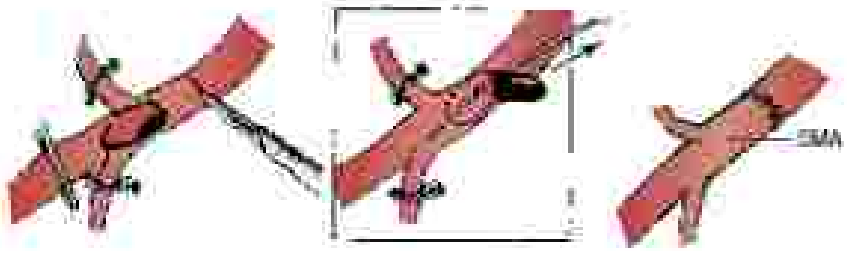

FIG. 6. Standard transverse arteriotomy for superior mesenteric artery embolectomy. (From Cronenwett, Johnston, editors: Rutherford's Vascular Surgery and Endovascular Therapy, 8th ed. Philadelphia: Elsevier; 2014.)

because it can always be converted to a longitudinal arteriotomy if the transverse closure is problematic. If a longitudinal incision is made or a transverse incision converted to a longitudinal one, it should always be closed with an autogenous vein patch.

Bypass

Revascularization for SMA thrombosis is typically undertaken in the setting of underlying atherosclerotic disease and abnormal splanchnic vessels. Because of this, the management of SMA thrombosis is more challenging and time-consuming than embolectomy. Although there might be multiple diseased visceral vessels, a single bypass graft to the SMA is adequate revascularization for AMI. Although antegrade bypass from the supraceliac aorta is associated with superior patency, the more difficult exposure of the supraceliac aorta and need for supraceliac clamping in these critically ill patients leads us to strongly recommend a retrograde bypass from the iliac arteries. Either of the common or external iliac arteries may be used for inflow and we tend to choose whichever vessel is the easiest to dissect out and has the least amount of calcification. In the standard literature, much is made about using the right common iliac artery for the inflow as the graft makes a gentle C-loop and is less likely to kink (Fig. 7). In our experience, kinking has not been a problem regardless of which iliac vessel is used. Our preferred conduit is autogenous saphenous vein, although if none is available it is reasonable to use a 6- or 8-mm prosthetic. Standard bypass techniques are used with the anastomosis to the iliac artery being performed first. Hemostasis is confirmed at the inflow, then we determine the best path for the bypass to the SMA. Not uncommonly, the bypass can be tunneled through the mesentery or retroperitoneally such that it lies nearly straight.

Endovascular Approaches

In the rare case in which there is very low suspicion for systemic bowel, such as in subacute mesenteric ischemia, an endovascular-only method can be taken. Although a totally percutaneous approach can be used, we prefer a left brachial artery cut down for access. This avoids leaving a frequently occlusive sheath in the brachial artery any longer than necessary and also avoids brachial artery complications. Although many wires and catheter combinations can be used, we use an 5F Omni Flush catheter (AngioDynamics Inc.) to assist in gaining wire access to the descending thoracic aorta and abdominal aorta. We exchange that for a 100 cm pigtail catheter to perform the diagnostic angiogram confirming the stenotic but patent SMA. After full heparinization, the brachial sheath is exchanged for a 6F or 7Fr 90 cm Shuttle Select sheath (Cook Inc.). The lesion is then crossed with an appropriate wire for the selected stent. Either a covered or uncovered balloon expandable stent may be used, although some recent preliminary data indicate that covered stents have better patency. The diameter should match the diameter of the normal artery with the length extending from a millimeter or two into the aorta to just distal to the lesion. Once the stent is deployed and confirmed to be appropriately placed, the wire and sheath are removed and the brachial artery is repaired with a 6-0 polypropylene suture. If the SMA is occluded from either atherosclerotic disease or thrombosis or is circumferentially heavily calcified, then the patient is probably best treated by an open surgical technique.

Hybrid Open and Endovascular Revascularization

Recent case series have confirmed open laparotomy with retrograde stenting of the SMA with access via a branch of the SMA. This approach

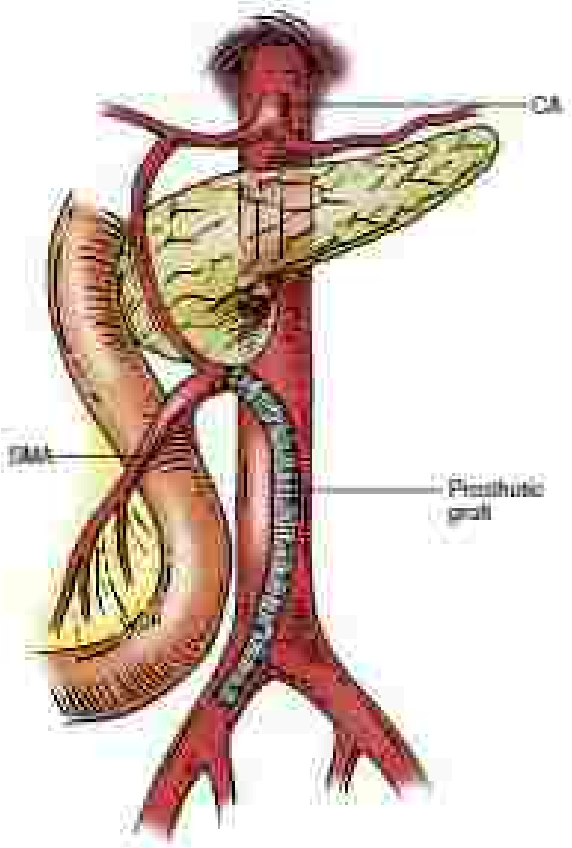

FIG. 7 Retrograde bypass from the common iliac artery (CA) to the superior mesenteric artery (SMA). SMV, Superior mesenteric vein.

avoids aortic clamping and the time required for bypass grafting but does require a hybrid operating room/endovascular suite. Illuzzi et al. reported 20% mortality and 45% primary patency in their series of 15 patients who presented with AMI and underwent retrograde open mesenteric stenting. Oderich et al. reported 8% mortality and 76% primary patency in their cohort of 48 patients. We do not have any experience with this technique and although interesting, we believe that an appropriately and expeditiously performed iliomesenteric bypass will have superior long-term patency with equal surgical time.

Management of Ischemic Bowel

In general, revascularization should precede resection of any bowel. This will allow repurfusion of any threatened areas of bowel and potentially decrease the length of bowel that must be subsequently resected. At the initial operation, frankly necrotic bowel should be resected and left in discontinuity. Questionably viable intestine should not be resected because the patient will be returned to the operating room in the next 24 to 48 hours to inspect the bowel and reestablish the discontinuous ends. Although much is made of mesenteric Doppler examination and fluorescein injection with Wood's lamp inspection after revascularization, we have not found it to be of much use because the bowel will declare itself, especially by the time of the second look operation. If after successful revascularization, all of the bowel is viable and no resection is necessary, a second look laparotomy is not mandatory.

In the rare case in which there is very low suspicion for necrotic bowel and an endovascular approach has been successful to revascularization, laparotomy can be avoided. However, a low threshold must be maintained for operative bowel evaluation. This can be done laparoscopically.

OUTCOMES

Even with revascularization, mortality in AMI is high with reported short-term mortality ranging from 22% to 90%. Factors associated with worse outcomes include older age, prolonged symptom duration, and the need for bowel resection. Although endovascular only management is associated with lower mortality rates, there is a clear selection bias to those patients who have an attempt at endovascular only management strategies. Much of the mortality in AMI can be attributed to the underlying atherosclerotic or embolic disease process, and even with successful revascularization, ongoing resuscitation and management in an intensive care unit are necessary.

POSTOPERATIVE MANAGEMENT

Following AMI, survivors should be on lifelong anticoagulation for an embolus or thrombus due to arrhythmia or hypercoagulable disorders. Aspirin is indicated for any revascularization using bypass grafting. Dual antiplatelet therapy with aspirin and clopidogrel should be used after stenting for at least the first 6 weeks then single agent therapy should be continued for life. Clopidogrel alone can be used for patients with an aspirin allergy or intolerance. Duplex ultrasound should be performed every 6 months for a year after bypass then yearly thereafter to detect graft stenosis.

Chronic Mesenteric Ischemia

Douglas W. Jones, MD, and Alik Farber, MD

Chronic mesenteric ischemia (CMI) results from inadequate arterial perfusion of the abdominal viscera, as supplied by the celiac artery, superior mesenteric artery (SMA), inferior mesenteric artery (IMA), and the rich collateral network between these visceral arteries. Atherosclerosis of the aorta involving the origins of the visceral arteries is the most common cause of CMI. In general, symptomatic CMI requires hemodynamically significant occlusive disease that involves at least two of the three visceral arteries and almost always involves the SMA. The most common disease pattern is involvement of the celiac artery and SMA, though concurrent SMA and IMA disease can also lead to symptomatic CMI. Atherosclerotic stenoses or occlusions often involve the visceral artery origins and may be confluent with aortic mural plaque (i.e., coral reef atherosclerosis). However, atherosclerotic lesions involving long segments of the visceral arteries are also seen. Dissection (spontaneous, posttraumatic, fibromuscular dysplasia) or arteritis (Takayasu's disease, giant cell arteritis, polyarteritis nodosa) of the visceral arteries may also cause CMI but these disorders are uncommon. Median arcuate ligament syndrome, compression of the celiac artery by the median arcuate ligament of the diaphragm, is an uncommon cause of postprandial abdominal pain caused by CMI. Although there are clearly demonstrated hemodynamic effects of median arcuate ligament syndrome, it has been argued that associated abdominal pain may be partially neurologic in origin resulting from celiac ganglion compression.

INDICATIONS FOR REVASCULARIZATION

Postprandial abdominal pain is the hallmark of CMI, also termed intestinal angina, and caused by episodic gut ischemia induced by eating. In the fasting state, gut and organ perfusion is normal, but fixed occlusive lesions limit the increase in visceral blood flow required for digestion in the postprandial state. Patients may exhibit sitophobia (fear of eating because of abdominal pain), which prevents adequate nutrition and causes progressive and potentially life-threatening weight loss. Diarrhea, constipation, nausea, and/or vomiting may also occur. Timely diagnosis and treatment of symptomatic CMI is essential because untreated CMI can lead to intestinal infarction, which is often lethal. In appropriately selected patients, revascularization successfully relieves symptoms, aids in weight gain, and most importantly, alleviates intestinal infarction.

Asymptomatic visceral artery stenoses are relatively common and given their indolent course should not be routinely treated by revascularization, which carries a risk of complications. Because of the high prevalence of asymptomatic visceral artery occlusive disease (observed in up to 20% of those older than 65 years) and ubiquity of nonspecific abdominal symptoms, it is essential to determine whether chronic and sometimes vague abdominal symptoms are convincingly attributable to occlusive lesions prior to pursuing revascularization. Gastroenterology consultation can be helpful in ruling out other causes of pain. Index of suspicion among providers should remain high, as there are some patients with atypical debilitating abdominal symptoms and demonstrable, hemodynamically significant visceral artery lesions that may benefit from revascularization. However, intervention is recommended only after other possible etiologies have been fully explored and ruled out.

When CMI is suspected, duplex ultrasound can determine whether hemodynamically significant lesions are present and which visceral arteries are affected. Duplex imaging of the visceral aorta is best performed in the morning, after an overnight fast, because the minimizes presence of bowel gas, which may preclude visualization of the visceral arteries by the vascular technologist. Diagnosis of significant visceral artery disease is based on measurements of peak systolic velocity (PSV), end diastolic velocity (EDV), and changes in the SMA velocity spectral waveform from a fasting to postprandial state (Box 1). Hemodynamically significant stenosis (>70% diameter reduction) is associated with elevated blood flow velocity across the lesion, typically demonstrated by: (1) PSV greater than 275 to 300 cm/s and (2) EDV greater than 45 to 55 cm/s (Fig. 1). The spectral waveform at and immediately distal to the stenosis demonstrates turbulence while downstream it appears dampened. A mesenteric aortic PSV ratio greater than 3 is also predictive of more than 50% stenosis. Steinkamp and colleagues reported a PSV threshold of 400 cm/s for more than 70% stenosis of the SMA (overall accuracy of 80%) and of 320 cm/s for more than 70% stenosis of the celiac artery origin (overall accuracy of 87%). Although mesenteric duplex ultrasound is technically demanding because of the depth of the visceral arteries, an interpretable study is possible in more than 80% of individuals, with excessive bowel gas being the primary reason for a suboptimal examination. Visceral duplex testing should be considered a screening diagnostic modality that complements clinical assessment of patients with suspected CMI, and when abnormal it should prompt additional imaging such as computed tomographic angiography (CTA) or magnetic resonance angiography.

CTA has high sensitivity and specificity for identifying visceral atherosclerosis and is useful for planning revascularization. It has the additional benefit of visualization of other intra-abdominal pathologies which may be contributing to symptoms. However, CTA does not provide hemodynamic information, its image quality is limited in the presence of severe calcification, and contrast load may not be tolerable for patients with chronic renal insufficiency or contrast sensitivity. Magnetic resonance angiography can be considered in some patients who cannot undergo CTA; however, its utilization in those fitted by implantable devices, patient intolerance, and variable image quality.

RECONSTRUCTION OPTIONS

Reconstruction options for visceral arterial occlusive disease take three forms: endovascular revascularization, open bypass grafting, and transaortic mesenteric endarterectomy. Anatomic disease patterns have important implications for which treatment option is most appropriate. For example, atherosclerotic lesions limited to 1 to 2 cm of a proximal visceral artery segment may be best treated by angioplasty and stenting (Fig. 2). In contrast, long occlusions, arterial dissection, and arteritis generally affect long segments involving both the main trunk and its branches and may require bypass grafting.

Endovascular Revascularization

Endovascular treatment of CMI has become increasingly common, with many centers adopting an endovascular first approach for most cases, while reserving open surgery for those patients who fail endovascular therapy. Angioplasty and stenting are best suited for the treatment of focal, ostial arterial lesions (Fig. 3). Revascularization of the SMA is the primary goal of endovascular therapy, though the celiac artery and IMA may also be treated, especially if the SMA is occluded and cannot be revascularized, and an extensive collateral network is seen (Fig. 4). Some have argued that two vessel revascularization (i.e., celiac artery and SMA) is superior to treating a single vessel; however, this remains controversial. In general, efforts should be made to revascularize the SMA first, if a severe stenosis or occlusion is present. If this is accomplished expeditiously, then it is reasonable to consider treating a diseased second visceral vessel as long as anticipated procedural risk is low.

Visceral arterial lesions, even though they may appear focal, are often caused by overflow aortic atherosclerotic thrombus. Balloon angioplasty is rarely adequate to treat calcified visceral artery lesions because of recoil and persistent stenosis after angioplasty alone. As a result, balloon-expandable stents (which have high radial force) are considered the endovascular treatment of choice. Careful attention is paid to make sure stents "flare" into the visceral aorta (Fig. 3) to prevent restenosis by extension of aortic plaque across an unstented ostium. Celiac artery stents should not be placed when uncorrected, hemodynamically significant compression by the median arcuate ligament is present, as suggested by preprocedure duplex ultrasound or CTA, as this can lead to stent deformation and vessel occlusion.

Stent grafts (stents covered by prosthetic material) are increasingly being used for CMI. Stent grafts provide protection against inadvertent visceral branch or aortic injury during the high-pressure inflation required to dilate a calcified plaque, and also trap atherosclerotic plaque against the vessel wall, limiting distal embolization. Stent grafts are also protected against restenosis due to ingrowth of hyperplastic material through stent interstices (as seen in bare metal stents). Oderich and colleagues have reported that stent grafts are associated with lower rates of restenosis and reintervention compared to bare metal stents, though this remains controversial.

Access site is an important consideration and must be planned carefully. Common femoral artery access is associated with fewer complications, but cannulation of the visceral artery origin can be challenging, especially if its origin is downgoing. These geometric disadvantages can usually be overcome with appropriate catheter selection or deflectable tip sheaths. However, tracking of a balloon-expandable stent into position for deployment may still not be possible due to acute angles and inadequate sheath support. In contrast, brachial access provides a better angle of approach to downgoing vessels. This is particularly useful when attempting to recanalize an occluded celiac artery or SMA origin, as this often requires substantial sheath support which is unattainable from a brachial access site. Advantages of brachial access must be weighed carefully against the higher access site complication rate, especially for larger sheath sizes. Radial access is increasingly used for mesenteric artery revascularization with good results.

The risk for embolization during the treatment of visceral occlusive disease, particularly when total occlusions are recanalized, has prompted some to use distal embolic protection devices (i.e., filters) to catch dislodged plaque fragments or thrombus during guidewire and catheter manipulations, although the benefit of this additional maneuver remains unclear.

In some cases, a lesion such as a flush ostial occlusion cannot be successfully treated using typical endovascular techniques. Accordingly, failure of endovascular therapy has become a common indication for open revascularization. However, some patients are poor candidates

BOX 1 Visceral Duplex Ultrasound Criteria for Normal and Stenotic Celiac Artery, SMA, and IMA Flow

Normal

Celiac: PSV 90–110 cm/s, low resistance flow pattern
SMA: PSV 95–110 cm/s, high resistance flow pattern in fasting state with EDV >5 after meal
IMA: PSV 90–180 cm/s, high resistance flow pattern

Diagnostic Testing (Fasting)

<70% Stenosis
Celiac: PSV <200 cm/s, EDV <55 cm/s; resistive index <0.75
SMA: PSV <300 cm/s, EDV <45 cm/s with diastolic flow reversal in distal SMA
IMA: PSV <200 cm/s, antegrade resistive flow (like SFA)

>70% Stenosis
Celiac: PSV >200 cm/s, EDV >55 cm/s with retrograde common hepatic artery flow with severe stenosis or celiac artery occlusion
SMA: PSV >300 cm/s, EDV >45 cm/s with loss of diastolic flow reversal
IMA: PSV >300 cm/s, antegrade flow with loss of diastolic flow reversal
Mesenteric aorta ratio >3

Velocity Spectra Changes With Test Meal

Increase in PSV in area of stenosis with dampening of distal waveform, and most frequently in assessing the significance of SMA occlusive disease

EDV, end-diastolic velocity; IMA, inferior mesenteric artery; PSV, peak systolic velocity; SFA, superficial femoral artery; SMA, superior mesenteric artery

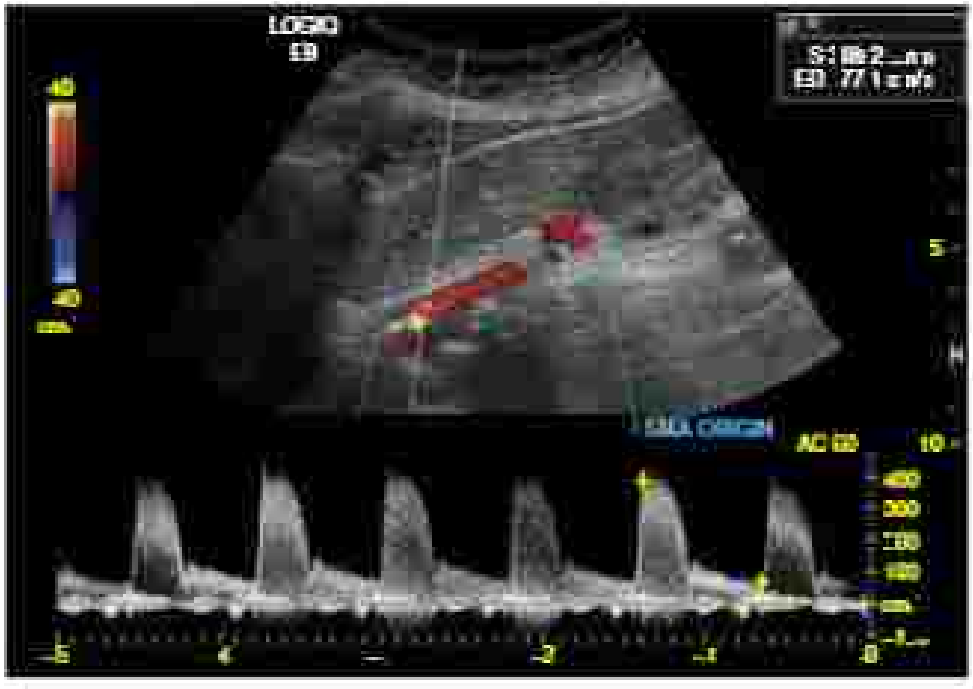

Fig. Splenic image and velocity spectra recorded from the origin of the superior mesenteric artery with a >70% diameter reducing stenosis based on a peak systolic velocity of 295 cm/s and end-diastolic velocity of 77 cm/s.

for open repair because of excessive comorbid disease, a hostile abdomen, or extensive aortoiliac calcification that would preclude clamp placement. Retrograde open mesenteric stenting, a hybrid approach that incorporates aspects of open and endovascular surgery, can be considered in such cases. A midline laparotomy is performed allowing for transabdominal exposure of the celiac artery or SMA. The vessel is directly accessed and a wire is passed through the visceral vessel into the aorta in a retrograde fashion; angioplasty and stenting can then be performed using principles described above. This technique is most commonly employed in the setting of acute mesenteric ischemia, when abdominal exploration may be a planned part of the initial procedure, facilitating access to the visceral vessels. Further, the use of prosthetic bypass in this setting may be limited by enteric contamination in the acute setting so other revascularization options may be preferred.

Arterial Bypass Grafting

The technique of bypass grafting for visceral artery occlusive disease is applicable to most disease patterns and is selected for patients with long segment stenoses or occlusions that are not amenable to endovascular revascularization. Because long-term outcomes with bypass tend to be superior to endovascular therapy, patients may be selected for primary open bypass if they are relatively young, have a low comorbidity burden, and demonstrate favorable anatomy. Bypass grafts to the mesenteric arteries can originate from a nondiseased supraceliac portion of the aorta (antegrade bypass) or from the infrarenal aorta or iliac artery (retrograde bypass).

FIG. 3 Lateral angiogram of the aorta showing atherosclerotic plaque involving the origin of the celiac and superior mesenteric arteries.

Antegrade Mesenteric Bypass

Aortic exposure for antegrade bypass is achieved through a transabdominal, transcrural approach (Fig. 5) or via a medial visceral rotation from the left. The transcrural exposure of the supraceliac aorta can be performed via midline or bilateral subcostal incision. The attachment of the left lobe of the liver is divided to expose the aorta. Intraoperative division of the median arcuate ligament and dissection of the aorta and its branches. Exposure of the aorta for cross-clamping is facilitated by self-retaining retractor blade placement. Bypass grafting with either a polyester or a polytetrafluoroethylene conduit is performed with local aorta endarterectomy at the proximal anastomosis, if necessary. Unless the celiac artery is completely free of disease, a bifurcated graft is used with separate limbs targeting the celiac artery and SMA.

The proximal anastomosis of an antegrade aortomesenteric bypass should be placed in a disease-free supraceliac or distal thoracic portion of the aorta. The bifurcated graft should be fashioned with a relatively short main body. In a minimally diseased aorta, a side-biting clamp can be used to perform the proximal anastomosis without complete occlusion of the aorta. However, total aortic cross-clamping may be required, particularly if disease burden makes partial aortic clamping unreliable or unsafe. Circumferential supraceliac aortic infiltration is not performed routinely unless there is an intervening part of intercostal arteries that need to be exposed for temporary control. Once the proximal anastomosis is complete, bifurcated limb length and alignment are easy to determine. The SMA limb is tunneled to a retroperitoneal plane (Fig. 5). An end-to-end celiac or end-to-side common hepatic artery anastomosis is constructed followed by an end-to-side SMA anastomosis.

Retrograde Mesenteric Bypass

The infrarenal portion of the aorta, the iliac artery, or a previously placed prosthetic aortic or aortoiliac graft all can provide inflow for a retrograde mesenteric bypass. Exposure of the aorta is performed via a standard infrarenal approach. The infrarenal aorta or the iliac artery is often used as inflow. The inflow anastomosis is performed end-to-side and the outflow (visceral branch) anastomosis performed either as end-to-end or end-to-side (Fig. 6). In contrast to the antegrade approach, a single vessel is targeted for retrograde bypass. If the SMA is the revascularization target, it is exposed beyond the duodenal arcus

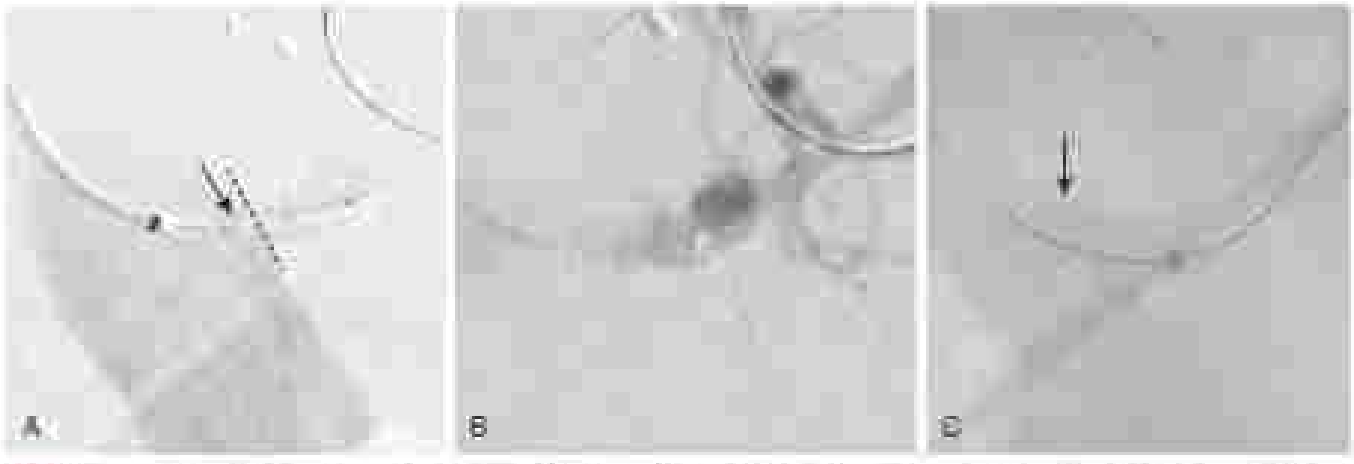

FIG. 4 Fluoroscopic images of visceral artery stent angioplasty. (A) Optimal position of the celiac stent, extending 1–2 mm into the aortic lumen. The arrow represents the proximal end of the stent. The dotted line represents the aortic wall. (B) Celiac stent after pressure-monitored deployment of a balloon-mounted stainless steel stent. (C) "Jailed" celiac stent, showing a flared proximal end (arrow). The inner white represents the location of the aortic wall.

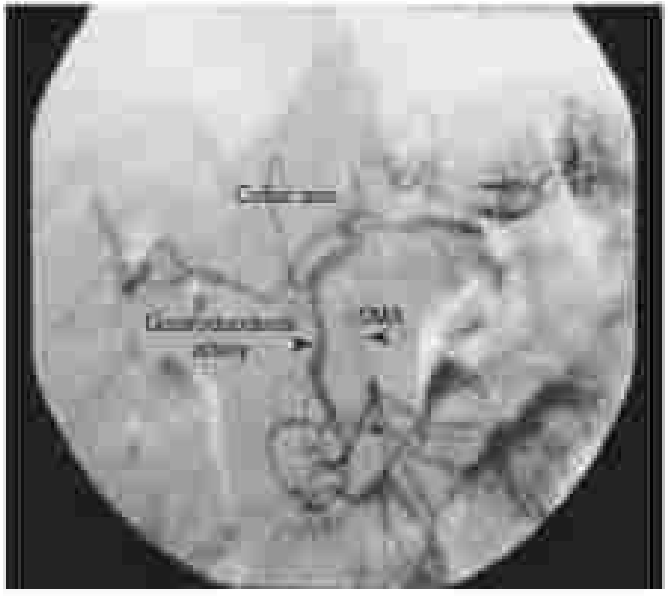

FIG. 4 Angiogram by selective contrast injection into the celiac axis with opacification of the superior mesenteric artery (SMA) via a large gastroduodenal artery in this case, reconstruction of either the celiac axis or the SMA could provide perfusion to the entire visceral circulation.

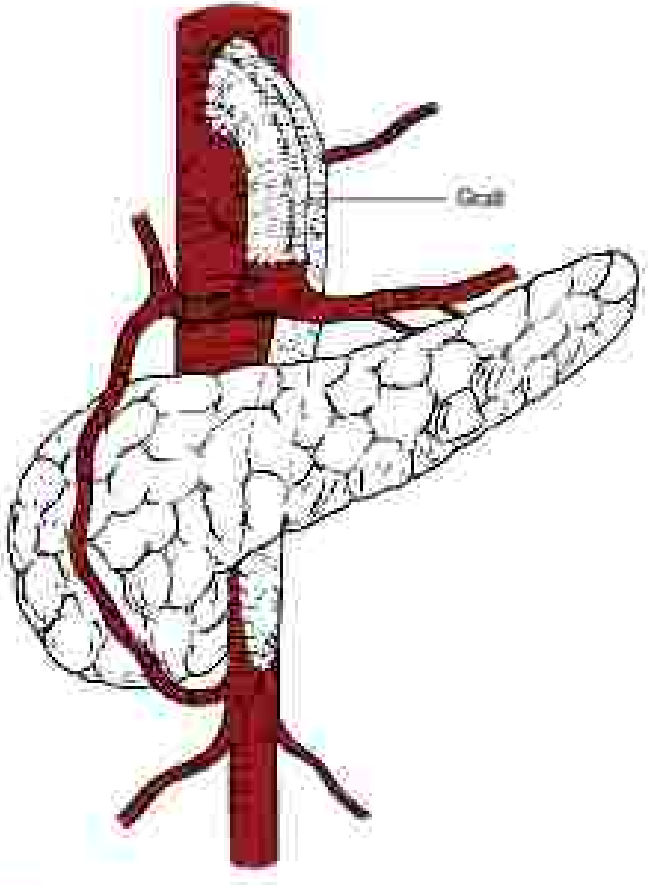

FIG. 5 Antegrade bifurcated aortomesenteric bypass. Limbs are oriented on top of each other in an anteroposterior orientation. Note end-to-end celiac artery anastomosis and end-to-side superior mesenteric artery anastomosis. (From Oderich GS, Gloviczki P, Bower TC, et al. Open surgical, endovascular, and hybrid treatment of chronic mesenteric ischemia. In: Cronenwett JL, Johnston KW, eds. *Rutherford's Vascular Surgery and Endovascular Therapy*. Philadelphia: Elsevier; 2014.)

in the root of the mesentery. For celiac artery occlusion, the common hepatic artery is usually selected as the graft target as it requires less dissection and the graft alignment is easier. To avoid graft torsion and kinking, use of a ringed polytetrafluoroethylene conduit in gentle C-shaped configuration is recommended. Autogenous vein conduit can be used, in the setting of enteric contamination; however special care needs to be taken to avoid graft kinking. In general, a retrograde bypass can be performed more quickly and obviates the need for supraceliac aortic cross-clamping in most cases.

Transaortic Mesenteric Endarterectomy

Plaque excision via an aortotomy allows endarterectomy of aortic wall plaque and each involved contiguous arterial branch using the aforementioned endarterectomy technique. Aorta exposure can be achieved via a midline abdominal incision, bilateral incision, or retroperitoneal left flank approach. For each approach, the left kidney remains in its anatomic position while the plane behind the left colon, spleen, pancreas, and stomach is developed to allow medial visceral rotation toward the midline. The diaphragmatic crus is often divided to gain further proximal exposure. If necessary, the entire aorta from the distal thoracic level to the aortic bifurcation can be exposed completely. Proximal and distal aortic clamping are required for control. A U-shaped trapdoor aortotomy circumscribes the orifices of the celiac and superior mesenteric arteries, and an eversion endarterectomy is performed to remove the aortic plaque and to circumferentially free the visceral orifices (Fig. 7). Endarterectomy is not typically extended to include the renal artery origins unless symptomatic renal artery stenosis is diagnosed preoperatively. The aortotomy is closed with running suture and often does not require a patch. Typically, the transaortic endarterectomy procedure can be completed with a visceral total ischemia time of less than 45 minutes.

Transaortic mesenteric endarterectomy has been largely supplanted by endovascular techniques and open bypass. However, it is still useful in certain situations, such as patients with multi-vessel orificial lesions that are contiguous with aortic atherosclerotic (coral reef) plaque. A limitation of endarterectomy is its ability to remove visceral artery plaque extending beyond 2 cm from the origin, which is more likely to be a challenge for the SMA. If inspection of the distal endarterectomy endpoint reveals a residual obstructing plaque, an additional longitudinal SMA arteriotomy can be performed to complete the endarterectomy, tack down distal plaque and perform standard patch closure. Alternatively, a stent can be deployed across the ostium.

OUTCOMES OF REVASCULARIZATION

The management of CMI has undergone a dramatic change in the past 2 decades. Though open bypass has traditionally been the dominant treatment modality, utilization of endovascular therapy has steadily increased, surpassing bypass in the early 2000s (in the United States). In 2014, endovascular therapy comprised close to 80% of CMI revascularization procedures. Concurrent with this trend has been the increase in overall, nationwide revascularization procedures for CMI. These trends imply that a larger number of patients are being considered eligible for revascularization given the improved perioperative safety profile of endovascular therapy.

Regarding perioperative outcomes, both endovascular and open revascularization have more than 90% rates of technical success and initial symptom relief, when performed in appropriately selected patients. Endovascular therapy is consistently associated with operative mortality rate less than 3%. Though open bypass mortality rates are variable, bypass can be performed with comparable mortality rates of 2% to 5% at high volume centers. However, nationwide mortality rates may be as high as 9% to 13% indicating that excellent perioperative results of open bypass may not be broadly applicable. In addition to potentially lower procedural mortality rates, endovascular therapy has been associated with lower morbidity rates, shorter length of stay and cost savings (at index revascularization procedure) compared to open bypass.

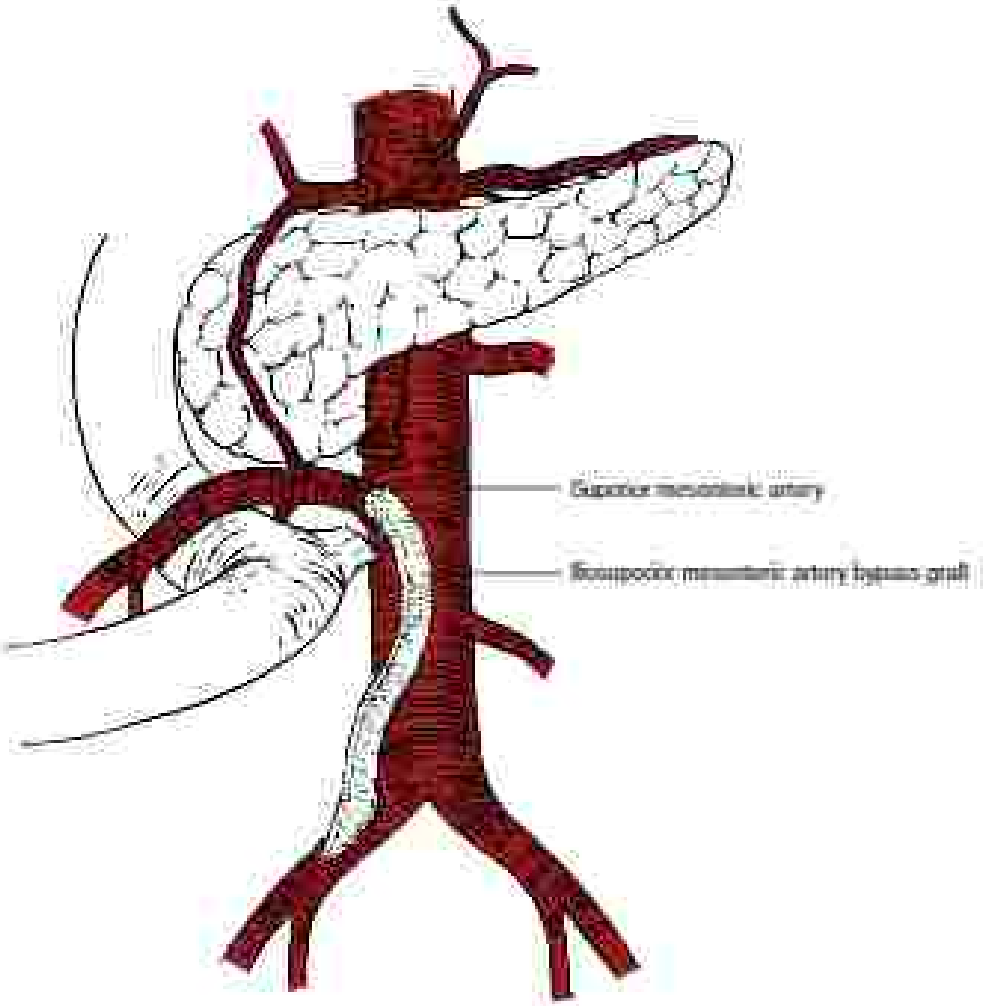

FIG. 6 Retrograde iliomesenteric bypass. Distal anastomosis can be end-to-end, as illustrated, or end-to-side. (From Chaikof, Lumsden, editors. Atlas of Vascular Surgery and Endovascular Therapy. Anatomy and Technique. Philadelphia: Saunders; 2010.)

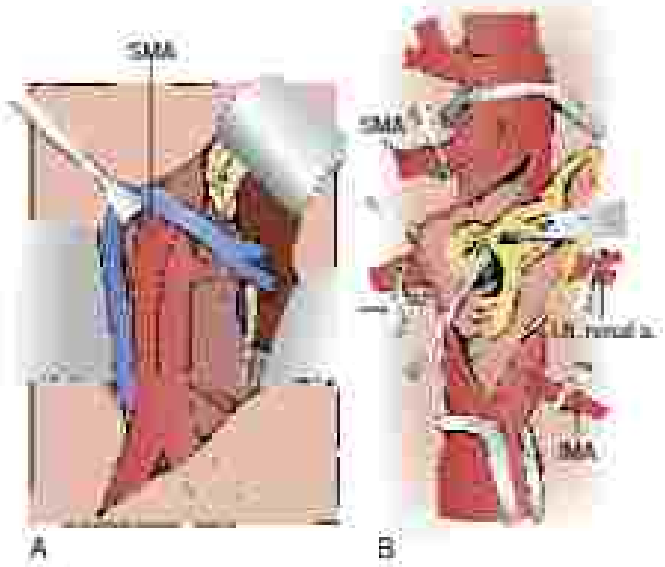

FIG. 7 Transaortic mesenteric endarterectomy. (A) Aortotomy is made to include the origins of the celiac artery and superior mesenteric artery (SMA). (B) Terminal endarterectomy of the celiac artery and SMA origins. IMA, Inferior mesenteric artery. (From Bergan JM, Yao JST, Kistner RL, Flinn WR. Techniques in visceral artery reconstruction (part I). Adv Vasc Surg. 1994;2:329–374.)

The procedural morbidity of open repair is higher than that of endovascular intervention, but endovascular interventions are less durable and treated patients require more secondary procedures for restenosis. High-quality long-term data are not available, but the patency rate of endovascular therapy has been reported to be <50% at 5 years, compared with 80% to 90% for open bypass. Rates of long-term symptom relief are also superior for open bypass.

Oderich and colleagues have reported on their experience using balloon-expandable stent grafts (61 patients) and bare-metal balloon-expandable stents (164 patients) for CMI. Primary patency at 3 years was 92% for stent grafts compared with 72% for bare metal stents ($P = .003$). Patients receiving stent grafts were also more likely to remain free of symptoms (92% vs 58%) and less likely to be reintervened on (0% vs 8%). These outcomes are promising and emphasize that developments in endovascular technology (such as stent grafts) have the potential to further improve long-term outcomes associated with endovascular therapy.

DUPLEX SURVEILLANCE AFTER MESENTERIC REVASCULARIZATION

Patients who develop recurrent CMI symptoms because of endovascular or bypass stenosis can be rendered symptom free again by repeat visceral artery intervention. This is preferentially performed with an endovascular approach, whenever possible. Resolution of a treated visceral artery may also be preserved by routine ultrasound surveillance, which may detect vessel restenosis before the development of clinical symptoms. Among reported series of mesenteric

revascularization, clinical follow-up alone inaccurately predicted graft occlusion and was associated with a sensitivity as low as 33%.

Duplex ultrasound testing is a useful technique to evaluate functional patency after visceral artery bypass grafting procedures or endovascular stent angioplasty. Repair site stenosis can be identified reliably, which assists in decision making regarding the need for reintervention to treat or prevent recurrent gut ischemia. Visceral duplex testing of a bypass graft or stent angioplasty site that shows PSV greater than 300 cm/s with EDV greater than 50 to 70 cm/s or a damped velocity spectra within a bypass graft and low PSV (<40 cm/s) should be considered for interrogation by visceral angiography to confirm or exclude severe stenosis (>70%).

The management of asymptomatic high-grade stenosis after both open and endovascular repair remains undefined. Fortunately, the embolic potential of symptomatic hyperplasia associated with surgical or endovascular reintervention is uncommon. Progressive stenosis of the original atherosclerotic lesion or restenosis/occlusion of the visceral artery remains the most common cause of recurrent symptoms among treated patients. Because recurrent symptoms are associated with intervention failure and increase the risk for gut necrosis, a more aggressive approach toward treating endovascular stent stenosis is appropriate in these patients. In asymptomatic patients, intervention should be limited to vessels showing more than 70% stenosis at the repair site as shown by duplex ultrasound, followed by confirmatory angiographic imaging with pressure gradient measurement, as necessary. Reintervention using endovascular therapy is usually successful, reduces PSV at the stenotic site, and is associated with continued relief of gut ischemia.

Hemodialysis Access Surgery

Bonnie E. Lonze, MD, PhD, and Thomas Ryan Ryder, MD

For the past decade, the overall prevalence of end-stage renal disease in the United States has increased at a rate of approximately 2% per year. An estimated 30 million Americans have a diagnosis of chronic kidney disease. In 2015, 124,111 new patients initiated dialysis treatment, bringing the total number of Americans living on dialysis to almost 500,000. For the vast majority of these patients, hemodialysis is the preferred mode of renal replacement therapy. The ability to deliver this lifesaving therapy is dependent on the creation and maintenance of adequate vascular access.

HISTORICAL NOTES

Over the course of approximately a century, end-stage renal failure went from a universally fatal illness to a tolerable chronic illness with reasonable long-term survival. In the United States a series of events involving science, medicine, and politics led to universally available and undeniable renal replacement therapy.

The concept of dialysis was introduced by the Scottish physical chemist Thomas Graham, whose experiments in the 1850s characterized the movement of water across semipermeable membranes and led to an understanding of the principle of osmosis. It was in fact Graham himself who first applied the term dialysis to describe the phenomenon of colloidal osmotic gradients to move solutes across a membrane separating two solutions.

Fifty years later, John Jacob Abel, a pharmacologist at the Johns Hopkins Hospital, first explored the application of dialysis to a clinical setting. Abel, working with Leonard Rowntree and B.B. Turner, described in 1914 the construction of the "artificial kidney," an apparatus that consisted of 37 tubes connected in series and encased in a large glass container filled with a dialysate solution. Using hirudin as an anticoagulant to prevent clotting in the tubes, they tested the invention on anesthetized animals. Using arterial cannulae to channel blood into the narrow tubes of the circuit, they demonstrated that animal blood could be dialyzed.

The first successful human use of dialysis is credited to Willem Kolff, a Dutch physician who had studied Abel's work. During the German occupation of the Netherlands in the 1940s, he designed and built, mainly from household items, a dialysis device he named the "rotating drum kidney." This device consisted of a large drum, covered with thin tubing that sat partly submerged in a large tank of dialysate. Blood passed through the series of tubes affixed to the drum that then rotated within the tank, facilitating dialysis of the blood across the tubing. Kolff's first surviving patient was a 67 year old woman with acute renal failure caused by sepsis. She endured an 11 hour dialysis session in which a measured 48 grams of urea were removed. Kolff foresaw many possible applications of hemodialysis and was astutely aware that its implementation for chronic renal failure would require durable vascular access.

The first solution to the access problem was developed by Belding Scribner at the University of Washington. Having been introduced to a newly engineered material called polytetrafluoroethylene or PTFE (Teflon) and recognizing its inert and noninflammatory properties, he conceived of using a U shaped Teflon tube to create an external arteriovenous connection that could be accessed for dialysis. On March 9, 1960, the first dialysis by way of the Scribner shunt was performed. Although this did establish an important proof of principle, Scribner shunts had unacceptably high rates of infection, thrombosis, and hemorrhage, and their functional patency rarely exceeded a few months. Seeking to improve on this, James Cimino and Michael Brescia invented the radiocephalic arteriovenous fistula and described the technique in their landmark *New England Journal of Medicine* article in 1966.

With safe and reliable vascular access technically feasible, widespread availability of hemodialysis had a final major obstacle to overcome: cost. Lobbying at local and national levels resulted in government funding for improvements in dialysis machine technology and the construction of more dialysis units. However, because of its cost, most people believed that, without federal government support, access would remain limited to the privileged few. In November 1971, a chronic dialysis patient named Shep Glazer and his nephrologist demonstrated a dialysis session before a congressional committee in Washington, DC. This had a tremendous impact on the committee

revascularization, clinical follow-up alone inaccurately predicted graft occlusion and was associated with a sensitivity as low as 33%.

Duplex ultrasound testing is a useful technique to evaluate functional patency after visceral artery bypass grafting procedures or endovascular stent angioplasty. Repair site stenosis can be identified reliably, which assists in decision making regarding the need for reintervention to treat or prevent recurrent gut ischemia. Visceral duplex testing of a bypass graft or stent angioplasty site that shows PSV greater than 300 cm/s with EDV greater than 50 to 70 cm/s or a damped velocity spectra within a bypass graft and low PSV (<40 cm/s) should be considered for interrogation by visceral angiography to confirm or exclude severe stenosis (>70%).

The management of asymptomatic high-grade stenosis after both open and endovascular repair remains undefined. Fortunately, the embolic potential of neointimal hyperplasia associated with surgical or endovascular reintervention is uncommon. Progressive stenosis of the original atherosclerotic lesion or restenosis/occlusion of the visceral artery remains the most common cause of recurrent symptoms among treated patients. Because recurrent symptoms are associated with intervention failure and increase the risk for gut necrosis, a more aggressive approach toward treating endovascular stent stenosis is appropriate in these patients. In asymptomatic patients, intervention should be limited to vessels showing more than 70% stenosis at the repair site as shown by duplex ultrasound, followed by confirmatory angiographic imaging with pressure gradient measurement, as necessary. Reintervention using endovascular therapy is usually successful, reduces PSV at the stenotic site, and is associated with continued relief of gut ischemia.

Hemodialysis Access Surgery

Bonnie E. Lonze, MD, PhD, and Thomas Ballinger, MD

For the past decade, the overall prevalence of end-stage renal disease in the United States has increased at a rate of approximately 2% per year. An estimated 30 million Americans have a diagnosis of chronic kidney disease. In 2015, 124,111 new patients initiated dialysis treatment, bringing the total number of Americans living on dialysis to almost 500,000. For the vast majority of these patients, hemodialysis is the preferred mode of renal replacement therapy. The ability to deliver this lifesaving therapy is dependent on the creation and maintenance of adequate vascular access.

HISTORICAL NOTES

Over the course of approximately a century, end-stage renal failure went from a universally fatal disease to a tolerable chronic illness with reasonable long-term survival. In the United States a series of events involving science, medicine, and politics led to universally available and undeniable renal replacement therapy.

The concept of dialysis was introduced by the Scottish physical chemist Thomas Graham, whose experiments in the 1850s characterized the movement of water across semipermeable membranes and led to an understanding of the principle of osmosis. It was in fact Graham himself who first applied the term dialysis to describe the phenomenon of colloidal osmotic gradients to move solutes across a membrane separating two solutions.

Fifty years later, John Jacob Abel, a pharmacologist at the Johns Hopkins Hospital, first explored the application of dialysis to a clinical setting. Abel, working with Leonard Rowntree and B.B. Turner, described in 1914 the construction of the "artificial kidney," an apparatus that consisted of 37 tubes connected in series and encased in a large glass container filled with a dialysate solution. Using hirudin as an anticoagulant to prevent clotting in the tubes, they tested the invention on anesthetized animals. Using arterial cannulae to channel blood into the narrow tubes of the circuit, they demonstrated that animal blood could be dialyzed.

The first successful human use of dialysis is credited to Willem Kolff, a Dutch physician who had studied Abel's work. During the German occupation of the Netherlands in the 1940s, he designed and built, mainly from household items, a dialysis device he named the "rotating drum kidney." This device consisted of a large drum, covered with thin tubing that sat partly submerged in a large tank of dialysate. Blood passed through the series of tubes affixed to the drum that then rotated within the tank, facilitating dialysis of the blood across the tubing. Kolff's first surviving patient was a 67 year old woman with acute renal failure caused by sepsis. She endured an 11 hour dialysis session in which a measured 48 grams of urea were removed. Kolff foresaw many possible applications of hemodialysis and was astutely aware that its implementation for chronic renal failure would require durable vascular access.

The first solution to the access problem was developed by Belding Scribner at the University of Washington. Having been introduced to a newly engineered material called polytetrafluoroethylene or PTFE (Teflon) and recognizing its inert and noninflammatory properties, he conceived of using a U shaped Teflon tube to create an external arteriovenous connection that could be accessed for dialysis. On March 9, 1960, the first dialysis by way of the Scribner shunt was performed. Although this did establish an important proof of principle, Scribner shunts had unacceptably high rates of infection, thrombosis, and hemorrhage, and their functional patency rarely exceeded a few months. Seeking to improve on this, James Cimino and Michael Brescia invented the radiocephalic arteriovenous fistula and described the technique in their landmark *New England Journal of Medicine* article in 1966.

With safe and reliable vascular access technically feasible, widespread availability of hemodialysis had a final major obstacle to overcome: cost. Lobbying at local and national levels resulted in government funding for improvements in dialysis machine technology and the construction of more dialysis units. However, because of its cost, most people believed that, without federal government support, access would remain limited to the privileged few. In November 1971, a chronic dialysis patient named Shep Glazer and his nephrologist demonstrated a dialysis session before a congressional committee in Washington, DC. This had a tremendous impact on the committee

members, which led congress to act. In October of 1972, President Nixon signed into law a bill authorizing Medicare coverage of dialysis.

In this chapter, we review and summarize our current practices for the evaluation, placement, and maintenance of hemodialysis access. In 2002, the Society for Vascular Surgery and the American Association for Vascular Surgery published recommendations for standardized reporting of dialysis access techniques, procedures, and configurations. For purposes of brevity, however, we preferentially use common nomenclature throughout the following discussion.

NATIONAL PRACTICES AND GUIDELINES

In 2009, the End-Stage Renal Disease Program alone consumed 6% of the overall Medicare budget—a total of $29 billion—and this staggering sum is rising annually. As health care cost containment has become a major national focus, there has been great motivation within the dialysis community to identify best practices that minimize costs and maximize patient benefit. Until recently, most new accesses placed had been prosthetic grafts. Certainly, some of these grafts were placed out of necessity. Unfortunately, convenience, lack of surgeon experience, and the higher reimbursement rate for prosthetic grafts undoubtedly played a role in their preferential placement. Specifically, in 1990 ePTFE grafts were placed twice as frequently as autogenous arteriovenous fistulas. According to the Centers for Disease Control and Prevention, in 1995 just over 20% of patients on dialysis were using autogenous access. Clear evidence has since emerged that autogenous fistulas are associated both with better outcomes and lower costs, and this has drawn attention to the unacceptably low proportion of patients in the United States undergoing dialysis through autogenous access. The disproportionate and often inappropriate use of prosthetic grafts fueled the National Kidney Foundation's Kidney Disease Outcomes and Quality Initiative (KDOQI). This is a comprehensive analysis of the best practices with regard to the management of end-stage renal disease. An offspring of KDOQI was the Centers for Medicare and Medicaid Services' Fistula First Breakthrough Initiative, which aimed to promote awareness among patients and physicians of the superiority of autogenous access. More recently there has been pushback from some in the vascular community who believe that there are certain patients who should preferentially have prosthetic access. This has been rebranded as Fistula First Catheter Last. Although we agree in principal, the best access remains a good arteriovenous fistula. The current national goal is to place autogenous access in at least 66% of new dialysis patients, and the effort seems to be working. In 2015 according to the United States Renal Data System's (USRDS) annual report there were nearly twice as many autogenous fistulas placed than prosthetic grafts.

Currently, the three main avenues for hemodialysis access are tunneled central venous catheters, arteriovenous prosthetic grafts, and autogenous arteriovenous fistulas. Clearly, the worst outcomes are associated with catheter usage, and therefore every effort should be made to avoid them. To this end, current KDOQI guidelines stipulate that all patients should be referred to a surgeon for the placement of autogenous access when they reach stage 4 chronic kidney disease (glomerular filtration rate <30). This allows sufficient time for fistula placement and maturation before the commencement of dialysis. The caveat to this scenario is that not all patients have a suitable vein for autogenous fistula creation. Only those with suitable veins should have them access placed far in advance of the initiation of dialysis, and this access should be an autogenous fistula. The most common cause of prosthetic graft failure is stenosis at the venous anastomosis due to neointimal hyperplasia. This worsens with time, so if a prosthetic graft is required, it should only be placed when dialysis is imminent or has already begun.

The options for dialysis access are frequently impacted by treatment options instituted years before the patient reaches end-stage renal disease. Patients and physicians alike must be aware that for those with any degree of renal dysfunction, subclavian vein central lines and ports, PICC (peripherally inserted central catheter) lines, and even forearm intravenous catheters (sparing only an distal cephalic vein) should be avoided whenever possible. PICC lines are the curse of the dialysis access surgeon. Not only do they frequently ruin a typical good access vein, the basilic vein, but they are also associated with rates of central venous stenosis or thrombosis estimated up to 65%, which renders the arm unsuitable for the most common and durable access types.

FIG. 1 Mature radiocephalic arteriovenous fistula 6 weeks after surgery.

The algorithm for selecting which fistula to place is fairly straightforward. One should begin distally and work proximally in the nondominant arm: radiocephalic (Fig. 1), brachiocephalic, then upper arm basilic transposition. We believe that the benefits of autogenous access are so great that many exceptions to the standard algorithm are permitted. Although use of the nondominant arm is preferable, frequently the veins are better in the more active dominant arm. In this circumstance, the dominant arm is used without hesitation for fistula placement. If a patient has no suitable vein for autogenous access, then a prosthetic graft may be used. A good prosthetic graft is better than a bad vein. Although prosthetic grafts may be placed between any artery with sufficient flow and any suitable vein with unobstructed outflow, it is best to begin as far distally as possible and reserve more proximal sites for the future. For example, we would consider these configurations in the following order: distal brachial artery to distal brachial vein forearm loop, distal brachial artery to proximal brachial vein or distal axillary vein straight graft, and, finally, proximal brachial artery to proximal brachial vein or distal axillary vein upper arm loop. With education and careful attention to best practices, autogenous access can be preferentially placed, and the use of prosthetic grafts can and should be limited.

PREOPERATIVE EVALUATION

End-stage renal disease is rarely an entity that exists in isolation, and dialysis patients have a higher incidence of significant comorbid conditions. According to the USRDS, among the cohort of new dialysis patients who were registered in 2006 to 2008, 84% had hypertension, 31% had coronary artery disease, 32% had congestive heart failure, 25% had insulin dependent diabetes, 14% had peripheral vascular disease, 9% had a history of previous stroke or transient ischemic attack, and 7% were unable to ambulate. Briefly stated, these patients are poor operative candidates. The preoperative evaluation involves assessing cardiopulmonary reserve and selecting the arm/limb with the least risk. At the current time most of our arm accesses are placed using supraclavicular or infraclavicular nerve blocks.

Aside from a history of events relevant to cardiopulmonary status and prior dialysis access attempts, it is imperative to inquire as to all previous venous access procedures including dialysis catheters, subclavian lines or ports, PICC lines, pacemakers, and defibrillators. Prior trauma to the upper extremities or clavicles should be noted. The physical examination should include auscultation of the heart

and lungs and an evaluation of the extremities to determine the patient's best option for dialysis access. The radial, ulnar, and brachial pulses should be palpated bilaterally. Uncommonly a radial pulse is present with an occluded brachial artery. An Allen's test to confirm adequacy of ulnar flow to the hand should be performed if a radiocephalic fistula is contemplated. It cannot be overemphasized that the preoperative physical examination is incomplete unless a venous tourniquet is used to assess the superficial veins.

Duplex ultrasound–based vein mapping before dialysis access surgery was essentially mandated by the KDOQI guidelines. We strongly disagree with this blanket recommendation. Although vein mapping at times may be helpful for operative planning, it is frequently unnecessary, adds cost, and may not always give valid information. In patients already on dialysis via a catheter we rarely request a vein map. If no suitable vein is found at surgery (see operative techniques below) then the patient will require a prosthetic graft. In patients referred before the initiation of dialysis, vein mapping may be helpful in those who are obese, intravenous drug abusers, or have had prior PICC lines. It may also be helpful in patients with normal sized arms where neither an adequate basilic nor cephalic vein is palpable with a tourniquet in place. Last, with the ubiquity of portable ultrasound machines, surgeon performed vein mapping on the OR table after nerve block anesthesia is in place frequently reveals usable veins that were deemed inadequate on preoperative imaging. This has become our routine.

Venography is an important component of successful dialysis access surgery. Its primary use is not to roadmap the arm veins but rather to confirm central vein patency. Our practice is to use it liberally in any patient with a history of arm swelling or prior central venous cannulation on the side of proposed access. In profoundly ill patients carbon dioxide may be used as a contrast agent, thereby avoiding the risks of iodinated contrast induced nephropathy. If a hybrid endovascular operative suite is available, the venogram may be obtained at the beginning of the access case, allowing for a combined procedure that is more convenient for the patient.

Last, for the safety of the surgical team, any patient with a history of intravenous drug use should have a plain radiograph of the upper extremity to evaluate for the presence of foreign bodies.

Prior to surgery, standard blood chemistries and a complete blood count are all that are necessary. The surgeon can assume that uremic platelet dysfunction will always be present, and we have found no utility in checking bleeding times pre operatively. Uncommonly arginine vasopressin at a dose of 0.3 μg/kg will be needed during surgery to control oozing. Additionally, aspirin use does not seem to impact bleeding significantly, and, considering the cardiovascular risk profile of these patients, we routinely administer a dose of 81 mg in the preoperative area. Clopidogrel does seem to increase oozing in some patients, so this should be held for 5 to 7 days, unless the patient has recently undergone coronary artery stenting. Many patients are also on warfarin. In general we do not advocate holding warfarin and feel comfortable proceeding with access surgery with an international normalized ratio up to 2.5.

OPERATIVE TECHNIQUES

The best option for anesthesia depends on the patient's comorbid conditions, the anesthesiologist, and the proposed surgery. Although local anesthesia is a viable option for many patients, it works best for patients undergoing radiocephalic or nontransposed brachiocephalic fistulas. Although we have used it successfully for upper arm basilic transpositions, it tends to be somewhat less than ideal for both patient and surgeon due to the relatively large area that must be anesthetized. Over the last several years we have gone almost exclusively to supraclavicular or infraclavicular regional nerve blocks. The blocks are placed in the preoperative area by a dedicated block team while the preceding case is underway. This helps to maximize efficiency and shorten turnover time. If the skin incision approaches the deltopectoral groove or the axilla, supplementation of the regional block with local anesthetic may be necessary particularly with an infraclavicular block. Because of this we are using supraclavicular blocks more often.

Autogenous Arm Fistulas

The patient is positioned supine with the shoulder of the operative side near the edge of the bed. The arm board should be positioned such that the arm rests in the center of the board. A standard skin preparation including the shoulder and axilla is performed. If available, an arm board drape is most convenient otherwise an extremity drape will suffice.

Radiocephalic Fistula

A 3- to 4-cm incision is placed just proximal to the wrist along the lateral or radial aspect of the arm. Once the skin is incised, the surgeon and assistant both lift the skin with Adson forceps facilitating easy identification of the cephalic vein after some gentle blunt dissection. The vein is encircled with a vessel loop and then sharply dissected out, tying all branches with 4-0 or 5-0 ties. The radial artery is dissected out circumferentially in a standard fashion and controlled with vessel loops. Any side branches are tied but not divided, which helps to maintain its orientation. The cephalic vein is divided distally, gently dilated with sequential coronary dilators, and then flushed with heparinized saline solution. After flushing the radial artery, a spatulated end-to-side anastomosis is performed using a 6.0 or 7.0 polypropylene suture. Any large proximal vein branches are ligated through separate 1-cm incisions. Closure consists of 3-0 interrupted absorbable dermal sutures and a 4-0 running absorbable subcuticular suture. On occasion the vein is so superficial that a very short skin line incision can be made over the snuffbox and the anastomosis done there just as described above. If a snuffbox anastomosis is used, then we usually ligate any large distal forearm venous branches to enhance maturation of the cephalic vein.

Upper Arm Fistula

If there is a proximally good cephalic vein, then a transverse incision is made in the antecubital crease (Fig. 2A), and the cephalic vein is identified (Fig. 2B). If of suitable size it is dissected out to its confluence with the median cubital vein, ligated distally, and divided. Sequential coronary dilators are gently passed cephalad and should easily pass if there is no intraluminal scarring. Although a sufficient length of vein can be mobilized at this point to easily reach the brachial artery, we frequently convert the incision into a hockey stick shaped incision (with the handle of the stick along the cephalic vein, Fig. 2C) and mobilize 10 to 15 cm or more of the vein (Fig. 2D and E). Not only does this allow ligation of the accessory cephalic vein and other small branches, it also allows superficial tunneling of the vein (Fig. 2F), which is necessary in all but the thinnest of arms. With the vein transposed, accessing the fistula can be performed earlier (as soon as 4 weeks depending on vein size), easier, and more commonly enabling earlier removal of dialysis catheters. Dissection of the distal brachial artery through the medial aspect of the antecubital incision is done in a standard fashion with control obtained with vessel loops. If the brachial artery appears smaller than expected, the patient most likely has a high brachial bifurcation. In these cases, the more suitable donor artery almost always is the deeper of the two vessels and should be evaluated before proceeding with the anastomosis. The vein is tunneled just beneath the skin making sure that there is no kink or twist at the most proximal site of mobilization (Fig. 2G). Once an arteriotomy is made and the artery flushed with heparinized saline solution, the vessel loops are replaced with baby bulldog clamps. This eliminates any vessel stretching and makes the end-to-side anastomosis easier to perform. Closure consists of 5-0 absorbable suture to the subcutaneous tissue and 5-0 nylon vertical mattress skin sutures (Fig. 2H). In our experience, subcuticular closures in the upper arm have been associated with postoperative wound problems

FIG. 1 Brachiocephalic arteriovenous fistula creation. (A) Anecubital incision. (B) Identification of cephalic vein in anecubital fossa. (C) Hockey-stick incision. (D) Proximal dissection of cephalic vein. (E) Ligation of cephalic vein branches, dissection of brachial artery in anecubital fossa. (F) Superficial tunneling of mobilized cephalic vein. (G) Completed arteriovenous anastomosis. (H) Closure of skin with vertical mattress nylon sutures.

much more frequently than with interrupted nylon closures. In addition, patients are much more apt to keep their follow-up appointments if they have sutures that need to be removed. If the cephalic vein is not of adequate size or quality, then the median cubital vein is identified near the medial aspect of the incision. If the median cubital vein is adequate, it is ligated distally, divided, and flushed with heparinized saline solution. We then extend the medial end of our skin incision in a hockey-stick fashion along the medial aspect of the arm nearly to the axilla. The vein is dissected circumferentially over its course toward the axilla as it joins the basilic vein, which subsequently joins the proximal brachial vein. If the median cubital vein is not adequate, then the basilic vein is used. In this instance we place two surgical towels under the upper arm to improve positioning and then make a new incision just anterior to the medial epicondyle of the humerus. Once the basilic vein is identified and found to be of appropriate size and quality, the incision is extended proximal and distally until enough vein for a transposition has been exposed. The brachial artery is then dissected out in the antecubital fossa either through a separate incision or through the medial aspect of the antecubital incision if that incision had already been made to inspect the cephalic vein. The vein is then tunneled and the anastomosis prepared and performed as described above. The fascia and subcutaneous layers are reapproximated with running 3-0 absorbable suture. The skin is closed with interrupted 3-0 nylon vertical mattress sutures. At the end of the case there should be a palpable thrill in the fistula. If there not), then there is a technical problem, and the incision should be reopened. Of note, if intraoperative vein mapping is used, then the initial incision should be over the most suitable vein as described above.

Prosthetic Arteriovenous Grafts

If there is no suitable vein then a prosthetic graft must be placed. Although the most commonly used graft is 6-mm ePTFE, bovine carotid artery, bovine mesenteric vein, and polyurethane urea (Vectra) grafts may also be used. A transverse incision is made over the brachial artery in the antecubital fossa. The brachial artery and vein (if at least 5 mm in diameter) are isolated and controlled with vessel loops. The vein should be generously dissected out to allow a long venous anastomosis. A second smaller counterincision is made on the lateral volar surface of the mid forearm on the radial side. Placement of the counterincision in this fashion draws the graft toward the radial aspect of the forearm, and this allows the patient's arm to be in a comfortable position during a dialysis session. The venous anastomosis is performed first (when using ePTFE, however, if using a biologic graft, the arterial anastomosis is performed first), particularly if the graft has a pretunneled flared end. The graft is tunneled in a gentle arc in the counterincision and then back to the anticubital fossa. Tunneling is best accomplished with a Kelly-Wick tunneler

(IMPBA), although an aortic clamp may be used. The arterial anastomosis is then performed, and the incisions are closed. If the brachial vein is too small at the antecubital fossa then a second incision is made on the proximal medial aspect of the upper arm and the proximal brachial or distal axillary vein is used for the venous outflow. Whereas this describes the two most common graft configurations, in reality any suitable artery and vein may be used. We strongly believe in limbs first and therefore do not agree with the use of forearm grafts to help mature upper arm cephalic or basilic veins.

OPTIONS FOR NONCONVENTIONAL ACCESSES

Not uncommonly patients present for dialysis access after many months of catheter usage and have developed upper extremity central vein occlusion or stenosis (Fig. 3). Placing brachial artery–based access ipsilateral to this problem will lead to significant arm edema and an unusable access. Long standing dialysis patients with central vein stenosis or thromboses pose a particular challenge. Options must be carefully considered in these cases, and there is no room for error. Failure to establish access can quickly turn into a life threatening situation.

HeRO

The HeRO graft (hemodialysis reliable outflow) is an option for upper extremity access in the setting of central vein stenosis that uses the right atrium for venous outflow. The HeRO consists of a standard ePTFE graft and a reinforced single lumen venous outflow catheter. This device requires that wire access across the stenotic segment of central vein can be achieved. Once stiff guidewire access to the right atrium is obtained, then the venous outflow catheter is placed over the wire and positioned in the right atrium. The other end of the catheter is then tunneled laterally in the deltopectoral groove and attached to the standard ePTFE graft via a manufacturer supplied alloy connector. The ePTFE graft is then tunneled like any other graft and the opposite end is sewn to the brachial artery in the standard fashion. The HeRO can also be used to create unimpeded venous outflow to salvage a functioning autogenous arm access in the event that a central vein stenosis or occlusion has developed. After the HeRO catheter has been placed and tunneled to the upper arm, it is connected to the venous end of the fistula using a small cuff of the ePTFE with the attached alloy connector. Last, one can modify the HeRO by replacing the graft with an early puncture graft (Access or Thru-Vent) and then attaching it to the HeRO catheter using the recently available Super HeRO adapter. This allows one to gain vein access to the right atrium using the patient's dialysis catheter. Obviously, there is no catheter for postoperative dialysis, so these patients should be admitted until there is confirmation that dialysis can performed using the early puncture graft. Although the HeRO obviates the need to move the access to the leg, it comes with all the problems that are associated with nonautogenous access, including graft infection and thrombosis. Long term warfarin anticoagulation should be strongly considered to all patients being dialyzed via a HeRO.

Low-Volume Access

Radial or ulnar artery–based accesses have lower volume flows than those based off of the brachial artery. Not uncommonly we have seen patients with failed upper arm grafts and ipsilateral central vein occlusion who mysteriously have a usable cephalic or basilic vein. Using forearm artery inflow creates a usable but low volume flow access and generally doesn't lead to significant arm swelling in spite of the central venous issues. Admittedly this doesn't always work, and we have had to ligate the accesses of several patients because of massive arm swelling.

Leg Access

In general, the leg is only used for access once all upper extremity options have been exhausted. However, young women and pumpkin may prefer a primary thigh access, the former to avoid the obvious arm scarring and the latter because they depend on their arms for mobility. The most common leg access is a thigh loop of ePTFE, although autogenous options exist including saphenous and femoral vein fistulas. Although we have extensive experience using the femoral vein and find it particularly useful when translocated to the upper extremity for home hemodialysis patients, its use for a thigh fistula should be carefully planned and works best in thin legs. The saphenous vein may also be used as a thigh fistula (tunneled anteriorly as a straight fistula and anastomosed to the distal superficial femoral artery), but if the vein is not generous in size (at least 5 mm) failure to mature into a useful access is common. For a prosthetic thigh graft, an oblique skin line incision is made just distal to the groin crease and either the deep femoral or proximal superficial femoral artery is used for arterial inflow. Through the medial aspect of that incision, the proximal saphenous vein or saphenofemoral junction is preferentially used for venous outflow. The proximal femoral vein may be used but the dissection is somewhat more difficult.

COMPLICATIONS AND MANAGEMENT

Infection is the most frequent complication of hemodialysis access and is a major cause of morbidity and mortality in the dialysis population (Table 1). Up to 20% of all deaths in dialysis patients are due to infections, and most come from vascular access sites. Compared with autogenous fistulas, the relative risk of infection related death is 10 times greater in those dialyzing through catheters and 1.3 times

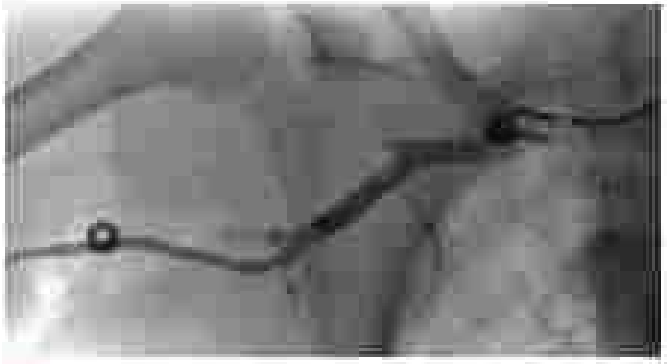

FIG. 3 Superior vena cava occlusion as demonstrated by upper extremity venogram in a dialysis patient with history of multiple prior dialysis catheters and failed upper extremity accesses.

TABLE 1 Relative Frequencies of Dialysis Access–Derived Infections in a Single-Center Study of 1574 Consecutive Dialysis Access Surgery Patients

Overall incidence of infection, n (%)	132 (8.5%)
Category of infection, n (%)	
Dialysis center derived infection (>30 days after surgery)	66 (50%)
Spontaneous infection in nonfunctional graft	30 (22.7%)
Infection in remaining stump of partly excised graft	22 (16.7%)
Operative site infection (<30 days after surgery)	6 (4.5%)
Postinterventional radiology thrombectomy	8 (6.0%)

greater in those draining through prosthetic grafts. The cumulative probability of developing a catheter-related infection is greater than 50% after 2 months of dialysis through a catheter. Diabetes and human immunodeficiency virus are also independent risk factors for greater infection rates among all access types. Staphylococcal species are the most frequently isolated organisms. Access-derived infections other than 5% rate for arm access infections and 15% for leg access) lead to metastatic infectious complications including bacterial endocarditis, osteomyelitis, septic emboli, and septic arthritis. For catheter-related bacteremia, management consists of culture-directed parenteral antibiotics and removal or exchange of the infected catheter. For infected ePTFE grafts, management must be guided by an attempt to balance the benefits of preserving a functioning access with the severity of infection. Some localized infections can be successfully treated with aggressive intravenous antibiotic therapy combined with resection and replacement through clean tissue of a portion of the graft, though recurrent infection is not uncommon. There is a lower recurrent infection rate when the entirety of the graft is removed, but the operations tend to be more difficult and access is lost.

The risk of access failure due to thrombosis is more common in prosthetic grafts than in autogenous fistulas. Early failure is generally due to technical factors but can also be related to hypercoagulability, low flow states, or use of inadequate vein. In mature accesses most problems will be detected by the dialysis unit. High venous pressures, poor arterial inflow, recirculation, and diminishing effectiveness of the dialysis all indicate access problems. The anatomic location of the problem usually can be ascertained by physical examination. The lack of bruit and thrill indicates thrombosis. A weak thrill or bruit suggests inflow problems. Pulsatility in a fistula generally indicates an outflow venous problem. Early intervention can often salvage an otherwise threatened fistula or graft. A duplex scan can further pinpoint the area of the problem but is frequently unnecessary. In general, the diagnostic test of choice is fistulography, at which time therapeutic interventions including thrombectomy, angioplasty, and stenting can be carried out. Occasionally open revision is necessary with many options available to improve either arterial inflow or to relieve venous outflow obstructions.

Almost all arm accesses create a steal syndrome, but significant steal occurs less than 15% of the time, with brachial artery–based accesses presenting the highest risk. Loss of a palpable distal pulse at the time of fistula creation indicates that a significant steal syndrome could develop. Manual compression of the fistula should result in restoration of the distal pulse. Options for improving distal perfusion include ligation, plication, banding, proximalization or distalization of the arterial inflow, and the DRIL (distal revascularization with interval ligation) procedure. The DRIL has the benefit of leaving the functioning fistula undisturbed and alleviates the physiologic pathway for the steal and restores downstream perfusion. We do not routinely perform arm angiography before performing a DRIL, but, if the patient has demonstrable atherosclerotic disease in other areas, then this should be considered. Lastly, although the use of saphenous vein for the bypass portion of the DRIL is standard, we have frequently used the fistula vein without consequence.

Other complications that occur with varying frequencies and degrees of morbidity include edema due to venous hypertension, seromas, wound problems, and carpal tunnel syndrome. Aneurysmal dilation of mature grafts or fistulas generally does not need to be addressed with surgery unless there is overlying skin breakdown or impending breakdown as demonstrated by thin, stretched, shiny skin. In general, having a low threshold to investigate and intervene on a fistula that is not performing optimally will minimize the need for repeated access surgeries.

CONCLUSIONS

- Assume dialysis is forever, so when performing access surgery, do not jeopardize future options.
- Try to avoid all catheters and if possible prosthetic materials; that is, use fistula first.
- Fistula dysfunction mandates prompt investigation and intervention to maximize chances of fistula salvage.
- Dialysis access performed properly will be rewarding for the patient, as well as the surgeon.

VENOUS THROMBOEMBOLISM: PREVENTION, DIAGNOSIS, AND TREATMENT

Jonathan A. Cardella, MSc, MD, FRCS, and Rowena S. Amarasekara, MD, MSc, FACS

Venous thromboembolism (VTE) is a condition in which thrombi form inappropriately in the venous circulation. VTE has been commonly been subcategorized to comprise deep venous thrombosis (DVT) and pulmonary embolism (PE) and has been recognized as a significant health issue representing the third leading vascular-based diagnosis after myocardial infarction and stroke. Despite significant improvement in prophylaxis and treatment of VTE, the incidence has not changed over the past 3 decades. The cost to the US healthcare system for acute treatment of venous thrombosis is in the billions of dollars per year. The sequelae of postthrombotic syndrome and chronic thromboembolic pulmonary hypertension are sources of morbidity, loss of functional status, and diminished quality of life. Therefore, identifying the patients at risk for VTE, strategies to mitigate VTE, and prompt diagnosis of DVT/PE are important considerations in the care of the surgical patient. This issue reached national importance in the late 2000s, which resulted in the US Surgeon General's Call to Action to Prevent Deep Venous Thrombosis and Pulmonary Embolism. This initiative, along with the Agency for Healthcare Research and Quality, deemed VTE prevention as an important priority to improve patient safety.

greater in those draining through prosthetic grafts. The cumulative probability of developing a catheter-related infection is greater than 50% after 2 months of dialysis through a catheter. Diabetes and human immunodeficiency virus are also independent risk factors for greater infection rates among all access types. Staphylococcal species are the most frequently isolated organisms. Access-derived infections other than 5% rate for arm access infections and 15% for leg access) lead to metastatic infectious complications including bacterial endocarditis, osteomyelitis, septic emboli, and septic arthritis. For catheter-related bacteremia, management consists of culture-directed parenteral antibiotics and removal or exchange of the infected catheter. VENOUS THROMBOEMBOLISM: PREVENTION, DIAGNOSIS, AND TREATMENT

Jonathan A. Cardella, MSc, MD, FRCSC, and Rwamu S. Amankwah, MD, MSc, FACS

Venous thromboembolism (VTE) is a condition in which thrombi form inappropriately in the venous circulation. VTE has been commonly been subcategorized to comprise deep venous thrombosis (DVT) and pulmonary embolism (PE) and has been recognized as a significant health issue representing the third leading vascular-based diagnosis after myocardial infarction and stroke. Despite significant improvement in prophylaxis and treatment of VTE, the incidence has not changed over the past 3 decades. The cost to the US healthcare system for acute treatment of venous thrombosis is in the billions of dollars per year. The sequelae of postthrombotic syndrome and chronic thromboembolic pulmonary hypertension are sources of morbidity, loss of functional status, and diminished quality of life. Therefore, identifying the patients at risk for VTE, strategies to mitigate VTE, and prompt diagnosis of DVT/PE are important considerations in the care of the surgical patient. This issue reached national importance in the late 2000s, which resulted in the US Surgeon General's Call to Action to Prevent Deep Venous Thrombosis and Pulmonary Embolism. This initiative, along with the Agency for Healthcare Research and Quality, defined VTE prevention as an important priority to improve patient safety.

EPIDEMIOLOGY OF VTE

VTE represents a significant impact on US healthcare with respect to prevention, treatment, and expenditure. Clinically, patients with VTE may present with DVT, PE, or both. Roughly two-thirds of patients will be treated for DVT and one-third for PE, which is the principal cause of mortality associated with VTE. Sudden death represents the first symptom in 25% of individuals who have a PE. VTE is recognized as a complex (multifactorial) disease involving both environmental exposures (clinical risk factors), genetic, and environmental interactions.

Incidence

Presently, there is no national surveillance program for VTE; therefore, the calculated prevalence and incidence is theoretically underestimated. Additionally, the rates of VTE for minority populations is unknown and unaccounted for in current estimates. Information from clinical organizational databases as well as hospital and community-based studies estimate the overall incidence in the United States to be approximately 1 to 2 per 1000 of the population, or 300,000 to 600,000 cases.

When examining the incidence by age, race, and gender, there are differences (Table 1). The overall rate of VTE is highest in African Americans and lowest in Asians. VTE is predominantly a disease of older age. In the absence of thrombophilia or a central venous catheter, it is rare prior to late adolescence. The occurrence of VTE is increased in both men and women with age; however, age adjusted incidence is higher for men (120 per 100,000) than women (108 per 100,000) although, women have a higher incidence during their childbearing years. PE accounts for an increasing proportion of VTE with increasing age for both sexes. The incidence of idiopathic VTE are estimated at 25% to 50%.

Recurrence

Although early diagnosis and the individualized course of anticoagulation (range 3–6 months) for VTE in the surgical patient setting is decreasing the immediate morbidity and mortality, about 30% of patients develop recurrence within the next 10 years. The highest risk occurs within the first 6 to 12 months with the risk decreasing successively but never falling to zero. Utilization of secondary prophylaxis (beyond the 3- to 6-month period) is beneficial in preventing recurrence; however, the duration of the acute management does not affect the rate of recurrence after 3 months of adequate anticoagulation has been fulfilled, which suggests that VTE is a chronic disease with episodic recurrence.

There are several independent predictors for recurrence (Box 1). Among patients with cancer, the risk of recurrence is increased in those individuals with lung, gastrointestinal, or genitourinary disease. Men have been reported to have a higher risk of recurrent VTE than women. When adjusting for sex specific risk factors gender is not an independent predictor for recurrence. Persistent elevated D-dimer in patients with idiopathic VTE and potentially residual vein thrombosis have also been described as a risk factor for relapse, therefore, secondary chemoprophylaxis should be considered in this cohort of individuals.

The reported risk of recurrence by incident event type, PE or DVT alone, varies in the literature. Patients with recurrence are more likely to be afflicted by the same event type as the primary incident event. Therefore, DVT begets DVT and PE begets PE. Provided with the information that the 7 day survival is greater for DVT (96%) than for PE (71%), secondary prophylaxis should be continued beyond the standard 3- to 6-month regimen for patients with PE although consideration of patient and thrombosis factors should be considered. This should be particularly considered in those patients with PE and decreased cardiopulmonary reserve because these individuals are more likely to die from a recurrent PE.

Survival, Morbidity, and Mortality

Our ability to diagnose DVT and PE has improved tremendously over the past several decades; however, the incidence of VTE and the long term survival after VTE has not changed despite aggressive treatment protocols. The mortality rate in the United States has been estimated between 100,000 and 180,000 deaths annually. The probability of early mortality within 1 month is approximately 6% in individuals with a DVT and 10% of those with a PE. The mortality rate for PE has been estimated to be 30% in investigations that included autopsy-based PE diagnosis, which demonstrates that many PE are not clinically recognized before death. Mortality rates are lower among patients with idiopathic venous thrombosis and higher among those whose thrombosis occurs in the setting of cancer. Other factors that predict reduced survival after VTE are increasing age, male gender, lower body mass index, confinement to a hospital or nursing home at the onset of VTE, congestive heart failure, chronic lung disease, and serious neurologic disease.

Morbidity such as postthrombotic syndrome (PTS), venous insufficiency, recurrent thromboembolic events, and chronic pulmonary hypertension are reported after the first episode of VTE. Thirty to 50% of patients with lower extremity DVT develop PTS and chronic

BOX 1 Predictors of Recurrence

- Increasing age
- Body mass index
- Neurologic disease with leg paresis
- Active cancer
- Lupus anticoagulant
- Antiphospholipid antibody
- Antithrombin deficiency
- Protein C and S deficiency
- Hyperhomocysteinemia
- Inflammatory bowel disease

venous insufficiency. These lifelong conditions are characterized by pain, swelling, skin necrosis, and ulceration. Quality of life (QOL) is adversely affect up to 4 months after DVT with further declining QOL in those individuals with PTS. Patients perceive the diagnosis of VTE as a reduction in their QOL, compounded with the potential morbidity and limitations placed by therapeutic anticoagulation are taken into consideration.

Risk Factors

The pathophysiology of VTE is based on the postulation, in the mid-nineteenth century by Rudolph Virchow, that thrombosis was the result of at least one of a triad of factors that comprise endothelial injury, hypercoagulability, and stasis of flow. This hypothesis has been validated by numerous studies, with greater than 90% of patients diagnosed with VTE having at least one of the three risk factors. It is clear that VTE is a multifactorial condition that involves inherited (genetic) and both continuous and transitory acquired risk factors (Table 2), which can be stratified, based on their risk (Table 3). Although not fully elucidated, a threshold seems to exist in the presence of one risk factor does not portend disease status; however, an interactive effect of several prothrombotic events can lead to clot formation. It is estimated that 10% of cases are idiopathic, with no acquired risk factor identified while in another 10% to 20% there is no identifiable acquired or inherited risk factor determined. This exposes our understanding that there are still undescribed inherited and/or acquired risk factors.

An impression exists that the risk factors for DVT and PE are quite different from risk factors for coronary artery disease. There is evidence to demonstrate that VTE is a cardiovascular disease and that risk factors for arterial and venous thrombosis may be similar. This was outlined in a study that demonstrated an association between asymptomatic carotid disease and DVT development. Furthermore, it has been determined that there is a fivefold increase in subsequent myocardial infarction in the decade following an unprovoked DVT when compared with controlled subjects. Although there appears to be a relationship between arterial disease and venous thrombosis, a cause and effect remains intangible. There have been suggestions that some cardiovascular risks (obesity, hypertension, diabetes, high cholesterol, and smoking) that are modifiable may reduce the development of potential VTE in the future; however, this concept requires further corroboration and has been challenged. The risk factor that appears agreed on that can be modified is smoking.

Often when considering risk factors, the surgeon is focused on the hospitalized patient. The surgeon must keep in mind that three of four VTE events occur outside the hospital setting. There is an association between a hospital stay or surgical procedure within the preceding 90 days and development of an acute DVT and/or PE. A population-based cohort study in Olmsted County, Minnesota, found that the independent risk factors for VTE included: surgery, trauma, hospital stay, placement in a nursing home, and cancer. In the Worcester Venous Thromboembolism Study, three-quarters of the VTE events occurred after the period of hospitalization. During the preceding 3 months, 23% had undergone surgery and 36% had been hospitalized. Among these patients, two-thirds experienced VTE within 1 month of their hospital discharge and more than one half of these events occurred in individuals 65 years of age or older. There was also noted a significant increase in major bleeding episodes in this age group. Therefore, when abstracting risk factors for VTE, it is imperative that the surgeon consider the entire continuum of care and treat individuals accordingly.

TABLE 2 Risk Factors for Venous Thromboembolism

Genetic	Acquired	Transient/Acquired
Family history of thrombophilia	Advance age	Pregnancy
Factor V Leiden	Antiphospholipid antibodies	Oral contraceptives
Prothrombin G20210A	Cancer	Hormone therapy
Protein C deficiency	Chronic disease	Hospitalization
Protein S deficiency	Obesity	Surgery
Antithrombin deficiency		Trauma
Sickle cell trait		Immobilization

PREVENTION AND PROPHYLAXIS OF VTE

The initiative by the Agency for Healthcare Research and Quality, the American Public Health Association, the Centers for Disease Control and Prevention, the National Quality Forum, the Centers for Medicare and Medicaid Services, the US Congress, and the US Surgeon General were started to raise public awareness and improve patient safety and quality related to VTE. Despite these measures and acknowledgment that VTE prophylaxis is an important patient safety measure, adoption of this measure was initially inadequate. The Epidemiologic International Day for the Evaluation of Patients at Risk for Venous Thromboembolism in the Acute Hospital Care Setting study of more than 68,000 hospitalized patients in 32 countries noted only 58.2% of surgical patients and 39.5% medical patients received American College of Chest Physicians (ACCP) guideline–appropriate VTE

TABLE 3 Levels of Thromboembolism Risk in Surgical Patients Without Prophylaxis

	DVT (%)		PE (%)	
Level of Risk	Calf	Proximal	Clinical	Fatal
Low risk: age <40 yr and uncomplicated surgery no risk factors	2	0.4	0.2	<0.01
Moderate risk: age >40 yr; minor, prolonged, or complicated surgery with risk factors	10–20	2–4	1–2	0.1–0.4
High risk: age 40–60 yr or >60 yr; major surgery additional risk factors (prior VTE, CA, hypercoagulability	20–40	4–8	2–4	0.4–1
Highest risk: Surgery in patient with multiple risk factors (i.e, prior VTE); hip, knee surgery, trauma	40–80	10–20	4–10	0.2–5

prophylaxis. A 2005 audit of the surgical services at Johns Hopkins found only 33% of 522 randomly selected patients were prescribed prophylaxis in line with ACCP guidelines. The steps in achieving VTE prevention requires attention to each stage of the process: (1) assessment of both VTE and bleeding risk, (2) selecting risk appropriate VTE prophylaxis, and (3) administration of risk appropriate VTE prophylaxis (Fig. 1). Evidence-based guidelines from the ACCP are published and updated regularly to address the subject of VTE prevention, prophylaxis, and management in medical and surgical patients. Other organizations such as the Eastern Association for the Surgery of Trauma and the American Academy of Orthopedic Surgeons also issue evidence-based guidelines for this subgroup of patients.

Assessment of VTE and Bleeding Risk

There are several risk assessments that have been developed for medical, orthopedic, and nonorthopedic surgery patients. These use the risk factors previous described. Currently, there is not one single model that is collectively accepted by the medical community; however, a model that is applied frequently is the Modified Caprini Risk Assessment Model (Table 4). Patients are separated according to their estimated VTE risk (VTEr) in the absence of pharmacologic or mechanical prophylaxis. Therefore, a very low risk score (Caprini score = 0) represents a VTEr less than 0.5%. In contrast, a high risk score (Caprini score ≥6) would correspond to a VTEr of at least 6%. This assessment model has been validated and has been used to assess patients undergoing general (breast, thyroid, and parathyroid), abdominal and pelvic surgery (gastrointestinal, urologic, and gynecologic), and critically ill patients. Presently, there are few data regarding vascular and bariatric patients; however, the model performs appropriately for these groups.

Despite the many scoring systems available, for the surgical patient that requires VTE prophylaxis an assessment of the risk for major bleeding commences with a full evaluation of the patient's history and

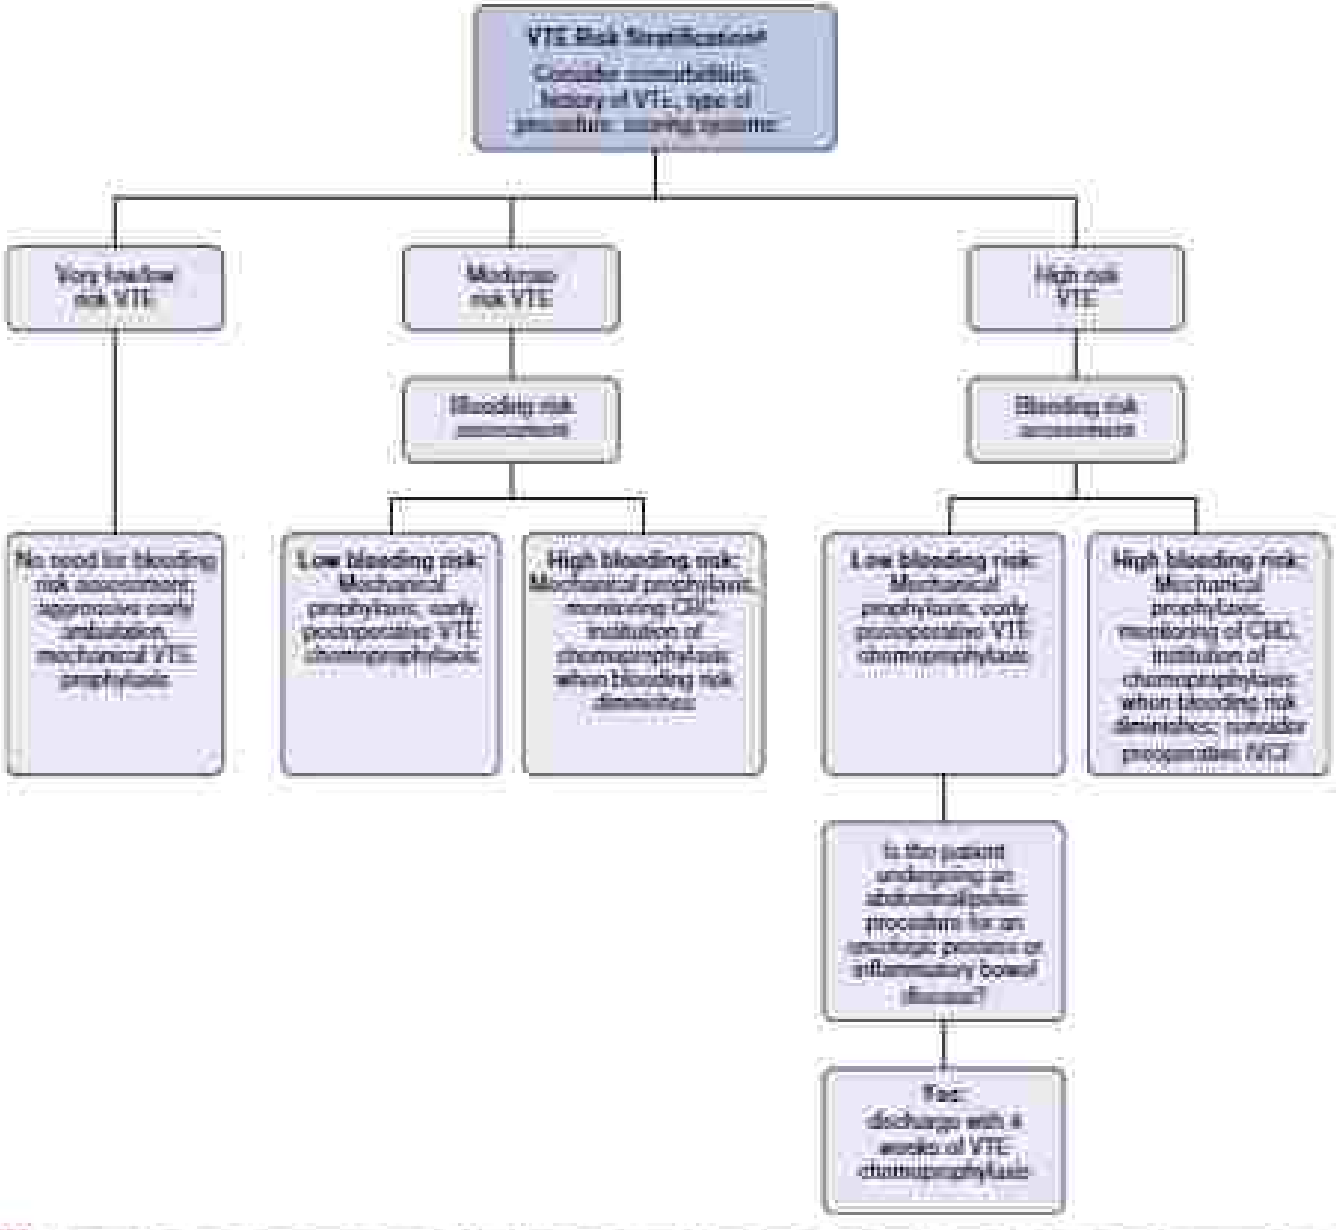

FIG. 1 Perioperative venous thromboembolism prophylaxis guidelines, adapted in part from the American College of Chest Physicians recommendations. CBC, complete blood count; IVCF, inferior vena cava filter; VTE, venous thromboembolism. *For patients undergoing general, vascular, gastrointestinal, urologic, bariatric, gynecologic, or plastic reconstructive surgery.

TABLE 4 Modified Caprini Risk Assessment Model for VTE in General Surgical Patients

1 Point	2 Points	3 Points	5 Points
Age 41–60 yr	Age 61–74 yr	Age ≥75 yr	Stroke (<1 mo)
Minor surgery	Arthroscopic surgery	History of VTE	Elective arthroplasty
BMI >25 kg/m²	Major open surgery (>45 min)	Family history of VTE	Hip, pelvis, or leg fracture
Swollen legs	Laparoscopic surgery (>45 min)	Factor V Leiden	Acute spinal cord injury (<1 month)
Varicose veins	Malignancy	Prothrombin 20210A	
Pregnancy or postpartum	Confined to bed (>72 hr)	Lupus anticoagulant	
History of unexplained or recurrent spontaneous abortion	Immobilizing plaster cast	Anticardiolipin antibodies	
Oral contraceptives or hormone replacement	Central venous access	Elevated serum homocysteine	
Sepsis (<1 mo)		Heparin-induced thrombocytopenia	
Serious lung disease, including pneumonia (<1 mo)		Other congenital or acquired thrombophilia	
Abnormal pulmonary function			
Acute myocardial infarction			
Congestive heart failure (<1 mo)			
History of inflammatory bowel disease			
Medical patient at bed rest			

Interpretation

Surgical Risk Category	Score	Estimated VTE Risk in the Absence of Pharmacologic or Mechanical Prophylaxis (%)
Very low	0	<0.5
Low	1–2	1.5
Moderate	3–4	3.0
High	≥5	6.0

The table is applicable only to general, abdominal pelvic, bariatric, vascular, and plastic and reconstructive surgery. Use zero for other types of surgery (e.g., cancer surgery).

BMI, body mass index; VTE, venous thromboembolism.

From Gould MK, Garcia DA, Wren SM, et al. Prevention of VTE in nonorthopedic surgical patients: antithrombotic therapy and prevention of thrombosis, 9th ed: American College of Chest Physicians evidence-based clinical practice guidelines. Chest. 2012;141:e227S.

an examination. Major bleeding is usually defined as fatal bleeding, symptomatic bleeding in an organ or critical area, bleeding which causes a drop in the hemoglobin of 2 g/dL or greater or requiring a transfusion of two or more units of whole blood or red cells. Bleeding related to VTE prophylaxis differs among the types of patients. A study looking at 33 randomized controlled trials with 33,813 patients undergoing general surgery evaluated pharmacologic prophylaxis and calculated the bleeding complications. Minor complications found were injection site bruising (6.9%), wound hematoma (5.2%), drain site bleeding (2.0%), and hematuria (1.4%) were most common. Major bleeding complications, such as gastrointestinal tract (0.2%) or retroperitoneal (<0.1%) bleeding, were infrequent. Discontinuation of prophylaxis occurred in 2.0% of patients and less than 1% of patients required subsequent operation. Analysis of the use of high versus low dose unfractionated heparin demonstrated that the use of the lower dose had a reduced rate of discontinuation and subsequent operation. The baseline risk for bleeding has not been fully investigated; however, The American College of Chest Physicians have outlined risk stratifications and estimated the bleeding risk based on review of several studies. They have determined the baseline risk for being less than 1.0% for general (abdominal and pelvic), bariatric, thoracic, neurosurgery (craniotomy and spinal), plastic and reconstructive surgery. There is a higher risk of bleeding (>2%) in patients undergoing Cardiac surgery or involved in a trauma or requiring emergent surgery for trauma. Bleeding must also be examined by the surgeon regarding the potential for low and high bleeding risk. This will be based on individual risk factors for bleeding. These risk factors can include those with active bleeding, patients suffering from intracranial hemorrhage, patients with moderate to severe coagulopathy or patients with a genetic hematologic disorder or thrombocytopenia. The surgeon must be cognizant of these components to reduce potential injury to their patient.

Selecting Risk Appropriate VTE Prophylaxis and Administration

The rate of thrombosis reported in patients undergoing a general surgical procedure without prophylaxis has been reported between

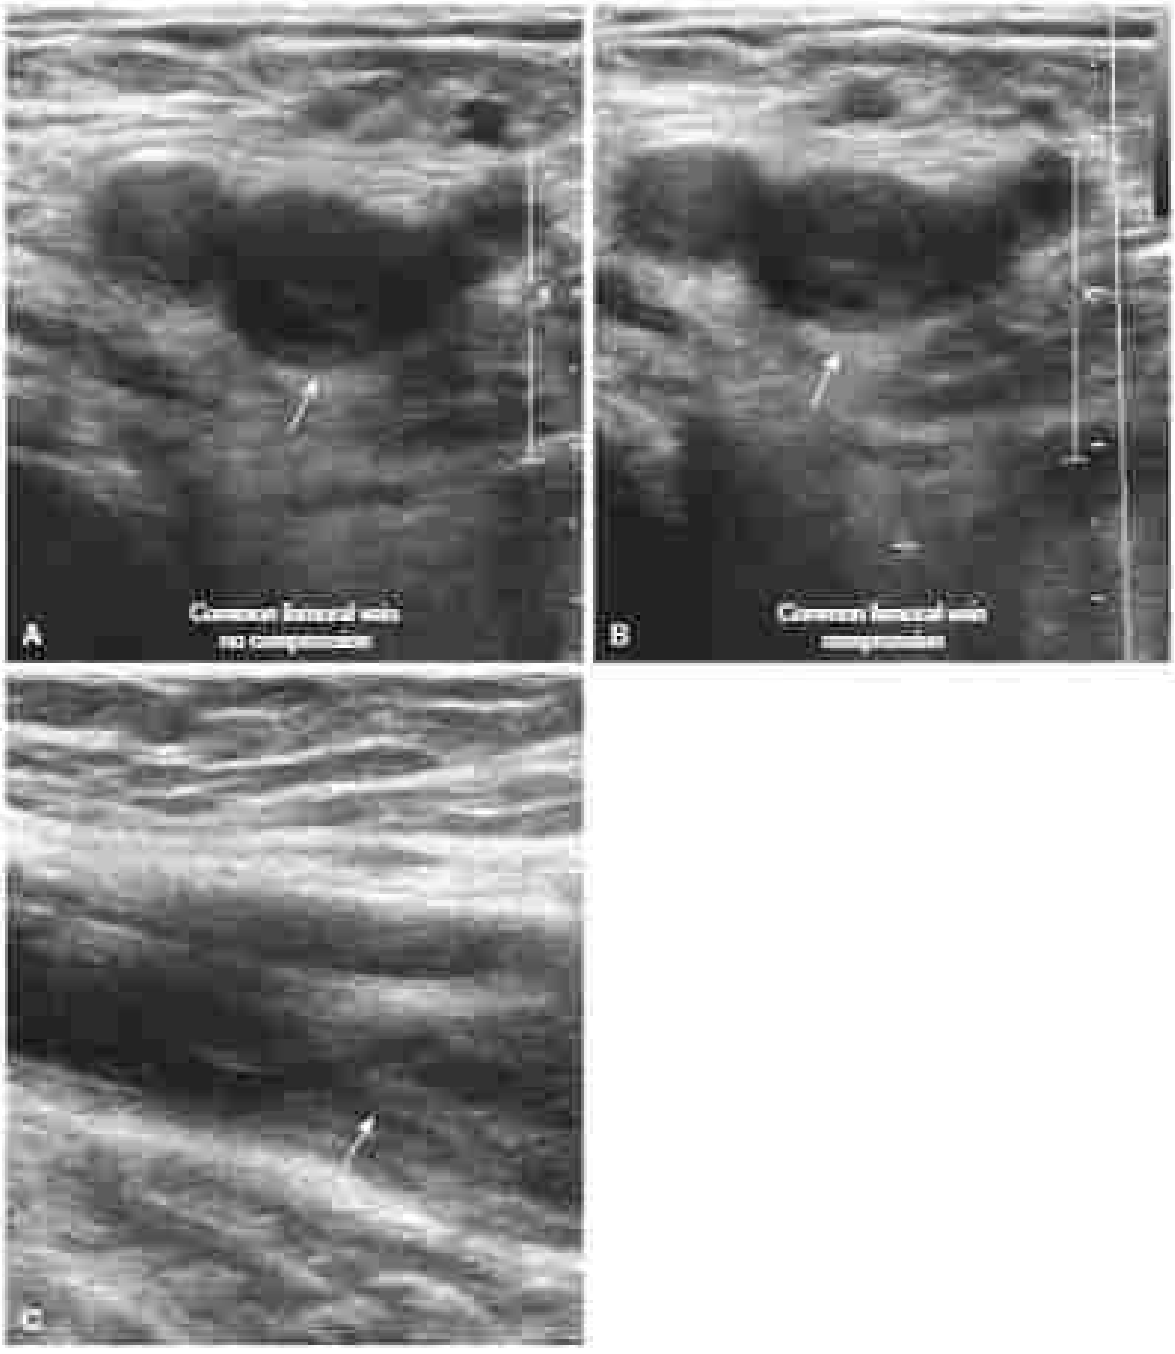

FIG. 3 (A) Cross-sectional venous ultrasound image showing noncompressibility and hyperechoic thrombus (arrow). (B) Compression view. (C) Longitudinal ultrasound image of the common femoral vein with nonhomogenous thrombus (arrow).

15% in 30%, with PE ranging between 0.2% and 5% and fatal PE < 0.002% (Table 3). Hospital initiatives of early mobilization of the patient post operatively, shorter hospital stay, utilization of perioperative antibiotics and greater use of thromboprophylaxis have demonstrated a significant impact in the reduction of VTE in the surgical patient. Selecting the appropriate thromboprophylaxis will be based on assessment of the risk of VTE and the risk of bleeding (Fig. 1). Methods for VTE prophylaxis include pharmacological, mechanical and a combination of both. The goal is to prevent VTE while reducing bleeding risk.

Mechanical methods of prophylaxis include graded compression stockings (GCS) and pneumatic compression device (PCD) which often are applied together. They are designed to eliminate stasis or interrupt thrombus development. None of these mechanical methods have been as rigorously investigated compared to pharmacological methods for reducing DVT. No trials to date have demonstrated mechanical devices alone are able to reduce the frequency of fatal PE. Utilization of GCS in isolation is not supported except in patients with high risk for bleeding. There are data to support a reduced incidence in DVT when used compared to controls. Additionally, when implemented in conjunction with low dose unfractionated heparin (LDUH) there is a 75% rate reduction in DVT compared to those patients treated with only LDUH. Pneumatic compression devices used with GCS have shown to be beneficial in reducing DVT. The PCD as stated above, is based on increasing lower extremity blood flow and as an adjunct to increasing native fibrinolytic activities.

FIG. 3 Computed tomography scan demonstrating pulmonary embolism (PE).

Studies demonstrate its efficacy, however, compliance tends to be the concerning issue and particular clinical situations prevent its use. When applied with LDUH it can be effective. In a randomized trial of cardiac surgical patients, the combination of PCD and LDUH was shown to reduce the rate of symptomatic PE from 4% to 1.5% when compared to the use of LDUH alone. In the surgical patient with multiple risk factors and high risk for VTE a combination of pharmacological and mechanical prophylaxis with GCS and/or IPC should be used.

The most prevalent methods for the prevention of VTE in moderate to high risk patients is LDUH, low molecular weight heparin (LMWH), Warfarin and fondaparinux. It was the International Multicenter Trial published in 1975 that randomized 4121 patients over 40 undergoing major surgeries to either a control group or to receive LDUH. This study led to the discovery that employing heparin decreased the frequency of fatal PE and that heparin based thromboprophylaxis prevented DVT. This investigation made a significant contribution to our understanding of preventative management and significantly changed patient outcomes. Since that investigation there have been numerous studies and guidelines that have continued to provide supportive evidence in terms of both efficacy and safety using these pharmacological agents for the prevention of VTE in the perioperative period.

Conventionally, systemic intravenous LDUH (loading dose 80 U/kg and the infusion then adjusted to achieve a partial thromboplastin time 2 to 2.5 times normal) has been administered for several days during which time an oral anticoagulation has been initiated. LMWH is administered subcutaneously and weight based adjusted (1 mg/kg to 100 mg/kg twice a day). The advantage of this treatment is that it does not require monitoring. Circumstances that dictate monitoring are in patients who are obese, pregnant or in renal failure. This form of treatment can be easily continued in the outpatient setting. Fondaparinux is a weight based administered medication (5 mg/kg for body weight <50 kg; 7.5 mg/kg body weight for 50 to 100 kg; 10 mg/kg body weight for >100 kg) for the treatment of DVT as well as PE. The recommendation is treatment for at least five days with concurrent administration of oral anticoagulation. It has also been suggested as an anticoagulant when the patient has been diagnosed with heparin induced thrombocytopenia (HIT). Warfarin is one of the earliest oral anticoagulants. Typical dosing is 5 mg/day till the predetermined therapeutic level is reached, which is usually an INR between 2 and 3. When the INR level is achieved close monitoring will allow the dose regimen to be appropriately adjusted to stay within that range. This medication is started after anticoagulation has been initiated for several days to prevent warfarin skin necrosis. This occurs as a result of a transient hypercoagulable period where warfarin inhibits Protein C and S prior to other coagulation factors. Other pharmacological agents are Factor Xa inhibitors (apixaban, rivaroxaban) and direct thrombin inhibitors (dabigatran), which are first choice oral anticoagulants for long term anticoagulation.

COMPLICATIONS

One of the most formidable complications that a surgeon will confront with anticoagulation is bleeding. The first 5 days of anticoagulation with LDUH it has been reported that 10% of patients will experience some form of bleeding. The report incidence of major bleeding with Warfarin and an INR of 2 to 3 is roughly 6% per year. When encountered the proper management is administration of protamine for the reversal of heparin and the initiation of vitamin K and/or fresh frozen plasma to correct the INR.

The other complication associated with anticoagulation using LMWH or LDUH is heparin induced thrombocytopenia (HIT). This is a result when heparin dependent antibody immunoglobulin binds to activate platelets. The ensuing interaction causes thrombosis and thrombocytopenia. This is typically seen 5 to 14 days after the initiation of anticoagulation with LMWH or LDUH. It can occur earlier if the patient has had any prior exposure to heparin. Close monitoring of the hematocrit, hemoglobin and platelets after the commencement of anticoagulation will allow the surgeon to recognize any acute change and act accordingly.

HIT occurs in 0.6 to 30% of patients exposed to heparin. The diagnosis should be suspected when there is a drop of greater than 50% in the platelet count, a drop in the platelet count below 100,000/μl, or there is unexpected thrombosis while the patient is on heparin. Laboratory assay testing must be carried out to make the diagnosis. Once diagnosed or if there is a high index of suspicion of HIT, heparin must be stopped immediately. Direct thrombin inhibitors hirudin, lepirudin and argatroban are the treatments of choice. The surgeon treating their patients should know that lepirudin is excreted by the kidneys and argatroban is excreted by the liver and will need to be prescribed correctly when dealing with liver and renal failure patients.

DIAGNOSIS

Clinical suspicion for VTE should prompt rapid diagnosis and treatment as the consequences of untreated DVT can lead to PE, which can be fatal. Initially, a careful history and physical can help guide diagnostic testing and management when the diagnosis of DVT or PE is considered. VTE should be considered in any patient with presenting complaints of leg swelling and shortness of breath. On history, patients may have had prior surgery, active cancer, recent surgery or a family or personal history of hypercoagulability, to name a few. Presenting signs and symptoms of DVT can include erythema, swelling, pain, dilated superficial veins as well as skin changes. Infrequent but serious sequelae of DVT that can lead to a surgical emergency are phlegmasia cerulea dolens or phlegmasia alba dolens. These conditions represent a continuum of worsening (cerulea) and ultimate occlusion (alba) of venous outflow resulting in an ischemic limb that requires immediate surgical attention. Patients presenting with PE may complain of pleuritic, chest pain, shortness of breath and hemoptysis. Signs and symptoms can range from tachycardia, a new onset of atrial fibrillation or complete cardiopulmonary collapse.

The role of serum based testing in VTE is debatable. The D-dimer test is a marker of endogenous fibrinolysis and has been used in two main scenarios, whole blood agglutination and Enzyme Linked Immunosorbent Assay (ELISA) tests. The reported sensitivity of these tests is 85% and 95%, respectively. Both tests are plagued by low specificity. While not useful as a screening tool for VTE they may provide an adjunct in medical patients, as the false positive rate is exceedingly high in the post surgical patients. Evaluation of blood or genetic tests for the diagnosis of hypercoagulable states is not useful

in the acute setting and should not delay treatment. However, obtaining these tests can be useful in the long term, with respect to the management of anticoagulation.

The diagnosis of DVT is primarily made by duplex ultrasound (Fig. 2). The advantage of this imaging modality is its availability, high resolution and lack of radiation, which make it an attractive diagnostic choice. Limitations to venous duplex ultrasound utilization are the body habitus of patient, intra-operator variability as well as patient sensitivity or pain precluding compression by the ultrasound probe. Furthermore, venous duplex does not routinely directly image the iliofemoral system. Therefore, adjuncts such as magnetic resonance imaging (MRI) or computed tomography (CT) scanning with the addition of intravenous contrast dye timed to the venous phase may be of utility. In unusual circumstances, catheter based venography can be used to aid in diagnosis, but it is more frequently used in treatment of deep femoral or caval pathology.

The gold standard for the diagnosis of PE is CT scan (Fig. 3). This technology is readily available at most hospitals and with the adjunct of intravenous (IV) contrast it can provide rapid, high resolution images to allow evaluation of pulmonary anatomy and the identification of filling defects within the pulmonary arterial tree suggestive of pulmonary emboli or thrombus. The drawback to this type of imaging is its use of IV contrast and radiation. The use of IV contrast may be prohibitive in patients with renal insufficiency or patients with a dye allergy. The use of radiation can pose a health risk to patients who require recurrent scans for other medical issues due to the cumulative dose associated with recurrent radiation exposure. An alternative option is ventilation–perfusion (V/Q) scanning. The test is highly specific (97.7%) for the diagnosis of PE but not particularly sensitive (77.4%) as other pulmonary pathology can result in a positive V/Q scan. Despite this, V/Q scanning remains a choice when CT scanning is not preferred.

Application of echocardiography has similarly assisted in the diagnosis of PE. Either transthoracic or transesophageal echo can be utilized to demonstrate right ventricular strain or overload and occasionally can visualize thrombus within the right heart. Its main utility is in patients who are too critically ill to be moved to the CT scanner. Also, echocardiography is valuable in the operating room in patients who have decompensated acutely without obvious cause. Although considered beneficial in three scenarios, a CT with contrast should be sought when the patient is stable to confirm diagnosis.

Other imaging modalities for PE such as MRI have not gained widespread use. While conventional catheter based angiography can be useful its role is usually reserved for those patients undergoing therapy for PE. Plain film imaging, while able to demonstrate some findings associated with PE, should not be solely used for definitive diagnosis.

TREATMENT

Treatment goals of VTE are directed at elucidating the underlying cause of the thrombosis as well as preventing clot propagation, PE or future thrombotic events. Furthermore, efforts may be directed at preventing long term sequelae of VTE, such as post thrombotic syndrome (PTS).

Superficial Venous Thrombophlebitis

Superficial venous thrombophlebitis (SVT) typically presents as a painful, palpable cord that may be associated with some erythema or local edema. While generally benign, SVT is more common than DVT and can present as a concomitant finding with DVT. In fact, some studies estimate that SVT presents concomitantly with DVT in up to 25% of patients. When, SVT encroaches the junction with the deep venous system, the risk for a subsequent DVT can be as high as 18%. While there are no consensus treatment guidelines for SVT initial workup should include a duplex ultrasound to look for DVT as well as clot proximity to the deep venous system. While not entirely evidence based, treatment consists primarily of nonsteroidal anti-inflammatory drugs (NSAIDs) as well as treatment of local symptoms and when used in combination with low molecular weight heparin (LMWH) or fondaparinux for 45 days can reduce extension of SVT. For cases of SVT that encroach on the deep venous system surgical ligation of the phlebitic vein can be considered as an anticoagulation.

Deep Venous Thrombosis

The initial phase of DVT treatment is focused toward the etiologic causes of the thrombotic event as well as medical management of the thrombosis with therapeutic anticoagulation. Consideration should be given to patient factors such as risk of bleeding, recent surgery, history of GI or other major bleeding events. Furthermore, an understanding of the situation that has led to the thrombotic event should be evaluated, that is, provoked vs. unprovoked, underlying malignancy, post-surgical etc. The goal of initial medical management hinges around stabilization of the existing thrombus, reduction of PE risk, reduction of possible recurrence and prevention of DVT related morbidity, namely PTS.

Choice of Anticoagulant

An understanding of the etiologic factors contributing to VTE are paramount to directing choice of anticoagulant. According to the 2016 guidelines from the ACCP suggest the following anticoagulation regimens based on the etiologic factors leading to VTE/PE. In patients with VTE not associated with malignancy (i.e., postsurgical), recommendations are for the use of novel oral anticoagulants (NOACs; rivaroxaban, apixaban, or edoxaban) in obligation over the use of vitamin K antagonists (VKAs), and, VKAs, over the use of LMWH. The basis of this recommendation is that there were fewer bleeding events observed when using NOAC versus VKA and patient convenience is favored when using NOAC.

In patients with VTE and cancer, the recommendations are different. Because the recurrence rate is lower in patients treated with LMWH versus VKA, and, the efficacy and risk of bleeding is similar between VKA and NOAC, the recommendation is for the use of LMWH over VKA and NOAC.

Duration of anticoagulation is generally based on etiologic factors and risk of recurrence. In general, duration of anticoagulation for most patients will be for 3 months. Included in this group would be unprovoked DVT, postsurgical DVT, and DVT provoked by other factors. In patients with recurrence of VTE or malignancy, suggestions would be for anticoagulation duration to exceed 3 months. In this determination, consideration should be given to the patient's risk of bleeding and periodic assessment of the patient's ongoing anticoagulation requirements should be made.

Role of Intervention

The role of venous thrombectomy has become markedly diminished in the era of endovascular venous techniques. However, in limb threatening phlegmasia situations, open venous thrombectomy remains an important tool for limb salvage. Aside from this rare condition, most venous interventions in the setting of VTE will be endovascular in nature.

In patients with acute iliofemoral DVT, approximately 20% will develop postthrombotic syndrome. PTS is characterized by pain, swelling, aching, and heaviness in a patient with a history of DVT in the ipsilateral limb. There are some small, randomized trials that have suggested that the dissolution of acute clot with endovascular means (thrombolysis, mechanical thrombectomy) can prevent the development of PTS. As a result, many patients with iliofemoral DVT have been treated with clot dissolution techniques (Figs. 4 and 5).

The Acute Venous Thrombosis: Thrombus Removal with Adjunctive Catheter-directed Thrombolysis (ATTRACT) trial randomized patients

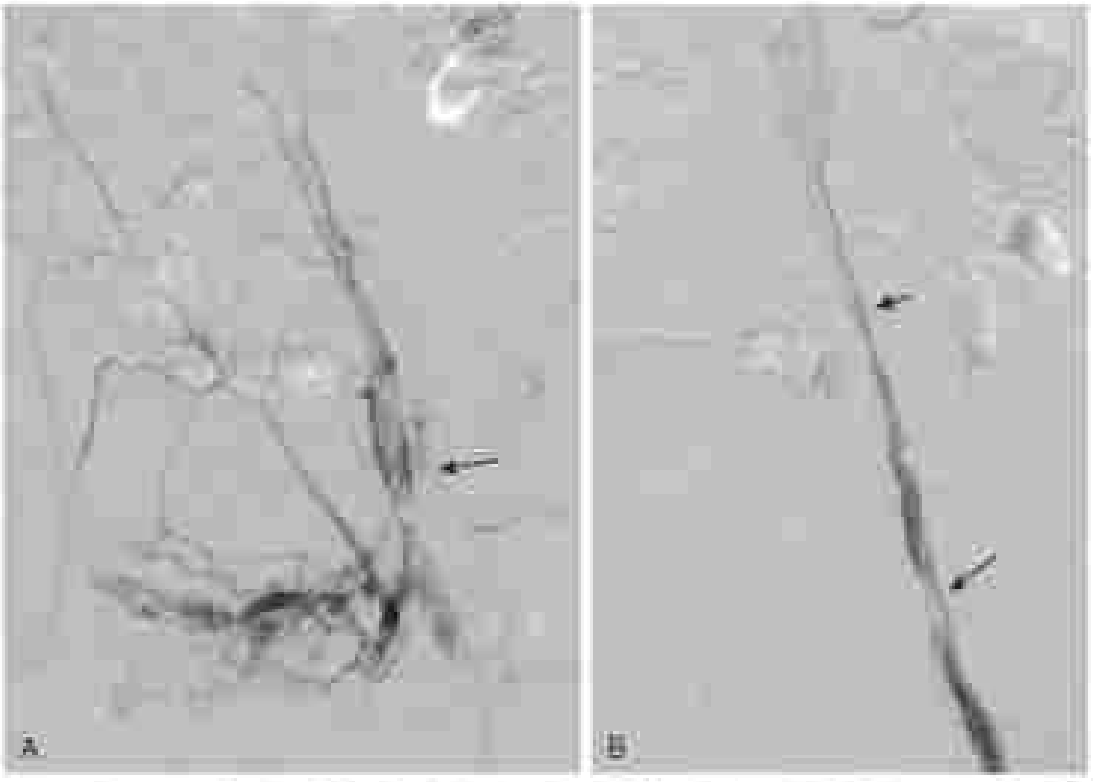

FIG. 4 (A) Lower extremity venogram of patient with ileofemoral deep vein thrombosis. Note the irregularity of the lumen as well as the filling defect in the ileofemoral segment (*arrow*). (B) The same patient after 24 hours of thrombolytic treatment as well as mechanical thrombolysis. Note the decrease in venous occlusion as well as improved luminal patency.

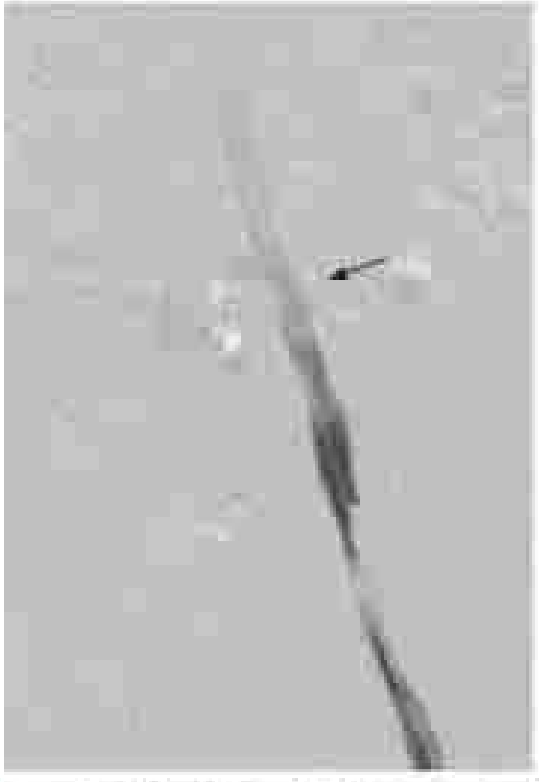

FIG. 5 Successful venous stenting (*arrow*) after pharmacomechanical lysis of deep vein thrombosis.

with DVT involving femoral, common femoral, and iliac veins to undergo pharmacomechanical thrombolysis and anticoagulation versus anticoagulation alone. The primary endpoint was development of PTS at any point in the 24 month follow up. The results showed no difference in the development of PTS (47% on mechanical vs 28% control). However, there was a significant increase in major bleeding events in the treatment arm versus the control arm (1.7% vs 0.3%). The authors concluded that the use of pharmacomechanical thrombolysis in patients with proximal DVT did not prevent the development of PTS but did put patients at risk of major bleeding.

These results differ from those of the Catheter directed Venous Thrombolysis (CaVenT) in which patients with isolated iliofemoral DVT treated with catheter directed therapy (CDT) and anticoagulation versus anticoagulation alone. In this study, in patients treated with CDT, there was a significant reduction in PTS (average relative risk, 14.8%) versus anticoagulation alone.

Possibilities for the disparate results from these two landmark trials may lay in the inclusion of femoral DVT in the Acute venous Thrombosis: Thrombus Removal with Adjunctive Catheter directed Thrombolysis trial versus iliofemoral DVT only in CaVenT. Furthermore, the methods of CDT were more uniform and there were less venous stents used for the in the CaVenT trial.

The decision to perform CDT in patients with DVT should be based on assessment of the individual bleeding risk and should only be used in DVT of the iliofemoral segment. Informed consent should include the risk of bleeding and the relatively high rate of PTS in patients with iliofemoral DVT following CDT treatment.

Pulmonary Embolism

Although PTS presents a significant morbidity for patients with DVT, the most feared and dangerous complication of DVT is PE. The

treatment strategy for PE is guided by the clinical assessment of cardiac and pulmonary status of the patient.

Specifically, patients with hypotension or systemic shock in the setting of an acute PE would be classified as high risk PE. For these patients, an assessment of bleeding risk should be made; in patients without significant bleeding risk and high-risk PE, systemic thrombolysis should be considered. For patients in whom the bleeding risk is high, systemic thrombolysis has failed, or are at risk of decompensation before thrombolysis can take effect should be considered for CDT to decrease clot burden.

Patients without cardiac compromise in the setting of PE would be considered low to moderate risk PE. These patients without contraindications to anticoagulation should begin an anticoagulation regimen (unfractionated heparin or LMWH) with transition to oral anticoagulation. Intravenous therapy can be avoided if NOACs are used. The sole exception would be in a patient with subsegmental PE and no DVT. These patients may be treated with clinical surveillance.

Inferior Vena Cava Filters

The role of inferior vena cava (IVC) filters in patients with DVT is that of salvage to prevent the migration of clot from the legs to the pulmonary circulation. They are to limited to those patients with a contraindication to anticoagulation or failure of anticoagulation with recurrent VTE.

Current ACCP guidelines do not recommend IVC filter therapy for patients who are eligible for or currently on anticoagulation. There are no guidelines that would support the routine use of IVC filters outside of contraindications to anticoagulation or failure of anticoagulation.

In fact, the Prevention and Risque d'Embolie Pulmonaire par Interruption Cave (PREPIC) trials have shown that IVC filters do prevent PE; however, there was no mortality benefit compared with the use of anticoagulation alone, and, the use of IVC filters came at the cost of more DVTs. Although PREPIC 1 used nonretrievable filters and PREPIC 2 used retrievable filters, the authors concluded that in patients with severe PE, a retrievable filter in addition to anticoagulation did not prevent recurrences.

The use of IVC filters is not without complication. Filter fracture, migration, and perforation of IVC into surrounding structures have all been reported. Most filters placed today are retrievable and despite the instructions for use as well as a US Food and Drug Administration guideline to remove the filters when not clinically useful, many IVC filters do not get removed. This has become a highly litigated area of vascular surgery practice. We recommend strict guidelines related to insertion and an electronic database to follow patients with filters in situ so there are not lost to follow up and assessment can be made as to the clinical utility of the filter with a view to removal if not clinically warranted.

SUMMARY AND CONCLUSIONS

VTE is a spectrum of disease that includes DVT, CVT, and PE and is common in both medical and surgical patients. VTE is often clinically silent but can result in significant morbidity and even mortality for patients. A high level of clinical suspicion as well as timely use of imaging modalities can help provide timely diagnosis and treatment. While there are a number of risk factors for VTE, postsurgical patients are all at least at intermediate risk of developing VTE and should therefore receive appropriate prophylaxis. Acute diagnosis should lead to a bleeding risk assessment followed by anticoagulation and potentially catheter directed therapy. Duration and agent of anticoagulation will depend on the etiologic factors leading to the thrombotic event. IVC filters, although having a role, do not improve mortality and should be used judiciously with a view to removal when their clinical utility has expired. Individual patient factors as well as VTE factors should be evaluated when planning therapy.

Vena Cava Filters

Caroline Iyad Orfoua Chaar, MD, MS

Venous thromboembolism (VTE) remains a major health concern and a common cause of vascular morbidity and mortality. Anticoagulation is the cornerstone of therapy to prevent propagation, promote thrombus resolution, and prevent recurrence. Even though anticoagulation is administered to medical and surgical patients affected by VTE, several considerations come into play in the surgical patient population. Bleeding is a risk for every surgical procedure and anticoagulation can amplify that risk and is sometimes contraindicated. On the other hand, surgeries, especially with a long operating time, general anesthesia, and postoperative immobilization, are unique VTE risk factors in the surgical patients. Vena cava interruption is an important alternative therapy to prevent pulmonary embolism (PE). This chapter will provide an overview of the indications, techniques, and complications of vena cava filter placement and retrieval.

EVOLUTION AND CURRENT STATE

The concept of vena cava interruption was first introduced as an open surgical procedure consisting of ligation or plication of the inferior vena cava (IVC) to prevent embolization of thrombus from the lower extremities to the lungs. It evolved with the introduction of a variety of external clips that were applied surgically to the IVC via laparotomy. The Greenfield filter introduced in 1972 allowed, through its conical shape, trapping of significant thrombus volume without interfering with venous return and avoiding complete thrombosis of the vena cava. Its design represents the platform that most current IVC filters are based on. The Greenfield filter was initially inserted via surgical exposure of the jugular vein or femoral vein. Later, the development of percutaneous delivery systems increased the use of IVC filters in the United States by making the procedure minimally invasive and expanding its use to nonsurgical vascular specialists. Retrievable IVC filters fueled an exponential increase in placement of IVC filters in the past decade as these were perceived as "safe" alternatives to anticoagulation in patients who have contraindications for treatment or even prophylaxis as they can be retrieved when the risk of VTE resolved. Nationally low retrieval rates and increasing numbers of late complications from retrievable IVC filters led the US Food and Drug Administration (FDA) to issue a warning in 2010 mandating vascular specialists to follow the patients after IVC filter placement and retrieve them when the risk of PE resolves. In a recent study reviewing the Nationwide Inpatient database from 2003 to 2013, the incidence of VTE admissions had significantly increased but the associated mortality decreased. Although the use of catheter-directed thrombolysis has been steadily on the rise, the use of IVC filters increased from 2003 to 2009 significantly and then decreased in the latter part of the study period, suggesting that the medical community has become more aware of the potential dangers of IVC filters and therefore adopted more stringent criteria for placement (Fig. 1).

Indications

The decision to place an IVC filter should be individualized based on the patient's risk of VTE and taking into consideration the likelihood of bleeding and the potential duration of interruption of anticoagulation. There has been significant variation between different societies on the recommendations for IVC filter insertion. Although the American College of Chest Physicians strictly recommends placement of IVC filters in patients who have absolute indications, the Society of Interventional Radiology has traditionally endorsed a variety of indications that are clinically plausible but are not supported by high level of evidence. Indications for IVC filter placement can be divided into absolute, relative, and prophylactic (Table 1).

Absolute Indications

Patients who develop VTE and have contraindication for anticoagulation should be treated with an IVC filter based on consensus statements from multiple societies. These include patients with diagnosed VTE undergoing surgery with high risk of bleeding, neurosurgery, or patients with hemorrhagic stroke. On the other hand, up to 10% of patients who are started on anticoagulation for VTE develop a bleeding complication that warrants interruption of anticoagulation. Placement of a retrievable IVC filter provides protection from PE until anticoagulation is safe to be resumed. After the patient is stable on anticoagulation, the IVC filter should be removed. On the other hand, patients affected by recurrent VTE while on anticoagulation are considered therapy failures and traditionally treated with IVC filters. The availability of multiple direct oral anticoagulants (DOACs) on the market has shifted that practice slightly because some specialists may recommend trying a different anticoagulation agent before

Vena Cava Filters

Caroline Syed Ochoa Chaar, MD, MS

Venous thromboembolism (VTE) remains a major health concern and a common cause of vascular morbidity and mortality. Anticoagulation is the cornerstone of therapy to prevent propagation, promote thrombus resolution, and prevent recurrence. Even though anticoagulation is administered to medical and surgical patients affected by VTE, several considerations come into play in the surgical patient population. Bleeding is a risk for every surgical procedure and anticoagulation can amplify that risk and is sometimes contraindicated. On the other hand, surgeries, especially with a long operating time, general anesthesia, and postoperative immobilization, are unique VTE risk factors in the surgical patients. Vena cava interruption is an important alternative therapy to prevent pulmonary embolism (PE). This chapter will provide an overview of the indications, techniques, and complications of vena cava filter placement and retrieval.

EVOLUTION AND CURRENT STATE

The concept of vena cava interruption was first introduced as an open surgical procedure consisting of ligation or plication of the inferior vena cava (IVC) to prevent embolization of thrombus from the lower extremities to the lungs. It evolved with the introduction of a variety of external clips that were applied surgically to the IVC via laparotomy. The Greenfield filter introduced in 1972 allowed, through its conical shape, trapping of significant thrombus volume without interfering with venous return and avoiding complete thrombosis of the vena cava. Its design represents the platform that most current IVC filters are based on. The Greenfield filter was initially inserted via surgical exposure of the jugular vein or femoral vein. Later, the development of percutaneous delivery systems increased the use of IVC filters in the United States by making the procedure minimally invasive and expanding its use to nonsurgical vascular specialists. Retrievable IVC filters fueled an exponential increase in placement of IVC filters in the past decade as these were perceived as "safe" alternatives to anticoagulation in patients who have contraindications for treatment or even prophylaxis as they can be retrieved when the risk of VTE resolved. Nationally low retrieval rates and increasing numbers of late complications from retrievable IVC filters led the US Food and Drug Administration (FDA) to issue a warning in 2010 mandating vascular specialists to follow the patients after IVC filter placement and retrieve them when the risk of PE resolves. In a recent study reviewing the Nationwide Inpatient database from 2003 to 2013, the incidence of VTE admissions had significantly increased but the associated mortality decreased. Although the use of catheter-directed thrombolysis has been steadily on the rise, the use of IVC filters increased from 2003 to 2009 significantly and then decreased in the latter part of the study period, suggesting that the medical community has become more aware of the potential dangers of IVC filters and therefore adopted more stringent criteria for placement (Fig. 1).

Indications

The decision to place an IVC filter should be individualized based on the patient's risk of VTE and taking into consideration the likelihood of bleeding and the potential duration of interruption of anticoagulation. There has been significant variation between different societies on the recommendations for IVC filter insertion. Although the American College of Chest Physicians strictly recommends placement of IVC filters in patients who have absolute indications, the Society of Interventional Radiology has traditionally endorsed a variety of indications that are clinically plausible but are not supported by high level of evidence. Indications for IVC filter placement can be divided into absolute, relative, and prophylactic (Table 1).

Absolute Indications

Patients who develop VTE and have contraindication for anticoagulation should be treated with an IVC filter based on consensus statements from multiple societies. These include patients with diagnosed VTE undergoing surgery with high risk of bleeding, neurosurgery, or patients with hemorrhagic stroke. On the other hand, up to 10% of patients who are started on anticoagulation for VTE develop a bleeding complication that warrants interruption of anticoagulation. Placement of a retrievable IVC filter provides protection from PE until anticoagulation is safe to be resumed. After the patient is stable on anticoagulation, the IVC filter should be removed. On the other hand, patients affected by recurrent VTE while on anticoagulation are considered therapy failures and traditionally treated with IVC filters. The availability of multiple direct oral anticoagulants (DOACs) on the market has shifted that practice slightly because some specialists may recommend trying a different anticoagulation agent before

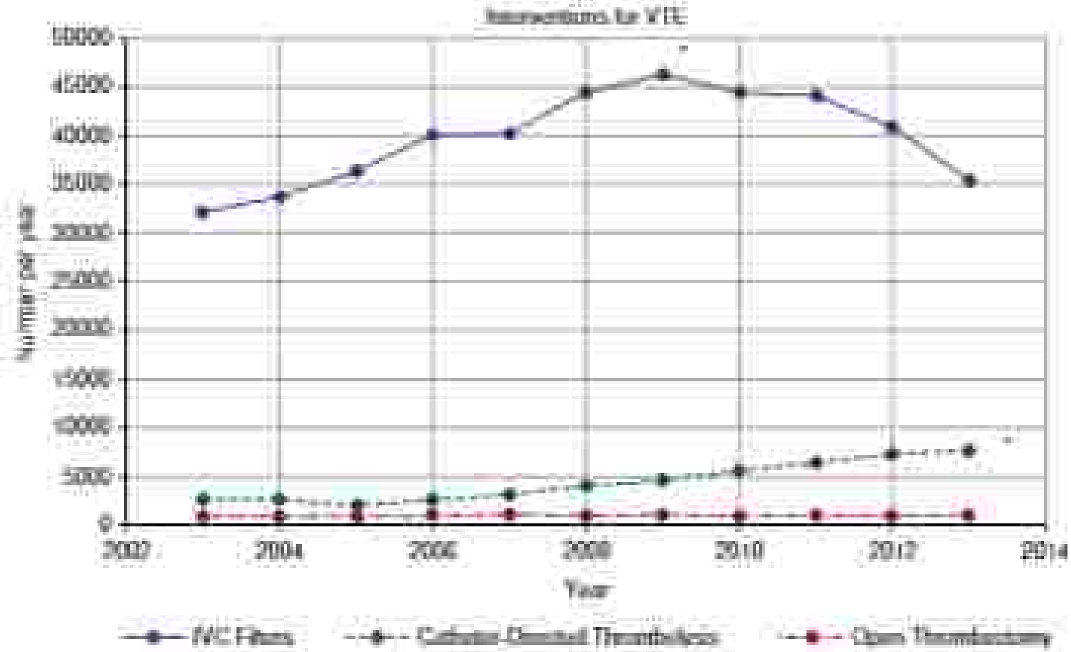

FIG. 1 Trends in inferior vena cava (IVC) filter placement. Trends of inpatient IVC filter placement, catheter-directed thrombolysis, and open thrombectomy for patients admitted with venous thromboembolism between 2003 and 2013. IVC filter placement significantly increased from 2003 to 2009 and subsequently significantly decreased from 2010 to 2013.

TABLE 1 Indications for IVC Filter Placement

Indications	Endorsed by	Patient Characteristics
Absolute	ACCP SIR AHA	Patient with VTE and one of the following: 1. Contraindication to anticoagulation 2. Failure of anticoagulation
Relative	SIR AHA (only characteristics 1 and 2)	Patient with VTE and one of the following: 1. Limited cardiopulmonary reserve 2. Massive PE treated with thrombolysis, thrombectomy 3. Chronic PE treated with thromboendarterectomy 4. Large free-floating iliocaval thrombus 5. Iliocaval DVT 6. Thrombolysis for iliocaval DVT 7. Recurrent PE with filter in place 8. Difficulty establishing therapeutic anticoagulation 9. Poor compliance with anticoagulant medications 10. High risk of complication of anticoagulation (i.e. ataxia, frequent falls)
Prophylactic	SIR	Patient at risk with no documented VTE: 1. Trauma patient with high risk of VTE 2. Surgical procedure in patient at high risk for VTE 3. Medical condition with high risk of VTE

ACCP, American College of Chest Physicians; AHA, American Heart Association; IVC, inferior vena cava; SIR, Society of Interventional Radiology; VTE, venous thromboembolism.

placement of an IVC filter. The current position of most societies on this situation is to place an IVC filter. A permanent device should be considered if the patient requires lifelong anticoagulation.

RELATIVE INDICATIONS

In certain circumstances, placement of IVC filters may provide additional protection from PE to patients with VTE tolerating anticoagulation. These patients can be divided into three categories. The first group suffer already from advanced cardiopulmonary disease, and a recurrent insult to the pulmonary circulation would be poorly tolerated or fatal. Patients already affected by massive PE, cor pulmonale, or undergoing pulmonary thromboendarterectomy for chronic thromboembolic pulmonary hypertension have very limited reserve. The second group includes those patients with increased odds of recurrent PE related to special characteristics of deep vein thrombosis (DVT) in the lower extremities. Patients with a heavy thrombus burden such as iliocaval DVT or free floating thrombi are thought to be at increased risk of PE and may benefit from an IVC filter. Sharifi et al. demonstrated that placement of an IVC filter during catheter directed

thrombolysis of lower extremity DVT reduce the risk of iatrogenic PE 8 times but there was no effect on mortality. The last group of patients have difficulty with the efficacy of anticoagulation or its safety. Patients on warfarin sometimes require a long time to reach a steady state therapeutic level or have difficulty with maintaining it. The introduction of DOACs has provided a reasonable alternative for these patients. Still, some have contraindications to DOACs and can be treated with IVC filters. Noncompliant patients and patients at high risk of falls (elderly, alcohol) can be effectively anticoagulated and monitored in the hospital but represent a high risk of failure of anticoagulation after discharge. Placement of retrievable IVC filters in these patients and reassessing compliance and safety of anticoagulation in the outpatient setting is a reasonable treatment option. Even though the benefit of placement of IVC filters in clinical scenarios that fall under "relative indications" is plausible, the level of evidence to support it is low and often lacking.

Prophylactic Indications

Patients at very high risk of VTE may benefit from IVC filter placement even if they have not developed a thrombotic event. The indication becomes more compelling if the patient has contraindication to pharmacologic VTE prophylaxis, is bedridden, and is expected to have a prolonged hospital stay or potentially have multiple trips to the operating room. The common scenario is a trauma patient with a combination of neurologic, blood and long bone fracture. Multiple studies have examined routine use of prophylactic IVC filters in specific groups of patients including trauma, bariatric surgery, high risk orthopedic spine surgery, surgical oncology, and high risk general surgery. The literature is very controversial and, despite multiple case series suggesting benefit, systematic reviews failed to show any advantage of routine use of IVC filters for prophylaxis in a predefined patient population. Thus, the decision of placement of prophylactic IVC filters should be individualized and discussed with the referring team of physicians. Also, it is important to acknowledge that IVC filters prevent PE and potentially a life threatening event, but do not protect against DVT. On the other hand, IVC filter placement can increase the risk of DVT.

TECHNIQUE

Planning

As with any surgery, planning for IVC filter placement involves a thorough review of the patient's chart and imaging focusing on the location and extent of the DVT if there is one documented. Access of a thrombosed vein should be avoided. Any cross-sectional imaging (computed tomography or magnetic resonance imaging) is helpful to assess the anatomy of the vena cava and its size. Anatomic variations can be detected before the procedure and will avoid trouble shooting in the operating room. An inferior filter are indicated for an IVC that ranges between 28 and 30 mm in diameter measurement, and documentation of the size of the cava is crucial. It is best to perform measurements on imaging obtained in an elective setting. Imaging obtained in dehydrated or bleeding patients can significantly underestimate the size of the IVC (Fig. 2).

Anticoagulation is held in the perioperative period. If the patient is on a heparin drip, it is held on call to the operating room. Patients on DOACs or low molecular weight heparin typically skip one dose before the procedure. Patients treated with warfarin as outpatients are asked to stop it 5 days before the procedure and are a low molecular weight heparin bridge. After IVC filter placement, anticoagulation is resumed in 24 hours.

Filter Type

IVC filters can be classified as permanent, retrievable (optional), convertible, and temporary. The first two are the most commonly used. A convertible filter is a device that is placed for interruption of the IVC and can be altered later to a no filtration state. The Veta Tech Convertible (R Stents) can be changed into a nonfiltration state by snaring the hook/apex of the filter, whereas Sentry (Novate Medical), recently approved by the FDA, spontaneously converts after dissolution of a biodegradable filament holding the arms of the filter together. Temporary IVC filters do not have wall fixation but are attached to a catheter or wire that traverses the venous system and is externalized. The Angel Catheter (Bard Medical) was approved by the FDA in 2011 to be placed at the bedside via femoral access and serve as an IVC filter as well as an infusion device for up to 30 days.

A permanent IVC filter should be used if the patient will require lifelong interruption of the vena cava. An analysis of the FDA Manufacturer and User Facility Device Experience database showed that the majority (86.8%) of reported long-term complications of IVC filter were due to retrievable filters, whereas permanent filters constituted only 13.2% of the cases. However, in a recent survey of vascular specialists, 42% of respondents chose to place a retrievable IVC filter and leave it in situ instead of using a permanent IVC filter. The most

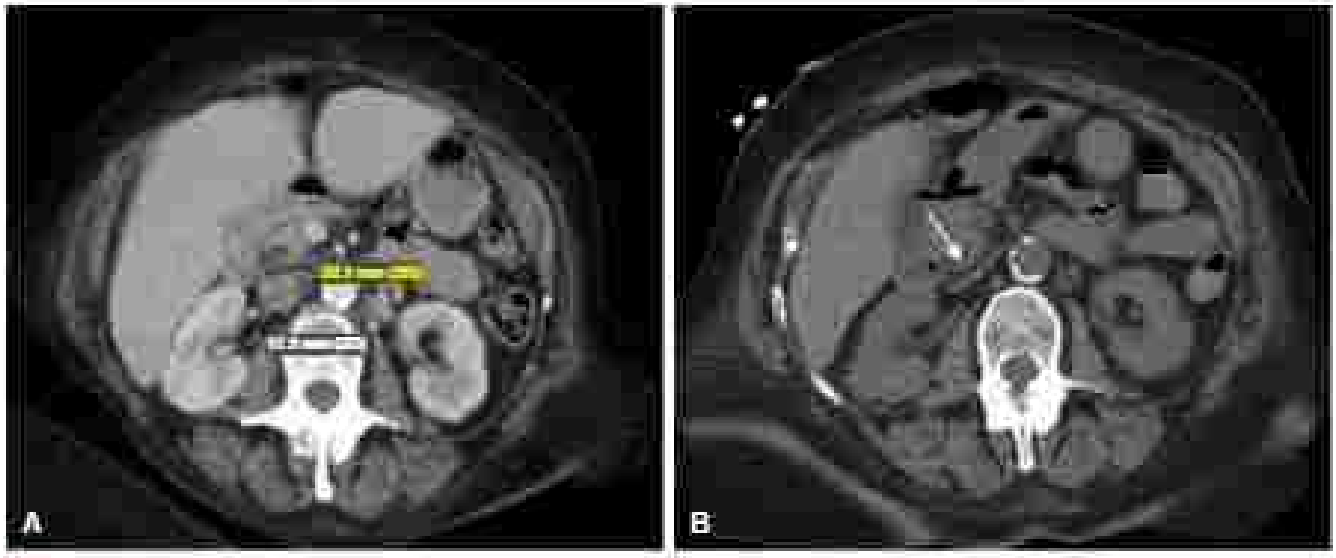

FIG. 2. Planning for inferior vena cava (IVC) filter placement. (A) Computed tomographic (CT) scan of a patient obtained for cancer surveillance on axial view demonstrates the vena cava with a diameter of 17 × 23 mm. (B) The same patient underwent CT scan emergently after an episode of bleeding and the IVC is totally collapsed.

common permanent filters used by operators were the Greenfield filter (29%) (Boston Scientific) and the Vena Tech LP (14%) (B. Braun). On the other hand, the Celect (27%) (Cook Medical Inc.) and Denali (20%) (Bard Peripheral Vascular) were the most popular retrievable filters. Both Celect and Denali have more advanced designs that incorporate a tilt centering mechanism to avoid tilting. Table 2 shows salient characteristics of commercially available IVC filters.

Access

Venous access is obtained under ultrasound guidance and using a micropuncture set to reduce iatrogenic injury. Ultrasound examination also confirms the patency of the vein and the absence of DVT. The vena cava is right sided in the vast majority of patients and access from the right femoral vein or right jugular vein is preferred as it provides optimal straight alignment and minimizes the risk of tilting with deployment. Left femoral vein access is a good alternative if the right sided veins are not accessible. IVC filter placement has been also described via brachial or popliteal vein access. A device with a long enough delivery system to deploy the filter in the desired anatomical location should be ensured in these special circumstances.

Venography

A 6Fr sheath is placed typically in the right common femoral vein. Angiogram can be performed through the sheath and can delineate the anatomy. A large volume of contrast, typically 20 mL (dilute contrast with saline 50:50), is needed to fully opacify the vena cava and visualize the confluence of the iliac veins and renal veins. Unlike arterial angiography, the branches in the venous system are tributaries and circulate blood into the IVC. This is analogous on angiography as rapid washing of contrast and mixing with blood (Fig. 3A). The renal veins commonly drain into the cava at the level of L1–L2 vertebral bodies while the confluence of the iliac veins is often at the level of L5. If there is uncertainty about the anatomy, a flush catheter can be placed at the confluence of the iliac veins and that typically improves visualization of the tributaries. (Fig. 3B) Alternatively, the iliac veins and renal veins in question can be selected and imaged individually.

This step is crucial to document the following:

1. Rule out IVC: In the presence of iliac vein thrombus, the operator should find alternative access to deliver the filter. Manipulation in the presence of thrombus should be avoided to prevent dislodgement and embolization.
2. Identify the optimal position for placement. The IVC filter should be placed in the infrarenal segment of the IVC with the tip/dome to or at the level of the lowest renal vein. As such, the filter does not interfere with the venous return of the kidneys. Having the tip at the level of the renal vein can prevent the formation of low flow state in the IVC above the filter if significant thrombus is trapped. The presence of thrombus in the infrarenal IVC is a contraindication for filter placement in that location. A suprarenal position is more appropriate if it is free from thrombus. Also, in pregnant women, IVC filters should be placed in the suprarenal position to avoid compression by the gravid uterus. A recent study of suprarenal IVC filters with up to 20 years of follow up found no incidence of renal vein compression. The authors suggested that suprarenal IVC filter placement is as safe as the infrarenal.
3. Measure the IVC diameter. As mentioned earlier, most IVC filters are indicated for placement in the vena cava with diameter between 28 and 30 mm, therefore, it is crucial to measure the IVC at the desired location of deployment to avoid embolization of the filter. This can be done with computerized software available in most angiography suites. Alternatively, a radiopaque marking ruler can be placed on the left side of the abdomen for calibration. Table 2 summarizes the diameter indicated for each IVC filter. The Bard's Recovery (Cook Medical Inc.) is a permanent filter and is the only device indicated for vena cava size between 28 and 40 mm.
4. Identify anatomic variation. Anatomic variations of the IVC that can affect filter placement are rare. Duplication of the vena cava resulting from persistence of the right and left supracardinal veins occurs in 0.2% to 3.0% depending on the series reported. The left-sided cava typically joins the left renal vein which then joins the right side IVC to form the suprarenal vena cava. This

TABLE 2 Characteristics of IVC Filters

Filter (Manufacturer)	Design	Maximum IVC Diameter (mm)	Delivery Sheath Size (Fr)	Mean Duration of Implantation Conversion (Range)
RETRIEVABLE				
Denali (Bard Peripheral Vascular)	Conical	28	6 F	149 days (5–34 days)
Günther Tulip (Cook Medical)	Conical	30	7	11 days (2–20 days)
Celect (Cook Medical)	Conical	30	7	55 days (7–869 days)
ALN (ALN)	Conical	28	7	85 days (78–108 days)
Option Elite (Argon Medical Devices)	Conical	30	6 F	Within 175 days
Option (Cordis Corporation)	Double basket	30	6	Up to 42 days
Convertible				
Vena Tech Convertible Filter (B. Braun)	Conical	28	10	130 days (15–391 days)
Permanent				
Stainless Steel Greenfield (Boston Scientific)	Conical	28	12	Life long
Titanium Greenfield (Boston Scientific)	Conical	28	12	Life long
Vena Tech LP (B. Braun)	Conical	28	7	Life long
Trapease (Cordis Corporation)	Double basket	30	6	Life long
Bard's Noir (Cook Medical)	Pre-shaped wires	40	12	Life long

IVC, inferior vena cava.

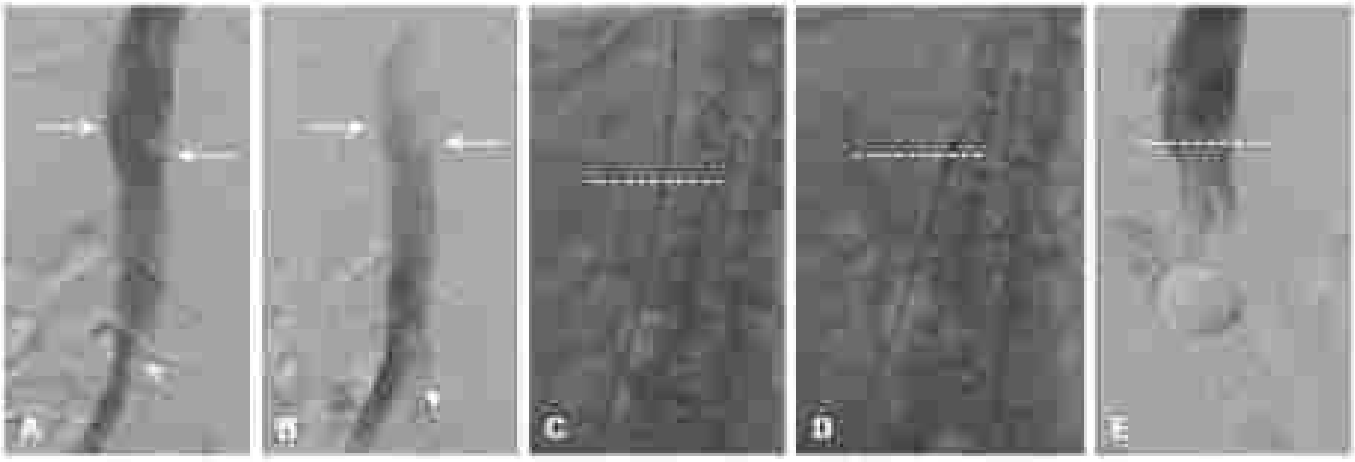

FIG. 1 (A) Placement of inferior vena cava filter (anteroposterior). Venography can be performed through a femoral sheath and normal anatomy is suggested by mixing of blood from the left. Blue vein (arrows). Pooling of blood at the level of L1–L2 demonstrates the location of the renal veins. (B) Alternatively a catheter can be placed at the confluence of the iliac veins and confirm the findings. A radiopaque graduated ruler helps with calibration and positioning and the lowest renal vein coincides with the 3-cm mark in this case. (C) The tip of the sheath is advanced to this mark (dotted line). (D) The inferior vena cava filter is unsheathed and the tip is maintained at the mark. (E) Completion angiogram demonstrating the alignment of the filter and tip location at the level of the lowest renal vein.

anomaly should be suspected when there is no opacification of blood at the iliac vein confluence and the IVC appears to be relatively small in caliber (Fig. 4A). Also, a relatively large left renal vein can be noted (Fig. 4B). The confirmation of this anomaly would require access of the left common femoral vein for angiography (Fig. 4C). The recommended treatment is placement of two separate IVC filters in each of the vena cava (Fig. 4D) or placement of a single suprarenal IVC filter. A single left sided IVC results from persistence of the left supracardinal vein and regression of the right one and occurs in 0.2% to 8.2% of them. The left sided IVC typically crosses to the right at the level of the renal veins. The presence of multiple renal veins on each side is common necessitating sometimes placement of a suprarenal IVC filter. Last, IVC atresia or the developmental absence of the IVC is a contraindication to placement and can be identified on preprocedure cross-sectional imaging or venography.

Deployment

IVC filters are deployed by unsheathing. All filters have delivery systems of variable calibers ranging from 6 Fr to 12 Fr (Table 1). The sheath and the catheter carrying the filter usually have markings to guide the operator in positioning. The sheath should be advanced over the wire under fluoroscopic guidance and the tip of the sheath (not the dilator) should be positioned at the desired location of the tip of the IVC filter (Fig. 3C). After, the filter is advanced all the way to the sheath. The filter is deployed by a pin and pull technique to unsheath the filter (Fig. 3D). Some filters have additional release mechanism that requires the operator to detach the filter from the delivery catheter when it is completely out of the sheath. After finishing deployment, the catheter carrying he filter should be retracted slowly under screen to make sure that the filter is completely detached, and the catheter is not trapped inadvertently between the legs of the filter.

Completion

A completion venogram is performed to ensure the position of the filter and the absence of tilting. Also, the relation of the filter to the renal veins is documented (Fig. 3E). The sheath is removed, and pressure is held on the access site for 15 minutes. Patients remain supine with bed rest for 3 hours after femoral puncture.

This is a comprehensive description for IVC filter placement under fluoroscopic guidance. Table 1 provides a summary for most frequently encountered anomalies encountered during the procedure. IVC filter placement can also be performed under guidance of intravascular ultrasound or transabdominal ultrasound at the bedside. These alternative techniques are particularly useful for unstable patients in the intensive care unit who cannot be transported safely to an operating suite. The learning curve is steep and there is higher incidence of filter malposition. Patients with advanced renal insufficiency may also benefit from ultrasound guidance. On the other hand, the use of carbon dioxide angiography can eliminate the need of nephrotoxic contrast dye.

OUTCOMES

IVC filter placement is a brief procedure with high technical success (94%–100%) and low complication rate (1%–3%). The Prevention of Recurrent Pulmonary Embolism by Vena Cava Interruption (PREPIC) trial randomized 400 patients with proximal DVT to anticoagulation alone compared with insertion of a Greenfield permanent IVC filter and anticoagulation. The results showed lower incidence of PE in the group of patients receiving IVC filters at 12 days (1.1% vs 4.8%, $P = .03$), 2 years (3.4% vs 6.3%, $P = .16$ not statistically significant), and 8 years (6.2% vs 15.1%, $P = .08$) of follow up. However, patients with IVC filters had significantly higher incidence of DVT at 2 years (20.8% vs 11.6%, $P = .02$) and 8 years (35.7% vs 27.5%, $P = .04$) compared with patients treated with anticoagulation alone. There was no difference in mortality or incidence of postthrombotic syndrome between the two groups. The PREPIC trial concluded that IVC filters offer protection from PE but increase the risk of DVT with no overall impact on mortality. Similarly, PREPIC2 randomized 399 patients with diagnosed DVT and PE to anticoagulation compared with insertion of an ALN retrievable IVC filter and anticoagulation. All the patients had at least one additional criterion of severity: age older than 75, active cancer, chronic cardiac or respiratory insufficiency, ischemic stroke with leg paralysis in the last 6 months, thoracal or bilateral DVT, or intermediate- or high-risk PE. Most filters were retrieved after evaluation at 3 months of insertion. There was no difference between the two groups in terms of recurrence of PE, recurrence of DVT, or mortality at 3 months and 6 months. PREPIC2 showed no benefit for the use of IVC filters in addition to anticoagulation in high risk patients and calls into question the relative indications for placement. In one study looking at patients with PE in the Nationwide Inpatient Sample, Stein et al. found that hemodynamically unstable patients with PE had lower mortality when IVC filters were placed compared to similar patients

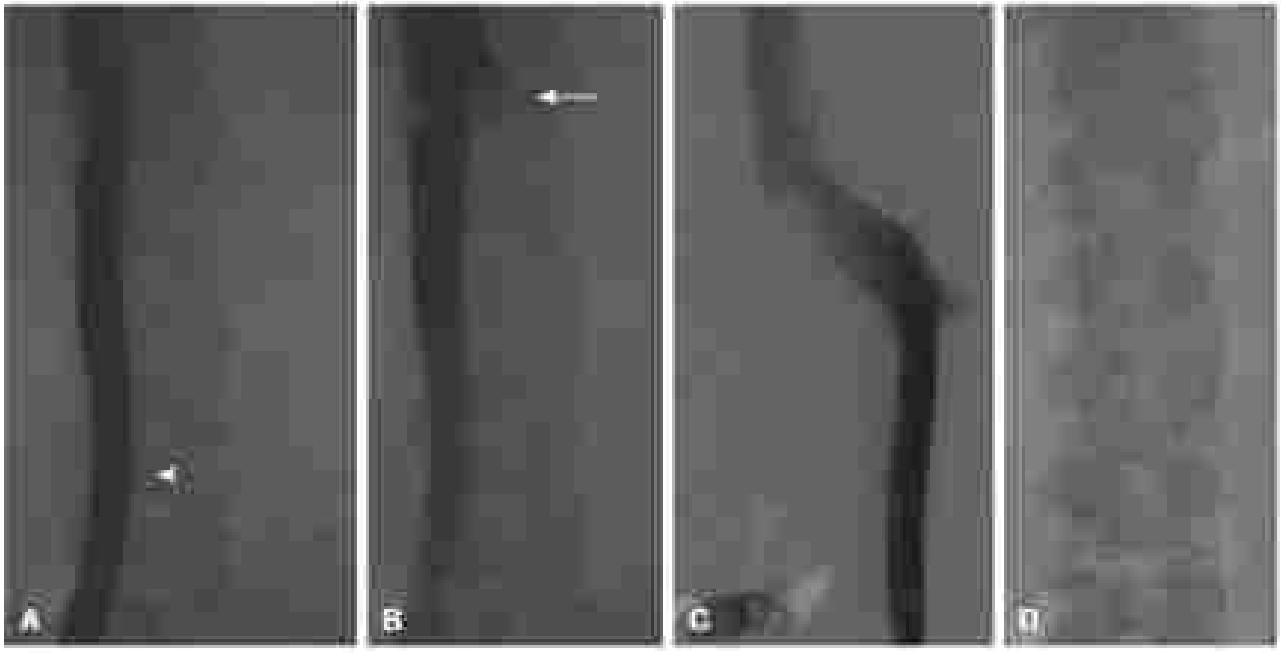

FIG. 4 (A) Duplication of the vena cava (preferred). The venogram of a patient with duplication of the inferior vena cava (IVC) demonstrates the relatively smaller right-sided IVC with lack of mixing of contrast at the expected location of the confluence (B, arrow) and a relatively large left renal vein. (C) Acquisition of the left femoral vein and duplicated venography demonstrates typical course of a left-sided IVC. (D) Patient treated with two separate IVC filters.

TABLE 3 Troubleshooting Unanticipated Findings on Venography During IVC Filter Placement

Unanticipated Finding	Suggested Action
Thrombus in ipsilateral iliac vein	Place IVC filter through alternative access
Thrombus in infrarenal IVC	Consider placement of suprarenal IVC filter via jugular access
IVC diameter >30 mm	Consider placement of Bird's Nest filter for IVC diameter 30–40 mm Consider placement of 2 separate iliac vein IVC filters
Duplication of the IVC	Consider placement of 2 separate IVC filters in each infrarenal cava Consider placement of suprarenal IVC filter
IVC stenosis	IVC filter contraindicated
Left-sided IVC	Consider suprarenal IVC filter placement depending on renal vein anatomy

IVC, inferior vena cava.

without IVC filters. The study suggested that IVC filters are associated with decreased mortality but has several limitations of large database analysis including lack of granularity and limited follow up.

COMPLICATIONS

Short-Term

The most common complications are related to access and include thrombosis, arteriovenous fistula, hematoma, and pneumothorax. These complications have likely decreased with the use of new lower profile devices and the use of ultrasound guided access. Filter tilt, malposition or incomplete opening also occur in some patients. Mortality is rarely reported (<1%) and is usually from patient comorbidities.

Long-Term

Breakthrough PE despite the presence of an IVC filter has been reported between 1% and 4% with different devices. Retrievable filters tend to have higher long-term complications including fracture, migration, and complete thrombosis of the IVC. Penetration of the struts through the wall of the cava is common and most patients remain asymptomatic. However, symptomatic penetration into adjacent structures have been reported to affect the aorta, ureter, bowel, pancreas, and ureter leading to significant morbidity and mortality. The incidence of these complications remains unknown and is the focus of the ongoing PRECISE (Predicting the Safety and Effectiveness of Inferior Vena Cava Filters) trial.

FILTER RETRIEVAL

Operators placing retrievable IVC filters should have a mechanism for follow-up for patients and educate them about the long term risks of filters and the importance of their removal. Every filter has a mean duration of implantation which is the window for safe retrieval (Table 2). Morales et al. used mathematical modeling incorporating the risks and benefits of IVC filter removal and suggested that the ideal time is between 29 and 54 days after implantation. Removing a filter in that time frame is usually a relatively simple and safe procedure performed via jugular access. A snare is used to capture the hook at the apex of the filter and a coaxial sheath is advanced to collapse it and free it from the wall of the vena cava. Prolonged dwell time, filter tilt, apposition of the hook to the wall of the cava, and penetration of the struts into adjacent structures make the procedure more challenging and can increase complications. Still, most IVC filters can be removed via endovascular means but require advanced techniques and skills. Brown and Haskal have a good review of the different advanced endovascular techniques described for IVC filter removal. These techniques require frequently multiple access sites and commonly involve the off-label use of devices such as bronchoscopy forceps, endoscopy

proper, and knee sheath. The retrieval rate of filters is 90% to 100% in experienced centers and filters have been removed up to 16 years after implantation. In rare cases, filter removal is impossible or deemed unsafe via endovascular means. If the patient has a complication from the IVC filter, then open surgical removal is a safe option via laparotomy. Alternatively, robot-assisted minimally invasive removal of IVC filter has also been described but requires transfer to a dedicated center where the appropriate expertise is available.

Treatment of Varicose Veins

Misaki Kiguchi, MD, and Ellen Dillavou, MD, FACS

Varicose veins are a sign of increased venous pressure and are present in 10% to 30% of the general population, with increasing prevalence in older subgroups. Elevated venous pressure often occurs with valvular incompetency, inadequate calf pump function, and/or venous obstruction, and often cause achiness, fatigue, swelling, heaviness, and throbbing. These symptoms are exacerbated by standing, resulting from increased venous pressure and improved with leg elevation or compression. The chronicity and degree of venous hypertension contribute to its sequelae, ranging from mild vein dilation to longstanding venous ulcers. These clinical signs are classified by the CEAP categorization, describing the clinical manifestation (C), etiology (E), anatomic disease distribution (A), and pathophysiology (P). Consistent and appropriate use of the CEAP classification, as well as use of current anatomic terminology, is important for interprovider communication as well as communication to payers.

Increased venous pressure, for the most part, is of low mortality and morbidity, but the resultant symptoms undoubtedly affect quality of life (QoL). For venous disease, validated QoL assessments particularly for venous symptoms (e.g., Aberdeen Varicose Vein Score; Chronic Venous Insufficiency Questionnaire; Temple IWT, Venous Insufficiency Epidemiological & Economic Study, Charing Cross Venous Ulcer Questionnaire) play a vital role in not only distinguishing which patients would benefit the most from intervention, but also help manage expectations relating to therapeutic choices.

DIAGNOSIS

A detailed history and physical is the cornerstone to the assessment of the venous patient because this will elucidate whether the patient's complaints are related to venous causes and could thus be improved with treatment. It is imperative that the patient has a chance to express their symptoms and has a physical examination, which can assess the likely anatomic culprits leading to venous insufficiency. A venous ultrasound examination, performed standing or while in deep reverse Trendelenburg, is then necessary to delineate anatomy (deep, superficial, and perforators), assess reflux in all these beds, measure reflux time/vein diameter, and evaluate for acute or chronic thrombus and scarring. These data are then evaluated in the context of the patient's history to determine if there is a correlation between the patient's complaints and the anatomic or functional pathology that is evident. Because much of venous disease is symptomatic, responsible practitioners need to have a high degree of certainty that a chosen therapy will improve symptoms, and thus, also meet patient expectations.

Thresholds for Reflux

Pathologic reflux is defined by reversal of flow greater than 500 ms in duration in the superficial system and perforators. Pathologic reflux in the deep system (femoral and popliteal veins) is defined as longer than 1 second in duration. Saphenous veins larger than 5.0 mm and perforating veins larger than 3.5 mm in diameter should be noted and considered significant during the ultrasound evaluation for chronic venous insufficiency.

The evaluation of reflux is important, as all reflux is not the same. A diminutive great saphenous vein (GSV) (2–3 mm) with very prolonged reflux (4–5 seconds) likely has a low volume of reflux and is unlikely to cause symptoms (Fig. 1). A large GSV (>8 mm) with high flow is more likely to be clinically significant. Isolated segments of reflux between competent valves are unlikely to be problematic, unless they feed a large perforator that causes distal incompetence. Varicosities and telangiectasias over the lateral malleolus are unlikely to improve with GSV ablation even if the vessel meets criteria for reflux, unless there are incompetent branches that lead to the symptomatic area. Predominant varicosities in this distribution are typically due to small saphenous vein (SSV) or local perforator reflux (Fig. 2). These types of anatomic and symptomatic variants are the challenging part of venous assessment and treatment because appropriate care with optimal results requires a pairing of the patient history, physical exam, and ultrasound findings.

Management of Deep Reflux

Although valve transplantation, valvuloplasty, and other surgical therapies have been attempted, there are no current recommendations for surgical correction of deep venous reflux. Compression, weight management, exercise, and leg elevation are all useful behavioral strategies.

MANAGEMENT OF SUPERFICIAL REFLUX

Techniques

Endovenous Surgical Techniques

Carlos Bond introduced venous laser ablation in 1999 and radiofrequency was commercially available with the VNUS ClosureFAST catheter in 2003. These treatments revolutionized venous care and

proper, and knee sheath. The retrieval rate of filters is 90% to 100% in experienced centers and filters have been removed up to 16 years after implantation. In rare cases, filter removal is impossible or deemed unsafe via endovascular means. If the patient has a complication from the IVC filter, then open surgical removal is a safe option via laparotomy. Alternatively, robot-assisted minimally invasive removal of IVC filter has also been described but requires transfer to a dedicated center where the appropriate expertise is available.

Treatment of Varicose Veins

Misaki Kiguchi, MD, and Ellen Dillavou, MD, FACS

Varicose veins are a sign of increased venous pressure and are present in 10% to 30% of the general population, with increasing prevalence in older subgroups. Elevated venous pressure often occurs with valvular incompetency, inadequate calf pump function, and/or venous obstruction, and often cause achiness, fatigue, swelling, heaviness, and throbbing. These symptoms are exacerbated by standing, resulting from increased venous pressure and improved with leg elevation or compression. The chronicity and degree of venous hypertension contribute to its sequelae, ranging from mild vein dilation to longstanding venous ulcers. These clinical signs are classified by the CEAP categorization, describing the clinical manifestation (C), etiology (E), anatomic disease distribution (A), and pathophysiology (P). Consistent and appropriate use of the CEAP classification, as well as use of current anatomic terminology, is important for interprovider communication as well as communication to payers.

Increased venous pressure, for the most part, is of low mortality and morbidity, but the resultant symptoms undoubtedly affect quality of life (QoL). For venous disease, validated QoL assessments particularly for venous symptoms (e.g., Aberdeen Varicose Vein Score; Chronic Venous Insufficiency Questionnaire; Temple IWT, Venous Insufficiency Epidemiological & Economic Study, Charing Cross Venous Ulcer Questionnaire) play a vital role in not only distinguishing which patients would benefit the most from intervention, but also help manage expectations relating to therapeutic choices.

DIAGNOSIS

referral to a source of minimally invasive, low morbidity, and highly effective treatment. Currently, a wide variety of minimally invasive therapies is available to treat patients safely and comfortably (Table II).

Radiofrequency Ablation

The ClosureFAST catheter (Medtronic) has a bipolar electrode to provide radiofrequency heat energy directly to the vein, causing endothelial destruction, contraction of the vein wall, and thrombus formation. The vein will contract and scar over the 6 months following treatment.

Steps for radiofrequency ablation (RFA) of saphenous veins:

1. Prep the appropriate leg in the standard, circumferential sterile fashion.
2. Ultrasound scan is performed as the first step of the sterile procedure as before prep; map out the saphenous and assess the vein for occlusion, aneurysm, exceptionally superficial venous locations, webbing, or other anatomic details that may make the procedure difficult or less successful.
3. Access the vein percutaneously using ultrasound guidance after anesthetizing the superficial skin with lidocaine. Access is most easily initiated just below the popliteal area on the medial calf for GSV. Accessing more distally on the great saphenous may be indicated for treatment of reflux along the length of the vein in CEAP 3 to 6 patients, but it increases incidence of saphenous nerve injury. Similarly, small saphenous access is typically in the mid to lower one third of the calf as more distal access can result in sural nerve injury.
4. Thread microwire through the needle and confirm under ultrasound guidance.
5. Remove the needle while keeping the microwire in place.
6. Flush the 7Fr introducer sheath with saline and place over the microwire into the vein.
7. Remove the inner dilator and wire. Flush sheath.
8. Attach catheter to the generator.
9. Flush the catheter with sterile saline and cap the Luer port.
10. Insert the catheter through the sheath and advance.
11. Optional: If the catheter does not advance easily, a 0.025-inch Glidewire (Terumo Corporation) may be backloaded into the catheter to guide catheter insertion. Alternatively, distal traction on the skin of the leg and stabilization of the vein with the contralateral hand frequently allows for the catheter to be passed through moderately tortuous veins.
12. Confirm tip position with ultrasound guidance to be at least 2 cm inferior to the epigastric vein immediately distal to the saphenofemoral junction. For the small saphenous, catheter tip should

TABLE 1 Advantages and Disadvantages of Endovenous Techniques

Technique	Advantages	Disadvantages
RFA	• Good for large veins >1 cm • Used for entrapment	• Nerve injury • Use of tumescence • Difficult in partially occluded or tortuous veins • Compression use postprocedurally
EVLA	• Good for large veins >1 cm • Used for entrapment	• Nerve injury • Use of tumescence • Not used in very superficial veins • Difficult in partially occluded or tortuous veins • Compression use postprocedurally
MOCA	• No tumescence • Good for veins <12 mm • Good for superficial veins • Coil distributes into varicosities and perforators	• Poor for entrapment • Difficult in partially occluded or tortuous veins • Compression use postprocedurally
Pfahlstand endovenous microfoam	• No tumescence • Good for tortuous veins • Good for veins <10 mm • Good for superficial veins • Coil distributes into varicosities and perforators • Used for entrapment • Easy to use in partially occluded or tortuous veins	• Compression use post procedurally • Treated veins are often tender and thrombosed for months • Risk of >1 / 1 from extravasation through perforators • Closure of vein on ultrasound is lower than seen with other forms of ablation, although this may not predict a failure of clinical result
Glue	• No tumescence • Good for veins <10 mm • Good for superficial veins • Glue distributes into varicosities and perforators • Used for entrapment • No postprocedural compression needed	• Difficult in partially occluded or tortuous veins • Foreign body left in vein • Hypersensitivity reaction to adhesive occurs in 5% to 10% of patients

DVT, deep vein thrombosis; EVLA, endovenous laser ablation; MOCA, mechanochemical ablation; RFA, radiofrequency ablation.

be positioned in the superficial portion of the small saphenous and not advanced past the point where the vein dives deep to form the saphenopopliteal junction (SPJ). This point is typically at least 3 cm from the SPJ. The catheter and vein can be imaged in the longitudinal access distance measured and recorded to ensure adequate distance.

15. Move the grommet to the end of the sheath to mark the position.
16. Administer tumescent to the perivenous tissue under ultrasound guidance, striving to create a halo of tumescence around the vein within the saphenous fascia. Tumescence should extend at least 2 cm proximal to the tip of the catheter to ensure adequate anesthesia and to form a barrier between the heat of the catheter and the deep veins.
17. Position the heel in a Trendelenburg position to facilitate vein collapse.
18. Apply compression over the length of the heating element to facilitate contact between the vein wall and heating element.
19. Press the white device button on the catheter handle to initiate treatment. Watts used during treatment cycle should fall to below 10 at some point during the cycle. Increasing compression can decrease the watts needed to treat the segment of vein.
20. When the treatment cycle is complete, index the catheter to the next shaft mark position. Apply compression over the entire heating element and start next treatment. Treat the segment close to the junction twice. Consider a third cycle near the junction or a second cycle more distally if vein is greater than 10 mm, if there are large branches or perforators exiting from the segment, or if the wattage does not fall below 10. Do not treat any segment more than three times.
21. Repeat withdrawal in sequential shaft marks, compression, and treatment.
22. Remove the sheath over the catheter once the vein is treated over the hashmarks on the catheter.
23. Withdrawal until the last index mark is seen. Apply compression over the entire heating element and start last treatment. Take care not to withdraw the catheter beyond the three hash mark area as a more superficial catheter location could possibly get the heating element too close to the puncture site and burn the skin.
24. Remove catheter and sheath, and apply compression over the access site for hemostasis.
25. Apply compression from the foot up to the thigh.
26. Review postprocedure instructions.

RDA treatment of perforating veins (Fig. 3) should be reserved for vein diameters greater than 3.5 mm at the fascial level, within ranges from 0.5 seconds (2 J) to 2 seconds, and under or in proximity to ulcers.

1. Position the perforator vein to long view.
2. Make a small nick in the skin.
3. Through the small nick, use the RF catheter to directly puncture, or use Seldinger technique to access the perforator vein under ultrasound guidance.
4. Position the tip of the RF catheter 2 to 3 mm from the deep vein or at the fascial level, depending on anatomy.
5. Remove stylet and confirm tip position again.
6. Infiltrate local anesthesia around the perforator tissue.
7. Treat four quadrants for 30 seconds each.
8. Withdraw catheter 3 to 5 mm and repeat treatment.

Endovenous Laser Ablation

The laser ablation catheter provides laser heat energy directly to the vein, causing endothelial destruction, contraction of the vein wall, and thrombus formation, similar to RFA. There are several commercially

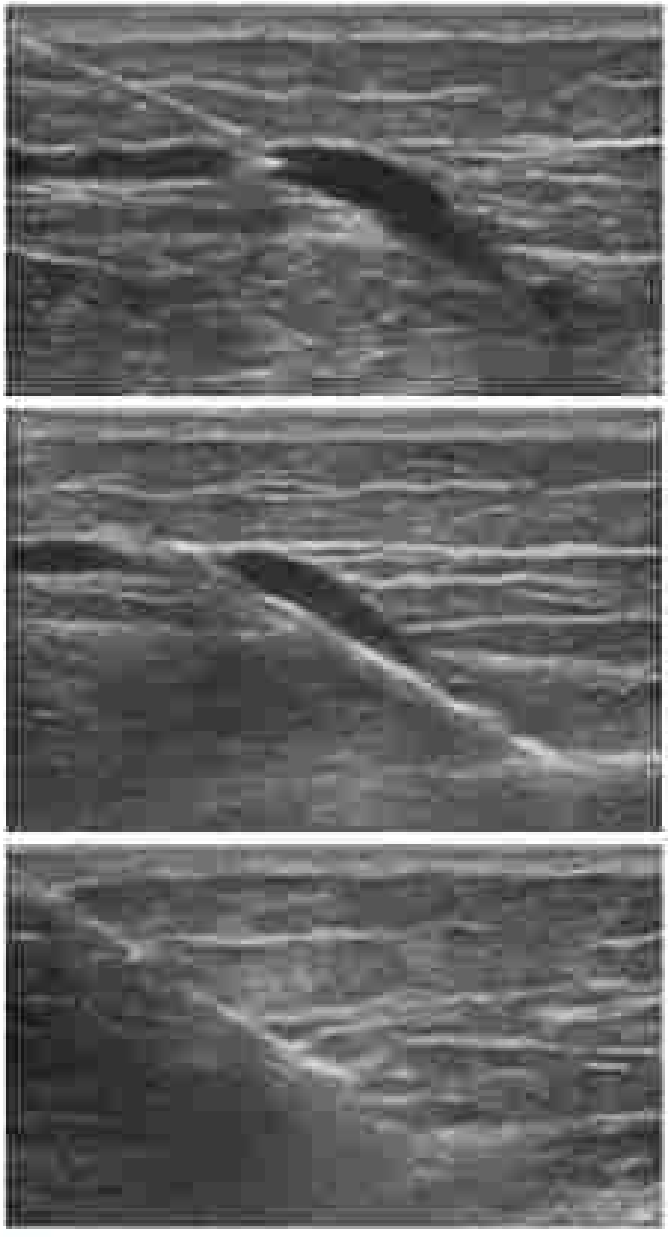

FIG. 3 Radiofrequency ablation of incompetent perforator with stylet in place.

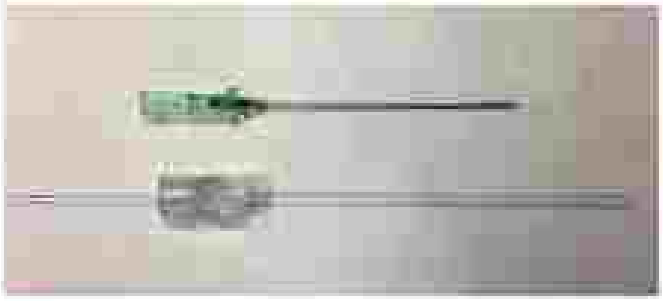

FIG. 4 Microsheath and introducer for perforator endovascular laser therapy.

available lasers in different wavelengths, from 980 to 1470 nm. The longer wavelengths are targeted to less dense matter (i.e., serum) and so are less likely to cause tissue destruction. Thus, 1470 nm is generally as effective as the shorter wavelengths but produces a more comfortable therapy.

Steps for endovenous laser ablation (EVLA) of saphenous veins are generally the same as for RFA. Differences related to use of the laser are described below:

1. Once a microsheath is in place as per the standard protocol, advance a 0.035-inch guide wire to the saphenofemoral junction under ultrasound guidance.
2. Remove the microsheath and select a long sheath based on the measured distance from the junction to the access site.
3. Remove the inner dilator and wire from the long sheath.
4. Advance fiber into the sheath.
5. Connect the fiber to the generator and aim the beam toward the skin.
6. While holding the fiber in place, the sheath is withdrawn to the locking mechanism and locked in place.
7. The tip of the fiber is exposed approximately 2 cm past the end of the sheath.
8. Confirm tip position with ultrasound guidance to be at least 2 cm inferior to the epigastric vein immediately distal to the saphenofemoral junction. For the small saphenous, the catheter tip should be positioned in the superficial portion of the small saphenous and not advanced past the point where the vein dives deep to form the SPJ. This point is typically at least 3 cm from the SPJ. The catheter and vein can be imaged in the longitudinal access, distance measured and recorded to ensure adequate distance.
9. Administer tumescence as described.
10. Position the bed in a Trendelenburg position to facilitate vein collapse.
11. Once the machine is turned and set to 5 to 7 watts from standby to ready mode, step on the foot pedal to deliver laser energy. Pull back the laser fiber and sheath together 1 cm every 5 to 6 seconds.
12. Treatment energy should be administered as per recommendations for each laser (ppm; 80 J/cm (1470 nm laser) and 80 J/cm (980 nm laser) are frequently used settings.
13. Stop treatment by releasing pedal when the laser fiber is 1 to 3 cm proximal to the entry site.
14. Remove fiber and sheath and apply compression over the access site for hemostasis.
15. Apply compression from the foot up to the thigh.
16. Review postprocedure instructions.

EVLA treatment of perforating veins (Figs. 4 and 5) should be reserved for vein diameters greater than 3.5 mm at the fascial level, reflux longer than 0.5 seconds, CEAP Rs 4 patients, and under or in proximity to ulcers.

1. Position the perforator vein in long view.
2. Make a small nick in the skin.
3. Through the small nick, direct puncture and Seldinger technique of the perforator vein under direct ultrasound guidance with the 21 g microneedle.
4. Thread a 1470 nm, 400 μm microfiber through the needle.
5. Position 2 to 3 mm from the deep vein or at the fascial level, depending on anatomy.
6. Infiltrate local anesthesia around the perforator tissue.
7. Set generator at 6 watts and treat with 50 to 100 J per 2 mm.

Mechanochemical Ablation

Thermal ablation requires tumescent anesthesia and has risks of thermal injury to the surrounding nerves and veins. Mechanochemical ablation uses a rotating wire to spasm the junction immediately before injecting sclerosant, which is then delivered with the mechanical agitation. The sclerosant creates chemical endothelial damage, causing fibrosis of the vein.

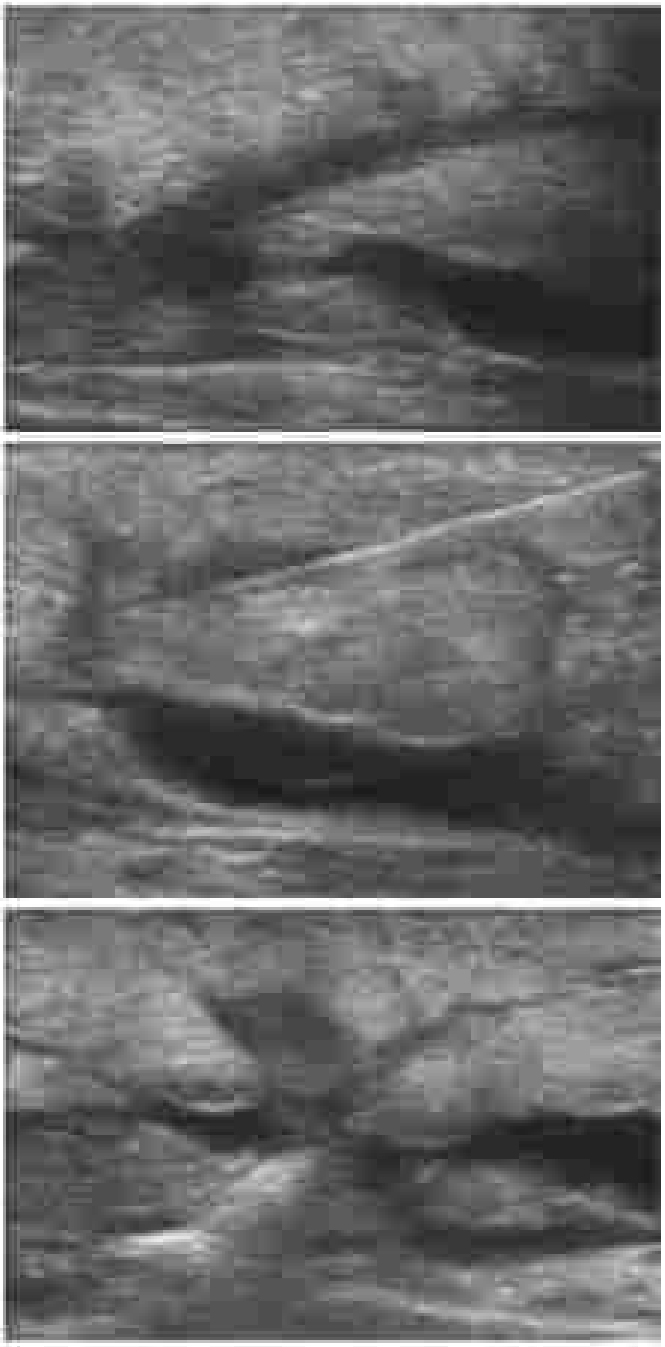

FIG. 8 Endovenous laser ablation treatment of incompetent perforator after local anesthesia infiltration.

Steps for mechanochemical ablation of saphenous veins:

1. The leg is prepped and the vein is accessed as per the RFA technique. Access can be much lower in the calf than for thermal ablation because there is no risk of thermal nerve injury.
2. Place 6F to 7F introducer at 45° angiocath into the vein.
3. A syringe is connected to the open end of the microsheath or angiocath while preparing the catheter.
4. Flush the ClariVein (Vascular Insights) catheter with saline. Place the stopcock in the closed position on the catheter luer lock. Have the sidearm face laterally when attached.
5. Attach the 5-mL sterile syringe containing sclerosant (typically 1% polidocanol or 1% to 3% sodium tetradecyl sulfate) to the stopcock. Ensure no air bubbles.
6. Place the catheter into the sheath or angiocath.

FIG. 9 Initial pull-back segment of ClariVein.

7. Under ultrasound guidance, place the wire tip at least 2 cm distal (inferior) to the SFJ. For SSV ablation, place the wire tip just distal to the fascial curve, within the straight segment of the SSV. If a gastrocnemius vein connects to the SSV, place the wire tip 2 cm inferior to the insertion.
8. Depress trigger briefly to test battery. An LED indicator should turn green.
9. Weld the catheter cartridge to the handle unit.
10. Pull back the cartridge wing further into the handle groove and turn slightly counterclockwise, clicking into the second stop position.
11. The tip of the fiber is exposed approximately 2 cm past the end of the sheath.
12. The index finger depresses the motor trigger while the thumb delivers sclerosant by pressing the syringe plunger after the stopcock is turned open.
13. Continue motor for 3 seconds to produce vasospasm with simultaneous pullback for 0.5 cm and initiate delivery of sclerosant after 0.5 cm pullback.
14. Continue treatment while pulling back 1.5 mm/s.
15. Treatment is stopped when 3 to 4 cm of catheter is left in the leg. A white mark on the catheter marks 4 cm distal to the catheter tip and alerts that only a short segment of catheter is remaining within the vein. Remember to pull the access device out of the vein and skin over the catheter before the catheter tip reaches the access site to ensure treatment of distal vein segments.
16. Once the vein segment is treated, ultrasound imaging of the vein is performed to assess for vein closure.
17. If the vein is patent, immediate retreatment is accomplished by passing the sheathed catheter tip proximally again for retreatment.
18. If the vein is occluded, the wire tip is redeployed by unclipping the syringe, twist the cartridge wing clockwise, and move the handle groove from the second lock position to the first.
19. Withdraw the catheter. Unbraid the wire and inspect.
20. Apply compression over the access site for hemostasis.

Endovenous Closure with Cyanoacrylate: Glue

Rather than using heat or sclerosant, VenaSeal (Medtronic) uses a medical adhesive to close the incompetent vein (Fig. 12). This mechanical technique also avoids nerve injury and then need for procedural anesthesia around the vein. The glue within the vein is technically a foreign body. There is a small population of patients who appear to have a sensitivity to the compound, and a local inflammation or phlebitis has been reported in up to 20% of treated veins or side branches. Steps for VenaSeal of the great/small saphenous veins include the following:

1. Prep the appropriate leg in the standard, circumferential sterile fashion.
2. Optional: a quick, sterile ultrasound scan is performed to mark the skin overlying the targeted treatment vein.

3. Access the vein percutaneously using ultrasound guidance after numbing the superficial skin with lidocaine. Access is routinely initiated at the most distal level of reflux. There is no risk of thermal nerve injury.
4. Insert the microwire and sheath, remove wire and dilator.
5. Advance the 0.035 J wire through the sheath into the vein and position just caudal to the junction. Confirm position under ultrasound.
6. Remove the introducer sheath over the wire and advance the 2Fr introducer/dilator from the system over the J wire to the junction.
7. Remove the wire and inner dilator.
8. Flush the sheath with sterile saline using a flushing syringe. Keep the syringe in place.
9. Position the tip of the sheath 5 cm inferior the junction under ultrasound guidance.
10. Extract the VenaSeal adhesive from its vial with a 3cc syringe. Purge air.
11. Connect the 3 mL syringe to the 5Fr catheter. Lock the 3 mL syringe attached to the catheter to the dispenser gun.
12. Prime the catheter by pulling the trigger to advance the adhesive to within 2 to 4 cm of the distal catheter tip.
13. Remove the saline filled flushing syringe from the introducer.
14. Insert the primed catheter/gun complex into the introducer and advance until the laser mark on the catheter is at the hub of the sheath.
15. Pull the sheath caudal another 3-4 cm. Advance the catheter cephalad and lock the sheath to the catheter/gun complex.
16. Verify tip is 5 cm away from the junction.
17. Position the ultrasound probe just cephalad to the catheter tip and apply pressure to compress the junction.
18. Deliver 0.10 mL of adhesive to the vein by pulling the trigger of the gun. Hold the trigger down for 3 seconds.
19. Immediately pull back 1 cm and deliver another 0.10 mL of adhesive and hold for 3 seconds.
20. Pull back the entire system 3 cm. Hold transverse compression at the junction for a minimum of 5 minutes.
21. Locate the catheter tip position with ultrasound. Apply probe compression caudal to the previous injection and cephalad to the catheter tip and deliver 0.15 mL of adhesive and hold the trigger down for 3 seconds.
22. Immediately pull back the entire system 3 cm and hold probe compression for 30 seconds.
23. Repeat steps of adhesive injection, pull back, and compression for 30 seconds, until 5 cm cephalad from access site.
24. Remove all catheters and apply manual pressure for hemostasis.

Polidocanol Endovenous Microfoam

Varithena (BTG Corp) is a commercially prepared 1% polidocanol microfoam that is uniform in density, size, and stability. This displaces blood within the incompetent saphenous vein, filling the vein, and damaging the endothelium with polidocanol subvenous. This nonthermal technology does not require tumescent anesthesia.

Steps for Varithena of the great saphenous veins are the following:

1. Prep the appropriate leg in the area of cannulation. Ultrasound as previously described, with special attention to marking perforators and large branches.
2. Access the vein percutaneously using ultrasound guidance after anesthetizing the superficial skin with lidocaine. Access is routinely initiated at the most distal level of reflux. There is no risk of thermal nerve injury.
3. Secure the intravenous or micropuncture catheter.
4. Elevate the leg 45 degrees.
5. Carefully the foam by connected the syringe to the canister and activating the canister to infuse foam into the syringe in 5 mL increments.
6. Inject the foam into the intravenous catheter while compressing the vein distally and compressing any perforators. Inject approximately 1 mL/s in the GSV and 0.5 mL/sec in accessory veins.
7. Monitor displacement of the foam into the saphenous vein during injection. Once the leading edge reaches 5 cm from the SFJ, occlude SFJ with an ultrasound probe for at least 5 minutes. At this point pressure to released from the distal aspect of the treated vein and over large branches. Pressure to continued over the perforators.
8. A maximum of 15 mL of foam is to be given in each treatment session. Patients can be brought back in as little as 24 hours to have repeat treatment as needed.
9. After 5 minutes, confirm with ultrasound that GSV spasm has occurred.
10. Remove IV. Hold external compression for hemostasis.
11. Additional local injections into untreated varicosities can be performed using a 23 gauge butterfly needle.
12. Keep leg elevated for 10 minutes while bandaged and compression is applied.

Postoperative Considerations for Endovenous Surgical Techniques

Most physicians use some type of compression for 7 to 10 days. The exception to this is cyanoacrylate closure, which does not require any postprocedure compression. Varithena instructions for use suggest compression for 14 days. Postprocedural duplex scanning is often performed within 48 to 72 hours of any vein ablation to assess for DVT and confirm closure of the treated vein. Patients are encouraged to ambulate immediately postprocedure and keep up normal activities as tolerated, including exercise.

Potential complications of all endovenous surgical techniques include postprocedural pain, ecchymosis, hematoma, infection, superficial vein phlebitis, deep vein thrombosis, and pulmonary embolism. Specific to thermal ablation, skin burn complications and nerve injury can occur if tumescence is not adequate or treatment involves the lower calf. Endovenous heat induced thrombosis (EHIT) is a specific complication to thermal ablations and is the formation of thrombus in the GSV, extending into the common femoral vein. Although often avoided by initiating treatment 2.5 cm away from the junction, the treatment of EHIT depends on the degree of clot extension into the deep system. Sclerosant use in endovenous surgical techniques, uniquely can cause neurologic complications such as strokes and transient ischemic attacks. Although rare and often self limiting, these symptoms can be quite jarring for both the physician and patient.

Open Surgical Techniques

Most varicose vein surgery is amenable to minimally invasive endovenous techniques. However, open techniques still have a role in treating varicose veins.

- If the target saphenous vein is less than 1 cm from the skin and the distance cannot be increased by tumescent anesthesia, thermal ablation is contraindicated because of the increased risk of thermal injury to the skin. Nonthermal or open techniques are thus preferred.
- Dilated, aneurysmal saphenous veins greater than 2.5 cm are preferentially treated by open techniques due to the risk of superficial thrombophlebitis and EHIT after endovenous treatment.
- The tortuosity of the saphenous vein may limit the passage of catheters. If the patient is not suitable for polidocanol endovenous microfoam, open surgery is then preferred.

Great Saphenous Vein High Ligation and Stripping

- After the standard sterile prep of the affected limb in the supine position, an oblique 2 to 4 cm incision is made over the SFJ as identified preprocedurally by duplex.
- The subcutaneous tissue and saphenous fascia are divided with electrocautery.
- Placement of a self retainer retractor will reveal the GSV underneath.
- The GSV close to the junction to the common femoral vein (CFV) should be dissected.

- Completely visualize the GSV proximally and distally to ensure the anatomy is appreciated and that the GSV is not injured.
- Place two vascular clamps on the GSV: 0.5 cm from the SPJ and the second one distally. Divide vein with Metzenbaum scissors.
- Double ligate the saphenous vein stump with 2.0 silk suture. Information may also come from the surgical site.
- The stripper is inserted into the distal aspect of the divided GSV and advanced to the upper part of the calf. This can be guided and detected manually or with ultrasound as dictated by body habitus.
- Stab the skin just above the end of the stripped with an 11 blade.
- Push the tip of the stripper outside the skin. Dissect the vein and ligate the distal end and divide the vein after the proximal GSV is tied to the stripper.

FIG. 7 Patient's veins are marked preprocedurally while patient is standing.

- The stripper and GSV are pulled out by an eversion technique.
- Place pressure on the GSV canal and place a pressure wrap on the leg for hemostasis.
- Close groin incisions in two layers: 2.0 Vicryl sutures for the fascia and 4.0 Monocryl for the subcutaneous skin.

Small Saphenous Vein Ligation and Stripping

- After the standard sterile preparation of the affected limb in the prone position, a transverse incision is made 2 cm below the SPJ, identified by duplex.
- After dissection of the superficial fascia, the SSV is identified and dissected out, avoiding the sural nerve.
- Placement of a self-retainer retractor will reveal the SSV underneath.
- All branches of the SSV at the SPJ should be double ligated and divided.
- Completely visualize the popliteal vein proximally and distally to ensure no missed SSV tributaries near the SPJ.
- Place two vascular clamps on the SSV: 0.5 cm from the SPJ and the second one distally. Divide vein with Metzenbaum scissors.
- Double ligate the saphenous vein stump with 2.0 silk suture.
- The stripper is inserted into the divided SSV and advanced to the upper part of the calf.
- Stab the skin just above the end of the stripped with an 11 blade.
- Push the tip of the stripper outside the skin. Dissect the vein and ligate the distal end and divide the vein after the proximal SSV is tied to the stripper.
- The stripper and SSV are pulled out by an eversion technique.
- Place pressure on the SSV canal and a wrap on the leg for hemostasis.
- Close larger incisions in two layers: 2.0 Vicryl sutures for the fascia and 4.0 Monocryl for the subcutaneous skin.

Phlebectomy

- All targeted veins should be marked preprocedurally, while the patient is standing (Fig. 7).
- After the standard sterile prep of the affected limb, using an 11 blade, small incisions are made along the previously marked vari cosities, following the direction of the Langer's lines, with the distal incisions being made first.
- Through the incision, the vein is hooked and pulled out of the skin and grasped with a pair of forceps or mosquitos as much as possible before being torn (Fig. 8).

FIG. 8 Vein is hooked and grasped with a pair of mosquito clamps.

- A wrap is started at the distal most incision and the leg is wrapped as the procedure moves cephalad. This minimizes blood loss and ensures distal hemostasis by the end of the procedure.
- Either close the incisions with 4.0 Monocryl or place Steri Strips.

Transilluminated Powered Phlebectomy

Although traditional stab phlebectomy can be performed often in the ambulatory setting, with a scalpel and vein hook, commercial transillumination devices exist to assist in locating the vein. Advantages of transilluminated powered phlebectomy include a limited number of incisions, removal of veins under direct visualization, and a faster removal of varicose veins, especially in clusters (Fig. 9). The power phlebectomy system is made of a central tower with two handpieces. One handpiece is introduced through a small incision to provide proper transillumination (Fig. 10) while another handpiece is introduced to hydrodissect the vein. Small punch incisions (Fig. 11) are made to allow for drainage of the blood and tumescence that may collect in the vein tract to limit postprocedural hematoma and bruising. This procedure is typically performed under general anesthesia.

Postprocedural Considerations for Open Surgical Techniques

- Patients should have compression to the treated leg immediately postprocedurally
- Check for bleeding at the incision sites
- Check for paresthesias of the treated leg
- Mobilize as soon as possible

Cosmetic Treatment of Spider Veins

A thorough history and physical examination should always be performed with any patient evaluation, but with a cosmetic vein evaluation in particular, specific attention should be paid to the patient's goals and expectations. Pretreatment consultation should include discussion of previous treatments and their response. Unrealistic expectations should be avoided. Photo documentation of before and after treatment is recommended. Patients who are pregnant or breastfeeding should not undergo sclerotherapy. Patients who take ethinylestradiol have a higher risk of permanent hyperpigmentation (staining). Patients with a patent foramen ovale should also proceed with sclerotherapy with caution.

Sclerotherapy

Sclerotherapy destroys the vein by direct injection of solution to induce endothelial injury and collapse. Although many agents have been used, the most commonly used sclerosing agents are hypertonic saline, sodium tetradecyl sulfate (STS), and polidocanol (POL).

Hypertonic saline is inexpensive and has minimal allergy potential but is historically painful and caustic to soft tissue outside the vein. STS is less painful and can be used from spider to larger veins (up to 1 cm). It is contraindicated in patients with severe asthma. POL is nearly painless, minimally allergenic, and ulceration with extravasation is rare. It can be used with all sizes of veins up to 1 cm. All sclerosants can cause hyperpigmentation but can be mitigated to some extent with the amount of volume and concentration used.

For telangiectasias and smaller veins, direct injection of a liquid sclerosant with a 30- or 32-gauge needle is recommended. Doses of

FIG. 9 Symptomatic varicosity appropriate for open phlebectomy or transilluminated powered phlebectomy.

FIG. 10 Transillumination of the vein.

FIG. 11 Small punch incisions are made along the treated vein to allow for drainage of the blood and tumescence.

FIG. 12 Tessari method of physician-compounded foam.

0.25% to 0.5% POL and 0.5% to 1.0% STS are typically used for small veins. The needle angle should be very shallow with the bevel up. The sclerosant is gently injected, so as to avoid extravasation.

Physician-compounded foam is created by mixing a gas (typically room air, or carbon dioxide) with the POL or STS to a 1:4 sclerosant to gas ratio, using agitation of the Tessari method (Fig. 12). Of note, creating foam from POL or STS is an off-label use of these FDA-approved sclerosants.

Physician-compounded foam is inexpensive and well tolerated but causes more neurologic side effects. Varithena is an available proprietary foam that delivers a commercially prepared microfoam with a POL/oxygen base. No studies directly compare the safety and efficacy of physician-compounded foam to Varithena, although to extensive trials and aftermarket analysis there have been no published neurologic side effects of Varithena, whereas neurologic side effects, usually transient, are quite common with physician-compounded foam.

Foam sclerotherapy through a 22G butterfly needle allows for a longer period of contact with the vessel wall due to blood displacement rather than sclerosant dilution and a longer period of sclerosant/endothelial contact. The foam is also echogenic under ultrasound (Fig. 13), allowing more precise delivery to targeted veins such as incompetent perforators.

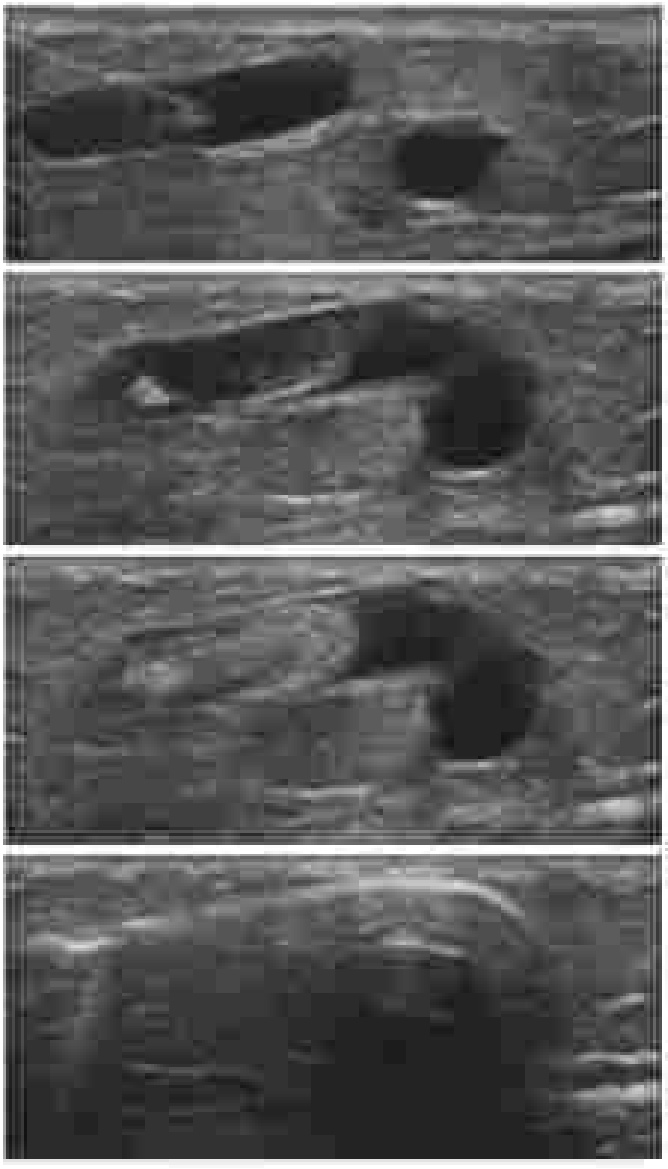

FIG. 13 Ultrasound-guided injection of physician-compounded foam. The foam can be seen to gradually fill and opacify the treated vein.

Comparative Studies

Rasmussen et al. performed 500 consecutive patients in a randomized clinical trial comparing EVLA, RFA, physician-compounded foam sclerotherapy, and surgical stripping of incompetent saphenous veins. Patients were examined by duplex imaging before procedure, after 3 days, at 1 month, and at 1 year. All examined treatments were initially efficacious, but recanalization was highest after foam sclerotherapy. Both RFA and foam sclerotherapy were associated with faster recovery and less postprocedural pain than EVLA and stripping, by QoL measures. A follow-up study at 3 years compared outcomes of recurrence, Venous Clinical Severity Score, and QoL. The treatment modalities were comparably efficacious and resulted in similar improvements in Venous Clinical Severity Score and QoL, but recanalization and reintervention were significantly more often in foam sclerotherapy. The newer nonthermal technologies all have performed very well in initial testing, with very high closure rates and patient satisfaction.

CONCLUSIONS

Endovenous treatments have revolutionized venous therapy, with current methodologies able to treat complex superficial venous pathology in the office with minimal side effects and recovery time. Thermal ablation is the most established of these techniques and delivers high efficacy venous closure with few complications. Radiofrequency may have the most durable results. Newer nonthermal technologies enable even more comfortable treatments that in short- and mid-term follow-up appear safe and effective. Sclerotherapy is a versatile technique to eliminate everything from small cosmetic veins to refluxing perforators causing ulceration. Choice of techniques depends on patient presentation, operator skill, and treatment setting. A thorough discussion of treatment options, expectations, recurrence, and possible morbidities is a mandatory part of any venous evaluation.

Lymphedema

George Kokosis, MD, Hallay Darrach, BS, and Jamie M. Sacks, MD, MBA, FACS

Lymphedema is a chronic, debilitating disease of the lymphatic system that results from failure of the lymphatic transport capacity to overcome the lymphatic load. Impairment of lymphatic transport leads to interstitial accumulation of a protein-rich fluid that includes excess water, plasma proteins, extravascular blood cells, and cell products that are normally transported by the lymphatic system from the interstitium into the circulation. In addition, the peripheral lymphatic vessels play a significant role in the immune system and serve to transport leukocytes and regulate the immune response.

Progressively, lymphatic impairment leads to dilation of the remaining functional lymphatic vessels, failure of valves to maintain unidirectional flow, and eventually stasis. Accumulation of these macromolecules increases the osmotic pressure and influx of excess water into the interstitium. Persistent stasis and abnormal fluid accumulation lead to an inflammatory process mediated mainly by CD4+ cells that over time results in progressive fibrosis of the lymphatic vessels obliterating the lumen, as well as eliminating the lymphatic pumping potential. Lymphedema ensues when the capacity current overcomes the load of lymphatic fluid. Additionally, fibroadipose tissue deposition is promoted in the subcutaneous and subdermal tissues. This progressive underlying pathophysiologic process is reflected by initially soft, pitting edema, followed by induration, hypertrophy, acanthosis, hyperkeratosis, and skin breakdown. Infectious complications follow, with recurrent episodes of cellulitis and lymphangitis. In its rarest form, this process can lead to malignancy, with highly aggressive lymphangiosarcoma (Stewart–Treves syndrome) being a known clinical entity associated with chronic lymphedema. The International Society of Lymphology updated the staging guidelines in 2016 (Box 1).

ETIOLOGY

Lymphedema can be primary or secondary. Primary lymphedema results from a developmental abnormality, lack of an offending injury, and frequently a positive family history. This form of lymphedema may present at birth, during adolescence, or later in life. Primary lymphedema can further be subdivided into congenital lymphedema, lymphedema praecox, and lymphedema tarda. *Congenital lymphedema or Milroy disease* (10% to 25% of primary lymphedema) is seen within the first 2 years of life. It usually affects females (2:1 ratio to males), is bilateral, and involves the lower extremities. It often is not progressive and may improve spontaneously with time. The associated gene is *FLT4* and inheritance is autosomal dominant. *Lymphedema praecox or Meige disease* (65% to 80% of primary lymphedema) is seen before the age of 35, typically at puberty. It predominantly affects females (4:1 ratio to males), is unilateral, and involves the lower extremities. The associated gene is *FOXC2*, and inheritance is autosomal dominant. *Lymphedema tarda* occurs spontaneously after the age of 35 and is the rarest of all primary forms.

Secondary lymphedema is an acquired failure of the lymphatic system. Inciting events can be either a disease, trauma, radiation, or iatrogenic causes. Worldwide, the most common cause is infection by the nematoda *Wuchereria bancrofti*, transmitted by various mosquito vectors, an entity that affects almost 300 million people in developing countries. Adult filarial worms reside in and obstruct lymphatic channels, causing irreversible scarring and fibrosis and often massive edema. In developed countries the vast majority of the cases are due to secondary lymphedema, and of these, nearly all are related to cancer therapy. In the United States the most common cause is secondary to treatment of breast cancer. In 20% to 30% of patients undergoing axillary lymph node dissection, they will go on to have secondary lymphedema develop. The advent of sentinel lymph node biopsy dropped the prevalence of this disease to 7% to 8%. Adjuvant radiation therapy used for the local treatment of nodal disease can lead to upper or lower extremity lymphedema. Other factors such as trauma, infection, and obesity contribute to secondary lymphedema.

DIAGNOSIS

The workup for lymphedema starts with a thorough history and physical examination (Box 2). The patient complains of swelling, heaviness, tightness, and decreased quality of life. Other causes of extremity edema must be ruled out first, mainly venous insufficiency, deep vein thrombosis, and cardiac, renal, and hepatic failure.

Physical examination maneuvers that can aid with the diagnosis of lymphedema are limb circumference and volume measurement. Limb circumference can be measured at defined anatomic locations—for example, 5 cm above and below the olecranon. Differences of 2 cm when compared with the contralateral limb can be diagnostic; however, their utility is limited by interrater variability and in patients with high body mass index. Volume measurements can be performed with water displacement, with volume differences of 200 ml, or 10% considered diagnostic.

Imaging studies are as important and in diagnosis but also planning of surgical procedures. Lymphoscintigraphy uses radionuclide technetium (^{99m}Tc) to assess drainage of the lymphatic basin. Additionally the transport index can be calculated through this study to measure the severity of the disease. Indocyanine green (ICG) near-infrared lymphangiography has been proven useful in diagnosis and planning of lymphedema treatment. In an off-label use of the ICG, injection in the web space of the extremity digits can help visualize the lymphatic system and diagnose disruption of lymphatic flow, tortuous abnormal lymphatics, and dermal backflow (diffuse leakage of dye into the interstitium). Magnetic resonance lymphangiography has gained popularity in assessment of the lymphatic system, as well as the surrounding soft tissue changes. Intravenous injection of low-enriched is used to isolate the contrast enhancement of the venous system to aid with direct visualization of the lymphatic system. These above-mentioned imaging modalities can help with operative

BOX 1 Lymphedema Staging

Stage 0: Latent or Subclinical

- Impaired lymphatic transport
- No evident edema, subtle changes in tissue fluid composition
- Changes to subjective symptoms
- May last months or years before progression

Stage I: Spontaneously Reversible

- Early accumulation of protein-rich fluid
- Pitting edema
- Subsides with elevation

Stage II: Spontaneously Irreversible

- Accumulation of protein-rich fluid
- Pitting edema may progress to nonpitting as excess fat and fibrosis develop
- Does not resolve with elevation alone

Stage III: Lymphostatic Elephantiasis

- Nonpitting
- Significant fibrosis
- Trophic skin changes

Data from the International Society of Lymphology. The diagnosis and treatment of peripheral lymphedema: 2013 Consensus Document of the International Society of Lymphology. Lymphology. 2013;46(1):1.

BOX 2 Diagnostic Workup for Lymphedema

Thorough history and physical examination
Rule out causes of edema (basic laboratory tests for renal and liver function)
Infectious disease workup (in patients with travel history or exposure)
Lymphatic imaging (lymphoscintigraphy, magnetic resonance lymphatic mapping, indocyanine green imaging)

planning and lymphatic vessel anastomosis when the decision is made to use microsurgical techniques.

CONSERVATIVE MANAGEMENT

Conservative therapies are usually used in early stages of lymphedema when fluid accumulation is predominant to prevent development of the cascade of further edema, inflammation, and fibrosis. Conservative management can be burdensome, and the main reason for failure is the need of lifelong treatment and thus noncompliance. It is important to discuss compliance with patients upfront, stressing that individual investment and long-term compliance are central to managing this chronic, lifelong condition. Conservative management includes lifestyle changes, pharmacologic treatments, compressive and decongestive therapy, laser therapy, and, more recently, advancements such as stem cell and growth factor or gene therapy. Additionally, a multidisciplinary team including a physiotherapist, an occupational therapist, a social worker, and even psychosocial support can be key in success of conservative modalities.

Lifestyle changes include daily hygiene and skin care to reduce skin breakdown and infection. Weight loss and aerobic exercise have recently been proven to help decrease the severity of lymphedema in large clinical studies.

Pharmacologic treatments are an area of study in lymphedema. If infection occurs, antibiotics are valuable in immediate treatment. Beyond antibiotics, further pharmacologic treatment has not been proven beneficial. Diuretics have been used historically; however, they are useful only in the case of comorbidities requiring their use. Diuretics may actually lead to further fibrosis and increased interstitial protein accumulation. The use of nutritional supplements such as sodium selenite or vitamin E with pentoxifylline have not demonstrated any significant benefit in patients with lymphedema.

Compressive therapy with compression garments, multilayered inelastic bandaging, and controlled compression therapy are widely used. Compression garments are utilized as swelling decreases. These methods reduced volume of edema by 30% to 45% approximately. External sequential compressive devices also have been used with variable success. Basic range of motion exercises can be a useful strategy as a complement to limb compression and elevation. Contraindications to compression include arterial disease, deep vein thrombosis, and painful postphlebitic syndrome.

Decongestive therapy is a more time intensive strategy. This modality involves manual lymphatic drainage through massage and use of compressive garments and intermittent pneumatic pumps. The combination of the above has been shown to be more beneficial than each individual approach of decongestive therapy. Additional nonsurgical modalities have been explored in recent years. Low-level laser therapy stimulates tissue changes through mechanical mechanisms. Autologous bone marrow–derived stem cells injected in the lymphedematous extremities resulted in significant volume reductions reported in recent studies. Growth factors (vascular endothelial growth factor [VEGF]) and gene therapy with adenoviral vectors have been tested in animal models, with promising results in decreasing swelling and increasing lymphangiogenesis.

SURGICAL TREATMENT

Surgical approaches to lymphedema had historically been used as a last resort in refractory cases; however, advances in microsurgical techniques have made surgery useful even in early stages of the disease. There are two main categories of surgical approach to lymphedema: Physiologic procedures and debulking or reductive procedures. Physiologic procedures are usually indicated in early stages of lymphedema to restore lymphatic continuity and improve the anterograde flow of lymph. Debulking or reductive procedures are more useful in later stages to remove fibrotic fatty tissue. Conservative therapy should be continued immediately after any surgical procedure; however, the goal is that the intensity of treatment should be significantly decreased.

Physiologic Procedures

Advances in technology that led to developing microscopic with higher magnification and instruments to support these "super microsurgical" approaches was paramount in the evolution of physiologic procedures. Lymphovenous anastomoses (LVA) and vascularized lymph node transfer (VLNT) have been shown to be effective treatment options in early stages of lymphedema.

LVA

This procedure was introduced in 1963 by Sherman and colleagues. Subdermal lymphatic vessels are anastomosed to adjacent venules using ICG near infrared lymphangiography (Box 3). This creates an artificial shunt to drain lymphedematous fluid into the venous circulation and thus improve lymphatic flow and drainage. ICG near infrared lymphangiography can be performed before surgical planning to help determine patient eligibility for LVA.

Chang et al reported a series of 100 patients undergoing LVA, resulting in improvement of symptoms in 96% of patients while they were able to show improvement in volume differential in 74%. Volume differential was reduced by >15% at 12 months after surgery for patients with disease stage I and II and overall 42%. Whereas this previous study focused more on upper extremity lymphedema, Campisi et al have reported their experience with more than 3600 patients treated for both upper and lower extremity lymphedema for more

BOX 3 Lymphovenous Bypass

1. Begin with lymphatic lymphangiography.
2. Inject 0.01 to 0.02 mL of indocyanine green into the web spaces in the extremity.
3. Visualize fluorescent images and mark visible lymphatic pathways and injection sites.
4. Inject local anesthetic with epinephrine.
5. Inject 0.1 to 0.2 mL of lymphazurin into the web spaces in the extremity.
6. Take subdermal postinjection dissection down to stained and lymphatic channels.
7. Use microsurgical *connection* to reestablish lymph flow with end-to-end anastomoses. End-to-side anastomoses can be used when veins are larger than the lymphatic channel.
8. Confirm that shunts are patent by observing passage of lymphazurin into the vein.
9. Evaluate postoperative flow and imaging studies.

BOX 4 Vascularized Groin Lymph Node Transfer

Donor Site

1. Palpate femoral pulse and design elliptical skin paddle lateral to pulse, inferior and parallel to the inguinal ligament.
2. Incise skin superficially.
3. Dissect from distal to proximal; see fascia of sartorius muscle as deep plane.
4. Harvest the superficial circumflex iliac vessels, lymph nodes, and surrounding fatty tissue.

Recipient Site

1. Make a transverse incision on the recipient site (e.g., wrist).
2. Transfer flap onto the recipient site.
3. Perform microvascular anastomosis to the radial artery and cephalic vein.
4. Consider *mesh* for extra coverage of the flap with a split-thickness skin graft.
5. Use a skin paddle for monitoring.

than 40 years using LVA or interposition vein grafted shunts for LVA that resulted in reduction of excess volume of more than 80%, with an average follow up of 10 years or more. There are, however, articles in the literature reporting variable results in symptomatic and volume improvement, and part of this discrepancy has to do with the lack of validated questionnaires or standardized measurements respectively.

LVA has also been used prophylactically in patients undergoing lymph node dissection. Boccardo et al reported their experience with 4 year follow up in 74 patients treated with prophylactic LVA at the same time with axillary lymph node dissection (ALND) what they called LYMPHA (Lymphatic Microsurgical Preventive Healing Approach). Lymphedema developed in only 8%, which compares favorably to the reported prevalence of 10% to 65%. Feldman et al performed the same approach in 27 patients (ALND and LYMPHA) but also had a control group of 16 patients (ALND) no LYMPHA). In a short-term follow up 36 months) the treatment group had development of lymphedema in 12.5% versus 50% in the control group.

VLNT

VLNT was first demonstrated in rats by Shioud in 1979 and used for a human patient by Chaoliu in 1982. This procedure harvests healthy fat tissue and lymph nodes and transfers them into the affected site (Box 4). Two mechanisms have been proposed for the effectiveness of VLNT. The first is the lymphatic "seed," the bridge of proximal and distal lymphatic vessels in the recipient site and a process of lymphangiogenesis stimulated by growth factors produced by the lymph nodes (VEGF) and antifibrotic interleukin 10. The second mechanism is the lymphatic "pump," which stems from lymphovenous communication within the lymph nodes of the transferred flap. Common donor sites are the supraclavicular area, the groin and the omentum. Chang et al have thoroughly discussed the supraclavicular lymph nodes found inferiorly within the posterior triangle of the neck, in the hamilla of fat between omohyoid and anterior scalene muscles. The fat is supplied by the underlying transverse cervical vessels. The nodes are usually harvested from the contralateral side to avoid any further disruption of the lymphatic flow. On the left side the surgeon should avoid the thoracic duct during dissection. The groin lymph nodes are another common donor site. It offers the advantage of a concealed scar and the use of a large skin paddle when needed. The lymph nodes are located at the level of the muscular aponeurosis and subcutaneous fat medial to the femoral artery. Preoperative magnetic resonance angiography has been used to identify lymph nodes, and Doppler imaging can confirm the location of the superficial circumflex vessels. Care must be taken not to dissect further caudally from the inguinal ligament or deep from the muscular aponeurosis, which risks damaging the lymphatic drainage to the lower limb. The benefit of using the groin flap is the opportunity to simultaneously perform an abdominal based autologous breast reconstruction and treat upper extremity lymphedema. However, other authors suggest staging these two approaches and only perform the groin lymph node transplantation once the autologous breast reconstruction has been deemed successful, this way the thoracodorsal vessels—as recipient vessels for the groin flap—are no longer needed for any potential salvage procedure (e.g., latissimus dorsi flap).

Dayan et al have suggested performing routine mapping of the lymphatic system to harvest only the expendable lymph nodes and to preserve those that drain the extremities and reduce donor site morbidity. Mapping of the lymphatic drainage is done by using technetium injected into the web spaces of the hand or foot and identifying the nodes using a gamma probe. Lymph nodes that drain the areas targeted for the flap are mapped using ICG (near infrared lymphangiography). In their study of 36 patients treated with VLNT and reverse lymphatic mapping, there had no donor site complications.

Another donor site that has gained popularity the last few years is the free vascularized omental lymph node transplant (VOLT). This is based off the right gastroepiploic vessels and can be harvested either through an approximately 8 cm upper midline laparotomy or via a minimally invasive laparoscopic approach. The remainder of the omentum is left behind to minimize the chances of donor site lymphatic congestion. However, the intraabdominal component of this approach does have associated risks, such as hernia development, bowel perforation and pancreatitis. Nguyen et al reported their outcomes of 42 patients treated with VOLT and followed up for an average of 14 months, resulting in subjective improvement in 83% and excellent volumetric improvement in 22%. Dayan et al have recently suggested splitting the VLNT in two parts to transplant to the proximal and the distal/middle aspect of the affected extremity in the case of significant edema to maximize the lymphatic flow through the extremity.

Overall the use of VLNT has been associated with appropriate outcomes. A systematic review of 18 studies in 305 patients undergoing VLNT revealed improvements in swelling (whether measured as limb circumference or volumetric difference) in 86% to 90% of patients with volume difference on average of 22% and no need for postoperative compression garment in about 50%.

Debulking Procedures

More advanced stages of lymphedema with significant fluid accumulation or established fibrosis (stages III/IV) require debulking procedures. There are three different approaches, liposuction that has been used in the treatment of lymphedema in the recent years and more aggressive, older approaches such as the Charles procedure and the Sistrunk procedure.

BOX 5 Liposuction

1. Mark out the affected area and 2 cm beyond.
2. Choose port sites to effectively reach all areas, both proximally and distally.
3. Inject tumescent solution (1 L lactated Ringer's solution mixed with 1 mL ampule of epinephrine 1:1000 and 50 mL of 1% lidocaine) until blanching is achieved and a moderate amount of output is seen.
4. Wait 30 to 45 minutes.
5. Suction with a 4- to 6-mm cannula in a deep plane in all areas, followed by a 2- to 3-mm cannula in a more superficial plane for a smoother contour.
6. Close port sites with absorbable sutures.
7. Apply sterile dressings and a pressure garment.
8. Advise the patient not to shower or remove the pressure garment for 72 hours, and encourage the patient to walk at least three times a day.
9. After 3 days, the patient can shower daily and may begin massaging the affected areas.
10. The pressure garment should be worn for 6 to 10 weeks.

Liposuction was first used for brachial lymphedema in 1987. Since then, the technique was refined in 1993 (Box 5). It is useful in addressing large adipose tissue deposits. It is safe and quick and allows for immediate decrease in volume and pressure of the lymph fluid, decreasing the burden and thus promoting better lymphatic flow. It is usually indicated when the excess volume is greater than 400 mL. Contraindications include presence of more than pitting edema, metastatic disease, open wounds, coagulation disorders, and reluctance to wear compression garments after surgery. Risks include lidocaine toxicity, thrombosis, need for cutdown, hematoma, seroma, and contour irregularities. Cart et al, in a systematic review of all surgical approaches of lymphedema, analyzed the results of liposuction and found that liposuction achieved an average excess volume reduction (the percent decrease in additional volume of the lymphedematous extremity compared with the contralateral side) of 56.6%, with additional improved overall well-being.

The Charles procedure (described by Charles in 1912) is an aggressive approach including radical excision of skin and subcutaneous tissue down to muscle fascia or epimysium (Fig. 1 and Box 6). Excised skin is used for grafting on the fascia, or other donor sites can be used. The van der Walt modification allows for negative pressure dressing, with grafting to be done in a delayed fashion. This approach is indicated for severe cases and carries a high risk of complications, including destruction of the remaining lymphatic vessels, infection, ulceration, hyperpigmentation, dermatitis, unstable scars, and a severely altered aesthetic outcome (excessive resection of leg tissues and exacerbated foot lymphedema bottleneck deformity). The Sistrunk procedure (1940) is a planned, staged excision of the affected subcutaneous tissues. This technique has been modified over the last 80 years and involves burying dermal flaps within skin flaps (Box 7). Long-term results include a reduction of at least half of the affected tissue in 75% of patients. The Sistrunk procedure is safe, reliable, and predictable. Complications include nerve damage to the affected area, epidermolysis secondary to poor blood supply, wound dehiscence, and infection.

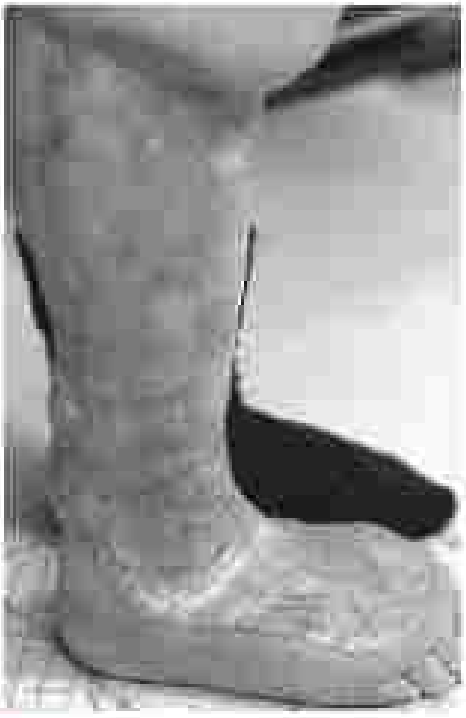

FIG. 1 Lower extremity after the Charles procedure.

BOX 6 Charles Procedure

1. Mark the lymphedematous area both proximally and distally.
2. Make an incision both medially and laterally down to the muscle fascia.
3. Excise all tissue superficial to this plane.
4. Remove the skin of the affected area with a dermatome for a split-thickness graft or with a knife for a full-thickness graft. If a full-thickness graft, make sure to remove all fat from the skin.
5. Use this graft to cover the exposed area.
6. Apply petroleum gauze or other nonadherent dressing over the graft.
7. Apply a pressure dressing via a vacuum-assisted device, bolster, or cotton.
8. Splint the extremity in the proper anatomic position.
9. Remove dressing after 3 to 5 days for a split-thickness graft or after 7 to 12 days for a full-thickness graft.

BOX 7 Sistrunk Procedure

1. Mark out the affected area.
2. Plan to excise and debulk sufficient tissue, leaving dermal flaps to bury beneath the skin to the closure. A variation of this is carried out in the Thompson procedure, in which dermal flaps are buried beneath the muscle.
3. Close the incision over drains.
4. Allow 12 weeks to heal before the next serial excision.

Combination of Procedures

Lymphedema, regardless of the stage, is a complex chronic process that requires multiple different modalities. Decongestive therapy is important and is almost always necessary, either alone or in combination with surgical procedures. More recently, combining different surgical approaches has become more common. Cart et al in their systematic review of the surgical treatment of lymphedema identified multiple different procedure combinations, including liposuction with VLNT, VLNT with Charles procedure, VLNT with LVA, and more in a total of eight studies involving 137 patients with variable results. Four of these studies used VLNT and identified the need for additional liposuction or radical reduction to 31.6% to adequately remove lymphedematous and fibrotic tissue. Likewise, in two LVA studies, an average of 16% of patients required liposuction after the LVA to achieve optimal reduction. The authors of this systematic review therefore suggest a thorough algorithm to approach lymphedema (Fig. 2).

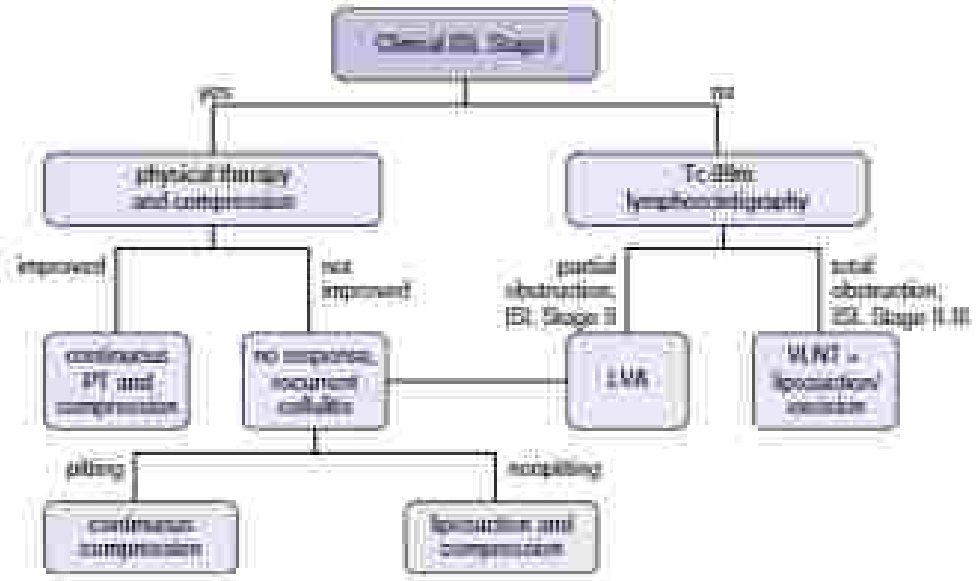

FIG. 2 Lymphedema treatment algorithm. ISL, International Society of Lymphology; LVA, lymphovenous anastomosis; PT, physical therapy; VLNT, vascularized lymph node transfer.

SUMMARY

Lymphedema is a challenging clinical problem that produces significant morbidity in a large population worldwide. All treatment modalities include long-term conservative measures along with support from a multidisciplinary team. Surgical procedures can be a useful adjunct to treatment according to the disease progression; physiologic procedures appear to be more successful in earlier stages of the disease, and debulking procedures are used only for later stages. Regardless of the treatment strategy chosen, patient commitment and lifestyle modifications are of paramount importance to achieving improvement in symptoms and quality of life.

LOWER EXTREMITY AMPUTATION

Samuel I. Schwartz, MD, and Glenn M. aMuraglia, MD

A nonambulatory patient with a prior transfemoral femoropopliteal artery bypass comes to your clinic with forefoot dry gangrene and an ankle brachial index of 0.3. The patient has been nonambulatory resulting from a stroke for more than 5 years. She is present with her health care proxy and is here to discuss amputation.

This patient's case is a common scenario seen by many different subspecialists: orthopedic surgery, general surgery, podiatry) but within the context of a prior bypass is usually managed by a vascular surgeon. The patient's long-term prognosis is very poor, having suffered a major disabling stroke and developing severe ischemia to the point of requiring a major lower extremity amputation. Historically, patients with critical limb ischemia, manifested as either rest pain or tissue loss, have an annual mortality rate of approximately 25%. This statistic has not changed much over the past few decades despite advances in medical care. In contrast, amputation rates have improved substantially over the past 20 years in the endovascular era, with roughly 40% declines in above- and below-knee amputations.

Early on, peripheral arterial disease manifests as short- or long-distance claudication. Interestingly, claudicants now have a 5-year amputation rate of only 1% to 2% (in contrast to 5% several decades ago) in large part from advancement of medical management of risk factors. If their disease progresses, patients can develop deep, dull, aching rest pain. Eventually, their circulation will not be able to maintain daily tissue homeostasis and develop a nonhealing ulceration that can develop into gangrene.

LOWER EXTREMITY AMPUTATION

Samuel I. Schwartz, MD, and Glenn M. LaMuraglia, MD

A nonambulatory patient with a prior thromboembolectomy of the popliteal artery bypass comes to your clinic with forefoot dry gangrene and an ankle brachial index of 0.3. The patient has been nonambulatory resulting from a stroke for more than 5 years. She is present with her health care proxy and is here to discuss amputation.

This patient's case is a common scenario seen by many different subspecialists (orthopedic surgery, general surgery, podiatry) but within the context of a prior bypass is usually managed by a vascular surgeon. The patient's long-term prognosis is very poor, having suffered a major disabling stroke and developing severe ischemia to the point of requiring a major lower extremity amputation. Historically, patients with critical limb ischemia, manifested as either rest pain or tissue loss, have an annual mortality rate of approximately 25%. This statistic has not changed much over the past few decades despite advances in medical care. In contrast, amputation rates have improved substantially over the past 20 years in the endovascular era, with roughly 40% declines in above- and below-knee amputations.

Early on, peripheral arterial disease manifests as short- or long-distance claudication. Interestingly, claudicants now have a 5-year amputation rate of only 1% to 2% (in contrast to 5% several decades ago) in large part from advancement of medical management of atherosclerosis. If their disease progresses, patients can develop deep, dull, aching rest pain. Eventually, their circulation will not be able to maintain daily tissue homeostasis and develop a nonhealing ulceration that can develop into gangrene.

Annual mortality of 25% in patients with critical limb ischemia is paramount in decision making regarding amputation surgery. Many of these patients have end stage cardiac disease, and a less aggressive approach may be warranted. Goals of care should be discussed with the patient, ideally while the patient is symptom and in an elective setting. Often, patients are emotionally reluctant to undergo amputations because they do not meet the absolute indications for amputation: intractable pain or uncontrolled sepsis. Patients that refuse amputation commonly present later to the emergency room in sepsis or strongly request the procedure because of unrelenting pain.

AMPUTATION PRINCIPLES

The primary goal of an amputation is to resect necrotic or nonviable tissue and provide a stable, healed extremity. Function is also extremely important; patients that were previously ambulatory should have the lowest possible amputation level to provide the highest likelihood of prosthesis assisted ambulation. Permanently nonambulatory patients or patients with severe contractures at the knee joint are the best candidates for single stage, above knee amputations. A word of caution must be discussed with the patient and family: nonambulatory status confers additional late complications (e.g., pneumonia, pressure ulcers) that can lead to premature death.

Preoperative Assessment

As seen with most vascular patients, the preamputation patient needs to be evaluated systematically and regarding specific technical ramifications.

Patient Evaluation

The patient's vascular related medical problems need to be ascertained; these include, but are not limited to diabetes, smoking history or chronic obstructive pulmonary disease, hypertension, cardiac history, renal insufficiency, and prior surgical history. Particularly, the prior amputation and vascular surgical history needs to be part of the current operative plan. The history also should include medications that may impede wound healing, anticoagulants that may need to be temporarily withheld, and the patient's nutritional status.

Physical examination plays an important role; a standard peripheral pulse examination should be performed as well as consideration of the presence of soft tissue or bony infection. Infected tissue should be treated with antibiotics or amputated urgently to get source control. A second stage formalization can be done at any proximal level permitting adequate arterial inflow for healing. Joint mobility and range of motion are paramount regarding the likelihood of developing areas of pressure breakdown after amputation creation. Last, a motor and sensory examination will help guide the clinical decision. A globally insensate or paralyzed foot should not undergo limb salvage by any means (TMA or toe amputation) due to the high likelihood of recurrent ulceration.

Laboratory Evaluation

Many tests can be performed to help guide the practitioner regarding likelihood of healing a desired amputation level. These tests include segmental blood pressures (and pulse volume recordings) and transcutaneous partial pressure of oxygen measurements ($TcpO_2$). These two tests are commonly performed at our institution.

A minimal ankle pressure of 50 mm Hg (or 90 mm Hg in a diabetic or end stage renal disease patient) is the desired minimum threshold to heal an amputation of the foot. Plethysmography or pulse volume recordings are also very useful and at least 5 mm of pulsatile displacement at the planned amputation level is associated with a higher amputation success rate. Digital or transmetatarsal plethysmography can be used to predict success of healing were distal forefoot digital amputations.

When available, $TcpO_2$ measurements can be performed with an oxygen electrode at 45°C at the desired amputation level. A level of 40 mm Hg is associated with a higher amputation success rate, whereas a level below 20 mm Hg is associated with failure. Of note, $TcpO_2$ levels can be unreliable in the presence of infection or inflammation. A baseline chest wall measurement is helpful in validating the test result (a low chest wall measurement may indicate a falsely low extremity measurement). From our experience, $TcpO_2$ has higher positive predictive value than negative predictive value regarding amputation success.

Radiographic Evaluation

Despite the patient in our case having a thrombosed bypass graft, the patient's arterial anatomy is vital to determining an amputation level. If the patient in our case had a high grade proximal profunda artery stenosis, an endovascular treatment of this lesion (balloon angioplasty with possible stenting) should be considered before an above knee amputation to optimize healing. If our patient had an occluded external iliac artery with reconstitution at the common femoral artery by hypogastric artery collaterals (via the profunda artery), a high grade distal hypogastric artery lesion would also warrant treatment to optimize above knee amputation healing. In this patient population, undertaking open arterial reconstruction to heal an amputation is discouraged; however, arterial inflow to the groin is usually necessary for the healing of an above knee amputation.

Acute Versus Chronic Lower Extremity Ischemia

An acutely ischemic limb that is globally insensate and paralyzed may require an upfront amputation because of extensive tissue necrosis and systemic toxicity. Patients may also be in intractable pain and an amputation will lessen their pain medication requirement. In a more delayed presentation without systemic toxicity, the tissue necrosis can demarcate which will help determine the amputation level. Renal and cardiac function should be frequently assessed; unrelenting pain can cause a cardiac event and worsening myoglobinuria can lead to acute renal failure.

Infection and Amputation

Determining whether the patient has wet gangrene is crucial. Most vascular patients have minimal physiologic reserve and quickly progress to septic shock. A timely workup for infection, consisting of an arterial lactate, blood cultures, and initiation of broad spectrum antibiotics, is key. Sometimes the exudate from the tissue bed can be cultured directly. Antibiotic coverage should include *Staphylococcus*, *Streptococcus*, gram negative organisms, and anaerobic organisms (see the chapter on the diabetic foot for more details regarding antibiotic selection). Wide debridement or guillotine amputation should be done in an urgent fashion to prevent worsening sepsis. Once adequate source control has been obtained, formalization should be performed once the patient has a normalizing temperature curve and favorable profile.

Specific Sites of Amputation

Digital Amputation

Digital or ballet toe amputations involve intraphalangeal resection with lateral flap coverage. The blood supply to the toe is at the 2 and 8 o'clock positions; hence, skin flaps need to be fashioned accordingly. Septic arthritis and forefoot or web space infection are major contraindications for a digital amputation. Postoperatively, the patient should be placed on a pressure offloading shoe and only heel weight bearing for the first 2 to 3 weeks depending on their circulation status. The incision needs to be assessed before allowing the patient full weight bearing, and the sutures should be removed when the wound has healed, usually around 4 to 6 weeks postoperatively.

Transmetatarsal Amputation

Transmetatarsal amputation, which is resection of the toe and corresponding metatarsal phalangeal joint, is indicated when dry or wet gangrene is involving the forefoot or web space. An important consideration regarding this amputation is the patient's foot stability and ultimate vascular disease trajectory. Using more than a single toe ray amputation may result in poor forefoot stability and development of

adjacent digital ulceration. A very durable long-term result is a complete forefoot transmetatarsal amputation; this is the ideal procedure for patients with neuropathy as there is uniform pressure distribution over the entire forefoot. Patients do very well with this amputation level even after decades of follow-up when their circulation may actually deteriorate. Predictors of a successful amputation include the following clinical criteria: control of active infection, good healthy appearing skin to flap, and an forefoot dependent ulcer. Theoretically, laboratory criteria that have been used include an ankle brachial index of over 0.35 (or 0.40 in the diabetic or dialysis population), palpable pulse volume recording of the forefoot, and a transcutaneous pO_2 measurement over 40 mm Hg.

Ankle Amputation

A Syme or ankle amputation is no longer performed due to pressure ulcer formation and the superior quality of below knee amputation prostheses.

Below-Knee Amputation

The patient in our scenario is nonambulatory and a below knee amputation is not indicated. In patients with ambulatory potential, a below knee amputation is an excellent option. A palpable popliteal pulse is the strongest predictor of adequate arterial inflow to heal a below knee amputation. Typically, a posterior flap (Burgess technique) is performed with the tibia transected 10 to 12 cm distal to the tibial tuberosity. The fibula is transected 1 to 2 cm proximal to the tibia transection level. Postoperatively, patients need to be kept in knee extension to prevent contracture formation while they undergo rehabilitation (Fig. 1).

Above-Knee Amputation

The above knee amputation, typically created with a fish mouth myocutaneous, would be the ideal amputation for the nonambulatory patient described here. In the setting of an occluded superficial femoral artery, a patent profunda artery is key to heal an above knee amputation. To prevent unopposed abduction, an adductor myodesis to the transected femur is typically done as well.

Newer Treatment Modalities

Transfemoral amputees can have problems with socket fit, especially in the setting of a short residual limb. Osseointegration provides a percutaneous, bone-anchored prosthesis that helps avoid socket-related problems. Preliminary data are promising, but the main risk remains development of a deep hardware infection.

FIG. 1 Knee right removable dressing.

The most promising results have been recently achieved with targeted muscle reinnervation (TMR). TMR gained initial popularity for upper extremity myoelectric prostheses, and recently has gained utility for lower extremity amputees. Transected nerves are surgically transferred to the motor nerves of adjacent denervated target muscles. This results in more coordinated neural control signals to the missing limb and resultant prevention and/or treatment of neuropathic pain. Currently, TMR for lower extremity amputations is done by plastic surgery at our institution with good early results (Figs. 2 to 4).

TABLE 1 Major Life-Threatening Conditions in Trauma

Condition	Assessment (Signs/Symptoms)	Management
Airway obstruction (tongue, foreign body, maxillofacial disarticulations, swelling (face, pharynx, larynx)	• ...uarse or absent breath sounds • Stridor • Use of accessory muscles • Paradoxical movement of chest and abdomen • Intercostal retraction	• Jaw thrust/chin lift • Inspection of oral cavity • Suction • Endotracheal intubation • Needle surgical cricothyroidotomy
Severe traumatic brain injury	• Glasgow coma scale ≤... • ...local and/or global neurologic deficit • Rapidly deteriorating neurologic state • Abnormal/absent reflexes	• Airway management • Ventilatory support, avoid hypoxia, hypercarbia • Intracranial pressure management (mannitol, hypertonic saline) • Neurosurgery consultation (craniotomy)
Tension pneumothorax	• Tachypnea, air hunger, distress • Decreased/absent breath sounds • Tracheal deviation (away) • Distended neck veins (may not be present in the setting of severe hemorrhage) • Tympany on percussion • Hypotension/shock (lack of response to fluid challenge)	• Needle decompression, fourth intercostal space • Tube thoracostomy, fourth to fifth intercostal space
Massive hemothorax	• Tachypnea, air hunger, distress • Decreased/absent breath sounds • Flat neck veins • Dull sound on percussion • Hypotension/shock (lack of response to fluid challenge)	• Tube thoracostomy, fourth to ...fth intercostal space • ...L3 transfusion protocol • Emergency thoracotomy for >1500 mL initial blood return and/or ...200 mL/kg/ 2 - 4 hours
Cardiac tamponade	• Tachycardia • Hypotension/shock • Muffled heart sounds • Distended neck veins (may be absent due to hemorrhage) • Electrical alternans (electrocardiogram) • Focused assessment with sonography for trauma positive (88%, 95%)	• Volume resuscitation • Emergency thoracotomy or sternotomy by qualified surgeon (subxiphoid pericardiotomy with ultrasound guidance can temporize)
Flail chest/pulmonary contusion	• Tachypnea, air hunger • Asymmetric chest wall movement • Worsening oxygenation	• Diagnosis via clinical examination, chest radiograph, or CT • Supplemental oxygen • Pain control with I.v. narcotics, local/regional anesthesia • Restrict fluid administration in the absence of shock • Endotracheal intubation and ventilatory support (for partial pressure of oxygen <60 or arterial oxygen saturation <90 or fraction of inspired oxygen ...>50%)
Blunt cardiac injury (cardiac contusion)	• Tachycardia chest discomfort • Hypotension/shock (acute or worsening heart failure) • Arrhythmias	• Monitor patient in intensive care unit • Consider echocardiogram • Caution: intracardiac thrombus formation, myocardial infarction, valvular disruption, delayed cardiac rupture • Cardiac surgery consultation for unstable patients or complications
Traumatic aortic disruption	• Common cause of sudden death • Cause of massive (left) hemothorax or pericardial tamponade • Diagnosis on chest radiograph/CT (widened mediastinum, obliteration of aortic knob, deviation of trachea, depression of left mainstem bronchus, obliteration of aortopulmonary window, widened paraspinal interface, apical cap)	• β-Blockade if no contraindications; goal heart rate <80, mean arterial pressure 60–70 mm Hg • CT/vascular surgery consult (open or endovascular repair)

TABLE 1 Major Life-Threatening Conditions in Trauma—cont'd

Condition	Assessment (Signs/Symptoms)	Management
Blunt esophageal rupture	• Chest pain • Left pneumothorax or hemothorax (often without rib fracture) • Air in mediastinum on CXR or CT • Signs and symptoms of sepsis	• Fluid-directed sepsis therapy • Broad-spectrum antibiotics • Thoracic surgery consult: wide drainage with or without repair
Diaphragmatic rupture	• Often minimal symptoms initially • Tachycardia, chest discomfort • Signs of gastrointestinal obstruction or ischemia • Stomach, intestinal organs, spleen, or other in the chest on CXR or CT (small injuries often missed)	• Operative repair
Ongoing external or internal hemorrhage	• Identify the source: (1) Thoracic: see signs for massive hemothorax (2) Abdominal: distension, positive fluid on FAST (3) Pelvic: fracture on anteroposterior film, scrotal hematoma, abdominal distension	• 1:1:1 transfusion protocol for class II–IV shock • External/extremity: direct pressure, pressure dressing, tourniquet, operative or interventional definitive management • Thoracic: tube thoracostomy, emergent thoracotomy or sternotomy • Abdominal/pelvic: resuscitative balloon occlusion of the aorta (in a setting with appropriate training and certification), compartmental packing, interventional or operative management

CT, computed tomography; *FAST*, [illegible] ultrasonography.

FIG. 1 Trauma care [illegible]

All interventions for airway and breathing management should be followed up with an anteroposterior (AP) plain film chest radiograph to verify proper position of the endotracheal and/or chest tube and document the extent of the injuries.

Circulation Assessment and Management of Perfusion

The most important initial steps in the management of circulation/perfusion are to control any active source of bleeding, to establish two large-bore intravenous (or intraosseous) access, and to recognize and manage shock. Most injured patients have some degree of hypovolemia; in most cases, this is caused by blood loss (hemorrhagic shock), but hypovolemia can also be caused by systemic vasodilatation (neurogenic shock) and fluid losses resulting from burns and exposure to heat (Table 2). Assessment of peripheral (radial) and central (carotid, femoral) pulses, noninvasive blood pressure monitoring, and the evaluation for clinical signs of hypoperfusion (altered central nervous system status, decreased urine output, cool pale skin with decreased capillary refill) allow quick classification of blood loss to classes I to IV (mild to severe, <750 to >2000 mL) and take appropriate steps for initial resuscitation.

In addition to hypovolemic shock, injured patients may suffer from cardiogenic shock (cardiac contusion, myocardial infarction), obstructive shock (tamponade, tension pneumothorax), and/or neurogenic shock (relative hypovolemia and lack of afterload). The most sensitive method of restoring adequate cardiac output, perfusion, and tissue oxygenation is to restore normal venous return by (1) stopping ongoing blood loss and restoring lost volume (hypovolemic shock) and (2) relieving mechanical or pericardial pressure (tension pneumothorax, tamponade). Only after the patient has received volume resuscitation and ongoing blood loss and obstruction have been ruled out is the use of vasoconstricting agents appropriate in neurogenic shock.

The amount of fluid/blood required for resuscitation is often difficult to predict initially. An initial bolus of 20 mL/kg for pediatric patients (<40 kg) and up to 1 to 2 L of warmed balanced (Ringer's solution for adults is most appropriate. The patient's response to fluid resuscitation should be monitored: a lack of response, or only a transient response, may indicate greater than expected losses and/or ongoing bleeding, and the need for early administration of blood products and interventions aimed at hemostasis (Table 3). Balancing the goal of organ perfusion with that of avoidance of rebleeding has led to the concept of "controlled" or "[illegible]" resuscitation.

TABLE 2 Classification of Shock

	Class I	Class II	Class III	Class IV
Blood loss	<15% <750 mL	15%–30% >1000 mL	31%–40% <2000 mL	>40% >2000 mL
Heart rate	Normal to <100	Slightly elevated >120	Elevated 120–139	Elevated >140
Blood pressure (systolic)	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal	Decreased	Decreased	Decreased
Respiratory rate (breaths/min)	Normal	Slightly elevated, <30	Elevated, 30–40	
Urine output (mL/h)	Normal <30	Normal to slightly decreased, >30	Decreased <30	Negligible
Central nervous system/mental state/ Glasgow Coma Scale	Normal	Anxious	Confused	Lethargic
Base deficit (mEq/L)	0–2	−2 to −6	−6 to −10	> −10
Need for blood products	Low likely; monitor	Possible	Yes	Massive transfusion protocol

Modified from American College of Surgeons Committee on Trauma: Advanced trauma life support (ATLS): 10th Edition, American College of Surgeons Committee on Trauma, Chicago, 2018. Other good data from Mutschler M, Nienaber A, Pfeifer R, et al. Could an early assessment of hemodynamic parameters predict the need for massive transfusion in severely injured trauma patients? Scand J Trauma Resusc Emerg Med. 2012;20:50. doi:10.1186/1757-7241-20-50.

TABLE 3 Response to Fluid Resuscitation

	Rapid/Complete	Transient	Minimal/No Response
Vital signs	Return to normal	Transient/incomplete improvement	Remain abnormal
Estimated blood loss	Minimal Class I, <15%	Moderate, ongoing Class II–III, 15%–40%	Severe, ongoing Class IV, >40%
Need for blood	Low Use type/cross-matched	Moderate to high Use type-specific	Immediate, massive transfusion protocol Use type O then type-specific or cross-matched
Presence of surgeon	Recommended	Required	Required

The recommended initial volume challenge is 20 mL/kg or colloid (~10 kg) and ~1000 mL of adult-dose crystalloid (largest amount of fluids, solutions). Lactated Ringer's solution may be repeated once or twice while "active consideration is" blood transfusion. Urinary output should be measured in all patients. With signs of hypovolemic shock, the goal is a urine output of ~1 mL/kg/h in children and ~30 mL/h in adults.

in which lower than normal blood pressure (>90 mm Hg systolic) is tolerated as bridge to definitive hemorrhage control.

Patients with class III or IV shock, ongoing losses, and minimal transient response to an initial volume bolus should be considered for early administration of blood products. If cross-matched blood is unavailable, type O red blood cells (Rh negative preferred) are indicated. To avoid hypothermia and associated coagulopathy, the use of blood warmers is critical. Each institution involved in the care of trauma patients should have a massive transfusion protocol. Severe coagulopathy is present on admission or develops in more than 30% of patients, and there is clear evidence that a ratio of blood plasma/platelets approaching 1:1:1 prevents excessive bleeding and related complications. Point of care testing (TEG, rotational thromboelastography), in addition to standard tests of coagulation can be helpful in the management of these patients.

External bleeding should be controlled first with direct manual pressure or a pressure dressing. If bleeding control cannot be achieved, a manual or pneumatic tourniquet (250–400 mm Hg) should be used and the patient transferred to the operating room in an expedited fashion. Active (hemodynamic internal bleeding (massive hemothorax, >1500 mL chest tube drainage initially or >200 mL/h for >3–4 hours) requires emergency thoracotomy in most cases, and management of the injury to the heart, great vessels, and/or lung. With internal abdominal bleeding, the use of the resuscitative endovascular balloon occlusion and with pelvic bleeding, the use of retroperitoneal pelvic packing may temporize patients on their way to the operating room or interventional angio suite. The trauma team leader must be committed to continuously reassess the patient's hemodynamic status (clinical examination, vital signs, urine output, laboratory values indicating perfusion) to prevent deterioration, and establishment of arterial lines and central lines serve as an adjunct but should not interfere with the adequate initial resuscitation.

Disability and Exposure

Every patient should have a focused baseline neurologic examination as part of the primary survey consisting of assessing the patient's general level of consciousness, pupillary size, and reaction, as well as the Glasgow coma score. A more comprehensive examination is completed during the secondary survey. Any patient with a Glasgow coma score less than 8, a deteriorating mental state, or a patient who is combative (a potential danger to himself or herself) should have an immediate placement of a secure endotracheal airway.

To allow for complete assessment, each patient must be completely undressed (undue movement of the patient/limbs should be avoided until injury has been ruled out); this may require cutting

all the patient's garments. Care must be taken to avoid hypothermia; the trauma room should be warmed, patients should be covered as soon as possible with warmed blankets, and intravenous fluid/blood warmers should be used whenever possible.

Monitoring and Adjunct Measures

While addressing the ABCDEs and identifying/managing injuries with potential threat to life and limb during the primary survey, each patient should receive: (1) adequate intravenous or intraosseous access; (2) supplemental oxygen and pulse oximetry; (3) cardiac and noninvasive blood pressure monitoring; and (4) basic blood work (complete blood count, prothrombin time/partial thromboplastin time, basic metabolic panel, and specialty studies as indicated (i.e., blood alcohol level, urine toxicology screen, arterial blood gas, lactate). Patients with significant injuries and/or the need for hemodynamic monitoring should also receive a urinary catheter. Gastric dilatation occurs frequently in trauma patients; it can cause bradycardia and hypotension (vagal response) and increases the risk of aspiration. Gastric decompression should be considered in all trauma patients, particularly patients with abdominal/chest trauma and those with altered mental state.

SECONDARY SURVEY

The secondary survey should not be done until the primary survey is completed and all potentially life-threatening conditions have been addressed. It answers the question "What injuries did the patient sustain?" and uses a systematic, comprehensive, head-to-toe evaluation as the main tool. The potential for missing an injury or failing to appreciate the significance of a subtle sign is significant, especially in unresponsive or unstable patients. Therefore, the secondary survey ideally is performed by one examiner, using inspection, auscultation, palpation, and the patient's responses to specific questions and commands. During the evaluation, distraction of the patient by other members of the team or interventions should be minimized and the examiner should verbalize his or her findings throughout the evaluation to allow the team and allow for concurrent documentation of all findings. Information about allergies, current medications, past illnesses, last meal, events/environment surrounding injury related to and the mechanism of the injury should be collected from the patient or family.

At the end of the secondary survey, the trauma team leader should be able to verbalize/initiate any needed diagnostic tests, specialist consultations, and be able to decide to what level of care the patient should be admitted. If the resources to provide optimal care are not available locally, this is also the time to initiate transfer to a higher level of care (trauma center), to avoid unnecessary delay.

TERTIARY SURVEY: REEVALUATION

Physiologic changes after injury are highly dynamic and injury severity is often underestimated in the initial phases of evaluation. Constant reevaluation of the trauma patient and timely review of test results are essential to prevent deterioration or secondary injury. This phase includes monitoring of vital signs, SaO_2, urine and mixed CO_2 monitoring, as well as urinary output; patients with altered mental state, (suspected) traumatic brain injury, or spinal cord injury should have serial neurologic evaluation. Patients with (suspected) abdominal/pelvic trauma should have serial abdominal examinations, and those with significant extremity trauma should have serial neurovascular examinations and compartment checks. The findings at reevaluations should be carefully documented and communicated to the members of the care team. Factors most commonly associated with worse outcomes in the posttrauma phase include (1) ongoing bleeding, (2) hypotension and hypoperfusion, (3) hypoxia and hypercarbia or hypocarbia and metabolic acidosis, (4) hypothermia, (5) coagulopathy, (6) compartment syndromes (abdomen, extremities, intracranial), and (7) evolving neurologic injury/deficit. These conditions must be actively sought and aggressively managed.

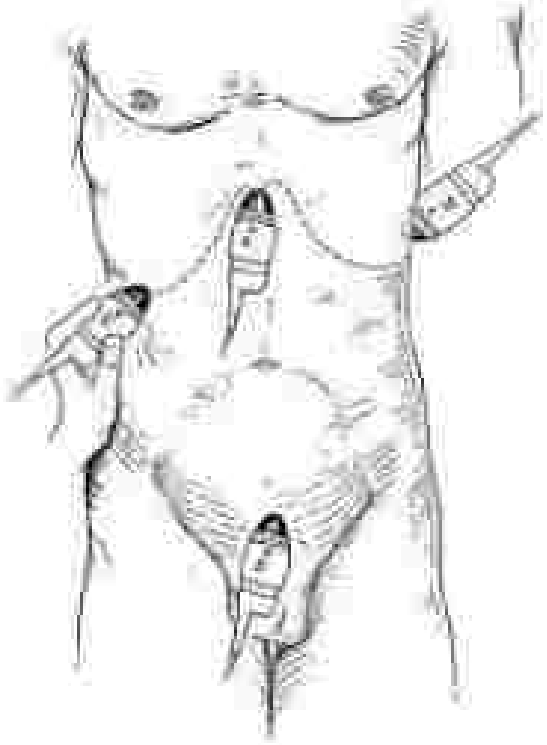

FIG. 2. Focused assessment with sonography for trauma windows for hemoperitoneum (right subcostal, left subcostal, and suprapubic areas). Demonstration of the urinary bladder before (top) and after (bottom) placement of an indwelling urinary catheter. Note the presence of fluid (arrows) in the bladder after catheterization. (From Tintinalli JE, Kelen GD, Stapczynski JS, et al. Emergency medicine: a comprehensive study guide. 6th ed. New York: McGraw-Hill; 2004.)

Diagnostic Imaging

Focused Assessment With Sonography for Trauma

Diagnostic peritoneal lavage has been supplanted by the adoption of focused assessment with sonography for trauma (FAST) and the improved quality and availability of high quality computed tomography. While its pitfalls include false positive results, injury to visceral structures and poor sensitivity to detect retroperitoneal injury, it remains useful (in lieu of diagnostic laparoscopy or formal exploration) to evaluate patients with equivocal FAST or CT findings (Fig. 2).

Bedside sonographic assessment of the trauma victim is considered standard of care and can be used as adjunct during both primary and secondary surveys. A low frequency transducer (3.5 MHz) is used to examine the hepatorenal and splenorenal recesses, subxiphoid area (pericardium) and the pelvic cul de sac. Identification of free fluid in these areas (blood, saccus, other) indicates a potential injury and necessitates further evaluation.

Approximately 200 mL of free fluid is required for detection; sensitivity ranges from 73% to 88%, and accuracy from 96% to 99%. In general, positive findings in a stable patient can be evaluated further with CT, whereas such findings in an unstable patient should prompt the surgeon to proceed with operative exploration. Performing the pelvic examination before insertion of a Foley catheter or after instilling 200 to 250 mL of saline can increase sensitivity and if patients are placed in the left or right lateral decubitus position, smaller amounts of fluid may be detected. Preexisting conditions such as ascites and peritoneal dialysis may render the assessment unusable, and since the FAST is somewhat dependent on operator experience, regular practice is recommended.

Plain Film Radiography

Even with the development of FAST and the ubiquitous availability of high resolution CT, (portable) plain film radiography continues to play an important role. Current trauma protocols advocate for obtaining an AP of the chest and AP pelvis radiograph because many potential life threatening injuries or complications can be rapidly identified and addressed. AP chest imaging may reveal a pneumothorax or hemothorax, rib fractures, location of foreign bodies, and endotracheal tube placement. An AP pelvis film can identify the type of pelvic fracture and guide further management, such as application of a binder or the need for external fixation/angiography.

Extremities with obvious deformities, joint swelling, or tenderness on physical examination should be investigated with additional plain film imaging. Obtaining images of the joint proximal and distal to the suspected injury may help identify additional injuries. AP and lateral views should be obtained routinely, and additional views after appropriate stabilization of the patient.

Although not routinely used, AP abdominal films may assist in the evaluation and surgical planning for penetrating injuries with unclear trajectory; when using a marker, the rough trajectory and location of the bullet/fragments can be identified. the same is true for gunshot trauma to the extremities. Plain film imaging of the spine (AP, lateral, odontoid, with or without oblique and/or swimmer's view) have been supplanted by the use of CT. Multidetector helical CT of the abdomen or chest offers more anatomical detail, routinely detects up to 40% more spine injuries, and does not require additional exposure. Adding dedicated CT imaging of the cervical spine requires minimal time and avoids inadequate imaging of the C1–2 and C7–T1 regions. According to the National Emergency X-Radiography Utilization study, patients with a normal level of alertness, no evidence of intoxication, no posterior midline C-spine tenderness, no focal neurologic deficits, AND no (painful) distracting injuries may be cleared clinically.

Computed Tomography

Helical multidetector computed tomography with and without contrast has become the most accurate diagnostic and screening method with patients with a wide spectrum of soft tissue, bony, vascular, and organ injuries. Its use has led to accepted classifications of organ injuries that affect the therapeutic approach. With current high resolution, high speed scanners, sensitivities, specificities, and accuracy approach 100%. The use of CT is particularly helpful in patients with altered mental state who cannot give a reliable examination. The routine use of oral contrast has fallen out of favor in trauma because of the risk of aspiration and time constraints, but intravenous contrast is recommended when evaluating for vascular, solid organ, and intestinal injuries. A high index of suspicion is required when looking for bowel injuries. Indicators are often indirect (free fluid, bowel wall thickening, mesenteric stranding) and can be missed. Active contrast extravasation, the detection of a vascular cutoff sign or pseudoaneurysm may provide the indication for angiography in solid organ injury.

Angiography

Angiography and CT angiography can be used for the assessment and treatment of trauma patients. Vascular injury, injury to solid organs, retroperitoneal and pelvic hemorrhage, as well as injury to named vascular structures of the head, neck, chest, and extremities may all be amenable to angiographic intervention (e.g., stenting, embolization, thrombectomy) in experienced hands. Hemodynamic stability and adequate volume resuscitation status should be established before transporting a trauma patient to a diagnostic procedure; the trauma surgeon must work together with the vascular surgeon, interventional radiologist, and/or orthopedic surgeon to properly prioritize and sequence the patient's care. If the patient is hemodynamically unstable or has clear loss of pulses, priority should be given to operative intervention. Angiography should be considered in any extremity trauma with a (left–right) difference in ankle brachial index, particularly if the injured side has an ankle brachial index less than 0.9. Patients with pelvic fractures and evidence of significant ongoing blood loss may benefit from angioembolization of the internal iliac arteries, regardless if the bleeding is arterial or venous. It is recommended that this be performed in a hybrid suite where conversion to an open exploration can be accomplished without delay, if necessary.

Special Populations

Children, pregnant patients, older adults, and medically obese patients warrant special consideration; these patients may exhibit a physiologic response to injury that does not follow expected patterns and/or may require special equipment or services (Table 6). Children have unique variations in anatomy, require weight based medication dosing, lose heat rapidly, and often compensate for prolonged periods with few signs of shock. When decompensation occurs, it is often sudden and deleterious. Pregnancy significantly alters the response to injury, circulating blood volumes, and coagulation, and adds the need for both fetal and maternal assessment and management. Older patients often have diminished physiologic reserve, preexisting conditions and medications may significantly interfere with the ability to respond to stress, and older patients commonly are overresuscitated or undertriaged. Despite these issues, older patients can do as well as younger patients, when optimally treated. Diagnostic and therapeutic procedures in morbidly obese patients are often more difficult or hazardous, and these patients may exhibit significantly reduced cardiopulmonary reserves. Familiarity with the special considerations in these patient groups and close monitoring is paramount for optimal outcomes.

CONCEPT OF DAMAGE CONTROL AND COORDINATED CARE

Many trauma patients present with a combination of injuries, requiring the coordinated approach of several specialists and functional areas within the acute care hospital. Physiologic changes after injury are highly dynamic and may require that one problem is addressed before another. The primary concerns center around the establishment of a secure airway and ventilatory support, as well as expeditious hemostasis and circulatory support. Secondary issues such as hypothermia, acidosis, and coagulopathy with their associated problems must be prevented or identified and corrected early and aggressively. Although progression to definitive care in the most expeditious fashion is the goal, attempting to provide or persisting with definitive treatment in the face of hemodynamic instability or physiologic deterioration may lead to poor outcomes. In such situations, a patient may do better with the initial goal of damage control under this paradigm, under continued resuscitation, the patient is moved between care areas (operating room, ICU, interventional radiology) for specific treatment goals, including temporary fixation of unstable fractures (i.e., external fixation), control of intestinal spillage (i.e., damage control laparotomy), restoration of blood flow (i.e., temporary shunt) or hemorrhage control (i.e., angiography), and the relief of intracranial hypertension (i.e., burr hole, craniotomy), interposed are periods of resuscitation to correct physiologic derangements and prepare the patient for further therapy. Once the patient has been stabilized, plans for (staged) definitive care of the patient's injuries is coordinated between the trauma team leader and all involved specialists.

Optimal care for injured patients is best delivered in well coordinated teams; these teams need to establish leadership, clear responsibilities, and communication patterns. To constantly improve and to allow team members to deal with the stress involved in trauma

TABLE 4 Patients Requiring Special Considerations

	Considerations
Pregnancy	• Rest initial treatment of the fetus is optimal treatment of the mother; when blood is needed, Rh-negative blood should be used; all pregnant Rh-negative mothers should receive Rh immunoglobulin within 72 hours unless injury to remote from the uterus • An obstetrician should be involved early; abdominal ultrasound should be done; fetal heart can be monitored with Doppler after 10 weeks; continuous fetal monitoring should be done after 20–24 weeks; all pregnant patients should be observed for at least 4 hours • Diagnostic imaging should be ordered with the same general indications as for nonpregnant patients; shield abdomen/pelvis with lead apron when possible • Uterus: intrapelvic until week 12, at umbilicus by week 20, to costal margin by weeks 36–40; uterus can cause vena cava compression and hypotension in supine position (third trimester), when possible, patients should be placed with the right side elevated at 15–30 degrees • Plasma volume increases throughout pregnancy and hematocrit decreases to 30%–35%; healthy pregnant patients can lose up to 1200 mL of blood before exhibiting signs of hypovolemia • Amniotic fluid can cause embolism and disseminated intravascular coagulation • Watch for signs of placental abruption (inelasticity can cause abruption in second and third trimester) and/or uterine rupture: uterine tenderness, frequent contractions or tetany, vaginal bleeding, abdominal rigidity, maternal shock, admission is mandatory for patients with these signs • Gastric emptying is delayed; consider decompression; consider antiemetics (metoclopramide, ondansetron) • To avoid fetal hypoxia, use supplemental oxygen
Pediatrics	• Because of increased body surface area, heat loss/hypothermia is more common • Skull, long bone, and rib fractures suggest high energy transfer; underlying organ injury must be sought • Need for weight-based dosing and resuscitation (use resuscitation tapes or calculators) • Airway smaller, shorter, and more anterior; use uncuffed endotracheal tube up to 3.5–4.0 kg/age 5–7 years; small children need 1 inch pad under body to avoid neck flexion; oral airways should only be used in unconscious children; preoxygenation is mandatory before intubation • Children often compensate for blood loss up to 30% without overt signs of hypovolemia/shock; normal systolic blood pressure for child is 80 to 90+ (2 × age in years), normal heart rate declines from <160 at birth to <100 at age 12–15 years; normal urine output is 2 mL/kg/h at birth and >0.5 mL/kg/h by age 12–15 years • Consider intraosseous access early if peripheral procedures; routine access in unsuccessful • When CT evaluation is necessary, radiation must be kept As Low As Reasonably Achievable; perform CT scans only when medically necessary when the results will change management, scan only the area of interest and use the lowest radiation dose possible • In serious trauma, brain injuries are more common; with TBI, increased intracranial pressure develops more frequently in children; neurosurgical consultation should be obtained early; children with bulging fontanelles or suture diastases should be assumed to have a more severe injury; persistent/recurrent vomiting and any seizure activity requires investigation by CT of the head • Spinal cord injury is uncommon in those <10 years old; the radiographic finding of pseudo-subluxation complicates 20%–40% of plain films in children <15 years • Child maltreatment should be suspected if suggested by suspicious findings on history or physical examination; these include discrepant history, delayed presentation, frequent prior injuries, injuries incompatible with developmental stage, and perineal injuries

care; trauma team leaders should actively debrief with the entire team, especially after resuscitation of severely ill multitrauma patients or trauma deaths.

PREHOSPITAL MANAGEMENT OF THE TRAUMA PATIENT

Jay Doucet, M.D, MSc, FACS, FCSC, and Jac Colvin, MD, PhD, FACS

Optimal outcomes for severely injured patients are obtained in the context of an organized trauma system. Using a disease model for trauma, most trauma death and morbidity can be considered preventable. Prevention of death and morbidity from injury is the goal of the trauma system. However, most trauma deaths occur before the injured patient reaches definitive care. Optimal prehospital care provided by trained bystanders (immediate responders) and by emergency medical services (EMS) reduces preventable death and morbidity and is an essential component of the trauma system. Immediate responders initiate EMS by activating systems such as the 911 system. They can provide first aid and immediate bleeding control. EMS is more than the transport of injured patients; it has goals of prevention of further injury and death, appropriate resuscitation, and safe, timely transport. As part of a trauma system, the EMS system must include a robust performance improvement process, a series of evidence- and consensus-based care protocols, trauma triage criteria, appropriate paramedic or emergency medical technician (EMT) training, well-proven equipment, and destination policies. Triage protocols, communications, and high-quality medical direction and dispatch are also required for optimal EMS outcomes. EMS transports patients to facilities that are part of the trauma system and are able to care for injured patients, bypassing nontrauma facilities even if they are closer.

The principles of modern prehospital management were derived from lessons learned in past military conflicts, and new lessons continue to be learned in modern conflicts that are being applied today. Many of the recent innovations to civilian EMS such as helicopter EMS (HEMS), prehospital blood product administration, tourniquets, and others were pioneered in military conflict health systems. This chapter reviews the main tenets of prehospital trauma evaluation, discusses system processes of field triage and tiered response, and examines how military experience has shaped practice.

Mortality in trauma classically has been divided into three temporal categories. Fifty percent of deaths occur immediately and are attributable to exsanguination and head trauma. These patients can be targeted via prevention and public health measures but are not salvageable with the use of prehospital trauma life support (PHTLS) interventions. Thirty percent of deaths occur within 1 to 3 hours of injury and are potentially avoidable through proper resuscitation and hospital efforts. Prehospital management of the trauma patient intercedes during that critical golden hour, when life and health saving interventions are possible. The final peak in mortality occurs within 1 to 2 weeks after trauma and is usually secondary to infections or organ failure.

INITIAL PHASES OF PREHOSPITAL CARE

Scene Assessment

The first priority for everyone involved with a trauma incident response is assessment of the scene. This involves first ensuring that the scene is safe, considering carefully the nature of the situation. Some situations are changing rapidly and may present danger of causing further deaths and injuries to responders and casualties, such as structural collapse, vehicular traffic, spreading fire, active shooters, darkness, environmental conditions, hazardous materials, blood, and infectious diseases. There may be multiple casualties and casualties in need of rescue or extrication. Most hospital-based providers have not received training in scene assessment, and if encountering such a scene should take direction from professional first responders or risk death, injury, and impeding the EMS response.

First Aid/Buddy Aid

A lesson from military conflicts and described in military PHTLS and the Tactical Casualty Combat Care course is the concept of self-aid or "buddy" aid. This includes training all personnel how to provide immediate actions for life threatening conditions, even if under enemy fire. Selected personnel are given additional training to combat bleeding skills to supplement military medics. When safe, skills include maintaining the airway of an unconscious patient with a chin lift or jaw thrust and use of the recovery position. Tension pneumothorax may be managed by needle or finger thoracostomy. Open pneumothorax or sucking chest wounds are managed with three-sided occlusive dressings or pressure chest seal kits. Bleeding is managed with direct pressure, and wound packing with hemostatic dressings or tourniquets. Success in these interventions has led to the civilian program "Stop the Bleed."

"Stop the Bleed" Training for Civilians

Uncontrolled hemorrhage is the leading cause of preventable trauma deaths. The Hartford Consensus group, including the American College of Surgeons Committee on Trauma (ACS COT), the National Association of EMTs, and other professional and government agencies, has provided EMS guidelines for response to mass casualty events such as bombings and active shooters. Surveys have revealed that the majority of Americans are interested in learning bleeding control skills such as direct pressure, and wound packing with hemostatic dressings or tourniquets. The Hartford Consensus and the Department of Homeland Security launched the Stop the Bleed (STB) program in 2015, which teaches interested civilians steps for response to a bleeding trauma patient: (1) ensure the scene is safe, (2) call 911 or have someone else call, (3) identify life threatening bleeding, (4) apply direct pressure, (5) if it is extremity bleeding, use an available tourniquet, and (6) if a tourniquet cannot be used or is unavailable, pack the wound with clothing, gauze, or hemostatic dressing and apply pressure. The STB effort is supplemented by efforts to place accessible bleeding control kits in public locations such as schools, airports, malls, and stadiums.

Although tourniquets had fallen out of use secondary to a perceived concern for limb loss, proper placement of the tourniquet proximal to the injury for less than 2 hours reduces hemorrhage and saves lives. Several studies have demonstrated that tourniquet use on the battlefield does not lead to unintended amputation or long-term disability and does reduce mortality in patients with severe blast injuries. In a study of deaths that occurred during Operation Iraqi Freedom, prehospital tourniquet use was associated with improved hemorrhage control. Of the deaths that did occur, up to 57% may have been prevented by earlier tourniquet use. When direct pressure fails, tourniquet placement should be attempted. In a civilian trial in Texas, mortality was improved, although initial compliance with the tourniquet protocol by paramedics or EMTs was suboptimal, with some tourniquet application opportunities missed.

INITIAL FIELD CARE BY THE PARAMEDIC OR EMT

The key principles of prehospital evaluation for the EMT follow standard trauma resuscitation guidelines. After ensuring scene safety, airway is addressed first, followed by breathing, then circulation/shock, disability and exposure and environment (the ABCDEs).

Airway

In patients identified in the field with respiratory distress, supplemental oxygen and adjuvants such as nasal trumpets, oral airways, and bag-valve masks can be used. Advanced noninvasive airways include the

King airway, laryngeal mask airway, or I-gel airway. Although effective, these do not prevent aspiration as they do not place a cuffed tube in the trachea. In patients identified with severe respiratory distress or in those with an inability to protect their airway (emesis, oropharyngeal bleeding, altered mental status with a Glasgow Coma Scale [GCS] score <8), endotracheal intubation is considered if paramedic or EMT skills and local protocols allow. Controversy exists regarding intubating patients in the field. Although intubation may serve to protect the airway and oxygenate and ventilate the patient, time spent intubating is precious, aspiration risk during intubation may be increased, tubes can be dislodged in transport, and inadvertent esophageal or malposition intubations may lead to significant hypoxia. Several retrospective and prospective studies have demonstrated an increase in morbidity and mortality in patients with traumatic brain injury (TBI) who were intubated in the field. This increased mortality may be secondary to severe hyperventilation or hypoxia. If airway adjuncts and bag-valve masks are adequate, the "scoop and run" technique without scene intubation usually allows for the most rapid transport to the trauma center. Inability to ventilate, inability to maintain saturations in the prehospital environment are very challenging and usually lead to poor outcomes. Surgical airways such as cricothyrotomy are performed rarely and many paramedics or EMTs lack confidence, recent experience, or a local protocol allowing performance.

If the resources are available, a valuable aid in intubated patients is end tidal capnography, which is most useful in verifying endotracheal tube position avoiding hyperventilation and hypoventilation. End tidal capnography is being incorporated more frequently in the prehospital setting and is particularly advantageous in TBI. Several studies have demonstrated that noninvasive reduces the mortality rate in patients once they reach the emergency department (ED). As part of the San Diego Paramedic Rapid Sequence Intubation trial, patients had a reduced incidence of severe hyperventilation. These patients with significant hyperventilation had a 50% mortality rate compared with a 30% mortality rate in patients without hyperventilation.

Breathing

Paramedic and EMT care here through the timely identification of tension pneumothorax. This diagnosis can be made readily and addressed in the field with needle or finger pleural decompression. Clinical findings include respiratory distress, unilateral decreased breath sounds, crepitus, tracheal deviation, distended neck veins, hyperresonance to percussion, increased difficulty in bag masking, and hemodynamic instability. The affected side can be decompressed by perpendicular insertion of a finger or large bore 12- to 14-gauge intravenous (IV) catheter 4.5 inch catheter is used in smaller adults, and 8 cm in larger adults. In children, the catheter placed in the second or third intercostal space, passed over the superior surface of the rib in the midclavicular line. In adults, it is placed in the fourth or fifth interspace, anterior to the midaxillary line. Failure to decompress or kinking of the catheter is a common problem. In case of needle catheter failure or if no such catheter is available, finger thoracostomy is made through a 2- to 3-cm incision placed in the fourth or fifth interspace, and the pleural puncture and spread with a Kelly type clamp. Common pitfalls include late recognition of tension pneumothorax, improper needle or clamp placement causing lung laceration, or poor depth of needle placement such that the pleural space is not entered. Subsequently, a chest tube should be placed at the hospital for definitive decompression.

Circulation and Shock

Assessment of the patient for shock by the paramedic or EMT is first completed of looking for evidence of hemorrhage and assessing total body and regional perfusion. Quick recognition of actively bleeding sites with application of direct pressure, wound packing with a hemostatic agent or a tourniquet can prevent exsanguination. Frequently missed locations of wounds include scalp, back, perineum, and axilla. Although IV access is usually sought, administration of large volume crystalloid resuscitation, especially in penetrating torso trauma, is associated with increased mortality. Shock due to torso intracavitary hemorrhage cannot be controlled by the paramedic or EMT with current technology. This has led to the supposition that the best prehospital resuscitative fluid to use in such cases is "about" to avoid excess IV crystalloid administration and shorten scene and transport duration with a "scoop and run" approach.

Data indicate that in uncontrolled torso hemorrhage, controlled resuscitation with a goal systolic blood pressure (SBP) of 80 to 90 mm Hg may decrease mortality. In studies of penetrating torso trauma, patients who did not receive fluid resuscitation in the field had lower mortality compared with patients who were resuscitated with fluid. Liberal fluid resuscitation was associated with an increase in acute respiratory distress syndrome, pneumonia, and coagulopathy. Possible reasons for this difference include fluid administration leading to increased arterial pressure and venous dilation of bleeding sites, disruption of newly established clot, and possible dilution of clotting factors. However, in patients with suspected head injury, decreased mean arterial pressure could decrease cerebral perfusion pressure to harmful levels; therefore in patients with TBI an SBP of 100 mm Hg is the goal. Small trials of prehospital administration of a hypertonic saline solution (HTS) to reduce cerebral edema, improve blood pressure, and improve TBI outcomes showed promise, but use of HTS in a large multicenter randomized trial was unsuccessful.

If access is difficult to obtain but necessary secondary to clinical signs of hemorrhagic shock or to administer drugs, the intraosseous (IO) route is available and considered the next best choice. Possible locations depend on the device used and include the proximal anterior tibia (most common), sternum (used frequently in the military and may have faster flow rates), humerus, femur, distal tibia, and superior iliac crest. The IO route has equivalent plasma kinetics to IV (tracheal drugs, and both crystalloid and colloid infusions can be given at similar rates to IV access. Compared with central line placement, IO access has higher first attempt success rates and faster time to insertion.

Circulation and Shock: Prehospital Blood Products

During World War II and the Korean War, British Commonwealth and U.S. forces used lyophilized freeze-dried plasma (FDP), reconstituted and administered to combat casualties in the field by medics. This innovation was later lost owing to problems with viral disease transmission, but new detergent solvent extraction techniques are making this product available to military medics and civilian paramedics and EMTs. Experience in Iraq and Afghanistan by coalition forward surgical teams with improved surgical hemostasis in casualties receiving whole blood has reignited interest in bringing blood products administration to prehospital trauma care. Military guidelines emphasize earlier administration of plasma and platelet products in massive transfusion. Several military and civilian studies support using 1:1:1 replacement of fresh frozen plasma to platelets to packed red blood cells. In a combat hospital setting, 19% mortality was found when the plasma to red blood cell ratio was 1:1 , compared with 34% mortality when the ratio was 1:2.5 and 65% mortality when the ratio was 1:8. A similar retrospective review of 466 massive transfusion civilian trauma patients also noted improved survival, decreased intensive care unit stay, and improved ventilator- and hospital-free days among the high plasma and high platelet patients. Survival was most enhanced by a plasma to red blood cell ratio of greater than 1:2. A trial using thawed plasma administered to 144 hypotensive and tachycardic trauma patients in shock by ground based EMS did not show a benefit, but another trial of thawed plasma given to 901 hypotensive and tachycardic trauma patients transported by HEMS showed 30-day mortality was significantly lower in the plasma group (23.2% vs 33.0%). Prehospital trials using FDP are planned. Additional trials of low titer, whole O group blood (LTWOB) are being performed in some EMS systems for injured patients in hemorrhagic shock. LTWOB provides a 1:1 replacement of fresh frozen plasma to platelets to packed red blood cells in each unit.

Circulation and Shock: Prehospital Tranexamic Acid

The role of the antifibrinolytic drug tranexamic acid (TXA) has been studied as an adjunct to control bleeding. The Military Application of Tranexamic Acid in Trauma Emergency Resuscitation Study retrospectively evaluated nearly 900 casualties, demonstrating a significantly lower mortality among soldiers receiving TXA than among those receiving traditional therapy. The Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage (CRASH-2) study showed similar results in 20,000 civilian trauma patients in nearly eastern settings. Several trials have revealed a decrease in mortality, although some have only demonstrated a reduction in transfusion requirements and coagulopathy, particularly in patients requiring massive transfusion. CRASH-2 recommendations for trauma patients with clinical signs of hemorrhage include a TXA loading dose of 1 g given intravenously over 10 minutes in the first 3 hours after injury, followed by 1 g infused after 8 hours. The drug must be administered early to be effective in reverse traumatic coagulopathy. It has been linked to an increased risk of death from bleeding when given to survivors more than 3 hours after injury. Secondary to reports of thrombotic complications when TXA is used in conjunction with prothrombin complex concentrate (PCC), trauma centers generally are not administering these medications simultaneously. Many U.S. Level I trauma centers use thromboelastography to identify clotting deficits at admission preferentially to TXA, and many elderly patients with atrial fibrillation are taking direct acting oral anticoagulants requiring PCC or other agents for reversal. Therefore, EMS protocols for TXA use must be coordinated with the trauma system and trauma centers.

Circulation and Shock: Prehospital Traumatic Cardiac Arrest

As discussed earlier, following the standard algorithm of assessing trauma patients should identify reversible causes of cardiorespiratory collapse such as airway compromise, tension pneumothorax, open pneumothorax, massive hemothorax, cardiac tamponade, and hemorrhage. Prehospital arrest has a worse prognosis in the setting of blunt trauma when compared with penetrating trauma and has an overall bleak prognosis when it occurs during transit to the hospital by EMS. Cardiopulmonary resuscitation (CPR) is futile if the victim of blunt trauma is found already in arrest by healthcare personnel. In penetrating trauma, if pupillary reflexes, spontaneous movement, or organized electrocardiogram activity is present, CPR should be attempted, and the patient brought immediately to the trauma center. In general, CPR in blunt trauma for more than 10 minutes without restoration of vitals is ineffective. Many jurisdictions do not allow the paramedic or EMT to declare death except in the most obvious of cases, and so trauma patients with prolonged CPR and no significant chance of survival are still brought to hospitals with CPR in progress. In the event of hanging, drowning, hypothermia, electrocution, arrest from a medical condition, or in children, the paramedic or EMT or their medical director often may continue resuscitative efforts. However, in children with blunt cardiac arrest and CPR more than 10 minutes, outcomes are just as dismal as in adults.

Circulation and Shock: Advanced Techniques of Hemorrhage Control

The quest to prevent exsanguinating hemorrhage has led to prehospital trials of new devices such as REBOA (Retrograde Endovascular Balloon Occlusion of the Aorta) catheter and the Military Junctional Tourniquet (MTJ). In 2014, the London United Kingdom HEMS service performed a REBOA procedure in a roadside traffic accident patient in severe shock from pelvic fractures who survived. However, REBOA was limited to the London system in HEMS units. Because of the need to obtain femoral arterial access to perform REBOA, the MTJ was developed, which places heavy compression on the abdomen and aorta. Neither device has been proven effective in a Level I evidence trial. REBOA can have severe complications including ischemia reperfusion injury, vascular access injuries, and inability to control or actual worsening of expanding/stagnant bleeding. There are few survivors in trials of intraluminal aortic placement of REBOA for more than 30 minutes. MTJ has many of the REBOA adverse effects and potential compression injuries to bowel, bladder, and nerves. Results of prehospital trials are awaiting.

Disability: Head and Spinal Trauma

Traditionally, blunt trauma patients in the field, particularly those with a concerning mechanism of injury or high suspicion of spinal injury, were "immobilized" with a backboard and rigid cervical collar. Although current techniques limit or reduce unilateral motion of the spine, they do not provide true spinal immobilization. For this reason, the term spinal motion restriction (SMR) has gained favor over spinal immobilization, although both terms refer to the same concept. Debate exists about prehospital clearance of the cervical spine by properly trained EMS personnel. Several studies have demonstrated that trained EMS personnel are able to appropriately clear cervical spines in standardized patients. However, in the more chaotic and dynamic setting of the unstandardized field patient, EMS personnel immobilize fewer patients in practice than do their physician colleagues. No data exist as to whether this discrepancy leads to adverse outcomes. In trauma systems that incorporate cervical spine clearance in the field, the two common criteria used for clearance are the National Emergency X-Radiology Utilization Study (NEXUS) and the Canadian C-Spine Rule. According to the NEXUS guidelines, clearance is achievable if the patient has no posterior midline cervical tenderness, is not intoxicated, has no alterations in mental status or focal neurologic deficits, and has no distracting painful injuries. Under the Canadian C-Spine Rule, the patient can be cleared and does not require imaging if he or she is younger than 65 years, has a low impact mechanism, has no paresthesias in extremities, is either ambulatory or sitting upright in the ED, has no midline tenderness, and is able to rotate his or her neck 45 degrees to the left and right. Of note, this determination takes some time and may interfere with rapid transport of the patient to definitive care (Fig. 1, table 1). The ACS-COT, American College of Emergency Physicians, and the National Association of EMS Physicians provide these indications for SMR following blunt trauma: (1) acutely altered level of consciousness (e.g., GCS <15, evidence of intoxication), (2) midline neck or back pain and/or tenderness, (3) focal neurologic signs and/or symptoms (e.g., numbness or motor weakness), and (4) anatomic deformity of the spine. Because of the risk of deep tissue injury and skin ulcers from prolonged use of SMR, once the patient is safely positioned on the ambulance cot, immobilization or extrication SMR devices may be removed. This requires an adequate number of trained personnel are present to minimize unnecessary movement during the removal process. If transport time is expected to be short, it may be better to transport a patient on the device and remove it on arrival at the hospital. If the decision is made to remove the extrication device in the field, SMR should be maintained by ensuring that the patient remains securely positioned on the ambulance cot with a cervical collar in place.

Exposure and Environment: Hypothermia

Approximately 66% of trauma patients in the civilian setting arrive at the ED with hypothermia. Prevention of hypothermia (body temperature <34°C) is a practice championed by the military, with the idea that instituting rewarming methods early impedes the spiral into the trauma triad of death of hypothermia, coagulopathy, and acidosis. Layers of blankets and modified jacket body bags to provide warmth are used in current combat situations. Passive rewarming can be achieved by increasing ambient temperatures, whereas active rewarming uses blankets and air or fluid circulating covers. Core rewarming uses fluid warmers to heat infusing fluid to 42°C. The key is to initiate prevention early in the field, as adequate rewarming is much more difficult to achieve once hypothermia occurs.

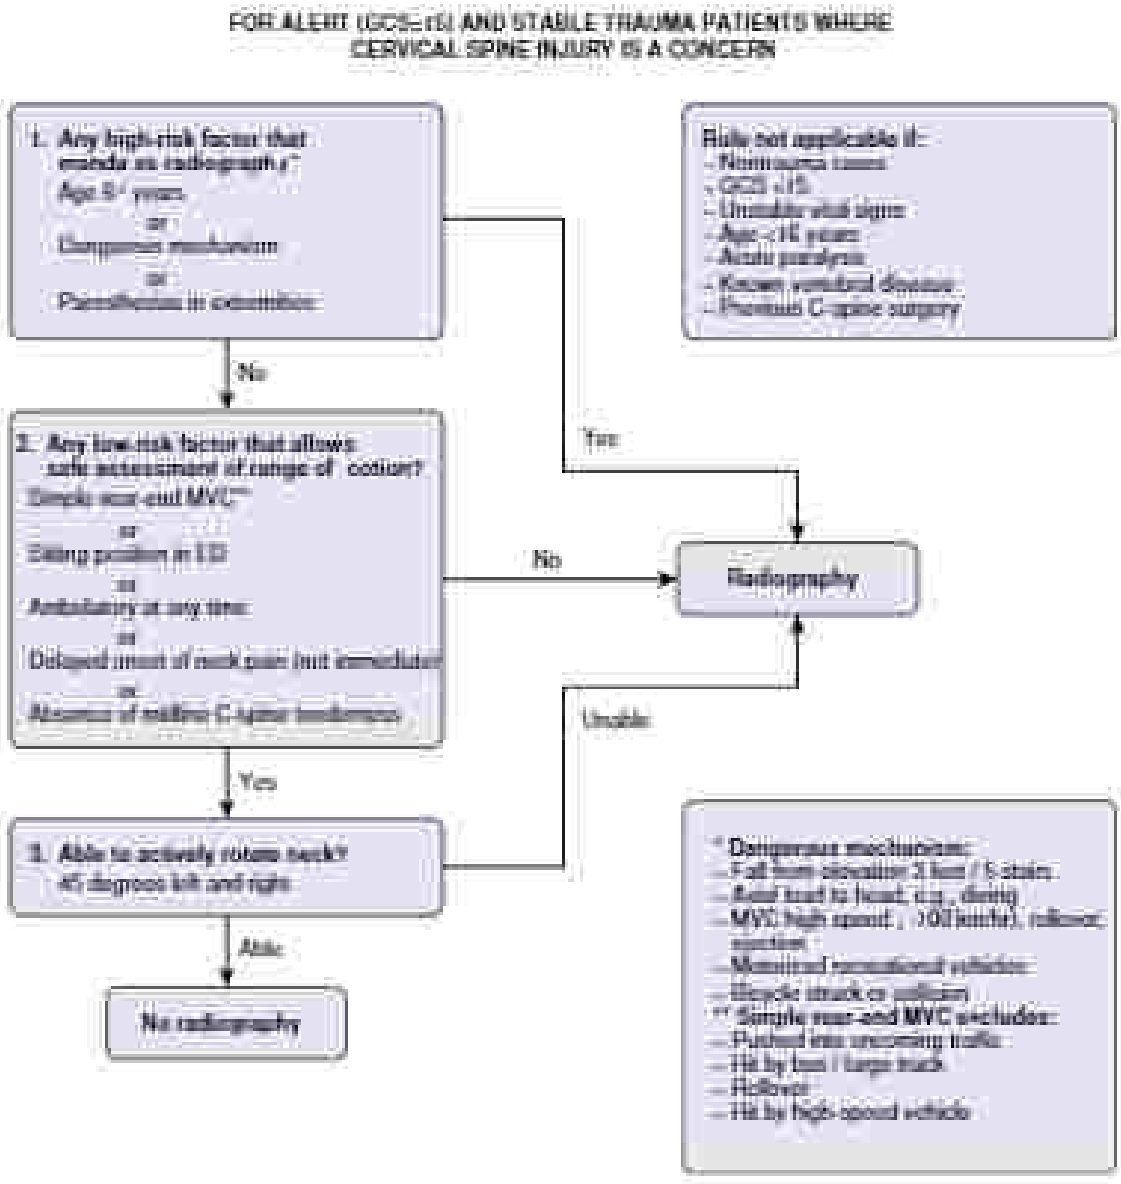

FIG. 1 Canadian C-spine rule (CCR). ED, emergency department; GCS, Glasgow Coma Scale; MVC, motor vehicle collision.

TABLE 1 NEXUS Criteria for Low Probability C-Spine Injury

1	No midline tenderness
2	No focal neurologic deficit
3	Normal alertness
4	No intoxication
5	No painful distracting injury

NEXUS, National Emergency X-Radiology Utilization Study.

Adjuncts: Splints

An adjunct frequently used in the prehospital setting is the splint; common materials include box, vacuum, and traction splints. In the case of obvious extremity fractures, splinting the injured extremity can stabilize the injury and potentially reduce pressure on skin and neurovascular structures, and decrease pain and bleeding. The splint must extend to the joints above and below the fracture to provide support.

CARE DURING TRANSPORT

Prehospital Field Triage

In the United States, in-hospital and 1-year mortality are significantly lower in trauma patients treated at trauma centers compared with those treated at nontrauma centers. Having a predetermined system in place to address injuries and triage patients saves lives. Trauma centers are divided into different tiers based on their capabilities. Level I trauma facilities have the resources for all-encompassing trauma care, including subspecialty providers, research capabilities, education, outreach, prevention, and rehabilitation. Level II trauma centers retain almost equivalent resources and can provide resuscitation and stabilization of patients, but do not provide similar education and research opportunities. Level III trauma centers have more limited resources and staff. They are able to treat minor traumas and possess the capability to stabilize and transfer more severely injured patients to a higher level of care. Allocation of trauma patients into these systems requires the use of thoughtful triage parameters in the field. Proper triage in the prehospital setting can lead to expedient transfer of the most ill patients to definitive care. The key is to maintain a balance between guaranteeing that the majority of

critically ill patients are transported to a higher level of care facility and ensuring that these systems are not overburdened with patients who have sustained minimal injuries. A 50% overtriage rate is tolerated to attain a 5% or lower undertriage rate per the ACS COT.

Prehospital triage situations can be divided into field triage and mass casualty. As per the Centers for Disease Control and Prevention (CDC) Guidelines for Field Triage of Injured Patients, a step-by-step algorithm is critical in filtering patients into appropriate avenues of treatment (Fig. 1). When measuring vitals and assessing GCS, patients with an SBP of less than 90 mm Hg, a respiratory rate of less than 10 or more than 29 breaths/min (<20 breaths/min in infants aged <1 year), the need for ventilator support, or a GCS score of less than 14 should be transported preferentially to the highest level of care available within the defined trauma system.

Similarly, EMT assessment and location of injury and mechanism and evidence of high impact. Specific injury patterns require evaluation in a Level I trauma center or at an institution with the most advanced care within that trauma system. The particular sequence of concern include penetrating trauma to the head, neck, torso, and extremities proximal to the elbows and knees (hall chest); two or more proximal long bone fractures; crushed, degloved, or mangled extremities; amputations proximal to the wrist or ankle; pelvic fractures; open or depressed skull fractures; and paralysis.

Depending on the particular trauma system, if the patient does not have the aforementioned clinical signs or anatomic indications, he or she does not necessarily need to be transported to the highest level of care. Indications for transfer to at least a lower level trauma center include high-impact mechanisms such as falls from higher than 20 feet (2 stories) in adults or more than 10 feet in children; intrusion of more than 12 inches in the occupant site or more than 18 inches in any site; ejection from a vehicle; death in a compartment; speed greater than 20 mph or patient thrown or run over in an automobile versus pedestrian or bicycle collision; and motorcycle collision at a speed greater than 20 mph. Decisions about transport to a trauma center or hospital capable of trauma management also should consider comorbidities, age, particularly older adults and children; burns; pregnancy greater than 20 weeks; premorbid conditions such as congestive heart failure and end-stage renal disease; or anticoagulation therapy are found on EMS judgment.

Type of transportation to definitive care (ground vs air) must take into consideration multiple factors, such as the patient's clinical condition, weather conditions, weight of patient and necessary equipment, location of helipads, distance to most appropriate level of care, and local emergency needs if there are limited EMS vehicles in the region and the patient must travel far.

Helicopter Emergency Medical Services

Approximately 400,000 patients are transported by HEMS in the United States annually. Uncertainty exists regarding the added benefits of HEMS versus ground EMS (GEMS). A 2015 Cochrane review of 38 HEMS studies did not show an overall benefit, because many studies had methodical problems. HEMS may have advantages in regions with difficult geography and can carry more specialized crew and equipment. From 1972 to 2014, there were 343 HEMS accidents, 123 of which had at least one fatality. In 1980, an HEMS crewmember had a 1 in 50 chance of being in a fatal accident, in 2014 the rate was 1:850, but being an HEMS crew member is still one of the most dangerous US occupations. In 2008, the US National Transportation Safety Board conducted an investigation into a spate of HEMS crashes and made recommendations to the Federal Aviation Administration that were largely accepted, since then the HEMS accident rate has reduced somewhat.

Given the risk benefit ratio of HEMS, triage criteria for safe HEMS use should be carefully created for the trauma system. Studies suggest that trauma patients most likely to benefit can be identified using validated scores such as the Air Medical Prehospital Triage (AMPT) Score. Factors in the AMPT include those patients with chest wall instability or deformity including flail chest or multiple rib fractures, tension pneumothorax, GCS score less than 14, respiratory rate less than 10 or greater than 29 breaths/min, multiple trauma (>1 anatomic body region injured), or any one physiologic criterion plus any one anatomic criterion present from the ACS COT national field triage guidelines (Fig. 2). Unfortunately, some HEMS operations are not full participants in regional or state trauma systems or in the planning for such systems, and HEMS is sometimes still used to cope with non-patient-related system issues such as inadequate local GEMS resources or lack of local verified trauma centers.

DISASTERS AND EMERGENCY PREPAREDNESS

In mass casualty situations, the paramedic or EMT must change focus on optimal care for a single or limited number of patients to providing a population-based standard of care. Resources are typically inadequate, communications are disrupted, and there may be severe environmental challenges including hazardous materials, weapons of mass destruction, and terrorist acts. Most EMS systems have a detailed plan for activation and execution to disasters, typically called the emergency operations plan (EOP). The EOP describes principles for preparation, planning, incident command, interoperability with other agencies, triage, dispatcher actions, regional plans, blast, radiation and chemical threats, special populations, recovery, and business continuity. Typically, an adjacent safe area is used for casualty collection and triage, and patients are sorted using a disaster triage protocol such as SALT (sort, assess, lifesaving interventions, treatment, and/or transport) or START (simple triage and rapid treatment) to the adjacent treatment area marked with red, yellow, and green tarpaulins. SALT uses the ABCDEs principles to assign a color code corresponding to triage tags that can be used to designate status. The walking wounded (green) have minor trauma and are ambulatory patients who can be removed from the scene, if they require care, it can be delayed for approximately 3 hours. Delayed (yellow) and immediate (red) victims are nonambulatory patients who require medical attention, with immediate patients having at least one derangement in respiration, perfusion, or mental status that requires emergent care. Therapy can be postponed for approximately 1 hour in delayed patients. Expectant (gray) victims are considered dead after one attempt to open or reposition the airway demonstrates no respirations. Comfortable, compassionate care also should be administered to these patients; the designation of expectant does not signify that no further interventions should be made, if the situation later improves the patient can be transported. It should be remembered that in some events, patients may leave the scene or be transported by bystanders before the EMS response can even be safely established, such as in the 2017 Las Vegas shooting.

HOSPITAL RESPONSE TO TRIAGED PATIENTS

Once the trauma center receives the field EMS call activation, the ED physician or mobile intensive care nurse determines whether the trauma team activation is warranted. To define the extent of the ED response and determine which resources should be apportioned, similar guidelines to those in CDC triage decision scheme are followed, with healthcare personnel weighing physiologic and anatomic parameters. Mechanism of injury is also considered but is less significant. Standard criteria for hospital activation response exist in few systems, and different institutions use distinct processes. Some trauma centers use an "all or none" approach, whereas others divide patients into two or three categories by number or color scheme to classify patients as critical, low severity (injured but with potential to decompensate), and minimally wounded. In patients with grave injuries, a full response from the hospital occurs with mobilization of the ED and trauma surgeons, residents, or fellows; nursing staff; respiratory therapy; the blood bank; radiology; and anesthesia made available. Partial responses require the ED attending physician, surgical residents,

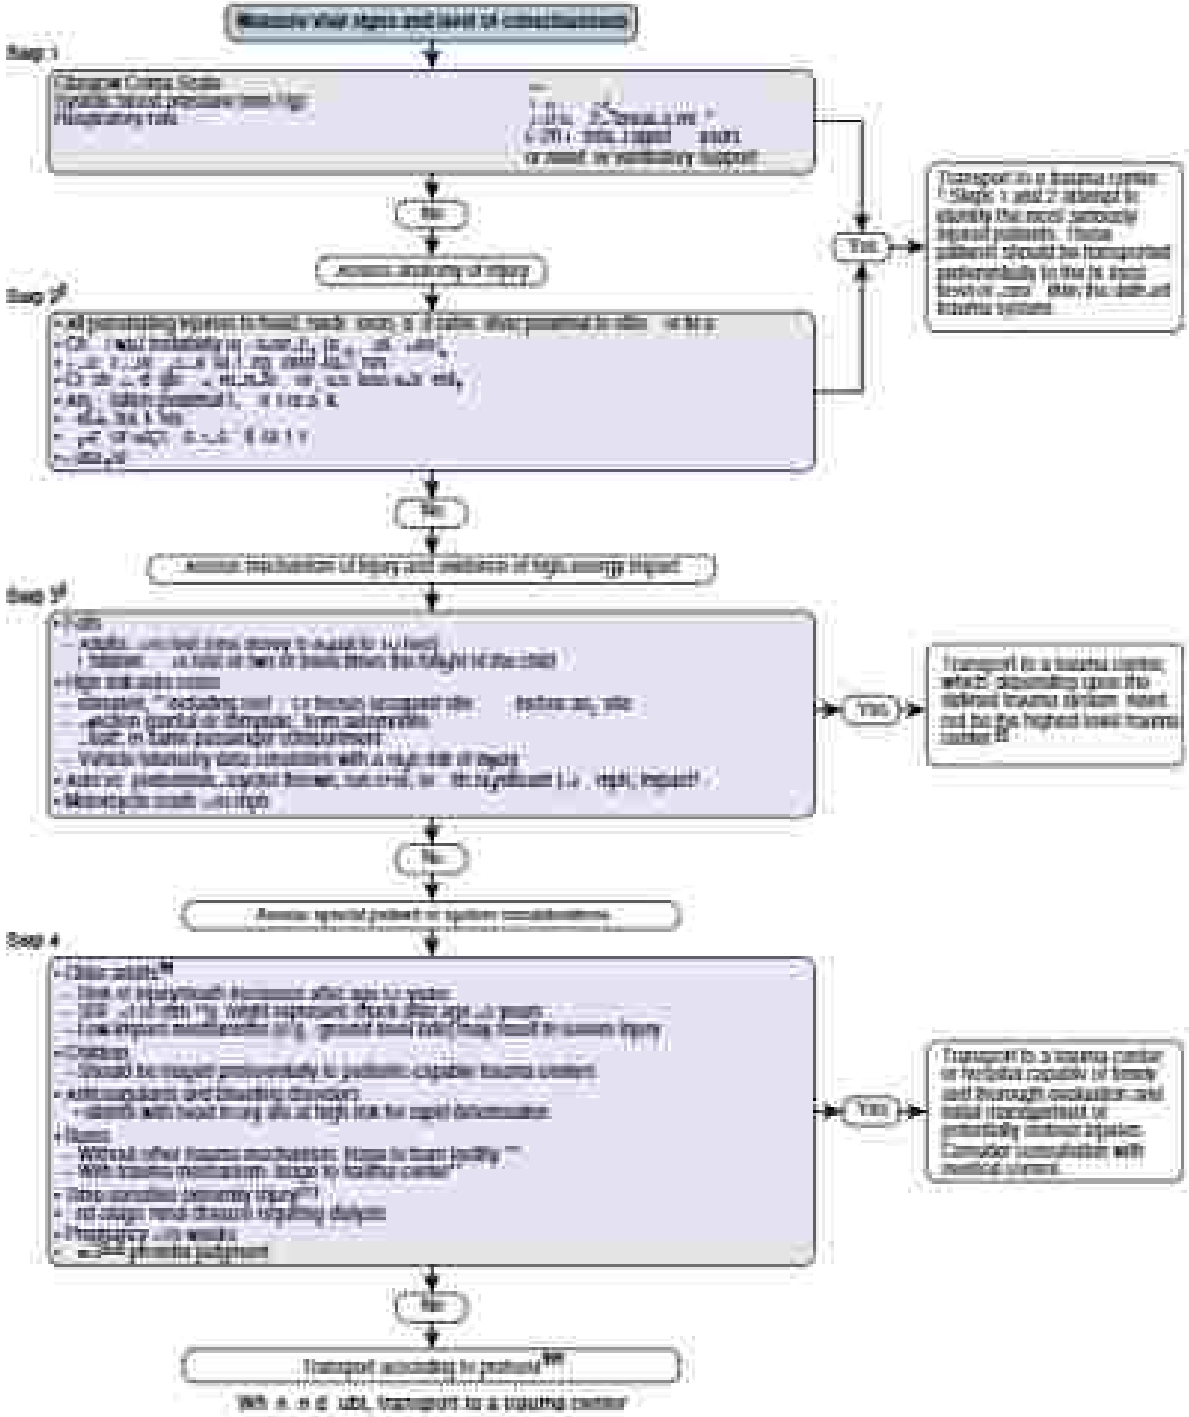

FIG. 2 Centers for Disease Control and Prevention Guidelines for Field Triage of Injured Patients. EMS, emergency medical services; GCS, Glasgow Coma Scale score; SBP, systolic blood pressure; RR, respiratory rate; AV, atrioventricular; ED, emergency department; IV, intravenous; MI, myocardial infarction; PE, pulmonary embolism; TBI, traumatic brain injury; VTE, venous thromboembolism. *Upper limit of respiratory rate in infants is >29 breaths per minute to maximize the likelihood of identifying the infant with severe thoracic trauma who requires immediate intervention. Consider infants at risk for head injury (e.g., ground level fall) may result in severe injury.

†Consider advanced interventions (e.g., ventilatory support, blood transfusion, surgical intervention, intracranial pressure monitoring, tranexamic acid administration) in the trauma bay.

‡Consider transport to a burn center for patients with burns and concomitant trauma (e.g., fracture, polytrauma, blast injury, inhalation injury).

§Consider transport to a burn center for patients with partial-thickness burns ≥10% total body surface area (TBSA).

¶Consider transport to a burn center for patients with full-thickness burns ≥5% TBSA.

**Consider transport to a burn center for patients with burns to the face, hands, feet, genitalia, perineum, or major joints.

††Consider transport to a burn center for patients with burns and electrical injury, including lightning injury.

‡‡Consider transport to a burn center for patients with burns and chemical injury.

§§Consider transport to a burn center for patients with burns and preexisting medical disorders that could complicate management, prolong hospitalization, or increase mortality.

¶¶Consider transport to a burn center for patients with burns and inhalation injury.

***Consider transport to a burn center for patients with burns in children who will be cared for in facilities that are not capable of providing definitive care to children.

†††Consider transport to a burn center for patients with burns who require special social, emotional, or long-term rehabilitative intervention.

nursing staff, and radiology. Having a structured and controlled response system in place with predetermined trauma team activation has been shown to decrease mortality and time for resuscitation, for transport to computer tomography scan and operating room, and to ED discharge. The handoff from EMS providers to the trauma team should be a structured communication with acknowledgement and feedback to ensure all prehospital information is transferred. A typical paramedic or EMT handover format is MIVT (mechanism of injury, injuries seen or suspected, vital signs, and treatments given).

LESSONS LEARNED FROM THE MILITARY

As described earlier, many practices in prehospital civilian resuscitation and care have been extrapolated from or reinforced by military practice, including guidelines for use of tourniquets and needle chest decompression, and the practice of IO access. Incorporation of methods for providing the use of field ambulances traces back to the Ambulance volante du modèle Larrey (flying ambulance) used by Dominique-Jean Larrey (1766–1842), Napoleon Bonaparte's chief surgeon, and helicopter transport of patients was initiated during the Korean and Vietnam wars. Resuscitation guidelines have been influenced strongly by combat trauma data, including hypotensive resuscitation to SBP of 80 to 90 mm Hg and massive transfusion protocols. Currently North Atlantic Treaty Organization forces are supporting flying trauma teams on medium helicopters in Afghanistan and Africa and combining the EMS, HEMS, and forward surgical team roles aboard the same vehicle, down directly to the point of wounding. Further innovations in pre-hospital care from military providers can be expected.

USE OF RESUSCITATIVE ENDOVASCULAR BALLOON OCCLUSION OF THE AORTA IN RESUSCITATION OF THE TRAUMA PATIENT

James N. Stewart, MD, FACS, and Megan P. ...on, MD, MS, FACS

Hemorrhage remains the most common potentially treatable cause of death in the trauma patient. The American College of Surgeons' Advanced Trauma Life Support (ATLS) curriculum encourages rapid identification and control of hemorrhage as the central tenet in caring for the injured patient. Initial attempts at direct pressure and application of hemostatic dressings are warranted for most bleeding. However, if these are not available or not effective, proximal control of the bleeding is warranted. For the extremities, hemostasis may be accomplished with a tourniquet. For noncompressible truncal hemorrhage, hemostasis can be accomplished by occlusion of the aorta.

Resuscitative thoracotomy (RT) was described by Dr. Ledgerwood and others as a method to avoid cardiovascular collapse upon laparotomy and the resultant release of tamponade in the patient with abdominal hemorrhage. Through the left anterolateral thoracotomy incision, the thoracic aorta can be clamped and open cardiac massage performed, thus providing direct resuscitation and proximal control for subdiaphragmatic truncal hemorrhage. In cases of noncardiac injury, pericardial tamponade can be relieved and thoracic hemorrhage can be controlled.

Another option for proximal control of the aorta that does not require a thoracotomy incision is balloon occlusion using endovascular devices. Endovascular balloon occlusion of the aorta for trauma was first described by Dr. Hughes in the 1950s. Other attempts were described in the 1980s but the technique fell out of favor because of cumbersome equipment and poor results. In the early 2000s, with the development of better endovascular equipment, endovascular balloon occlusion became more commonplace for the treatment of those with ruptured abdominal aortic aneurysms. With translational studies demonstrating potential physiologic advantages of endovascular occlusion over RT, military and civilian collaboration led to adoption of the technique as resuscitative endovascular balloon occlusion of the aorta (REBOA).

INDICATIONS

REBOA can be conceptualized as a tourniquet for the trunk. Most patients for whom rapid proximal control of truncal hemorrhage would be lifesaving may benefit from REBOA. Patients with an indication for REBOA can be divided into those without a palpable pulse (cardiac arrest) and those with a palpable pulse who are hypotensive but not responding to blood product administration and other standard resuscitative measures.

In the coding trauma patient who we feel is be a candidate for RT, REBOA is strongly considered as a means to augment cerebral and coronary perfusion. Fig. 1 is an adaptation of the military Joint Trauma System's guideline for managing trauma patients in cardiac arrest. In blunt trauma patients with cardiopulmonary resuscitation (CPR) ongoing for less than 5 minutes and no cardiac tamponade

nursing staff, and radiology. Having a structured and controlled response system in place with predetermined trauma team activation has been shown to decrease mortality and time for resuscitation, for transport to computer tomography scan and operating room, and to ED discharge. The handoff from EMS providers to the trauma team should be a structured communication with acknowledgement and feedback to ensure all prehospital information is transferred. A typical paramedic or EMT handover format is MIVT (mechanism of injury, injuries seen or suspected, vital signs, and treatments given).

USE OF RESUSCITATIVE ENDOVASCULAR BALLOON OCCLUSION OF THE AORTA IN RESUSCITATION OF THE TRAUMA PATIENT

James N. Bulger, MD, FACS, and Megan Brenner, MD, MS, FACS

Hemorrhage remains the most common potentially treatable cause of death in the trauma patient. The American College of Surgeons' Advanced Trauma Life Support (ATLS) curriculum encourages rapid identification and control of hemorrhage as the central tenet in caring for the injured patient. Initial attempts at direct pressure and application of hemostatic dressings are warranted for most bleeding. However, if these are not available or not effective, proximal control of the bleeding is warranted. For the extremities, hemostasis may be accomplished with a tourniquet. For noncompressible truncal hemorrhage, hemostasis can be accomplished by occlusion of the aorta.

Resuscitative thoracotomy (RT) was described by Dr. Ledgerwood and others as a method to avoid cardiovascular collapse upon laparotomy and the resultant release of tamponade in the patient with abdominal hemorrhage. Through the left anterolateral thoracotomy incision, the thoracic aorta can be clamped and open cardiac massage performed, thus providing direct resuscitation and proximal control for subdiaphragmatic truncal hemorrhage. In cases of noncardiac injury, pericardial tamponade can be relieved and thoracic hemorrhage can be controlled.

Another option for proximal control of the aorta that does not require a thoracotomy incision is balloon occlusion using endovascular devices. Endovascular balloon occlusion of the aorta for trauma was first described by Dr. Hughes in the 1950s. Other attempts were described in the 1980s but the technique fell out of favor because of cumbersome equipment and poor results. In the early 2000s, with the development of better endovascular equipment, endovascular balloon occlusion became more commonplace for the treatment of those with ruptured abdominal aortic aneurysms. With translational studies demonstrating potential physiologic advantages of endovascular occlusion over RT, military and civilian collaboration led to adoption of the technique as resuscitative endovascular balloon occlusion of the aorta (REBOA).

INDICATIONS

REBOA can be conceptualized as a tourniquet for the trunk. Most patients for whom rapid proximal control of truncal hemorrhage would be lifesaving may benefit from REBOA. Patients with an indication for REBOA can be divided into those without a palpable pulse (cardiac arrest) and those with a palpable pulse who are hypotensive but not responding to blood product administration and other standard resuscitative measures.

In the coding trauma patient who we feel is be a candidate for RT, REBOA is strongly considered as a means to augment cerebral and coronary perfusion. Fig. 1 is an adaptation of the military Joint Trauma System's guideline for managing trauma patients in cardiac arrest. In blunt trauma patients with cardiopulmonary resuscitation (CPR) ongoing for less than 5 minutes and no cardiac tamponade

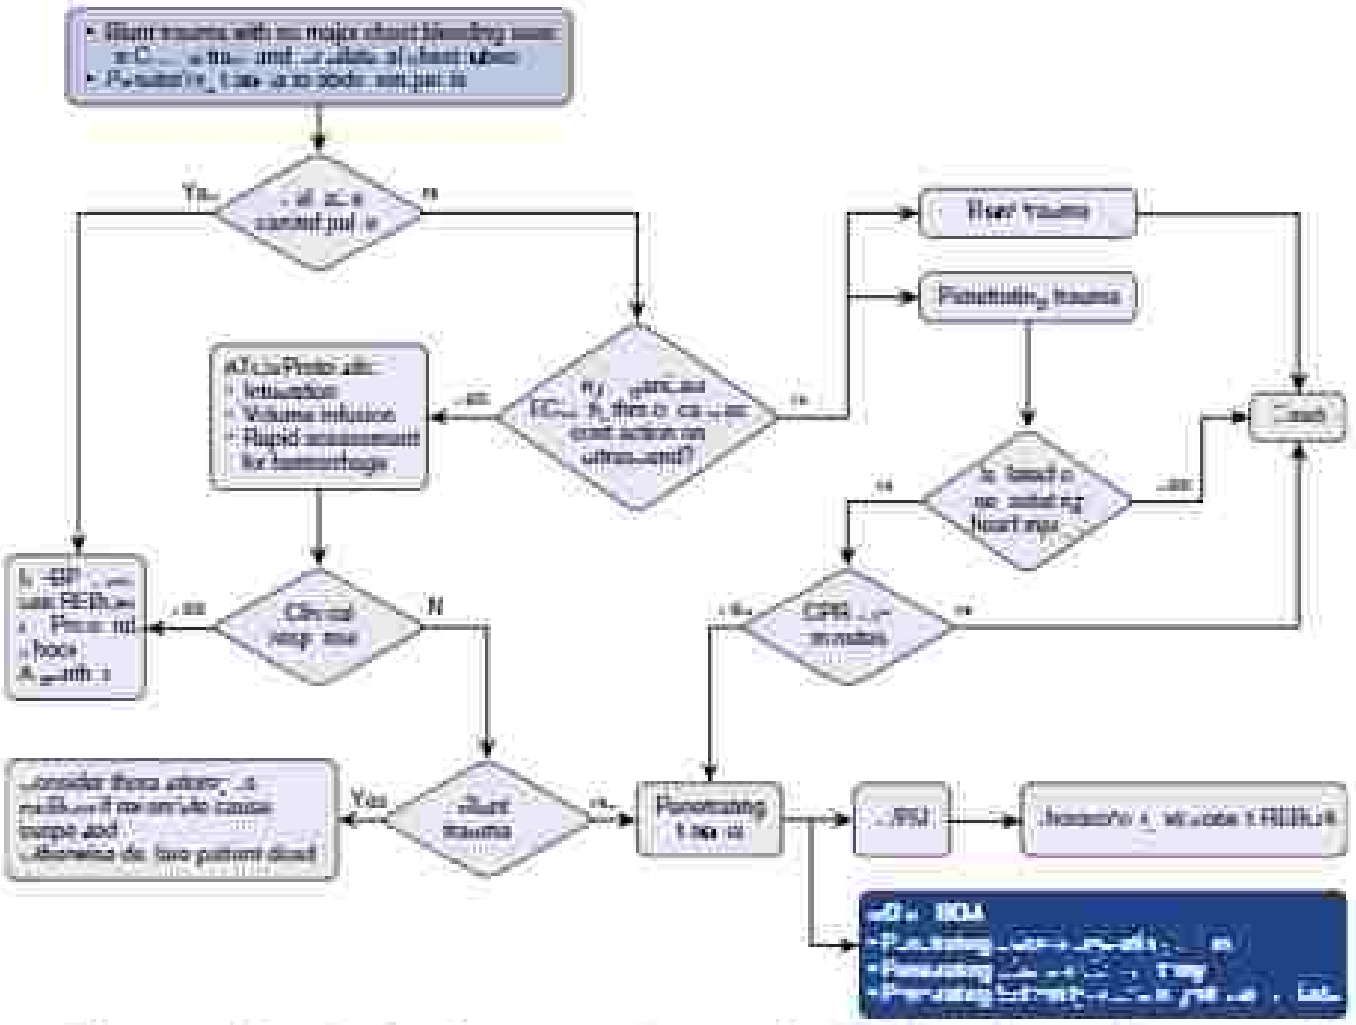

FIG. 1 US Department of Defense Joint Trauma System traumatic cardiac arrest algorithm. or pneumothorax on ultrasound evaluation, REBOA is strongly considered. The advantage to REBOA in this situation is that it can be performed without the need to stop chest compressions required for RT, permitting cardiac compressions throughout the procedure. Preliminary data suggest markers such as end tidal CO_2 are higher in patients with REBOA compared with RT with aortic cross-clamp likely due to the overall higher total cardiac compression fraction in REBOA patients. However, REBOA does not offer therapy for other causes of cardiac arrest in the trauma patient such as cardiac tamponade or tension hemothorax or pneumothorax. Both entities should be ruled out before performing REBOA using physical examination, extended focused assessment with sonography for trauma (FAST), and/or radiography. Small hemothoraces or pneumothoraces, rib fractures, and so forth are not a contraindication to REBOA because it is unlikely these conditions have predominantly led to the patient's severe physiologic derangement. For patients with penetrating mechanisms of injury and severe hemorrhage below the diaphragm, we consider REBOA. RT demands a sternal incision, whereas REBOA is less invasive and may minimize exposure risks to providers. In patients with penetrating thoracic trauma, RT is both diagnostic and potentially therapeutic, although REBOA may be performed in this setting purely for aortic occlusion.

We consider any trauma patient with evidence of truncal hemorrhage and a systolic blood pressure less than 90 mm Hg who is either a nontransfusion or transient responder to blood product administration to be a REBOA candidate (Fig. 2). In patients with hypotension but a palpable pulse, ATLS primary and secondary surveys and blood product resuscitation should take priority. We advocate early common femoral artery (CFA) arterial line placement in these patients. Should resuscitative efforts fail to restore the patient's hypotension and REBOA is considered, CFA access is usually the rate limiting step. As with the cardiac arrest patient, a thoracic cause for the refractory hypotension (massive hemothorax or cardiac tamponade) must be ruled out before REBOA. This is most commonly accomplished with chest radiography and a FAST exam. In civilian trauma patients with refractory shock secondary to noncompressible hemorrhage, REBOA can restore central perfusion and slow hemorrhage while hospital resources such as angiography or the operating room are being mobilized. In patients with severe pelvic fractures and hypotension not responding to resuscitative measures (pelvic binder and blood products), REBOA placed at the aortic bifurcation is an option to restore central and visceral perfusion and decrease pelvic bleeding until angiography can be performed (see Fig. 2).

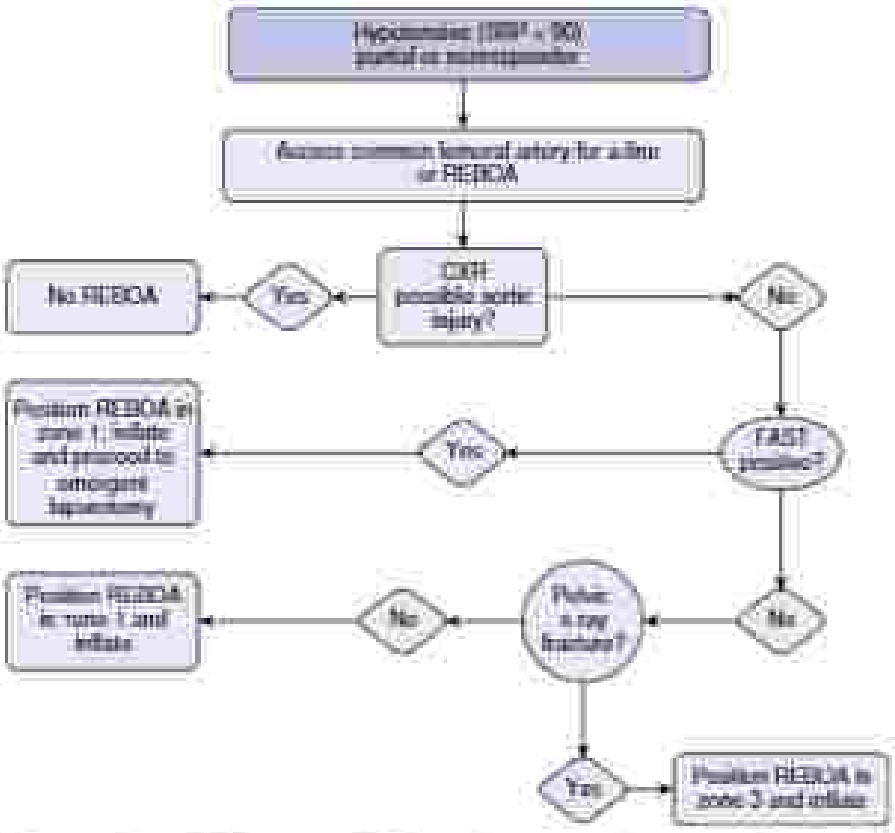

FIG. 2 Algorithm for REBOA zone selection. CXR, Chest x-ray; FAST, focused assessment with sonography for trauma; REBOA, resuscitative endovascular balloon occlusion of the aorta; SBP, systolic blood pressure. (from Moore LJ, Brenner M, Kozar RA, et al. Implementation of resuscitative endovascular balloon occlusion of the aorta as an alternative to resuscitative thoracotomy for noncompressible truncal hemorrhage. J Trauma Acute Care Surg. 2015;79(4):515.)

CONTRAINDICATIONS

Several contraindications to REBOA must be kept in mind. Patients who are not candidates for aggressive resuscitation (such as those with an pulse for more than 15 minutes or an obviously nonsurvivable injury) should not receive REBOA, although this decision is both physician and patient dependent. Patients with noncranial bleeding, such as from a proximal upper extremity or neck wound, should not receive REBOA unless direct control of bleeding is achieved before occlusion for resuscitation. For distal upper and lower extremity injuries, a tourniquet can be placed. Patients with widened mediastinum on chest radiography who have a mechanism consistent with a moderate to severe blunt thoracic aortic injury should not have REBOA placed because balloon inflation in an area distal to or at the level of thoracic aortic injury could result in worsening of injury and rupture. Using REBOA in patients with severe isolated traumatic brain injury (TBI) in the absence of hemorrhage below the diaphragm is generally not needed. However, in patients with TBI and truncal bleeding, REBOA should be considered if the patient's hypotension is thought to be caused by blood loss. Rapid definitive hemorrhage control in these patients can halt the worsening of primary and secondary TBI and, in cases of noncorrectable injury, can bridge patients to organ donation.

RISKS

One must be cognizant of significant potential risks REBOA poses to trauma patients. These risks must be weighed against the perceived benefit to the patient in deciding whether to proceed with REBOA. Furthermore, the practitioner placing REBOA must be aware of these risks, their mitigation, and their management for prompt identification and treatment to occur.

Any time the femoral artery is cannulated, the risk of thromboses and/or distal embolization leading to limb ischemia and possible amputation is present. This risk rises as the size of the catheter being used increases. This risk also increases as the size of the vessel being cannulated decreases. Because patients are often so hypotensive that pre-REBOA documentation of limb perfusion is not feasible, the importance of post-REBOA assessment of limb perfusion becomes paramount. Any question of limb ischemia after REBOA should elicit prompt diagnostic studies and/or vascular surgery consultation. Furthermore, with the larger sheaths required for REBOA, cannulation of the CFA rather than the superficial femoral artery (SFA) allows for collateral flow from the profunda femoris artery to serve the distal limb while the sheath is in place if the sheath is occlusive in the CFA. A strategy for consistent and accurate cannulation of the CFA is required of anyone performing REBOA. Data demonstrate that the rate limiting step in REBOA is time to CFA cannulation, thus it is a skill demanding proficiency with both open surgical and percutaneous methods with or without ultrasound.

REBOA is often placed in a highly dynamic and chaotic environment surrounding a severely hypotensive or coding trauma patient. Arterial blood may look very dark and may lack pulsatility. Inadvertent placement of the REBOA catheter in the venous system has been reported, and inflation of the balloon in the inferior vena cava not only does nothing to stop truncal bleeding, it may, in fact, worsen the patient's hemodynamic status by severely limiting cardiac preload. Furthermore, placing the REBOA catheter in the wrong location within the vascular tree may cause vessel injury or cardiac outflow

obstruction. The importance of imaging to ensure proper positioning of the REBOA catheter before inflation cannot be overemphasized. Imaging can greatly assist in avoiding complications such as balloon overinflation and malpositioning, which can lead to balloon rupture, aortic injury, thrombosis, and/or distal embolism and ischemia. Exceptions to device confirmation with imaging before balloon inflation include a patient in arrest, where CPR is not paused for x-ray, but rather is performed if and when return of spontaneous circulation occurs. Other exceptions to imaging confirmation include environments without this capability (austere), in which case the balloon can be palpated during exploration if required for definitive hemorrhage control or confirmed on fluoroscopy if angiography is the only mode of treatment required.

TECHNICAL POINTS

The first step of REBOA is to access the CFA. This is often the most technically challenging and rate limiting step of REBOA. For this reason, we often start CFA access before determining whether the patient is a REBOA candidate. Reliable access in the CFA is also paramount to avoiding limb ischemia–related complications. Knowledge of the CFA anatomy is the point is paramount (Fig. 2). The external iliac artery becomes the CFA as it traverses beneath the inguinal ligament and then bifurcates into the SFA and the profunda femoris artery 3 to 4 cm distal to the inguinal ligament. The inguinal ligament runs from the anterior superior iliac spine to the pubic tubercle. One should note that the groin crease is not useful for identifying the underlying vascular anatomy. To reliably cannulate the CFA, one of three methods may be used depending on the experience level of the surgeon, the clinical situation, and the availability of ultrasound: open cutdown, ultrasound guided percutaneous, and blind percutaneous. In the setting of ongoing CPR, percutaneous access can be exceptionally challenging, and data demonstrate that most of these patients are being cannulated via open surgical exposure. A vertical groin incision is used to identify the CFA as it appears from under the inguinal ligament. The CFA is cannulated under direct visualization. If percutaneous access is desired, ultrasound guidance is highly recommended to ensure the CFA, not the SFA, is cannulated. Lastly, for experienced providers, a blind percutaneous stick can be performed ensuring that the vessel is entered within 2 cm of the inguinal ligament. It is important to note that this requires a skin entry site more superior than is standard for a typical femoral arterial line placed in the resuscitation area. Experience with endovascular devices confirms that percutaneous CFA access is much easier to perform when a palpable femoral pulse is present.

Once the decision has been made to perform REBOA, the arterial line catheter or micropuncture catheter (whichever was used for initial access) must be upsized to a larger sheath. Depending on the device being used, this can range from 7Fr to 14Fr. External landmarks are utilized to estimate insertion lengths of devices within the aorta. While upsizing and inserting devices, the catheter should always move freely within the sheath and ilium. Advancing devices against resistance is unsafe because severe injury can occur. Utilizing tactile feedback, imaging, and experience can ensure a smooth procedure.

For the purposes of REBOA, the aorta has three zones (Fig. 4). Zone 1 starts at the left subclavian artery and ends at the celiac artery. Zone 2 runs from the celiac artery to the lowest renal artery, and zone 3 is the infrarenal aorta from the lowest renal artery to the aortic bifurcation. The goal is to inflate the REBOA catheter in zone 1 or zone 3. The balloon should not be inflated in zone 2 to avoid occlusion of visceral vessels impeding retrograde flow and promoting a thrombotic environment.

Choosing the location of balloon inflation involves determining the most likely site of bleeding and planning to inflate the balloon as distally as possible but proximal to the site of bleeding. Using chest

FIG. 3. Common femoral artery (CFA) demonstrated in a cadaver model. Wire is in the CFA. Top arrow indicates the bifurcation into the superficial femoral artery and profunda femoris. Bottom arrow indicates the inguinal ligament.

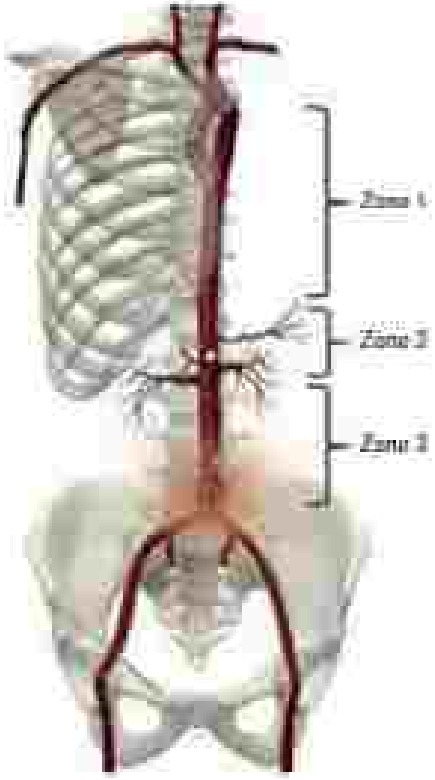

FIG. 4. Zones of the aorta with overlying surface landmarks. [From Inaba K, Lee WM, Karamanos E, Hall S, Teixeira PG, Matthews MR. Resuscitative endovascular balloon occlusion of the aorta with a low profile, axillary device: a game changer? Trauma Co e Rep. 2016;Suppl 1(1):7–9.]

radiographs, FAST, and pelvic radiographs, one can estimate the site of bleeding and plan for the proper aortic zone for inflation. A positive FAST exam denotes abdominal bleeding and requires zone 1 inflation to occlude occlusion proximal to the site of bleeding. An isolated pelvic fracture, on the other hand, requires only a zone 3 inflation to ensure occlusion of the aorta proximal to the bleeding site (see Fig. 2). For all patients in arrest, REBOA at zone 1 is indicated as both

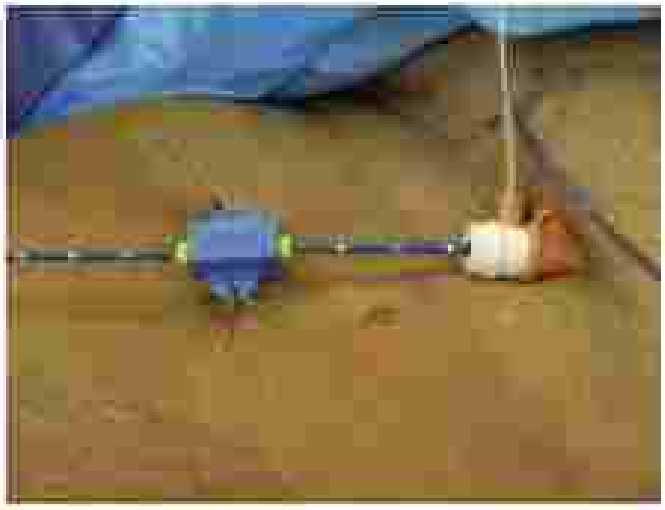

FIG. 3. ER-REBOA catheter (Prytime Medical) has centimeter markings for insertion length measurement. The catheter must be secured to the skin before, during, and after balloon inflation because the catheter will displace inferiorly with increasing proximal pressure.

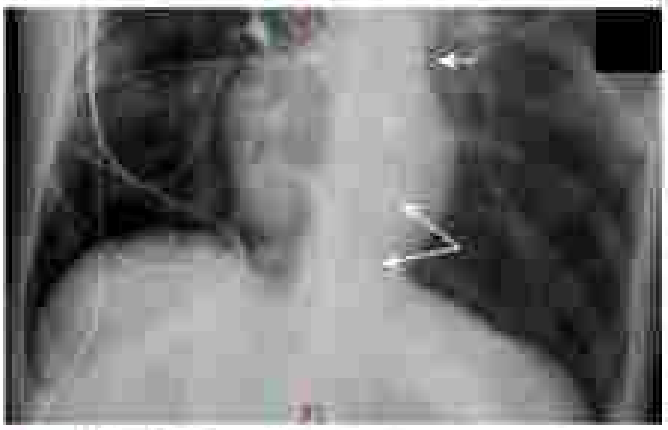

FIG. 4. ER-REBOA (Prytime Medical) can be seen in zone 1 for a patient with persistent hypotension, negative chest x-ray, and positive abdominal focused assessment with sonography for trauma exam. Chest radiography was used to confirm placement before inflation. Lung zones denote the proximal and distal extent of the balloon. Short arrow shows the end of the catheter.

a resuscitative tool for cerebral and coronary perfusion and secondarily as a measure to temporize distal hemorrhage.

Surface landmarks are used to estimate the required depth of catheter insertion to arrive at the desired aortic zone for balloon inflation. The xiphoid process corresponds to the inferior border of zone 1, and the umbilicus corresponds to the inferior border of zone 3. Depth of insertion of standard, over the wire balloon catheters is determined by placing the tolerable edge of the balloon just above the desired landmark (xiphoid process for zone 1 and umbilicus for zone 3) and measuring the distance to the end of the introducer sheath following the path of the iliac artery and aorta. Alternatively, when using the ER-REBOA catheter (Prytime Medical) (because the balloon is set back from the tip of the catheter), one can measure from the sternal notch to the end of the sheath for zone 1 and from the xiphoid process to the end of the sheath for zone 3.

Once the depth of balloon insertion has been determined, the catheter should be marked with tape, or, if the catheter has distance makers on it, the distance noted in the trauma flowsheet. The balloon is inserted over the guidewire and into the sheath if using a Coda type balloon (Cook Medical). If using an ER-REBOA catheter, no guidewire is required and the catheter is inserted directly into the sheath. The catheter is advanced to the previously determined depth and secured with suture, an occlusive dressing, or a catheter clip (Fig. 5). Before inflating the balloon, proper positioning of the catheter in the aorta should be confirmed with imaging. Most centers use x-ray (Fig. 4) or fluoroscopy, but ultrasound use to confirm that the balloon is in the aorta has also been described.

After confirmation of correct placement in the aorta, balloon inflation is begun until occlusion of the aorta is achieved. The balloon should be inflated with saline or dilute contrast material. Full-strength contrast is viscous and will clog the balloon lumen. The balloon is slowly inflated until the contralateral femoral pulse is lost. If arterial pulse waveform monitoring is available, this can be used as well to guide the volume of inflation. If the waveform is proximal to the balloon, as with the ER-REBOA catheter, inflation continues until a step-up is seen on the tracing. This is much like the changes one would see while floating a pulmonary artery catheter. If the arterial waveform is distal to the balloon, inflation would stop when the arterial waveform is lost. Lastly, in the absence of these signs, a subtle increase in resistance to further inflation can be detected by the surgeon. This should prompt cessation of further installation of saline or dilute contrast material. Alternatively, inflating the balloon with dilute contrast material under fluoroscopic visualization allows the surgeon to see in real time as the balloon makes contact with the wall of the aorta. The balloon will cease widening with further volume and will elongate the balloon. Inflation of the balloon should stop once this is visualized. Portable radiography can also demonstrate adequate aortic occlusion by the shape of the balloon. If overinflation has occurred, the balloon will appear as an oversized rectangle with "shouldering" at the proximal and distal portions (Fig. 7).

After aortic occlusion has been achieved, plans for definitive surgical or endovascular hemostasis should begin without delay. This requires immediate transport to the operating room or angiography suite. Safe duration of full aortic occlusion is unknown, but a goal of 30 minutes is reasonable and likely to avoid significant visceral ischemia. Zone 1 occlusion has been tolerated for most patients for up to 60 minutes. For zone 3, the maximum recommended duration of occlusion is less well defined, but ideally less than 60 to 90 minutes. With "normal" appearing vital signs during aortic occlusion and no open chest to remind the trauma team the severity of the situation, the teams sense of urgency may wane. It is the surgeon's responsibility to ensure the trauma team maintains focus on the urgent need to obtain definitive hemorrhage control and deflate the balloon.

When the aorta is occluded, one must bear in mind that the size of the vascular space has been drastically reduced, and the effects of such dramatic afterload increase in the heart and proximal organs are unknown in these patients. Adjustments in blood product resuscitation may be required and continuous monitoring of arterial pressure is mandatory.

On occasion, the clinical situation will not allow for definitive hemostasis within 30 minutes of balloon inflation. Intermittent balloon deflation to provide perfusion to visceral and distal vascular beds may help to prevent irreversible ischemia. This is an active area of investigation. Some have attempted to perform partial occlusion as a means of providing some blood flow to the distal organs without significant blood loss, potentially extending the time period to which the balloon may remain inflated. In practice, this is difficult to perform because very small changes in balloon volume result in large changes in blood flow distal to the balloon.

Balloon deflation can lead to highly labile vital signs due to washout of acidic blood from the bed of ischemia combined with the abrupt drop in afterload. Hypotension often results from a combination of relative hypovolemia and vasodilation. Close communication between the surgeon and anesthesiologist to ensure rapid availability of medications and volume expanders to combat these entities is paramount. The balloon should be deflated slowly over the course of 3 to 5 minutes initially, and sometimes this requires 15 minutes

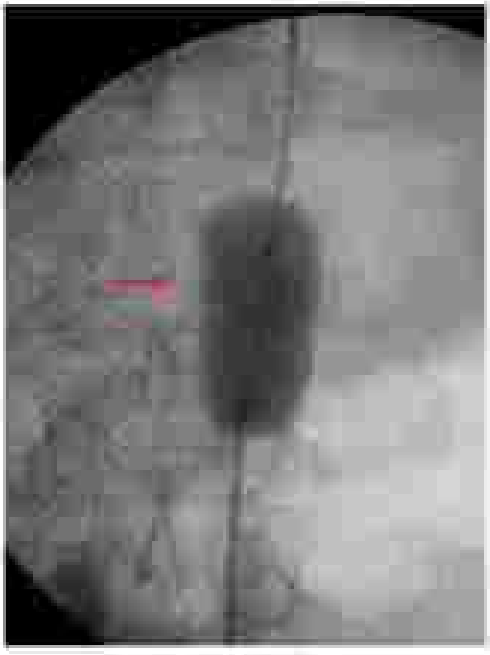

FIG. 7. Balloon overinflation demonstrated by extension of balloon far outside of balloon edge (arrow) in an oblong balloon.

or more. Less than 1 mL should be removed from the balloon at a time, pausing between each withdrawal to assess and treat any physiologic changes that may arise. As discussed earlier, very large changes in blood flow across the balloon occur over a small change to balloon volume. This inflection point is where the surgeon should be doubly cautious about removal of more than 1 mL from the balloon. Slow deflation in the setting of a completed exploratory laparotomy affords the opportunity to reexamine the abdomen for new onset bleeding not appreciated earlier with proximal occlusion.

With successful definitive hemostasis and balloon deflation, removal of the sheath is the next priority because of increasing ischemic complications to the limb with increasing sheath dwell time. In all patients, documentation of distal perfusion is required. This can be a formal angiogram documenting flow all the way to the foot or with Doppler signals symmetric to the contralateral leg. We recommend angiography, however, in situations where this is not readily available, an ankle to brachial index may be used before and after removal of the sheath. Any evidence of distal flow limitation should result in prompt angiographic imaging and involvement of a vascular surgeon in the therapeutic decision-making.

In patients who have had a cutdown approach to the CFA, surgical repair of the artery is required. Forgarty balloons should be used to clear the proximal and distal artery of any suspected thrombus to restore adequate inflow and outflow. Completion angiogram or documentation of symmetric Doppler signals is required. For patients with a percutaneously placed 7Fr sheath, the sheath may be pulled with pressure held for 30 minutes. Postremoval Doppler signal character and symmetry must be documented. Post REBOA lower extremity neurovascular checks should be done every hour for the first 12 hours after sheath removal. We suggest vascular ultrasound of the CFA puncture site at 72 hours for early identification of access site complications.

PITFALLS

The rate-limiting step for REBOA is accessing the CFA. Obtaining safe, accurate CFA access after the need for aortic occlusion has been recognized can be difficult and time consuming. With CFA access already established, REBOA becomes a more time efficient means of achieving aortic occlusion. Early CFA access in any patient with hypotension is highly recommended because this provides more accurate systolic blood pressure measurements than a standard cuff and secures access for REBOA if needed. With this strategy, CFA access is often in place by the time the patient is recognized as a non-responder to blood transfusions, and REBOA can proceed without delay. Wire free devices may further decrease procedural time from access to aortic occlusion.

Indiscriminate inflation of the balloon without careful attention to signs of aortic occlusion often leads to overinflation. Balloon overinflation can cause injury to the aorta in a patient who is already physiologically stressed, and in the worst case can turn a survivable injury into a unsurvivable combination of injuries. Other consequences include luminal injury to the aorta that can progress to dissection after balloon removal, and balloon rupture. To prevent this pitfall, the surgeon must remain aware of the endpoints of balloon inflation discussed previously. It is also important to know the relative size of the aorta to zone 1 and zone 3 in hypovolemic, vasoconstricted patients. The aortic diameter at zone 1 can vary between 15 mm and 38 mm in diameter, whereas at zone 3 the aortic diameter can vary between 6 mm and 28 mm. Most balloons will require only a fraction of their maximum volume to achieve occlusion.

Malposition of the balloon within the aorta can lead to ineffective hemostasis and ongoing bleeding, injury to visceral vessel origins, or injury to smaller than anterior. In addition, venous placement of the balloon leads to ongoing blood loss and possible venous injury when the balloon is inflated. In hypotensive patients, arterial blood often lacks pulsatility and may look dark like venous blood. The character of blood return is not adequate to determine arterial versus venous entry, nor is the strength of palpability. Despite guidewires and catheters designed to remain in the aortic lumen, inadvertent placement into branch vessels has been described. Using fluoroscopy or radiography to confirm proper location of the balloon before inflation is the most effective method for identifying and correcting malposition.

Failure to properly secure the sheath and balloon will lead to migration of the balloon distally. This can cause luminal injury, injury to the visceral vessels, or rebleeding as the balloon migrates distal to the site of hemorrhage. When using the IR REBOA device, the catheter must be secured within 5 cm of the sheath before balloon inflation (Fig. 5). When using a Cook type balloon, the guidewire must remain in place while the balloon is in place. The guidewire is the first thing in and the last thing out.

Occlusion of the aorta in trauma patients on the verge of exsanguination will cause a dramatic increase in measured blood pressure. Vital signs often appear normal despite the drastically altered physiology aortic occlusion creates. In the case of IFI, the trauma team has very apparent visual cues that the patient, despite normal appearing vital signs, remains critical and requires urgent progression to the next phase of care in the operating room. With REBOA, these visual cues (an open chest with a large protruding clamp) are not present. In trauma systems with little REBOA experience, there is a danger that the trauma team, as a group, will lose their sense of urgency to transport the patient to the next phase of care such as the operating room or angiography suite. It is the trauma surgeon's job as the team leader to ensure that the pace of care does not worsen once the vital signs improve with REBOA. Educating all members of the team on REBOA and the physiology it produces will help to avoid this phenomenon.

COMPLICATIONS

REBOA is an exciting minimally invasive technique to occlude the aorta in trauma patients. However, the procedure brings with it a new set of potential complications that must be anticipated, diagnosed early, and promptly treated to prevent serious injury, limb loss, or death.

Inadvertent SFA cannulation when attempting to gain CFA access can occur. When an 18-gauge arterial line is placed in the SFA, there is rarely an adverse outcome. However, when a 7Fr or larger sheath is placed into the SFA, the chance of adverse events rises dramatically. These events include ischemia due to thrombo-embolism, poor collateral flow, or dissection, which can lead to amputation. Reliable CFA access has been discussed earlier in this chapter and its role in preventing complications related to REBOA is paramount.

Dissection can occur at the groin access site or as a result of balloon trauma. Careful groin access and judicious inflation of the balloon after cross-once occlusion has occurred are the best strategies to avoid this complication. Angiography after the REBOA procedure is the most reliable way to diagnose a dissection early. Once diagnosed, prompt vascular surgery consultation is required to prevent progression and further complications.

All intravascular devices are a risk for thrombus formation. In most elective endovascular cases, this morbidity is managed with heparin administration. In actively bleeding trauma patients, however, heparin is contraindicated. Thrombus formation can occur at any location from the access site to the tip of the balloon or the guidewire. After balloon inflation, it is imperative to check distal pulses or Doppler signals. Before removing the introducer sheath, angiography is highly recommended to ensure no distal thromboembolism has occurred. Should these entities be detected, prompt vascular surgery consultation is warranted.

When the balloon is overinflated, aortic injury, balloon rupture, or both may occur. Deliberate and careful titration of balloon inflation is required to prevent these complications. We suggest using dilute contrast material under fluoroscopy to inflate the balloon whenever possible. In the case of balloon rupture, the patient will not have the expected improvement in blood pressure with inflation. There may be a temporary improvement of vital signs as the balloon achieves occlusion that suddenly reverses when the balloon ruptures. Aspiration of the balloon may reveal blood, imaging of the balloon will reveal an uninflated balloon. If balloon rupture occurs and the patient remains a candidate for aortic occlusion, the occlusion catheter may be removed and a new one placed or conversion to an REBOA may be used to achieve aortic occlusion.

CONCLUSION

REBOA is a minimally invasive method to achieve proximal control of bleeding in trauma patients with noncompressible torso hemorrhage. It can be performed on patients in the emergency department before they reach the point of cardiac arrest, and saves the patient the morbidity of RT. To safely deploy a REBOA balloon, the surgeon must understand the involved anatomy, physiology, and potential complications. Employed with careful technique, REBOA is a useful strategy for aortic control when caring for the trauma patient in refractory shock.

AIRWAY MANAGEMENT IN THE TRAUMA PATIENT

Samuel M. Galvagno Jr, DO, PhD, FCCM, and Thomas M. Scalea, MD, FACS, FCCM

Early, aggressive, definitive management of the airway is emphasized as a crucial initial priority for trauma patients because hypoxia and airway obstruction are closely linked to preventable morbidity and mortality. Airway management in trauma patients is frequently complicated by cervical spine instability, brain injury, hemodynamic instability, lack of patient cooperation, risk of aspiration, time pressure, and facial injuries. For these reasons, airway management is an essential skill given the well-defined adverse clinical outcomes that occur when trauma patients develop acute respiratory insufficiency and hypoxia due to delays in securing the airway. This chapter describes techniques that can be used to rapidly establish and maintain a patent airway, with an emphasis on the importance of providing adequate oxygenation and ventilation throughout all phases of airway management.

RAPID CLINICAL AIRWAY ASSESSMENT: INDICATIONS FOR MANAGEMENT

A patient who is alert, oriented, and speaking normally to the absence of any abnormal injuries to the head or neck has an adequate airway. Any change in voice, complaint of a sore throat, dysphagia, tachypnea, use of accessory muscles, noisy breathing (snoring or stridor), or unexplained agitation may be ominous signs of imminent airway compromise.

For patients who are not able to safely maintain a patent airway, a focused examination should be performed while preparing the necessary equipment. The majority of the anesthesiology literature suggests that a combination of airway parameters found during an airway examination will provide the best chance for predicting a potentially difficult airway. A systematic approach to airway assessment should be employed, following the line of sight of the anesthesia provider from the upper incisors to the vocal cords, with a focus on the inside

Inadvertent SFA cannulation when attempting to gain CFA access can occur. When an 18-gauge arterial line is placed in the SFA, there is rarely an adverse outcome. AIRWAY MANAGEMENT IN THE TRAUMA PATIENT

Samuel M. Galvagno Jr, DO, PhD, FCCM, and Thomas M. Scalea, MD, FACS, HCCM

Early, aggressive, definitive management of the airway is emphasized as a crucial initial priority for trauma patients because hypoxia and airway obstruction are closely linked to preventable morbidity and mortality. Airway management in trauma patients is frequently complicated by cervical spine instability, brain injury, hemodynamic instability, lack of patient cooperation, risk of aspiration, time pressure, and facial injuries. For these reasons, airway management is an essential skill given the well-defined adverse clinical outcomes that occur when trauma patients develop acute respiratory insufficiency and hypoxia due to delays in securing the airway. This chapter describes techniques that can be used to rapidly establish and maintain a patent airway, with an emphasis on the importance of providing adequate oxygenation and ventilation throughout all phases of airway management.

RAPID CLINICAL AIRWAY ASSESSMENT: INDICATIONS FOR MANAGEMENT

A patient who is alert, oriented, and speaking normally to the absence of any observed injuries to the head or neck has an adequate airway. Any change in voice, complaint of a sore throat, dysphonia, tachypnea, use of accessory muscles, noisy breathing (snoring or stridor), or unexplained agitation may be ominous signs of imminent airway compromise.

For patients who are not able to safely maintain a patent airway, a focused examination should be performed while preparing the necessary equipment. The majority of the anesthesiology literature suggests that a combination of airway parameters found during an airway examination will provide the best chance for predicting a potentially difficult airway. A systematic approach to airway assessment should be employed, following the line of sight of the anesthesia provider from the upper incisors to the vocal cords, with a focus on the inside

BOX 1 Airway Parameters That May Predict Poor Visualization of the Vocal Cords During Direct Laryngoscopy

- Prominent incisors or abnormal dentition
- Mandibular protrusion (Fig. 1)
- Mouth opening (>3 fingerbreadths or 5 cm, is normal)
- Mallampati classification (Fig. 2)
- Thyromental distance (>3 fingerbreadths, or 6 cm, is normal)
- Cervical range of motion (should not be tested in any patient with a suspected C-spine injury)
- Anatomic abnormalities (masses, swelling)
- Thickness of neck
- Length of neck (shorter neck associated with difficult intubation)

of the mouth and pharynx, concluding with examination of the mandibular space, neck, and chest. Box 1 and Figs 1 and 2 describe clinical traits that can be used to determine if visualization of the vocal cords is likely to be poor during direct laryngoscopy.

Of utmost importance during airway management is the ability to ventilate a patient with a mask. Independent risk factors for impossible mask ventilation include male sex, a history of sleep apnea, Mallampati 3 or 4 status, and the presence of a beard. Ultimately, few will argue that having an armamentarium of skills to manage the difficult airway is the most important aspect of management, especially considering the myriad factors that may preclude a thorough airway assessment in the trauma patient.

OXYGEN THERAPY AND AIRWAY ADJUNCTS

Initial interventions for airway management include provision of supplemental oxygen and a variety of noninvasive airway maintenance techniques. Complicating this process is the fact that the spinal cord must be protected until the possibility of a spinal cord injury has been excluded. Oxygen therapy should be provided to maintain the SpO_2 above 92%. A logical first step is to apply a nonrebreathing mask, which provides a FIO_2 greater than 60%. Oxygen therapy can then be deescalated accordingly after the patient has been assessed and stabilized, to a simple face mask (FIO_2 35%–55%), a Venturi mask (FIO_2 24%–60%), or a nasal cannula (FIO_2 24%–44%).

If the airway is compromised and the patient is not ventilating and oxygenating adequately, rapid noninvasive interventions are indicated during the interval preceding preparation for establishing a definitive airway. Bag-valve-mask (BVM) ventilation with 15 L/min of oxygen should be initiated (FIO_2 90%–100%). Addition of a nasal cannula beneath the mask is advised, when available to provide additional high-flow (>10 mL) oxygen throughout the intubation procedure. This technique may help prevent desaturation during intubation by improving preoxygenation while also providing apneic oxygenation during the intubation attempt. Oropharyngeal or nasopharyngeal airways can be inserted to alleviate airway obstruction by the tongue. Oral airway size can be gauged by measuring the airway from the corner of the patient's mouth to the external auditory canal. Nasopharyngeal airways should not be used if the patient has a suspected craniofacial injury for fear of inserting the device intracranially. The chin lift maneuver, which is performed by gently lifting the mandible without hyperextending the neck, may help open the airway. Alternatively, the jaw thrust maneuver can be performed by displacing the mandible forward while applying pressure to both angles of the mandible. Either technique is preferable for trauma patients since both techniques can be performed during in-line cervical stabilization.

RAPID SEQUENCE INDUCTION AND INTUBATION

A definitive airway in a trauma patient is defined by the placement of a cuffed tube in the trachea attached to a source of oxygen, and

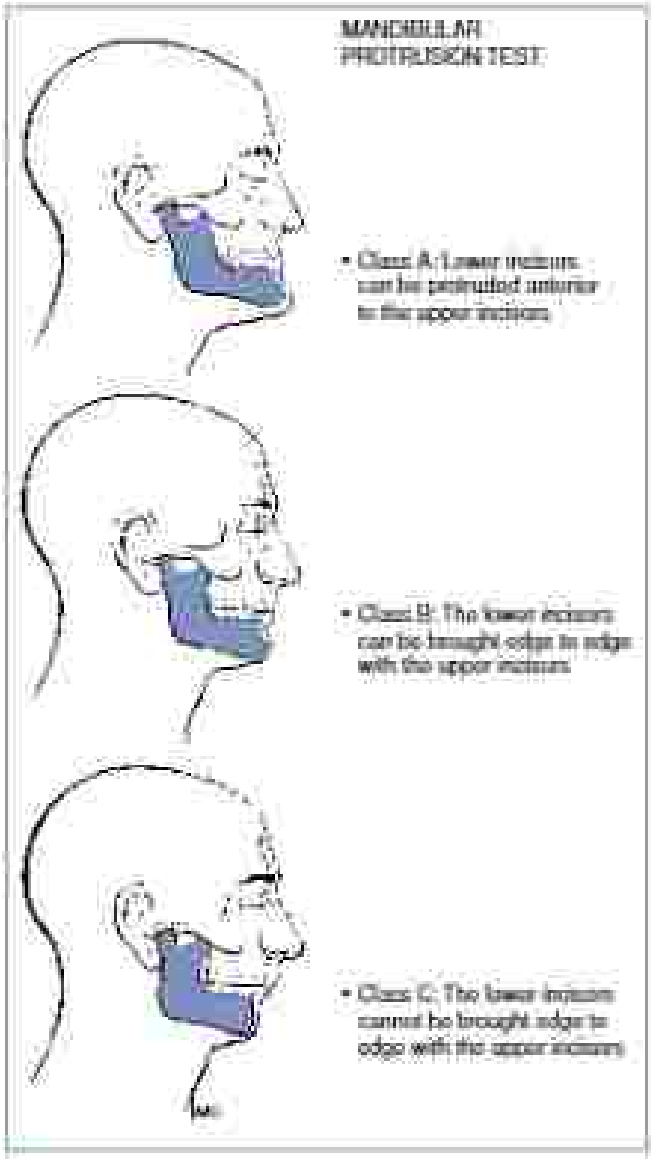

FIG. 1 *Mandibular protrusion test of jaw mobility. Class A portends better vocal cord visualization during direct laryngoscopy than class B or C. (Modified from Munoz LJ, de Bordalba A, Sanchez MS. Airway problems in pregnancy. Crit Care Med. 2005;33:S259–S260.)*

properly secured. Endotracheal intubation, nasotracheal intubation, cricothyrotomy, or tracheotomy can be performed to establish a definitive airway. In the majority of trauma patients, rapid sequence induction and endotracheal intubation (RSII) is used to establish a definitive airway.

RSII is predicated on the fact that the trauma patient has a full stomach, and excessive BVM ventilation will cause gastric insufflation with aspiration of gastric contents. RSII involves a highly organized sequence of events starting with preoxygenation for at least 3 minutes. The *6 Ps* of RSII describe the recommended sequence (Table 1). During the preparatory stage, a suction catheter is prepared and tested, an adequate source of oxygen is established and readied for connection, a pulse oximeter is attached to the patient, pharmacologic agents are prepared, and airway equipment organized. It should be noted that proper performance of RSII ideally requires at least four providers: one to apply cricoid pressure, one to maintain in-line cervical stabilization, one to ventilate with a BVM and intubate, and one to administer drugs and assist with airway devices (Fig. 3).

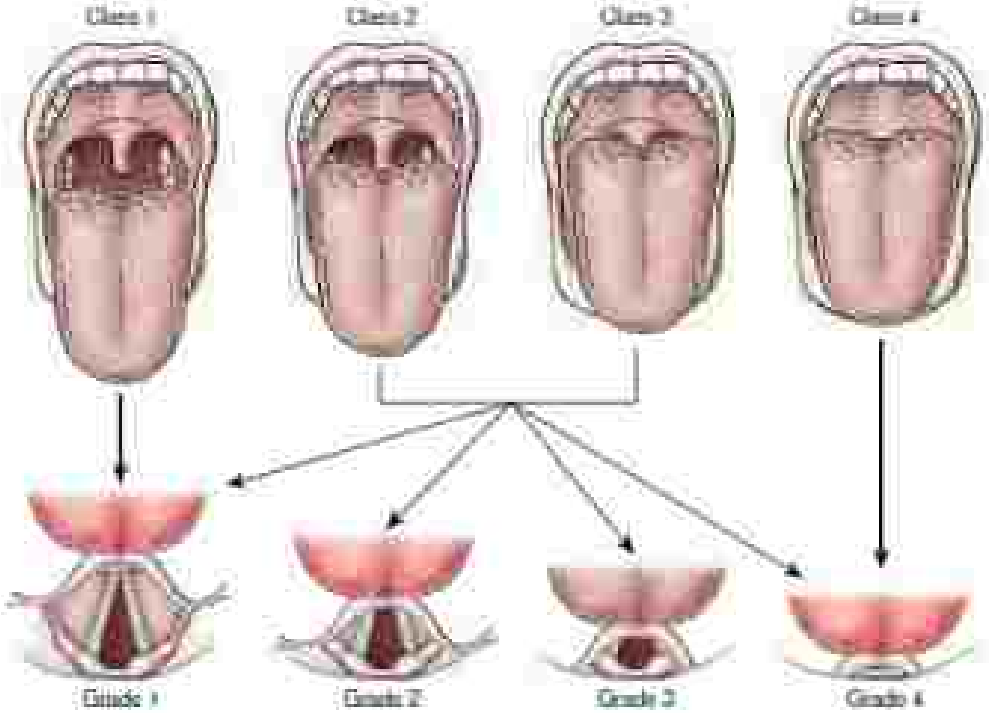

FIG. 3 Mallampati classification. The higher the class, the worse the Cormack-Lehane view of the vocal cords during direct laryngoscopy. (From Lippincott AE, ed. Cases in Diagnosis and Treatment in Otology. Head and Neck Surgery. 2nd ed. New York: McGraw Hill; 2004.)

TABLE 1 6 P's of Rapid Sequence Induction and Intubation

Step	Time Interval	Pharmacologic Agents
Preoxygenation	0–3 min	Oxygen, including addition of nasal cannula
Premedication	3 min	Induction agent + fentanyl, lidocaine, atropine, defasciculating agent (rocuronium, vecuronium, usually one-tenth the induction dose)
Paralysis	3.5–4.5 min	Midazolam, ketamine, etomidate, propofol or other induction agents followed by succinylcholine or rocuronium
Placement	6–6.5 min	Oxygen
Performance	7–7.5 min	Oxygen
Postintubation management	7.5 + min	Oxygen, sedatives, analgesics, etc.

FIG. 4 Four providers are recommended for securing the airway. Providers are assigned to (1) ventilate with the bag-valve-mask and intubate, (2) maintain in-line cervical stabilization, (3) administer cricoid pressure, and (4) push drugs and assist with airway devices.

Although avoidance of BVM ventilation has been the traditional recommendation in RSI, many practitioners find that gentle mask ventilation (inspiratory pressure <20 cm H_2O) is acceptable during the induction sequence. Gentle mask ventilation may help prevent hypoxemia in obese, pregnant, pediatric, and critically ill patients, and also allows testing for the adequacy of mask ventilation in the event that intubation attempts fail. Additionally, to help prevent desaturation, a nasal cannula can be applied before intubation at a high flow rate (10–15 L/min) to both help with preoxygenation and to provide some degree of apneic oxygenation during intubation attempts. If a high-flow humidified nasal cannula device is available, higher rates (up to 60 L/min) can be used at higher FiO_2 (100%).

Before paralytics are given, an induction agent is administered. A review of induction agents is provided in Table 2. Paralytics are recommended as part of RSI because attainment of neuromuscular blockade has been shown to result in suboptimal intubating conditions. Either succinylcholine (1–1.5 mg/kg) or vecuronium (0.8–1.2 mg/kg) is administered for paralysis. Succinylcholine can be administered intramuscularly if an intravenous line is not established, but an increased dose of 3 to 4 mg/kg is recommended for this route.

TABLE 2. Induction Agents Commonly Used for Rapid Sequence Induction and Intubation

Induction Agent	Dose	Onset	Duration of Action	Comment
Propofol	0.5–3 mg/kg	10–30 sec	5–10 min	Dose usually reduced, sometimes by as much as one-tenth of the recommended induction dose, causes decreased systemic vascular resistance and hypotension
Ketamine	1–2 mg/kg IV 2–4 mg/kg IM	30–60 sec	5–20 min	Acceptable for use in patients with increased ICP; direct myocardial depressant but has indirect stimulatory effects (best avoided in patients with coronary artery disease)
Etomidate	0.2–0.3 mg/kg	30–45 sec	10–20 min	Single dose causes adrenocortical suppression; recent evidence supports safety in septic shock
Remifentanil	1 μg/kg	30–60 sec	<10 min	250 times more potent than morphine; may cause hypotension; not a reliable amnestic; does not accumulate; broken down by nonspecific esterases
Midazolam	0.3–0.6 mg/kg	2–3 min	20–30 min	When combined with opioids, can cause marked hypotension and respiratory depression

ICP, intracranial pressure; IM, intramuscular; IV, intravenous.

In the majority of patients, both succinylcholine and rocuronium provide optimal intubating conditions by all accounts when dosed appropriately. Priming doses of nondepolarizing agents are usually not considered for trauma patients once these agents must be administered at least 3 minutes before the loading dose of muscle relaxant is administered, and in elderly or debilitated patients, pretreatment with a small dose of muscle relaxant may predispose to aspiration. Succinylcholine is contraindicated in patients with burns, open globe injuries, neuromuscular disorders, hyperkalemia, pseudocholinesterase deficiency, severe crush injuries, or chronic paralysis. Rocuronium, a nondepolarizing agent, is an alternative when succinylcholine is contraindicated, but this agent cannot be administered intramuscularly and the duration of action is much longer (typically up to 45 minutes) than succinylcholine (6–10 minutes).

Pharmacologic adjuvants such as opioids may be considered during RSII, but owing to time pressure, these agents are frequently omitted. If administered, fentanyl (2 μg/kg), alfentanil (20–30 μg/kg) or remifentanil (1 μg/kg) may help attenuate hemodynamic responses to intubation, but opioids alone do not provide adequate amnesia and are usually not recommended as sole induction agents for RSII due to a higher incidence of patient recall. Midazolam is a short acting benzodiazepine with excellent amnestic properties that may also be given intramuscularly, but this agent may take 2 to 3 minutes to work. Following preoxygenation, lidocaine may be given to attenuate increases in intracranial pressure, although strong evidence is lacking to support this purported benefit.

ENDOTRACHEAL INTUBATION

In many trauma centers, cricoid pressure is used throughout the RSII process to prevent regurgitation, although application of this technique remains controversial. Cricoid pressure involves backward and upward application of pressure to the cricoid cartilage to occlude the esophagus. 3 to 4 kg of pressure is recommended to occlude the esophagus. The use of cricoid pressure remains controversial since the technique is often incorrectly applied, may worsen laryngoscopic views, can cause airway trauma, and could impair BVM ventilation. Nevertheless, it is a reasonable initial measure recommended for use during RSII, but if the laryngoscopic view worsens with the technique, pressure can simply be released or adjusted as required to facilitate intubation.

Approximately 1.5% to 8% of all trauma patients may have an undiagnosed cervical spinal cord injury, hence, cervical immobilization is obligatory. Manual in-line stabilization has been shown to be superior for preventing inadvertent movement of the cervical spine during intubation as compared to a cervical collar alone. During intubation, one provider is dedicated to maintaining manual in-line stabilization.

Fig. 4 demonstrates the correct placement of a Macintosh or MacGill laryngoscopic blade. The laryngoscope should be held in the left hand and inserted into the right side of the patient's mouth, displacing the tongue to the left. The airway structures are blind into view, avoiding using the blade as a fulcrum on the teeth, and the epiglottis and vocal cords are visualized. The endotracheal tube should be gently inserted with the cuff past the vocal cords and inflated with enough air to provide a good seal (~20 cm H_2O). In general, intubation attempts should not take more than 30 seconds. Verification of tube placement is accomplished by auscultation of bilateral lung sounds, observation of chest rise, absence of epigastric/gastric gurgling or distension, and presence of end tidal carbon dioxide (CO_2) with either a colorimetric device or continuous capnography. If a colorimetric device is used, the color indicator should change from purple to yellow, and at least six ventilations with an appropriate color change should be observed to avoid potential false positives. A chest radiograph should be obtained to confirm the position of the tube.

In patients with suspected cervical spine injuries, the laryngoscopic view may be impeded by the requirement of in-line cervical stabilization. For patients with a Cormack–Lehane grade 3 or 4 view, the gum elastic bougie may be used to intubate the endotracheal tube. The bougie is a flexible, 60-cm, 15-French introducer with a Coude tip angled at 45 degrees, 3.5 cm from the distal end (Fig. 5).

The bougie is lubricated and inserted with the Coude tip directed anteriorly, advancing until at the level of the tracheal rings. The endotracheal tube is then advanced over the bougie into the trachea.

Video laryngoscopy (VL) has evolved as a technology that allows direct visualization of the airway by all airway team members. Studies have been mixed regarding advantages for use in patients with difficult airways, but some research has shown that VL results in a higher success rate at first attempt as compared to direct laryngoscopy, especially for less experienced airway providers. VL can be used at all stages of intubation, including initial laryngoscopy, awake intubation, and for helping to confirm proper endotracheal tube position.

SUPRAGLOTTIC AIRWAY DEVICES

A variety of supraglottic devices exist for use when attempts at endotracheal intubation or BVM ventilation fail. The laryngeal mask airway (LMA), multilumen esophageal airway (Combitube), and the laryngeal tube airway are three devices that can be placed without direct visualization of the glottis. Although these devices enable

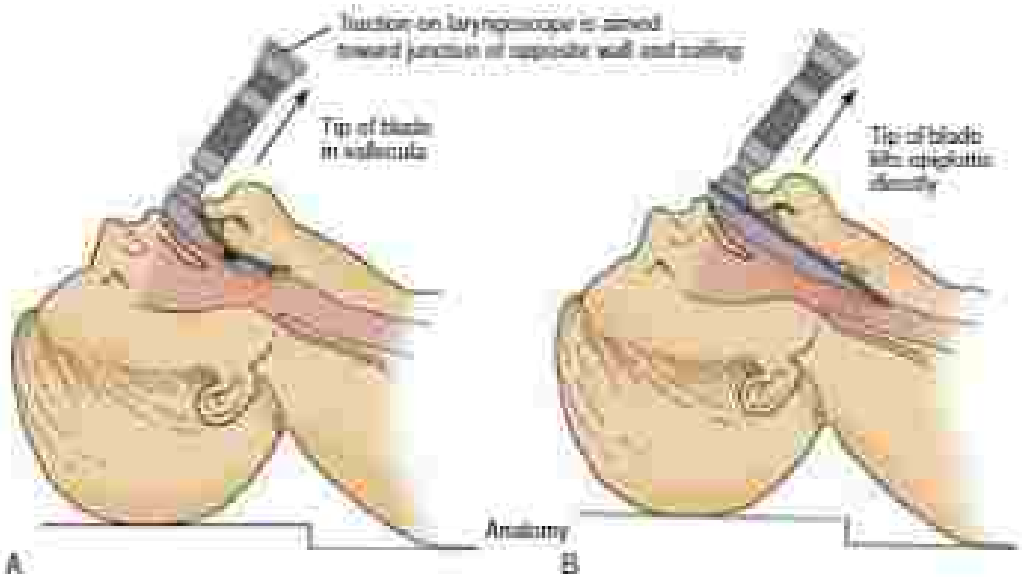

FIG. 4 (A) Macintosh blade. (B) McGill blade. Note that the patient in this figure does not have cervical spine precautions; in the majority of patients, manual in-line stabilization must be performed during intubation attempts to prevent exacerbation of neurologic damage.

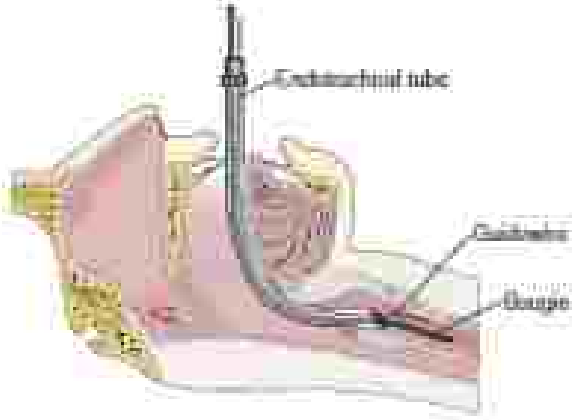

FIG. 5 Gum elastic bougie insertion. (From Hagberg MD, et al. [In: MGH Handbook of Anesthesia] Lippincott Philadelphia Boston 2016.)

ventilation, whether by providing a seal around the laryngeal inlet or occluding the esophagus, some of these devices represent a definitive airway. Each of these devices requires additional training, and all must eventually be replaced with a definitive airway in the trauma patient. In cases of traumatic arrest during prehospital management, immediate endotracheal intubation may not be feasible or safe. In these instances, placement of a supraglottic airway may be considered to prevent unacceptable pauses in chest compressions and to decrease the time to ventilation.

AWAKE FIBEROPTIC INTUBATION

When patients are suspected of having cervical spinal cord injuries, but do not require emergent intubation, awake fiberoptic intubation (AFOI) is one method that can be used to secure the airway. The term awake is a misnomer; the patient will maintain spontaneous ventilation throughout the procedure under sedation with amnestic agents. This method may be advantageous in patients with injuries to the cervical spine because cervical spine movement can be minimized, thus preventing neurologic impairment. Careful titration of sedation is mandatory for AFOI since abolition of spontaneous ventilation obviates any advantage when using this technique. Monitors are applied and oxygen is delivered via a nasal cannula. Patients are premedicated with glycopyrrolate (0.2–0.4 mg) to attenuate secretions (barring any known cardiac conditions where tachycardia might be avoided). Sedation is achieved by careful administration of midazolam (0.5 mg, titrated to effect). Opioids are avoided due to the synergistic respiratory depression that occurs when these agents are coadministered with benzodiazepines; however, opioids may be used instead of benzodiazepines, keeping in mind that these opioids do not provide reliable amnesia. Alternatively, a dexmedetomidine infusion (0.2–1.5 μg/kg/hr) may be considered, but for trauma patients, this agent is seldom used due to the preparatory time required and onset of action (>10 minutes). For topicalization, 2 to 3 mL of 5% lidocaine ointment is applied to the posterior tongue via a tongue depressor to anesthetize the glossopharyngeal nerve. Next, 1 to 2 vials of 4% lidocaine are emptied into a specimen cup and cotton balls (with strings attached to ensure easy retrieval from the airway) are soaked in this solution. Using either a Magill forceps or right-angle nasal hitcher, the cotton balls are gently introduced deep into the posterior nares and held in place for 60 to 90 seconds. The process is repeated for each side, effectively anesthetizing both branches of the superior laryngeal nerve. Finally, an oral airway is inserted (to prevent biting of the fiberoptic scope), and the fiberoptic scope is introduced. Once the vocal cords are visualized, 1 to 2 mL of 1% or 2% lidocaine is sprayed through the injection port on the fiberoptic scope directly on the vocal cords. This anesthetizes the recurrent laryngeal nerve. Once all three nerves are anesthetized, the endotracheal tube can safely be inserted with either a video laryngoscope (i.e., "awake" video laryngoscopy) or over a fiberoptic bronchoscope. Careful attention must be paid to the amounts of lidocaine used since a dose greater than 5 mg/kg may result in anesthetic toxicity. The technique can be modified accordingly for nasotracheal intubation with use of topical vasoconstrictors as well as anesthetics to anesthetize and mitigate bleeding in the nasal passages. It should be noted that this technique is not recommended for patients who are deemed to be at increased risk for aspiration.

AIRWAY MANAGEMENT DECISION MAKING

For patients in need of an immediate airway, Fig. 6 provides a decision algorithm. Initial priorities always include adequate preoxygenation

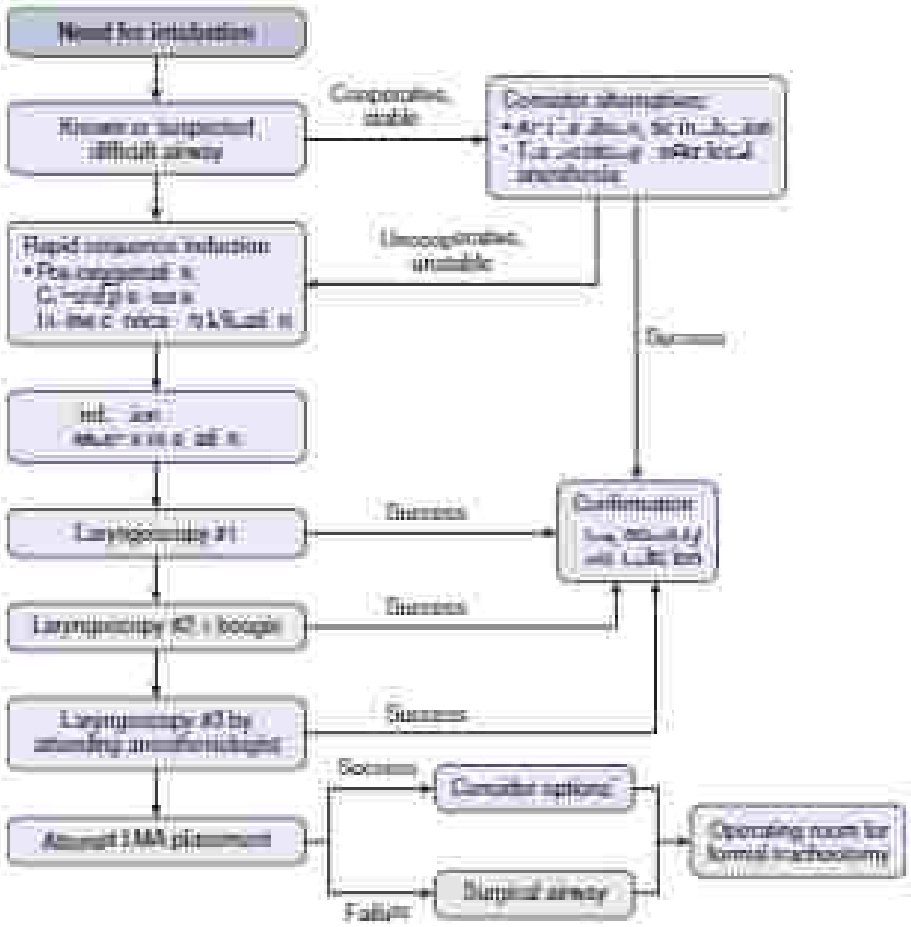

FIG. 1. Airway management algorithm at the R Adams Cowley Shock Trauma Center. Laryngoscopy may include the use of a video laryngoscope such as the GlideScope or Ranger (storz bett) as multiple steps. LMA, laryngeal mask airway. *Options after LMA placement include further intubation attempts, intubation through the LMA, and surgical airway. (From Stephens CJ, et al. The success of emergency endotracheal intubation in trauma patients: A 10-year experience at a large adult trauma center. Accid Anal Prev. 2009;41:837–842.)

and in-line cervical immobilization. In trauma patients, the option to wake up the patient, as one would do for an elective surgical procedure, is not feasible. After a third failed attempt at intubation by an attending anesthesiologist, an LMA can be inserted to facilitate the transition to a definitive airway via fiberoptic intubation or intubation through the LMA. However, if the airway cannot be expeditiously secured after the third laryngoscopy attempt, a surgical airway is necessary. It should be noted that in the hands of experienced trauma airway experts, the rate of conversion to a surgical airway has been reported to range from 0.2% to 2%.

SURGICAL AIRWAY

A patient committed to RSI (i.e., paralyzed), who subsequently cannot be ventilated or intubated, requires a surgical airway. Options include a surgical cricothyrotomy or tracheostomy; cricothyrotomy is preferred as the surgical technique of choice (Fig. 7). The patient is placed in the supine position with the neck in a neutral position. After the neck is prepped and draped, the thyroid notch, thyroid cartilage, cricothyroid membrane, cricoid cartilage, and trachea are identified by palpation. Stabilizing the thyroid cartilage with one hand, a 2.0- to 2.5-cm vertical incision is made over the cricothyroid membrane with a No. 10 or 11 surgical blade. A hemostat or tracheal spreader is introduced into the incision and rotated 90 degrees to open the airway. Either a cuffed endotracheal tube (6.0 or 6.5 mm) or tracheostomy tube is inserted through the cricothyroid membrane incision. The cuff is inflated, and placement of the tube is confirmed by lung auscultation, chest rise, and end tidal CO_2 detection.

In the event that there is insufficient time to complete the dissection for a full cricothyrotomy, a needle cricothyrotomy can be performed. After the neck is prepped and draped, the anatomic landmarks are identified, and a 12- or 14-gauge needle attached to a 5- to 10-mL syringe is used to puncture the skin in the midline directly over the cricothyroid membrane. A small incision with a #11 blade may enable passage of the needle through the skin. Once the needle has passed through the skin, the needle is angled 45 degrees caudally for insertion through the lower half of the cricothyroid membrane. Aspiration of air should be noted once the needle is in the airway, and the syringe is removed. The needle is then connected to a jet ventilation device. Alternatively, a 3-mL syringe can be connected to the needle and attached to a plastic endotracheal tube connector. This will allow for connection to a BVM device. Ventilation via a needle cricothyrotomy only maintains oxygenation for approximately 30 to 45 minutes; hypercarbia may quickly develop. For both needle and surgical cricothyrotomies, the airway is typically converted to a formal tracheostomy by 24 to 48 hours.

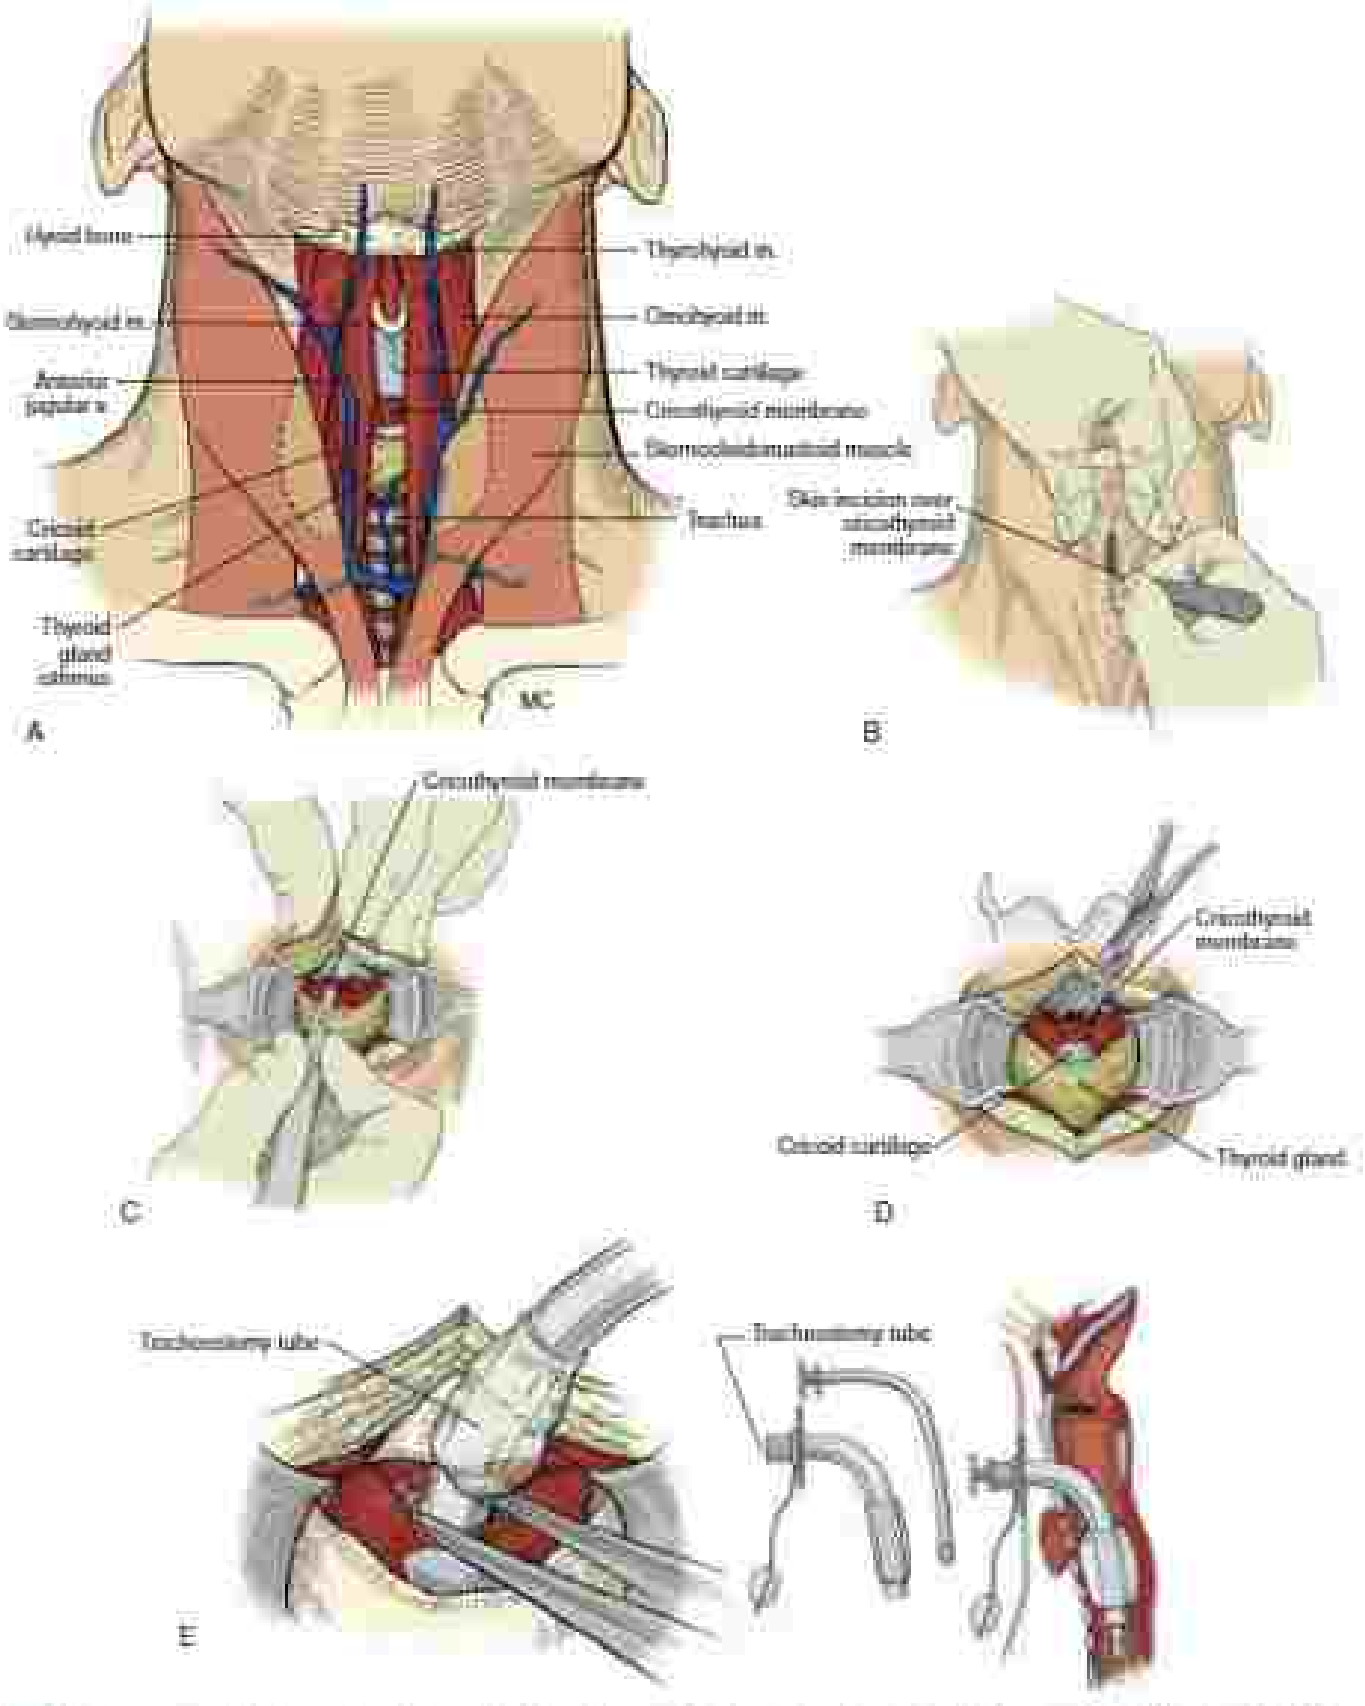

FIG. 7 Cricothyrotomy. (A) The cricothyroid membrane is located between the thyroid cartilage above and the cricoid ring below. (B) The operator's nondominant hand holds the thyroid cartilage, while the other hand performs the procedure. A vertical skin incision avoids the anterior jugular veins to minimize bleeding. (C) The cricothyroid membrane is incised transversely. (D) The opening is widened with a small hemostat. (E) The tracheostomy tube is placed into the airway and the cuff is inflated. Surgical Use of Ultrasound in the Trauma and Critical Care Settings

Alina Cross, MD, and Grace S. Rozycki, MD, MBA, RDMS

For more than 25 years, surgeons in US trauma centers have successfully performed, interpreted, and taught ultrasound examinations of patients who are injured or critically ill. According to the Rogers Diffusion of Innovations Theory, surgeons are considered to be early adopters of the technology and their presence in so many areas of the hospital helped to promote ultrasound as a useful tool for evaluating patients in the elective and emergent settings. Real-time imaging allows the surgeon to receive instantaneous information about the clinical condition of the patient and, therefore, helps to expedite the patient's management. In most trauma centers, ultrasound machines are standard equipment in the trauma resuscitation rooms. Although diagnostic peritoneal lavage and computed tomography (CT) scanning are still valuable diagnostic tools for detecting intraabdominal injury, ultrasound is faster, noninvasive, painless, and well tolerated by adults and children. Moreover, the portability of the ultrasound machine allows for an evaluation of the patient in multiple settings, including the trauma bay and intensive care unit (ICU).

As an extension of the physical examination, surgeons routinely use ultrasound in the acute setting to determine the presence or absence of fluid in the peritoneal cavity, the pericardium, and the pleural cavities. Additional uses of this modality include detecting pneumothoraces and sternal fractures. What follows is a discussion of the use of ultrasound in blunt and penetrating thoracoabdominal trauma with an additional discussion of the use of ultrasound in the ICU.

USE OF ULTRASOUND IN TRAUMA

Focused Assessment for the Sonographic Evaluation of the Trauma Patient

Developed for the evaluation of injured patients, the Focused Assessment for the Sonographic Evaluation of the Trauma Patient (FAST) is a rapid diagnostic examination to assess patients with potential injuries to the thorax or abdomen. The test sequentially surveys for the presence or absence of fluid in the pericardial sac and in the dependent abdominal regions, including the Morison's pouch of the right upper quadrant (RUQ), the left upper quadrant (LUQ) behind the spleen and between the spleen and kidney, and the pelvis posterior to the bladder.

The FAST is performed in a specific sequence: the pericardial area is visualized first so that blood within the heart can be used as a standard to set the gain. Most modern ultrasound machines have presets so that the gain does not need to be reset each time the machine is turned on. Occasionally, if multiple types of examinations are performed with different transducers, the gain should be checked to ensure that intracardiac blood appears anechoic. This maneuver ensures that hemopericardium will also appear anechoic and will be readily detected on the ultrasound image. The abdominal part of the FAST should begin with a survey of the RUQ, which is the location within the peritoneal cavity where blood most often accumulates and is most readily detected with the FAST. In a multicenter trial of 275 blunt and penetrating trauma patients, montgomery found that regardless of the injured organ (with the exception of patients who had an isolated perforated viscus), blood was most often identified on the RUQ image of the FAST. This can be a time saving measure because when hemoperitoneum in the RUQ view is identified on the FAST examination of a hemodynamically unstable patient, then that image alone, in combination with the patient's clinical picture, is sufficient to justify an immediate abdominal operation. In a hemodynamically stable patient, after examination of the RUQ, the LUQ and pelvis are visualized as discussed next.

Technique

Ultrasound transmission gel is applied on four areas of the abdomen/thorax, and the examination is conducted in the following sequence: pericardial area, RUQ, LUQ, and pelvis (Fig. 1). Abdominal structures are best imaged with a lower frequency transducer, which allows for deeper penetration into tissues (sacrificing some resolution). Most ultrasound transducers are now capable of imaging in multiple frequencies, allowing the sonographer to achieve the best balance of resolution (higher frequency) and tissue penetration (lower frequency) based on a patient's individual body habitus.

To begin the examination, a 3.5-MHz curvilinear transducer is oriented for sagittal or longitudinal views and positioned in the subxiphoid region to identify the heart and to examine for blood in the pericardial sac. The normal and abnormal views of the pericardial area are shown in Fig. 2. The subxiphoid image is usually not difficult to obtain, but a severe injury to the chest wall, a narrow subcostal area, subcutaneous emphysema, or morbid obesity can prevent a satisfactory examination. The two latter conditions are associated with poor imaging because air and fat reflect the wave too strongly and prevent penetration into the target organ. If the subcostal pericardial image cannot be obtained or is suboptimal, a parasternal ultrasound view of the heart should be performed.

Next, the transducer is placed in the right anterior or midaxillary line between the 11th and 12th ribs to identify a sagittal section of the liver, kidney, and diaphragm (Fig. 3). The presence or absence of blood is sought in Morison's pouch and in the right subphrenic space. Next, attention is turned to the LUQ and with the transducer positioned in the left posterior axillary line between the 10th and 11th ribs, the spleen and kidney are visualized and blood is sought in between the two organs and in the left subphrenic space (Fig. 4). The splenic window is often the most difficult to obtain because the presence of gas in the stomach may interfere with the imaging. To ensure the best imaging, the stomach may need decompression with a nasogastric tube. Further, the transducer should be placed significantly more posterior (posterior axillary line) and superior (one to two rib spaces higher) than with the RUQ window.

USE OF ULTRASOUND IN TRAUMA

Focused Assessment for the Sonographic Evaluation of the Trauma Patient

Developed for the evaluation of injured patients, the Focused Assessment for the Sonographic Evaluation of the Trauma Patient (FAST) is a rapid diagnostic examination to assess patients with potential injuries to the thorax or abdomen. The test sequentially surveys for the presence or absence of fluid in the pericardial sac and in the dependent abdominal regions, including the Morison's pouch of the right upper quadrant (RUQ), the left upper quadrant (LUQ) behind the spleen and between the spleen and kidney, and the pelvis posterior to the bladder.

The FAST is performed in a specific sequence: the pericardial area is visualized first so that blood within the heart can be used as a standard to set the gain. Most modern ultrasound machines have presets so that the gain does not need to be reset each time the machine is turned on. Occasionally, if multiple types of examinations are performed with different transducers, the gain should be checked to ensure that intracardiac blood appears anechoic. This maneuver ensures that hemopericardium will also appear anechoic and will be readily detected on the ultrasound image. The abdominal part of the FAST should begin with a survey of the RUQ, which is the location within the peritoneal cavity where blood most often accumulates and is most readily detected with the FAST. In a multicenter trial of 275 blunt and penetrating trauma patients, investigators found that regardless of the injured organ (with the exception of patients who had an isolated perforated viscus), blood was most often identified on the RUQ image of the FAST. This can be a time saving measure because when hemoperitoneum in the RUQ view is identified on the FAST examination of a hemodynamically unstable patient, then that image alone, in combination with the patient's clinical picture, is sufficient to justify an immediate abdominal operation. In a hemodynamically stable patient, after examination of the RUQ, the LUQ and pelvis are visualized as discussed next.

Technique

Ultrasound transmission gel is applied on four areas of the abdomen/thorax, and the examination is conducted in the following sequence: pericardial area, RUQ, LUQ, and pelvis (Fig. 1). Abdominal structures are best imaged with a lower frequency transducer, which allows for deeper penetration into tissues (sacrificing some resolution). Most ultrasound transducers are now capable of imaging in multiple frequencies, allowing the sonographer to achieve the best balance of resolution (higher frequency) and tissue penetration (lower frequency) based on a patient's individual body habitus.

To begin the examination, a 3.5-MHz curvilinear transducer is oriented for sagittal or longitudinal views and positioned in the subxiphoid region to identify the heart and to examine for blood in the pericardial sac. The normal and abnormal views of the pericardial area are shown in Fig. 2. The subxiphoid image is usually not difficult to obtain, but a severe injury to the chest wall, a narrow subcostal area, subcutaneous emphysema, or morbid obesity can prevent a satisfactory examination. The two latter conditions are associated with poor imaging because air and fat reflect the wave too strongly and prevent penetration into the target organ. If the subcostal pericardial image cannot be obtained or is suboptimal, a parasternal ultrasound view of the heart should be performed.

Next, the transducer is placed in the right anterior or midaxillary line between the 11th and 12th ribs to identify a sagittal section of the liver, kidney, and diaphragm (Fig. 3). The presence or absence of blood is sought in Morison's pouch and in the right subphrenic space. Next, attention is turned to the LUQ and with the transducer positioned in the left posterior axillary line between the 10th and 11th ribs, the spleen and kidney are visualized and blood is sought in between the two organs and in the left subphrenic space (Fig. 4). The splenic window is often the most difficult to obtain because the presence of gas in the stomach may interfere with the imaging. To ensure the best imaging, the stomach may need decompression with a nasogastric tube. Further, the transducer should be placed significantly more posterior (posterior axillary line) and superior (one to two rib spaces higher) than with the RUQ window.

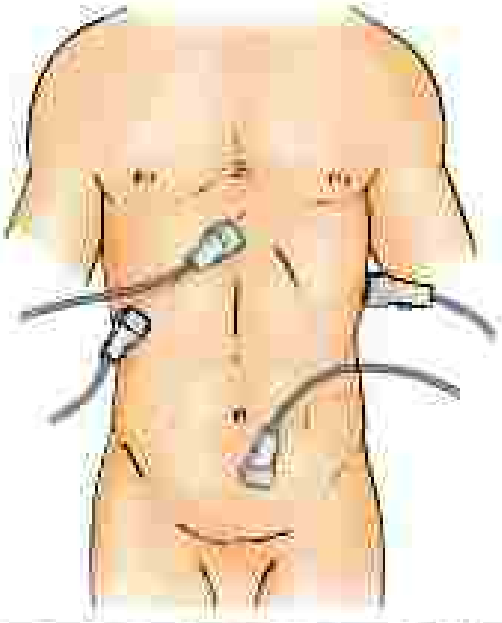

FIG. 1 Transducer positions for focused assessment for the sonographic evaluation of the trauma patient: pericardial, right upper quadrant, left upper quadrant, and pelvis.

Finally, the transducer is directed for a transverse view and placed about 4 cm superior to the symphysis pubis. It is swept inferiorly to obtain a coronal view of the full bladder and the pelvis examining for the presence or absence of blood (Fig. 5).

Accuracy

Improper technique; incompetence of the examiner; and inappropriate use of ultrasound have long been known to adversely impact ultrasound imaging, and, more recently, the etiology of injury, the presence of hypotension on admission, and select associated injuries have also been shown to influence the accuracy of this modality. Failure to consider these factors has led to inaccurate assessments of the accuracy of the FAST by inappropriately comparing it with a CT scan and not recognizing its role in the evaluation of patients with penetrating torso trauma. Both false-positive and negative pericardial ultrasound examinations have been reported to occur in the presence of a massive hemothorax or mediastinal blood. Repeating the FAST after inserting a tube thoracostomy improves the visualization of the pericardial area and decreases the number of false-positive and negative studies. Notwithstanding these circumstances in which false studies may occur, a rapid focused ultrasound survey of the subcostal pericardial area is an accurate method to detect hemopericardium in most patients with penetrating wounds to the "cardiac box." In a large multicenter study of patients who sustained either blunt or penetrating injuries, the FAST was 100% sensitive and 99.3% specific for detecting hemopericardium in patients with precordial or transthoracic wounds. Furthermore, the use of pericardial ultrasound has been shown to

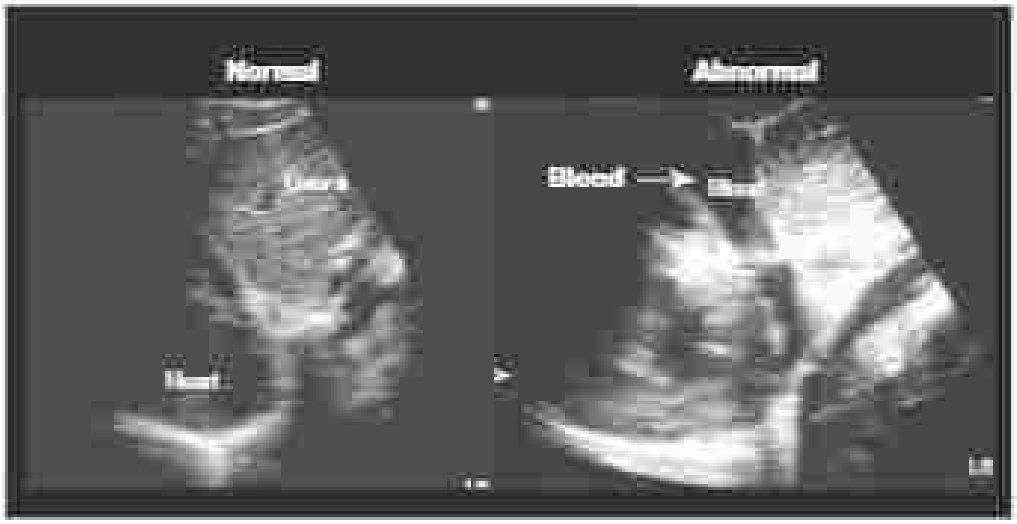

FIG. 2 Left, Normal sagittal view of pericardial area showing pericardium as single echogenic line. Right, Abnormal sagittal view of pericardial area showing separation of visceral and parietal areas of pericardium with blood (arrow) that appears anechoic.

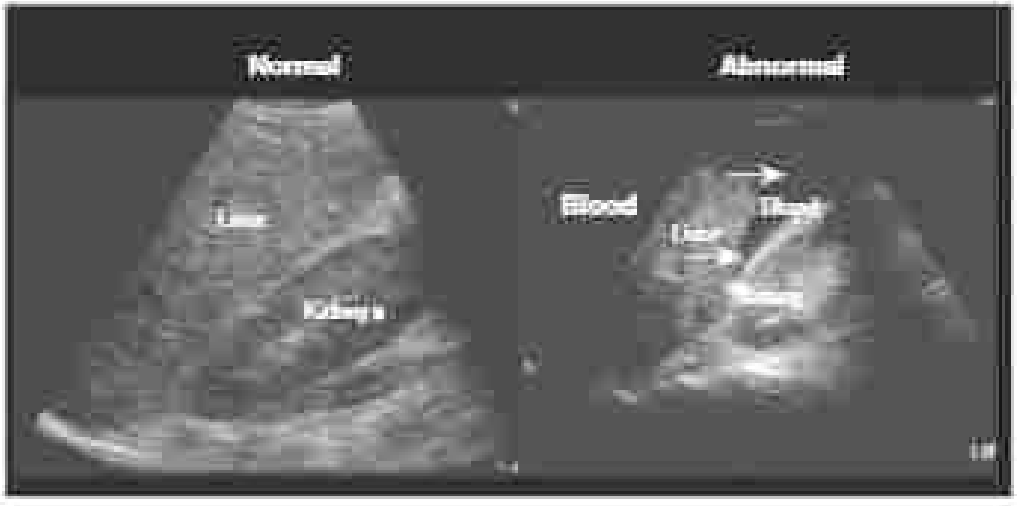

FIG. 3 Left, Normal sagittal view of liver, kidney, and diaphragm. Note: Gerota's fascia is hyperechoic. Right, Abnormal sagittal view of liver, kidney, and diaphragm. Note fluid (blood) in between liver and kidney (arrow).

be especially helpful in the evaluation of patients who have no overt signs of pericardial tamponade. This was highlighted in a study in which 10 of 22 patients with precordial wounds and hemopericardium on the ultrasound examination had admission systolic blood pressures greater than 110 mm Hg and were relatively asymptomatic. Based on these signs and the lack of symptoms, it is unlikely that the presence of cardiac wounds would have been strongly suspected in these patients and, therefore, this rapid examination provided an early diagnosis of hemopericardium before the patients underwent physiologic deterioration.

The FAST is a focused examination for the detection of fluid in dependent areas of the abdomen and designed to answer the simple question of "fluid or no fluid?" Therefore, its results should not be compared with those of a CT scan because the FAST does not readily identify intraparenchymal or retroperitoneal injuries. Therefore, select patients considered to be at high risk for occult intraabdominal injury should undergo a CT scan of the abdomen regardless of the FAST examination results. These patients include those with fractures of the pelvis or thoracolumbar spine, major thoracic trauma (pulmonary contusion, lower rib fractures), and hematuria.

Traumatic Hemothorax

A focused thoracic ultrasound examination was developed by surgeons to rapidly detect the presence or absence of a traumatic hemothorax in injured patients. This examination is worthwhile because it dramatically shortens the interval from the diagnosis of a hemothorax to the insertion of a thoracostomy tube.

Technique

The technique for this examination is similar to that used to interrogate the upper quadrants of the abdomen in the FAST and also uses the same type and frequency transducer. With the patient in the supine position, it is performed one to two rib spaces higher than the RUQ and LUQ FAST views. Ultrasound transmission gel is applied to the right and left lower thoracic areas in the mid- to posterior axillary lines between the ninth and fifth intercostal spaces (Fig. 4). The transducer is slowly advanced cephalad to identify the hyperechoic diaphragm and to interrogate the supradiaphragmatic space for the presence or absence of fluid (Fig. 5 and 6), which appears anechoic. In the positive thoracic ultrasound examination, the hyperechoic lung can be seen "floating" amid the fluid. The same technique can be used to evaluate a critically ill patient for a pleural effusion.

Accuracy

A study that compared the time and accuracy of ultrasound with that of the supine portable chest x-ray found both to have similar high sensitivities and specificities for the detection of hemothorax but the performance times for the thoracic ultrasound examinations were statistically much faster ($P < .0001$) than those for the portable chest

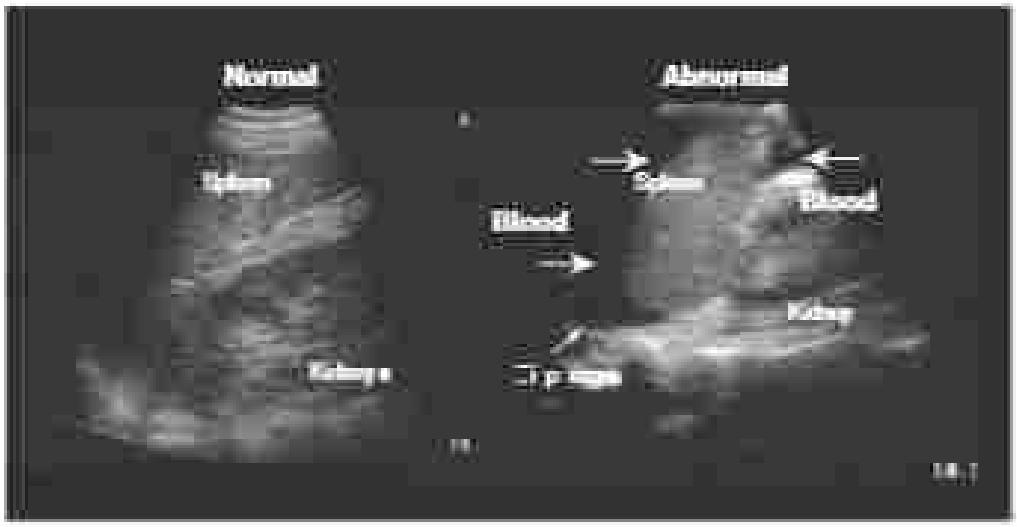

FIG. 4 Left, Normal sagittal view of spleen, kidney and diaphragm. Right, Abnormal sagittal view of spleen, kidney, and diaphragm with fluid (blood) in between spleen and kidney and above the spleen in the subphrenic space (arrows).

x ray. Although it is not recommended that the thoracic ultrasound examination replace the chest x ray, its use can expedite treatment to many patients and decrease the number of chest radiographs obtained.

Pneumothorax

Ultrasound examination for the detection of a pneumothorax is unique in that there is an absence of two findings. The first is a reflection artifact called a comet tail that occurs because of the interaction of air with the lung tissue (Fig. 6). The second finding is pleural sliding indicating the visceral and parietal layers of the pleura are in normal apposition. Hence a pneumothorax is not visualized on ultrasound but rather diagnosed by the absence of these two normal findings.

Technique

A 5.0- to 7.5-MHz linear array transducer is used to evaluate a patient for the presence of a pneumothorax. The examination may be performed while the patient is in the erect or the supine position. Ultrasound transmission gel is applied in the right and left upper thoracic areas at about the third to fourth intercostal space in the midclavicular line, and the presumed unaffected thoracic cavity is examined first. The transducer is oriented for longitudinal imaging, is placed perpendicular to the ribs, and is slowly advanced medially toward the sternum and then laterally toward the anterior axillary line. When a pneumothorax is present, air becomes trapped between the visceral and parietal pleura and does not allow for the transmission of the ultrasound waves. Therefore, the visceral pleura is not imaged and pleural sliding and the comet tail artifact are not observed. If desired, the examination may be repeated with the transducer oriented for transverse views, with images obtained with the probe parallel to the ribs.

Accuracy

Several studies have documented the sensitivity and specificity of ultrasound for the detection of a pneumothorax. Dulchavsky and colleagues showed that ultrasound can be successfully used by surgeons to detect a pneumothorax in injured patients. Of the 360 patients (262 trauma, 98 spontaneous) evaluated with ultrasound, 39 had pneumothoraces and ultrasound successfully detected 37 of them, yielding 95% sensitivity. Pneumothoraces in two patients could not be detected because of the presence of significant subcutaneous emphysema. The authors recommended that when a portable chest x ray cannot be readily obtained, the use of this bedside ultrasound examination for the identification of a pneumothorax could expedite the patient's management.

Sternal Fracture

Fractures of the sternum are visualized on a lateral x ray view of the chest but this film may be difficult to obtain in a patient with multisystem injuries. Therefore, an ultrasound examination of the sternum can rapidly detect a fracture while the patient is still in the supine position, thus avoiding the need to obtain a lateral x ray of the chest wall.

Technique

With the patient in the supine position, the ultrasound examination of the sternum is performed using a high-frequency linear array transducer that is oriented for sagittal or longitudinal views. Beginning at the suprasternal notch, the transducer is slowly advanced in a caudal direction to interrogate the sternum for a fracture and then the examination is repeated with the transducer oriented for transverse views. The examination of the lateral sternum is shown in Fig. 9. A sternal fracture is identified on the ultrasound examination as a disruption of the cortical reflex (Fig. 10). Investigators have found that the use of ultrasound for this diagnosis is as accurate as (and much more rapid than) a lateral x ray view of the chest.

Special Situations

Ultrasound would seem to be an ideal method for evaluating an injured pregnant patient but because of the anatomic changes of pregnancy, the data do not support it to be a very sensitive test for the detection of intraabdominal fluid.

Ultrasound for diagnosis of injuries after penetrating trauma has been studied much less extensively than its use in blunt trauma. Ultrasound has a high sensitivity and specificity for the diagnosis of hemopericardium in patients with penetrating injury to the cardiac box, but when compared with local wound exploration of a stab wound in the abdomen the sensitivity is poor. A report by Murphy

et al. examined the utility of ultrasound to diagnose fascial penetration after anterior abdominal stab wounds. In this study, 35 patients underwent ultrasonic evaluation of their anterior abdominal fascia with an 8.6 MHz linear array transducer followed by a local wound exploration. Although ultrasound had only a 69% sensitivity (13 of 32 patients), it did have 100% specificity with no false positive studies. Thus, if fascial penetration is noted on ultrasound, a more invasive wound exploration is probably not needed. But under these circumstances, a negative ultrasound evaluation is clearly less helpful and does not preclude peritoneal penetration.

USE OF ULTRASOUND IN SURGICAL CRITICAL CARE

Given technologic advancements in the technique, ultrasound has been shown to be a valuable tool for the evaluation of critically ill patients. Performed by the intensivist at the bedside, these focused examinations are useful for a number of diagnostic dilemmas and procedures, including detection and drainage of a pleural effusion, rapid evaluation of hypotension of unknown origin, diagnosis of deep vein thrombosis, and rapid diagnosis of critical venous line complications immediately after placement. In several studies, ultrasound findings have contributed to a change in the patient's management and, consequently, to a decrease in morbidity and length of stay.

Pleural Effusion

The superiority of ultrasound over plain radiography for detecting pleural fluid is well documented. On ultrasound, pleural effusion is identified as an anechoic area surrounded by the chest wall, lung, and diaphragm. Diaphragmatic motion with respiration and the movement of the lung in the surrounding pleural fluid effusion aid in the diagnosis. Once diagnosed, ultrasound-guided drainage optimizes the location, ensures complete drainage, and minimizes the complication of a pneumothorax.

Technique

The patient is placed in the supine position, and the head of the bed is elevated 45 to 60 degrees. A 3.5- or 5-MHz curvilinear transducer, oriented for sagittal sections is placed at the ninth or 10th intercostal space in the mid- to posterior axillary line. The transducer is advanced cephalad until the hyperechoic diaphragm, the subdiaphragmatic organs (liver or spleen), chest wall, lung, and effusion are seen. A felt-tipped pen is used to mark the spot where the needle will enter the chest. The image is frozen and the distance is measured from the mark to the midportion of the effusion so as to choose the correct needle length. The needle is attached to a syringe and advanced superior to the rib (to avoid the neurovascular bundle) while aspirating until pleural fluid return is returned. Using the same principles, the pleural effusion can be easily drained via a thoracostomy tube using Seldinger technique via a wide variety of commercially available drainage kits.

Venous Interrogation for Deep Vein Thrombosis

Venous thromboembolic disease is a common cause of morbidity and mortality in the critical care population and has a reported incidence of 5% to 40% in high-risk injured patients. The use of a focused ultrasound examination performed at the bedside by critical care physicians can provide valuable information to potentially support or exclude the diagnosis of deep vein thrombosis (DVT). In 2010, Parra and colleagues reported their results of a multicenter retrospective study of critically ill patients suspected of having a DVT. They compared a focused, intensivist-performed ultrasound evaluation with the standard duplex study and found that their focused examination compared favorably with the duplex study, showing a sensitivity and specificity of 88% and 98%, versus 81% and 100%, respectively. In addition, the intensivist-performed focused examination confirmed the diagnosis of DVT 18 hours sooner than the duplex study.

Technique

The patient is placed in the supine position with the leg externally rotated and the knee flexed. A high-frequency, 7- to 12-MHz linear transducer is placed in a transverse position just inferior to the inguinal ligament where the common femoral vein is identified. Compression is applied while sliding the transducer distally along the common femoral vasculature until the deep femoral vein and superficial femoral vein are visualized. The examination is repeated with the transducer oriented in the sagittal position (Fig. 11). If the vein is well visualized, it is followed distally to the popliteal area. Although this focused examination does not include flow dynamics, it covers the most common areas where DVT is found (i.e., common, deep, and superficial femoral and popliteal veins). The findings consistent with a DVT are inability to fully compress the vein and the presence of hyperechoic intraluminal material, i.e., clot (Fig. 12).

Placement and Confirmation of Central Venous Lines

In 2001, the Agency for Healthcare Research and Quality recommended the use of ultrasound guidance for the placement of central venous lines and these recommendations were subsequently endorsed by the American College of Surgeons. The benefits of using ultrasound for central line placement are ease of vessel cannulation and fewer complications, especially arterial punctures and pneumothorax. This description is limited to internal jugular venous access because the visualization of the subclavian vein is more difficult due to bone artifact.

Technique

Before preparing the patient's neck, anatomic landmarks (sternal notch, trachea, carotid) should be marked and the internal jugular vein scanned to ensure ease of compressibility and absence of clot. The patient's head should be elevated about 30 degrees and slightly extended and rotated to the contralateral side. A high-frequency linear transducer is held in the nondominant hand, placed in the transverse position (i.e., perpendicular to the long axis of the neck), and oriented so that the left side of the transducer correlates with the left side of the ultrasound screen. The ipsilateral carotid artery and pulsating internal jugular vein are identified. The insertion site is determined and the depth to the internal jugular vein is measured. The needle (attached to a syringe) is inserted at a 45- to 60-degree angle near the center of the transducer. The needle is advanced while aspirating the syringe and visual confirmation of the needle tip within the vein is confirmed along with venous blood return. The transducer is then rotated to the longitudinal position so that the guidewire is visualized within the lumen of the vein. The remainder of the procedure follows the guidelines of the Seldinger technique. Although a chest x-ray is still recommended for the confirmation of central line position, ultrasound offers an alternative method. The 2.5- to 5-MHz curvilinear transducer is selected for the sagittal view and placed in either the apical or subcostal parasternal areas to obtain the four cardiac chambers view. The distal port of the central venous line is flushed rapidly with 10 mL of sterile saline. A rapid atrial swirl is visualized on the ultrasound real-time image as a turbulence entering the right atrium from the superior vena cava immediately after the flush and then migrating into the right ventricle. The rapid atrial swirl indicates that the central venous line is in the correct position. Turbulence initially identified in the right ventricle is consistent with a central venous line that should be withdrawn into the atriocaval position and lack of turbulence indicates intracardiac placement and should be removed.

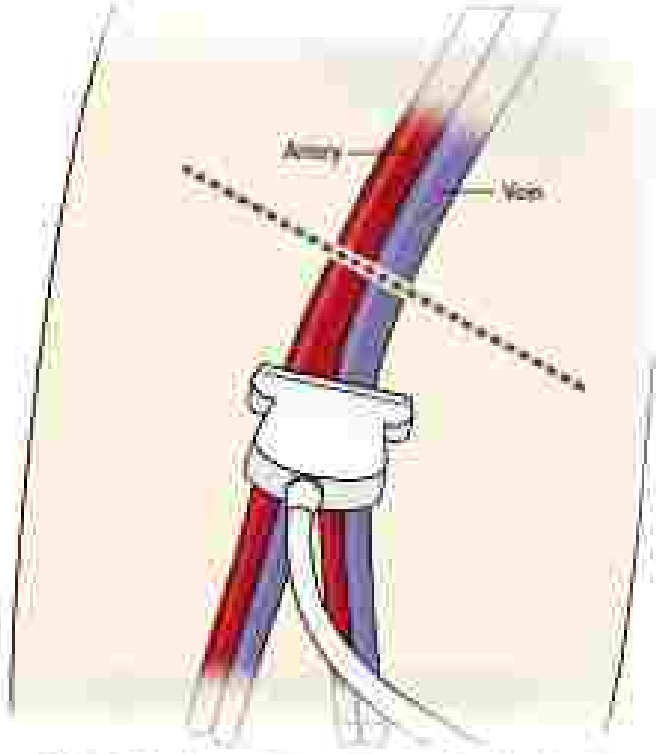

FIG. 11 Transducer position to interrogate the femoral vein.

USE OF ULTRASOUND TO ASSESSING INTRAVASCULAR VOLUME AND CARDIAC FUNCTION

For several years, ultrasound has been used by specialists to assess a patient's intravascular volume status. An inferior vena cava that is easily compressible indicates that the patient is hypovolemic, whereas an inferior vena cava that is noncompressible or has a diameter greater than 2 cm indicates that the patient is euvolemic or hypervolemic (Fig. 13).

Technique for Assessing Intravascular Volume Status

This focused examination is performed with the same transducer as that used for the FAST examination. With the patient in the supine position, the transducer is oriented for sagittal sections and placed in the subxiphoid area. The inferior vena cava is identified and then the transducer is rotated to obtain a long axis view. The width of the inferior vena cava is measured and then the vessel compressed. The transducer is once again rotated to obtain a transverse view of the vessel and the diameter measured and the vessel compressed.

depicts it graphically. Fig. 1 indicates the transducer positions and the resultant images.

SUMMARY

As the role of the general surgeon continues to evolve, the surgeons use of ultrasound will surely influence practice patterns, particularly for evaluating patients in the acute setting. With the use of real time imaging, the surgeon receives instantaneous information to augment the physical examination, narrow the differential diagnosis, or initiate an intervention. Algorithms for the suggested use of ultrasound in penetrating trauma and blunt abdominal trauma are shown in Fig. 1.

The advantages of ultrasound are easily seen in each of the following clinical scenarios. As a noninvasive, minimally radiation modality, ultrasound can be used to evaluate the injured pregnant patient and simultaneously identify the fetal heart so that its rate can be recorded. For the patient with multiple fractures who is in traction, the portable machine is wheeled to the patient's bedside and the FAST is performed without having to move the patient. If hypotension or an unexpected decrease in hematocrit occurs, an ultrasound examination can be easily repeated to exclude hemoperitoneum as the source of hypotension. When several patients with penetrating thoracoabdominal injuries present simultaneously to the emergency department, a rapid FAST examination with thoracic views can assess for pericardial effusion, massive hemothorax, or hemoperitoneum within seconds. This information helps the surgeon prioritize resources and triage patients. Finally, this painless noninvasive modality is well accepted, even by children, because it is performed at the bedside and is not intimidating.

Emergency Department Resuscitative Thoracotomy

Ryan R. Frankman, MD, and David T. [illegible], FACS

Noncompressible thoracic trauma (hemorrhage) is the number one cause of death in urgent/ed trauma centers. The emergency department (ED) resuscitative thoracotomy originally described during the late [illegible] is still arguably one of the most controversial procedures performed in the trauma field to date. It is a heroic last effort that has the potential to be lifesaving, if performed by an appropriate provider in the rapid elegant fashion it is intended. Using minimal instrumentation, access to the pleura, pericardium, and aorta can be achieved within minutes of patient arrival to the trauma bay.

The attraction of this procedure is the satisfaction of attempting drastic measures to save a life. The morbidity of the procedure is significant and identifying the appropriate patient is of utmost importance. Although the intention when accessing the chest of these patients is to save a life, even if successful, iatrogenesis can result in avoidable harm. This invasive intervention, if performed by an untrained hand is a futile effort at best, can be fatal (to an otherwise potentially salvageable patient), and places unnecessary personnel at risk for direct injury as well as exposure to copious amounts of bodily fluids. Iatrogenic injury to thoracic structures will lead to added injury including potential further blood loss, lung parenchymal compromise, nerve transection, and direct cardiac injury.

Over the years, multiple recommendations and guidelines have been provided and revised in an attempt to specify when it is appropriate to attempt this maximally invasive procedure. (Table 1) Although the supporting data are all retrospective in nature, the short number performed and reviewed by expert panels has allowed the creation of some recommendations for elective intervention. It should be remembered that the thoracotomy is performed for two distinct reasons: (1) access the chest for a direct surgical intervention (relief of tamponade, hemorrhage control) and/or (2) optimize resuscitation (open pericardial massage, aortic cross-clamping). Often, both needs are present; however, outcomes are very different depending on the patient's mechanism of injury, physiologic state, and presenting characteristics (age and comorbidities).

All current guidelines rely on a few key factors to best advise the practitioner on which candidates would likely benefit as opposed to those in which intervention would be futile. Mechanism and location of injury are two common starting points on various intervention models along with supporting downstream intervention clues' points such as time of last perfusing vital signs, electrical cardiac activity, pupillary response, and cardiac activity on bedside echocardiogram.

The patient in extremis with a single penetrating stab injury to the cardiac box (often loosely defined as the anatomic area of the anterior chest where a stab may penetrate to the pericardium) with evidence of pericardial tamponade on bedside echocardiogram and witnessed loss of vital signs in the [illegible] is the most likely to benefit from this intervention, with the highest proven survival rates approaching close to 70%. Access to the heart is gained via the left hemithorax with evacuation of pericardial clot and direct repair of the cardiac injury. In contrast, a patient who is in traumatic cardiac arrest after blunt trauma, with unwitnessed loss of vital signs in the prehospital setting, have close to, if not zero survival. Based on retrospective data, ED thoracotomy intervention for thoracic trauma secondary to stab injuries have an improved outcome versus gunshot wounds. Traumatic cardiac injuries have increased survivability compared with noncardiac traumatic injuries, in particular, single chamber pathology and penetrating injuries are favorable compared with blunt injuries.

With the amount of controversy surrounding this topic, there are relative indications allowing some form of discretion to remain at the hands of the provider. Penetrating abdominal, pelvic, or extremity trauma with witnessed loss of vitals in the [illegible] and blunt abdominal trauma with loss of signs of life in the trauma bay are deemed appropriate candidates, with survivability reaching up to 10%. ED thoracotomy performed for abdominal trauma associated cardiac arrest is undertaken with the goals of cross-clamping the descending aorta, prioritizing perfusion to the brain and heart, ruling out intrathoracic pathology, stopping active arterial hemorrhage into the abdomen, and simultaneously allowing access to the heart for open massage and defibrillation in the event of cardiac arrest.

Although absolute indications (and contraindications) are clear, there remains a wide swath of patients with relative indications. They are conditionally recommended for ED thoracotomy because there remains an extremely low likelihood of survival and for those that live, there is a high incidence of some form of neurologic disability and, in more unfortunate cases, complete vegetative states (and ascending cost). However, this is balanced against the chance for some to enjoy a meaningful survival. Operating in the smallest of "what if" and not "what if" gives this small percentage of potential survivors a chance.

It needs to be remembered that the resuscitative thoracotomy is just a beginning maneuver and rapidly proceeding to definitive management of the downstream injuries is vital to the patient's survival. Additionally, the open chest introduces another large wound to these severely injured patients. Another very important concept is that the ED thoracotomy, unlike other invasive procedures, is truly an operation. Pathology findings need to be definitively addressed whether for cardiac repair or lung resection. At the very least, in a patient who survives with a resuscitative thoracotomy, the chest needs to be closed with precision.

Anterolateral Thoracotomy

Adhering to the Advanced Trauma Life Support algorithm approach to the trauma patient, a resuscitative thoracotomy would systematically fall into the circulatory bucket, succeeding airway intubation, chest decompression, blood pressure assessment with infusion protocols, and pulse check. In reality, a patient in arrest calls on all hands-on deck efforts (that is, where resources permit, intubation occurring simultaneous to the performance of the thoracotomy). Although an anterolateral thoracotomy may be performed rapidly, it does take some time and requires familiarity with anatomic physiology and an understanding of the subsequent repair to injuries that the patient will receive.

When the decision is made to undertake the procedure, the site is identified at the anterolateral chest wall, the left arm is raised above the patient's head while the patient is in the supine position, and the chest cage rapidly painted with an antiseptic, usually with betadine. If possible, placement of an orogastric tube down the esophagus may assist in differentiating it from the aorta. The anterior chest should be cleared of all equipment in case of the need for clamshell extension for further exposure.

A left anterolateral thoracotomy incision is made from the left sternosternal margin approximately at the fourth/fifth intercostal space; the left inferior mammary fold (in a female) or just below the nipple (in a male) is an excellent external landmark, with the intention to target the inferior border of the pectoralis major muscle group on the chest wall; this minimizes the amount of tissue to go through as well as subsequent problematic bleeding of the thoracotomy is successful. When performing this procedure to a female with large breasts, the mammary tissue should be retracted toward the ipsilateral shoulder and maintained in place to optimize exposure. The incision

Does not pertain to isolated cranial injuries.
Poor data and largely based on speculation of patient preference.

FIG. 1 Line of the left anterolateral thoracotomy note that it follows the curve of the rib. The inframammary fold (in a woman) or the lower border of the nipple are key landmarks for righting the incision.

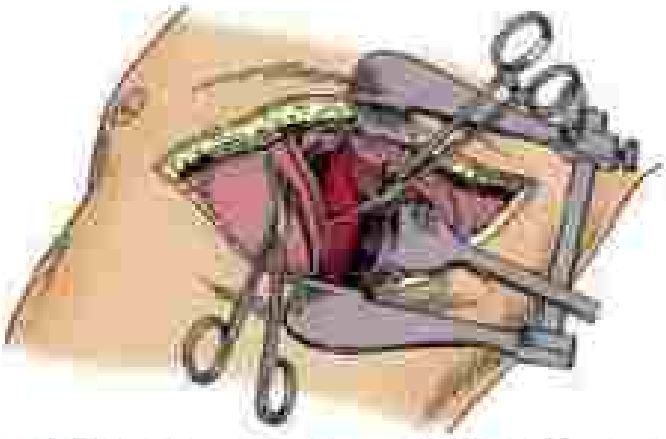

FIG. 2 The pericardiotomy is made anterior and parallel to the phrenic nerve.

follows the natural curvature of the rib vertically down toward the stretcher (Fig. 1). The intervention is carried out in a rapid fashion, moving through the skin and subcutaneous tissue, exposing serratus anterior musculature for transection and finally allowing access to the intercostal muscle group for access into the chest cavity. At this level, entrance into the thoracic cavity through the intercostal muscle can be done bluntly with the Mayo scissors. Using a finger to protect the underlying lung, the incision can be rapidly made again with the Mayo scissors. special attention should be placed on maintaining the incision on the superior aspect of the inferior rib to avoid damage to the intercostal neurovascular bundle. With anatomical awareness, the internal mammary artery may be avoided when approaching the lateral sternum. Posterolaterally, the chest wall is opened all beyond the midline border of the latissimus dorsi. There is no need to divide the latissimus dorsi muscle, which again, if done, results in problematic bleeding if the thoracotomy is successful. A patient who has arrested and requires a thoracotomy will have no bleeding as the procedure is started but will definitely bleed a lot once effective cardiac activity has been restored. Occasionally, patients will have pleural adhesions, so attention should be paid to the lung parenchyma when entering the chest as to not cause parenchymal damage.

A Finochietto retractor (rib spreader) is placed and the ribs are spread. There is debate over the optimal orientation of the retractor. If a dumbbell extension is possibly required, then the handle is placed closer to the stretcher (i.e., away from the sternum to allow extension to the contralateral side). In the event of thoracotomy extension, the incision is taken across the sternum down to the bone and extended in the same fashion down the right hemithorax. A heavy set shears or if one has access to a Lebsche knife this can be used to transverse the distal sternum. Unfortunately, anatomically, when extending the initial thoracotomy across the sternum, both internal mammary arteries will be transected and will require ligation once blood flow has been restored.

PERICARDIOTOMY AND CARDIORRAPHY

Upon entering the chest, immediate inspection allows for assessment of pathology. The pericardium should be opened routinely to rule out cardiac injury and tamponade and facilitate open cardiac massage. An incision on the pericardium should be made anterior to the phrenic nerve (usually will note with an accompanying fat stripe) and extended parallel to the phrenic nerve as superiorly as possible and inferiorly to the cardiac apex (Fig. 2). The pericardium is tough and fibrous and is often difficult to grasp with forceps, especially if bulging with blood. A nick with a scalpel blade is often required. Inspection alone can give a great deal of information, which helps drive therapeutic intervention. Is there cardiac injury or pericardial blood? Is the heart empty and still moving (in which case, more effective intravascular repletion may be warranted)? Does the heart have effective electromechanical activity (does it need cardioversion)?

In the event of tamponade, cardiac delivery should precede the evacuation and methodical examination of the myocardium. If cardiac injury with active extravasation is identified, prompt control with light digital pressure should be swiftly undertaken. A number of options have been well described for temporary control of full thickness cardiac injuries and include Foley catheter placement (through the injury into the chamber) with balloon inflation and minimal traction, staples (know the size of the staples to be used), vascular

clamps may be effective on atrial injuries), or suture control until definitive cardiorrhaphy can be achieved in the operating room. Remember that gunshot wounds to the heart most frequently have both entrance and exit wounds, so thorough inspection of the heart is vital to management.

NON-CARDIAC-RELATED THORACIC HEMORRHAGE

Access to the posterior thorax allows for ligation of the inferior pulmonary ligament. This is well identified by grasping the inferior lobe from below with one's left hand and slipping a finger posteromedially to the left lobe. It will fall into the groove between the lung and the medial thoracic border. Gentle lateral retraction demonstrates the thin ligamentous tissue for sharp division. Care must be taken to stay short of the hilar vessels. This releases the left lower lobe for easy superior traction and provides access to the inferior descending thoracic aorta. Intentional collapse of the left lung further aids visualization. With the assistance of the airway management team, the endotracheal tube can be advanced into the right main stem bronchus to collapse the left lung, allowing optimum exposure of the left hemithorax.

In the event of entering the chest and encountering a significant hemothorax without evidence of cardiac or descending aortic injury, blood should be evacuated and immediate exploration should begin for identification of the source. When identified, temporizing measures with direct pressure should be attempted if control cannot be achieved in the ED until the patient gets to the operating room because most of the aortic branch mediastinal vascular injuries are nearly impossible to achieve adequate exposure for repair in the ED. Pulmonary parenchymal injury as the source of hemorrhage is another likely source of major blood loss, and these injuries, when encountered, should be controlled with direct finger occlusion or clamp placement until the patient is transported to the operating room for formal dissection and repair. Many trauma texts also describe the ability for pulmonary hilar clamping or complete twisting of the lung about the pulmonary hilum once the inferior pulmonary ligament has been divided. This maneuver is effective in the way of completely occluding vascular inflow for hemorrhage control yet will also cause atrition in the lung and has a high morbidity and mortality rate with the physiologic stress it places on the already shocked myocardium with its increased pulmonary vascular resistance increase and resultant right heart stress and resultant right heart failure. It should therefore be a last ditch effort at life preserving intervention.

Aortic Cross-Clamping for Nontho ac Hemorrhage Control

Control of the aorta during an emergency thoracotomy is achieved by pressure at the distal descending thoracic aorta. The aorta runs anterior to the vertebral bodies and directly near and to the left of the esophagus in this location. It is separated from the left hemithorax proper by the mediastinal pleural tissue and posteriorly the prevertebral fascia is quite firm. The aorta is easily palpable where there is a pulse that may be difficult to feel as distinct from the esophagus in the arresting patient. As mentioned previously, a nasogastric versus orogastric tube helps to distinguish the aorta from the esophagus.

The inferior pulmonary ligament will need to be released and lung collapse should be facilitated with main stem endotracheal tube placement. Initial aortic control may be achieved with manual pressure of the aorta against the vertebral bodies. This has the disadvantage of blocking effective manual cardiac massage should that be required as well.

To expose the aorta for placement of a cross-clamp the overlying mediastinal pleural needs to be opened over the aorta. This is often difficult to get started. One trick is to use a clamp with the tips pushed against the vertebral column just posterior to the aorta and spread parallel to both structures. This should cause a rent in the fascia and

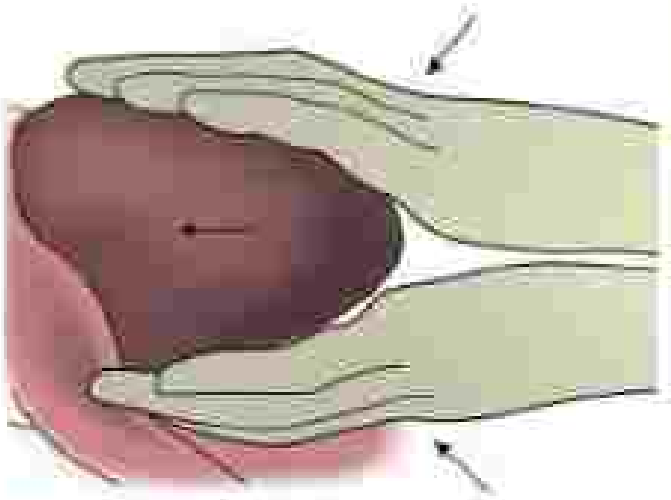

FIG. 3 Open cardiac massage is best achieved with a bimanual open, fist-basket approach.

facilitate the dissection. Finger fracturing will allow exposure of the aorta and esophagus off their respective pleural covering anteriorly and prevertebral fascial tissue posteriorly and will also allow separation of the two structures from one another. Once this has been achieved, the aorta should be accessible and mobile enough to allow enough elevation for aortic clamp placement and successful cross-clamping. When placed for proximal distal hemorrhage control, once cardiac activity is attained, the patient must proceed expeditiously to the operating room for other definitive management.

Although this maneuver allows for preferential blood shunting to the brain and the myocardium, all distal structures will in turn be exposed to prolonged ischemia with simultaneous massive physiologic changes proximally. As with all arterial clamping, an effort needs to be made to minimize clamp time. Restoration of global perfusion can be challenging given the punishing physiologic stress of reperfusion and reperfusion injury. Acidosis, hyperkalemia, and shock all should be anticipated but with prolonged continual aortic clamp times (>40 minutes), this is frequently fatal.

Approach to Open Cardiac Massage

Effective internal cardiac massage should be undertaken as soon as cardiac arrest is identified and appropriate ED surgical intervention has been completed. The bimanual approach is the preferred approach to effective cardiac massage is a "finger clapping" motion using the entirety of the palms of the hands and fingers commencing the compression at the apex of the heart and completing the compression at the base. This maneuver can be further described by firmly adducting the fingers and cupping the anterior hand with the posterior base hand in a rigid, flat, supinated position, allowing a flat surface for the heart to be compressed against. Appose both palmar aspects of the hands to firmly compress the myocardium (Fig. 3). This provides effective circulation and avoids direct cardiac injury.

RESUSCITATIVE ENDOVASCULAR BALLOON OCCLUSION OF THE AORTA

There is a growing enthusiasm for the use of endovascular aortic occlusion in the management of a selected group of severely injured patients. Tried first in the early 1950s with the idea of an intraluminal rapid occlusion of the descending thoracic aorta/abdominal aorta without the morbidity of thoracotomy, there has been a resurgence of its use and promulgation in the past several years, primarily because of practical and specifically designed catheters. Femoral dependent, the technique is commenced percutaneously or via vascular cutdown of

the femoral vessel, an arterial puncture needle with Seldinger's technique, and introducer catheter followed by the balloon occlusion device are inserted into the chest via the aorta over the guidance wire. Alternatively, the device is positioned without guidewire assistance, using catheters with pressurized markings.

Position the balloon occlusion catheter in the thoracic aorta above the renal arteries (zone 1) for intraabdominal hemorrhage control or just above the aortic bifurcation (zone 3) for control of pelvic hemorrhage. Once again, depending on the brand, positioning can later be confirmed with fluoroscopy or computed tomography imaging if the balloon is filled with dye mixed saline in the place of air. It is vital to understand that the ED resuscitative thoracotomy and the resuscitative endovascular balloon occlusion of the aorta (REBOA) are not interchangeable procedures. It is obvious that REBOA would have no use in a patient that arrives with penetrating thoracic trauma, neck trauma, and blunt thoracic trauma related hemopericardium and/or hemothorax with arrest and in fact would be contraindicated. However, for patients who require subthoracic hemorrhage control with aortic occlusion, REBOA is a very attractive alternative to the traumatically invasive traditional full thoracotomy.

Multiple algorithms are being used to ascertain the optimum scenario for ED REBOA placement. The one most fitting with the best success data is in those patients arriving in extremis (i.e., having vital signs, yet unstable), with minimal or no response to volume resuscitation and no evidence of aortic trauma on simple chest films (e.g., severe pelvic fractures). As for the ideal positioning of the device, the Focused Assessment with Sonography for Trauma examination is undertaken with a positive result requiring positioning of the balloon occlusion in zone 1 (above the celiac artery) and a negative result requiring a pelvic plain film. Should the pelvis show any signs of instability, the balloon is deployed in zone 3 (below the renal arteries and above the aortic bifurcation) and if the film proves to be unremarkable the balloon is deployed in zone 1.

There is a growing body of evidence supporting the effectiveness of the ED REBOA; however, definitive data remain lacking. As with any intervention, it too is associated with adverse outcomes, high mortality rates, and the potential for significant morbidity, yet it certainly has a place and role in the acute care trauma setting being an effective intervention and tool to buy the trauma surgeon time for definitive operative intervention in a controlled setting.

Management of Traumatic Brain Injury

Christina Ramirez, MD, and Debora ... ez, MD, M. H

Traumatic brain injury (TBI) is a leading cause of death after injury. There is nothing that can be done to reverse the primary insult to the brain that occurs at time of injury. However, secondary injuries to the brain are the indirect result of injury that can occur immediately after the primary insult. It is the result of factors including cerebral hypoxia, hypotension, edema, and intracranial hypertension. Therefore, treatment strategies in severe TBI are targeted at preventing and treating these factors.

INITIAL TRAUMA EVALUATION AND TREATMENT

All trauma patients should undergo evaluation per Advanced Trauma Life Support guidelines. Initial interventions should be focused on treating any life-threatening injuries identified in the primary assessment. Ensure the patient has an intact airway, is receiving adequate oxygen delivery (with optimal oxygen saturations [SpO_2] of at least 94%) and maintaining a systolic blood pressure (SBP) of greater than 100 mm Hg. Concurrent life-threatening injuries should be identified, and any hemorrhage should be rapidly controlled to prevent and/or minimize hypotension. This should be done as expeditiously as possible.

The patient's medical history should be promptly obtained from family or emergency medical services, including any use of antiplatelet or anticoagulant medications before presentation. A focused neurologic examination should be performed, including brainstem reflexes, motor function in all extremities, and the Glasgow Coma Scale (GCS) score. The GCS is a quick and reliable method to assess the level of consciousness and quickly classify the severity of TBI: mild (13–15), moderate (9–12), and severe (3–8). The GCS score was last updated in 2014 to address variations in examination techniques (Table 1). The most important steps in the initial trauma evaluation in suspected TBI involve (1) maintaining normal oxygenation, ventilation, and blood pressure; (2) antiplatelet and anticoagulation reversal; and (3) identifying herniation.

Oxygenation, Ventilation, and Blood Pressure Management

Providing adequate oxygenation, ventilation, and blood flow is critical to maintaining adequate oxygen delivery to the brain. Derangements in blood pressure, oxygenation, and ventilation are independently associated with increased morbidity and mortality in TBI. Hypotension is historically defined as an episode of SBP less than 90 mm Hg and is one of the most significant predictors of poor outcomes. However, the *Guidelines for Management of Severe T...*, 4th edition, by the Brain Trauma Foundation (BTF) currently recommend maintaining SBP of 100 mm ...g or higher for patients 50 to 69 years old and SBP 110 mm Hg or higher for other ages because these thresholds are associated with decreased mortality and improved outcomes. Fluid resuscitation and rapid definitive treatment of hemorrhagic injuries is essential to limit the secondary brain injury that can result from hypotension. Normal saline is the preferred resuscitative fluid because it is hyperosmotic, thereby avoiding cerebral edema. Arterial line monitoring and vasopressor support may be indicated in those with labile pressures.

the femoral vessel, an arterial puncture needle with Seldinger's technique, and introducer catheter followed by the balloon occlusion device are inserted into the chest via the aorta over the guidance wire. Alternatively, the device is positioned without guidewire assistance, using catheters with pressurized markings.

Management of Traumatic Brain Injury

Christina Ramirez, MD, and Deborah Stein, MD, MPH

Traumatic brain injury (TBI) is a leading cause of death after injury. There is nothing that can be done to reverse the primary insult to the brain that occurs at time of injury. However, secondary injuries to the brain are the indirect result of injury that can occur immediately after the primary insult. It is the result of factors including cerebral hypoxia, hypotension, edema, and intracranial hypertension. Therefore, treatment strategies in severe TBI are targeted at preventing and treating these factors.

INITIAL TRAUMA EVALUATION AND TREATMENT

All trauma patients should undergo evaluation per Advanced Trauma Life Support guidelines. Initial interventions should be focused on treating any life-threatening injuries identified in the primary assessment. Ensure the patient has an intact airway, is receiving adequate oxygen delivery (with optimal oxygen saturations [SpO_2] of at least 94%) and maintaining a systolic blood pressure (SBP) of greater than 100 mm Hg. Concurrent life-threatening injuries should be identified, and any hemorrhage should be rapidly controlled to prevent and/or minimize hypotension. This should be done as expeditiously as possible.

The patient's medical history should be promptly obtained from family or emergency medical services, including any use of antiplatelet or anticoagulant medications before presentation. A focused neurologic examination should be performed, including brainstem reflexes, motor function in all extremities, and the Glasgow Coma Scale (GCS) score. The GCS is a quick and reliable method to assess the level of consciousness and quickly classify the severity of TBI: mild (13–15), moderate (9–12), and severe (3–8). The GCS score was last updated in 2014 to address variations in examination techniques (Table 1). The most important steps in the initial trauma evaluation in suspected TBI involve (1) maintaining normal oxygenation, ventilation, and blood pressure; (2) antiplatelet and anticoagulation reversal; and (3) identifying herniation.

Oxygenation, Ventilation, and Blood Pressure Management

Providing adequate oxygenation, ventilation, and blood flow is critical to maintaining adequate oxygen delivery to the brain. Derangements in blood pressure, oxygenation, and ventilation are independently associated with increased morbidity and mortality in TBI. Hypotension is historically defined as an episode of SBP less than 90 mm Hg and is one of the most significant predictors of poor outcomes. However, the *Guidelines for Management of Severe TBI*, 4th edition, by the Brain Trauma Foundation (BTF) currently recommend maintaining SBP of 100 mm Hg or higher for patients 50 to 69 years old and SBP 110 mm Hg or higher for other ages because these thresholds are associated with decreased mortality and improved outcomes. Fluid resuscitation and rapid definitive treatment of hemorrhagic injuries is essential to limit the secondary brain injury that can result from hypotension. Normal saline is the preferred resuscitative fluid because it is hyperosmotic, thereby avoiding cerebral edema. Arterial line monitoring and vasopressor support may be indicated in those with labile pressures.

TABLE 2 Reversing Anticoagulant and Antiplatelet Agents

Anticoagulant	Mechanism	Reversal Strategy
Vitamin K antagonist (e.g., warfarin)	Inhibits vitamin K–dependent clotting factors	PCC, fresh frozen plasma, TXA, vitamin K
Direct thrombin inhibitor (e.g., dabigatran)	Competitive, reversible direct inhibition of thrombin	Idarucizumab (Praxbind), PCC (including FEIBA, rFVIIa), TXA
Direct factor Xa inhibitor (apixaban, rivaroxaban)	Competitive, reversible direct inhibition of factor Xa	PCC, TXA, andexanet
LMWH (e.g., enoxaparin)	Potentiation of antithrombin III	Protamine sulfate, rFVIIa
COX inhibitor (aspirin)	Irreversible cyclo-oxygenase inhibition	Platelet transfusion, desmopressin
Antiplatelet agents (clopidogrel, ticagrelor)	Irreversibly reduce platelet aggregation	Platelets, desmopressin

COX, cyclo-oxygenase; FEIBA, factor VIII inhibitor bypassing activity; LMWH, low molecular weight heparin; PCC, prothrombin complex concentrate; rFVIIa, recombinant activated factor VIIa; TXA, tranexamic acid.

Similarly, hypoxia (defined as SpO_2 <90%) is associated with significant detrimental outcomes in TBI. Irreversible brain damage can occur after only 4 to 6 minutes of cerebral anoxia. Therefore, all patients should have continuous SpO_2 monitoring. Those with evidence of severe TBI or persistent hypoxia should be intubated both for airway protection and to ensure adequate oxygenation. Oxygen supplementation or ventilator support should be adjusted to maintain a goal SpO_2 higher than 94% or a partial pressure of oxygen in arterial blood (PaO_2) level greater than 70 mm Hg. However, be aware that prolonged hyperoxia has also been associated with worse outcomes secondary to free radical toxicity and cerebral vasoconstriction. The few studies evaluating the effects of high levels of fraction of inspired oxygen and high PaO_2 levels have demonstrated poor functional outcomes including higher mortality rates, lower discharge GCS scores, and longer hospital length of stay compared with patients with normal oxygen levels.

Patients with severe TBI should also have continuous end-tidal carbon dioxide ($EtCO_2$) monitoring to ensure eucapnia because both hypocapnia and hypercapnia can worsen TBI. Significant hypercapnia results in cerebral vasodilation, which can further increase intracranial pressure (ICP). However, hypocapnia results in cerebral vasoconstriction, which compromises cerebral blood flow and decreases oxygen delivery to the brain. Routine prophylactic hyperventilation has been associated with increased mortality and is no longer supported. Instead, controlling the ventilator rate to important to maintain eucapnia (partial pressure of carbon dioxide in arterial blood [$PaCO_2$] to a normal range of 35–40 mm Hg). Hyperventilation is utilized only as a temporizing measure to reduce elevated ICP in dire situations, such as ongoing signs of herniation.

Antiplatelet and Anticoagulation Reversal

Anticoagulant or antiplatelet agents should be reversed in the setting of intracranial hemorrhage (ICH). A list of antidotes for common anticoagulants is listed in Table 2. Laboratory assays should be obtained in all patients, including prothrombin time, activated partial thromboplastin time, and platelet count. If available, thromboelastography can be helpful in determining the coagulopathic dysfunction present in patients. This is especially useful with patients on direct oral anticoagulants (such as factor Xa inhibitors) or with patients whose prehospital medication status is unknown. Any coagulopathic dysfunction should be rapidly corrected. Platelets are typically transfused for platelet counts of less than 100 × 10⁹ cells/L in patients with ICH. However, the exact threshold for transfusion is still debatable.

Identifying Herniation

Signs of impending herniation should be identified as quickly and efficiently as possible. Pupils should be examined for symmetry and reactivity. A dilated or "blown" pupil is concerning for uncal herniation on the ipsilateral side of the dilated pupil. Loss of motor function and/or the presence of a Babinski reflex is concerning for

contralateral brain injury. Decerebrate or decerebrate posturing is especially concerning for brainstem injury. Similarly, certain breathing, such as Cheyne-Stokes ventilations (repeating cycle of slow, shallow breaths followed by deeper and rapid breaths) are also concerning for brainstem injury and/or compression. Significant systolic hypertension (with or without bradycardia) can be secondary to a Cushing's reflex in severe intracranial hypertension and should not be rapidly reversed.

If the patient has any lateralizing signs or evidence of impending herniation, urgent neurosurgical consultation should occur to evaluate for immediate surgical intervention. Measures to decrease ICP should also be initiated, which is later discussed. Otherwise, a computed tomography (CT) head scan without intravenous contrast should be obtained to evaluate for the extent of TBI. Specific findings should be identified on imaging, including the presence of intracranial blood, midline shift, mass effect, herniation, and/or skull fractures. Neurosurgical consultation should shortly follow. If neurosurgery is not available, the patient should be transferred as expeditiously as possible to the nearest neurosurgery-capable facility.

MEDICAL MANAGEMENT

Fortunately, most patients with TBI can be medically managed. Maintaining normal oxygenation, ventilation, and blood pressure is still paramount. Patients with severe TBI are typically admitted to the intensive care unit because they require close monitoring, specifically blood pressure, oxygen saturation, and neurologic status. As previously mentioned, these patients require continuous SpO_2 and $EtCO_2$ monitoring, as well as an arterial or central venous line (if indicated). They require hourly neurologic examinations, because the pathophysiology of TBI is a dynamic process. Examination findings may fluctuate significantly within a short time and change management. Any acute change in neurologic examination should trigger an additional head CT scan to evaluate for bleeding or herniation, which could require surgical intervention.

Monitoring Intracranial Pressure

Another significant predictor of poor outcome in TBI (besides hypotension) is prolonged ICP elevation. Thus monitoring and treating ICP is often the mainstay of treatment. Previously, the 3rd edition of the BTF guidelines recommended ICP monitoring in all salvageable patients with a severe TBI and an abnormal CT scan findings. They also recommended monitoring in patients with severe TBI and an unremarkable CT scan if two or more features were present on admission: age greater than 40 years, unilateral or bilateral posturing, or SBP less than 90 mm Hg. However, the updated 4th edition did not carry forward these guidelines given the lack of supportive evidence. Instead, the guidelines only recommend "management of severe TBI patients using information from ICP monitoring...to reduce in-hospital and 2-week post-injury mortality." Thus, the decision to place a monitor should be made in consultation with neurosurgery.

There are three main methods of invasive neurologic monitoring: external ventricular drain (EVD), intraparenchymal pressure monitor (IPM, also known as bolt), and continuous brain tissue oxygen tension (PbO_2) monitor. EVDs are useful because they are both diagnostic and therapeutic. EVDs are placed in one of the lateral ventricles and can be used to both measure ICP and drain cerebral spinal fluid (CSF). However, they can be difficult to place and are more subject to blockage by hemorrhage or debris. Conversely, IPMs are easier to place because their placement is less precise and not influenced by midline shift or brain swelling. The risk of hemorrhage and infection is also less with IPMs compared with EVDs. A PbO_2 monitor is performed by placing a probe in the penumbra of injured parenchyma and enables quantification of tissue oxygenation in areas that are at the highest risk for secondary brain injury. PbO_2 levels less than 15 mm Hg should be treated by increasing systemic oxygenation. Alternative noninvasive methods include optic sheath diameter measurements or transcranial Doppler ultrasound, both of which are promising but not regularly used in the clinical setting.

Once an ICP monitor is in place, it can be used to track ICP and calculate cerebral perfusion pressure (CPP, where CPP = mean arterial blood pressure − ICP). Treatment of ICP higher than 22 mm Hg is recommended because values higher than this level are associated with increased mortality. Similarly, the recommended target CPP for survival and favorable outcomes is between 60 and 70 mm Hg. A CPP level less than 50 mm Hg is associated with brain ischemia, whereas a CPP level persistently elevated higher than 70 mm Hg is associated with increased rates of acute respiratory distress syndrome with no improvement in outcomes.

Managing Intracranial Pressure

The Monro-Kellie doctrine states that the relationship between intracranial contents, mainly consisting of brain tissue, blood, and CSF, remain constant to maintain ICP. Therefore, if the volume of one component increases (such as ICH), then the other components must be compensated to maintain ICP within normal ranges (<15 mm Hg). If the volume of one component continues to increase past a critical threshold, brain herniation and death will ultimately occur. Medically decreasing ICP is therefore targeted at these main components: brain, blood, and CSF.

Decreasing CSF is typically performed with CSF drainage using an EVD. Brain cell volume is decreased by reducing cerebral parenchymal cell water through osmolar therapy. Cerebral blood flow (CBF) and volume are most affected by cerebral metabolic requirements. As previously mentioned, $PaCO_2$ values are strongly and directly related to CBF; a lower $PaCO_2$ results in low CBF and vice versa. However, both hyper- and hypocapnia are associated with detrimental outcomes, so ventilators should be adjusted to maintain $PaCO_2$ levels between 35 and 40 mm Hg. The head and neck should be maintained in a neutral position to prevent cerebral venous outflow obstruction. Poor head position (such as flexion) and tight-fitting cervical collars have been demonstrated to cause significant increases in ICP, especially in children, who typically have larger occiputs and floppier necks. Other factors that affect CBF and volume include hyperventilation therapy, medications, and core temperature.

Hyperosmolar Therapy

Hyperosmolar therapy can decrease ICP by decreasing blood viscosity and cerebral parenchymal cell water, thereby decreasing the volume of cerebral blood and brain tissue. Hypertonic saline is becoming increasingly utilized to maintain serum sodium levels above 140 in severe TBI (or a minor GCS <8). Mannitol can also be utilized but its diuretic effect is detrimental in hypotensive patients or patients being actively resuscitated. The fourth edition of the BTF guidelines makes no formal recommendation on the ideal hyperosmolar therapy, given the lack of sufficient evidence. However, the previous edition recommended restricting mannitol in patients with signs of transtentorial herniation or progressive neurologic deterioration that is not attributed to extracranial causes.

Sedation, Analgesics, and Seizures

Anesthetics, sedatives, and anesthetics help prevent unnecessary movement, coughing, and agitation, which is important in intubated patients. However, they are also used for neuroprotection and to control ICP. They help suppress cerebral metabolism, oxygen consumption, and oxygen radical mediated lipid peroxidation. Decreasing metabolic demands also decreases the CBF requirement, which subsequently decreases cerebral blood volume and ICP. Short-acting agents such as fentanyl for pain control and propofol for sedation are ideal because they can be held for frequent neurologic examinations. Generally, continuous infusions should be used instead of boluses to decrease hypotension and mitigate rebound ICP elevation. Other agents, such as dexmedetomidine or midazolam, can also be used, especially when ICP elevation is associated with agitation.

Barbiturates are used as a last line to control elevated ICP refractory to maximum standard treatment because they have been shown to reduce both ICP and cerebral metabolism but can cause hypotension and fail to improve overall outcomes.

Normothermia

Temperature management is important in severe TBI because hyperthermia is associated with increased cerebral metabolic demands, resulting in increased CBF and elevated ICP. Normothermia should be maintained using a combination of acetaminophen, ice packs, and external and/or central cooling. Conversely, previous research has shown hypothermia to have neuroprotective and ICP reducing effects. However, the risks of hypothermia, including coagulopathy, immunosuppression, cardiac dysrhythmias, and death, outweigh the benefits. Recent trials have also failed to show any benefits to outcome. Therefore, routine prophylactic hypothermia is not recommended to improve outcomes in patients with severe TBI.

Preventing Hemiation

The dosage of analgesics, sedatives, and hyperosmolar therapy can be increased as needed to maximum doses or given in boluses. However, despite optimal and maximum medical management, ICP can continue to increase, resulting in herniation. Short-term ventilation can be utilized ($PaCO_2$ <35 mm Hg). The neurosurgery department should be notified of any elevated ICP that persists despite medical management. If intracranial hypertension remains refractory, barbiturate therapy, and/or therapeutic hypothermia can be considered, but the outcomes are generally poor.

General Considerations

In addition to ensuring adequate oxygenation, ventilation, blood pressure, and normal ICP and CPP, other systemic considerations need to be addressed, including managing seizure prophylaxis, nutrition, glucose levels, infections, and venous thromboembolism (VTE).

Seizure Prophylaxis

Patients with acute TBI are at risk for seizures because ischemic or damaged brain tissue can be lost to produce seizures. Generalized seizure activity can also be induced by hypoxia, hypoglycemia, or electrolyte abnormalities. When generalized seizures occur, the excessive neuronal activity rapidly decreases oxygen and glucose levels and can further worsen cerebral ischemia. Post-traumatic seizures (PTSs) are early if they occur within 7 days of injury. Risk factors for early PTS include GCS score of 10 or less, immediate seizures, post-traumatic amnesia >30 minutes, linear or depressed skull fracture, penetrating head injury, age 65 years or younger, chronic alcoholism, and either subdural, epidural, or intracerebral hemorrhage. Phenytoin is recommended by the BTF to decrease the incidence of early PTS. Levetiracetam is also often used but the available studies are inconsistent for BTF guideline recommendations. Early PTS has not been associated with worse outcomes, although it can result in prolonged hospital stay. Prophylactic use of antiepileptics is not recommended to prevent late (>7 days) PTS.

Nutrition and Glucose Management

Glucose is a primary fuel source to the brain. However, glucose metabolism is depressed in severe TBI, and the duration of glucose depression increases with age. In the absence of glucose, ischemic neurons can be permanently damaged. The location of depressed metabolism is important because as higher metabolic rates in the thalamus, brainstem, and cerebellum correlate positively with levels of consciousness. Hyperglycemia can also jeopardize ischemic brain tissue; prolonged serum glucose level greater than 150 mg/dL has been associated with a poorer neurologic outcome. Therefore, maintaining normoglycemia (serum glucose <180 mg/dL) is critical in the management of severe TBI. This is one of several reasons why ensuring adequate nutrition is critical in all patients with TBI. The American Society for Parenteral and Enteral Nutrition recommends initiation of enteral feeding within the first 24 to 48 hours of admission, meeting nutritional goals over 48 to 72 hours. BTF guidelines also emphasize the need for feeding by at least the end of the first week, indicating that early feeding improves outcomes.

Infection Prophylaxis

Patients with severe TBI are often at risk for infection due to a variety of reasons including mechanical ventilation and invasive monitoring (such as central lines and EVDs). Ventilator-associated pneumonia in TBI patients may be as high as 40% and is associated with longer mechanical ventilation days. Thus, early tracheostomy is recommended to reduce mechanical ventilation days, even though there is no evidence that doing so reduces mortality or pneumonia rates. Antimicrobial-impregnated catheters should be utilized whenever possible because they are associated with lower rates of infection and catheter bacterial colonization. Prophylactic antibiotics are not currently recommended because there is no difference in mortality and they are associated with an increased risk of developing antibiotic resistance.

Venous Thromboembolism Prophylaxis

TBI is an independent predictor of VTE in trauma patients, with a three- to fourfold increase in VTE despite the use of mechanical and chemical prophylaxis. The risk is increased as the severity of TBI increases, usually due to hypercoagulability from brain injury, focal motor deficits, and prolonged immobilization. However, there is also an increased risk of worsening ICH with chemical prophylaxis. Therefore, the VTE prophylaxis should always be considered if the brain injury is stable and the benefits outweigh the risks. Because there is insufficient evidence, there are currently no BTF recommendations regarding the preferred agent, dose, or timing of pharmacologic prophylaxis.

Steroid Use

Steroid use is not recommended to reduce ICP or improve outcomes. The 2004 Corticosteroid Randomization After Significant Head Injury (CRASH) trial demonstrated high-dose methylprednisolone to be associated with increased mortality and severe disability. Another 2004 study demonstrated an increased risk of late seizures with use of glucocorticoids less than 1 week in the post-traumatic period.

SURGICAL THERAPY

As described by the Monro-Kellie doctrine, elevated ICP can cause brain tissue displacement, leading to cerebral herniation. This is often caused by mass effect from ICH or cerebral edema that occurs as a result of primary and secondary brain injury. Decompressive craniotomy (DC), or surgical removal of a portion of the skull, is performed to relieve elevated ICP by removing ICH and providing room for the brain to expand.

According to the Surgical Management of TBI Author Group, acute subdural hematomas should typically be evacuated if the hematoma is more than 10 mm thick or if there is midline shift greater than 5 mm. An epidural hematoma greater than 30 cm^3 should be evacuated regardless of GCS. DC is also indicated with severe TBI and frontal or temporal contusions greater than 20 cm^3 in volume with midline shift of at least 5 mm and/or cisternal compression on CT scan, or patients with lesions greater than 50 cm^3. Urgent indications for operative intervention include any signs of transtentorial herniation and deterioration of neurologic function secondary to parenchymal lesions. The role of DC in diffuse injury and elevated ICP refractory to medical management is debatable because of insufficient and controversial evidence. The Decompressive Craniectomy (DECRA) trial was a 2006 randomized control trial that compared early bifrontal unilateral DC with medical management for refractory raised ICP (>20 mm Hg). DC was demonstrated to reduce ICP and intensive days in the intensive care unit, but it was also associated with poorer outcome scores at 6 months compared with medical care. The most recently published RESCUEicp trial is another randomized

control trial comparing DC with medical care in patients with refractory elevated (ICP >25 mm Hg). They found DC to be associated with lower mortality but higher rates of vegetative state and severe disability compared with medical therapy. Based on these studies, the BTF guidelines do not recommend DC to improve outcomes in patients with severe TBI who have diffuse injury (without mass lesions) or ICP elevations >20 mm Hg for more than 15 minutes within a 1 hour period that are refractory to first tier medical therapies. Those with open cranial fractures should undergo operative intervention to prevent infection if there is clinical or radiologic evidence of dural penetration, significant intracranial hematoma, depression greater than 1 cm, frontal sinus involvement, gross cosmetic deformity, gross wound contamination, or pneumocephalus. Closed (simple) depressed fractures can typically be treated nonoperatively.

Complications of DC include infection, CSF absorption disorders (subdural hygroma, hydrocephalus, and CSF leak), postoperative hematoma expansion, and surgical site infection. Contralateral hematoma after DC occurs in up to 7.4% of patients. Subdural hygromas can occur due to an imbalance between production and reabsorption of CSF. Post DC hydrocephalus is seen in 2%–30% of cases, can complicate prognosis, and occasionally require placement of a ventriculoperitoneal shunt. A CSF leak can also lead to infections, wound complications, and prolonged recovery. Subsequent cranioplasty, or interval replacement of the bone, is also associated with an increase of infection, cerebral edema, and decreased bone flap reabsorption.

BRAIN DEATH

Brain herniation ultimately results in brain death, or the complete, irreversible cessation of brain function. Determination of brain death consists of prerequisite criteria, neurologic assessment(s), and ancillary confirmatory tests (if indicated). The American Academy of Neurology guidelines state that the patient must be normothermic (>36°C) and normotensive (SBP >100 mm Hg) with an irreversible and proximate known cause of the coma. The presence of central nervous system depressants, neuromuscular blocking agents, or severe electrolyte, acid base, or endocrine disturbances should be excluded. The patient must lack all evidence of responsiveness to noxious stimuli. Brainstem reflexes (pupillary, oculocephalic, oculovestibular, corneal, grimace, gag, and cough) and be apneic. An apnea test is performed by disconnecting the patient from the ventilator but preserving oxygenation (after ensuring normotension, normothermia, euvolemia, eucapnia, and no prior evidence of CO_2 retention). The test is positive if respiratory movements are absent and $PaCO_2$ of 60 mm Hg or greater (or a 20 mm Hg increase over baseline). The test can be repeated if it is inconclusive. Other ancillary tests, including electroencephalogram, CT angiography, or nuclear scan, can also be performed to confirm brain death. Hospital guidelines and state law may dictate additional requirements/criteria for pronouncing brain death.

CHEST WALL, PNEUMOTHORAX, AND HEMOTHORAX

Gregory Sutton, DO, FACS, FACOS, and Mary McCarthy, MD, FACS

Chest wall injury describes of fractures of the thoracic cage, including the ribs, sternum, and costal cartilage. Associated injuries to the thoracic cavity carry significant morbidity and mortality and are described elsewhere. Chest wall injury is one of the most common injuries encountered by the acute care surgeon, with over 140,000 patients in the United States presenting yearly and carries a mortality rate as high as 20%. Chest wall injury results not only in significant pain, but decreased pulmonary function, inability to cough and clear secretions, atelectasis, pneumonia, and respiratory failure. These injuries can place a significant burden on the healthcare system by increasing length of hospitalization, overall healthcare expenditures, and long-term disability. The chronic disabling pain is not often appreciated by surgeons who provide the majority of their care during the acute phase of injury in the hospital. In one study, patients with two or more rib fractures were more disabled at 30 days than a reference population of chronic illness. In the same study, the total mean days lost from work and usual activity was 70 ± 41 days and the number of rib fractures correlated with pain levels, days lost from work, and self-reported energy levels. Of patients who were followed 5 years after their rib fractures, less than one third had returned to full time employment. Greater than 50% of patients complained of thoracic cage pain and mild dyspnea, and 25% reported subjective chest tightness and a decline in overall activity. Incentive spirometry readings were abnormal in over half of these patients. These findings underscore the need for a comprehensive and evidence-based approach when caring for patients with these complex injuries.

INITIAL EVALUATION

Patients with suspected trauma to the chest wall should initially undergo emergency stabilization protocols, such as those outlined in Advanced Trauma Life Support. Initial priorities include performing lifesaving interventions to the airway, breathing, and circulation as needed. Special attention should be paid to the chest wall with inspection for external signs of injury, observation for equal chest rise, and auscultation for bilateral breath sounds. The absence of unilateral breath sounds in combination with jugular venous distention and tracheal deviation should raise suspicion of tension pneumothorax. This should be promptly treated with needle decompression of the chest followed by placement of a thoracostomy tube. Absent unilateral breath sounds without findings of tension pneumothorax

control trial comparing DC with medical care in patients with refractory elevated (ICP >25 mm Hg). They found DC to be associated with lower mortality but higher rates of vegetative state and severe disability compared with medical therapy. Based on these studies, the BTF guidelines do not recommend DC to improve outcomes in patients with severe TBI who have diffuse injury (without mass lesions) or ICP elevations >20 mm Hg for more than 15 minutes within a 1 hour period that are refractory to first-tier medical therapies. Those with open cranial fractures should undergo operative intervention to prevent infection if there is clinical or radiologic evidence of dural penetration, significant intracranial hematoma, depression greater than 1 cm, frontal sinus involvement, gross cosmetic deformity, gross wound contamination, or pneumocephalus. Closed (simple) depressed fractures can typically be treated nonoperatively.

These findings underscore the need for a comprehensive and evidence-based approach when caring for patients with these complex injuries.

INITIAL EVALUATION

Patients with suspected trauma to the chest wall should initially undergo emergency stabilization protocols, such as those outlined in Advanced Trauma Life Support. Initial priorities include performing lifesaving interventions to the airway, breathing, and circulation as needed. Special attention should be paid to the chest wall with inspection for external signs of injury, observation for equal chest rise, and auscultation for bilateral breath sounds. The absence of unilateral breath sounds in combination with jugular venous distention and tracheal deviation should raise suspicion of tension pneumothorax. This should be promptly treated with needle decompression of the chest followed by placement of a thoracostomy tube. Absent unilateral breath sounds without findings of tension pneumothorax

can be suggestive of pneumothorax or hemothorax. The presence of paradoxical chest wall motion is suggestive of, but not necessarily diagnostic for, flail chest. These findings are concerning for significant chest injury and should promptly be evaluated radiographically. The patient's blood pressure should be rapidly assessed and peripheral large bore intravenous line should be placed. Tachycardia and hypotension should be assumed to be a result of hemorrhage and fluid, and/or blood administration should be initiated promptly. Tension pneumothorax, cardiac tamponade, and cardiogenic shock due to blunt cardiac injury should also be considered in the patient with blunt chest trauma. Following the primary survey, resuscitation moves into a secondary survey that should include a focused history and a head to toe examination of the patient. Adjuncts to the secondary survey should include laboratory tests and radiographic imaging including a chest x ray and pelvic x ray. Attention should be paid to the chest x ray for the presence of pneumothorax, hemothorax, rib fractures, and widening of the mediastinum. The focused abdominal sonogram for trauma (FAST) is increasingly being used in both trauma and nontrauma centers. With regards to the thorax, ultrasound can quickly be utilized to detect the presence of cardiac tamponade. This so-called extended FAST or eFAST also evaluates the pleural cavity for the presence of pneumothorax or hemothorax with relatively good sensitivity.

Computed tomography (CT) has become the workhorse of rapid diagnosis of injuries in trauma patients. While routine CT scans of the chest are costly and could expose the patient to unnecessary radiation, thoracic injuries can carry major morbidity and mortality. The National Emergency X-ray Utilization Study (NEXUS) chest criteria have been developed to help identify patients at risk for thoracic trauma and guide clinical decision regarding necessity of CT scans. The rate of occult pneumothorax, that is those that are seen on CT but not seen on chest x ray, is as high as 22% in some series. Three-dimensional (3D) reconstructions of the ribs and sternum can be extremely useful in evaluating chest wall injuries. The anatomic nature of the ribs, which extend through three planes, makes it difficult to evaluate with plain films or even axial computed tomography. Three-dimensional imaging can improve visualization of displacement and flail segments and is especially useful in planning for surgical intervention.

SPECIFIC INJURIES

Rib Fractures

In 10% of patients with multisystem trauma and 59% of patients with blunt chest trauma, two or more rib fractures will be identified. As previously noted, these injuries carry a high morbidity that can lead to a need for mechanical ventilation, pneumonia, increased length of stay, and chronic pain and disability. Many rib fractures can be identified on plain chest x rays, but CT scans carry increased sensitivity and specificity and allow for more precise identification of fracture morphology. Multiple studies have shown that with increasing number of rib fractures, the risk of complications and mortality are increased. Ribs four to nine are the most commonly injured ribs, which is important because these are the ribs most involved in respiration. Injuries of lower ribs (9–12) may portend injury to upper abdominal viscera such as the spleen or liver, while high rib fractures (1, 2) can be associated with blunt cerebrovascular injury. Extremely posterior rib fractures (within 3 cm of the transverse process), are usually well tolerated as these fractures are stabilized by the erector spinae musculature. Similarly, very anterior fractures are cartilaginous in nature and do not carry significant pulmonary morbidity.

Flail chest is poorly defined in the literature, but most experts have come to agree that there exists both clinical and anatomic flail chest. Clinical flail chest is the more classical description of a patient with paradoxical chest wall motion in which the chest wall moves inward during inspiration. Anatomic flail chest, on the other hand, describes a single rib that is fractured in two or more places (flail segment), thus being free floating and disconnected from the thoracic cage. Clinical flail chest can be caused by a flail segment but may also be seen with severely displaced contiguous rib fractures, or with bilateral rib fractures near the sternum. It is therefore possible to have clinical flail chest without anatomic flail chest, and vice versa. In any case, flail chest carries significant morbidity and mortality, with up to three-fourths of patients exhibiting pulmonary contusion, hemothorax, or pneumothorax.

Pain control is essential in patients with rib fractures (Box 1). The ideal strategy would provide complete and prolonged analgesia, permit deep breathing and secretion clearance, allow patient cooperation, minimize central nervous system and systemic side effects, allow for early mobilization, be safe, and be cost effective. Unfortunately there is no agent that can provide all these benefits while providing adequate pain relief. A multimodal pain control strategy, such as those outlined in the table, should be used in an attempt to minimize narcotic use. Opioids, such as morphine or fentanyl, cause sedation, respiratory depression, cough suppression, hypotension, immune suppression, constipation, and are highly addictive. When these drugs must be used in higher doses, a patient-controlled analgesia device should be employed to minimize some of these side effects. Acetaminophen can be used around the clock fashion as a baseline pain control. Nonsteroidal antiinflammatory drugs (NSAIDs), such as ibuprofen or ketorolac, have been shown to be extremely effective in patients with rib fracture. In one study, a treatment group of patients with multiple rib fractures that received ibuprofen was shown to have decreased daily morphine use and lower overall pain scores and length of stay versus a control group. NSAIDs, however, must be used with caution in patients with renal impairment, cardiovascular disease, gastrointestinal ulcers, and orthopedic injuries. Other nonnarcotics including gabapentin and muscle relaxers are advocated by many clinicians who care for patients with rib fractures, but currently there is little evidence supporting their use. Another interesting option is intravenous ketamine, which blocks N-methyl-d-aspartate receptors, thus reducing the risk for opioid hyperalgesia. The low doses of ketamine used for its analgesic effect (typically 1–3 μg/kg per minute) are not associated with the side effects of delirium, hallucinations, respiratory depression, and sedation seen at higher doses.

BOX 1 Standardized Pain Regimen for Patients with Multiple Rib Fractures

Acetaminophen 650 mg qid
Ibuprofen 600 mg qid*
Gabapentin 300 mg tid*
Oxycodone 5 mg q4h prn

For Refractory Pain (Pain Score >6 Despite Above):
Intercostal block or paravertebral infusion catheter
Ketamine drip, 1–3 μ kg/min
Consider intravenous narcotics (patient controlled analgesia)
Consider epidural catheter
Consider surgical stabilization of rib fractures

*Use with caution in elderly and renal failure patients

Local regional anesthesia is an excellent option for pain control. Intercostal nerve blocks were one of the earliest attempts at local pain relief for rib fractures and continue to be used in some centers. Local anesthetic in the form of bupivacaine or ropivacaine is injected just below the rib proximal to the fracture site. Due to the overlapping innervation of the intercostal nerves, it is important to block at least one rib above and one rib below the injured segment. Unfortunately, the effects of local anesthetics begin to wane after only 6 hours. The need for multiple injections and the risk of pneumothorax make this an unattractive option. Liposomal bupivacaine, whose effects linger for up to 72 hours, offers a theoretical advantage if the block is performed properly. Topical lidocaine patches, which were developed to treat postherpetic neuralgia, have been attempted in some centers. A randomized controlled study of 58 patients, however, showed no improvement in pain scores or narcotic usage versus a placebo.

Epidural anesthesia has been extensively studied in this patient population. These catheters can easily be placed in the high thoracic spine at the bedside and using continuous infusion of local anesthetic, opioids, or both. This provides excellent pain relief to the rib cage while avoiding the sedation and respiratory depression associated with narcotics. This allows the patient to continue to participate in the pulmonary toilet and cough adequately. Multiple studies have shown that epidural anesthesia decreases mortality and pulmonary complications in patients with rib fractures, while increasing functional residual capacity, lung compliance, and oxygenation. Furthermore, this translates into a decreased intensive care unit (ICU) and hospital length of stay, especially in the older patient population. Unfortunately, the use of epidural catheters can be limited in the trauma population. Possible risks of placement include hypotension, epidural hematoma, infection, and spinal cord injury. They should not be used in patients with elevated intracranial pressure, or those with suspected abdominal trauma as injuries can be masked. Other relative contraindications include spinal fractures, history of spinal surgery, valvular heart disease, and coagulopathy. The placement of an epidural catheter should not preclude use of chemoprophylaxis for deep venous thrombosis.

Paracostal infusion combines the benefits of an epidural catheter with the safety and relative ease of placement of an intercostal block. An entry site is chosen inferior to the lowest fractured rib two fingerbreadths lateral to the spinous process. After making a small skin incision, a tunneler is used to create a longitudinal subcutaneous tract that is just superficial to the rib cage. The infusion catheter is then inserted and the peel away sheath removed. The catheter is then secured using tape and the catheter is connected to a reservoir containing bupivacaine. In a study of 102 patients with greater than 3 rib fractures, placement of the paracostal infusion catheter was shown to improve pain scores, lung volumes, and respiratory rates compared to historical controls.

Surgical Stabilization of Rib Fractures

Reduction and fixation of acute fractures is one of the central tenets of orthopedic surgery. Although there have been historical attempts at external fixation of the ribs using traction or sand bags, the very nature of the ribs' movement with each breath makes this impractical, and may worsen respiratory complications. Surgical stabilization of rib fractures (SSRF) has gained popularity in the early twenty-first century due to development of low profile, anatomically contoured plates that allow for extrathoracic internal fixation. Multiple retrospective studies have now shown that SSRF decreases length of mechanical ventilation, need for tracheostomy, incidence of pneumonia, ICU length of stay, hospital length of stay, and overall cost of care. In perhaps the first prospective study, Pieracci et al. evaluated 30 patients over a 2-year period. For the first year of the study, patients with flail chest, three or more displaced rib fractures, 30% or greater hemithorax loss, and severe pain or respiratory failure were managed medically and followed. In the second year, patients with the same criteria underwent SSRF. The operative group was found to have a 76% lower incidence of respiratory failure and an 82% lower need for tracheostomy. With regards to the timing of surgery, a retrospective review of 551 patients over a 10 year period at four high-volume SSRF centers showed improved outcomes in the first 24 hours of hospitalization.

Indications for SSRF are influenced by the results of these studies as well as expert opinion (Box 3). SSRF of flail segments is nearly universally agreed upon, and a multicenter prospective randomized trial of patients with three or more rib fractures, sponsored by the Chest Wall Injury Society (CWIS; NCT01928498; ELAIN), is ongoing.

The decision to proceed with operative intervention for rib fractures should take into account the above guidelines, as well as the patient's overall clinical picture. The goal of the operation should be for a muscle-sparing exposure, open reduction, and internal fixation of all clinically significant rib fractures, irrigation and evacuation of any hemothorax, and local regional pain control. A thorough understanding of chest wall anatomy is critical when planning the operative approach. The most commonly encountered muscles include the latissimus dorsi, which arises from the transverse processes of lower thoracic and lumbar vertebrae and courses superiorly and anteriorly just inferior to the scapula before inserting on the humerus. The trapezius is found superior and medial to the latissimus dorsi and forms the so-called *triangle of auscultation* with the inferior border of the scapula. The serratus anterior is found deep to these muscles and the scapula. The positioning on the operating room table will depend on the location of the fractures. The majority of fractures are posterolateral, which are best approached through a standard posterolateral thoracotomy type incision with the patient in the lateral recumbent position. Hinging or "breaking" the bed, while typically used when performing a thoracotomy, is not recommended when performing SSRF. The chest wall may be accessed in a muscle sparing fashion by elevating muscle flaps through the triangle of auscultation. More inferior fractures can also be exposed by splitting the latissimus dorsi in the direction of its fibers. We find that this technique with the assistance of a circular wound protector provides excellent exposure (Fig. 1). Anterior fractures are approached with the patient supine and via a submammary incision, with elevation of a pectoral flap. Posterior fractures often require prone positioning of the patient, with a vertical incision made halfway between the spinous processes of the upper thoracic vertebra and the scapula. When repairing a large flail segment, a second vertical incision can be made anteriorly.

The past decade has seen an explosion in the availability of commercial rib fixation hardware systems. U plates were one of the early innovations and are placed over the superior margin of the rib and secured in place with bicortical screws after drilling holes on either side of the fracture. Precontoured plates, applied to the exterior surface of the rib and designed to match the specific contours, are similarly fixated with bicortical screws. Fixation plates with self-tapping monocortical screws are also available. No matter which fixation system is used, attention should be made to adequately reduce all fractures into anatomic alignment. Dissection of the rib periosteum is minimized to ensure adequate blood supply. The chosen plate should be anatomically contoured to the rib to be repaired. The plate should be affixed to the middle or slightly superiorly on the rib to avoid damage to the intercostal bundle. A variety of instrumentation is available to secure the plate as holes are drilled and screws inserted. Right angled instrumentation is essential when working in low clearance areas, such as under the scapula. All current systems require three to four screws to be placed on either side of the fracture. Most experts recommend repair of all accessible fractures from ribs 3 to 10. We find that repairing the most easily accessible fracture first affords repair of subsequent ribs that may be in more challenging locations. Following adequate reduction and internal fixation of all fracture ribs, pleural irrigation and drainage of any hemothorax should be undertaken. This can be thoroughly performed through a chest tube without the

BOX 3 Indications for Surgical Stabilization of Rib Fractures*

- Flail chest (anatomic or clinical)
- ≥3 displaced rib fractures
- Failure of medical management
  - Pain score > 6 despite maximal therapy
  - Respiratory insufficiency requiring ICU transfer or intubation
- During thoracotomy performed for another indication
- Chronic nonunion or malunion

*Modified from Chest Wall Injury Society consensus.

FIG. 1 *Posterolateral approach to exposure of the chest wall for surgical stabilization of rib fractures. A wound protector can be useful for soft tissue retraction.*

need for entering the pleural cavity. The necessity of leaving a chest tube is debatable, but we generally advocate for leaving a small-bore pleural drainage catheter postoperatively. Finally, local regional pain control should be provided at the time of surgery. This can be performed with either an intercostal block or the placement of a paravertebral infusion catheter placed under direct visualization.

Sternal Fractures

Historically called a *steering wheel injury*, motor vehicle crashes remain the most common cause of sternal fractures despite the widespread use of shoulder restraints. One fourth of sternal fractures are isolated, with the remainder being most commonly associated with extremity fractures, head and neck injuries, rib fractures, spine injuries, and pulmonary contusions. Many clinicians fear complications such as blunt cardiac injury or great vessel injury, but these have been shown to be present less than 2% of the time. Because they carry significant morbidity, these injuries should promptly be evaluated for with liberal use of CT angiography of the chest. Blunt cardiac injury (BCI, formerly known as a cardiac contusion) is poorly defined in the literature but generally describes blunt force trauma to the myocardium, which may be clinically silent, produce arrhythmias, or result in deadly myocardial rupture. Patients with suspected BCI should be observed for electrical abnormalities, such as unexplained sinus tachycardia (most common), premature ventricular contractions, new bundle branch block, or ST segment changes. Echocardiography should also be considered to evaluate for valvular or wall motion abnormalities.

Operative considerations for repair of sternal fractures is similar to that for rib fractures, that is, patients with displaced sternal fractures that are refractory to medical management. Chest CT with 3D reconstruction of the sternum is useful in surgical planning. A median sternotomy provides adequate exposure and a variety of plating systems are available. Newer sternal plating systems can extend on to the ribs, providing repair of the parasternal cartilage and allowing for stabilization of the entire anterior chest wall.[1]

Pneumothorax

A pneumothorax occurs when air enters the pleural space and the visceral and parietal pleura are separated. The pneumothorax may be occult and contain a small, stable amount of air, or extend to a complete, tension pneumothorax, where the lung is completely collapsed and additional air enters the pleural space, creating an increase in pleural pressure and a shift of the mediastinum to the opposite side, with resulting impaired venous return, hypotension, shift of the trachea, and distended neck veins. The diagnosis of pneumothorax is suggested on physical exam, noting decreased or absent breath sounds on the side of the lesion. This may be accompanied by subcutaneous emphysema palpable in the chest wall or pain due to rib fractures. An anteroposterior chest radiograph performed in the trauma bay on arrival may initially appear normal as it is done in the supine position and air rises to the front of the chest. Look closely for the presence of a deep sulcus sign, which provides a clue to the presence of air in the hemithorax. An eFAST includes an assessment at the second intercostal space—failing to demonstrate lung sliding and comet tails in the presence of a pneumothorax. A CT scan performed as part of the trauma evaluation is highly sensitive and specific for the presence of pneumothorax.

If the pneumothorax is occult and stable, it may be observed. Initial treatment for a simple pneumothorax is placement of a small-bore chest tube (e.g., 20 Fr) under sterile conditions. In the trauma bay, the potential for elevation of the diaphragm or presence of a diaphragmatic hernia should be considered; the tube may be placed at the upper margin of the fourth or fifth intercostal space in the midaxillary line. A short skin tract will ensure a seal when the tube is removed. After sweeping the chest to ensure the absence of adhesions, the tube should be directed posteriorly and toward the apex. Appropriate placement is confirmed by the presence of condensate in the chest tube and bubbling in the drainage chamber as air is evacuated. The tube should be secured with a large silk suture to prevent slippage, connected to an underwater suction collection device, and a sterile occlusive dressing applied. The connections should not be covered with tape, but secured with nylon cable tie ties to ensure visible security of connections. A mesentery should be placed around the drainage tube so that traction on the tube will not directly pull on the site of chest entry. Blunt trocars may shorten introduction time; however, limited data are available on their risks, benefits, and complications compared to more traditional methods. Sharp trocars should never be used to place chest tubes in trauma, as they are associated with a higher incidence of malposition and significant complications. Tube placement and lung expansion should be confirmed by chest radiograph prior to breakdown of the sterile field. If this is done, repositioning is available as an option, whereas if the field is broken down, a new site should be chosen for chest tube reintroduction.

A tension pneumothorax is a clinical, not a radiologic, diagnosis. Decompression should be performed with a 14-gauge angiocatheter introduced in the second intercostal space in the midclavicular line (MCL), a site that may be identified by carrying the line from the sternomanubrial junction to the MCL and inserting the needle perpendicular to the chest wall. If the diagnosis is correct, when the chest is entered a rush of air will be heard, and the patient's hemodynamic status will improve. In obese patients or patients with developed pectoral muscles, the angiocath may not be of sufficient length to enter the pleural space. Therefore, alternative sites have been described on the lateral chest wall to the fourth or fifth intercostal space (ICS). After needle decompression, a definitive chest tube should be placed. Even if there is no visible pneumothorax on the chest radiograph, a pneumothorax may develop abruptly later in an unmonitored setting, and cause harm to the patient.

Hemothorax

Hemothorax may be the result of chest wall, pulmonary parenchymal, cardiac or mediastinal bleeding. Blood accumulates in the pleural space; the symptomatic presentation will depend on the amount of

blood and the rate of ongoing bleeding. Breath sounds will be diminished or absent and hemodynamic instability may occur. Opacification of the entire chest may be seen when the radiographic film is done in the supine position in the trauma bay. An *e*FAST is useful in the identification of the hemithorax. A tube thoracostomy should be placed in the fifth ICS, with the same concerns for potential abdominal visceral injury as seen in the placement of a tube for pneumothorax. The tube should be at least 28 to 32 Fr in a trauma population requiring open chest tube drainage. Larger tubes are not required and pain may be reduced. An initial blood loss of 1200 cc or ongoing blood loss of 200 to 250 cc/hour should prompt consideration for thoracotomy.

Continuing air leak should be addressed early, within 72 hours, using video assisted thoracoscopy (VATS) with closure of lung lacerations. Residual hemothorax may result in empyema or fibrothorax if not addressed early in the patient's course within 48 to 72 hours. Irrigation of the tube thoracostomy immediately after placement with 1 liter of warmed sterile saline will reduce the need for secondary intervention. Ongoing bleeding or delayed clot formation may require VATS. Concurrent evacuation of the hemithorax when rib fixation is performed is essential.

Blunt Abdominal Trauma

L.D. Britt, MD, MPH, FACS, and Michael Mareyak, MD

The abdomen remains one of the most critical and vulnerable anatomic regions in blunt trauma. Prior to focusing on any specific management strategy for a patient who has sustained blunt abdominal trauma, an initial assessment of the entire patient is imperative. The concept of initial assessment includes four essential components: rapid primary survey, resuscitation, a detailed secondary survey (evaluation), and re-evaluation. Integrated into primary and secondary surveys are often necessary adjunct interventions, such as electrocardiographic monitoring, arterial blood gas determination, pulse oximetry, insertion of urinary and/or gastric catheters, and obtaining necessary radiographs and other diagnostic studies, when applicable. The management of blunt abdominal trauma continues to evolve more in the nonoperative arena, as opposed to surgical intervention. The workup has shifted largely from the use of a physical examination, plain radiographs, laboratory findings, and diagnostic peritoneal lavage to physical exam and liberal use of computed tomography (CT) and ultrasonography. Treatment for visceral injury has traditionally been surgical. However, many forms of solid organ injury can now be successfully managed nonoperatively or with minimally invasive and interventional radiology techniques. Nonoperative management of the multiple injured trauma patient at level I trauma centers, with state of the art techniques, has conclusively shown significantly improved patient outcomes and survival.

DIAGNOSTIC AND IMAGING ADJUNCTS

Diagnostic peritoneal lavage has now been essentially supplanted by the adoption and now popularity of abdominal sonography—focused abdominal sonography for trauma (FAST). The utilization of diagnostic peritoneal lavage has diminished substantially. Originally described by Root in 1965, diagnostic peritoneal lavage (DPL) was once a mainstay in the management of blunt abdominal trauma for over four decades. Before the era of routine CT scanning, it was used as a screening tool to evaluate patients having blunt or penetrating abdominal trauma, with an accuracy rate reported between 92% and 98%. CT scans and FAST are now the diagnostic modalities of choice in the assessment of the injured patient. However, DPL remains an excellent tool for further workup of occult bowel injury or in unstable patients when FAST is not available or has questionable findings. In the workup for occult bowel injury, traditional parameters (Table 1) should be used to guide therapy. In unstable patients and when FAST is not an option, a diagnostic tap is usually all that is necessary and exploration is indicated when there is aspiration of greater than 10 mL of gross blood.

The pitfalls of DPL are a relatively high false-positive rate, risk of creating visceral injury and poor sensitivity for detecting injury to retroperitoneal structures such as the pancreas and duodenum. Iatrogenic errors are minimized if a Foley catheter and nasogastric tube are placed prior to the procedure. Patients with pelvic fractures and suspected retroperitoneal hematoma or pregnant females should undergo a supraumbilical approach.

Focused Abdominal Sonography for Trauma

In the diagnostic assessment of the acutely injured patient, the bedside ultrasonographic for detection of cardiac and intraabdominal injury is considered the standard of care. Because focused abdominal sonography for trauma is of a noninvasive nature, this diagnostic modality allows the operator to perform an exam simultaneously during the initial resuscitation and stabilization of a multiple injured trauma patient. Due to the relative insensitivity of abdominal examination in the severely injured patient, this technique may provide evidence of significant hemorrhage early in the course of an evaluation. An ultrasound probe is used to examine four key windows for fluid: the subxiphoid area permits visualization of the pericardium, the left subcostal area visualization of the splenorenal recess, right subcostal area visualization of Morison's pouch, and the suprapubic area visualization of the pelvic cul de sac (Fig. 1). The presence of fluid may indicate presence of cardiac tamponade fluid in the pericardial space, intraabdominal hemorrhage, hollow viscus perforation,

blood and the rate of ongoing bleeding. Breath sounds will be diminished or absent and hemodynamic instability may occur. Opacification of the entire chest may be seen when the radiographic film is done in the supine position in the trauma bay. An *e*FAST is useful in the identification of the hemothorax. A tube thoracostomy should be placed in the fifth ICS, with the same concerns for potential abdominal visceral injury as seen in the placement of a tube for pneumothorax. The tube should be at least 28 to 32 Fr in a trauma population requiring open chest tube drainage. Larger tubes are not required and pain may be reduced. An initial blood loss of 1200 cc or ongoing blood loss of 200 to 250 cc/hour should prompt consideration for thoracotomy.

Continuing air leak should be addressed early, within 72 hours, using video assisted thoracoscopy (VATS) with closure of lung lacerations. Residual hemothorax may result in empyema or fibrothorax if not addressed early in the patient's course within 48 to 72 hours. >7% EAAT amylase	

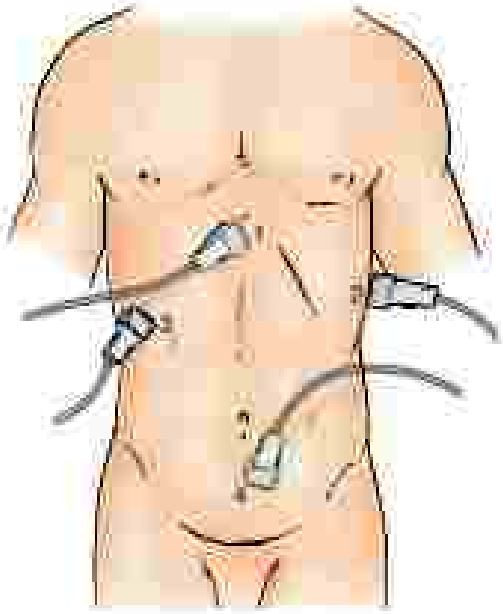

FIG. 1 Schematic showing sonographic windows for (1) Morison pouch, (2) left subcostal, (3) right subcostal, and (4) suprapubic areas. Distension of the urinary bladder either prior to Foley catheter placement or by installation of 150 to 200 mL normal saline will enhance sensitivity. [illegible]

hemoperitoneum, or ascites. False positive results secondary to pre-existing ascites or false negatives due to operator error and/or body habitus are the main limitations. Scanning the suprapubic area with distension of the urinary bladder will enhance the sensitivity of the exam for the detection of pelvic fluid.

A threshold of at least 200 mL of fluid in the abdominal cavity is necessary for detection and intraabdominal injuries must be associated with the presence of this much free fluid for a positive finding. Reported sensitivities range between 73% and 88% and specificity between 98% and 100%. Accuracy rates range from 96% to 98%. FAST is an inexpensive, rapid, portable, noninvasive technique that can be performed in serial fashion, if there is a change in patient stability. Additionally, it obviates the risk of exposing pregnant females to radiation. Positive findings in stable patients can be further evaluated with CT, while unstable patients with a positive finding should prompt the surgeon to take the patient to the operating room for emergent exploration.

Computed Tomography

Steady advances in the technology and speed of CT have continued to be an integral part of the diagnostic management of trauma patients. Multidetector scanners have dramatically improved resolution and accuracy of these imaging studies. Negative predictive values as high as 99.5% have been reported for patients sustaining significant mechanisms of blunt trauma allowing the use of CT as a reliable and noninvasive screening tool for screening patients with blunt abdominal trauma. In light of modern day CT capabilities, prospective data have demonstrated that patients with a significant mechanism and a benign abdomen can be released from the emergency department if a CT scan of the abdomen shows no evidence of visceral injury provided that there are no other reasons for hospitalization.

CT reliably identifies injuries to solid organs such as the spleen, liver, and kidney because of the associated vascular nature demonstrating disruption of normal architecture, associated free fluid, and the so called vascular blush. Established grading scales continue to be used for accurate classification and determination of management plans (Tables 2 to 4).

Detection of bowel injury via CT scan in patients, who are intoxicated, intubated, or have associated closed head injury or other distracting injuries, can present a diagnostic challenge in absence of a reliable abdominal exam. The incidence of blunt bowel injury varies from series to series but is generally reported in the 1% to 5% range in all blunt trauma patients admitted to level I trauma centers. A high index of suspicion is predicated on mechanism of injury and physical exam findings, such as abdominal wall ecchymosis, tattooing, and/or seat belt sign. CT findings may be overt, such as extravasation of oral contrast or pneumoperitoneum, or more commonly, subtle findings such as bowel wall thickening, stranding of the mesentery, or free fluid in the absence of solid organ injury. Indirect findings may be fairly nonspecific and secondary to bowel edema from resuscitation or pre-existing ascites. In reproductive age females may have a small amount of normal or physiologic pelvic fluid present, sometimes adding to the complexity of the evaluation. Patients on positive pressure ventilation or with significant barotrauma may develop mediastinal or subcutaneous emphysema that can track through the peritoneum or retroperitoneum and give the appearance of free air. Great care in the radiologic interpretation and clinical correlation are necessary in such cases. The liberal use of diagnostic modalities (e.g., abdominal CT scan) in the hemodynamically normal injured patient may prevent nontherapeutic laparotomies. Obviously, when significant doubt remains, abdominal exploration may be required to confirm an injury.

The role of oral contrast in the evaluation of the acutely injured patient has recently come under question. Little time is usually available in the emergency setting to permit adequate opacification of the small bowel. Patients are further at risk for aspiration of the contrast media and administration often requires placement of a nasogastric tube. There have been several reports that have shown that elimination of oral contrast media does not lead to an increased incidence of missed bowel injury. Many centers have now safely eliminated the use of oral contrast media from their routine trauma protocols expediting management and ease of patient care. Resuscitation edema may cause a hazy appearance around the head of the pancreas and duodenal C loop causing the question of a pancreas or duodenal injury. Further clarification in this situation can be obtained when it occasionally occurs via repeat CT scan with the administration of oral contrast and/or injection of 300 to 500 mL bolus of air down the nasogastric tube in order to make pneumoperitoneum obvious.

Computed tomography may also be of great importance in identifying patients with arterial hemorrhage related to pelvic fracture. CT imaging may demonstrate an arterial blush or large hematoma in the vicinity of a pelvic fracture indicating the need for pelvic arteriography or pelvic external fixation. A CT cystogram may also be helpful and eliminate redundancy of radiographic evaluation. The Foley catheter is clamped after placement in the trauma bay. Real-time interpretation of the CT scan is performed by the evaluating physician, which may dictate further delayed images or a formal three view (anterior/posterior, lateral, and post void) stress cystogram.

TABLE 2 Spleen Injury Scale of the American Association for the Surgery of Trauma

Grade[a]	Injury	Description
I	Hematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, <1 cm parenchymal depth
II	Hematoma	Subcapsular, 10%–50% surface area; intraparenchymal, <5 cm in diameter
	Laceration	1–3 cm parenchymal depth that does not involve a trabecular vessel
III	Hematoma Laceration	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma Intraparenchymal hematoma >5 cm or expanding >3 cm parenchymal depth or involving trabecular vessels
IV	Laceration	Laceration involving segmental or hilar vessels producing major devascular ization (>25% of spleen)
V	Laceration Vascular	Completely shattered spleen Hilar vascular injury that devascularizes spleen

[a]Advance one grade for multiple injuries, up to grade III.

TABLE 3 Liver Injury Scale of the American Association for the Surgery of Trauma

Grade[a]	Injury	Description
I	Hematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, <1 cm parenchymal depth
II	Hematoma	Subcapsular, 10%–50% surface area; intraparenchymal, <10 cm in diameter
	Laceration	1–3 cm parenchymal depth, <10 cm in length
III	Hematoma Laceration	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma Intraparenchymal hematoma >10 cm or expanding >3 cm parenchymal depth
IV	Laceration	Parenchymal disruption involving 25%–75% of hepatic lobe or 1–3 Couinaud's segments within a single lobe
V	Laceration Vascular	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud's segments within a single lobe Juxtahepatic venous injuries (retrohepatic vena cava/central major hepatic veins)
VI	Vascular	Hepatic avulsion

[a]Advance one grade for multiple injuries, up to grade III.

TABLE 4 Kidney Injury Scale of the American Association for the Surgery of Trauma

Grade[a]	Injury	Description
I	Contusion	Microscopic or gross hematuria, urologic studies normal
	Hematoma	Subcapsular, nonexpanding without parenchymal laceration
II	Hematoma	Nonexpanding perirenal hematoma confined to renal retroperitoneum
	Laceration	Parenchymal depth of renal cortex (<1.0 cm) without urinary extravasation
III	Laceration	Parenchymal depth of renal cortex (>1.0 cm) without collecting system rupture or urinary extravasation
IV	Laceration Vascular	Parenchymal laceration extending through the renal cortex, medulla, and collecting system Main renal artery or vein injury with contained hemorrhage
V	Laceration Vascular	Completely shattered kidney Avulsion of renal hilum that devascularizes kidney

[a]Advance one grade for bilateral injuries up to grade III.
Modified from Moore EE, Shackford SR, Pachter HL, et al. Organ injury scaling: spleen, liver, and kidney. *J Trauma*. 1989;29:1664.

While computed tomography can be an important diagnostic modality in the assessment of the trauma patient, it is contraindicated in the hemodynamically unstable patient who is in shock.

SPECIFIC CONSIDERATIONS FOR BLUNT TRAUMA

Bowel

There is no place for nonoperative management of hollow viscus injury, and the success of nonoperative management of blunt abdominal trauma is, therefore, the missed bowel injury and all its catastrophic consequences. Otherwise, most management is straightforward; debridement and primary repair for nondestructive injuries and resection with primary repair versus ileostomy formation for destructive injuries.

Radiographic Findings of Blunt Bowel Injury

There are two basic types of findings of bowel injury on CT scan, direct and indirect. Direct findings are usually straightforward if present and consist of extravasation of oral contrast (if administered) and free air, which have been reported to occur in 8% and 28% of the time, respectively. Indirect findings include mesenteric hematoma or contrast blush, bowel wall edema, unexplained free fluid, fat stranding, and bowel loops, which do not opacify with intravenous contrast.

Mesenteric hematoma is nonspecific and can occur from associated injuries, such as pelvic fractures or renal injuries with hematomas from these structures expanding into the bowel mesentery. However, a vascular blush in the lumen of the mesentery is indicative of active hemorrhage until proven otherwise and, generally, a determinant for immediate operative exploration. Bowel wall edema and ascites are common in blunt trauma patients, can occur from resuscitation of other injuries, and do not necessarily connote bowel injury. Free fluid in the absence of solid organ injury can be further evaluated with

19%, if the abdominal cavity is unviable. Fat stranding can occur with mesenteric contusion and does not necessarily portend an operative indication. Unopacified bowel loops can indicate vascular disruption of the mesentery or simply be due to poor contrast timing to an under-resuscitated patient. Evidence of these findings increases the likelihood of finding an injury at exploration and increased when there was an increasing number of these findings.

Operative Management

Appreciation of the American Association for the Surgery of Trauma (AAST) organ injury grading scale is helpful in describing wounds of the bowel. Grade I injuries are contusions and partial thickness lacerations of the bowel wall without perforation. Grade II injuries are full thickness wounds involving less than 50% of the bowel wall circumference. Grade III are lacerations comprising greater than 50% of the bowel wall circumference without complete transection. Grades IV and V injuries represent complete transection of the bowel wall and transection with segmental tissue loss and/or devascularization of the mesentery, respectively. The terms destructive and nondestructive simplify the terminology; nondestructive wounds are those injuries that can be managed with debridement and primary suture enterorrhaphy and are comprised of grades I through III. Destructive wounds require resection of an entire segment of the bowel due to loss of bowel integrity or devascularization of the mesentery and encompass grades IV and V (tables 5 and 6).

The distinction between destructive and nondestructive wounds is important in terms of the prescribed management. Nondestructive wounds of the large or small bowel can generally be repaired without further consideration. Most small bowel destructive injuries should be resected and reconstituted unless damage control conditions prevail. In contrast to the small bowel, the management of colon injuries has received great scrutiny. Ushering in the dawn of modern-day trauma surgery, the World War II military experience dictated that all colon wounds, destructive or not, be managed by colostomy. This philosophy remained surgical dogma until the 1980s. In a comprehensive review of the literature since 1979, primary repair of the colon for nondestructive wounds was shown to have a leak rate of 1.6%. Compared to patients receiving colostomy for similar types of wounds, the incidence of intraabdominal abscess was 0% for primary repair and 12% for colostomy, and overall complication rate was 14% for primary repair and 30% for colostomy. Mortality rates were similar at 0.11% for primary repair and 0.14% for colostomy. These findings clearly show the superiority of primary repair for nondestructive wounds of the colon.

Several risk factors for anastomotic failure pertaining to destructive colon injury have been addressed in the literature: hypotension, shock, interval from injury to operation, amount of fecal contamination, associated organ injury, transfusion requirement, and comorbid disease. No data have conclusively shown that any of these risk factors increase the likelihood of anastomotic failure. Patients with massive blood loss or shock may be better served by undergoing a damage control procedure, with delay of definitive repair. Interval from injury to repair greater than 12 hours can be a relative contraindication to definitive repair; if there is widespread (more than one quadrant) fecal contamination. Greater than one or two organ system injury has been a concern, but this may just be a marker for degree of shock and overall physiologic derangement. Comorbidities, such as AIDS and cirrhosis, deserve special consideration, and these patients may be better off with the establishment of an ostomy diversion. Patients with any of these risk factors have a higher incidence of intraabdominal abscess and overall complication rates.

Notwithstanding the caveats of the previously mentioned comorbidities, colonic resection and primary anastomosis for destructive wounds would be permissible in most trauma settings. In a collective review of 207 patients reported in the literature, management of destructive bowel injury with resection and primary anastomosis had a reported leak rate of 7.2%, with a mortality of 1.7% attributable to

TABLE 5 American Association for the Surgery of Trauma Small Bowel Injury Scale

Grade*	Injury	Description
I	Hematoma	Contusion or hematoma without devascularization
	Laceration	Partial thickness, no perforation
II	Laceration	Laceration <50% of circumference

*Advance one grade for multiple injuries, up to grade III.

the colon wound. In the largest single institution experience, Murray showed a leak rate of 11% in 112 patients undergoing resection and primary anastomosis for destructive colon wounds, with two deaths related to leaks. However, the ultimate decision for the choice of operation should be up to the discretion of the surgeon, at the time of operation, and on a case-by-case basis.

At laparotomy, the bowel should be examined in its entirety after all other sources of major bleeding are controlled. Small injuries should be noted and tagged with an identifiable suture for easy reference. Larger wounds contributing to ongoing soiling can be temporarily controlled with a whip stitch (quick running suture) or Babcock clamps. Mesenteric injuries are identified and active bleeding controlled appropriately. Attention should be directed to the location of the superior mesenteric artery for injuries approaching or in the root of the mesentery. Mesenteric hematomas should be explored with ligation of injured vessels and mesenteric defects closed by careful approximation of the peritoneal edges so as not to compromise any associated vasculature. Bowel viability should be noted in relation to any mesenteric injury. Clusters of grade I through III injuries may be resected or multifocally repaired depending on the particular injury pattern. In blunt trauma, there is usually only one or two grade II or III wounds that can be repaired primarily or one or more devitalized segments that require resection.

Small, superficial grade I injuries can be left alone, while deeper, longer grade I injuries can be closed with a simple running suture or interrupted Lembert sutures. Grade II and III wounds should be

debrided back to healthy, viable bowel and closed transversely preventing narrowing of the lumen of the bowel. Single layer running or interrupted closure is generally sufficient for repair of small bowel. When there is significant bowel wall edema, peritonitis or soiling, a two layer closure with a running inner layer and interrupted Lembert outer layer may be preferential. Grade I and II colon wounds may be managed with single layer closure. However, grade III colon wounds should be closed in two layers for added protection.

The leak rate associated with stapled versus handsewn anastomosis for destructive wounds of the bowel has been an area of ongoing controversy. In two retrospective studies totaling 284 patients undergoing stapled versus handsewn anastomosis, Brundage showed that handsewn procedures had lower leak rates. Two other retrospective studies totaling 484 patients showed no difference in the leak rate of stapled versus handsewn procedures. Brundage's two studies included 78 colon wounds, while the other studies were confined only to the small bowel. Stapled procedures may be a little quicker, particularly if there is more than one anastomosis. In general, the technique chosen according to the literature can be a matter of surgeon's preference. However, with edematous bowel, the handsewn technique is a more prudent approach.

Spleen

The spleen is the most commonly injured intraabdominal organ, followed by the liver and small bowel in blunt trauma patients. The spleen's location in the left upper quadrant lends susceptibility to injury from broken ribs, deceleration, and blunt percussion forces. Clinically, patients with splenic injury may present with hypotension, left upper quadrant pain or tenderness to palpation or diffuse peritonitis from extravasated blood. Referred pain to the left shoulder on deep inspiration, in face of splenic hematoma, is known as Kehr's sign.

Nonoperative Management

Most series indicate that approximately 60% to 80% of patients presenting with blunt splenic injury can be managed nonoperatively at level I or II trauma centers. Facilities without the resources and experience of a busy life trauma team may not easily meet the demands of nonoperative management and should consider patient transfer. Patients selected for nonoperative management must have normal vital signs, be free of peritoneal signs or other concern for hollow viscus injury and have no evidence of free extravasation of intravenous contrast from the splenic parenchyma (Fig. 2).

Considerable debate remains regarding risk factors for failure of nonoperative management. Higher AAST splenic injury grade, age greater than 55 years, evidence of large hemoperitoneum, subcapsular hematoma, and portal hypertension have all been suggested to increase the risk of failure. Early reports on the evolution of nonoperative management regarding AAST grade did not demonstrate higher failure rates for higher grade injury. More recent reports using high resolution multidetector CT scanners allow better assessment of injury grade. The data from these studies show that patients with injury grades III to V to be at increased risk for nonoperative failure. Age continues to be controversial subject matter in the literature, with numerous reports claiming that age greater than 55 years is or is not a risk factor for failure. Documentation of a moderate or large hemoperitoneum is suggestive of a major injury and should be considered a significant factor in individual patient assessment.

Patients with splenic subcapsular hematoma or history of portal hypertension are specific subgroups of patients that deserve special consideration. These patients are at increased risk for delayed rupture 4 to 8 days following injury and may already be discharged from the hospital if they have isolated injury. Furthermore, splenic embolization is not a very effective treatment of this condition because it usually necessitates coiling of the main splenic artery, which can lead to significant pain and abscess formation. History of portal hypertension or cirrhosis, while not an absolute contraindication to nonoperative management, certainly should serve as a caveat. The general risks of laparotomy in a Child Pugh B or C cirrhotic need to be carefully weighed against the risk of ensuing and worsening coagulopathy. This scenario may indeed dictate the need for splenic artery embolization. None of these risk factors alone should dictate the decision to proceed immediately to operative intervention. Non operative management does reduce hospital length of stay and transfusion requirement, however, the morbidity of splenectomy should remain low in any surgeon's hands. Overall, the patient's condition, including comorbidities, coagulopathy, and other problems (such as traumatic brain injury, aortic injury and suspicion for concomitant hollow viscus injury) factor into the decision making process. No one should ever succumb to splenic hemorrhage that was undergoing nonoperative management.

Approximately 20% of patients initially undergoing nonoperative management of blunt splenic injury require further intervention. Failure has been associated with the presence of a contrast blush in up to two thirds of these patients. The presence of a contained contrast blush within the parenchyma of the spleen represents pseudoaneurysm formation of a branch of the splenic artery. Angioembolization is now commonly used to selectively occlude the arterial branches containing these injuries. Implementation of this salvage technique at centers that routinely screen for the presence of pseudoaneurysm has increased the success of nonoperative management to 95% or greater. Pseudoaneurysm formation has been observed in even grade I and II injuries and may not be present on the initial imaging. Therefore, a follow up CT scan is recommended on all patients with splenic trauma within 24 to 48 hours after injury. If these images show stable injuries, without pseudoaneurysm formation, expectant management can continue.

Long term data are unavailable concerning the risk of outpatient or delayed rupture, but the incidence is low and has been reported to be about 1.4%. The average date to readmission for delayed splenectomy after discharge was 8 days in this study. Lower grade (I, II) injuries tend to heal quicker, and most all injuries are healed by 5 to 6 weeks. However, approximately 20% of blunt splenic injuries will not show complete healing and may be at risk for pseudocyst formation. A CT scan should be repeated in 4 weeks for grade I and II injuries and 10 to 12 weeks in grades III to V before allowing patients to return to normal activity.

Splenectomy

Patients requiring urgent or emergent intervention for splenic hemorrhage may develop hypothermia, coagulopathy, and visceral edema. The most expeditious and safest course of action under these conditions is removal of the spleen. The general assumption of abdominal exploration for trauma is that there are known and, possibly, unknown injuries. The operative approach to via a midline vertical incision that allows the best exposure and facilitates temporary abdominal closure should visceral edema or damage control measures be necessary.

With respect to performing a splenectomy, an UMBNF retractor can be used to expose the left upper quadrant. The spleen is retracted medially, with some downward compression, while taking down the posterior attachments with the cautery. Once these attachments are freed, the spleen can be mobilized medially for optimal exposure. The assistant stands on the left side of the table and supports the spleen while the surgeon ligates short gastric and hilar vessels. Being careful to avoid the tail of the pancreas, a large clip placed on the specimen side of the splenic hilum, will reduce backbleeding and expedite the procedure. Once the spleen has been removed, the splenic fossa is meticulously inspected for further bleeding with a rolled laparotomy pad.

Splenorrhaphy

Hemodynamically stable patients found to have small to moderate amounts of parenchymal hemorrhage, or lacerations, may be

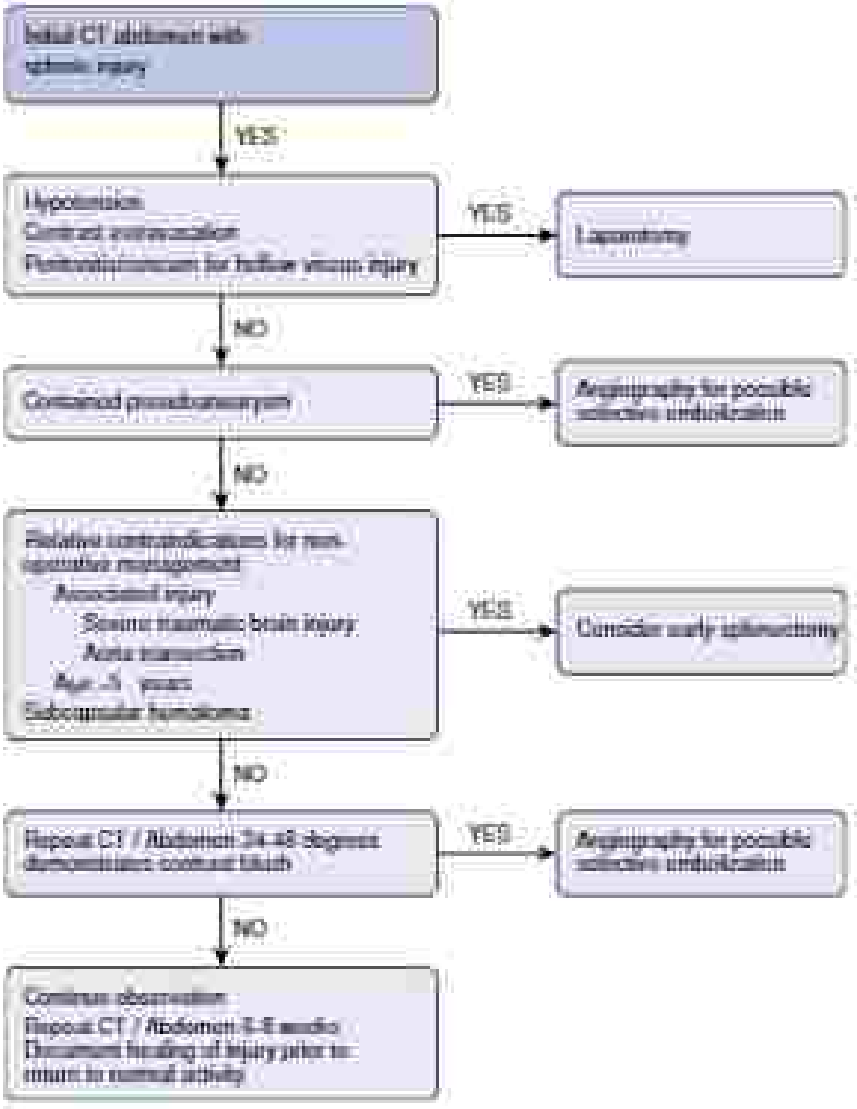

FIG. 2. Management of blunt splenic injury CT, Computed tomography.

candidates for splenic preservation. The spleen is mobilized into the wound using the same technique as for splenectomy. The injury to the spleen is assessed and a decision is made whether to resect a portion if the parenchymal injury extends into the hilum or if arterial bleeding is coming from within the splenic laceration itself. If the decision is made to resect the upper or lower pole, the pancreatic tail is divided with the cautery and the associated hilar vessels are taken with clamps and ties. Any arterial bleeding from the parenchyma is controlled with suture ligature and the cautery is used to control oozing from the parenchyma. A tongue of omentum is then sutured into the laceration or to the raw surface of the remaining spleen in the case of a partial splenic resection. Approximately 50% of the spleen is required to preserve adequate phagocytic and immunologic function. If this cannot be achieved, a splenectomy is probably the best option.

Overwhelming Postsplenectomy Infection

The incidence of overwhelming postsplenectomy infection (OPSI) following trauma is not well understood because it may not be appreciated when it occurs, along with the fact that it is not routinely reported. However, the reported incidence of OPSI in adult patients undergoing splenectomy for all causes is 0.9% with a mortality of 0.8%. The risk of OPSI in adults following trauma is felt to be lower than the incidence seen after splenectomy for hematologic disorders such as idiopathic thrombocytopenic purpura, lymphoma, and thalassemia. Children are at greater risk for OPSI and should receive prophylactic penicillin V 125 mg twice daily until age three and then 250 mg twice daily until age five. Currently, anyone greater than 2 years of age should receive the 23 valent pneumococcal vaccine and a one time dose of the *Haemophilus influenzae* and meningococcal vaccine. A one time booster dose of the pneumococcal vaccine is recommended 5 years after the original vaccine.

Hepatobiliary System

Blunt trauma contributes over 75% of mechanisms of injuries for most of the trauma centers in the United States. The liver, the largest solid organ in the body, is one of the most frequently injured abdominal organs by either blunt or penetrating mechanisms. Fortunately, the majority of hepatic injuries are low grade injuries and require no surgical repair (Table 7). Suspicion of liver injury is predicated on several factors including clinical suspicion derived from the mechanics of the crash, hemodynamic state of the patient, and findings obtained during abdominal examination (Fig. 3). High energy

TABLE 7 American Association for the Surgery of Trauma Liver Injury Scale (1994 Revision)

Grade	Injury	Description
I	Hematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, <1 cm parenchymal depth
II	Hematoma	Subcapsular, 10%–50% surface area Intraparenchymal <10 cm in diameter
	Laceration	Capsular tear, 1–3 parenchymal depth, <10 cm in length
III	Hematoma	Subcapsular, >50% surface area or ruptured subcapsular or parenchymal hematoma Intraparenchymal hematoma >10 cm or expanding
	Laceration	>3 cm parenchymal depth
IV	Laceration	Parenchymal disruption involving 25%–75% hepatic lobe or 1–3 Couinaud segments
V	Laceration	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud segments within a single lobe
	Vascular	Juxtahepatic venous injuries, i.e., retrohepatic vena cava/central major hepatic veins
VI	Vascular	Hepatic avulsion

crashes involving application of force to the upper abdomen or to the right thoracoabdominal area should arouse immediate suspicion of a possible hepatic injury. Hemodynamic lability, although not an exclusive feature of liver injury, mandates evaluation to exclude it as the source of the hemorrhage. Tenderness to the right upper quadrant, in the absence of other signs, can be supportive of subcapsular hematoma requiring attention and further evaluation. Unfortunately, the physical examination is not perfect and has a false-positive rate of approximately 50% and a false-negative rate of 40%.

The additional methods available to evaluate the abdomen include FAST, CT, and DPL. FAST has become a highly reliable test used when seeking to determine whether there is blood in the abdomen in a patient who is hemodynamically labile. In the stable patient in whom liver injury is suspected, the use of CT has become widespread. Several classification schemes have been described for liver injuries, but the grading scheme proposed by the AAST is now in wide use (see Table 7).

Approach to the Injured Liver

With hepatic injuries, the paramount decision is to determine if and what intervention is needed to control hemorrhage. Hemodynamic instability mandates expeditious operative management or angiographic embolization (if the patient can be stabilized with volume resuscitation in order to make transportation to the radiographic suite less risky for the patient). The hemodynamically stable patient may be evaluated by any of the methods noted earlier. Minor grade I or II injuries frequently require no operative intervention. When diagnosed by CT scan, the surgeon must be cognizant of the magnitude and anatomy of the liver injury. Contusion contained within the liver capsule or minor lacerations, such as in grade I or II injuries, may be observed. These diagnoses together constitute most liver injury cases, accounting for ≈80% or 70%. Grade III injuries (deeper, larger wounds with more tissue destruction) occur in approximately 25% of cases. Grade IV and V injuries, involving large amounts of tissue destruction, have an incidence of 7% and 3%, respectively, and are highly lethal. It should be emphasized that evidence of blood in the peritoneal paracolic gutters, in the pelvis, or tracking along the preportal tissues is suggestive of a more significant injury than the liver anatomy may indicate and mandates exploration. Also, the concomitant existence of hollow viscus injury occurs in 5% to 15% of major hepatic injuries.

In addition, it is important to realize that massive parenchymal injuries can occur with surprisingly little bleeding and that minor lacerations may bleed profusely. An understanding of the tissue architecture of the liver is a prerequisite to successful management. Most blunt lacerations may occur along segmental fissures, as the vascular and biliary duct structures are moderately tissue resistant. This explains why a large midline or "four claw" laceration may be seen, with little or no intraperitoneal blood in a hemodynamically stable patient. This can be managed nonoperatively with observation and repeated CT scan. Nonoperative treatment of the stable patient sustaining a blunt liver injury is the management approach of choice today. Table 8 highlights the reported failure rates for nonoperative management of hepatic trauma.

Commonly, deceleration forces are responsible for a shear effect that can result in avulsion of the hepatic veins from the vena cava or major branches of the portal venous or hepatic venous systems. Hemorrhage is devastating, difficult to control, and responsible for the high mortality rate seen with such injuries.

Intraoperative Decisions: General Principles

Once the decision to operate has been made, the surgeon needs to proceed in an orderly fashion in a fully equipped operative theater with invasive monitoring capabilities. Before opening the abdomen, the surgeon must ensure that there is optimal venous access. Large bore central access is essential. The prudent, historical dictum is that access should be from the upper torso in the event there is a retrohepatic caval injury. The blood bank must be notified of the potential for massive transfusion of packed cells and blood components to treat the often associated coagulopathy. The development of blood salvage systems has greatly improved the care of these patients; shed blood from the operative field can be washed and reinfused, provided there is no evidence of gastrointestinal contamination. Infusion systems are available that allow rapid delivery of large volumes of warmed fluid to help minimize hypothermia and hypovolemia. Hypothermia is a common cause of coagulopathy and must be aggressively defended against. Invasive monitoring capabilities are essential in the management of these critically injured patients.

Optimal surgical exposure is essential and starts with performing a midline vertical incision for expedient entry into the abdominal cavity. The incision should extend from the xiphoid process to the symphysis pubis. Such an approach allows, if necessary, relatively easy extension into the thorax through either a median sternotomy or a lateral thoracotomy.

Performing a cholecystectomy could potentially decompress the gallbladder, thereby necessitating expeditious vascular control. The need to perform an emergency thoracotomy for vascular control of the aorta before opening the abdomen is rarely indicated. Such control of the bleeding can usually be obtained with the assistant's manual compression of the liver.

Once the abdomen is open, a rapid assessment of the injury is made and priority management begun. All clots are evacuated, and the four quadrants are packed to control bleeding. A sequential examination is then carried out with priority given to control of blood loss followed by control of any enteric content spillage.

The general approach to the liver injury requires adequate visualization of the anatomic features of the injury. This may require mobilization of the liver along the falciform and triangular ligaments. Full mobilization of the liver allows delivery into the abdominal wall that can often facilitate suture repair of a hepatic wound in a difficult area. While mobilizing the liver, care must be taken that the hepatic veins are

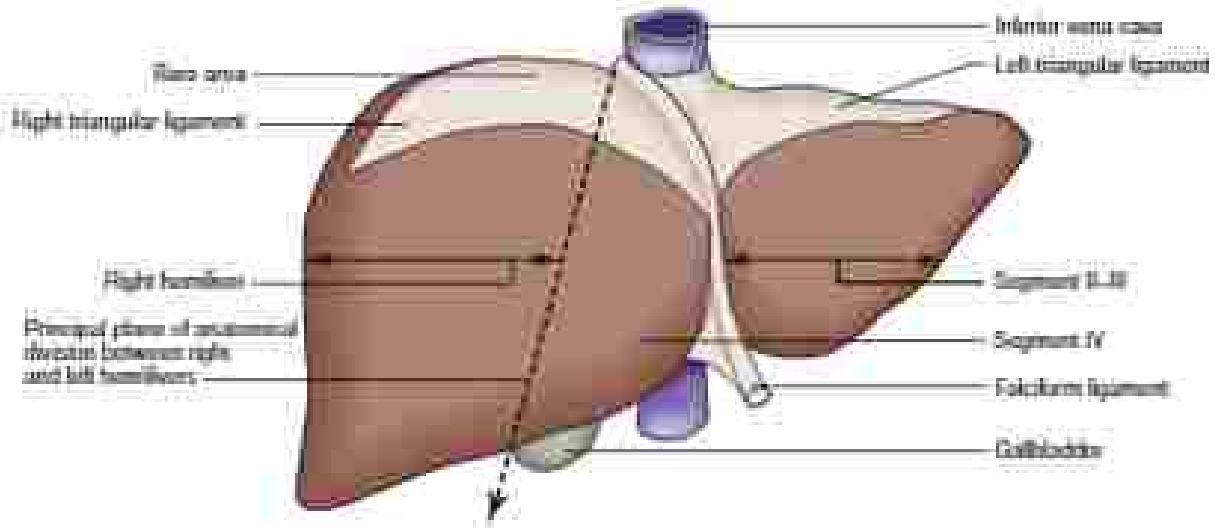

FIG. 8 Juxtahepatic (or retrohepatic) vena cava is in direct contact with the posterior aspect of the liver. (From Cantlie JJ, Parks AW: Historical and Practical Surgery [...]. Bristol, Bradshaw, 1898.)

TABLE 8 Failure Rates for Nonoperative Management of Liver Trauma

Study (year)	No. of Patients	Immediate Surgery (%)	Overall Failure Rate (%)	Liver Failure Rate (%)	Other Failure Rate* (%)
Meredith (1994)	116	8	3	3	0
Cmiel (1995)	156	18	11	5	6
Pachter (1996)	804	53	12	11.5	0.5

Christmas (2005)	361	32‡	1.8	0.8	1.4

*Other failure refers to failure due to injuries from other intraabdominal organs such as the spleen, kidney, pancreas, or bowel.
†53% for liver bleeding.
‡13% for liver bleeding.

and injured. The coronary ligaments are in close proximity to hepatic veins. Also, the surgeon must be cautious during the mobilization of the liver that venous return through the vena cava is not obstructed for a prolonged period. Hemorrhage control during mobilization can often be done by the assistant applying direct pressure with laparotomy packs, compressing the liver between the hands.

As noted previously, most of the injuries encountered are grade I or II and require little more than simple suture repair. Grade III, IV, and V injuries require an organized approach for successful control of hemorrhage, which includes manual compression, direct ligation, or clipping of lacerated vessels, along with sophisticated techniques for more complex wounds.

Vascular occlusion of the portal triad (performing the Pringle maneuver) is a useful method of controlling hepatic arterial and portal venous inflow to the liver. A noncrushing or vascular clamp can be applied to the porta hepatis and safely left in place for approximately 45 minutes, although the specific duration threshold is not known for the hemodynamically labile patient. Also, an umbilical tape placed around the porta hepatis structures can be used for such control. If this maneuver markedly reduces the liver's bleeding, the parenchymal injury can be assessed and a method of repair decided on. However, if hemorrhage persists, then an intrahepatic portal vein injury or a major hepatic vein injury must be suspected.

Proceeding with laparotomy for localization and control of hemorrhage requires facilitous cooperation between the surgeon and the first assistant. With the depth of the hepatic wound exposed, it is usually the first assistant who controls the bleeding. The finger fracture technique for hepatectomy, with the first assistant compressing the liver, is very effective. The operating surgeon using the fingertips or the handle of a scalpel to separate the liver parenchyma and the assistant using a multiple loaded clip applier, made popular for laparoscopic cholecystectomy, ligate severed vessels. Nonabsorbable suture ligation can also be performed to control vessels as each is encountered. Knowledge of the anatomy of the liver (along with reported anatomic variants) is a prerequisite to this approach. The confluence of the left and middle hepatic veins must be kept in mind to avoid unrecognized ligation (Fig. 6). Likewise, the position of the inferior vena cava and the hepatic veins in the caudate lobe should be noted to avoid unnecessary injury that may complicate the surgical exposure. The placement of random deep sutures is fraught with difficulty. Failure of the above mentioned maneuvers to control hepatic bleeding means that the surgeon either has not adequately identified the source or is dealing with coagulopathic bleeding (or both).

Although specific ligation of the hepatic artery or portal vein branch supplying a specific portion of the liver is rarely needed, the suspected branch should be isolated, and its occlusion should control hemorrhage while the Pringle maneuver is released. If such is the case, then the identified branch should be ligated.

Being able to perform a resection of a needle wound should be in a surgeon's armamentarium when dealing with penetrating hepatic

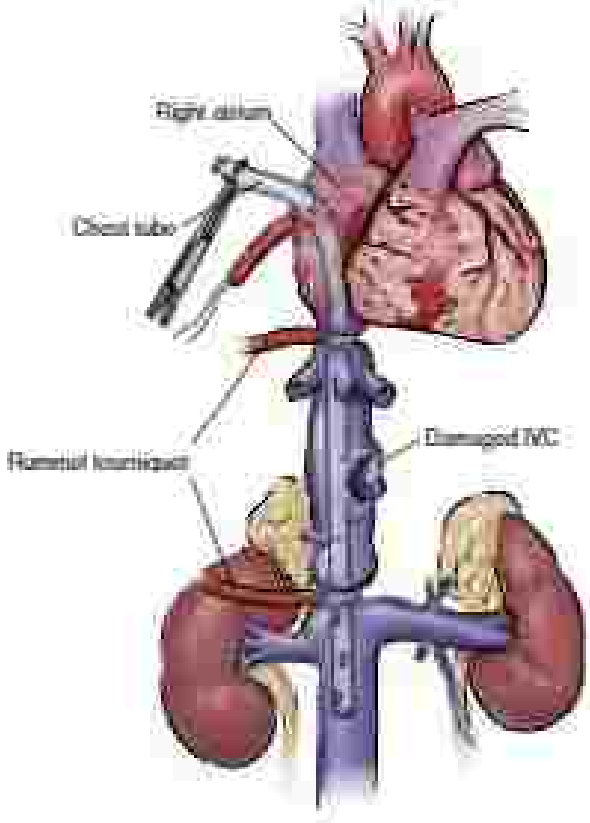

FIG. 4. After obtaining the necessary exposure (thoracotomy, median sternotomy), an opening, along with 2-0 Prolene purse-string sutures, is created in the right atrial appendage to provide the access needed for insertion of the atriocaval shunt, which is usually a No. 36 chest tube. An extra hole needs to be made at the level of the right atrium. With the chest tube holes being outside of umbilical tape occluders, blood is directed from the lower half of the body and the kidney through the atriocaval shunt. IVC, inferior vena cava. (From Richardson J., Kerwin AM, Rich's Vascular Trauma, 2nd ed. Philadelphia: Saunders; 2010.)

injury. In addition, a variety of methods designed for tamponade of the bleeding outside tract have been described, using various materials. Shuett, et al. described a tamponade device with multiple Penrose drains dragged through the liver tract. However, it is more preferable to open the liver and suture or clip control the bleeding site directly, if possible.

Liver injury, infrequently, follows the anatomic lines of demarcation delineating the right and left lobes, much less the segments. Anatomic resection, a once popular approach, is associated with high mortality rates. This technique has been, essentially, abandoned. Resectional debridement of devitalized liver is not formal lobectomy but rather a completion of the injury to remove unviable hepatic tissue and to facilitate vascular control. This usually entails a degree of larger fracture through uninjured liver, which allows visualization of the bleeding raw surface and more direct control. Application of specific liver clamps, such as the Lin clamp, designed to aid in lobectomy, is difficult because of positioning of the injury laceration and maneuvering around the clamp.

Once the bleeding has been controlled, the large, raw surface of the liver can be problematic, as persistent oozing of bile or blood continues. A viable omental patch sutured to the liver bed is an excellent hemostatic agent and internal drain. Stone and Lundy popularized the omental pack in their initial report. Pachter and Stone reported 90% successful hemostatic control with this procedure. For large, raw liver surfaces resulting from debridement or trachotomy, the omental patch held in place with several liver sutures is an excellent hemostatic agent. Also, utilization of the argon beam coagulator is another option in addressing bleeding of raw liver surfaces. The argon gas removes the blood from the hepatic tissue and ionizing energy is transmitted. A maximum of 110°C is achieved and an eschar is formed.

An alternative to surgical repair of the injured liver is a small wedge inserted to provide compression, to control bleeding, and to close parenchymal defects. Delaney et al. reported success in six liver injuries controlled in this manner. Stuart et al. reported 35 liver injuries wrapped for control. Sequential CT examination of the patients demonstrated progressive restoration of normal liver architecture.

The premise underlying much of the preceding discussion is that liver bleeding can be controlled. However, even when advanced techniques of liver control are used, hemorrhage control can be precarious, at best. A critical error that can be made when dealing with major liver injury is to continue operative intervention in the face of a hypothermic (less than 32°C), acidotic patient who has developed coagulopathy. Although the specific time to make a decision to pack the liver and initiate normothermia and coagulation factors is not always clear, the operating surgeon should always have a low threshold for temporary packing and prepare the patient to be expeditiously transferred to the intensive care unit for aggressive resuscitation and monitoring. Once a patient has required a 10 U transfusion, packing should be seriously considered. Patients with severe injuries, hypothermia, refractory hypotension, coagulopathy, and acidosis need early packing. It needs to be emphasized that large wound bleeding must be controlled before packing can be effective.

Perihepatic packing was popularized during World War II. The high incidence of complications, plus the advent of more sophisticated techniques for control of liver bleeding, led to the demise of packing until its revival in the 1970s. The major indications for perihepatic packing being persistent coagulopathy that developed as an extensive subcapsular hematoma or capsular avulsion. It is also a valuable adjunct to resectional debridement and tracheotomy. The use of a folded, disposable plastic drape is helpful. It is placed against the liver and the packs placed on it, preventing the laparotomy pads from adhering to the liver and possibly minimizing the recurrent bleeding upon removal of the packs. Gauze packs are then placed to compress the liver. The packs should be placed at both the superior and inferior surfaces of the liver. The packing should be tight enough to control the bleeding but not so tight that it unnecessarily compresses the renal vessels and possibly the inferior vena cava, resulting in intraabdominal hypertension. Patients who have undergone packing will require continued sedation with mechanical ventilation until pack removal because of the interference of optimal diaphragmatic excursion. Abdominal wall closure is rapid and is performed by towel clips or by running nylon suture in the skin. Utilization of silo like closures with sterile towels and plastic drapes should be used to minimize fluid loss and to maintain abdominal pressure. In addition, there should always be a high index of suspicion for the development of intraabdominal compartment syndrome.

Pack removal can be planned when the patient has required no vasopressors and coagulation parameters have been normalized. This usually occurs within 24 to 72 hours. Packs are then removed during a second operation, and the surgical team again must be prepared to manage bleeding. Repacking at the second operation might be indicated. The complication rate of packing is appreciable. There is an increased incidence of sepsis in a group of patients subjected to liver packing. An additional benefit of liver packing is that it may allow transport of a critically ill patient from one center to a definitive treatment center where the liver injury can be treated.

Juxtahepatic Venous Injuries

The lethality of juxtahepatic venous injuries to blunt hepatic trauma and the management challenges of definitively addressing such injuries have been well chronicled. Fortunately, such liver wounds are

seen infrequently. However, the downside is that very few acute care surgeons are familiar with and comfortable operating in this specific setting. Depending on the specific series, the mortality ranges from 50% to 80%, with massive hemorrhage being the overwhelming cause of death.

The deadly nature of this injury is a result of the difficulty in expeditiously getting access to the injury site. The retrohepatic vena cava and major hepatic veins are within the depth of the least midlife area of the liver—making exposure and direct control of bleeding very challenging. Attempting to rotate the liver in an effort to access the injury can actually extend the wound and cause increased bleeding. Also, such a misguided effort could result in a fatal air embolus.

Detailed knowledge of the pertinent anatomy is imperative for any surgeon attempting an operative management strategy. The juxtahepatic vena cava, which is within the "bare area" of the liver, extends for approximately 2 cm and is bordered by the phrenic veins and right adrenal vein—cephalad and caudad, respectively. Approximately 3 cm above the most superior aspect of the retrohepatic vena cava, the inferior vena cava enters the right atrium. The retrohepatic cava is an extrapericardial/intrapericardial structure. The three major hepatic veins, along with its tributaries, enter directly into the anterior aspect of the retrohepatic vena cava. This anatomy is relatively constant, with major anomalies being uncommon. While the course of the extrapericardial hepatic veins is short, the intrapericardial veins have a long course. Substantial blunt trauma can lacerate/avulse either or both.

Probably because of its highly lethal nature, juxtahepatic venous injuries are infrequently managed. Surrounding structures can provide a tamponade effect and contain juxtahepatic venous hemorrhage. Such structures include the liver, the diaphragm, and the suspensory ligaments of the liver. Adequate containment of hemorrhage by these structures might allow an attempt at expectant or minioperative management. However, if these supporting structures are disrupted, substantial bleeding will ensue. As a consequence, overly aggressive or injudicious hepatic mobilization can result in uncontrollable hemorrhage.

Juxtahepatic injuries, which can be caused by blunt or penetrating injuries, are often classified as type A or B, with the former being hepatic venous wounds that are intrapericardial and the latter being extrapericardial venous wounds. Both type A and B injuries can occur together. In addition, there can be associated injuries to the portal vein and its tributaries, which occur more frequently with type A wounds. Fortunately, the extrapericardial hepatic venous or the associated retrohepatic caval injuries are infrequent. Penetrating wounds to this anatomic region or the sheer forces from blunt injury are the predominant mechanisms of injury. Irrespective of the reported series on the management of juxtahepatic venous injuries, the mortality rates are overwhelmingly high.

There are, basically, three operative approaches in the management of juxtahepatic venous injuries: (1) direct repair of the venous wound(s), (2) surgical resection, and (3) pressure application (containment/tamponade measures) with reinforcement of the natural containment structures that have been disrupted. While there have been several reports of the specific strategy and efficacy of operative exposure and direct repair of juxtahepatic venous injuries, the success is sporadic and overall outcomes dismal. In 1966, Feldman was credited with reporting the first successful application of direct suture repair of a juxtahepatic venous injury. Schrock reintroduced, in 1968, the concept of vascular isolation with the utilization of an atriocaval shunt (see Fig. 4). However, the majority of surgeons have abandoned atriocaval shunting because of the challenges related to the technique and the overall dismal outcomes. The paramount or overarching principle in establishing vascular isolation is obtaining proximal and distal control of all vessels to totally isolate the liver. Heaney maneuver advocates a more expedient approach to achieve vascular isolation (Fig. 5) to surgically address juxtahepatic venous injuries and other complex liver wounds. At all times, it is imperative that the patient is optimally resuscitated and closely monitored. Another alternative, with respect to achieving vascular isolation in an effort to access retrohepatic wounds, is the establishment of a venovenous bypass (Fig. 6). This approach necessitates cannulation of the femoral vein and the axillary vein in the upper arm. The cannulas are connected by a heparin-coated tubing, with a flow assisted by a centrifugal pump. Both supra- and infrahepatic clamps are required for the venovenous bypass. Along with incompetence in the

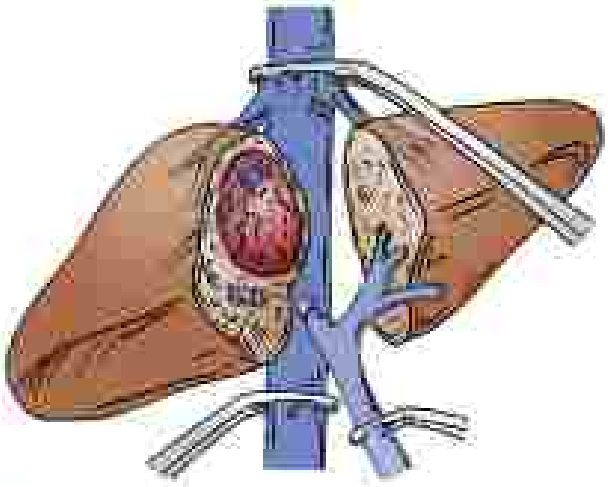

FIG. 5 The Heaney maneuver. Vascular isolation of the injured liver by applying vascular clamps to the suprahepatic and infrahepatic inferior vena cava, in addition to a Pringle maneuver. (From Blaisdell's Surgery of the Liver, Biliary Tract, and Pancreas, 4th ed. Philadelphia: Elsevier; 2007.)

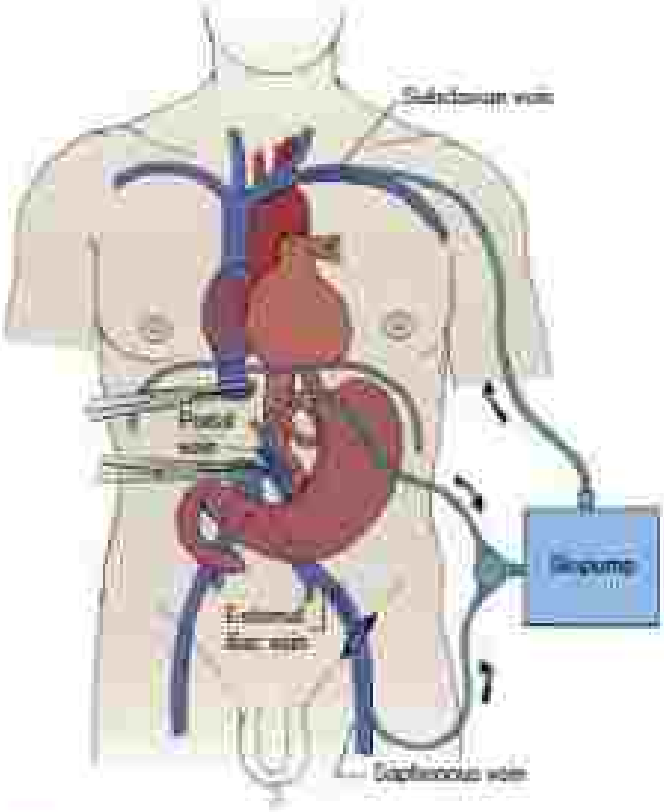

FIG. 6 The venovenous bypass requires cannulation of both the femoral vein and the axillary vein. A heparin-coated tubing connects the two cannulas. Flow is assisted by a centrifugal pump. (From Underhill G et al. Critical Care Nursing. 8th ed. Philadelphia: Elsevier; 2010.)

above techniques, major blood loss with associated coagulopathy precludes successful utilization of any of the shunting interventions. Operative hepatic resection, in an effort to access these retrohepatic wounds, is associated with a high mortality rate and should not be attempted.

Because of the inherent and overwhelming risks of surgical management of these complex injuries, tamponade with containment followed by angiography and possible embolization has become a stable option (when possible) in the management of juxtahepatic venous injuries. Such an approach often requires temporarily leaving the abdomen open. Although omentum has been proposed to create the tamponade effect, gauze packing is more expedient and effective. Pachter et al. described a "nonshunting approach," which consists of four components: (1) manual compression and aggressive fluid resuscitation; (2) prolonged portal triad occlusion (mean occlusion time, 91 min); (3) rapid and extensive finger fracture for vascular control, almost always through normal hepatic parenchyma to the site of injury; and (4) wide mobilization of the hepatic attachments with medial rotation of the liver to provide access to both the retrohepatic cava and the hepatic vein. In their series, six of the nine "nonshunted" patients survived.

Porta Hepatis

Injuries to the porta hepatis are rare, usually complex, and highly lethal. Review of the recent literature showed three large series that cumulatively report 180 patients treated between 1965 and 1994. These injuries are usually penetrating, occurring in 50% to 100% of the populations reported. Isolated injuries to the portal structures occur and are far more survivable than are multiple injuries. Overwhelming hemorrhage is the usual cause of death in all reported series.

The porta hepatis is composed of the hepatic artery, extrahepatic bile duct system, and the portal vein. The proximity of these structures to other major structures, and their relatively difficult exposure, explains their high lethality. In the multiinstitutional survey compiled by the Western Trauma Association and reported by Jurkovich et al., an overall 51% mortality rate was recorded. When broken down, the mortality rate in single structure injuries is still 45%, whereas the mortality rate in multiple structure injuries rises to 80%. This is in line with results in other reports in the literature.

Portal Vein

Injuries to the portal vein are responsible for most deaths ascribed to trauma to the portal structures. Once identified and the bleeding controlled, the question of repair versus ligation must be addressed. Ligation of the portal vein can be tolerated, in that there will be decompression of the portal hypertension by collateral vessels. Unfortunately, in patients subjected to ligation of the portal vein, the mortality rate is as high as 90%. This is in disagreement with survival rates of 50% to 80% reported previously by Pachter et al. and Jamie et al. Patients treated by ligation of the portal vein have greater circumferential disruption of the vein and overwhelming hemorrhage, and ligation is used as a rapid method of bleeding control. Repair of the portal vein is used with lesser degrees of injury—in circumferential injury less than 25%—and is reported to have increased survivability. Many of the deaths occur because of massive hemorrhage before a repair can be accomplished. When confronted with a portal venous injury, repair is preferable to ligation, although ligation is an acceptable option. Second look laparotomy to check for bowel viability has been advocated when the portal vein has been ligated.

Hepatic Artery

The liver receives a dual blood supply from the hepatic artery and the portal vein, allowing ligation of the hepatic artery without absolutely compromising hepatic blood supply. Lobar artery ligation is well tolerated, but overall mortality rate remains in excess of 40%.

Extrahepatic Biliary Ducts

Bile duct injuries are uncommon, even in this relatively uncommon injury cluster. Partial circumferential disruption can be treated by primary repair as well as demonstrated from the experience with iatrogenic bile duct injury at the time of cholecystectomy. Complete or complete disruption of the ductal tree is best managed by biliary enteric anastomosis tied to end anastomosis has an excessive stenosis rate. Adequate drainage of the area is essential, as bile leaks can occur. On rare occasions, stenting and external drainage have been used in an unstable patient, with biliary reconstruction accomplished at a later date.

The key to the diagnosis of bile duct injury is suspicion that the injury has occurred. Evidence of bile staining and the presence of a duodenal injury should prompt investigation that is best done by an intraoperative cholangiogram. Small injuries may be missed at initial exploration. Endoscopic retrograde cholangiopancreatogram with stenting may provide a diagnostic therapeutic answer if a patient develops a fistula subsequent to a missed injury.

Resuscitative Endovascular Balloon Occlusion of the Aorta

Bleeding remains the leading cause of preventable death in trauma patients who reach the hospital. Both penetrating and blunt trauma can lead to life-threatening injury of the abdominal vasculature. Traumatic injury to vessels may occur via direct laceration and transection or blunt injury resulting in dissection or thrombosis. While endovascular treatment of abdominal vascular injuries has become increasingly utilized, the unstable patient with active hemorrhage will still require open surgical intervention. Appropriate management of these patients centers on prompt recognition of the injury, rapid exposure, and control of hemorrhage. Despite advances in technology, mortality from abdominal vascular injury remains high and survival of these patients hinges on rapid exposure and control of the hemorrhage. Resuscitative endovascular balloon occlusion of the aorta, also known as REBOA, is gaining popularity as an adjunct for controlling major intraabdominal hemorrhage. The technique was first described in 1953 during the Korean War by Dr Lt Colonel Hughes on three soldiers in hemorrhagic shock. He surgeon placed a Foley through the femoral artery to provide proximal vascular control. Although some of the three patients survived, Lt Colonel Hughes noted temporary improvement with inflation of the balloon. However, the procedure was not widely adopted during this time, likely due to concerns regarding the technical difficulty of the procedure and availability of the equipment needed. It was not until 2006, when Ozenberg and colleagues first described the use of an aortic balloon occlusion device to control hemorrhage prior to endovascular repair for ruptured abdominal aortic aneurysms in three patients. As the use of REBOA has continued to increase in the field of vascular surgery, it has also recently gained momentum as an effective method of obtaining proximal control in the setting of life-threatening abdominal or pelvic trauma.

The goal of REBOA is to provide proximal control of abdominal vascular hemorrhage prior to transport to the operating room or angiography suite (Fig. 74). After the groin has been prepped, the common femoral artery is accessed with a standard hollow 18 gauge vascular access needle. It is important that incorrect placement, either too proximally into the iliac artery or too distally into the superficial femoral artery, be avoided. As many of these patients may not have a readily palpable femoral pulse, the artery can be accessed using standard anatomic landmarks, ultrasound guidance, or via direct exposure through an open cutdown. Once the artery is accessed, a 0.035-inch wire is fed through the needle in standard

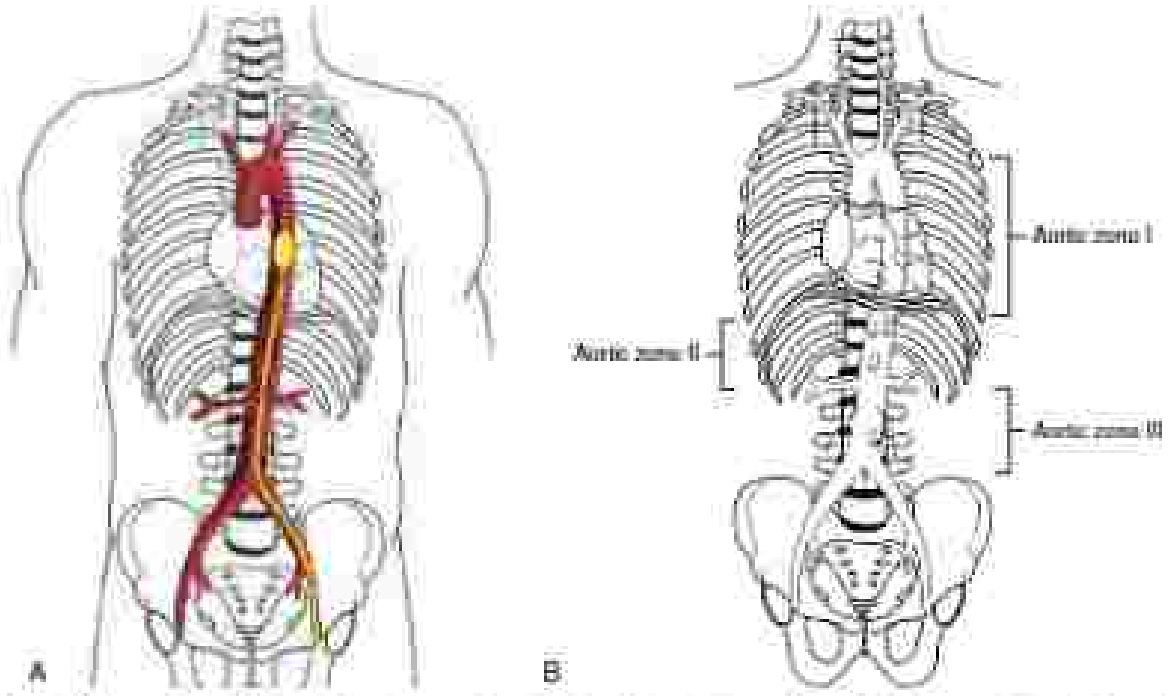

FIG. 7. (A) Aortic balloon occlusion device. (B) Aortic zones for positioning of Resuscitative endovascular balloon occlusion of the aorta device. Zone I between subclavian artery and celiac artery; zone II between the celiac artery and the lowest renal artery; and zone III between the lowest renal artery and the aortic bifurcation. (*Source:* A, Image B, from: [illegible] Resuscitative endovascular balloon occlusion of the aorta (REBOA) as an adjunct for hemorrhagic shock. J Trauma. 2011;71(1 Suppl 1):S48–S55.)

Seldinger fashion. Traditionally, a 6Fr vascular sheath and dilator are placed and then upsized to an 11Fr to 14Fr sheath depending on the size of the balloon being used; however, newer "low pass" sheaths and dilators are currently in production for the trauma setting. Once the appropriate size sheath is in place, a stiff Amplatz guidewire is placed through the sheath. The balloon device is then fed over the guidewire to the correct position.

The location of the balloon in the aorta is determined by the presumed location of the trauma, divided into three distinct zones (Fig. 7B). Zone I is the proximal zone of the descending aorta between the left subclavian and celiac trunk. Placement of the balloon in this zone is recommended for abdominal and visceral trauma. Zone II encompasses the abdominal vasculature from the celiac artery to the lowest renal artery. Placement of the balloon in zone II is contraindicated as it is possible to directly occlude the celiac artery, superior mesenteric artery, or renal arteries resulting in organ ischemia. Zone III extends from the lowest renal artery to the aorta bifurcation. Positioning of the balloon in this zone provides proximal control for pelvic hemorrhage while still maintaining perfusion to the abdominal organs. Correct positioning of the balloon can be accomplished with either fluoroscopy, plain film x-ray in the trauma bay, or by physical landmarks.

Once positioned, the balloon is then inflated with either saline or a 1:1 mixture of saline and contrast if fluoroscopy is being utilized. Appropriate filling of the balloon can be confirmed by either visualization of the balloon flattening against the wall of the aorta if using fluoroscopy or loss of a pulse in the contralateral femoral artery. Several animal studies have demonstrated that aortic occlusion times greater than 60 minutes may result in severe physiologic derangement and irreversible organ failure; thus it is imperative that the surgeon be mindful of the duration of balloon inflation and should limit this to less than 60 minutes. After hemorrhage has been controlled, the balloon should be slowly deflated with ongoing communication between the surgeon and the anesthesiologist, as there may be abrupt periods of hypotension as the balloon is deflated.

Concerns regarding the use of REBOA focus on incorrect placement of the device, effectiveness in controlling hemorrhage, and potential for organ ischemia. One of the initial case series in 1980 documented the use of REBOA in trauma patients and found that trauma surgeons were able to appropriately position and deploy the balloon and the balloon was able to control hemorrhage in 11 out of 21 patients with refractory hemorrhagic shock. Brenner and colleagues published a recent case series of six trauma patients with severe hemorrhagic shock in which REBOA was utilized prior to angiographic or surgical control of the hemorrhage. REBOA resulted in an average increase in systolic blood pressure of 55 mm Hg, and none of the patients died as a result of hemorrhage. Additional studies have shown similar rates of successful placement and control of hemorrhage in patients with both blunt and penetrating abdominal trauma.

While in many situations, the most effective method to control hemorrhage will be direct control via laparotomy or embolization, REBOA is a technically feasible and potentially life-saving adjunct in the patient with refractory and end-stage hemorrhagic shock. As the technology for the REBOA devices improves and more clinical research is performed, REBOA will likely become more widespread as a rapid and effective method of hemorrhage control prior to definitive surgical repair for life-threatening abdominal and pelvic trauma.

CONCLUSION

In addition to the management of abdominal trauma that has been underscored throughout the chapter for blunt trauma, there are several proposed treatment paradigms for many of the injuries sustained by trauma. However, the standard of care management for an individual is heavily dependent on the resources and personnel available, along with transport options, if any. There are resource rich

trauma systems throughout the country, with highly qualified personnel. However, these systems are not uniform throughout the nation and the concept of regionalization has not been perfected for all the regions in the country. The overarching goal remains the same: optimal management for everyone, irrespective of where the patient receives trauma care.

Penetrating Abdominal Trauma

David V. Feliciano, MD

While blunt mechanisms account for 80% of injuries in the United States, patients with penetrating abdominal wounds continue to present to all trauma centers and emergency departments. The reasons for this have not changed over the past 75 years and include the following:

1. The tendency of young men to solve domestic and other interpersonal disputes with the use of the most lethal weapon available
2. The ready availability of handguns in the United States
3. Gang-related violence in urban areas and the sale of illicit drugs

TRANSPORT AND RESUSCITATION

Interventions in the field or emergency department do not control intraabdominal bleeding or gastrointestinal contamination in the patient with a penetrating abdominal wound that causes injury. Therefore transport and resuscitation in such patients is different than that used in patients with blunt multisystem trauma. For example, the application of a cervical collar or spinal immobilization in the field is unnecessary unless the patient has a specific complaint at the scene. Rapid transport takes precedence over the insertion of intravenous catheters at the scene in urban areas where a trauma center is only 15 to 25 minutes away. Even with longer transport times to the trauma center, the military concept of hypotensive resuscitation (limited or no resuscitation before operation) is now applied by many civilian emergency medical services during transport. Obviously, this would be inappropriate in a patient with an associated traumatic brain injury. The ideal perioperative systolic or mean arterial blood pressure during hypotensive resuscitation in the symptomatic patient with a penetrating abdominal wound is unknown.

In the emergency department, emergency intubation is indicated in patients with the following:

- Profound hypotension (ATLS class III or IV shock) or recent cardiopulmonary arrest
- Associated wounds to the neck or chest affecting the airway or breathing
- Depressed neurologic state secondary to shock, acute alcoholism or illicit drugs
- Extreme agitation preventing evaluation and resuscitation

Intravenous lines are inserted into the upper extremities, subclavian veins, or jugular veins, and venous blood is withdrawn for type and cross match and routine laboratory testing. In the patient with ATLS class III or IV shock, most level I trauma centers will initiate a massive transfusion protocol (MTP) and administer packed red blood cells immediately. Smaller centers or those without an MTP often still administer a crystalloid solution initially and then transfuse when type specific blood is available. Many centers have moved from *damage control resuscitation* with administration of rapid ratios of packed red blood cells, plasma, and platelets to *goal directed* hemostatic resuscitation. The latter is based on thromboelastography (TEG) or rotational thromboelastometry.

As resuscitation is ongoing, a surgeon performed ultrasound examination of the pericardium, peritoneal cavity and pleural cavities (expanded FAST or eFAST) is performed with a 3.5 MHz ultrasound probe in patients with multiple wounds, including the abdomen. Although this examination is primarily indicated in patients with blunt multisystem trauma, it has diagnostic advantages in patients with possible penetrating abdominal trauma, as well. For example, the presence of fluid (blood) in the pericardial sac might prompt a median sternotomy or anterolateral thoracotomy even before a needed laparotomy. Or the rapid diagnosis of a hemothorax or pneumothorax (without the need for emergency chest radiography) would prompt the insertion of a thoracostomy tube before a needed laparotomy. Finally, the presence of fluid (blood) in the peritoneal cavity

trauma systems throughout the country, with highly qualified personnel. However, these systems are not uniform throughout the nation and the concept of regionalization has not been perfected for all the regions in the country. The overarching goal remains the same: optimal management for everyone, irrespective of where the patient receives trauma care.

Penetrating Abdominal Trauma

David V. Feliciano, MD

While blunt mechanisms account for 90% of injuries in the United States, patients with penetrating abdominal wounds continue to present to all trauma centers and emergency departments. The reasons for this have not changed over the past 75 years and include the following:

1. The tendency of young men to solve domestic and other interpersonal disputes with the use of the most lethal weapon available
2. The ready availability of handguns in the United States
3. Gang-related violence in urban areas and the sale of illicit drugs

TRANSPORT AND RESUSCITATION

Interventions in the field or emergency department do not control intraabdominal bleeding or gastrointestinal contamination in the patient with a penetrating abdominal wound that causes injury. Therefore transport and resuscitation in such patients is different than that used in patients with blunt multisystem trauma. For example, the application of a cervical collar or spinal immobilization in the field is unnecessary unless the patient has a specific complaint at the scene. Rapid transport takes precedence over the insertion of intravenous catheters at the scene in urban areas where a trauma center is only 15 to 25 minutes away. Even with longer transport times to the trauma center, the military concept of hypotensive resuscitation (limited or no resuscitation before operation) is now applied by many civilian emergency medical services during transport. Obviously, this would be inappropriate in a patient with an associated traumatic brain injury. The ideal perioperative systolic or mean arterial blood pressure during hypotensive resuscitation in the symptomatic patient with a penetrating abdominal wound is unknown.

In the emergency department, emergency intubation is indicated in patients with the following:

- Profound hypotension (ATLS class III or IV shock) or recent cardiopulmonary arrest
- Associated wounds to the neck or chest affecting the airway or breathing
- Depressed neurologic state secondary to shock, acute alcoholism or illicit drugs
- Extreme agitation preventing evaluation and resuscitation

Intravenous lines are inserted into the upper extremities, subclavian veins, or jugular veins, and venous blood is withdrawn for type and cross match and routine laboratory testing. In the patient with ATLS class III or IV shock, most level I trauma centers will initiate a massive transfusion protocol (MTP) and administer packed red blood cells immediately. Smaller centers or those without an MTP often still administer a crystalloid solution initially and then transfuse when type specific blood is available. Many centers have moved from *damage control resuscitation* with administration of rapid ratios of packed red blood cells, plasma, and platelets to goal *directed* hemostatic resuscitation. The latter is based on thromboelastography (TEG) or rotational thromboelastometry.

As resuscitation is ongoing, a surgeon performed ultrasound examination of the pericardium, peritoneal cavity and pleural cavities (expanded FAST or eFAST) is performed with a 3.5 MHz ultrasound probe in patients with multiple wounds, including the abdomen. Although this examination is primarily indicated in patients with blunt multisystem trauma, it has diagnostic advantages in patients with possible penetrating abdominal trauma, as well. For example, the presence of fluid (blood) in the pericardial sac might prompt a median sternotomy or anterolateral thoracotomy even before a needed laparotomy. Or the rapid diagnosis of a hemothorax or pneumothorax (without the need for emergency chest radiography) would prompt the insertion of a thoracostomy tube before a needed laparotomy. Finally, the presence of fluid (blood) in the peritoneal cavity

confirms that a knife or gunshot wound has penetrated beyond the abdominal wall.

Patients who will be taken to surgery for an emergency or urgent laparotomy (see below) are administered an intravenous dose of a second- or third-generation cephalosporin antibiotic. As a general rule, patients with penetrating abdominal wounds and overt indications for an emergency laparotomy should be moved to the operating room within 10 minutes of arrival in the trauma room.

INDICATIONS FOR LAPAROTOMY AFTER PENETRATING ABDOMINAL TRAUMA

The timing of operation in such patients in a busy trauma center will depend on the patient's hemodynamic status and associated injuries, as well as the hemodynamic status of other patients with penetrating or blunt trauma who are being evaluated simultaneously (Box 1).

PATIENTS WITHOUT CLEAR-CUT INDICATIONS FOR LAPAROTOMY

Just as in patients with blunt abdominal trauma, the diagnosis of peritonitis on a physical examination after a penetrating abdominal wound, particularly a stab wound, may be difficult. This is particularly true in patients who are intoxicated, have impaired mental drugs, have associated injuries to the brain or spinal cord, or have multiple penetrating wounds in areas adjacent to the abdomen (thoracoabdomen, pelvis, flank, back). When serial physical examinations may not be helpful, standard diagnostic adjuncts are used, preferably in a sequence agreed on by staff trauma surgeons (Box 2).

In patients in whom contrast enhanced computed tomography (CT) will be part of the diagnostic workup, a 64 slice scanner should be used. A 64 slice scanner has a 4 cm scan width, and scanning of the trunk can be completed with a limited number of revolutions in a short period of time.

Dual energy CT in which images are acquired at two different energy levels simultaneously is now available in some hospitals, and attenuation differences allow for suppression of artifacts and enhanced images. This technology is now being used to image the brain and aorta and will soon have an impact on truncal imaging in injured patients.

The obvious goal of further diagnostic evaluation in patients without clear cut indications for an emergency or urgent laparotomy is to avoid an unnecessary or nontherapeutic laparotomy. Patients undergoing such procedures have a fixed rate of postoperative complications and an extended length of stay as compared with those managed with observation or further diagnostic testing.

POSSIBLE PENETRATING ABDOMINAL TRAUMA/HEMODYNAMICALLY UNSTABLE/MULTIPLE TRUNCAL AND EXTREMITY WOUNDS

One of the common sense observations about patients with multiple gunshot wounds is that associated hypotension is likely related to one wound ("one bad bullet"). When there is no external bleeding from an injured neck or extremity to explain the hypotension, surgeon performed ultrasonography is the diagnostic test of choice. As previously noted, an eFAST examination will document whether the hypotension is from pericardial tamponade, intraperitoneal hemorrhage, or intrapertoneal hemorrhage. An equivocal eFAST examination or lack of availability of an ultrasound machine should prompt an open diagnostic peritoneal tapvarage in the hypotensive patient, a rapidly performed diagnostic test in the modern era.

BOX 1 Indications for Laparotomy After Penetrating Abdominal Trauma*

- Hypotension in absence of other site of potential hemorrhage (i.e., penetrating cervical, thoracic or peripheral vascular wound with active hemorrhage)
- Peritonitis on initial or subsequent physical examination
- Evisceration of bowel and, in some centers, omentum (controversial)
- Bleeding from stomach (hematemesis or bloody return from nasogastric tube) or rectum (bright red blood or hematochezia on finger examination or proctoscopy)
- Bleeding from genitourinary tract (exception would be flank wound in stable patient and CT evidence of isolated nonhilar renal injury amenable to observation or angioembolization)
- Contrast enhanced CT demonstrates perforation of gastrointestinal tract, intraperitoneal bladder or severe (American Association for the Surgery of Trauma Organ Injury Scale Grade V) solid organ injury

*Modified from Nikolaou DV. Abdominal trauma revisited. Orv Hetil. 2007;148:1193–202.
CT, Computed tomography.

BOX 2 Diagnostic Adjuncts in Evaluating Patients with Possible Penetrating Abdominal Trauma

- Local exploration of anterior stab wounds
- Diagnostic peritoneal tapvarage
- Surgeon performed ultrasound examination (FAST)
- Contrast enhanced CT of the abdomen and pelvis
- Diagnostic laparoscopy

CT, Computed tomography.

POSSIBLE PENETRATING THORACOABDOMINAL TRAUMA/ HEMODYNAMICALLY STABLE

The thoracoabdomen is defined as the region to costal margin from the midline to the anterior axillary line. Penetration through the diaphragm into the peritoneal cavity from a wound in the thoracoabdomen will occur in approximately 15% of stab wounds and more than 65% of gunshot wounds (Fig. 1).

Once again, surgeon performed ultrasonography is the initial diagnostic test of choice in the patient without an obvious indication for a laparotomy. An ipsilateral pneumothorax or hemothorax can be confirmed, whereas the presence of intraperitoneal fluid (blood) documents that the hemidiaphragm and, possibly, intraabdominal viscera have been injured. An eFAST examination in which no intraperitoneal fluid is visualized is not helpful because only modest bleeding may result from a penetrating wound of the hemidiaphragm alone.

In the modern era, documentation of intraperitoneal fluid (blood) in the asymptomatic or mildly symptomatic patient) does not prompt an immediate laparotomy. With a wound in the right thoracoabdomen, triple contrast (intravenous, oral, rectal) CT is performed to evaluate the liver, right kidney, duodenum, and colon. This is a labor-intensive study for the radiology technician because all 3 contrast agents are administered simultaneously. In addition, metallic fragments from a bullet may create enough "scatter" to compromise the accuracy of one of the contrast studies. A patient with a wound to the liver or right kidney only without extravasation of contrast (no active bleeding) is managed nonoperatively with serial physical examinations for 24 to 36 hours. If desired, healing of the injury to the liver

FIG. 1. Patient with left thoracoabdominal gunshot wound had 3-day delay before wounds to left hemidiaphragm and stomach were diagnosed.

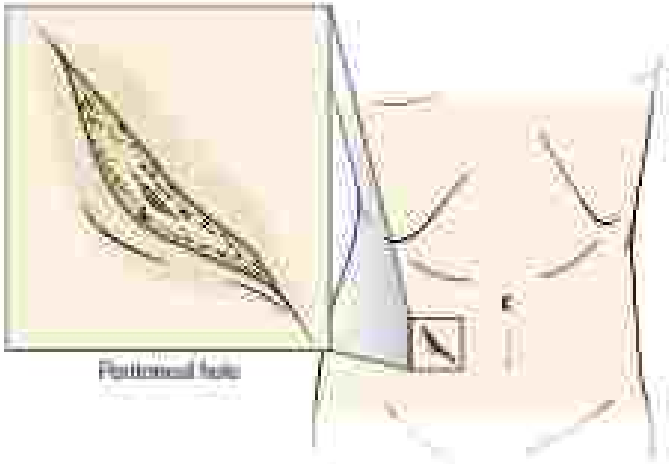

FIG. 2. Peritoneal perforation on a local wound exploration after a stab wound to the anterior abdominal wall mandates admission and serial physical examinations.

or right kidney can be evaluated on a follow-up CT examination in 5 to 7 days. In such a patient, the small penetrating wound to the right hemidiaphragm is not fatal. This is because omental herniation through the right-sided defect essentially never occurs, and the complication of a bronchobiliary fistula is so rare. A triple contrast CT is performed after a penetrating wound to the *left* thoracoabdomen as well, with the goal of evaluating the liver, spleen, left kidney, stomach, and colon. Even if a patient has a midintestinal wound to the left lobe of the liver, spleen, or left kidney and no extravasation of gastrointestinal contrast, the wound to the left hemidiaphragm must be repaired. This will prevent herniation of the omentum into the left hemithorax secondary to the negative intrapleural pressure of respiration. This can be accomplished via a laparoscopic approach depending on the surgeon's expertise.

Because of the labor intensive nature of triple contrast CT, some centers choose to perform diagnostic laparoscopy instead after a wound to the left thoracoabdomen. An equivocal triple contrast CT after a wound to either the right or left thoracoabdomen should be followed by diagnostic laparoscopy as well. Using a 30-degree laparoscope with the patient under general anesthesia in the operating room will allow for a careful inspection of the peritoneal hemidiaphragm and intraabdominal viscera.

PENETRATING ANTERIOR STAB WOUND/ HEMODYNAMICALLY STABLE

The anterior abdomen is defined as the area from the costal margins to the inguinal ligaments between the anterior axillary lines. Historic data have documented that stab wounds to this location penetrate the peritoneal cavity only 20% to 30% of the time. Even in patients with documented peritoneal penetration, only 50% to 55% will present with overt indications for a laparotomy. In the remaining 15% to 20% who undergo serial physical examinations, only half will eventually become symptomatic and require laparotomy.

A local wound exploration under sterile conditions and local anesthesia in the trauma room is the first diagnostic maneuver. Contraindications would include the agitated or uncooperative patient or one who is morbidly obese. A very localized layer-by-layer exploration will, at the least, document whether the anterior aponeurosis of the muscular abdominal wall has been penetrated. In many centers, the local wound exploration is terminated at this point and the patient admitted for serial physical examinations or further diagnostic testing. Other centers will continue the exploration through the muscular layers of the abdominal wall to determine whether the posterior aponeurosis, peritoneum, or both have been perforated (Fig. 2). If it can be confirmed that this has not occurred, the wound is irrigated and closed in layers, a tetanus immunization shot is administered, and the patient is discharged.

In most centers an asymptomatic or mildly symptomatic patient with penetration of the anterior aponeurosis or peritoneum will then undergo serial physical examinations every 6 to 8 hours for 24 hours. Almost all patients with continued bleeding from a solid organ, the mesentery, or omentum or peritonitis from a gastrointestinal wound will become symptomatic within 6 to 16 hours. Despite the delay to operative management that inevitably occurs in this small subset of patients, postoperative morbidity is surprisingly low.

Another option to the asymptomatic or mildly symptomatic patient is to perform an immediate diagnostic peritoneal tap/lavage. This option has become less popular over time because of false-positive examinations results from intraperitoneal blood related to the injury to the abdominal wall. Also, there has been continuing controversy about whether a red blood cell count of 100,000/mm^3 (as in patients with blunt trauma) or 5000/mm^3 (to pick up a small wound of the hemidiaphragm) should be used to mandate a laparotomy. The accuracy of this approach using a cell count of 100,000 red blood cells or 500 white blood cells/mm^3 ranges from 80% to 92%.

PENETRATING ANTERIOR STAB WOUND AWAY FROM LEFT HEMIDIAPHRAGM/ OMENTAL EVISCERATION

Evisceration of a large piece of omentum should prompt an emergency laparotomy. This allows for replacement of the omentum into the peritoneal cavity, a complete exploration for associated injuries (theoretically a higher incidence than if a smaller defect in the abdominal wall), and repair of the abdominal wall. Commonly exits, however, when a small piece of omentum is evisceration (Fig. 3). In such patients, an emergency laparotomy will be unnecessary in 20% to 60% of patients. Therefore some centers will ligate the base of the eviscerated omentum, excise it, return the remainder to the peritoneal cavity, close the defect in the abdominal wall, and perform serial physical examinations for 24 hours. This option is safe and has a ability to operative management essentially the same as if an omental evisceration had not occurred.

PENETRATING FLANK OR BACK TRAUMA/HEMODYNAMICALLY STABLE

The flank is defined as the sixth intercostal space to the iliac crest between the anterior and posterior axillary lines, whereas the back is the rest of

FIG. 3 Small external excoriation does not mandate laparotomy in all trauma centers.

the scapulae to the iliac crests posterior to the posterior axillary lines. Wounds in these areas may penetrate the peritoneal cavity or the visceral/vascular areas of the retroperitoneum. A historic policy of mandatory laparotomy for penetrating wounds [illegible] in symptomatic patients has been abandoned over the last 30 years because the negative [illegible] these areas.

The [illegible] patients are [illegible] serial physical examinations and triple contrast CT. The concern with serial physical examinations is that perforation of the retroperitoneal duodenum, ascending colon, or descending colon will cause retroperitonitis or a delayed onset of symptoms. [illegible] abdomen. [illegible] patients [illegible] hours after [illegible] serial physical examinations after penetrating stab wounds [illegible] applies to patients [illegible] or back [illegible] as well, and [illegible] the trauma surgeons in a given center extending the period for serial [illegible].

Triple contrast enhanced CT scans to evaluate patients with [illegible] in the 1990s. [illegible] with [illegible] intraperitoneal or [illegible] retroperitoneal visceral or vascular injury.

In summary, serial physical examinations [illegible] for surgical team, or triple contrast CT [illegible] for radiology technicians are acceptable diagnostic options, with a delayed diagnosis [illegible].

FLANK-ANTERIOR ABDOMINAL WALL GUNSHOT WOUNDS AND ANTERIOR ABDOMINAL WALL THROUGH-AND-THROUGH WOUNDS

In the modern era, there is a tendency for victims facing an assailant holding a handgun to turn away. Also, obesity is present in more than [illegible]% of adults in some states in the United States. This results in numerous patients having oblique missile tracts in proximity to the abdominal contents from the flank to the anterior abdominal wall, from the anterior abdominal wall to the flank, and from one location in the anterior abdominal wall to another.

When physical examination cannot rule out peritonitis, the diagnostic test of choice is abdominal CT with intravenous contrast. A preliminary [illegible] will often confirm that the gunshot wound is extraperitoneal. Because the kinetic (muzzle) energy of missiles from handguns is less than 1000 ft-lbs (with the exception of a .44 caliber), a shock wave injury to an intraabdominal viscus would be highly unlikely in such a patient. [illegible] of an intraperitoneal track in the patient with a persistent equivocal physical examination should be followed by a diagnostic laparoscopy in the operating room because 20% to [illegible]% of such patients will have an intraabdominal injury.

SELECTIVE NONOPERATIVE MANAGEMENT OF ABDOMINAL GUNSHOT WOUNDS

[illegible] and colleagues from Los Angeles County Hospital/University of Southern California reported on selective management of [illegible] patients with abdominal gunshot wounds [illegible] in 2001. The group of [illegible] patients ([illegible]%) who were selected for nonoperative management did not have any of the following: hypotension, associated injury to brain or spinal cord, intoxication, or need for sedation or intubation. Delayed laparotomy for new symptoms was performed in [illegible] patients ([illegible]%), and [illegible] patients ([illegible]%) did not have a laparotomy. The rate of unnecessary laparotomy in operated patients was 14[illegible]. The series presumably included many patients with oblique or extraperitoneal missile tracks as previously described. It confirmed, however, that the criteria used to choose nonoperative management in patients with stab wounds in proximity to the abdomen could be used in patients with gunshot wounds as well.

SUMMARY OF NONOPERATIVE MANAGEMENT

A patient with negative physical examination results (over 24 to [illegible] hours) or a normal contrast-enhanced CT after sustaining a possible or confirmed penetrating abdominal, flank, or back wound is given specific written instructions at the time of discharge. These state that a new onset of an elevated body temperature, abdominal pain, lightheadedness, hematemesis, rectal bleeding, hematochezia, or hematuria should prompt immediate return to the trauma center. The phone number of the trauma service is included, as well.

GENERAL PRINCIPLES OF TRAUMA LAPAROTOMY

The patient is placed in the supine position with the upper extremities at the sides unless there is a high likelihood of a simultaneous left anterolateral thoracotomy being performed. In such a patient, the left chest is elevated 30 degrees to allow for access to the descending thoracic aorta and thoracic esophagus, and the left upper extremity is rotated superior to the patient. Placing the upper extremities at the patient's sides allows for easy insertion of self-retaining abdominal retractors and ready access for a median sternotomy. Skin preparation and draping extends from the chin to the knees and encompasses the anterior and lateral trunk. This allows for ready access for removal of the greater saphenous vein from the groin and thigh, if needed. Throughout the trauma laparotomy, all the standard warming maneuvers are used to reverse or prevent hypothermia (increase room temperature; turn up heating cascade on anesthesia machine; cover patient's head and extremities with warming device; infuse blood and fluids through warming device; irrigate tubes, nasogastric, thoracostomy, and open body cavities with warm saline solution if hypothermia is persistent).

Depending on the patient's hemodynamic status, the midline incision is not opened until type-specific blood is available in the operating room. Once the peritoneal cavity is opened, blood, clots, and gastrointestinal contents are evacuated using laparotomy pads and a [illegible] suction device. Sites of hemorrhage in the mesentery, bowel, retroperitoneum or solid viscera are exposed and controlled with clamps or packing. Then, all perforations in the gastrointestinal tract are controlled with bowel, vascular, Babcock, or Allis clamps or

BOX 3 Rapid Operative Techniques After Penetrating Abdominal Trauma

Gastrointestinal Tract

Single layer closure of gastrointestinal perforations
Colon repair instead of colostomy
Delay gastrointestinal reconstruction

Solid Viscera

Hepatotomy, tractotomy, debridement, or perihepatic packing instead of formal hepatic resection
Topical agent, suture, or absorbable mesh splenorrhaphy for AAST OIS grade I–III injury instead of splenectomy
Avoiding placement of drains after stabilization or repair of grade I–II hepatic or pancreatic injuries, splenorrhaphy, splenectomy

Diaphragm

Single layer permanent suture repair

Named Arteries

Temporary intraluminal shunt instead of complex repair of proximal superior mesenteric artery, common iliac artery, or external iliac artery (these vessels are never ligated)

Named Veins

Ligation major injury to portal vein, superior mesenteric vein, splenic vein, left renal vein at midline, infrarenal inferior vena cava, common iliac vein, or external iliac vein

a stapling device. Depending on the patient's hemodynamic status, number and magnitude of gastrointestinal perforations and associated injuries, the perforations are repaired and the peritoneal cavity irrigated with a saline antibiotic solution. Then, treatment of injuries to solid organs or to retroperitoneal blood vessels is performed. This sequence is reversed in patients with active visceral or vascular hemorrhage.

As a general rule, the track of a knife or missile wound is followed first, with repair or resection of injuries as needed. Then, a formal exploration of every intraabdominal organ including retroperitoneal viscera and vessels, especially those in proximity to the track, is performed. The organs most commonly injured in patients with stab wounds to the abdomen are the liver, small bowel, diaphragm, colon, and stomach. In patients with gunshot wounds, injuries to the diaphragm fall by one half as compared with stab wounds, and injuries to named abdominal vessels are present in 20% to 25% of patients in large reviews. In any patient with multiple abdominal injuries from a penetrating wound, not just those undergoing a damage control laparotomy, rapid operative techniques are performed (Box 3).

A "damage control" laparotomy is indicated in patients with profound hypothermia (temperature 32°–34°C), a metabolic acidosis (pH <7.2), signs of an intraoperative coagulopathy, or some combination of these. This limited laparotomy controls hemorrhage and gastrointestinal contamination, only, and should be completed within 60 to 90 minutes. Leaving the abdominal wall open under a vacuum assist device or a plastic silo is appropriate after a damage control laparotomy, when distention of the midgut precludes a safe closure or when intraabdominal packs have been inserted. An early reoperation after a damage control laparotomy is occasionally necessary. This is

BOX 4 Goals at a First Reoperation After Damage Control Laparotomy

Remove and count packs and confirm absence of continued bleeding from liver or retroperitoneum
Inspect all repairs and search for missed injuries
Complete gastrointestinal anastomoses and/or create stoma
Insert nasojejunal feeding tube (or do gastrostomy or jejunostomy)
Irrigate abdominal cavity with saline solution containing antibiotic
Decide if formal suture closure of linea alba is safe

indicated when there is a continuing need for hourly transfusion of two units of red blood cells after a coagulopathy has been mostly corrected based on monitoring with TEG. Otherwise, a reoperation after an original damage control procedure is performed when the patient is normothermic, no longer acidotic, not coagulopathic, and has reasonable respiratory and cardiovascular function—usually at 48 to 72 hours. The goals of the first reoperation after a damage control laparotomy are listed in Box 4.

SUMMARY

In patients undergoing laparotomy after abdominal stab wounds, the survival rate is 98% and only 27% of patients required a blood transfusion in one large review. The most common postoperative complication was an infection in the incision (1.0%).

In patients undergoing laparotomy after abdominal gunshot wounds, the survival rate was 88% (97% in those without an abdominal vascular injury, 61% in those with an abdominal vascular injury) in one large review. The most common postoperative complications were an intraabdominal abscess (3.9%), infection in the incision (3.4%), and reoperation for persistent bleeding (2.2%).

Management of Diaphragmatic Injuries

Chair: [illegible] ... FACS, FCCM, Professor, Division of Trauma, Surgical Critical Care, Burns, and Acute Care Surgery, University of Arizona, Tucson, AZ

[illegible], MD, FACS

Traumatic diaphragmatic injuries (TDIs) continue to be a diagnostic and therapeutic challenge for surgeons who care for trauma patients. Clinical presentations are variable and associated thoracic and abdominal injuries often distract surgeons from the early identification and treatment of TDIs. In addition, missed diagnoses place patients at increased risk for visceral hernia and strangulation. The objectives of this chapter are to review the epidemiology, anatomy, and physiology of TDIs and provide current recommendations for diagnosing and managing TDIs in both the acute and chronic phases.

EPIDEMIOLOGY

The incidence of acute TDI after thoracoabdominal trauma ranges from 0.8% to 8% with TDI from blunt and penetrating injury accounting for 75% and 25%, respectively. Bilateral TDIs are uncommon, occurring in only 0.2% of patients with TDI. After either penetrating or blunt trauma, a higher incidence of left-sided TDI exists given the presence of a congenital weakness along the costal and lumbar portions of the left hemidiaphragm and because the liver provides some degree of protection along the right hemidiaphragm. Although TDI represents only 5% of all diaphragmatic hernias, it is responsible for 40% of hernias that eventually become incarcerated.

ANATOMY

An understanding of diaphragmatic anatomy is important to avoiding missed injuries and in minimizing iatrogenic phrenic nerve injury during operative repair. The diaphragm is a dome-shaped muscular-aponeurotic barrier that separates the thoracic from the abdominal cavity and is the main respiratory muscle of the body with expiratory and respiratory functions. Muscle fibers originate anteriorly from the sternum's xiphoid process, laterally, inferiorly, and posteriorly from the costal cartilages and osseous portions of the lower ribs and from the lumbar vertebral bodies and their intervertebral discs (Fig. 1). These fibers all insert into the diaphragm's aponeurotic portion known as the central tendon, which underlies the pericardium. The right dome is naturally 2 cm higher than the left due to the mass exerted by the underlying liver.

The diaphragm has three separate hiatuses, allowing for the passage of the inferior vena cava (IVC), esophagus, and aorta. Located at the T8 level, the aponeurotic canal opening allows the IVC and often the right phrenic nerve to traverse body cavities. The diaphragm's lumbar origin includes left and right crural fibers, which form the boundaries of the esophageal and aortic hiatus. The esophagus and the vagus nerves traverse the esophageal hiatus—a gap between the right crural fibers—at the T10 level. The aortic hiatus, formed by the fibers of the left and the right crura, is located at the T12 level, posterior and just to the left of midline, and allows for passage of the aorta, thoracic duct, and variably the azygos and the hemiazygos veins.

The diaphragm's blood supply comes from inferior and superior phrenic arteries, which arise directly from the thoracoabdominal aorta. Superior epigastric and intercostal arteries provide blood to the muscle's costal margins. Phrenic veins provide venous drainage directly into the IVC. The left and right phrenic nerves supply the diaphragm with its motor and sensory innervation. The left phrenic nerve passes through the muscular diaphragm more anteriorly than the right phrenic nerve, which passes through the aponeurotic central tendon through or close to the caval opening. The two main trunks typically divide into three main branches: anterior, intermediate, and posterior. Sensory innervation to the central tendon of the diaphragm and pericardium is through the phrenic nerves, whereas the intercostal nerves provide sensory nerve supply to the diaphragm periphery.

MECHANISMS OF INJURY AND ASSOCIATED INJURIES

The diaphragm is rarely injured in isolation. In fact, TDI is considered a marker for severe associated injuries, especially in the setting of high-grade blunt trauma. In patients sustaining blunt TDI, Meyers and McCabe reported a 60% incidence of associated pelvic fractures, a 25% incidence of associated hepatic and splenic injuries, and a 5% incidence of associated aortic tears. Thus, the presence of TDI in the setting of blunt trauma should alert the surgeon to a high probability of associated solid organ and pelvic injury.

DIAGNOSIS

Patients with missed or untreated TDIs often present in a delayed fashion with symptoms related to intestinal herniation or strangulation. Over time, small diaphragmatic defects can increase in size as a result of the constant activity of the muscle, and the pressure gradient between pleural and peritoneal cavities can result in herniation of intraperitoneal organs into the chest. Clinical presentations vary from mild nausea and vomiting from intermittent bowel obstructions, to severe pain from incarceration and intestinal ischemia, to septic shock and death from strangulated, necrotic, or perforated viscus. Undoubtedly, the consequences of an untreated TDI can be devastating and life threatening.

The diagnosis of a TDI in a patient who does not otherwise warrant immediate thoracic or abdominal surgical intervention can be challenging. Generally, the ability to make an accurate diagnosis outside an operating room relates to the size of the defect.

The physical examination is often unreliable for diagnosing TDIs because there are no highly sensitive signs to detect an underlying injury. However, there are certain signs that are suggestive of injury, including unilateral decreased breath sounds, bowel sounds in the chest, and respiratory distress. Although these signs are nonspecific findings, their presence should not be discounted in assessing for diaphragm injury. After penetrating injuries, the trajectory of the knife or bullet is more important than the actual location of the skin wound; the trajectory is usually difficult to accurately elicit. Probing a thoracoabdominal wound, especially one overlying the rib cage, is discouraged for fear of creating or exacerbating a pneumothorax or intercostal bleeding.

A focused assessment with sonography for trauma scan using a 5.5-MHz phased array ultrasound probe is the first screening tool used in the diagnosis of TDIs but has limited sensitivity; however, the presence of pleural fluid, subphrenic effusion, nonvisualization of the spleen, or the visualization of the spleen in the thorax can suggest TDI.

A chest radiograph is commonly performed but rarely diagnostic, especially for penetrating trauma where TDIs are small and plain films are seldom helpful. A chest radiograph more commonly contributes to the diagnosis after a blunt mechanism. Examples of such radiographic signs include air or an air–fluid level within a hollow viscus overlying the thorax or with the abdominal classic finding of the curling supradiaphragmatic nasogastric tube (Fig. 2). Suggestive findings include abnormality in the contour, shape, or position (e.g., elevation) of the hemidiaphragm, pleural effusion or atelectasis, and mediastinal shift (Fig. 3). However, the chances of seeing these signs in the intubated patient with TDI may be reduced because positive pressure ventilation causes the contour of the lower lobes of the lungs to expand, mimicking that of the intact diaphragm.

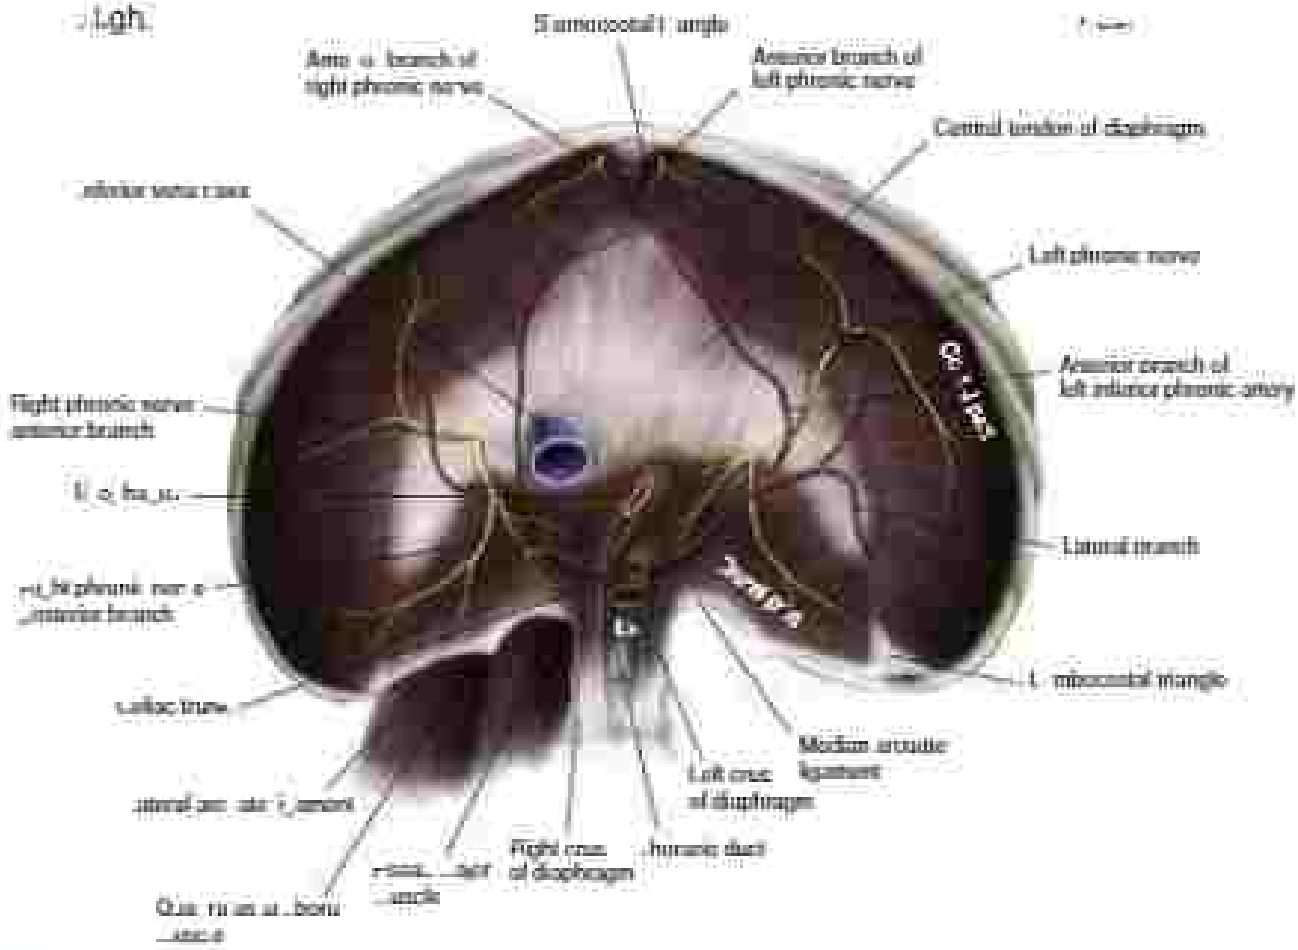

FIG. 1 Anatomy of the diaphragm (with additional structures). (From Anne G. M. Campbell, Clare Hall, Jonathan Ritchie, Gray's Surgical Anatomy, Philadelphia, 2020, Elsevier.)

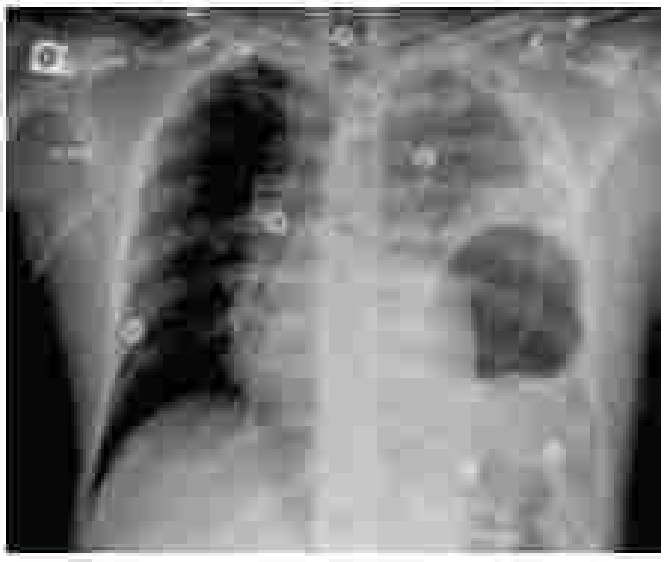

FIG. 2 Chest radiograph depicting typical findings of an acute traumatic diaphragmatic injury with a hernia containing stomach. Notice the left hemithorax, multiple rib fractures, an air-fluid level, and a curled nasogastric tube in the left side of the chest. (From Chason JK, Fox JC, Jr. Traumatic diaphragmatic injury. In: Tintinalli JE, Stapczynski JS, Ma OJ, Yealy DM, Meckler GD, Cline DM, eds. Tintinalli's Emergency Medicine: A Comprehensive Study Guide. 8th ed. New York: McGraw-Hill Education; 2016.)

With its greater sensitivity and specificity, computed tomography (CT) scan may detect discontinuity of the diaphragm or a wound tract extending up to a hemidiaphragm, but conclusive evidence includes intrathoracic abdominal contents (Fig. 4). CT has a greater sensitivity for blunt trauma, where injuries tend to be larger, and is less helpful after penetrating mechanisms, where diaphragmatic defects are small and acute herniation is rare. Penetrating TDIs also present a spectrum of radiographic findings distinct from those in blunt trauma, with contiguous injury and transdiaphragmatic trajectory acting as best predictors. Diaphragmatic discontinuity, thickening, elevation, or segmental nonvisualization and intrathoracic herniation of abdominal viscera are strong predictors of blunt diaphragmatic rupture.

Surgery remains the gold standard for diagnosing an injury to the diaphragm. Diagnostic laparoscopy is the procedure of choice for assessing the diaphragm in hemodynamically stable patients who lack a clear indication for laparotomy. Laparoscopy provides excellent visual access as well as access for repair to areas that can be difficult to see and reach through standard laparotomy. However, during peritoneal insufflation, the surgeon must be cautious about introducing air into the pleural cavity and subsequently creating a tension pneumothorax. For this reason, in draping such a patient for laparoscopy, the chest should be prepared in case a thoracostomy tube needs to be inserted if not already present at time of laparoscopy. Given the risk for creating a tension pneumothorax, as pneumoperitoneum is introduced, it is imperative to monitor airway pressures, oxygen saturation, and tidal CO_2 and mean arterial pressure. Until the abdominal surface of the diaphragm is evaluated and deemed free of injury, insufflation pressures should not exceed 10 to 12 mm Hg.

With a strategy of low pressure pneumoperitoneum, careful attention to ventilatory parameters, and early diaphragmatic inspection, an iatrogenic tension pneumothorax may be considered a rare event.

As with laparoscopy, thoracoscopy may be used for the diagnosis of TDI and is an exceedingly sensitive modality. Diaphragm repair through the chest can be accomplished without concern for creating a tension pneumothorax. However, because the diaphragm is rarely injured in isolation, an intraperitoneal approach may be preferred in patients who would benefit from operative assessment for intraabdominal injuries. Whereas most pleural cavity injuries may be safely managed with a thoracostomy tube, a perforated intraabdominal hollow viscus or hemorrhage emanating from a solid viscus injury requires a timely diagnosis and expeditious surgical intervention.

Before the advent of minimally invasive scoping techniques, TDIs were most commonly detected at laparotomy. This remains the current mode of diagnosis in patients who require immediate abdominal exploration for hemodynamic instability or peritonitis. In patients who are acutely hemorrhaging from a chest injury with an indication for thoracotomy, an injured diaphragm may be detected and addressed from the chest as well. Concomitant abdominal injuries may be ruled out via an additional laparotomy or, in rare selected cases, by a transdiaphragmatic approach to the upper abdomen.

In patients with chronic diaphragmatic hernias related to trauma, a proper history and physical examination may be suggestive. These missed injuries often present with alimentary tract obstruction, incarceration, or strangulation. They are almost always found on the left hemidiaphragm and the diagnosis can usually be made with plain radiography, although CT scan is frequently used to better delineate size, location, and visceral involvement.

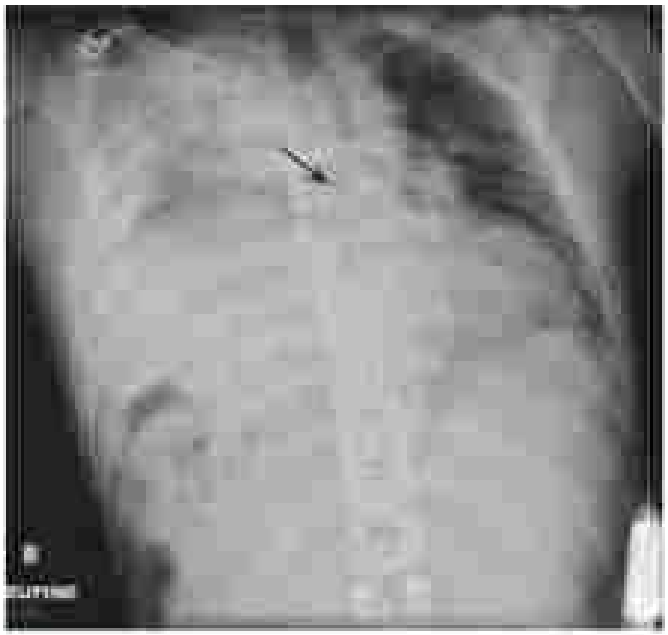

FIG. 3 Portable chest radiograph. Note complete opacification of the right hemithorax with only partial aeration of the anterior segment of the right upper lobe. There is collapse of the bronchus intermedius (arrow) and associated collapse of the right lower lobe. There is shift of the mediastinum and trachea to the left. Fluid is present along the right upper pleural surface, consistent with a hemothorax. The right hemidiaphragm is markedly elevated with indistinct margins. Although edema has secondary to a collapsed lung also caused elevation of the diaphragm, presence of contralateral mediastinal shift suggests a space occupying mass and favors diaphragmatic rupture. *From Coward S, Allen A, ... Smith M. Right sub-diaphragmatic injury resulting from blunt trauma. J Emerg ... Med. 2008;34(1):65–67.*)

MANAGEMENT

Acute Phase

TDIs are graded on a scale of I to V in the American Association for the Surgery of Trauma ... Injury Scale, developed in 1994 (Table 1).

Higher grade TDIs are typically from blunt trauma whereas lower grade injuries are from penetrating injuries. The treatment for an injured diaphragm is, for the most part, operative whether an injury is acute or chronic. Irrespective of localization, all acute diaphragmatic injuries encountered at surgery should always be repaired. Controversy exists regarding right sided injuries when there are no indications for operative intervention. Although most would agree that for large defects or for lower lateral or lower anterior wounds, which afford less protection from herniation by the liver, repair should be pursued. Regardless of mechanism, acute injuries can usually be repaired primarily. Repair may be achieved via laparoscopy/laparotomy or via thoracoscopy/thoracotomy, depending on the patient's hemodynamic stability and associated injuries and the surgeon's experience with

FIG. 4 (A) Chest radiograph followed by (B) computed tomography scan of the chest, abdomen, and pelvis showed a left-sided diaphragmatic hernia with stomach, pancreas, omentum, colon, and small bowel within the left hemithorax. *From Pikoulis E, Petsas ..., Spyrti ..., and Skiadas K. Late ... of chronic traumatic "slap" syndrome: Report of ... cases and review of the ... literature. Surg Case Rep. 2015;2:15. doi: ...*)

TABLE 1 American Association for the Surgery of Trauma Diaphragmatic Injury Grading Scale

Grade	Description
I	Contusion
II	Laceration <2 cm
III	Laceration 2–10 cm
IV	Laceration >10 cm with tissue loss <25 cm²
V	Laceration with tissue loss >25 cm²

Advance one grade for bilateral injuries.

FIG. 5 Laparoscopic port placement for repair of diaphragmatic injury. Supraumbilical trocar used to insert the laparoscopic 30-degree camera. (From Lane J, Asensio JAM. Diaphragm injury. In: Cornwell EE, Asensio JA, Whitman E, eds. Atlas of Surgical Techniques in Trauma. 1st ed. Cambridge, UK: Cambridge University Press; 2015:216.)

minimally invasive technique (Figs. 5 and 6). Laparoscopic technique continues to gain traction for definitive exploration and repair, especially for penetrating acute diaphragmatic defects with low associated injuries. As with all surgical procedures, full exposure of the diaphragm is essential for repair. The upper abdominal viscera must be retracted in a way that allows for the entire intraperitoneal diaphragmatic surface to be evaluated, which may be difficult especially posteriorly on the left. Positioning the operating room table in reverse Trendelenburg with the right side down is indicated, as is the use of a 30-degree scope for improved visualization. If a nonpenetrating injury to the diaphragm is found, a chest tube should be placed not only to prevent a potential tension pneumothorax but also because a lung injury cannot be excluded.

When there is a large diaphragmatic defect, the ipsilateral lower lung lobe may be inspected for injury. If injury to the lung cannot be ruled out, it may be efficacious to copiously lavage the pleural cavity with sterile saline if there is a concomitant full-thickness bowel injury to reduce the incidence of an empyema.

Repair of the injured diaphragm involves debridement of devitalized tissues (Fig. 7). This is especially important for firearm injuries, where inadequate debridement may play a role in the breakdown of the repair. Nonabsorbable sutures should be placed and tied either intra- or extracorporeally. The type of repair—interrupted versus running, one layer versus two—has not been shown to matter in terms of recurrence. An interrupted suture repair may include a simple, figure of 8, or horizontal mattress technique (Figs. 8 and 9). Running repairs are often performed in a simple, locked fashion by grasping the lacerated edges with an Allis or Babcock clamp. Zero or No. 1 nonabsorbable suture material (e.g., polypropylene) is preferred. Most surgeons repair the diaphragm in a single layer, aiming for an airtight closure.

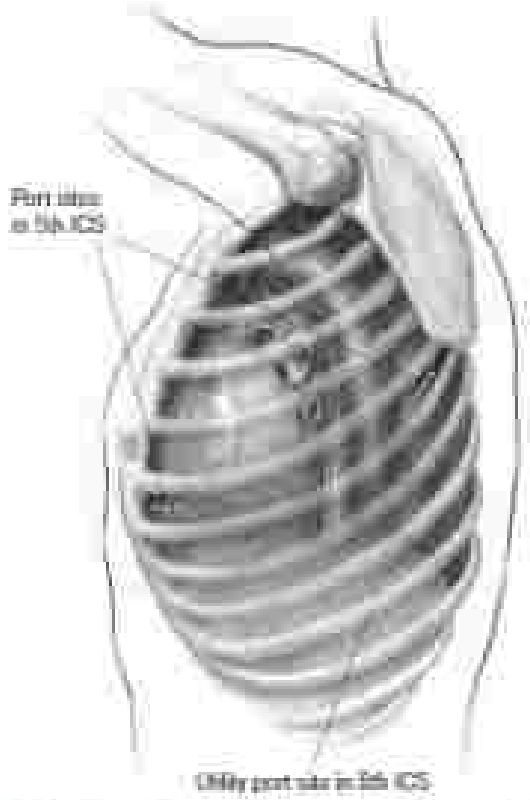

FIG. 6 Video-assisted thoracoscopic surgery port placement for repair of diaphragmatic injury. IC, intercostal space. (From Blackmon S, Schipper P. Video-assisted thoracoscopic surgery diaphragm plication. In: Shah A, Nason K, Cardoso R, Onaitis M, eds. Atlas of Thoracic Surgery. Philadelphia, PA: Elsevier; 2018:e1–e4.)

FIG. 7 Diaphragmatic defect of 4 × 3 cm seen after reduction of hernia contents showing ragged margins all around. (From Gupta G, Mandal D. Traumatic diaphragmatic hernia presenting late with nonspecific symptoms. Ann Int Surg. 2013;3:120–123.)

FIG. 8 Posterolateral diaphragmatic defect closed with interrupted polypropylene sutures. (From Dutta C, Morelli E. Traumatic diaphragmatic hernia presenting late with nonspecific symptoms. Arch Int Surg. 2011;1:108–109.)

FIG. 9 Laparoscopic repair of injured diaphragm using interrupted horizontal mattress sutures. (From Parker LB, Lange VC, Stone JE. Traumatic injury of the diaphragm. In Mattox KL, et al. Trauma. 9th ed. Philadelphia: McGraw-Hill Education; 2017:354.)

An experienced laparoscopist may perform the repair and address associated injuries without necessarily converting to an open procedure in the hemodynamically stable patient. If the repair is deemed technically difficult or the exploration deemed suboptimal, converting to laparotomy is indicated. Additionally, any instability should prompt consideration for conversion to laparotomy. In preparation for laparotomy, the supine patient is prepared and draped as for any trauma laparotomy. Principles of operative trauma are followed: packing, hemorrhage control, and minimization of contamination. Diaphragmatic evaluation should be thorough, especially for penetrating trauma. On the right, the *round ligament* can be clamped and ligated and the falciform ligament incised, allowing the liver to be retracted for better visualization. Division of the right triangular and coronary ligaments will allow the surgeon to mobilize the liver inferiorly and medially to expose the inferosurface of the right hemidiaphragm. On the left, the stomach and the spleen are retracted inferiorly and medially with gentle traction. Herniation through an injured diaphragm is usually readily apparent and should be immediately reduced to prevent respiratory insufficiency. Because associated injuries are likely to divert attention from an injured diaphragm intraoperatively, it is important to maintain a high index of suspicion and to thoroughly evaluate the entire undersurface on inspection and on palpation to prevent a missed injury.

Prosthetic mesh patches (Gore-Tex, Composix) and biologics (Strattice, AlloDerm) are preferred for large defects or for those where primary repair produces too much tension. Interrupted polypropylene sutures should be used to sew in the patch. In the event of an accompanying bowel injury, a nonabsorbable mesh is contraindicated and instead a biologic acellular tissue matrix such as AlloDerm or Strattice may be used. In the rare event that the diaphragm has avulsed from the chest wall, it may be reattached as a primary fashion using polypropylene sutures placed circumferentially around the ribs. Alternatively, bone suture anchors appropriately sized for rib thickness can also be used to secure the avulsed diaphragm to the chest wall.

Indications for thoracoscopic exploration remain undefined because intraabdominal organs can rarely be adequately assessed operatively without an additional laparotomy incision. However, several studies have found that for posterior and right sided TDI, thoracoscopy is a more appropriate screening tool and potentially better than laparoscopy. However, if a TDI is found, intraabdominal injury still needs to be excluded.

Chronic Phase

Surgery is indicated for chronic diaphragmatic hernias. Thoracotomy has a definite role in these patients because there is no concern for an associated intraabdominal injury. Additionally, reduction through the chest may be easier because adherent lung can make for a tedious and difficult dissection transabdominally. For the treatment of a chronic hernia, where primary approximation of the diaphragm would likely involve tension, producing suboptimal results, a mesh repair is warranted. After thoracotomy a chest tube should be used. If a laparotomy is performed, a red rubber catheter may be used to suction out air from the pleural cavity as the final stitches are tied to negate the need for a thoracostomy tube.

MORBIDITY AND MORTALITY

Patients with TDI from blunt trauma, as opposed to penetrating trauma, have higher mean injury severity scores and an increased mortality rate, primarily as a result of injuries to other organs including the brain and pelvis. As compared with left sided injuries, right sided TDI are associated with higher rates of death. Overall, mortality in patients with TDI approximates one in five. Additional morbidity may be incurred when TDIs are missed or not surgically addressed during the acute presentation; this usually presents in the form of symptomatic visceral herniation, obstruction, or strangulation.

Complications related to the diaphragm repair include a disruption of the repair, phrenic nerve injury, and peridiaphragmatic infection. Disruption of a repair is more common with large injuries or with those involving avulsion from the chest wall. Left or right phrenic nerve injuries may be caused by the diaphragmatic rupture at the time of impact or may be iatrogenic as a result of the repair. Peripheral injuries and repairs are much less likely to cause damage to main branches of the phrenic nerves. Diaphragmatic injuries just lateral to the esophageal and caval openings carry a high risk for left

and right nerve lesions, respectively, and must be repaired with the nerve distribution in mind to prevent an iatrogenic injury.

Subdiaphragmatic abscess and empyema are recognized postoperative infections and may be more common with associated hollow visceral injuries. These complications lengthen the duration of intensive care unit and hospital stay and increase morbidity and mortality. Pneumonia is also more common in patients with diaphragmatic rupture.

A missed or inadequately repaired right TDI often associated with a deep liver injury can lead to a bilateral pleural fistula. Although pigtail catheter thoracostomy and biliary stenting are often performed, they are frequently unsuccessful because negative intrapleural pressures maintain the output of the fistula. These patients often require a thoracotomy for diaphragm repair and lung decortication.

A missed TDI with subsequent herniation may lead to severe sequelae. Often in a delayed fashion, these patients may present with symptoms of bowel obstruction, sepsis secondary to strangulation and necrosis, or pulmonary insufficiency. A missed injury may result in sepsis, shock and death.

The repair of a chronic diaphragmatic hernia is more difficult than in the acute setting given the dense intrathoracic adhesions. Because the muscle edges have retracted and thinned over time and with pressure from the abdominal contents, these repairs are much more involved, routinely require mesh, and not uncommonly result in complicated hospital courses.

Management of Traumatic Liver Injury

Sandra R. DiStasio, MD, PhD, and Elliot R. Haut, MD, PhD, FACS

Although management of liver injury has evolved significantly over the past decade, including more nonoperative and interventional approaches, surgeons should still carry a healthy sense of respect for liver trauma. Treating a liver injury calls for an evidence-driven approach administered by trauma surgeons with both an experienced mind and skilled hands. It is imperative to employ the fundamentals of trauma care, sticking to a structured algorithm for initial evaluation and subsequent treatment, while maintaining a high index of suspicion for severe, lurking injuries that may not be obvious at the time of presentation. Regarding massive injury, the liver follows no rules, requiring the surgeon speed, fortitude, and teamwork to save the patient.

INITIAL EVALUATION

Trauma protocols call for a systematic approach to every patient, and those with liver injury are no exception. Evaluating the hemodynamic stability of the patient, the mechanism of injury, and findings on primary and secondary survey will guide decision making. In the unstable patient with a high index of suspicion of intraabdominal injury based on physical examination, history (i.e., high speed motor vehicle collision or gunshot to the abdomen), and rapid ultrasound evaluation, the surgeon should not hesitate to proceed with immediate operative management.

In the hemodynamically stable patient or one who responds well to initial fluid resuscitation, imaging is helpful. An early chest radiograph can inform the team about the severity of the mechanism (Fig. 1). For instance, after a motor vehicle collision, multiple rib fractures to the right side of the chest raise suspicion for liver injury. The focused assessment with sonography for trauma (FAST) examination, although convenient, is truly inadequate in evaluating for the presence and severity of liver trauma. A positive FAST with intraabdominal blood is helpful in the hypotensive trauma patient, driving immediate surgical intervention. However, a normal FAST should not put the team entirely at ease. The absence of fluid in Morrison's pouch does not rule out a liver injury and should not prevent the trauma team from proceeding with resuscitation or to computed tomography (CT) scan for a more thorough evaluation of possible liver injury (Fig. 2A). When obtaining a CT, it is imperative to include intravenous contrast to evaluate explicitly for arterial extravasation (Fig. 2B), which could be treated with interventional angioembolization. The most frequently used liver injury grading scale, developed by the American Association for the Surgery of Trauma, can help guide management based on the anatomic grade of injury (Table 1).

SELECTIVE NONOPERATIVE MANAGEMENT

Blunt Injury

Most blunt liver trauma can be managed nonoperatively with a combination of serial abdominal examinations and serial hemoglobin checks. Guidance from the Eastern Association for the Surgery of Trauma (EAST) and other groups suggest that nonoperative management is appropriate for hemodynamically stable patients, regardless of injury grade, age, neurologic status, or presence of other concomitant but nonoperative injuries. Historically, anecdotes suggested bed rest 1 day longer than the grade of injury to decrease the risk of further bleeding; however, newer data have shown earlier ambulation to be safe. In a recent series of more than 30,000 trauma admissions, only 1,412 patients had liver injuries, and less than 0.5% of these were grade IV or higher, and few even high grade injuries required operative intervention. Overall, compared with historical controls, studies show that a nonoperative approach and active monitoring have resulted in decreased utilization of transfusion and improved survival. EAST guidelines remind us that selective nonoperative management is appropriate only in environments where close clinical monitoring is feasible and where an operating room would be available for urgent laparotomy as needed.

Penetrating Injury

For nearly a century, surgical dogma has suggested that any penetrating injury violating the peritoneum merits operative exploration. However, in isolated penetrating injury to the liver, there are certain cases in which a selective, nonoperative approach can be appropriate.

and right nerve lesions, respectively, and must be repaired with the nerve distribution in mind to prevent an iatrogenic injury.

Subdiaphragmatic abscess and empyema are recognized postoperative infections and may be more common with associated hollow visceral injuries. These complications lengthen the duration of intensive care unit and hospital stay and increase morbidity and mortality. Pneumonia is also more common in patients with diaphragmatic rupture.

A missed or inadequately repaired right TDI often associated with a deep liver injury can lead to a bilipleural fistula. Although pigtail lobotomy and biliary stenting are often performed, they are frequently unsuccessful because negative intrapleural pressures maintain the output of the fistula. These patients often require a thoracotomy for diaphragm repair and lung decortication.

A missed TDI with subsequent herniation may lead to severe sequelae. Often in a delayed fashion, these patients may present with symptoms of bowel obstruction, septic secondary to strangulation and necrosis, or pulmonary insufficiency. A missed injury may result in sepsis, shock and death.

The repair of a chronic diaphragmatic hernia is more difficult than in the acute setting given the dense intrathoracic adhesions. Because the muscle edges have retracted and thinned over time and with pressure from the

Management of Traumatic Liver Injury

Sandra R. DiStasio, MD, PhD, and Elliott R. Haut, MD, PhD, FACS

Although management of liver injury has evolved significantly over the past decade, including more nonoperative and interventional approaches, surgeons should still carry a healthy sense of respect for liver trauma. Treating a liver injury calls for an evidence-driven approach administered by trauma surgeons with both an experienced mind and skilled hands. It is imperative to employ the fundamentals of trauma care, sticking to a structured algorithm for initial evaluation and subsequent treatment, while maintaining a high index of suspicion for severe, lurking injuries that may not be obvious at the time of presentation. Regarding massive injury, the liver follows no rules, requiring the utmost speed, fortitude, and teamwork to save the patient.

INITIAL EVALUATION

Trauma protocols call for a systematic approach to every patient, and those with liver injury are no exception. Evaluating the hemodynamic stability of the patient, the mechanism of injury, and findings on primary and secondary survey will guide decision making. In the unstable patient with a high index of suspicion of intraabdominal injury based on physical examination, history (i.e., high speed motor vehicle collision or gunshot to the abdomen), and rapid ultrasound evaluation, the surgeon should not hesitate to proceed with immediate operative management.

In the hemodynamically stable patient or one who responds well to initial fluid resuscitation, imaging is helpful. An early chest radiograph can inform the team about the severity of the mechanism (Fig. 1). For instance, after a motor vehicle collision, multiple rib fractures to the right side of the chest raise suspicion for liver injury. The focused assessment with sonography for trauma (FAST) examination, although convenient, is truly inadequate in evaluating for the presence and severity of liver trauma. A positive FAST with intraabdominal blood is helpful in the hypotensive trauma patient, driving immediate surgical intervention. However, a normal FAST should not put the team entirely at ease. The absence of fluid in Morison's pouch does not rule out a liver injury and should not prevent the trauma team from proceeding with resuscitation or to computed tomography (CT) scan for a more thorough evaluation of possible liver injury (Fig. 2A). When obtaining a CT, it is imperative to include intravenous contrast to evaluate explicitly for arterial extravasation (Fig. 2B), which could be treated with interventional angioembolization. The most frequently used liver injury grading scale, developed by the American Association for the Surgery of Trauma, can help guide management based on the anatomic grade of injury (Table 1).

SELECTIVE NONOPERATIVE MANAGEMENT

Blunt Injury

Most blunt liver trauma can be managed nonoperatively with a combination of serial abdominal examinations and serial hemoglobin checks. Guidance from the Eastern Association for the Surgery of Trauma (EAST) and other groups suggest that nonoperative management is appropriate for hemodynamically stable patients, regardless of injury grade, age, neurologic status, or presence of other concomitant but nonoperative injuries. Theoretically, anecdotes suggested bed rest 1 day longer than the grade of injury to decrease the risk of further bleeding; however, newer data have shown earlier ambulation to be safe. In a recent series of more than 30,000 trauma admissions, only 1,412 patients had liver injuries, and less than 0.5% of these were grade IV or higher, and few even high grade injuries required operative intervention. Overall, compared with historical controls, studies show that a nonoperative approach and active monitoring have resulted in decreased utilization of transfusion and improved survival. EAST guidelines remind us that selective nonoperative management is appropriate only in environments where close clinical monitoring is feasible and where an operating room would be available for urgent laparotomy as needed.

Penetrating Injury

For nearly a century, surgical dogma has suggested that any penetrating injury violating the peritoneum merits operative exploration. However, in isolated penetrating injury to the liver, there are certain cases in which a selective, nonoperative approach can be appropriate.

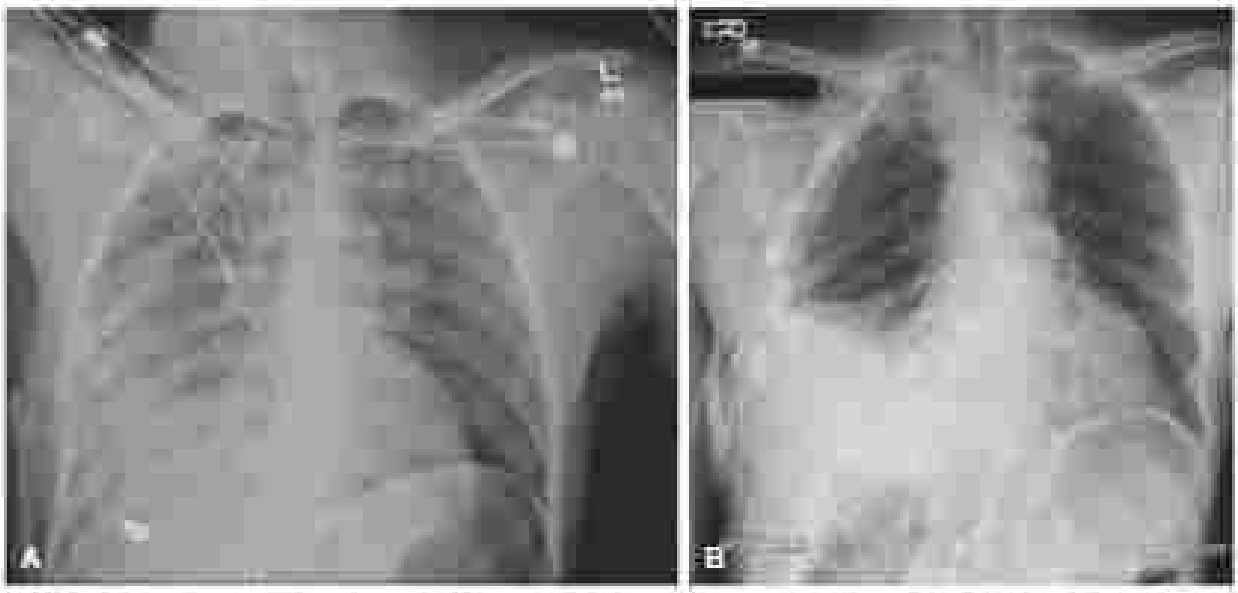

FIG. 1 (A) Chest radiograph to detect liver injury after gunshot wound to right thoracoabdominal region. (B) Chest radiograph to detect liver injury after blunt trauma to right thoracoabdominal region with multiple rib fractures and flail chest.

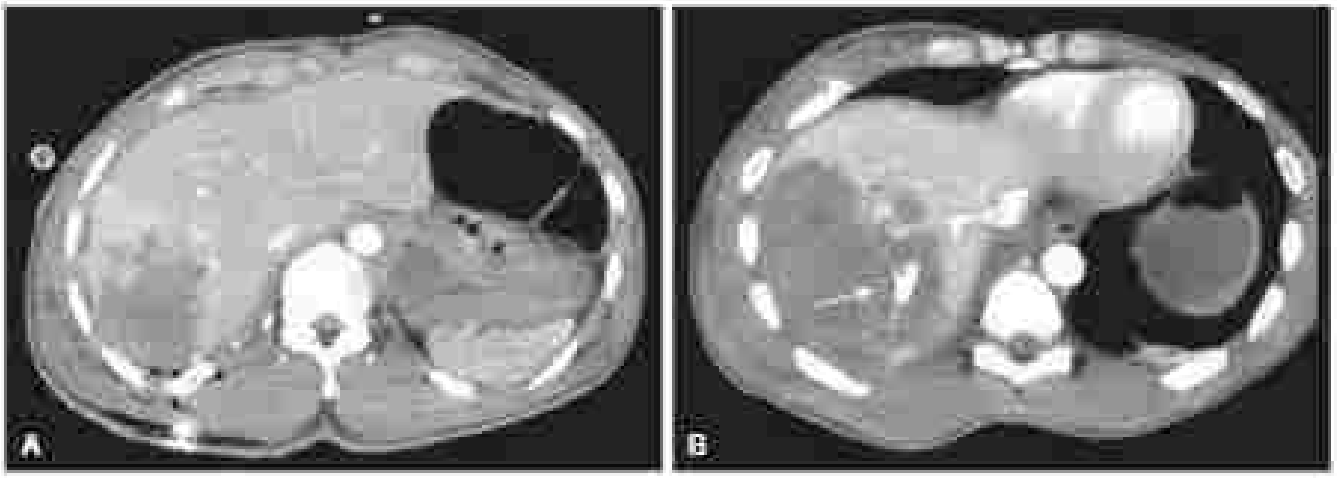

FIG. 2 (A) Computed tomography (CT) image demonstrating liver injury with bullet posteriorly below skin. (B) Gunshot wound to liver with active arterial extravasation on CT scan (arrow).

TABLE 1 American Association for the Surgery of Trauma Liver Injury Scale

Grade	Injury	Description
I	Hematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, <1 cm parenchymal depth
II	Hematoma	Subcapsular, 10%–50% surface area Intraparenchymal, <10 cm diameter
	Laceration	1–3 cm parenchymal depth, <10 cm length
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma
	Laceration	>3 cm parenchymal depth
IV	Laceration	Parenchymal disruption involving 25%–75% of hepatic lobe or 1–3 Couinaud segments in a single lobe
V	Laceration	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud segments within a single lobe
	Vascular	Juxtahepatic venous injuries (i.e., retrohepatic vena cava/central major hepatic veins)
VI	Vascular	Hepatic avulsion

From Moore EE, Cogbill TH, Jurkovich GJ, et al. Organ injury scaling: spleen and liver (1994 revision). J Trauma. 1995;38(3):323–324.

This approach has gained increasing traction in the last decade. EAST guidelines suggest that hemodynamically stable patients with penetrating trauma, particularly stab wounds to the right upper quadrant, who have no diffuse abdominal tenderness and who can provide a reliable physical examination do not necessarily require a laparotomy and can be closely observed. When undertaking this approach, we recommend the liberal, routine use of CT scan to help ensure the right patients get appropriate interventions in a timely fashion, even those for whom the physical examination results are normal. It should be noted that this management should be used selectively, and only in stable patients who can be monitored closely for development of subtle clinical changes or rapid deterioration.

INTERVENTIONAL TECHNIQUES TO AVOID THE OPERATING ROOM

Interventional radiology techniques are indispensable in the treatment of trauma to many organs including the liver and are important to have available at any trauma center. In a stable or transiently responsive patient with clear, active hemorrhage on CT, transarterial angioembolization can stop the bleeding and prevent the need for open operative management (Fig. 1). In patients undergoing embolization for other indications such as pelvic hemorrhage or splenic hemorrhage, relatively small bleeds from concomitant liver injury can be managed simultaneously. Angiography should be first-line therapy in cases where hemoglobin drops but the patient remains hemodynamically stable. Not all trauma centers have interventional radiology available at all hours, and this availability may drive decisions about which patients require transfer to higher levels of care.

Although interventional techniques are most often performed by interventional radiologists, some centers have vascular or trauma surgeons with this skill set. At some institutions, hybrid interventional operating room suites can accommodate intraoperative angioembolization. This would allow for operative exploration, injury identification, treatment of concomitant injuries, and immediate intraoperative angioembolization after packing, even with an open abdomen, all in the same trip to the main operating room.

FIG. 1 Angiographic imaging of active arterial extravasation from gunshot wound to liver (arrow).

Additionally, interventional techniques can be used in a delayed fashion for patients who have initially undergone either nonoperative or surgical management. They are frequently used to drain fluid collections, such as abscesses, hematomas, or bilomas. Other interventions include therapy targeted toward the biliary tree, via either percutaneous or endoscopic approaches, discussed later in this chapter.

OPERATIVE MANAGEMENT

For unstable patients presenting with signs of shock and a high suspicion for liver injury or intraabdominal hemorrhage, the immediate plan should be expeditious movement toward the operating room. The FAST examination can confirm hemoperitoneum and help finalize the operative plan. Although there has been a recent push toward resuscitative endovascular balloon occlusion of the aorta, it has not been adopted at all centers and is not yet in routine use. This procedure requires placing an arterial catheter into the femoral artery and advancing it above the level of injury where a balloon can be inflated to temporarily stop bleeding and allow more time for definitive repair. Although it is mostly utilized for pelvic bleeding, if placed proximally enough, it can impede liver blood flow.

In the operating room, it is of the utmost importance that the surgical, nursing, and anesthesia teams maintain excellent communication. Before starting the intervention, the anesthesia team should secure blood products and consider activating the massive transfusion protocol. The nursing team should be prepared with warming devices; operative equipment to tackle the liver bleeding, including packing materials and topical hemostatic agents; and specialized energy devices such as the argon beam, Cavitron ultrasonic surgical aspirator, and/or radiofrequency dissector (i.e., Tissuelink). In cases of major liver trauma, the primary surgeon should also anticipate complex surgical maneuvers and plan for adequate operative assistance. This may be from a nontrauma surgeon (e.g., surgical oncologist, hepatobiliary surgeon, or transplant surgeon), depending on local expertise. The patient should be prepared quickly and widely from clavicles to knees, leaving all options open including sternotomy, thoracotomy or sternotomy, which may be required for adjunctive procedures or control of the supradiaphragmatic vena cava.

Exposure is key in liver trauma. If a midline incision is chosen, it should be generous, extending to the xiphoid to allow for thorough evaluation of the liver. If high-grade liver or retrocaval injury is known or suspected, a bilateral subcostal (chevron) incision allows for excellent visualization and access to the entire liver and retrohepatic vena cava. This option is a great choice for rapid abdominal access if the patient has had prior midline incisions, allowing the team to avoid inadvertent injury to underlying bowel.

In keeping with standard trauma principles, all four quadrants should be packed, beginning with the suspected site of hemorrhage. This maneuver allows the anesthesia team time to catch up on the resuscitation and the surgical team time to evaluate the rest of the abdomen. The urge to approach the hemorrhage first must be resisted, and the landscape should be surveyed. If the packing is holding, spillage or contamination from hollow viscus injury can be addressed swiftly, with clamps, staples, or quick sutures. The surgeon should not feel compelled to definitively repair bowel injuries before evaluating the source of hemorrhage. After the rest of the abdomen has been evaluated, spillage is controlled, and the patient has been resuscitated, the surgical team should communicate their intention to approach the liver so everyone in the operating room can share their focus. If the packs are holding, having stopped the hemorrhage, the surgeon has two main choices to continue with the surgery for more definitive repair or to leave the packs in place for damage control and retreat to the intensive care unit (ICU) with an open abdomen. This damage control technique, with therapeutic packing in place, will allow the patient to be resuscitated and reverse coagulopathy, allowing the surgical team the opportunity to fight another day.

In most patients, further exploration is appropriate, starting with systematic pack removal to reveal the underlying source of hemorrhage. Hemostatic efforts should be proportional to the magnitude of injury. For minor injuries, compression alone may have solved the problem. Clots should be gently removed and the area can be further treated with superficial techniques. For small injuries, electrocautery or argon beam coagulation can be adequate.

Hepatorrhaphy requires a gentle touch and a somewhat intact liver capsule. We prefer a large absorbable suture (i.e., 0 chromic gut, 0 PDS) on a large blunt tip needle to place simple interrupted stitches, mimicking the curve of the needle, making sure to include capsule on entry and exit. The sutures must be tight enough to achieve hemostasis but not overly tight because that will pull through the tissue and cause worse bleeding. Pledgets are an option, but not necessarily required. The team should also be mindful of other, larger, more distinct injuries that may be lurking beneath the packing and should take care to perform any repair as expeditiously as possible.

For a moderate or severe injury, it is imperative to prevent an organized attack, all the while keeping in mind that managing severe liver injury may require damage control surgery maneuvers. First, inflow occlusion should be performed with a Pringle maneuver by first inserting fingers behind the portal triad and applying gentle pressure across the three structures—hepatic artery, portal vein, and common bile duct. A Rummel tourniquet or vascular clamp can be applied with an eye on the clock, intermittently loosening the device and allowing for reevaluation of the hemorrhage, venous decongestion of upstream organs (i.e., small bowel), and oxygenation of liver tissue. In addition to being therapeutic, the Pringle maneuver can be helpful to diagnose. If the Pringle does not control the hemorrhage, injury to extrahepatic venous structures such as the inferior vena cava or hepatic veins is most likely present.

The power of manual compression should not be underestimated, and if a liver injury is itself is the cause of hemorrhage, sturdy compression in combination with a Pringle maneuver can buy time for resuscitation. If therapeutic repacking is necessary, topical hemostatic gauze (i.e., QuikClot [*sic*] Medical, Wallingford, CT) can be used. These products come in different sizes and some are now approved by the US Food and Drug Administration for internal use in a damage control setting. One important caveat is that they must be removed in future procedures because they do not degrade. Other topical hemostatic agents are also available and have the benefit of not needing removal such as fibrin sealants (i.e., Evarrest, Ethicon) or oxidized cellulose (i.e., Surgicel, Johnson & Johnson, New Brunswick, NJ). If hemorrhage is under control with packing and the patient is severely physiologically deranged with the "lethal triad" of coagulopathy, hypothermia, and acidosis, damage control principles should be followed and the patient should be taken to the ICU with an open abdomen. An abdominal vacuum dressing can be applied and will augment the tamponade of packing in most cases. Data suggest that if interventional radiology resources are available, angiogram and subsequent angioembolization should be undertaken in most, if not all, of these patients. Upon return to the operating room, the field is often surprisingly dry after coagulopathy, hypothermia, and acidosis have been corrected (Fig. 4).

If a retrohepatic vena cava or hepatic vein injury is suspected, mobilization of the liver can release a valuable tamponade and result in rapid exsanguination. This is to say that mobilization should be pursued thoughtfully, not as a simple matter of course, in addition to deep right lobe or posterior liver injuries. A full mobilization and delivery of the liver toward the midline may be necessary to evaluate a deep posterior wound.

To repair deep hemorrhage, there are numerous possible techniques—which is a surefire sign that none are perfect. Selective vessel ligation is appropriate for individual large arteries or veins, but this technique is often more difficult than it sounds. Finger fracture deep into the wound should be performed, essentially extending the injury to identify and pursue actively bleeding vessels. When identified, they can be clamped and ligated with sutures. Clips are convenient and quick, but have the drawback of easily coming off in the course of operating when packs are placed or removed. After vessels are secured, packing the large defect with a pedicle of vascularized omentum can augment hemostasis of smaller vessels and help seal small biliary leaks. It is important to preserve the inflow and outflow of the omental pedicle so it does not simply break down and result in a large liver abscess. This is best done by tacking the omentum perpendicular to the greater curvature of the stomach, then tacking the omentum into the liver defect. The omentum can then be incorporated into the interrupted hepatorrhaphy sutures described previously or can be separately affixed to the liver with several loose stitches to preserve the blood flow.

FIG. 4. Intraoperative image of liver after removal of packing at reoperation. Note the packs in place superior to the liver from initial damage control laparotomy.

For a transhepatic (through and through) penetrating injury, a balloon tamponade device can be lifesaving. Using either a Blakemore tube or a homemade red rubber catheter inside a Penrose drain, the device is inserted through the tract and inflated gently with saline until tamponade is achieved (Fig. 5*). The device can be left in place in a damage control setting and reevaluated after further resuscitation or angioembolization (Fig. 5B). For all surgeons taking trauma call, we suggest attending the Advanced Trauma Operative Management course sponsored by the American College of Surgeons Committee on Trauma to provide hands-on instruction on these techniques. Being facile with all available options allows surgeons to gain rapid control of bleeding and definitively repair injuries safely and effectively.

The role of major hepatectomy in liver trauma is an ongoing debate, and there are frequent swings of the pendulum. We continue to promote nonoperative therapy as a first line treatment, reserving major hepatectomy for delayed treatment in most cases. However, in certain instances expeditious resection is the only option for hemorrhage control or to access the site to control major bleeding. If it is deemed necessary, the resection line should be marked in healthy tissue using electrocautery. Finger fracture and selective vessel ligation can be used along the line of resection using one of many available specialized devices. The quickest, safest method often continues to be finger fracture, electrocautery, and vascular staplers. Many acute care surgeons encourage elective exposure to liver surgery to gain comfort in this area of practice, allowing them to brush up on skills and learn new techniques.

In rare cases in locations with the resources immediately available, venovenous bypass has been used to buy time needed to repair major liver injuries. Exceedingly rarer cases may require complete explant, back table repair, and immediate reimplantation or liver transplantation for the most severe grade V or VI injuries. Both of these techniques are highly resource intensive and are limited by availability of machinery, highly specialized personnel, and time.

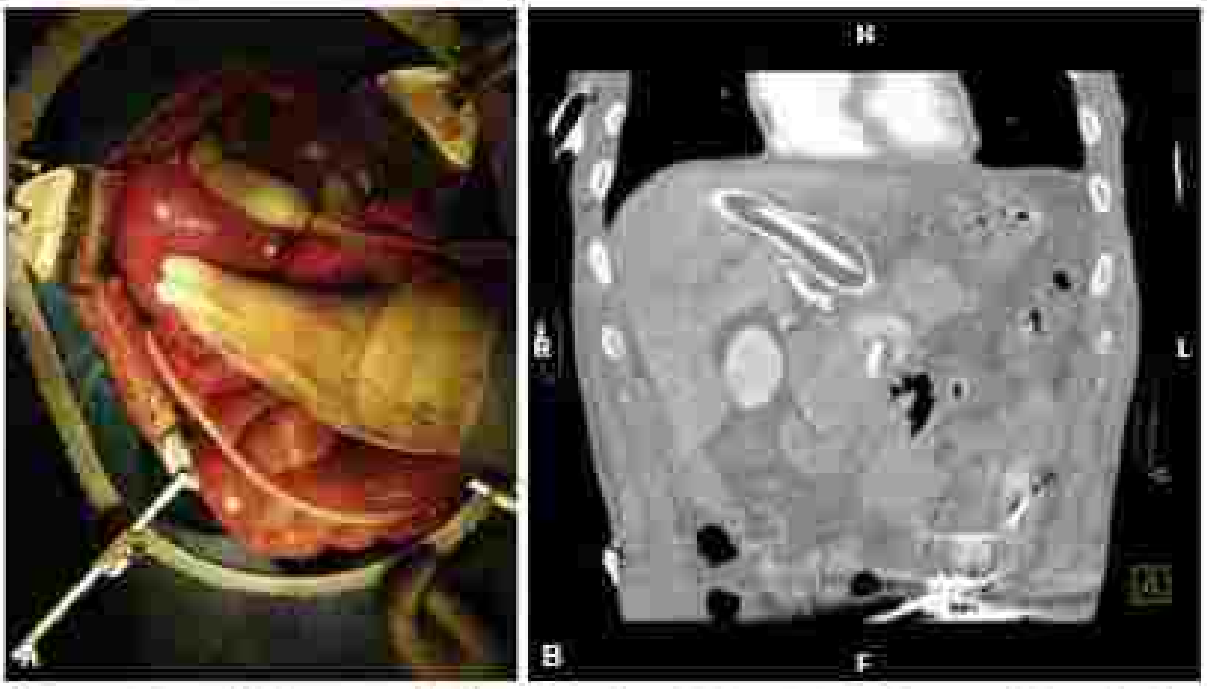

FIG. 5 (A) Intraoperative image of balloon tamponade in place across gunshot track in liver. (B) Computed tomography image of balloon tamponade in place for gunshot wound to liver.

EXTRAHEPATIC INJURY

Retrohepatic Inferior Vena Cava

Injury to the retrohepatic vena cava is every trauma surgeon's nightmare. To deal with this situation, it is imperative to proceed in a stepwise manner, but also to appreciate that outcomes after this injury are extremely poor and that, despite best efforts, the patient may not survive. The first principle to appreciate is that a contained retrohepatic hematoma does not require immediate exploration. However, the degree of containment is not always clear, and although it is easy to say in retrospect that one should not have explored the area, sometimes exploration is necessary. If a retrohepatic caval injury is suspected from the outset, mobilizing the liver is not recommended. Leaving the liver in situ will allow a natural tamponade and can aid in packing the injury. If the injury is identified after mobilization, the surgeon should restore containment with packing if possible. To gain exposure for suprahepatic control of the inferior vena cava (IVC), the laparotomy incision should be extended, often requiring a median sternotomy for control of the suprahepatic IVC within the pericardium. Total hepatic isolation, defined as control of the IVC above and below the liver and with a Pringle in place, may facilitate direct repair in a dry field. The atrocaval "Schrock" shunt is an important tool to have in the trauma surgery armamentarium, although the number of actual survivors is likely quite small. Once the vessels are isolated, a chest tube or endotracheal tube can be placed through a purse string made in the right atrium and down through the IVC, allowing flow through the tube and bypassing the injury in the IVC. To succeed, the decision to shunt must be made as *early* as possible, before the patient arrests or cannot be resuscitated. Using the shunt is only a temporizing measure to allow better visualization in a dry surgical field and allow attempts at hepatic vein or vena cava repair.

Extrahepatic Biliary Tree

The biliary tree is often an afterthought in most major liver trauma surgery or damage control operations. Patients will see the inconvenience of bile leaking, as opposed to bleeding, but the long-term outcomes can certainly be affected by thoughtful management of biliary injuries. In the moment, a quick whipstitch of an injured gallbladder is adequate to gain control of spillage and to move forward with the rest of a needed repair to the liver. In that case, a subsequent cholecystectomy is warranted. A major common bile duct injury can be clipped or controlled and drained externally to facilitate damage control, allowing reconstruction in the best possible circumstances. Placement of a choledochostomy tube can also allow control of biliary drainage if the downstream flow of the common bile duct is disrupted. In the most dire of circumstances, if the duct cannot be located, a drain can be left in Morison's pouch until the return operation. When it is time to repair a biliary injury, a T tube may be sufficient, for instance, in a clean stab wound injury. In larger more complex injuries, a Roux-en-Y hepaticojejunostomy is recommended for definitive reconstruction. Delayed workup with magnetic resonance cholangiopancreatography can provide more anatomic definition of the site and severity of injury. Endoscopic retrograde cholangiopancreatography (ERCP) or interventional radiology approaches can be considered for treatment if leaks are identified (Fig. 6). Definitive treatment may include long-term stent placement to allow the injury to heal with or without external biliary drainage via percutaneous tube.

COMPLICATIONS

Because the liver is such a highly vascular organ, traumatic injury to the liver carries risks of delayed venous or arterial bleeding. Teams should have a high suspicion of rebleed, particularly in the setting of new-onset pain, hypotension, tachycardia, change in drain output, or gastrointestinal bleeding. Arterial pseudoaneurysm can be a life-threatening complication that may not be recognized until it results in a massive bleed, even weeks or months after the original insult. Clinically evident gastrointestinal bleeding can be caused by a pseudoaneurysm bleeding into the biliary tree. Any small, unstable bleed, whether from a drain or gastrointestinal tract, should be investigated as possible hemobilia. The diagnosis can be confirmed on CT angiography and should be managed with interventional radiology as the first step.

After surgical repair or embolization of high grade liver injury, the liver frequently has some necrosis. Although it can be sterile, it

FIG. 6 Endoscopic retrograde cholangiopancreatography after gunshot to liver with resulting intrahepatic bile leak (arrow).

can become secondarily infected, particularly in patients with concomitant gastrointestinal injury or after biliary instrumentation during ERCP, which can seed the necrotic area with enteric organisms. Infected hematomas or other abscesses can be identified on CT scan and are best managed with percutaneous drainage as a first step, with surgical management only occasionally being needed.

Delayed biliary complications such as bile leak may require management as described earlier using combinations of surgical, interventional radiology, and/or advanced therapeutic endoscopic techniques.

CONCLUSION

Treatment of traumatic liver injury encompasses the spectrum from nonoperative watchful waiting with short hospital stay to massive open repair requiring damage control principles. In hemodynamically stable patients, selective nonoperative management is the treatment modality of choice but requires close monitoring and frequent reevaluations. For stable patients or those who are transiently responsive with arterial extravasation on CT, interventional angioembolization can provide excellent hemostasis. Hemodynamic instability and peritonitis necessitate immediate operative intervention. Surgeons should be encouraged to ask for assistance as needed, using any and all tools at their disposal to gain control of the field in an expeditious manner.

Pancreatic and Duodenal Injuries

Faris K. Azar, MD, Rachel L. Cheron, MD, and Joseph A. Salcedo, MD, MPH, FACS

Injuries to the pancreas and duodenum are challenging to diagnose and surgically manage. The first description of a duodenal injury was in 1814 by Larrey in France. Later in 1827, Travers described the first pancreatic injury in England. Although 200 years of surgical advancement have passed, these injuries continue to be associated with high morbidity and mortality. They remain difficult to manage because of their complex relationship with neighboring organs and vascular structures. A high index of suspicion must be maintained because delayed recognition of duodenal and pancreatic injuries results in increased morbidity and mortality. Early mortality in both injuries is a result of concomitant vascular trauma, whereas late mortality is typically related to infectious complications.

DUODENAL INJURIES

Outcomes

Although duodenal injuries are not common, they are associated with high morbidity and mortality. Overall mortality of patients with duodenal injuries ranges from 12% to 60%. Penetrating injuries are associated with higher mortality as compared with blunt injuries (25% vs 12%, respectively). Of those patients with delayed mortality, one third of the deaths are secondary to the duodenal injury itself.

Diagnosis

Early recognition is paramount in managing duodenal injuries to improve outcomes. The delayed identification of duodenal injuries beyond 24 hours is not uncommon and has even been described to occur in up to 20% of patients with duodenal injuries. Additionally, mortality rates of patients with delayed operative management beyond 24 hours are 40% compared with 10% of patients who undergo immediate surgical intervention.

The mechanism and pattern of injury should be considered when developing the differential of possible injuries. Blunt force trauma to the epigastrium from objects like seatbelts, handlebars, or steering wheels can result in injuries to the duodenum or pancreas, given their location deep to the abdominal wall against the spine.

A plain radiograph can reveal a right psoas stripe indicating retroperitoneal air, which signifies a duodenal injury, but this is rarely seen. Because early recognition is paramount, the fastest way to detect an injury is by computed tomography (CT) or operative exploration. Although CT scan has been shown to be the best radiologic method for early diagnosis, it is still associated with a high missed injury rate—reported as high as 22% in blunt injury. In patients with duodenal injuries identified beyond 24 hours, most of these patients actually have subtle findings on admission CT scan indicating the presence of injury. Although the use of oral and intravenous

FIG. 6 Endoscopic retrograde cholangiopancreatography after gunshot to liver with resulting intrahepatic bile leak (arrow).

can become secondarily infected, particularly in patients with concomitant gastrointestinal injury or after biliary instrumentation during ERCP, which can seed the necrotic area with enteric organisms. Infected hematomas or other abscesses can be identified on CT scan and are best managed with percutaneous drainage as a first step, with surgical management only occasionally being needed.

Delayed biliary complications such as bile leak may require management as described earlier using combinations of surgical, interventional radiology, and/or advanced therapeutic endoscopic techniques.

CONCLUSION

Treatment of traumatic liver injury encompasses the spectrum from nonoperative watchful waiting with short hospital stay to massive open repair requiring damage control principles. In hemodynamically stable patients, selective nonoperative management is the treatment modality of choice but requires close monitoring and frequent reevaluations. For stable patients or those who are transiently responsive with arterial intravasation on CT, interventional angioembolization can provide excellent hemostasis. Hemodynamic instability and peritonitis necessitate immediate operative intervention. Surgeons should be encouraged to ask for assistance as needed, using any and all tools at their disposal to gain control of the field in an expeditious manner.

Pancreatic and Duodenal Injuries

Faris K. Azar, MD, Rachel L. Chevron, MD, and Joseph V. Sakran, MD, MPH, MPA

Injuries to the pancreas and duodenum are challenging to diagnose and surgically manage. The first description of a duodenal injury was in 1814 by Larrey in France. Later in 1827, Travers described the first pancreatic injury in England. Although 200 years of surgical advancement have passed, these injuries continue to be associated with high morbidity and mortality. They remain difficult to manage because of their complex relationship with neighboring organs and vascular structures. A high index of suspicion must be maintained because delayed recognition of duodenal and pancreatic injuries results in increased morbidity and mortality. Early mortality in both injuries is a result of concomitant vascular trauma, whereas late mortality is typically related to infectious complications.

DUODENAL INJURIES

Outcomes

Although duodenal injuries are not common, they are associated with high morbidity and mortality. Overall mortality of patients with duodenal injuries ranges from 12% to 40%. Penetrating injuries are associated with higher mortality as compared with blunt injuries (25% vs 12%, respectively). Of those patients with delayed mortality, one third of the deaths are secondary to the duodenal injury itself.

Diagnosis

Early recognition is paramount in managing duodenal injuries to improve outcomes. The delayed identification of duodenal injuries beyond 24 hours is not uncommon and has even been described to occur in up to 20% of patients with duodenal injuries. Additionally, mortality rates of patients with delayed operative management beyond 24 hours are 40% compared with 10% of patients who undergo immediate surgical intervention.

The mechanism and pattern of injury should be considered when developing the differential of possible injuries. Blunt force trauma to the epigastrium from objects like seatbelts, handlebars, or steering wheels can result in injuries to the duodenum or pancreas, given their location deep to the abdominal wall against the spine.

A plain radiograph can reveal a right psoas stripe indicating retroperitoneal air, which signifies a duodenal injury, but this is rarely seen. Because early recognition is paramount, the fastest way to detect an injury is by computed tomography (CT) or operative exploration. Although CT scan has been shown to be the best radiologic method for early diagnosis, it is still associated with a high missed injury rate—reported as high as 22% in blunt injury. In patients with duodenal injuries identified beyond 24 hours, most of these patients actually have subtle findings on admission CT scan indicating the presence of injury. Although the use of oral and intravenous

contrast is the best diagnostic test for duodenal injury, the sensitivity and specificity of noncontrast CT scans has recently been compared favorably to blunt hollow viscus injury.

Alternative diagnostic tools include upper gastrointestinal series using water soluble contrast, followed up barium contrast if the first is negative. Although this is a diagnostic option, it is not a good initial test in trauma patients. Diagnostic peritoneal lavage is also an option to identify hollow viscus injuries, but it is not a great study to isolate duodenal injuries, given that second and third portions reside in the retroperitoneum.

Surgical Exposure of the Duodenum

Operative exploration is also a diagnostic tool to identify duodenal injuries. During exploration, retroperitoneal air, staining, hematoma, or hematoma should raise suspicion for duodenal injury. In this setting, the duodenum should be investigated and examined. Additionally, in penetrating trauma, following the trajectory of the bullet, knife, or foreign object can help determine the injury pattern.

Kocher Maneuver

The first step of the Kocher maneuver is to mobilize the right colon off the inferior aspect of the duodenal C loop by dividing the white line of Toldt. The lateral peritoneal attachments are incised and the second portion of the duodenum is rolled medially (Fig. 1). This dissection can be carried to the first and third portions of the duodenum. Doing so elevates the pancreatic head and exposes most if not the retroperitoneum.

Cattell-Braasch Maneuver

The Cattell-Braasch maneuver medially retracts the viscera to expose retroperitoneal structures. To explore the duodenum, the Kocher maneuver should be extended and a Cattell-Braasch maneuver completed. The white line of Toldt should be divided down to the cecum and up the root of the small bowel mesentery (Fig. 2). This allows for further mobilization of the duodenal C loop and pancreatic head to expose some of the retroperitoneum.

Dividing the Ligament of Treitz

Finally, to complete duodenal exposure, the fourth portion of the duodenum is exposed by dividing the ligament of Treitz. Combining all three maneuvers allows the surgeon to inspect the entirety of the duodenum, from the pylorus to the proximal jejunum.

Treatment

Duodenal Hematoma

Duodenal hematomas are usually seen in children; 50% of cases are secondary to abuse. Duodenal hematomas do not typically require operative management. About one third of patients present 48 hours from initial injury with symptoms of gastric outlet obstruction. Diagnosis can be made via CT scan or upper gastrointestinal series, although only 25% of patients have findings consistent with wall thickening, narrowed lumen, or displacement of the duodenum.

Duodenal hematomas can be managed nonoperatively with nasogastric suction and parenteral nutrition. Most do not require surgical management, but there is a 20% to 40% rate of concomitant pancreatic injury in both the pediatric and adult populations with duodenal hematomas. Therefore, exclusion of other injuries is imperative. A second upper gastrointestinal series with enteral contrast should be completed after 5 to 7 days of therapy to rule out continued obstruction or leak and ensure patency prior to resuming a diet.

If the nonoperative management fails after 2 weeks, operative intervention should be pursued to rule out stricture or pancreatic head injury. If the duodenal hematoma is identified on injury presentation intraoperatively, the duodenum should be thoroughly mobilized for exploration to rule out perforation. Once perforation is ruled out, a gastrojejunostomy or jejunostomy feeding tube should be considered.

Primary Repair

Injuries to the duodenum should be repaired primarily if possible. In cases of partial or complete duodenal transection without significant involvement and with little tissue loss, successful edge debridement and primary repair should be pursued. The goal is for a secure closure without compromise of the duodenal lumen. A two layer closure technique should be utilized if possible to include an inner layer of absorbable suture and an outer layer of silk Lembert sutures. If the second layer results in narrowing of the duodenum, a single layer closure can be buttressed with an omental pedicle. All patients with duodenal injuries should have wide drainage of the repair. Typical postoperative management includes nothing by mouth (NPO) with nasogastric drainage for 3 to 5 days and a dynamic enteral contrast study to evaluate the repair before reintroduction of a diet.

Many studies advocate for primary duodenal repair, even in grade III, IV, and V duodenal injuries (Table 1). No difference in morbidity, mortality, or length of stay is seen in patients repaired with duodenorrhaphy or resection with primary anastomosis when compared with pyloric exclusion. However, in cases of multiple duodenal injuries or those concomitant with pancreatic injuries, we prefer a more durable procedure with intraluminal drainage or enteric diversion to allow for healing.

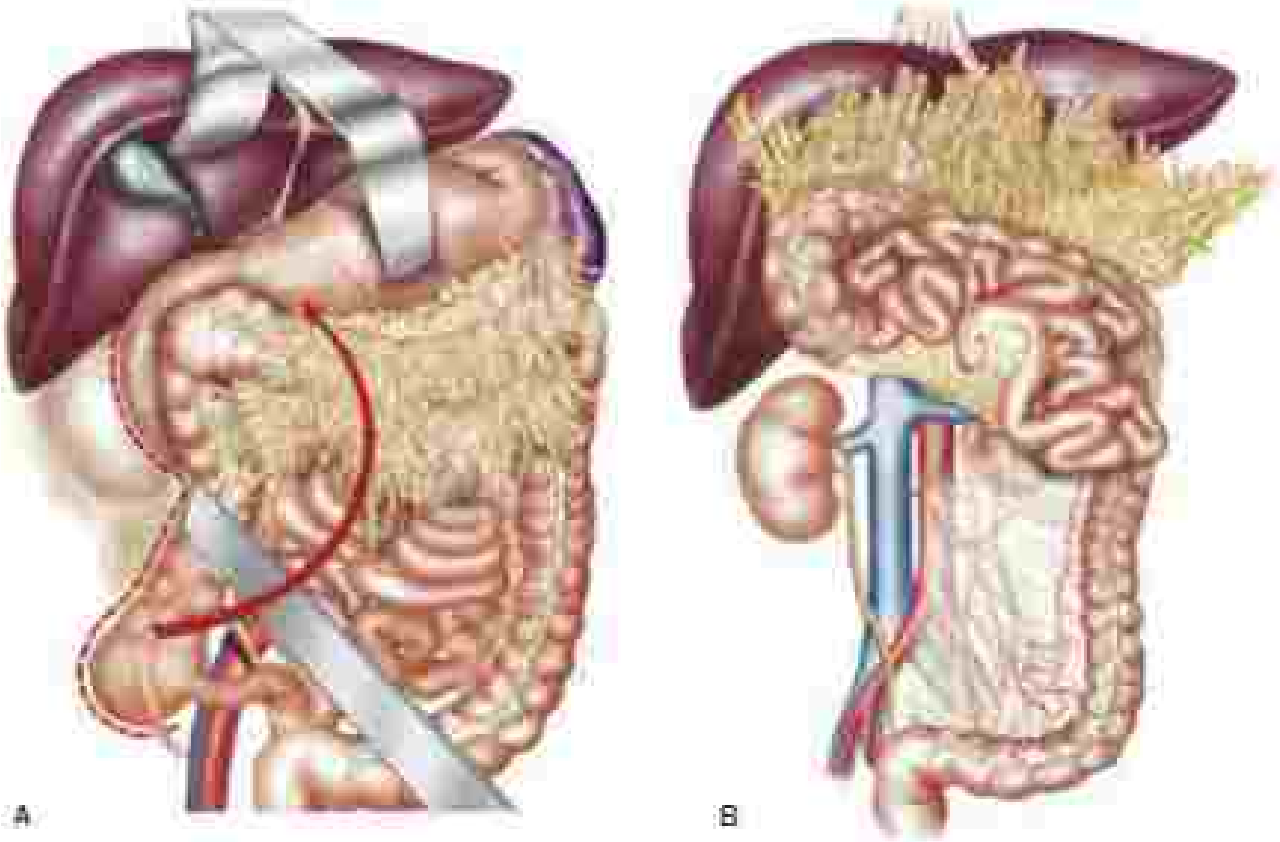

FIG. 2 Cattell-Braasch maneuver. Division of the lateral peritoneal attachments with extension up the root of the mesentery (A) and medial visceral rotation (B). (From Voigt J, Li M. Abdominal hysterotomy or damage control laparotomy: why when and how to do it? Vasc Surg. 2005;39:484 suppl.)

TABLE 1 American Association for the Surgery of Trauma Duodenum Injury Scale

Grade*	Injury	Description
I	Hematoma Laceration	Involving single portion of duodenum Partial thickness, no perforation
II	Hematoma Laceration	Involving more than one portion Disruption <50% of circumference
III	Laceration	Disruption 50%–75% of circumference of D2 Disruption 50%–100% of circumference of D1, D3, D4
IV	Laceration	Disruption >75% of circumference of D2 Involving ampulla or distal common bile duct
V	Laceration Vascular	Massive disruption of duodenopancreatic complex Devascularization of duodenum

*Advance one grade for multiple injuries up to grade III.
D1, first portion of duodenum; D2, second portion of duodenum; D3, third portion of duodenum; D4, fourth portion of duodenum.
From Moore EE, Cogbill TH, Malangoni MA, et al. Organ injury scaling, II: pancreas, duodenum, small bowel, colon, and rectum. J Trauma. 1990; 30(11):1427–1429.

Duodenal Diverticularization

Primary repair has been proven safe and acceptable but it is not always feasible. Duodenal diverticularization was first described in 1974 by Berne et al. It involves a gastric antrectomy with an end-to-side gastrojejunostomy, biliary T-tube placement, proximal duodenostomy tube placement, closure of the duodenal injury, and wide drainage (Fig. 3). This procedure results in permanent enteral diversion. We describe this for historic reasons but do not recommend its use in the traumatically injured patient. Duodenal diverticularization subjects patients to a larger physiologic insult and is associated with both increased operative time and complications.

Pyloric Exclusion with Gastrojejunostomy

Pyloric exclusion was first described by Summers in 1904. This technique diverts enteral contents away from the duodenal repair via a loop gastrojejunostomy and a temporary anatomic diversion. Pyloric exclusion can be completed with a transverse anastomosis stapler across the distal antrum, but we favor suturing the pylorus closed with absorbable suture through a gastrotomy (Fig. 4). Stapling of the gastric mucosa will result in recanalization of the distal stomach after several weeks.

Whereas some studies have suggested improved morbidity when using the pyloric exclusion technique in complex duodenal injuries, most studies have not shown a difference in outcomes when compared with primary repair even in severely injured patients.

Roux-en-Y Duodenojejunostomy

In the setting of severe duodenal injuries that cannot be repaired primarily, we favor the use of Roux-en-Y duodenojejunostomy reconstruction. Before reconstructing the duodenum, it is important to

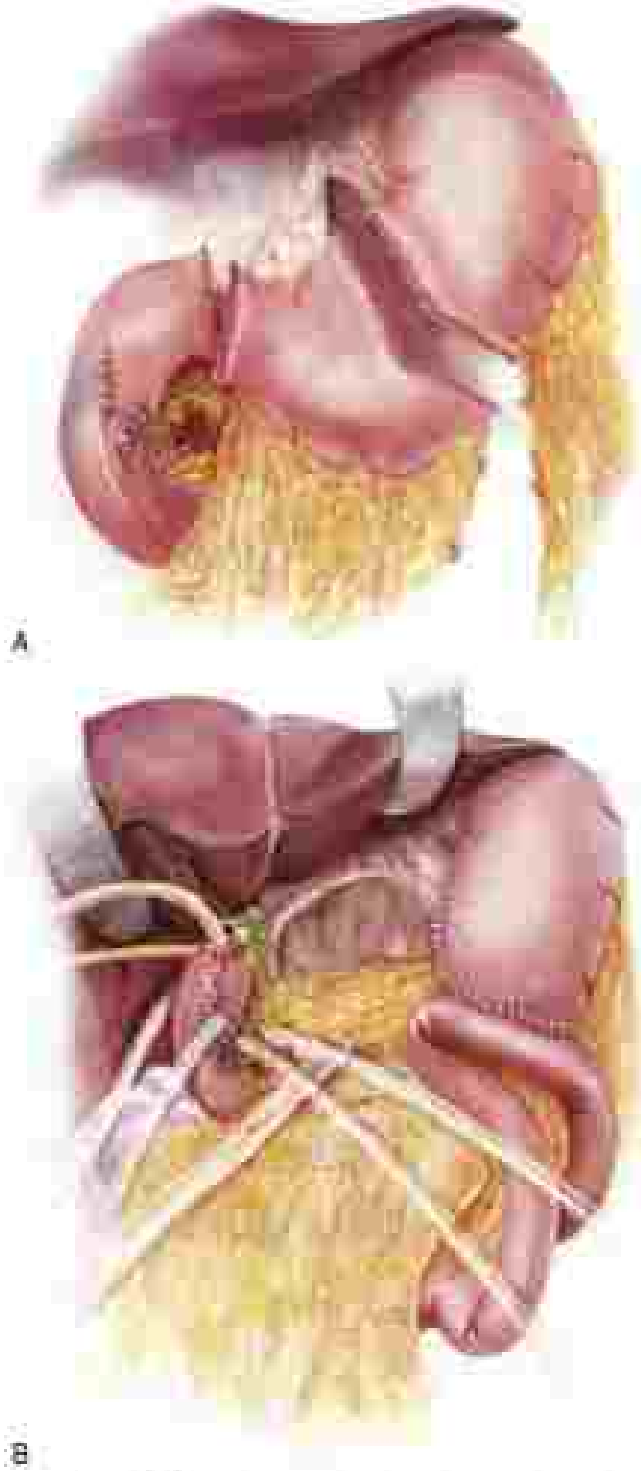

FIG. 3 Duodenal thoracostomy shown for lesions undermining. Gastric anastomosis (A) with a gastrojejunostomy, biliary T-tube, duodenostomy tube, and wide drainage (B). (Courtesy Carmine Sansone. From Cameron J, Sanfelice C. Atlas of Gastrointestinal Surgery, vol 1. 2nd ed. Shelton CT: People's Medical Publishing; 2007.)

understand the proximity of the injury and the ampulla of Vater because an enteric anastomosis impinging on unidentified ampulla could result in devastating consequences. If the ampulla cannot be visualized or identified via the duodenal injury itself, the gallbladder can be dissected off the liver bed and cannulated just above or through the cystic duct with a Fogarty catheter, which is manually guided down the common bile duct through the ampulla into the duodenum (Fig. 5).

If the ampulla is not immediately adjacent to the injury and its patency will not be compromised, a Roux-en-Y duodenojejunostomy should be fashioned. This anastomosis is ideally fixed securely in two layers in an end to side fashion (Fig. 6). However, a side to side anastomosis can also be done for injuries to the lateral aspect of the second portion of the duodenum. This repair is also favored in the setting of concomitant pancreatic injuries; primary duodenal repairs are at high risk for breakdown in the setting of pancreatic secretion.

exposure, whereas a Roux-en-Y duodenojejunostomy provides more protection. Patching a duodenal injury with jejunal serosa has also been used, but our preference is for a more durable reconstructive procedure when possible.

Intraluminal Decompression Tubes

A duodenal leak after repair is a morbid complication that surgeons should avoid. Tenuous primary duodenal repairs that are not secure enough to warrant enteric diversion can be protected with internal drainage. Reducing the flow of biliopancreatic and gastric contents across the repair allows for healing.

Direct drainage of the duodenum through the duodenal suture line via a lateral duodenostomy tube should be avoided. This method of drainage is associated with high morbidity with direct complications including development of a difficult fistula.

A "triple tube" technique for decompression is favored by many surgeons. This provides duodenal decompression with both an antegrade gastrostomy tube and a retrograde jejunostomy tube; additionally, distal feeding jejunostomy is placed. Although this may provide thorough internal drainage, the antiperistaltic direction of the retrograde jejunostomy tube can cause it to fly out of place or become a possible point of obstruction or intussusception.

Our preferred method of internal drainage involves the use of a proprietary triple-lumen Mini gastrojejunostomy tube, which alone has the same functionality as the triple tube technique. It is a rigid 18F tube with large holes above and below the pylorus that allows for effective drainage of both the stomach and duodenum. Additionally, it is proprietatic, allowing for gastric and duodenal suctioning while having the capability for enteral feeding via a long distal port (Fig. 7).

More complex injuries to the duodenum such as those that involve the ampulla or pancreas, head are sometimes not salvageable; they may necessitate reconstruction via a pancreaticoduodenectomy, which is discussed later in this chapter.

PANCREATIC INJURIES

Outcomes

Pancreatic injuries are associated with high morbidity and mortality. Overall mortality of patients with pancreatic injuries range from 9% to 34% and rates of morbidity ranging from 30% to 60%. Early mortality is often a result of massive bleeding from an associated vascular or solid organ injury. The highest mortality is in patients with severe concomitant injuries requiring damage control laparotomy.

Diagnosis

It is critical to diagnose and manage pancreatic injuries immediately because delayed diagnosis and intervention leads to increased mortality. Physical examination in the trauma identifies area may reveal contusion to the epigastric region of the abdomen with pain out of proportion to the examination. An injury mechanism including high impact to the epigastrium from handlebars or a steering wheel should alert the surgeon to this possible injury pattern. Additionally, associated injuries, such as Chance fracture, have been associated with concomitant pancreatic injuries; suspicion for injury should increase in that setting. Laboratory testing resulting in elevated amylase and lipase is specific but not sensitive for predicting pancreatic injury. Importantly these laboratory values have been found to be nondiagnostic within the first 6 hours after injury, the most critical time to establish diagnosis.

CT scan is the radiographic test of choice in trauma patients. CT scan findings consistent with pancreatic injury include parenchymal disruption, intrapancreatic or peripancreatic hematoma, fluid in the lesser sac, peripancreatic edema, thickened left anterior renal fascia, and retroperitoneal fluid. Although CT scan is the test of choice in hemodynamically stable patients, the test still fails to identify all injuries, which can result in operative delay. The multicenter EuroSTAR CT study published in 2009 identified a 13% missed injury rate and a higher mortality in the patients with missed injuries.

Other tests can be time consuming and are not typically used in the acute workup after injury. However, in the hemodynamically stable trauma patient with an equivocal CT scan and an operative indication, endoscopic retrograde cholangiopancreatography can be both diagnostic and therapeutic for a pancreatic ductal disruption. Additionally, magnetic resonance cholangiopancreatography can also assess the integrity of the pancreatic duct.

Surgical Exposure of the Pancreas

Anterior Exposure

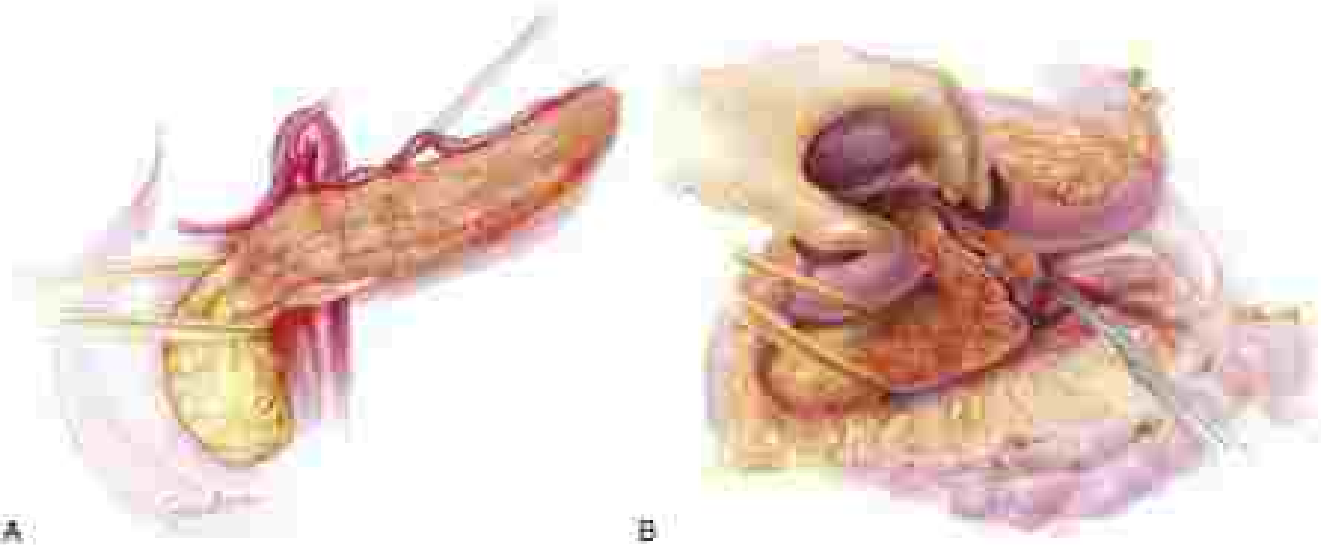
To gain anterior exposure of the pancreas, the right colon is mobilized inferiorly, the transverse mesocolon dissected free from the head of the pancreas, and the lesser sac is entered. The gastrocolic ligament is taken down with an energy device or clamps and tied to allow the omentum and transverse colon to be reflected inferiorly. This leaves the anterior aspect of the pancreas in view (Fig. 8). With the transverse mesocolon reflected inferiorly, venous tributaries can be followed down to identify the superior mesenteric vein (SMV) crossing anterior to the third portion of the duodenum.

Posterior Exposure

The posterior aspect of the pancreatic head is evaluated with the Kocher maneuver. The posterior aspect of the pancreatic body and tail can be exposed by medially rotating the spleen. Using the Attil maneuver, the spleen is detached from its attachments to the diaphragm, retroperitoneum, colon, and kidney. A plane is developed posterior to the splenic vessels and the organ is retracted medially to expose the posterior pancreatic body and tail (Fig. 9). This also serves as good exposure to identify injuries to zones I and II of the left retroperitoneum. Once all the maneuvers described for exposing the duodenum and pancreas have been completed, the only structures that remain tethering the pancreas to the retroperitoneum are the superior mesenteric vessels.

Interrogation of the Pancreatic Duct

The pancreas should be inspected for ductal injury. In cases where ductal injury is unclear, water soluble contrast with fluoroscopy or methylene blue dye can be used to look for pancreatic ductal injury. Using the same method described for passing a Foguty balloon to find the ampulla, a cholangiocatheter is passed with injection of the ductal system to radiographically or directly look for ductal disruption. Another method to perform a pancreatogram is to place a large bore intravenous line directly into the gallbladder with injection for



A B

FIG. 9 Posterior exposure of the pancreatic body and tail. Control of the splenic artery (A) before medial rotation of the pancreas out of the retroperitoneum (B). fluoroscopy. Although this is less invasive and the defect in the gallbladder can be primarily repaired, it may not be best method to interrogate the pancreatic duct because contrast or dye is injected quite proximally and tends to pool in the gallbladder. These techniques can be time consuming and are only sometimes helpful in diagnosing a ductal injury.

Historically some advocated for interrogation of the pancreatic duct by direct cannulation after creating a duodenotomy or even performing a distal pancreatectomy. These procedures are not necessary, potentially dangerous, and result in additional injuries for enteric leak or pancreatic fistula formation. Direct cannulation of the pancreatic duct should be done only if a ductal injury already exists and provides easy access to the main pancreatic duct.

Treatment

Surgical Planning

The American Association for the Surgery of Trauma organ injury scoring classification for traumatic pancreatic injuries correlates and predicts morbidity and mortality (Table 2). In 2017, the Eastern Association for the Surgery of Trauma published practice management guidelines based on a systematic review of 37 articles. Grade I or II pancreatic injuries should have nonoperative or nonoperational management. For grade III or IV pancreatic injuries identified radiologically on CT scan or during intraoperative exploration, they conditionally recommend pancreatic resection. There were no conclusive recommendations for grade V injuries.

Surgical Intervention Based on Injury Grade

Grade I and II Injuries: Wide Drainage

Grade I and II injuries are consistent with lacerations or contusions to the pancreatic parenchyma without ductal involvement. Management of these injuries should consist of hemorrhage control and wide drainage. Parenchymal injuries should not be repaired, to avoid pancreatic fistula formation. Without concomitant injuries or contraindications, enteric nutrition should be given as soon as possible.

Grade III Injuries: Distal Pancreatectomy

Grade III injuries violate the pancreatic duct at the level of the pancreatic body or tail. A distal pancreatectomy is the procedure of choice in those patients with disruption of the main pancreatic duct.

TABLE 2 American Association for the Surgery of Trauma Pancreas Injury Scale

Grade*	Injury	Description
I	Hematoma Laceration	Minor contusion without duct injury Superficial laceration without duct injury
II	Hematoma Laceration	Major contusion without duct injury or tissue loss Major laceration without duct injury or tissue loss
III	Laceration	Distal transection or parenchymal injury with duct injury
IV	Laceration	Proximal† transection or parenchymal injury involving ampulla
V	Laceration	Massive disruption of pancreatic head

*Advance one grade for multiple injuries up to grade III.
†Proximal pancreas is to the patient's right of the superior mesenteric vein.
From Moore EE, Cogbill TH, Malangoni MA, et al. Organ injury scaling, II: pancreas, duodenum, small bowel, colon, and rectum. J Trauma. 1990;30(11):1427-1429.

Intraoperatively, the lesser sac is entered and the short gastric vessels divided. If the tortuous splenic artery is encountered along the superior aspect of the pancreas, it is encircled with a vessel loop for control. The spleen is elevated from the retroperitoneum on a plane deep to the splenic vessels (Fig. 9). Ideally the splenic artery and vein are dissected free from the pancreas and individually ligated with sutures. However, if the patient is hemodynamically unstable secondary to hemorrhagic shock, a distal pancreatectomy and splenectomy can be quickly achieved by firing a linear cutting stapler across the splenic vessels and again across the pancreas. The splenic vessels deep to the remaining pancreas should be inspected for hemostasis. Care should be given to the inferior mesenteric vein because it usually drains into the splenic vein.

After pancreatic division, we oversew the transected end of the pancreas using overlapping 3-0 absorbable figure of 8 or U stitch

sutures. Two factors that decrease the pancreatic leak rate after pancreatectomy are firm gland texture and visualization of the duct. Thus, if the duct is small, it should be oversewn with 5-0 synthetic absorbable suture. Distal pancreatic stumps should be widely drained, especially considering that the rate of pancreatic leak is higher in pts. (for distal pancreatectomy than for a pancreaticoduodenectomy (25% vs 15%, respectively).

Most trauma patients should undergo distal pancreatectomy with splenectomy because splenic preservation lengthens operating times significantly. With appropriate postoperative vaccinations, removal of the spleen in an adult patient rarely results in infectious complications. In fact, the operative morbidity associated with splenic preservation is higher. The splenic vessels must be meticulously dissected from the tail of the pancreas all the way to the splenic hilum, taking care to individually ligate small venous tributaries to the splenic vein. Splenic preservation should be done only by an experienced surgeon in a stable patient.

The goal of surgery for pancreatic injuries is to remove the segment of the pancreas with a violated duct and to preserve as much of the gland as possible. The exception to this dogma is for an injury to the body of the pancreas, which should not be treated with a segmental central pancreatectomy and pancreaticojejunostomy to the distal pancreas. We recommend against doing this in the trauma setting because this operation is morbid and yields two areas for potential pancreatic leak. We prefer an extended distal pancreatectomy with splenectomy for injuries to the pancreatic body. Even though this may waste pancreatic tissue and increase the likelihood of diabetes, it is a safer procedure with only one potential surface for pancreatic fistula formation.

Grade IV and V Injuries: Pancreaticoduodenectomy

Injuries consistent with proximal transection of the pancreatic head or parenchymal injury involving the ampulla are classified as grade IV pancreatic injuries. Massive disruption to the pancreatic head is consistent with a grade V pancreatic injury. It is not uncommon to have an associated duodenal injury in these patients as well. If these injuries cannot be managed by closed suction wide drainage alone, a Whipple operation may be necessary. In 2016, Krige et al. published a prospective study on 76 patients with grade V pancreatic and duodenal injuries. Nineteen of these patients underwent pancreaticoduodenectomy within this subpopulation there was a 16% mortality rate. If injuries are wide and dispersed throughout the pancreas, then a total pancreatectomy may be needed.

COMBINED DUODENAL AND PANCREATIC INJURIES

Complex injuries to the pancreatic head and duodenum or those duodenal injuries encroaching on the ampulla may necessitate a pancreaticoduodenectomy. These injuries are rare but can be seen with penetrating trauma and are usually associated with additional intra-abdominal injuries. The number one cause of mortality in patients with combined pancreatic and duodenal injuries is hemorrhagic shock from associated vascular injuries. Therefore, initial management is hemorrhage control.

After hemorrhage control, pancreatic and duodenal injuries need thorough evaluation with particular attention to the ampulla and biliopancreatic ductal structures. If the ampulla, distal common bile duct, or pancreatic duct is not intact in the setting of a severe duodenal injury, pancreaticoduodenectomy is the procedure of choice.

Damage Control Pancreaticoduodenectomy

Once a pancreaticoduodenectomy is determined to be necessary, deciding on a staged operation is critical. Trauma patients who undergo both resection and reconstruction during the initial operation are significantly more acidotic, hypothermic, and coagulopathic; additionally, they have significantly longer operative times. Therefore, the goals of the index operation are to achieve hemostasis and control contamination.

Once hemostasis is achieved, the right colon should be mobilized and the duodenum exposed using the Kocher maneuver. The transverse mesocolon is dissected from the pancreatic head and the lesser sac is entered by dividing the gastrocolic ligament. The SMV is dissected out over the third portion of the duodenum and the tunnel behind the pancreatic neck is initiated inferiorly.

The hepatoduodenal ligament is opened to reveal the portal triad. Care should be taken to avoid injuring aberrant vasculature such as a replaced right hepatic artery. The gastroduodenal artery (GDA) is encircled with a vessel loop. Our preference is to prevent spillage from the common hepatic duct by encircling it twice with the vessel loop using a Pilot technique and circling it down with a Rummel tourniquet. Next the gastrocolic arcade is divided and the distal stomach or proximal duodenum is divided. The common hepatic duct is then divided above the level of the cystic duct and a cholecystectomy is performed. The GDA is next clamped then divided using two 0 silk ties and the stump oversewn with a 3-0 Prolene suture. The underlying portal vein is exposed and the tunnel behind the pancreas can be completed from above. If time permits, stay sutures are placed superiorly and inferiorly to the pancreas before the gland is divided to control the pancreatic mesenteric vessels. The gland should then be divided with a stapler for temporary closure.

Ideally the pancreaticoduodenectomy specimen is removed as the index operation to remove any devitalized tissue. If possible, attention is turned to the intramesocolic compartment, where a segment of proximal jejunum is divided and the ligament of Treitz is taken down. Taking this down at a later operation risks bleeding from dilated mesenteric vein tributaries. The duodenum can then be passed below the mesenteric vessels. The final step is the dissection of the uncinate process off the portal vein and SMV. The liver stage of the damage control operation can be considered complete and a temporary abdominal closure device should be placed.

Reconstruction can be pursued in a second operation once resuscitation in the intensive care unit has been completed. Temporary closure of the hepatic and pancreatic ducts in the index operation allows them to dilate, making reconstruction easier in the subsequent operation. The jejunal limb is brought up in a retrocolic fashion through the base area of the transverse mesocolon. We perform an end-to-side duct-to-mucosa pancreaticojejunostomy in two layers. A posterior row of 3-0 silks is followed by a pancreatic duct to jejunal mucosal anastomosis with 5-0 absorbable monofilament sutures. An anterior row of interrupted 3-0 Lembert silk sutures is placed to complete the two layer anastomosis. Distal along the afferent limb, an end-to-side choledochojejunostomy is performed with a single layer of 4-0 absorbable monofilament sutures. Mesenteric defects are then closed.

A Hofmeister gastrojejunostomy is then created, our preference is a two layered hand-sewn anastomosis. We usually perform this anastomosis in an antecolic fashion in the trauma setting. Finally, a pedicle of omentum or falciform ligament is placed over the GDA to try to occlude it and prevent hemorrhagic complications in the case of a pancreatic fistula. Two closed suction drains should be placed above and below the anastomoses.

Ultimately, there are many ways to reconstruct during a Whipple operation (Fig. 103). The surgeon should utilize past experience and perform whichever technique are most comfortable.

OUTCOMES AND COMPLICATIONS

Complications after elective pancreatic and duodenal surgery are common, but when they are managed in high volume centers they usually do not lead to long-term consequences. In the trauma population, because of altered physiology and concomitant injuries, the complication rate is higher. Wide drainage of injuries and repairs cannot be overemphasized. More likely than not, a patient undergoing a

FIG. 18 Whipple procedure reconstruction: pancreaticojejunostomy, choledochojejunostomy and gastrojejunostomy. (Courtesy Carrie Stoltzfus, from Cameron J, Sandone C. Atlas of Gastrointestinal Surgery, vol 1, 2nd ed. Shelton CT: People's Medical Publishing; 2007.)

Whipple procedure for trauma will experience a complication. Our philosophy in dealing with this complex area of the body is that the simplest and safest techniques should be utilized.

Duodenal Leak

Leakage from a duodenal repair can be managed conservatively if the patient is adequately drained and clinically stable. These patients should be kept NPO and parenteral nutrition started. A dynamic contrast study should be done before an attempt at feeding to ensure that the leak has sealed.

Biliary Leak

While drainage is diagnostic and can be therapeutic as well. A biliary leak can be managed by interventional radiology with a percutaneous transhepatic catheter passed through the choledochojejunostomy to maintain the biliary leak. Endoscopic procedures should be avoided because insufflation of the afferent limb can lead to anastomotic disruption.

Pancreatic Fistula

Pancreatic fistula formation is higher for distal pancreatectomy than for pancreaticoduodenectomy, and usually drainage is sufficient. These are usually diagnosed by measuring drain amylase levels once the patient has resumed a diet. More clinically significant leaks may require NPO, intravenous nutrition, and possibly a somatostatin analogue like octreotide to promote closure. A leak from a distal pancreatectomy usually irritates the posterior wall of the stomach and can lead to ulcerating nausea.

Delayed Gastric Emptying

Delayed gastric emptying (DGE) after pancreaticoduodenectomy can delay diet resumption. This phenomenon is poorly understood and is common after a Whipple operation. It is typically managed conservatively with prokinetic agents such as erythromycin and supportive care. DGE usually resolves over 2 to 3 weeks. Ultimately, if conservative management fails, a percutaneous gastrojejunostomy feeding tube may need to be placed for enteral feeds.

Hemorrhagic Complications

The most morbid of complications is postpancreatectomy hemorrhage. Subtle signs of bleeding and drain character should be followed closely. Early bleeding is the result of incomplete hemostasis and usually requires operative exploration. Delayed bleeds are usually the result of pseudoaneurysm formation from caustic GI/pancreatic secretions and are associated with high morbidity and mortality.

A change in drain output character to sanguineous indicates a wound bleed with several options; this can quickly lead to massive bleeding with exsanguination. If the patient is hemodynamically stable, the preferred course of action is to take the patient directly to interventional radiology for a diagnostic and potentially therapeutic procedure. Delayed bleeding after a Whipple operation is usually from a GDA pseudoaneurysm, whereas following a distal pancreatectomy, the splenic artery is usually the source. If bleeding is uncontrolled radiographically or the patient is unstable, the patient should be brought back to the operating room.

CONCLUSION

Duodenal and pancreatic injuries remain difficult to diagnose and treat. Although rare, they are associated with high morbidity and mortality. Early diagnosis along with a thorough understanding of hepatopancreaticobiliary anatomy and the techniques available to deal with such injuries are paramount to achieving the best outcomes.

Injuries to Small and Large Bowel

Lily Tang, MD, and Carrie A. Sims, MD, PhD, FACS

The likelihood of sustaining injury to the small or large bowel depends greatly on the mechanism. With blunt abdominal trauma, the bowel can be crushed against the vertebrae, causing injury, or there can be a sudden increase in intraluminal pressure, leading to rupture. Injury can also occur with rapid deceleration, causing tangential tears at relatively fixed points (e.g., hepatic and splenic flexures). Overall, blunt abdominal trauma results in a fairly low incidence of bowel injury (1%–4%). In contrast, the small and large bowel are the most frequently injured organs in penetrating abdominal trauma. Abdominal stab wounds are associated with injury to the bowel in 20% of cases. The incidence dramatically increases to 80% after gunshot wounds.

If diagnosed promptly, the treatment of bowel injuries is fairly straightforward and results in minimal injury-specific morbidity. Missing an injury for more than 8 hours, however, has been shown to significantly increase not only morbidity but also mortality. A delay of 8 to 24 hours increases the mortality from 2% to 9.1% and a delay of more than 24 hours increases the risk of death to 30.8%. Unfortunately, there is no single diagnostic test, other than surgical exploration, that can definitively confirm or exclude a bowel injury. Given that routine laparotomy is nontherapeutic in roughly 50% of cases and carries up to a 4% lifetime risk of morbidity, there has been increasing interest in developing practice guidelines that utilize minimally invasive diagnostic adjuncts such as computed tomography or diagnostic laparoscopy.

DIAGNOSING BLUNT BOWEL INJURIES

The diagnosis of small bowel or colon injuries after blunt abdominal trauma can be challenging and requires a high index of suspicion. We have adopted the Eastern Association for the Surgery of Trauma algorithm for blunt abdominal trauma to standardize the evaluation of blunt bowel injury (Fig. 1). Although a physical examination should be performed, it lacks the necessary sensitivity and specificity needed to be a reliable screening tool. That being said, there are nonspecific clinical findings (e.g., tachycardia, abdominal tenderness, or peritonitis) that could be the result of a bowel injury and warrant further investigation. Additionally, identifying lower abdominal ecchymosis caused by the lap portion of the seatbelt ("seatbelt sign") or radiographic evidence of a lumbar vertebral body compression fracture (Chance fracture) should increase the suspected concern for bowel injuries. Nonspecific abnormal laboratory values, including elevated white blood cell (WBC) count, hypercoagulants, and lactic acidosis, may also suggest hollow viscus injury and warrant further investigation.

Imaging plays a critical role in diagnosing blunt intraabdominal injuries. Although focused assessment with sonography for trauma (FAST) is a good triage tool to assess intraabdominal bleeding in unstable patients, its use in evaluating bowel injury is remarkably limited. In addition to being operator dependent, the FAST cannot detect less than 100 mL of abdominal fluid and cannot distinguish between ascites, blood, or mucus. Similarly, radiographs are not useful for identifying intraabdominal injuries and only serve to delay the patient's evaluation and treatment.

Computed tomography (CT) scans are currently the best imaging modality available to evaluate intraabdominal injuries in the hemodynamically stable patient. Sensitivity and specificity for diagnosing blunt bowel or mesenteric injuries on CT scan is as high as 88.3% and 99.8%, respectively. CT findings that suggest a blunt bowel or mesenteric injury (Table 1) include intraperitoneal free fluid without signs of solid organ injury, pneumoperitoneum, stranding around the bowel or mesentery, bowel wall thickening, bowel wall ischemia, mesenteric hematoma, vascular blush, and oral (or rectal) contrast extravasation. Although CT scans have high sensitivity and specificity for intraabdominal injuries, segmental small bowel devascularization injuries secondary to mesenteric avulsion ("bucket handle") remain difficult to diagnose. This type of injury may present only with free fluid on imaging, which may be confounded by the presence of solid organ injuries and concomitant hemoperitoneum. As such, the surgeon must have a high clinical suspicion and a low threshold for going to the operating room. When CT scans are inconclusive for bowel injury and there are no other indications to go to the operating room, a nonoperative approach with serial abdominal examinations and serial laboratory work can be considered. If a nonoperative approach is pursued, patients with intraabdominal injuries will typically manifest signs or symptoms (e.g., tachycardia, hypotension, increased abdominal tenderness, development of peritonitis, increase in WBC or lactate) within 9 hours of observation.

When CT scans are unavailable, historically diagnostic peritoneal lavage (DPL) has been described as an option for diagnosing blunt bowel injury. DPL can also be used in patients who have free fluid on CT scan with no evidence of solid organ injury to help determine whether there is a hollow viscous injury that requires operative intervention. Although DPL has a high sensitivity for blunt bowel injuries (99%), it is an invasive procedure with low specificity (83%).

DIAGNOSING PENETRATING BOWEL INJURIES

Penetrating abdominal trauma is frequently associated with bowel injuries. In unstable patients, these injuries do not require imaging and should be identified on laparotomy. In stable patients, the diagnostic algorithm depends on the mechanism of wounding (Fig. 2).

Gunshot Wounds

Given that 80% of abdominal gunshot wounds are associated with bowel injuries, it should be assumed that patients with this mechanism of injury will require a laparotomy. This is particularly true if there is evidence of peritonitis, evisceration, hematemesis, gross blood per rectum, or hematuria. For hemodynamically stable patients who do not meet these criteria, radiographs of the chest, abdomen, and pelvis can be used to ascertain the bullet's trajectory, to determine whether retained fragments are present, and to help triage the thoracic cavity. Obviously, any evidence of free air mandates surgical exploration. Although the FAST examination cannot rule out a bowel or mesenteric injury, it can assess for the presence of intraabdominal free fluid. If these imaging modalities are negative (or inconclusive) or the patient does not have a reliable abdominal examination result, a CT of the abdomen/pelvis can be obtained. Findings on CT imaging that suggest small bowel or large bowel injury include intra-abdominal free air, free fluid without evidence of solid organ injury, bowel wall thickening, lack of bowel wall enhancement, mesenteric stranding or active extravasation, or extravasation of oral contrast. Although DPL has been historically performed, its role in the management of abdominal gunshot wounds is limited to situations where CT imaging is unavailable. Positive DPL findings include more than 10 mL of gross blood on initial aspiration, more than 100,000 red blood cells/mm^3, more than 500 WBC/mm^3, or the presence of bile, bacteria, or food particles.

Any concern for bowel injury should prompt operative exploration. However, there are two pathways for managing stable patients with negative (or inconclusive) CT imaging and reassuring clinical examination results. These patients can either be observed with

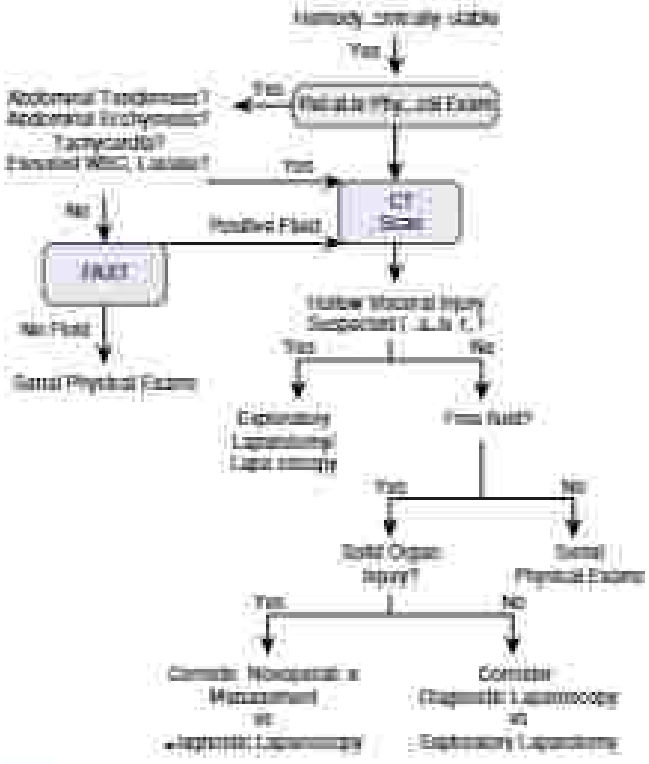

FIG. 1 Evaluation of blunt abdominal bowel injury. CT, Computed tomography; FAST, focused assessment with sonography for trauma; WBC, white blood cell count.

TABLE 1 Computed Tomography Findings Suggestive of Bowel Injury

CT Findings	Percentage With Findings
Free fluid	82.4%
Free fluid without solid organ injury	2.3%
Bowel wall thickening	10.2%
Pneumoperitoneum	7.2%
Mesenteric stranding	8.6%
Contrast extravasation	3.4%
Chance fracture	1.2%

J Trauma. 2011;70(2):298–304.

serial examinations or undergo surgical exploration with a diagnostic laparoscopy or exploratory laparotomy. If injuries are identified on diagnostic laparoscopy, the procedure should be converted to a laparotomy.

Stab Wounds

Hemodynamically unstable patients with stab wounds to the abdomen warrant immediate surgical intervention (see Fig. 2). Evidence of evisceration, impalement, or peritonitis should also prompt surgical exploration. However, in contrast to gunshot wounds, stab wounds to the abdomen are less likely to result in bowel injuries and can be managed in a number of ways. A screening upright chest radiograph can be used to evaluate all abdominal stab wounds and the presence of free air mandates either laparoscopy or laparotomy. The absence of pneumoperitoneum, however, does not exclude a bowel injury, and further evaluation is guided by the location of the injury.

Anterior Abdominal Stab Wounds

Hemodynamically stable and reliable patients with anterior abdominal stab wounds can be managed nonoperatively with serial abdominal examinations or they can be evaluated for peritoneal violation using local wound exploration or diagnostic laparoscopy. If local wound exploration is positive for anterior fascial penetration, the patient should undergo diagnostic laparoscopy to rule out peritoneal violation. In the setting of peritoneal violation, either a therapeutic laparoscopy or exploratory laparotomy is indicated, depending on the surgeon's skill set. CT imaging can also be successfully used and has reported negative predictive value of 100%. CT scan findings that are suggestive of peritoneal penetration or bowel injury require abdominal exploration.

Flank and Back Stab Wounds

Stab wounds to the flank or back are less likely to cause small bowel injuries but may injure the colon. Unlike anterior stab wounds, physical examination and FAST are unreliable adjuncts for evaluating flank or back wounds given the retroperitoneal location of the ascending and descending colon. Thus CT imaging, with or without rectal contrast, has become the preferred diagnostic modality. Surgical exploration is warranted with any evidence of contrast extravasation from the colon, hematoma or stranding near the colon, free air in the retroperitoneum, pneumoperitoneum, or free fluid in the peritoneal cavity. The decision to proceed with laparoscopy or laparotomy should be dictated by patient stability and the surgeon's technical ability.

Thoracoabdominal or Upper Abdominal Stab Wounds

Although thoracoabdominal or upper abdominal stab wounds may result in bowel injuries, they are more frequently associated with injuries to the diaphragm. As such, the potential for diaphragm injury and herniation drives the management. Physical findings (e.g., hemothorax, pneumothorax) or CT scan findings suggestive of bowel injury (see Table 1) warrant immediate exploration. The presence of either pneumothorax or hemothorax on chest radiograph or CT scan strongly suggests diaphragm violation and warrants early laparoscopy. In all other cases, diagnostic laparoscopy should be performed within 8 to 12 hours to rule out a diaphragm injury.

MANAGEMENT OF SMALL-BOWEL INJURIES

Before incision, antibiotics with broad spectrum aerobic and anaerobic coverage should be given. If a hollow viscus injury is identified, antibiotics should be given for only an additional 24 hours. Regardless of mechanism of injury, the management of small bowel injuries begins with "running the bowel" from ligament of Treitz to cecum to identify all injuries. Free perforations can be temporarily managed with gentle occlusion using umbilical ties. All hematomas to the bowel wall or mesentery should be explored to ensure no injuries are missed. This is particularly true with stab wounds, where a hematoma can look deceptively benign. It is also worth noting that gunshot wounds will have a zone of injury that should be debrided before definitive repair. The management of small bowel injuries is dependent on the grading system cited by the American Association for the Surgery of Trauma (AAST) (Table 2). AAST grade I injuries (contusion or hematoma without devascularization, partial thickness laceration with no perforation) can be repaired by reapproximating the seromuscular layers with a single layer of 3-0 silk sutures (Lembert or Gehrken). Grade II (lacerations that comprise less than 50% of the bowel circumference) and grade III injuries (lacerations >50% of bowel circumference without transection) are repaired by limited

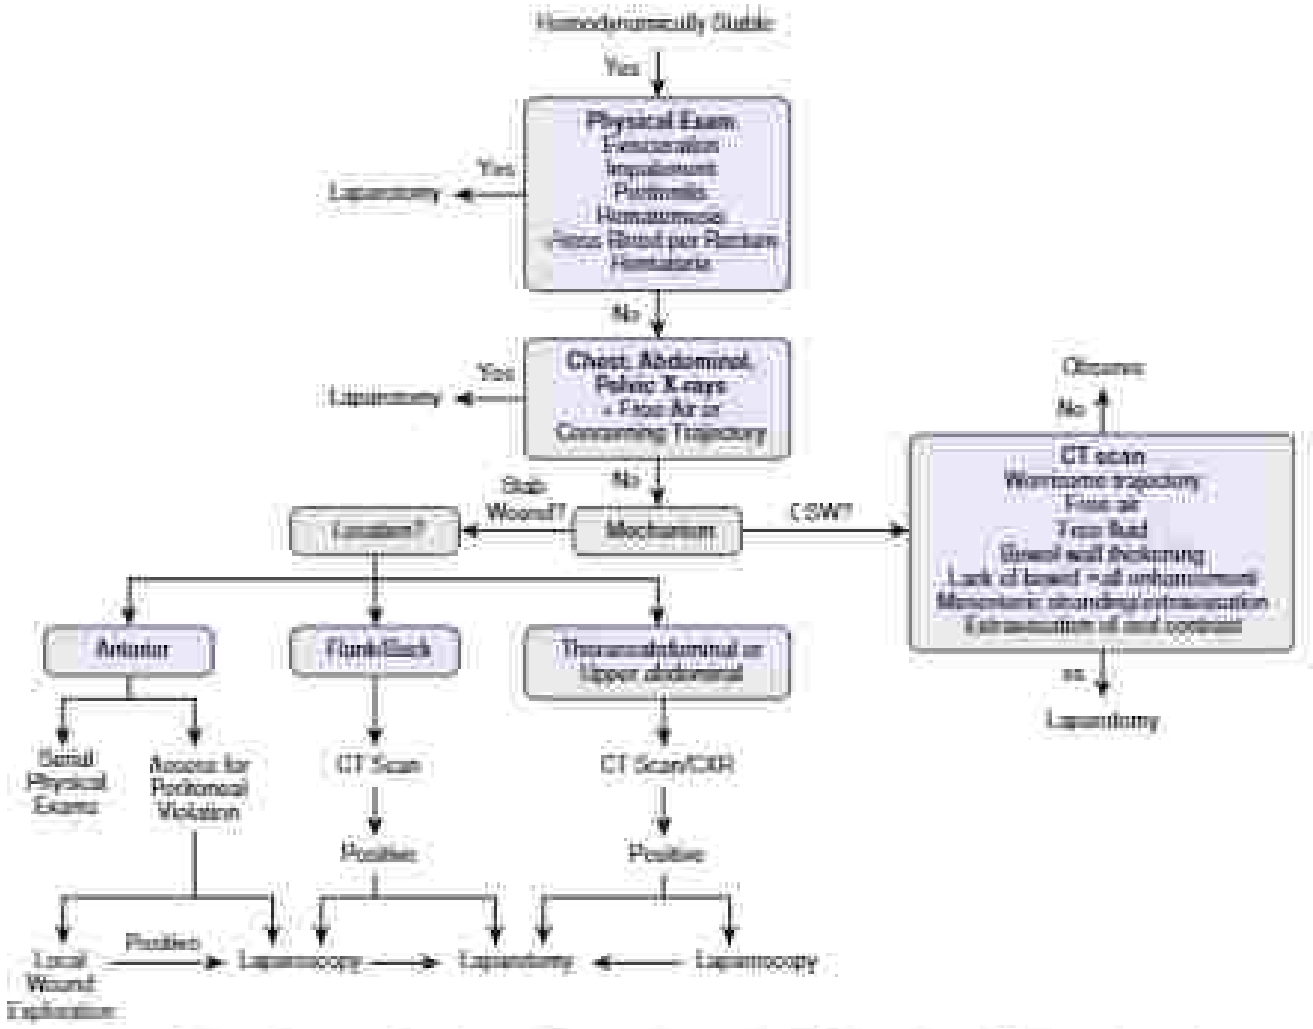

FIG. 2 Evaluation of penetrating bowel injury. CT, Computed tomography; CXR, chest radiograph; *GSW*, gunshot wound.

debridement and closure in two layers in a transverse manner to minimize any potential luminal narrowing. If there are multiple grade II or III injuries close to each other, a resection with primary anastomosis should be considered. Grade IV and V injuries require resection and reanastomosis. Damage control surgery should be considered if the patient is hemodynamically unstable, has had significant blood loss requiring multiple transfusions, is acidotic, coagulopathic, or hypothermic (Box 1). In such cases, the injured portion of bowel can be rapidly resected with a stapling device and the bowel left temporarily to discontinuity. It is imperative that a functioning nasogastric tube be placed to decompress the proximal bowel. After resuscitation, the patient should return to the operating room in approximately 24 hours for reanastomosis or the creation of an ostomy, depending on physiologic stability.

Whether to perform a hand-sewn or stapled anastomosis is a hotly debated topic. Although prospective studies have not been performed, a number of retrospective studies in trauma patients suggest that hand-sewn anastomoses have a significantly lower rate of anastomotic failure when compared with stapled anastomoses (0% vs 1.9%). In light of this, we recommend hand-sewn technique, particularly in patients with intraabdominal contamination.

As mentioned, penetrating abdominal trauma can be managed laparoscopically. With the right expertise, laparoscopy is safe and feasible. It is associated with decreased hospital length of stay and fewer perioperative complications. Importantly, although laparoscopic management of abdominal trauma can take longer, it is not associated with a higher rates of missed injuries. Thus, if the surgeon is comfortable with advanced laparoscopic techniques, we recommend therapeutic laparoscopy in stable patients be attempted, with a low threshold for conversion to open laparotomy.

MANAGEMENT OF LARGE BOWEL INJURIES

Antibiotic choice and duration are identical to those recommended for small bowel injuries and include broad-spectrum antibiotics for no more than 24 hours postoperatively. The colon should be carefully examined from the ileocecal valve to the rectum. If there is concern for a rectal injury below the peritoneum, a rigid proctoscopy should be performed. All bowel and mesenteric hematomas should be carefully explored to rule out underlying injury. The management of large bowel injuries depends on the stability of the patient and the destructiveness of the injury. Gunshot wounds leave a zone of injury in the bowel that should be debrided before definitive repair. As with small bowel injuries, the AAST grade of colon injuries can be used to guide operative decision-making (Table 3). AAST grade I colon injuries (serosal tears only) can be repaired with a single layer of Lembert sutures. Grade II colon injuries (laceration <50% of circumference) should be repaired primarily in two layers. Grade III, IV, and V injuries are considered destructive injuries and require a resection with either anastomosis or colostomy. The decision to create an anastomosis or an ostomy should be based on physiologic criteria. Patients

TABLE 2 American Association for the Surgery of Trauma Small Bowel Injury Scale

Grade*	Injury	Description
I	Hematoma	Contusion or hematoma without devascularization
	Laceration	Partial thickness, no perforation
II	Laceration	Laceration <50% of circumference
III	Laceration	Laceration ≥50% of circumference
IV	Laceration	Transection of small bowel
V	Laceration	Transection of small bowel with segmental tissue loss
	Vascular	Devascularized segment

BOX 1 Factors to Consider When Deciding to Pursue Damage Control Surgery

Hemodynamic instability
Any of the lethal triad: acidosis (pH <7.2), coagulopathy, hypothermia (<35°C)
Massive transfusion (>10 units packed red blood cells) or massive blood loss (>4 L)
Prolonged operative time (>90 min)
Lactate >5
Question of bowel viability
Massive intra-abdominal contamination requiring subsequent washout

without significant comorbidities, high dose steroid use, high blood transfusion requirements, acidosis, hypothermia, or significant intra-abdominal contamination may safely undergo colon resection with primary anastomosis. As with small bowel injuries, hand-sewn anastomoses are associated with fewer failures. In unstable patients, the colon can be tied off with umbilical ties or stapled with a stapling device. Definitive management of the colon injury can then be delivered until return to the surgical suite. It should be noted, however, that primary colonic anastomosis after damage control is associated with a 27% suture line failure rate. If a colostomy is performed, strong consideration should be given to creating a double barrel ostomy with afferent and efferent limbs exiting the same fascial defect. This will facilitate a less complex takedown procedure and obviate the need for reoperations.

Although the creation of a colostomy is often considered "safer" than primary anastomosis in patients with destructive colonic injuries, it is actually less morbid to perform a primary anastomosis in hemodynamically stable patients with minimal contamination or blood loss. Moreover, colostomies have their own acute and chronic postoperative complications, including ischemia, necrosis, obstruction, retraction, parastomal hernia, and subcutaneous abscess. Patients may also have difficulty with their colostomy appliance, particularly if the ostomy was placed near a wound or at a location where the patient cannot easily visualize it, such as below the belt line, in a skinfold, or under the pannus.

Traditionally, colostomy reversal was not considered for at least 3 to 6 months after hospital discharge. Recently, however, it has been shown that diverting colostomies can be safely reversed within 3 to 7 weeks after their creation. Regardless of timing, a contrast enema should be performed before reversal to rule out distal strictures and to assess colonic healing.

Current Management of Rectal Injury

Andrew B. Peitzman, MD

The management of rectal injury has undergone several paradigm shifts over the past 100 years. Rectal injury is uncommon in civilian trauma practice, seen in 1% to 3% of civilian injuries. On the other hand, rectal injury occurs in 5% of military casualties. Thus, observations made during major conflicts have provided the clinical basis for most of this literature. During the American Civil War, colorectal injuries were treated nonoperatively, with surgical management limited to possible manual reduction of eviscerated bowel and closure of the fascial defect; mortality rates were greater than 90%. In World War I, treatment of rectal injuries consisted of wide local debridement and external drainage, with mortality rates of 70%. Mortality was reduced to 36% early in World War II by the incorporation of proximal colostomy for all injuries to the rectum; this was eventually mandated in the treatment guidelines issued by the Department of the Army (Letter 178). By the conclusion of World War II, mortality rates were as low as 8% with the addition of posterior drainage procedures. In the Vietnam War, changes in injury patterns with the severity of high-velocity firearm and mine-related injuries led to routine washout of the distal rectum as a component of the management of rectal injury. Mortality for rectal injury was reported as 12% for this conflict, aided by advances in resuscitation and antibiotic therapy, rapid evacuation, and increased usage of blood products. A report from military experience in Afghanistan described pelvperineal wounds as the signature injury in the conflict. Mortality, predominantly exsanguination, was 47% for perineal injury and 13% for perineal injury with associated pelvic fracture. During the decades of these wars, the key principles of the 4 Ds in the management of rectal injury have been supported, diversion of the fecal stream, distal washout, proximal drainage, and direct repair of the defect. The management concepts that are supported currently include closing the defect if readily accomplished and diversion. In very selected circumstances which we discuss here, proximal drainage and distal washout may still have a role.

As discussed, management of rectal injury in the civilian population over the past 50 years has mirrored the treatment strategies used by the military. The rectum can be injured from blunt injury (often associated with pelvic fracture), gunshot or stab (static) penetrating injury, impalement injury, foreign body injury, or blast injury. Two key principles must be acknowledged as we discuss rectal injury. First, rectal injury in wartime is produced by high-energy firearm injury or an explosive device. The destructive power is far greater than seen from a gunshot wound in civilian practice. Thus, extrapolation of management principles between military and civilian injury may not be valid. Second, management of rectal injury differs for intraperitoneal versus extraperitoneal rectal injury.

ANATOMIC CLASSIFICATION OF RECTAL INJURY

The rectum is a 12- to 15-cm segment of bowel that extends from the rectosigmoid junction to the dentate line and functions as a fecal reservoir. Associated vascular injury, urologic injury, or pelvic fracture is also a concern in managing the patient with rectal injury. Rectal injury is classified as intraperitoneal or extraperitoneal (Fig. 1). The extraperitoneal rectum comprises the posterior aspect, which is adherent to the presacral soft tissues along the curvature of the sacrum, and the lower one third of the anterior portion. Injuries to the anterior and lateral surface of the upper two-thirds of the anterior portion are classified as intraperitoneal. This is the only segment of the rectum that contains a serosal layer. Injury is graded on the basis of whether the injury is partial or full thickness, the percentage of rectal lumen compromised, and the extension into the peritoneum (Table 1). This classification is limited in clinical decision-making because it does not differentiate intraperitoneal from extraperitoneal rectum, nor does it account for differences in wounding energy that impact appropriate management. The rectum is well vascularized, with the upper third supplied by the superior rectal artery as it branches off the inferior mesenteric artery. The middle third is supplied by the middle rectal arteries from the internal iliac arteries, and the distal third is supplied by the internal pudendal arteries. The superior rectal veins drain into the portal system via the inferior mesenteric vein, whereas the middle and inferior rectal veins drain into the internal iliac and internal pudendal veins, respectively.

DIAGNOSIS

Recognition of a rectal injury requires a high index of suspicion when evaluating the patient with a penetrating wound to the lower abdomen, pelvis, perineum, buttock, or upper thigh. After the primary survey (Advanced Trauma Life Support) is done, complete exposure of the patient is critical to avoid missed injury to the folds and clefts. Digital rectal examination (DRE) is essential in evaluating the patient with potential rectal injury. Information gleaned on DRE is presence of gross blood in the rectal vault, palpable bony fragments within the rectum, defects within the rectal wall, and position of the prostate gland. When positive, DRE findings are generally nonspecific, revealing blood within the rectal vault. DRE is also insensitive and cannot reliably exclude rectal injury. Thus, proctosigmoidoscopy is an essential step in the workup of the patient suspected to have a rectal injury. In addition, a rectal injury may be obscured by blood or stool on proctosigmoidoscopy. Even if the rectal injury itself is not visualized on proctosigmoidoscopy, the finding of gross blood on examination confirms 90% of rectal injuries. Computed tomography (CT) obtained in the stable trauma patient may reveal the trajectory of a bullet/missile, demonstrate extraluminal air, or associated abdominal injuries. With the high likelihood of concomitant genitourinary injury, CT cystography may confirm a bladder injury preoperatively.

TREATMENT

The treatment protocol for rectal trauma is based on the anatomic classification of the injury. In addition to the anatomic distinction rather, characteristic extraperitoneal injuries as high or low based on whether they are proximal or distal to the peritoneal reflection. In addition, the hemodynamic status of the patient is a critical factor for decisions in the surgical management of these injuries. Patients should be placed on the operating table in the lithotomy position to facilitate rigid proctosigmoidoscopy and possible transanal repair of low-lying injury (Fig. 2). Before operation, broad-spectrum antibiotics with gram-negative and anaerobic coverage should be administered and continued for 24 hours postoperatively. The Eastern Association for the Surgery of Trauma published guidelines in 2011 for management of penetrating extraperitoneal rectal injury. The recommendations for patients with

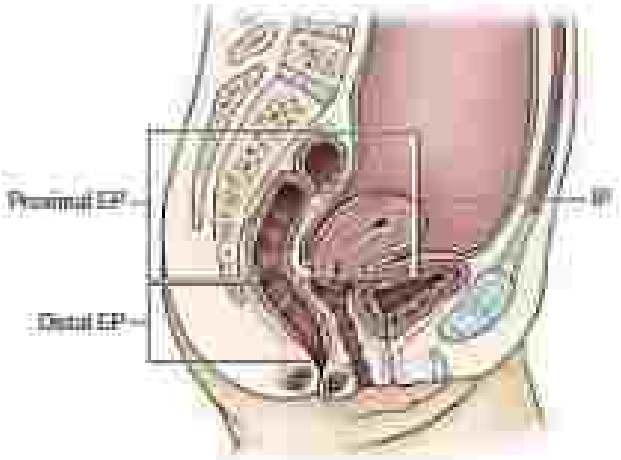

FIG. 1 The intraperitoneal (IP) and extraperitoneal (EP) divisions of the rectum. (From Weinberg JA, Fabian TC, Magnotti LJ, et al. Penetrating rectal trauma: management by proximal diversion, exposure, and closure. J Trauma Acute Care Surg. 2013;75:608–614.)

TABLE 1 American Association for the Surgery of Trauma Rectal Injury Grading Scale

Grade*	Type of Injury	Description of Injury
I	Hematoma	Contusion or hematoma without devascularization
	Laceration	Partial thickness, no perforation
II	Laceration	Laceration <50% of circumference
III	Laceration	Laceration >50% of circumference
IV	Laceration	Full thickness laceration with extension into perineum
V	Vascular	Devascularized segment

Modified from Moore EE, Cogbill T, Malangoni MA, et al. Organ injury scaling, II: pancreas, duodenum, small bowel, colon, and rectum. J Trauma. 1990;30(11):1427–1429.
*Advance one grade for multiple injuries up to grade III.

nondestructive extraperitoneal rectal injury (based on overall low-quality evidence) were:

1. perform proximal diversion
2. not place presacral drain
3. not perform distal rectal washout

Intraperitoneal Injury

The management strategies for intraperitoneal rectal injuries are similar to those used for colon wounds. The approach currently is that primary repair of a colon injury is safe in all but the sickest patient, regardless of location of the colon injury (right vs transverse vs left), degree of colon injury, or whether stapled or hand-sewn anastomosis. Nondestructive injuries without devitalization of tissue that do not require significant debridement (American Association for the Surgery of Trauma [AAST] Organ Injury Scaling grades I to III) can be repaired primarily. We perform a two-layer closure, using a full-thickness running absorbable suture followed by interrupted silk seromuscular sutures. With significant tissue loss or vascular compromise, resection of the injured segment is necessary. Consideration for primary anastomosis without diverting colostomy is appropriate in the presence of hemodynamic stability. On the other hand, with evidence of shock (prolonged hypotension, transfusion requirement greater than 4 to 6 units of packed red blood cells) or competing injuries (Injury Severity Score > 25), end colostomy with closure of the rectal stump is advised. The specific number of units of packed red cells transfused to push the decision to colostomy remains controversial. Interestingly, a recent AAST survey by Brown et al. reported that 82% of patients with intraperitoneal rectal injury underwent proximal diversion. Independent risk factors for abdominal complications with intraperitoneal injuries included high-grade injury and penetrating mechanism. Proximal diversion did not impact mortality. In this series, extraperitoneal rectal injuries were diverted in 76% of patients. Seventeen percent of extraperitoneal injuries underwent distal rectal washout and 27% had presacral drains placed. Independent risk factors for abdominal complications of extraperitoneal rectal injuries were presacral drainage and distal rectal washout. As with intraperitoneal rectal injuries, proximal diversion had no impact on mortality with extraperitoneal rectal injuries.

The posterior wall of the rectum must be assessed along the trajectory of the bullet if possible, to prevent missing injury to the posterior rectum. If a distal extraperitoneal wound cannot be definitively excluded, the patient should be managed as if a distal extraperitoneal injury were present.

Proximal Extraperitoneal Injury

Injury involving the extraperitoneal rectum proximal to the peritoneal reflection can be repaired with limited mobilization of the mesorectum. If injury is suspected, because of either crepitus of an anterior or lateral injury or the presence of a hematoma within the proximal mesorectum, perform primary repair using the two-layer technique described previously without the need for proximal diversion or presacral drainage. As with intraperitoneal injury, the decision to perform a diverting colostomy should be based on the patient's physiologic status, suspicion of a more distal injury, and

complexity of the surgical repair. Destructive rectal injuries not amenable to immediate primary repair should be treated with Hartmann's procedure.

Distal Extraperitoneal Injuries

Primary repair of extraperitoneal injury below the peritoneal reflection is hindered by difficult exposure, limited space (especially in males), proximity of neurovascular and genitourinary structures, and anatomic distortion secondary to associated injuries. If the wound is encountered while addressing another injury and is easily accessible, limited dissection and repair can be performed. However, only 20% of extraperitoneal wounds are amenable to repair, and extensive distal mobilization in search of a suspected wound is contraindicated because of risk for iatrogenic nerve, rectal, urologic, or vascular injury. Several authors have described irrigating laparotomy and performing laparoscopic assisted diverting loop sigmoid colostomy in hemodynamically stable patients without signs of peritonitis. However, we proceed with exploratory laparotomy and diversion of these patients, to allow assessment of the mesorectum and potential repair of proximal extraperitoneal injuries. Diversion is accomplished via a loop sigmoid colostomy. The sigmoid colon must be mobilized sufficiently to avoid tension and the posterior wall of the loop is maintained above the level of the skin. A Silastic rod or red rubber catheter is placed beneath the loop to prevent retraction. If fashioned properly, loop colostomy is effective for diversion of the fecal stream and outcomes are equivalent to those seen with end colostomy.

For wounds to the posterior portion of the distal extraperitoneal rectum, we practice presacral diversion. For injuries to the anterior portion of the distal extraperitoneal rectum, we do not routinely place a presacral drain, and injuries are managed primarily with proximal diversion. We place a presacral drain only in the setting of low anorectal injury with high likelihood that the drain will actually be in proximity to the posterior anorectal injury.

The presacral drain is inserted via a curvilinear incision between the coccyx and anus, followed by blunt dissection through Waldeyer's fascia to enter the presacral space. Place a closed suction or 1-inch Penrose drain within the space and gradually withdraw between postoperative days 5 and 7 (Fig. 3).

As mentioned, presacral drainage in these patients remains controversial. In a series of 32 patients, Armstrong and colleagues demonstrated a reduction in the pelvic abscess rate from 36% to 25% with the use of presacral drainage. Nash and colleagues also showed a significant decrease in infections within the presacral space, and a report by McGrath in 1998 also demonstrated a reduction in morbidity when drainage was used. Several subsequent reports have failed to demonstrate a reduction in morbidity or mortality. Gonzalez and colleagues published a prospective, randomized study evaluating 48 patients with rectal injuries and failed to demonstrate a reduction in infectious complications. They postulated that civilian injuries are different from the high velocity injuries encountered during combat and that violation of the presacral space actually may result in increased infectious complications.

Distal Rectal Washout

During the Vietnam War, irrigation of the distal colon and rectum was added to the treatment regimen for these injuries to reduce contamination and septic complications secondary to stool within the rectal vault. As the sigmoid colon is exteriorized for the creation of a diverting loop colostomy, a purse-string suture is placed on the distal segment of the sigmoid colon. A colostomy is made; a large-bore Foley or red rubber catheter is inserted into the colonic lumen, and 3 to 4 L of saline is instilled via gravity drainage into the colon. As the fluid is introduced, the distal rectum is dilated digitally to facilitate drainage, and drainage is continued until the effluent becomes clear.

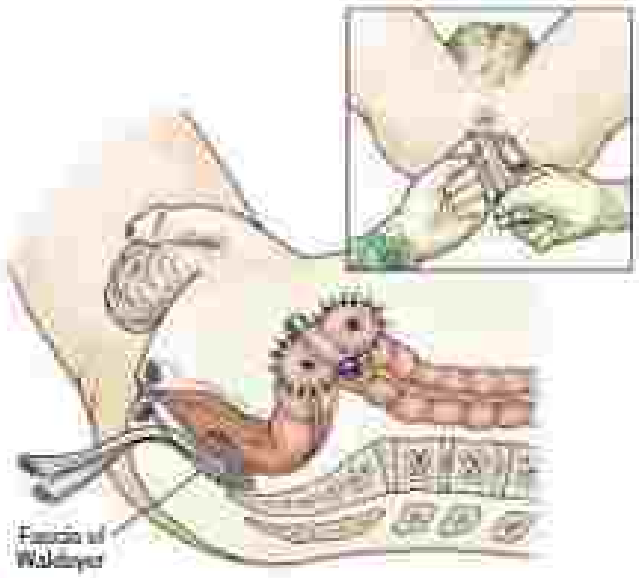

FIG. 3 Technique for presacral drainage and proximal diversion for low posterior anorectal injury. (*Courtesy Baylor College of Medicine, Houston, TX.*)

In 1988, Shannon and colleagues reported their experience with distal rectal washout in a series of 27 patients, demonstrating an incidence of pelvic abscess formation in 8% of patients who received rectal irrigation versus 36% in those who did not. The greatest benefit was observed in patients with high velocity gunshot wounds or other destructive injuries, such as pelvic crush injuries. Several authors have expressed concern that irrigation in patients who have not undergone primary repair may contaminate the surrounding soft tissues and increase the risk of pelvic abscess. Multiple subsequent studies have failed to demonstrate a benefit to the procedure. The benefit in combat situations may be related to the chronic debridement and contagion experienced by soldiers in the field combined with high velocity, destructive rectal and soft tissue injuries. We do not routinely include this procedure as a component of our treatment algorithm but will apply washout with wounds secondary to high-caliber weaponry or explosives.

Anorectal Injury

Most injuries to the anus and anal sphincters occur as iatrogenic injuries due to perineal tearing or midline episiotomy. Traumatic injury to the anal sphincter complex is often secondary to sexual assault, forceful introduction of a foreign body, or blunt injury due to complex pelvic fracture or straddle-type perineal injury. Injury also has been reported with insertion of enema tips or rectal thermometers and during anorectal procedures such as lateral internal sphincterotomy, hemorrhoidectomy, polypectomy, and endoscopic dilatation.

DRE is essential, palpating for mucosal defects, bony fragments, or gross blood. DRE should also include assessment of resting and squeeze sphincter tone. As mentioned earlier, DRE is insensitive to detection of anorectal injury. A simple laceration to the anal mucosa can be repaired primarily, but complex lesions involving the distal perineum and rectum may require diverting colostomy. With extensive perineal and anorectal injury, plan debridement of nonviable tissue and daily operative debridement and lavage for the first 3 days. If extensive tissue debridement is required, overlapping sphincteroplasty is the repair of choice; simple apposition of muscle is associated with a failure rate of 40%. In cases of complex injury to the pelvic floor with significant soft tissue defect, referral to a colorectal

operative for transposition of the gluteus or gracilis muscle with creation of a neosphincter is advised.

Rectal foreign bodies were first described in the sixteenth century. Household objects such as bottles and glasses are inserted most frequently. However, the full list of objects is long and imaginative. The patient may be embarrassed to discuss the situation. Remember that the object may have been placed as a method of assault. If the patient is clinically ill or has peritonitis, proceed for laparotomy with the patient in lithotomy. CBCT is an essential part of the evaluation. Abdominal films will demonstrate the foreign body and detect free air. A foreign body in the sigmoid colon is more likely to require operation than one more distal. Transanal extraction of a foreign body is successful in 70% of patients. The approach is with the patient in lithotomy, adequately sedated, and with adequate lubrication. If the object cannot be reached by this approach, then proceed with sigmoidoscopy. If this is unsuccessful, move to the operating room to assist via laparotomy or laparoscopy. On occasion, colotomy will be required to extract the foreign body. After extracting the foreign body, perform rigid sigmoidoscopy to evaluate for injury to the pararectal rectum.

TIMING OF COLOSTOMY CLOSURE

Colostomy closure is performed when the patient has recovered from the initial injury, subsequent operations, and associated morbidities. Resolution of inflammation, normalization of nutritional status, and proper healing of injuries are essential before performing colostomy reanastomosis. Rosa and colleagues have reported safe utilization colostomy closure on patients with rectal injuries, using contrast enema 5 to 10 days after injury to exclude a clinically occult leak. This was followed by closure as early as 9 days after injury without any reported complications related to leakage from the rectal wound. This approach has not been adopted widely. We perform several 2 to 3 months after hospital discharge to allow resolution of the chronic inflammatory adhesions resulting from laparotomy and healing of intraabdominal injuries.

MANAGEMENT OF COMPLICATIONS

Daily evaluation of the wounds, perineum, and presacral drain site (if performed) is essential to monitor the patient for possible pelvic infection or sepsis. The introduction of rectal thermometers or suppositories should be avoided. If the patient exhibits fever, leukocytosis, or other signs of infection 4 to 5 days after surgery, CT of the abdomen and pelvis is appropriate. The most common complication in these patients is intraabdominal abscess. Small abscesses (<2 cm) usually can be treated with intravenous antibiotic therapy alone. Larger abscesses can be treated with percutaneous drainage. If the collection is not amenable to drainage or if the patient has signs of sepsis, reexploration with irrigation and drainage is indicated. If feculent material is aspirated from the abscess cavity, the patient has a colonic fistula. Distal colonic fistulae generally resolve with time and adequate drainage. The catheter should be left in place and flushed twice daily with normal saline to prevent occlusion. Once drainage is minimal and there is radiographic confirmation that the abscess cavity has collapsed, the drain can be removed slowly over the course of several days.

The complication most directly attributable to initial injury is infection within the retrorectal space and the resulting pelvic sepsis. This may be seen as an isolated abscess within the presacral space or an extensive retroperitoneal infection tracking into the perineum and thighs. As with any necrotizing soft tissue infection, early broad-spectrum antibiotics and prompt surgical debridement are the mainstays of therapy, along with admission to an intensive care unit, hemodynamic monitoring, and crystalloid resuscitation.

Wound infections have been reported in up to 20% of patients with injuries to the colon and rectum. As such, the skin should not be closed at the time of fecal closure. Either the wound can be left to heal by secondary intention or delayed primary closure can be performed after 3 to 5 days. Given the contamination inherent in rectal trauma and stoma creation and the frequency of concomitant vascular, genitourinary, and orthopedic injuries, leaving the wound open is the preferred option.

The Injured Spleen

Martin A. Croce, MD, and Michael Fitzgerald, MD

The spleen is one of the most commonly injured solid organs following blunt trauma. Its close relationship with the ribs and multiple attachments provide many locations for disruption of the capsule and injury to the parenchyma. In an adult, the spleen weighs approximately 100 to 250 grams, however, it can become enlarged due to various causes such as malaria, mononucleosis, hematologic diseases, and portal venous hypertension. This pathologic enlargement can make the spleen more susceptible to injury. Debate continues about the optimal management of patients with splenic injuries.

ANATOMY

Anatomically, the spleen is located in the left upper quadrant and is intimately related to the left hemidiaphragm and left ribs 9 through 12. Laterally, it is fixated by the splenophrenic ligament. Posteriorly, it is closely associated with the left adrenal gland and left kidney and is attached via the splenorenal ligament. Medially, it is closely associated with the tail of the pancreas. Identification of the tail of the pancreas is essential to safe mobilization of the spleen and splenectomy. Medially the spleen is adjacent to the greater curvature of the stomach and short gastric arteries, which must be ligated for total splenic mobilization. Inferiorly the spleen is in close proximity to the distal transverse colon and splenic flexure and is attached via the splenocolic ligament.

The blood supply of the spleen is provided by the splenic artery and the previously mentioned short gastric arteries. The splenic artery is a branch of the celiac axis and travels in a variably tortuous path along the superior aspect of the pancreas and terminates in the splenic hilum where it branches into the segmental blood supply of the spleen. It also receives blood from the short gastric arteries that come from the greater curve of the stomach and are an extension of the left gastroepiploic artery. The venous drainage of the spleen mirrors the arterial supply. The splenic vein joins the inferior mesenteric vein, which then joins the superior mesenteric vein to create the portal vein. The short gastric veins drain into the left gastroepiploic vein.

Functionally the spleen is divided into red and white pulp. The red pulp is responsible for filtration of old red blood cells, trapping bacteria and presenting the bacteria to the lymphocytes. The white pulp consists primarily of the lymphocytes, which are presented the bacterial antigens developed by the red pulp, and produce immunoglobulins to these antigens. The white pulp also plays a role in production of opsonins and complement activation.

CHILDREN

There are multiple differences between the adult and pediatric spleen that should be taken into consideration during management of splenic injuries. The spleen is larger in children due to its function in red blood cell production as well as its previously stated functions in the adult of filtering senescent red blood cells, trapping bacteria, developing antigens and presenting them to lymphocytes for the development of immunoglobulins. As children age and the bone marrow becomes more mature, the spleen does reduce in size relative to the other intraabdominal organs. In addition to the larger size of the spleen in children, the pediatric chest is much more flexible and allows for more significant force to be transferred without rib fractures. The capsule is thicker and parenchyma is firmer, which leads to lacerations in parallel with the vasculature. The orientation of laceration may be a reason for improved nonoperative success. Pediatric patients are excellent candidates for nonoperative management. They have lower incidences of delayed bleeding, are more likely to have isolated splenic injury secondary to one such mechanism, and the injured spleens are more likely to lacerate in a pattern parallel to the arterial supply secondary to the smaller composition. Children are also at a higher risk after splenectomy for overwhelming postsplenectomy infection. Thus, nonoperative management is not only more successful in children, it is preferred for long term functional immunity.

MANAGEMENT

Injury to the spleen can occur from either penetrating or blunt mechanisms. Regardless of mechanism, it is essential to carefully evaluate all other potentially injured structures given the spleen's close relationship with the pancreas, colon, kidney, stomach, and left hemidiaphragm.

Blunt Injury

The spleen is one of the most frequently injured solid organs after blunt trauma. The initial assessment of the patient will lead down one of two pathways. If upon initial evaluation the patient is found to have hemodynamic instability or evidence of peritonitis, the patient should be taken emergently to the operating room for exploratory laparotomy. In the setting of altered mental status or significant multisystem injuries, the abdomen should be evaluated using focused ultrasonographic evaluation (FAST) or diagnostic peritoneal aspirate/lavage. This can add a level of confirmation prior to heading to the operating room; however, if the patient is in extremis, time should not be wasted. Forty–five percent of patients with splenic injury present with hemodynamic instability and require emergent exploratory laparotomy.

If the patient is found to be hemodynamically stable the Eastern Association for the Surgery of Trauma guidelines state "Nonoperative management of blunt splenic injuries is now the treatment modality of choice in the hemodynamically stable patient, irrespective of grade of injury, patient age, or the presence of associated injuries." The initial assessment of the hemodynamically stable patient should always begin with assessing the airway, breathing and circulation, with keen attention to blood pressure and heart rate to not miss signs of reflective shock. Next, a detailed history of the event including mechanism should be obtained. A detailed past medical history including history of hematologic disease, preexisting conditions (malaria, mononucleosis, hepatic disease), anticoagulation, aspirin use, and previous abdominal surgeries should also be obtained. Physical examination should pay close attention to the left thorax and abdomen. Ecchymosis or abrasions to the abdomen should be noted. The presence of generalized abdominal pain, and, more specifically, left upper quadrant pain should raise suspicion of a possible injury. Left lower rib pain, specifically posterior rib pain can suggest a possible splenic injury as well. Left shoulder pain, known as Kehr's sign can also be present due to left hemidiaphragm irritation. Hemoglobin/hematocrit, coagulation studies and amylase and lipase should be evaluated for evidence of acute blood loss anemia, coagulopathy, and possible evidence of pancreatic injury. Imaging should begin with plain radiographs. Chest radiographs can offer clues to left upper quadrant trauma with evidence of left sided rib fractures, left sided hemothorax, or evidence of diaphragmatic rupture. Pelvic radiographs have minimal value beyond identifying additional locations of hemorrhage in the setting of pelvic fractures. A FAST exam can be performed and offers nonspecific information such as the presence of free fluid in the abdomen; however, in the setting of hemodynamic stability, the patient will be taken for computed tomographic (CT) scan of the abdomen and pelvis with intravenous (IV) contrast, which is the gold standard diagnostic test for splenic injury. With continued improvement of CT resolution, significant information can be gathered about the potential splenic injury. It is imperative that the study is done with

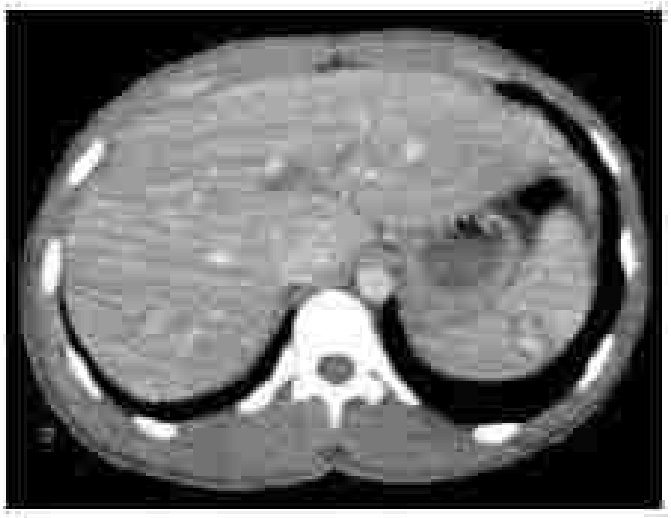

FIG. 1 Pseudoaneurysm on contrast computed tomographic scan.

IV contrast to help identify a contrast blush, which is indicative of a pseudoaneurysm (Fig. 1). Oral contrast has not been found to be helpful. Hematoma and parenchymal disruption appear as hypodense regions within the spleen. Free fluid suggestive of hemoperitoneum is often seen in Morison's pouch, the paracolic gutters, and the pelvis. Free fluid is a nonspecific finding and can also represent a bowel or mesenteric injury. The pancreas, left kidney, liver, and left hemidiaphragm should also be closely inspected. CT evidence of contrast extravasation, which appears as a hyperdense area of concentrated contrast, suggests a disruption of splenic parenchyma and ongoing bleeding. However, its significance is questionable in the setting of hemodynamic normalcy and does not necessarily mandate further intervention. Therapeutic possibilities include angiography with embolization, laparotomy, or continued close observation. A finding that should draw concern is evidence of pseudoaneurysm, which indicates vessel damage. The presence of a circumscribed extravascular contrast blush is diagnostic of a pseudoaneurysm. In a hemodynamically stable patient, this finding requires further evaluation with angiography since these patients have a higher incidence of delayed rupture.

Splenic injuries can be graded by various techniques. The most accepted grading scale is the American Association for the Surgery of Trauma Splenic Injury Scale, which grades the injury from I to V based on severity of splenic laceration and/or hematoma (Table 1). It is important to remember that these injury grades are not a perfect correlation with injury and can over- or underestimate the damage. The grade of injury and clinical course can be roughly correlated, but it is important to take into consideration factors such as pseudoaneurysms and bleeds. Angiography has been recommended for grade III or greater injuries, however, data to support this are conflicting. Angiography is a useful adjunct to nonoperative management, but it does have potential for complications, which include failure to control bleeding in up to 15% of patients, missed injury, and splenic abscess.

After completion of the workup, patients with nonoperative splenic injury should be admitted for close observation. As previously stated, regardless of patient's age, grade of injury, quantity of hemoperitoneum, or associated injuries, as long as the patients remains hemodynamically stable, nonoperative management is an appropriate treatment plan. However, lower threshold for surgical intervention may be considered in patients who are above the age of 55 or have significant traumatic brain injuries due to their increased sensitivity to hypotension. It is also essential that serial hematocrits and abdominal exams can be performed and in event of decompensation the operating room can be quickly mobilized for operative intervention.

Although research is bountiful in regard to nonoperative management of blunt splenic injury there are still details that have not been completely refined. There are no evidence based recommendations for the time interval between hematocrit checks or abdominal exams, and there is no set number of units of blood transfused that signal nonoperative failure. Also, the data are inductive on the need for repeat CT scans and appropriate time until resuming normal activity.

A consensus suggests an appropriate plan is admission to the intensive care unit (ICU) for grade II and above injuries, nothing by mouth (NPO) status, and serial hematocrit and abdominal exams at 6- to 8-hour intervals. Prompt angiography is recommended for patients with evidence of a pseudoaneurysm and may be considered in stable patients with confined contrast extravasation or higher grade injuries. Duration of ICU and NPO status have not been determined, but stable observation over 48 to 72 hours appears to be standard, followed by transfer to the floor, discontinuation of serial labs, and initiation of a diet. There are conflicting studies addressing the need for repeat CT; however, at our institution we routinely obtain 24 hour follow up CT scans on grade II or above injuries since some pseudoaneurysms appear later. There is currently no evidence for vaccinations in nonoperative blunt splenic injury. DVT prophylaxis may be started within 24 hours if the patient remains hemodynamically stable. The majority of nonoperative failure occurs within the first 8 days, and time until discharge mirrors this. Time to return to normal activity is also unclear. The spleen is not healed before 6 to 8 weeks and return to activity is at the physician's discretion, with time ranging between 2 and 6 months.

Failed nonoperative management can be marked by hemodynamic instability or peritonitis, which necessitates exploratory laparotomy for splenectomy and evaluation for potential missed hollow viscus injury.

Penetrating Injury

As with all penetrating injuries to the abdomen, it is essential to establish violation of the peritoneum. After this has been established, the patient should undergo surgical exploration. In the setting of a splenic injury, it is essential to evaluate the left hemidiaphragm, pancreas, and stomach to ensure there were no additional injuries. Operation for penetrating splenic injuries usually results in splenectomy, but splenic salvage may suffice in selected patients with minimal splenic injury.

OPERATION

To begin mobilization of the spleen the lateral attachments of the splenophrenic and splenorenal ligaments should be taken starting lateral to medial at the level of the esophageal hiatus. As the lateral attachments are taken down the spleen should be carefully elevated to the midline, it is important to ensure the appropriate plane is entered and the kidney stays in its retroperitoneal position. The short gastric arteries should be isolated and individually clamped and tied. Care should be taken to not tie to close to the stomach, which may lead to necrosis. If it too difficult to stay away from the stomach, the lateral short gastrics can then be oversewn. Once the spleen has been adequately mobilized, the kidney and distal pancreas can be completely evaluated. The splenocolic ligament connecting the inferior pole of the spleen and the transverse colon should then be divided. Lap pads can then be placed in the splenic fossa and the spleen can be further elevated and mobilized prior to ligation of the hilar vessels. With the spleen removed from the left upper quadrant, the left hemidiaphragm should be reevaluated. The pancreatic tail and splenic hilum should then be carefully inspected. The splenic artery and vein should be isolated and individually ligated to prevent arteriovenous fistula.

Once the spleen has been removed from the operative field, the surrounding structures should be reassessed and lap pads removed. The splenic fossa can be more carefully evaluated by placing a lap pad deep in the splenic fossa and slowly rolling it deep to superficial to

TABLE 1 American Association for the Surgery of Trauma (AAST) Splenic Injury Grade

AAST Grade/ AIS Severity	Imaging Criteria	Operative Criteria	Pathologic Criteria
I/1	Subcapsular hematoma <10% surface area Parenchymal laceration <1 cm depth Capsular tear	Subcapsular hematoma <10% surface area Parenchymal laceration <1 cm depth Capsular tear	Subcapsular hematoma <10% surface area Parenchymal laceration <1 cm depth Capsular tear
II/2	Subcapsular hematoma 10%–50% surface area; intraparenchymal hematoma <5 cm Parenchymal laceration 1–3 cm	Subcapsular hematoma 10%–50% surface area; intraparenchymal hematoma <5 cm Parenchymal laceration 1–3 cm	Subcapsular hematoma 10%–50% surface area; intraparenchymal hematoma <5 cm Parenchymal laceration 1–3 cm
III/3	Subcapsular hematoma >50% surface area; ruptured subcapsular or intraparenchymal hematoma ≥5 cm Parenchymal laceration >3 cm depth	Subcapsular hematoma >50% surface area or expanding; ruptured subcapsular or intraparenchymal hematoma ≥5 cm Parenchymal laceration >3 cm depth	Subcapsular hematoma >50% surface area; ruptured subcapsular or intraparenchymal hematoma ≥5 cm Parenchymal laceration >3 cm depth
IV/4	Any injury in the presence of splenic vascular injury or active bleeding confined within splenic capsule Parenchymal laceration involving segmental or hilar vessels producing >25% devascularization	Parenchymal laceration involving segmental or hilar vessels producing >25% devascularization	Parenchymal laceration involving segmental or hilar vessels producing >25% devascularization
V/5	Any injury in the presence of splenic vascular injury with active bleeding extending beyond the spleen into the peritoneum Shattered spleen	Hilar vascular injury that devascularizes the spleen Shattered spleen	Hilar vascular injury that devascularizes the spleen Shattered spleen

AIS, Abbreviated injury scale.

identify any missed short gastric vessels or overt bleeding. Drains are not routinely used unless a renal or pancreatic injury has been identified throughout the case.

POSTSPLENECTOMY AND COMPLICATIONS

Postoperative complications that occur can vary. Bleeding can occur from the short gastric arteries or the splenic hilum, which can be reduced with meticulous evaluation and individually ligating the short gastric arteries. Although rare, gastric distension can lead to the dislodgement of ties on the short gastric arteries. Gastric necrosis can occur at the site of short gastric artery ligation leading to gastric leaks and abscess formation. Inadequate dissection and mobilization can place the pancreatic tail on tension and lead to iatrogenic injury. Arteriovenous fistulas can occur when the splenic artery and vein are not ligated separately. Thrombocytosis can occur following splenectomy, but is usually managed expectantly. The loss of the spleen does remove an important filter of senescent red blood cells; however, this is well tolerated. The removal of the spleen also leads to reduction of antigen exposure to lymphocytes and compromises the immune system, which can present with significant postoperative complications.

Overwhelming post splenectomy infection is the most concerning and life-threatening complication. It is extremely rare following splenectomy for trauma in adults compared to splenectomy for hematologic disease in young children, but it is still a potential concern. It is essential to have a low threshold for initiation of broad spectrum antibiotics and resuscitation in a patient who develops significant sepsis following splenectomy. Encapsulated organisms such as Pneumococcus, Meningococcus, and Haemophilus are the most common offenders. It is important to ensure the patient receives vaccines to these three bacteria postoperatively. The exact timing of vaccination is controversial, but it is essential that patients receive their vaccines prior to discharge.

Retroperitoneal Injuries: Kidney and Ureter

Benjamin ... Breyer, MD, MAc., and Andrew J. Cohen, MD

URETER

Ureteral trauma is relatively rare. Genitourinary injury accounts for about 10% of trauma overall but ureteral injury accounts for only 1% of all genitourinary trauma. Although 96% of such traumatic injuries are related to penetrating trauma, less than 5% of all gunshot victims have ureteral involvement. Traumatic injuries affect the upper ureter two thirds of the time, and the middle and lower ureter are afflicted about equally.

The ureter is also subject to iatrogenic injury, with estimated rates during hysterectomy, for example, approximately 0.5% and during radiologic procedures about 1%. There is some evidence the risk of ureteral injury has increased with the utilization of laparoscopic surgery, but it remains unclear whether this is secondary to learning curves, patient selection, or other factors. With swift recognition, many low grade ureteral injuries may heal with ureteral stenting alone. True incidence rates of ureteral injury likely are underestimated given not all cases are reported and many resolve without investigation.

In the setting of multiple injuries, complex ureteral reconstruction may not be appropriate particularly if a patient is unstable or has other more pressing injuries. The focus in these cases is preserving renal function, which is easily accomplished by percutaneous nephrostomy tube. It is always appropriate to save complex reconstruction for a delayed setting because such cases may be prolonged and expose the patient to additional operative risk. For these more complex injuries, the armamentarium is plentiful with techniques to bridge any length of devitalized ureter. In recent years, especially in the delayed setting, robotic and laparoscopic techniques are increasingly used to repair these injuries. Intraoperative decision making is important, but careful tissue handling and a tension-free anastomosis will increase successful outcomes.

Anatomic Considerations

The ureter courses anteriorly from the renal pelvis posterior to the renal vasculature in the retroperitoneum. It is lateral to the gonadal vessels near its origin, but ultimately the gonadal vessels cross anterior to its surface on their course toward the gonads. The ureter courses medially and lies on top of the iliac vessels. The most reliable place to identify the ureter is just anterior to the bifurcation of the internal and external iliac arteries. In the male it courses deep to the vas deferens before inserting cephalad to the bladder neck on the posterior surface of the bladder. In females it runs deep to the uterine artery and ovarian ligament.

Because of the proximity of vertebrae and pelvic skeletal anatomy, the ureters are relatively protected from injury. The distal ureter's blood supply is lateral from branches of the iliac vessels and vesical pedicle, whereas the proximal ureter derives its supply medially from renal vessels.

Diagnosis

The first step to identifying ureteral injury in a stable patient already in the operating room is often cystoscopy with retrograde pyelogram. If injury was suspected during open or laparoscopic surgery, direct inspection of the ureter can be extremely valuable. Ureteral injury may be graded (Table 1). If no clear injury is seen, cystoscopy with retrograde pyelogram is appropriate. Ureteral stenting, even in cases of only suspected injury, has little downside and may protect the ureter from the sequela of thermal or crush injury, which may not be visually apparent. If stenting is not possible, percutaneous nephrostomy should be pursued. The extent of injury can be assessed with antegrade study or computed tomography (CT) urogram.

High resolution CT scan with delayed views provides excellent anatomic detail of the examined ureter. Medial extravasation of contrast from the hilum is the most common finding of renal ureteropelvic junction injury. In the setting of complete avulsion, the proximal ureter will not fill, a partial tear will likely show distal ureteral filling. The presence of a hematoma or extravasation may indicate the site of ureteral injury.

In cases of endourologic injury such as perforation during kidney stone treatment, endoscopic ureteral stent alone may be a viable treatment strategy. After stent removal, ultrasound to assess for distal hydronephrosis is paramount because ureteral strictures left untreated could lead to loss of renal function. Strictures can then be treated using endoscopic techniques or more complex surgery depending on stricture length and location and patient comorbidity and symptoms.

In the unstable patient, injuries to adjacent organs such as bowel, vena cava, major vascular, or injury to the kidney itself should be assessed first and addressed primarily. The ureter can be inspected in this setting but complex repair should not be attempted. Clipping the open end of the ureter, if identified, can aid in later localization. The patient should get a percutaneous nephrostomy tube to protect kidney function, and delayed repair of the ureter may be planned.

Diagnosis in Delayed Setting

Some patients may present 2 to 3 days after a traumatic event or surgery with symptoms of hematuria, dysuria, palpable flank mass, or peritonitis. Ureteric injury, if suspected, can be detected on CT urogram. Urinoma, urinary ascites, or new hydronephrosis may suggest ureteral injury, whereas extravasation of contrast from the ureter is pathognomonic. For postsurgical patients with a drain in place, sending fluid for creatinine analysis can identify urinary leakage, but further investigation will be required to identify the source.

Prevention

There is growing interest in preventing iatrogenic ureteral damage using preoperative stents for complex pelvic surgery such as removal of colorectal malignancy or complex gynecologic surgery. Prospective stenting has not been shown to decrease incidence of ureteral damage but may improve detection at the time of injury.

Surgical Approach to Repair

The location of ureteral injury dictates the options for repair (Table 2). Efforts should be made to maintain the blood supply during mobilization of the ureter; a fully skeletonized ureter is not desirable and likely prone to future stricture. Nonetheless, a tension-free anastomosis is vital, so careful ureteral mobilization will be required. Appropriate ureteral debridement to a bleeding edge is also key. Keep in mind that high velocity projectiles can result in blast injury and ischemia, which can produce occult injury up to 2 cm away from the transection.

Many ureteral injuries proximal to the iliac vessels may be repaired primarily over a stent in a tension free fashion. Using a 4-0 or 5-0 absorbable suture in spatulated suture is recommended. Spatulating both ends of the ureter is typical and ensures an mucosa apposition the gold standard (Fig. 1). Distal to the iliac vessels, a ureteral reimplantation with maneuvers such as psoas hitch or Boari flap are

recommended. Most distal injuries can be treated with a simple psoas hitch. The bladder is mobilized, particularly the contralateral side from the pelvic side wall. Occasionally the contralateral superior vesical pedicle must be ligated. The bladder is then affixed to the psoas muscle. The posting sutures are placed in the direction of the muscle fibers to minimize nerve entrapment.

Traditionally, a Boari flap in conjunction with a psoas hitch has been utilized to bridge a 6- to 8-cm gap of proximal ureter (Fig. 2). The base of the flap should be at least 4 cm wide to avoid flap necrosis. The base width must increase proportionally with planned length. Using umbilical tape or ruler the length of flap may be estimated. Small contracted bladders due to radiation or other causes are not suitable candidates for Boari reconstruction.

Other bladder flap shapes such as spiral flaps may allow for longer ureteral length at the expense of bladder capacity. If tension is still evident, the incision may be enlarged and mobilization of the kidney may provide enough ureteral length to proceed.

For trauma involving long segments of ureter, other reconstructive options include ileal ureter substitution, transureteroureterostomy/autotransplant, or nephrectomy. Consider referral to specialty center for complex injuries.

For cases when complex reconstruction is not attainable given patient comorbidity or status, clipping the ureter proximal to injury and obtaining percutaneous drainage is a reasonable alternative. At some point, ureteral reconstruction will become necessary. Given likely formation of adhesions this should be performed within the first 7 days of injury or delayed (typically for about 3 months). If reconstruction is planned in a delayed setting, percutaneous nephrostomy tubes are typically exchanged every 6 weeks. In a delayed setting, the reconstructive procedure can be attempted laparoscopically or robotically for the experienced surgeon.

TABLE 1 American Association for the Surgery of Trauma Ureteral Injury Scale

Grade	Injury
I	Hematoma, contusion or hematoma without devascularization
II	Laceration: <50% transection
III	Laceration: >50% transection
IV	Laceration, complete transection with <2 cm of devascularization
V	Laceration, avulsion with >2 cm of devascularization

Modified from Moore EE, Cogbill TH, Jurkovich GJ, et al. Organ injury scaling: III. Chest wall, abdominal vascular, ureter, bladder, and urethra. J Trauma. 1992;33(3):337–339.

Complications and Follow-up

Urine extravasation may continue despite repair. Such patients may present with urinoma or infected abscess best treated with antibiotics and percutaneous drainage. Ureteral stent, if already removed, should be replaced if extravasation is suspected. Long-term ureteral stenting can be successful in managing minor defects in repair.

Long-term sequelae from primary ureteral repair may include ureteral stricture. Patients should be followed with ultrasound imaging. Functional studies such as nuclear medicine Lasix renal scan can be pursued if hydronephrosis is noted. The goal of continued follow-up is to prevent renal disease secondary to asymptomatic obstruction. Strictures, if identified, can be repaired. High-volume centers have had recent success with the use of buccal mucosal graft placed at the site of focal ureteral stricture.

Future Directions

Application of robotic and laparoscopic techniques to reconstructive procedures has grown in the past decade. Other innovative techniques on the horizon include the use of injected indocyanine green to visualize a devitalized area of the ureter under near-infrared fluorescence. Attempts at utilizing engineered tissues in the urinary tract to replace or augment damaged areas remain in their infancy. In rare cases of complete ureteral loss, robotic autotransplantation or robotic ileal ureter interposition are reported at centers with extensive robotic expertise.

KIDNEY

Renal injury management has evolved in the past several decades toward conservative treatment for even high-grade injury. Renal trauma accounts for an estimated 3% of trauma cases. For these patients who experience abdominal trauma, renal injury occurs in about 10%. Given certain anatomic realities, pediatric patients may have higher risk of injury than adults. Luckily, only a small percentage of cases require surgical intervention.

With the refinement of endovascular technology, bleeding events that in past decades would have led to open surgery and sometimes nephrectomy can now be salvaged. Injuries such as artery leak often

TABLE 2 Strategies for Ureteral Repair Based on Injury Location

Injury Location	Injury Length	Primary Procedure	Fallback Procedure
Common (any)	1–2 cm	Retrograde and stent	Percutaneous nephrostomy tube
Upper one-third	1–3 cm	Pyeloplasty Ureteroureterostomy	Renal pelvic flap Downward nephropexy Autotransplant
Middle one-third	1–3 cm	Ureteroureterostomy Transureteroureterostomy	Downward nephropexy Appendix substitution (right) Ileal ureter Autotransplant
Distal one-third	Up to 8 cm	Reimplantation Ureteroneocystostomy	Psoas hitch Boari flap
Complete loss	Complete	Ileal ureter Autotransplant	Nephrectomy

studies on their own or, at worst, require arterial stent or percutaneous drain. Operative renal trauma at present is reserved for cases of complex, multiorgan injury or penetrating trauma. The key to proper management is proper staging of injury (Table 3, Fig. 3). The American Association for the Surgery of Trauma Kidney Injury Scale has been prospectively evaluated and injury stage is predictive for the need for interventions.

General principles of surgery in the traumatic abdomen such as packing quadrants and systematically identifying areas of injury apply to these situations. A key consideration before renal intervention is identifying whether the retroperitoneum has been violated or expanding hematoma is present. Many methods have been devised to repair renal parenchyma and avoid nephrectomy, however, with ongoing and severe hemorrhage, nephrectomy may be prudent. The primary objective of managing these patients is to control life-threatening bleeding while preserving enough nephron mass to avoid renal disease.

Anatomic Considerations

The kidneys are paired compartmental structures. The psoas muscle lies posterior to each kidney and the colon lies on the anterior surface. The kidneys are surrounded by perirenal fat and Gerota's fascia, which encapsulates the adrenal glands and kidneys. The lower poles of the kidney are inferior to the 11th rib and are somewhat more prone to injury, whereas the superior aspect and hilum are more protected by the ribs.

The kidneys have a segmental arterial supply. In general, blunt injuries fracture along the planes between the segmental vessels, whereas penetrating injuries may involve and cross segmental arteries. Varied vascular anatomy may be encountered. The most common variant is an accessory lower pole renal artery, which may be present in about 10% of patients. Ureteral duplications and pelvic and horseshoe kidneys are also possible and make subsequent surgical exploration complex.

The anterior axillary line is an important landmark to consider during the kidney. This is the vertical line that runs along the anterior axillary fold. Abdominal side wounds anterior to the anterior axillary

TABLE 3 American Association for the Surgery of Trauma Kidney Injury Scale

Grade*	Injury
I	Contusion or nonexpanding subcapsular perirenal hematoma and no lacerations
II	Superficial laceration <1 cm depth and does not involve the collecting system (no evidence of urine extravasation) Nonexpanding perirenal hematoma confined to retroperitoneum
III	Laceration >1 cm without extension into the renal pelvis or collecting system (no evidence of urine extravasation)
IV	Laceration extends to renal pelvis or urinary extravasation Injury to main renal artery or vein with contained hemorrhage Segmental infarctions without associated lacerations Expanding subcapsular hematomas compromising the kidney
V	Shattered kidney Avulsion of renal hilum: devascularization of a kidney due to hilar injury Uncategorized: avulsion Complete laceration or thrombus of the main renal artery or vein

Modified from Moore EE, Shackford SR, Pachter HL, et al. Organ injury scaling: spleen, liver, and kidney. *J Trauma*. 1989;29(12):1664–1666. Advance one grade for bilateral injuries up to grade III.

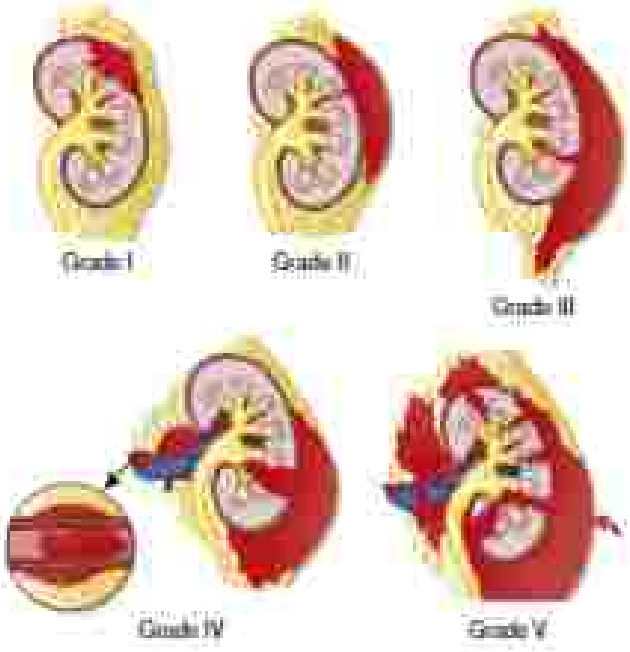

FIG. 3 Trauma kidney injury scale. (From Adams JG, Auster J, Collings J, Dibbell DM, Cassidy MA, Nadel ES, eds. *Emergency Medicine: Clinical Essentials, 2nd ed*. Philadelphia: Elsevier; 2013.)

[ion are often associated with concomitant abdominal injuries. Renal injuries posterior to this line rarely impact the colon but in general are much less likely to involve intraabdominal organs.

Children under 16 are vulnerable to renal injury. They have relatively large kidneys with underdeveloped Gerota's fascia and less perirenal fat, which is protective in adults. Because of incomplete ossification of the lower ribs, children's kidneys are more likely located in the true abdomen. Moreover, shock is an unreliable indicator of injury extent in children because they can have a robust catecholaminergic response to stress that may mask severe blood loss.

Diagnosis

Physical manifestations of possible injury generally include flank ecchymosis, rib fractures, and transverse spinal process fractures. Hematuria is also a common sign of trauma to the kidneys; however, the presence and degree of hematuria does not correlate with injury severity. Likewise, the absence of hematuria does not rule out injury. If possible, the patient should be instructed to void before resuscitation efforts because mild hematuria may clear quickly in the setting of aggressive fluid resuscitation. The presence of hematuria can guide whether further imaging is indicated.

Decisions on diagnostic imaging are predicated on mechanism of injury (blunt vs penetrating), the presence of hematuria (gross vs microscopic), and shock (blood pressure <90 mm Hg). In adults, blunt trauma with gross hematuria requires further imaging. In contrast, adults with blunt trauma and microscopic hematuria require no imaging because no associated significant injury is expected. These patients with suspected blunt trauma, microscopic hematuria, and shock do require imaging. The mechanism of injury itself can prompt imaging; for example, major acceleration or deceleration injuries such as a fall from height or high-speed motor vehicle accident should prompt imaging. In penetrating injuries, any degree of hematuria or an injury location suspicious for renal trauma should prompt imaging. Patients who do not initially undergo renal imaging who later develop hematuria should also be imaged.

Given their abnormal blood differences, lower imaging thresholds for children exist. Any pediatric trauma (<16 years) with any degree of significant hematuria (>50 red blood cells per high-powered field) should be imaged.

Contrast-enhanced CT with additional 10 minute delay scans is the gold-standard imaging modality to stage the stable renal trauma patient and is both sensitive and specific for renal injuries.

There are some situations in which CT scan is not possible or ill-advised given patient instability. For these patients, a single-shot high-dose intravenous urography (IVU) can provide some useful information. Briefly, it confirms the presence of two functional kidneys, may show extravasation of the collecting system, and, in penetrating injuries, may show the course of the projectile. One-shot trauma IVU consists of 2 mL/kg of body weight of standard 60% intravenous contrast injected intravenously, followed by an abdominal radiograph 10 minutes later. The patient requires a suitable blood pressure (usually about 90 mm Hg) for satisfactory study.

Nonoperative Management

Numerous years of research have demonstrated that most renal injuries can safely be managed nonoperatively. Lower grade injuries are typically managed with bed rest, hemodynamic monitoring, and serial hemoglobin measurement. New evidence has emerged suggesting bed rest may not be required, especially in patients without hematuria. Transfusions may be given as needed. If hemodynamic instability develops, additional imaging with angiography and possible embolization or surgical exploration may be required. One exception for angiography is if a patient requires two units of blood. We also strongly consider angiography if any patient has persistent gross hematuria or develops suspected pseudoaneurysm or arteriovenous malformation.

Angiography with superselective embolization therapy for renal trauma has evolved. It is a minimally invasive approach and can be

TABLE 4 Indications for Operative Management of Renal Trauma

Absolute indications	Relative indications
Expanding pulsatile retroperitoneal hematoma	Urinary extravasation without visible ureter
Renal pedicle avulsion	Concurrent colon/pancreas trauma: exploration with incomplete staging or grade III or greater concurrent renal injury
Persistent life-threatening shock or hemorrhage	Renovascular hypertension
Ureteropelvic junction disruption or avulsion	Failed embolization

effective in stopping bleeding, because there is no significant collateral arterial blood supply to the kidney, embolization stops hemorrhage at the expense of nephrons.

Those patients with high-grade injuries should be managed with second CT urogram 3 to 5 days after initial presentation to evaluate for persistent urine leak or urinoma. While being managed conservatively, patients may develop new fever or flank pain which should prompt earlier restaging. On additional imaging, large urine leaks should prompt indwelling stent placement. It is prudent to leave a urethral catheter in such cases to prevent reflux of urine. Antibiotics should also be considered to prevent infected urinoma. Large or infected urinomas seen on subsequent imaging without ongoing extravasation can be drained percutaneously.

Surgical Approach to Repair

A critical decision in renal trauma is when to proceed to operative intervention (Table 4). The approach to renal trauma can be accomplished with proximal vascular control or in a lateral to medial approach. Although some prefer proximal control in most settings that require exploration, the lateral approach involves mobilizing the overlying colon, and dissecting the kidney from Gerota's fascia. The vasculature is approached in a lateral to medial direction. During this work, a Satinsky clamp, sponge stick, or manual pressure can be used to stop bleeding while the kidney is repaired. Particularly for lateral parenchymal injuries, isolating each vessel for possible clamping may not be necessary.

Particularly if there is a medial hematoma, we believe early vascular control ultimately decreases the nephrectomy rate. Uncontrolled hemorrhage may lead to unplanned nephrectomy, when approached in a systematic fashion, vascular control can be done quickly and efficiently. Such control should reduce unplanned nephrectomy in trauma.

We approach the injured kidney through a standard trauma laparotomy midline incision from the pubic symphysis to the xiphoid. A fixed retractor such as the Bookwalter may be employed, but surgical assistants may perform manual retraction effectively with such an incision. The transverse colon is wrapped in moist sponges and placed on the chest or in ample abdominal is can be packed. The small intestine can be placed in a bowel bag or protected with moist lap sponges and retracted superiorly or placed on the chest to the right. Ultimately, all the bowel must be moved to the root of the mesentery and the ligament of Treitz are exposed.

With great care, the retroperitoneum is incised over the aorta superior to the inferior mesenteric artery and the incision is extended to the ligament of Treitz (Fig. 6). If a retroperitoneal hematoma prevents palpation of the aorta, consider an incision medial to the inferior mesenteric vein (IMV). The IMV runs a few centimeters to the left of the aorta and is usually easily identifiable, even if aortic pulsations are not. Continue to open the retroperitoneum along the anterior surface of the aorta until the left renal vein is encountered at its crossing. In less than 1% of cases, the left renal vein will be retroaortic. Once identified, a vessel loop should be placed around the left renal vein. This vessel can be used as a guide to help find the remaining renal vasculature. Once found, they too may be encircled with vessel loops. Most bleeding can be controlled during repair with manual compression of the kidney; rarely will vessel occlusion be necessary. But with this dissection complete, the vasculature can quickly be occluded with building clamps or other means as necessary.

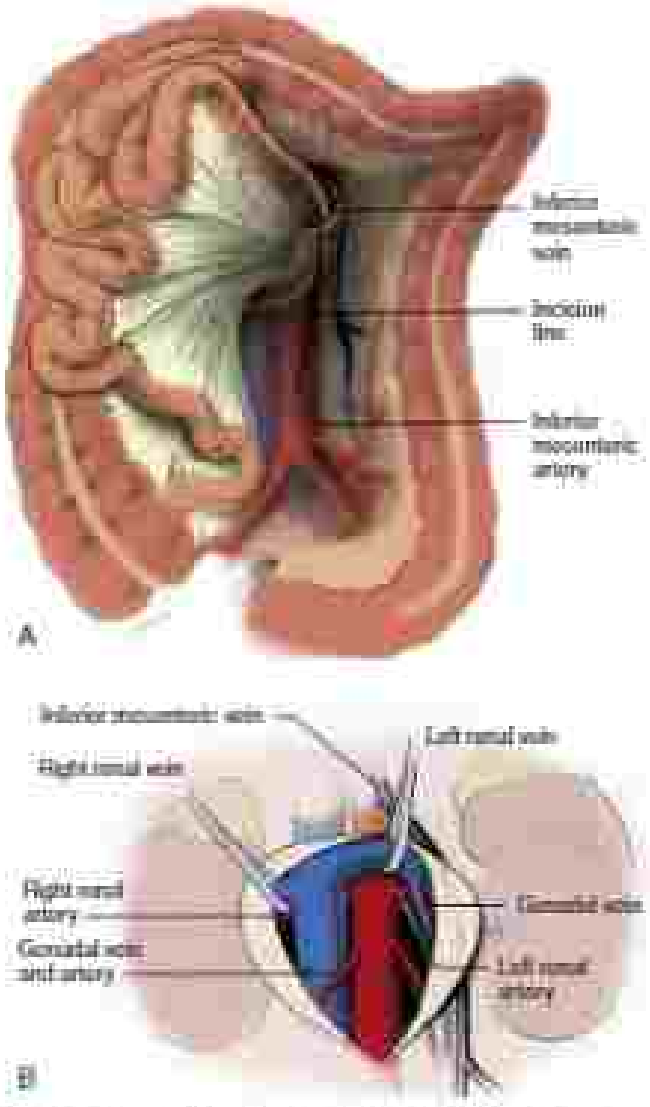

FIG. 6 Technique to obtain vascular control. (A) Exposure of the major vessels. (B) Relationship of the renal vasculature after incision of the posterior peritoneum over the aorta. (From Mc, Inc JW Surgery for renal trauma. In Novick AC, Streem S., Pierce JF., eds. Stewart's Operative Urology. Baltimore: Williams and White; 1989.)

Next, the injured kidney may be exposed in the typical fashion by mobilizing the ipsilateral colon along the white line of Toldt and reflecting it medially. Gerota's fascia is then incised along its lateral aspect. We prefer a lateral approach at this point to avoid renal vein thrombosis, subcapsular dissection or ureteric injury. It also may help preserve perinephric fat for later reconstruction. Renal capsule preservation is particularly important because this fascia is a strength layer needed during reconstruction and tearing it results in more bleeding.

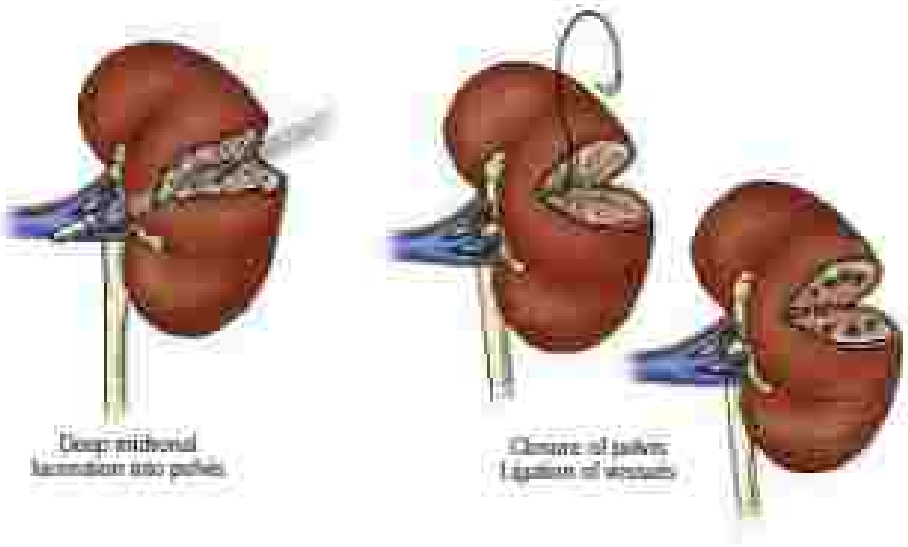

FIG. 5 Example of closure for traumatic penetrating renal injury from *[Grant Kim H, Mullens WK, Hill W. Kidney trauma [penetrating and vascular injuries] repair and nephrectomy. In: Gill WC, Asensio JA, Adams CA, et al., eds. Atlas of Traumatic Emergency Surgical Techniques. Philadelphia: Elsevier, 2018.]*

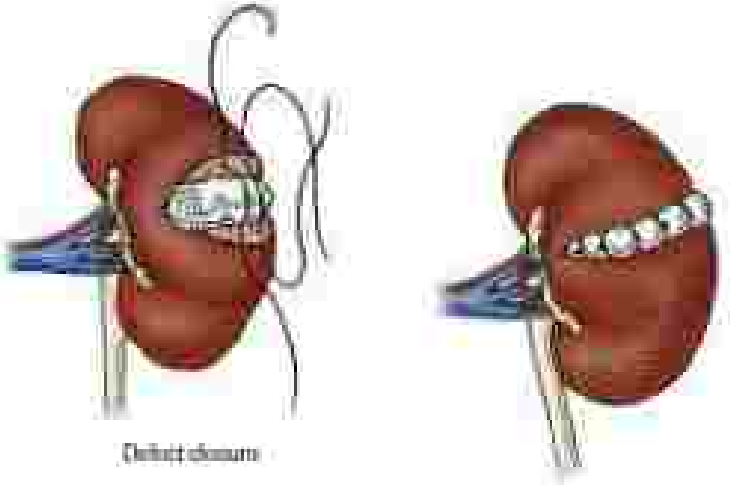

FIG. 6 Example of closure for traumatic penetrating renal injury with buttress *[Grant Kim H, Mullens WK, Hill W. Kidney trauma [penetrating and vascular injuries] repair and nephrectomy. In: Gill WC, Asensio JA, Adams CA, et al., eds. Atlas of Traumatic Emergency Surgical Techniques. Philadelphia: Elsevier, 2018.]*

Generally, in a hemodynamically stable patient, renal reconstruction should be employed. Coagulopathic patients or those with life-threatening hemodynamic signs should be monitored for nephrectomy. In some cases, after controlling hemorrhage and packing the retroperitoneum, further resuscitation is required and a planned return to the operating room should be arranged. Heroic reconstructive measures should be employed for patients with solitary kidneys. Renal injury reconstruction is analogous to the repairs performed during a partial nephrectomy for cancer. First, perform sharp excision of all nonviable parenchyma. Meticulous hemostasis of individual bleeding vessels can be obtained with sutures, cautery, or argon beam. In particular, the collecting system should be closed to a watertight fashion with absorbable sutures to prevent urinoma or ongoing extravasation (Fig. 5). It is prudent to place an antegrade ureteral stent for significant collecting system reconstructions. Parenchymal defects can also be reconstructed by approximating capsular edges over a hemostatic absorbable buttress such as Surgicel, or thrombin soaked Gelfoam (Fig. 6). In some cases, heminephrectomy may be required due to extent of injury. Omental interposition can be used to separate the injured kidney from any concurrently injured abdominal organs. Placing omentum between the lower pole and ureter can also help prevent perinephric fibrosis (Fig. 7).

It is important to recognize situations in which reconstruction may be counterproductive and nephrectomy preferred: shattered kidneys, kidneys with major vascular lacerations, or an unstable patient.

Complications and Follow-up

Complications typically occur early and are most often related to the collecting system. In particular, urinoma formation and prolonged urinary extravasation are most common. Infected urinomas may become symptomatic. Patients may present with fevers, flank pain, or sepsis. Such abscesses typically require percutaneous drainage and antibiotics. Prolonged urinary extravasation can typically be managed with a ureteral stent. Ongoing or delayed hemorrhage after repair can be evaluated via angiography and consideration given to embolization if continued transfusions are required.

Delayed bleeding, abscess formation, urinary fistula, hypertension, and hydronephrosis are considered late complications. Pseudoaneurysm or arteriovenous fistula either from the initial injury or the repair may result in delayed bleeding about 2 to 4 weeks after surgery. Embolization typically can effectively treat this issue. As stated previously, abscess formation is treated by percutaneous drainage and systemic antibiotics. A delayed urinary fistula requires further evaluation to determine its location either via CT urogram

or retrograde study. Concurrent ureteral stricture or injury may be identified at this time. An indwelling stent and/or percutaneous drainage of the kidney should be attempted with planned repair 3 to 4 months in the future.

Hypertension is a rare long-term complication that results from either arterial stenosis (Goldblatt kidney) and chronic upregulation of the renin/angiotensin axis or direct parenchyma compression (Page kidney). If hematoma causing renal compression is the possible cause, surgical decompression may be useful but hypertension is ideally controlled medically. Hydronephrosis may develop due to unrecognized ureteral injury or after perinephric fibrosis resulting from injuries to the ureteropelvic junction or lower pole of the kidney. Interposition of omentum or perinephric fat between the injured kidney and the ureter at the time of repair may prevent this issue. Ultimately, it may be prudent to pursue renal ultrasound and blood pressure measurement for patients who have undergone renal reconstruction in the setting of trauma.

Tenets of Damage Control

J. David Richardson, MD, and Nicholas A. Nash, MD

Classical surgical teaching espoused the principles that once an operation had been undertaken, it should be continued to completion with an attempt to correct all the issues or problems encountered even in the setting of physiologic derangements. The mantra "do it right the first time" often prevailed. In the situation of the severely injured patient with major hemorrhage, this approach often resulted in a lethal triad of hypothermia, profound metabolic acidosis, and coagulopathy. This triad usually resulted in a death spiral from which the patient could not be salvaged, with a mortality approaching 90%.

The term *damage control* was adopted from the Warfare Manual of the Department of the Navy. It was stated as "the capacity of a ship to absorb damage and maintain mission integrity." Although the principal tenets of damage control had been espoused earlier, in 1983 Rotondo and Schwab described their experience with what could be termed *abbreviated laparotomy* when with abdominal packing and subsequent reoperation in an attempt to decrease the mortality in penetrating injuries causing exsanguination. Using this mindset, they reported greatly improved survival with a strategy to rapidly control bleeding and stabilize the patient before attempting definitive treatment.

The central tenets of damage control surgery are (1) control the threatening hemorrhage, (2) limit or prevent contamination, and (3) maintain end organ perfusion. The improved results of this concept led to its widespread adoption, but efforts to codify improved resuscitative strategies lagged behind the utilization of damage control operative techniques. Major conflicts in the Middle East led combat surgeons

Tenets of Damage Control

J. David Richardson, MD, and Nicholas A. Nash, MD

Classical surgical teaching espoused the principles that once an operation had been undertaken, it should be continued to completion with an attempt to correct all the issues or problems encountered even in the setting of physiologic derangements. The mantra "do it right the first time" often prevailed. In the situation of the severely injured patient with major hemorrhage, this approach often resulted in a lethal triad of hypothermia, profound metabolic acidosis, and coagulopathy. This triad usually resulted in a death spiral from which the patient could not be salvaged, with a mortality approaching 90%.

The term *damage control* was adopted from the Warfare Manual of the Department of the Navy. It was stated as "the capacity of a ship to absorb damage and maintain mission integrity." Although the principal tenets of damage control had been espoused earlier, in 1983 Rotondo and Schwab described their experience with what could be termed *abbreviated laparotomy* when with abdominal packing and subsequent reoperation in an attempt to decrease the mortality in penetrating injuries causing exsanguination. Using this mindset, they reported greatly improved survival with a strategy to rapidly control bleeding and stabilize the patient before attempting definitive treatment.

The central tenets of damage control surgery are (1) control the life-threatening hemorrhage, (2) limit or prevent contamination, and (3) maintain vital organ perfusion. The improved results of this concept led to its widespread adoption, but efforts to codify improved resuscitative strategies lagged behind the utilization of damage control operative techniques. Major conflicts in the Middle East led combat surgeons

to develop the concept of *damage control resuscitation*, emphasizing the earlier and greater use of the components of whole blood instead of traditional crystalloid infusion for initial resuscitation.

The term *damage control* and its underlying tenets have now been applied to virtually all aspects of emergency surgical procedures, including orthopedic surgery and neurosurgery. However, the scope of this chapter is limited to five basic themes: (1) the proper mindset and recognition of patients who might require damage control procedures, (2) damage control resuscitation, (3) damage control laparotomy for trauma or general surgical emergencies, (4) abbreviated thoracotomy, and (5) pitfalls or downsides to possible overuse of these techniques.

DAMAGE CONTROL MINDSET

To properly implement successful damage control strategies, it is imperative that surgeons have the proper mindset. This mindset should initiate an early thought process that triggers a set of responses that will begin immediately. Therefore, a successful damage control strategy in a patient who presents with hypotension should begin in the emergency department. The mindset should include a rapid assessment, a comprehensive resuscitation strategy, and a plan for early operative or radiologic intervention, depending on the type of injury.

Many patients who will require a damage control laparotomy or thoracotomy present to the emergency department with obvious signs of physiologic derangement on admission. They may be actively bleeding, have altered coagulation profiles early (if studied), and signs of hypoperfusion. Certainly surgeons with adequate experience in the care of the injured may recognize these signs immediately and proceed with a proper mindset; those with less experience may not do so, leading to delays in appropriate resuscitation and poor operative management. For example, damage control resuscitation (see later in this chapter) should not be initiated after the patient is already coagulopathic. Likewise, relying on abdominal packing to control bleeding after the patient is well into the coagulopathy phase of the triad will generally have an unsatisfactory outcome.

Making these decisions requires sound judgment, which usually comes from experience. One obviously should not initiate massive blood transfusion on a patient who has transient mild hypotension but does not otherwise appear seriously injured, nor should the surgeon pack an abdomen immediately when hemorrhage could be controlled using time-honored surgical techniques. However, in a patient who is clearly severely injured, timely treatment is vital and delays may lead to the patient's eventual death.

The principles for the use of abbreviated thoracotomy are less clear to our practice, and the consequences of strategies, such as packing the thorax, may be more deleterious. With these considerations in mind, we are somewhat more reluctant to employ this technique for thoracic injuries. However, in appropriately selected patients, it may be lifesaving. Recently, damage control vascular surgery has been promulgated. In our experience where most injuries can be repaired expeditiously, these techniques are not widely used, whereas in a combat zone, in a rural hospital, or when there is no experienced surgeon available to treat the injured blood vessel, vascular damage control techniques may be appropriate.

In summary, a proper mindset regarding damage control surgery means one must be able to rapidly assess the individual situation and apply proper judgment as to the treatment needed.

The proper mindset for damage control procedures in emergency general surgery or the occasional elective operation that proceeds badly is often different from that needed in hemorrhage from trauma situations. In our experience, there are generally three scenarios within the abdomen in which damage control techniques may be useful: (1) the patient has an obvious intra-abdominal catastrophe that may be manifested by sepsis, hypotension, or major physiologic derangement; (2) the patient may have an obvious abdominal problem but the extent of the situation and remedy required are not obvious until the procedure commences; or (3) the patient has an elective operation in which an untoward event occurs that is usually manifested as major hemorrhage. In the first scenario (obvious intra-abdominal catastrophe and altered physiology), the surgeon should have a damage control strategy at the top of their mind. This may involve source control of infection if possible, drainage of purulent material, and an abbreviated procedure that likely will require reoperation. Temporary abdominal closure may be indicated, particularly if the patient is unstable.

In the second scenario the surgeon may be unprepared for the extent of the problem and may be tempted to overreach in an attempt to solve the problem completely. Provided the patient is hemodynamically stable, complete correction is desirable, but occasionally in complex problems unrecognized preoperatively, temporization is a preferable option. In such situations, early planned reoperation may permit a better outcome. We have been involved in many cases through the years where the third scenario of major unanticipated hemorrhage occurs during an elective operation. Examples include abdominal trocars placed into the vena cava, aorta, or iliac vessels or major pelvic bleeding from oncologic or gynecologic procedures. Because these events were not anticipated, a different mindset is necessary. Temporary packing while blood is obtained and appropriate consultation achieved is mandatory. Notification of family members with the patient should be done promptly. If major bleeding is encountered, then a shift in mindset from operative completion to patient salvage should occur.

Although the considerations about mindset may appear self-evident, in our experience the reality may be different. Even surgeons who virtually never encounter significant bleeding in their elective procedures should have a default option in the unlikely event that the unthinkable occurs. The lead author of this chapter was once consulted intraoperatively by a plastic surgeon who transfused seven units of blood after encountering bleeding from an unnamed large vein on the chest wall during a breast procedure. The safe practice of surgery requires a prepared mind and a proper mindset to deal with the myriad of situations that may be encountered in both elective and emergent procedures.

DAMAGE CONTROL ASSESSMENT AND RESUSCITATION IN TRAUMA PATIENTS

After initial triage by prehospital providers, patients at risk for major hemorrhage should be rapidly identified. The principles of the Advanced Trauma Life Support manual should be followed, but in an extremely timely manner. Failure to identify a problem may be catastrophic, but the assessment cannot be done at a leisurely pace in high-risk patients. Once the airway is secure, a rapid diagnostic evaluation should be performed, which may include a focused assessment with sonography for trauma (FAST), and a chest and pelvic radiograph (if indicated). Although diagnostic peritoneal lavage is not used commonly, it still can have value in the patient with unexplained hypotension and an equivocal FAST examination. The hospital's massive transfusion protocol should be initiated to alert the blood bank regarding the potential for a patient with major blood requirements.

Damage control resuscitation (DCR) should ideally be used in tandem with a damage control operation. While the hemorrhage may be easily controlled with standard surgical techniques, such as a splenectomy, the nature of an abbreviated procedure should be reconsidered from the outset if the bleeding is not readily controlled. DCR, as currently practiced, has a three-pronged strategy: (1) permissive hypotension, (2) limitation of crystalloid infusion, and (3) hemostatic resuscitation. Permissive hypotension is the concept of ensuring circulation adequately to perfuse vital organs without complete resuscitation, which may actually increase bleeding. The adequacy of circulation in the practice of permissive hypotension can potentially be judged on two factors: preservation of sensation and the ability to palpate at least a weak radial pulse. The practice of permissive hypotension was initially found to be beneficial in treating patients with

ruptured abdominal aortic aneurysms. The Ben Taub group in Houston demonstrated its safety and efficacy in patients with penetrating trauma and short transport times to a trauma center.

The second limit to DCR involves limiting the infusion of crystalloid solutions. Although crystalloid infusions have great value in certain situations, in patients with major hemorrhage their overuse before surgery may cause a dilution of clotting factors with subsequent clot disruption. Additionally, crystalloid solutions, especially when administered in large volumes, have a proinflammatory effect that may potentiate organ failure. In severe hemorrhage, the early use of blood components appear to be advantageous.

The third limit revolves around the early use of what is termed *hemostatic resuscitation*. For several decades before the ongoing Middle East conflicts, the use of blood products for hemorrhage control was a foreign concept. Blood components were replaced as needed, often based on measuring the hematocrit, obtaining a platelet count, or using other laboratory measurements for calculating the need for component replacement. However, the seminal work by United States military surgeons demonstrated that early replacement of whole blood or its constituent parts decreased transfusion requirements and resulted in a decreased mortality. These experiences have been replicated in numerous civilian experiences. Although the use of fresh whole blood is not feasible in nonmilitary settings, the replacement of its constituent components is feasible. The initial mantra for component replacement was 1:1:1 with a unit of platelets and fresh frozen plasma (FFP) for each unit of packed red blood cells. Although there has been some debate about the correct ratio of components and there has been no randomized control trials for DCR, there is an overwhelming clinical experience supporting these concepts in patients with major blood loss. There are theoretical reasons to avoid the transfusion of "old" blood in massive blood situations. Storage of blood leads to various degradative products over time and these storage lesions are likely proinflammatory. The practicality of this approach in clinical settings is less clear.

In addition to the aforementioned principles, there are other considerations that may need to be addressed, especially in patients with major blood loss.

Hypothermia Prevention

Hypothermia is a part of the lethal triad, but some of its effects may be partially ameliorated if addressed early. After the patient has been fully exposed to exclude associated injuries, warm blankets and forced air warming devices should be applied to decrease heat loss. Fluids and blood products should ideally be warmed during infusion. Supplemental oxygen should be maximally titrated. However, if the patient cannot be promptly resuscitated, hypothermia may continue despite warming efforts.

Acidosis Prevention

This topic remains controversial. Normal saline has a pH of approximately 5.5, whereas Ringer's lactate is more physiologic. Hence, large volume infusion of normal saline should be avoided.

Pharmacologic Adjuncts

Medications are available for rapid infusion that may aid in reversing the effects of coagulopathic bleeding and aid in the DCR process. Prothrombin complex concentrates (PCCs) are drugs consisting of clotting factors (three factor PCCs consist of clotting factors II, IX, and X; four factor PCCs add clotting factor VII). These products mimic the effects of FFP but act more rapidly and are much easier to deliver to the patient with less volume required (the drug comes in powder form). Antifibrinolytics (tranexamic acid [TXA] or aminocaproic acid) have also become a mainstay of most DCR situations with massive blood loss. They act to prevent hyperfibrinolysis, whereby the body's natural breakdown of clots occur in a pathologic, accelerated process. Some centers are able to quickly decide which patients would best benefit from this therapy with thromboelastogram evaluations. Others without this technology can use TXA based on clinical judgment (hypotension, presumed need of massive transfusion protocol) given the overall safety profile of the drug and its proven ability to decrease the amount of blood transfusions necessary in such circumstances.

DAMAGE CONTROL LAPAROTOMY FOR TRAUMA

A surgeon attempting to perform damage control laparotomy should have the proper mindset, as previously mentioned. Most patients who will need a damage control operation for bleeding will present with evidence of significant blood loss, preoperative acidosis, abysmal lactate, hypothermia, or other suggestive signs. There are other situations where the level of hemorrhage may not be readily apparent but becomes so after clots are dislodged or visceral structures are manipulated. In our opinion, a midline incision should always be used in exploration (laparotomy) for trauma. Blood and clots must be evacuated and the source of the hemorrhage isolated as rapidly as possible. Our teaching is to attempt to locate the source of bleeding by quadrants, if possible, while realizing that some patients will have multiple bleeding sites. The targeted areas should have abdominal packs placed rapidly for tamponade in all four quadrants, including the pelvis.

In patients with significant ongoing hypotension, the aorta may be occluded at the diaphragm by manual compression or may be controlled with a metallic aortic occluder or cross-clamped with a vascular clamp. The cross clamping of the aorta is one of those techniques that is much easier to describe than to actually do, even for the experienced surgeon. It can be accomplished by rotating the esophagus slightly to the left after rapidly and safely encircling it. The muscular fibers overlying the aorta may be rapidly divided, and a large noncrushing vascular clamp can then be used to cross clamp the aorta. Our teaching is to actually attempt to clamp the spine and, in that case, one is more likely to actually have the aorta clamped. Although aortic clamping is more difficult than simply compressing the aorta, if it can be accomplished rapidly and successfully it does allow for better hemostasis and facilitates exposure in the upper abdomen without the need for an assistant to provide continuous manual compression. Control of the aorta at the hiatus allows resuscitation by the anesthesia team. Aortic control may be obtained in the prehospital or emergency department setting, with the use of a technique called *resuscitative endovascular balloon occlusion of the aorta*, in which a balloon catheter is passed retrograde through the femoral artery into the aorta. The balloon is then inflated, resulting in aortic occlusion. This technique is useful in skilled, experienced hands, but is of doubtful utility for the novice who might consider its use. Packs should then be removed serially. Our practice is to remove those that are not bleeding initially, leaving the suspected site of hemorrhage until the final pack removal.

The areas that are most problematic for hemorrhage control in our experience are the liver and major vascular structures.

Hepatic Hemorrhage

Liver injuries may present in all shapes and sizes. If there are visible arterial and/or venous vessels bleeding from within a crack in the liver, these may be able to be safely controlled with direct vessel ligation. In our experience, putting clips on hepatic bleeding is not efficacious because they tend to fall off and rarely is there an accessible vessel to be adequately clipped. Although there are those who have condemned the use of hepatorrhaphy by using a large blunt liver needle to suppositionate crevices in the wound, we have occasionally found this to be a successful strategy. One should not strangulate tissue to the point that it becomes necrotic, but coaptating tissue may facilitate hemorrhage control, even if packing is necessary.

If there is a nonbleeding, contained hematoma in the retrohepatic region, under no circumstances should that hematoma be opened. Retrohepatic venous bleeding, which could come from a torn hepatic vein, is by definition a low-pressure system. Many of these will heal and not cause long-term sequelae if they are unopened.

Major arterial bleeding from deep within the liver must be stopped. Although packing is efficacious for venous bleeding, it does not control arterial hemorrhage. There is controversy about whether a patient should be taken from the operating suite to a hybrid operating room or an angiography suite to radiologically control major hepatic arterial bleeding. Such decisions would depend on the resources available within the facility, the expertise of both the surgeon and the radiologist who might be available to care for the patient, as well as the inherent stability of the patient at the time.

The use of control of the portal triad through cross clamping with the Pringle maneuver may be valuable while attempting to obtain control of hepatorrhaphy. Generally we request that our cross-clamp time be measured and, in 15- to 30-minute increments, we then remove the clamp for a few minutes to allow liver reperfusion, even if the clamp needs to be reapplied.

In our experience, a generalized venous bleeding from the hepatic parenchyma itself is extremely difficult to control with suture techniques. If there is a segment of liver that is amenable to resection, newer resective techniques using staple devices are efficacious in nonanatomic resections to control hemorrhage. Ongoing venous bleeding that is not rapidly controlled by either sutures or staple techniques should be considered for perihepatic packing.

We attempt to count the number of packs used to avoid having a retained sponge. As in many aspects of surgery, perihepatic packing may be a bit of an art. Simply stuffing packs in an insertion to posterior direction to compress the liver may effectively decrease bleeding, but it also may compress the vena cava and impede venous return to the heart, not allowing the patient to ever be adequately resuscitated. Rather, the packs should be placed in a superior to inferior position, such that the liver is compressed from top to bottom as opposed to the anterior to posterior direction. Whereas some surgeons advocate placing a nonadherent dressing over the wound before packing, we prefer to pack directly on the wound, believing the tamponade effect is actually greatest by direct sponge contact.

Spleen

A ruptured spleen causing major hemorrhage, whether as an isolated injury or in combination of others, should be treated with a rapid splenectomy. Attempts to salvage splenic injuries by splenorrhaphy or partial splenectomy should be strongly discouraged and a rapid splenectomy performed.

Renal

Any small, nonpulsatile, and nonexpansive hematomas involving the kidney should not be opened. If the patient has active, ongoing bleeding with an expanding perirenal hematoma, the treatment is more controversial. In a totally isolated situation, there are occasions where one may actually be able to salvage a portion of the kidney by a variety of techniques after control of the renal artery proximally. However, in our experience, this has been exceedingly rare and generally, once the hematoma is opened, a nephrectomy will be required. Before opening a hematoma, one should ensure presence of the contralateral normal-sized kidney.

Pancreas

Hemorrhage control of the pancreas is typically achieved with simple suture ligation or packing. It is important to remember contamination from a pancreatic duct injury. This can be controlled with simple drainage at the index operation, and more definitively with formal resection at the second look laparotomy (distal pancreatectomy, subtotal pancreatectomy, or Whipple, depending on the site of injury), if needed.

Pelvic Hematoma with Associated Pelvic Fracture

There can be significant amounts of blood in the pelvis and even further layering in the retroperitoneum with significant pelvic fractures. Intraperitoneal packing of the pelvis may provide some benefit. Depending on the extent the laparotomy incision, a separate incision can be made in the suprapubic area and the preperitoneal space of Retzius can be accessed and expanded toward the sacrum. Three laparotomy pads can be placed in both sides of the pelvis to help tamponade bleeding. Efforts at embolization of the internal iliac arteries can be made immediately after the operation and the interventional radiology or vascular teams should be mobilized during the operative phase.

Vascular Injuries

There are myriad types of vascular injuries. As previously stated, major arterial bleeding will require control through suture, staples, shunts, or some type of mechanical hemostasis. Likewise, most major venous injuries will require a primary repair as well. Venous bleeding from armored vessels or small vessels may be controlled by packing.

Control of hemorrhage is the initial priority in damage control surgery for trauma, but a secondary issue is the control of contamination from hollow viscus injuries. The source of visceral contamination should be isolated, identified, and may be controlled initially with a noncrushing clamp. If the intestine is devitalized, it may need to be rapidly resected using staple devices with a secondary anastomosis or ostomy creation at a later time with a planned reoperation. Some have advocated simply using a whipstitch to close visceral injuries, but in our experiences some of these will leak and cause major problems with sepsis and intestinal fistula at a later date. If the hemorrhage can be rapidly controlled, then taking a few additional minutes to perform a secure closure of bowel injuries is worthwhile. The decision required in terms of rapid cessation of the operation versus ensuring a secure closure depends on the judgment of the surgeon.

In damage control operations for emergency general surgical procedures where hemorrhage is not the concern, the use of an abbreviated laparotomy will generally be dictated by the physiologic state of the patient. Devitalized tissue should be removed, purulent collections drained, and necrotic intestines resected. Primary anastomoses may be delayed if the patient's condition warrants.

Whether the damage control laparotomy is performed for injury or an emergent nontrauma problem, the abdominal fascia will rarely be able to be closed primarily. Although the abdominal contents need to be adequately packed to control venous bleeding, closure of the fascia or skin may result in a deleterious increase in intraabdominal pressure and subsequent abdominal compartment syndrome. There are commercial systems available for an open abdomen that rely on negative pressure (e.g., ABThera), but we often use a homemade system with suction drains placed under the fascia to control the drainage of fluid from the open abdomen (this is important to prevent moisture on the body surface, which accelerates bowel loss). A layer of a nonadherent material is placed over the viscera, followed by a layer of sterile towels or packs.

Finally, an occlusive dressing (e.g., Ioban) is placed over the wound (Fig. 1). The patient is then returned to the operating theater for an attempt at definitive repair 24 to 72 hours later. A vigorous attempt should be made for primary fascial closure at the second procedure, or as early as feasible.

There are situations in which the abdomen cannot be closed during the initial hospitalization. Although this problem was once very common, we are encountering it much less frequently. Limiting crystalloid resuscitation and the use of DCR has decreased the problem of abdominal swelling somewhat. Negative pressure systems may allow more rapid fascial reapproximation.

FIG. 1 This patient has undergone a damage control laparotomy. The abdominal dressing consists of suction tubes for fluid evacuation, sponges to facilitate negative pressure therapy, and an iodine-impregnated sealing dressing.

Our unit has also championed the use of "direct peritoneal resuscitation" in which 2.5% glucose based dialysis fluid (Delflex) is used to irrigate the abdominal cavity and decrease visceral edema. Our results showed an increased ability to accomplish earlier fascial closure.

DAMAGE CONTROL THORACIC SURGERY

There are several indications for a thoracotomy for trauma. These include cardiac tamponade or evidence of cardiac injuries on FAST scan, massive thoracic hemorrhage or ongoing bleeding from the chest, or persistent or high likelihood of injuries to other intrathoracic structures, such as the bronchus or esophagus. Here we confine our remarks to patients who need an abbreviated operation for major thoracic hemorrhage.

Intrathoracic hemorrhage results from cardiac injuries, pulmonary injuries, or chest wall bleeding in most circumstances. On occasion, vascular injuries of the thoracic outlet may produce intrathoracic hemorrhage as well. This latter category of injuries must be controlled by appropriate operative or endovascular techniques. However, the principles of care for pulmonary injuries have changed somewhat in the past decade. With the increase in caliber and velocity of firearms, destructive pulmonary injuries are currently much more common than those encountered several decades ago, when the simple placement of a tube thoracostomy and reexpansion of the lung often led to the arrest of bleeding.

Major pulmonary hemorrhage should be controlled when possible by the minimum amount of pulmonary resection. However, devitalized tissue that tends to ooze may be difficult to control with simple suture closure. Nonanatomic resection with a stapling device often will suffice to controlling pulmonary bleeding. If the bleeding is massive, the hilum may need to be controlled to facilitate exposure of the bleeding vessels. Hilar control may be accomplished by placing a noncrushing clamp across the hilum or simply twisting the lung 180 degrees to occlude blood flow. The latter maneuver will capture tension of the inferior pulmonary ligament to the level of the inferior pulmonary vein. Anatomic lobectomy may be the standard for a cancer patient with good pulmonary function, but it is rarely indicated in most situations of pulmonary hemorrhage. On occasions, when bleeding from deep within the parenchyma is encountered, a "tractotomy" may be used to expose the bleeding vessel. Although this appears to be a simple technique when illustrated on a two-dimensional diagram in a textbook, in the cylindrical shape of the lung it sometimes is more difficult. Placing a stapling device within the minitract and firing it to expose the deeper portion of the lung may facilitate visualization of the bleeding vessel within the parenchyma, which can then be sutured. Major pulmonary resection, such as a pneumonectomy, should be avoided unless it is the only measure that will not result in an operative death. The results of a pneumonectomy for trauma are usually poor, with postoperative mortality resulting from delayed right heart failure.

Bleeding from chest wall vessels may occur from destructive missile wounds, such as a shotgun wound or from blunt trauma with multiple rib fractures, which may shear intercostal vessels. In the latter situation, the use of encircling sutures around the ribs may control bleeding. On rare occasions, we have actually taken the patient to our hybrid room for angiographic control of intercostal vessels that were not amenable to suture ligation. Occasionally, a patient is encountered who has continuous oozing from the chest wall that is not amenable to either suture or angiographic control. In this instance, packing the chest wall and performing an abbreviated thoracotomy may be lifesaving. We have also found occasional instances of significant diaphragmatic bleeding, where packing the inferior thorax may help temporarily quell hemorrhage. Cardiac wounds exposed by a median sternotomy may not, on occasion, be amenable to normal closure. The system used for managing the open abdomen is employed in these cases.

Although the principles of abdominal packing are now well recognized, the indications for packing the chest are less well defined, and the outcome is not always predictable. The use of significant packing within the thorax may limit pulmonary excursion and lead to ventilatory problems. Unlike the abdomen, in our experience, some type of closure of the chest is generally indicated to prevent herniation of the lung through the open thoracic cavity with subsequent lung entrapment and a poor ventilatory status. We have not found that packing the pulmonary parenchyma itself is practical or feasible. The use of towel clips or rapid suture closure of the skin of the thorax to prevent pulmonary herniation is useful. Similarly, the principles of oxygenation after adequate resuscitation and correction of physiologic derangements would mirror those of damage control surgery of abdominal injuries.

DAMAGE CONTROL VASCULAR SURGERY

Much has been written about damage control vascular surgery, particularly in a review of injuries suffered in combat. In war theaters, the ability to do vascular repair is limited by a number of factors, including the availability of skilled surgeons and the necessity for treatment of other injuries. In managing civilian injuries, the need for damage control vascular surgery may differ significantly. In our experience, the two primary indications for the necessity of damage control vascular surgery in civilian trauma are the need to (1) transport a patient from an initial managing facility to a more sophisticated level of care; and (2) temporize the effects of ischemia due to arterial injury, primarily in the extremities, while more urgent, life-threatening injuries are managed. If the patient is stable, other life-threatening injuries are not present, and there are adequate surgical capabilities for primary vascular repair, then the use of damage control strategies is not indicated, in our opinion. In situations where there is not adequate surgical capability, we rarely encounter patient transfers to us of ischemic wounds. Generally, these patients

are simply transported in the most compact manner possible, rather than attempting to open the extremity, place a shunt, and then transfer the patient. The judgment required in these types of decisions are extremely complex and would vary greatly from one institution and individual surgeon to another. However, in patients where bleeding is minimized from an extremity or cervical injury, such that operative control was mandatory, the use of a shunt may be an excellent bridge while the patient is transferred to a facility where a definitive repair can be undertaken. That said, however, our general impression is that if surgeons are able to place the shunt, they often are able to do a repair. In our trauma center, we use shunting on occasion in patients who have other severe injuries that must be managed, and the shunt is then used as a temporizing device. In such a situation, it is imperative that one closely monitors the distal flow to ensure the shunt has not clotted and is functioning properly. The principles that we attempt to follow for shunt placement are as follows.

- As one attempts to place a shunt, we recommend that the vessels be tested for backbleeding in the distal artery. If there is inadequate flow or poor backbleeding, a balloon catheter embolectomy should be performed to ensure no clots are present proximally or distally or that any existing clots are removed. We then follow this with the instillation of heparinized saline into both the proximal and distal limb of the transected vessels. Vessels then can be occluded using a vessel loop or Rumel tourniquet. We do not advise systemic heparinization in patients who are multiply injured.
- An appropriately sized shunt is then used by cutting to a length adequate to ensure it is secure at both the proximal and distal ends of the vessel. Blood flow can then be reestablished as the shunt is placed within the vessel. The shunt should be secured in place by using a sturdy ligature of heavy silk or nonabsorbable suture. We recommend that the vessel not be dilated or resected to normal artery because this can be better accomplished at the time of definitive repair.
- Distal perfusion must be assessed with Doppler ultrasound. Flow should be biphasic, or optimally triphasic. In our experience, pulses are generally not palpable in these patients.
- In patients with ischemic injuries, a rapid fasciotomy may need to be undertaken to ensure that compartment syndrome does not abrogate the effects of perfusion to the extremity with the shunt.

In these situations, definitive repair should be performed within 24 hours once resuscitation is complete. On occasion, shunts may be left in place for 2 to 3 days, but it is imperative that distal perfusion be adequately monitored.

DEFINITIVE OPERATION AFTER DAMAGE CONTROL SURGERY

Once the patient has been adequately resuscitated and normal hemodynamic and clotting status restored, the patient should be returned to the operating room as early as reasonably possible for definitive repair of injuries. In some situations, such as major hepatic bleeding, which has been controlled by packing, we prefer to leave the patient at least 24 hours, even if the resuscitation is complete within 6 to 8 hours. The mechanical effects of the packing itself on local coagulation is often important.

Regardless of which type of damage control operation is performed, the wound (and any subsequent) procedure performed must be meticulous. The potential for wound injuries due to a hurried initial operation is always a threat. Therefore, a comprehensive reexploration is mandatory.

Our practice is to radiograph the body cavity (chest or abdomen) of any patient who has had a damage control operation. Although we attempt to count sponges at the first operation, such sponge counts may often be inaccurate, thus the need for thorough radiologic evaluation of the cavity is vital. On more than one occasion, we have encountered situations where an inadequate radiograph failed to detect a sponge that was hidden in the recesses of a body cavity that was not properly evaluated. Thus, multiple views of the chest and abdomen may be required to ascertain that no foreign body is still in place.

MISUSE OF DAMAGE CONTROL OPERATIONS

There is a tremendous amount of literature on the *efficacy* of damage control operations (DCOs), particularly with abbreviated laparotomy.[1] Although the principles for these techniques are continually being refined, the basic elements of management of these patients is relatively well established. However, it is important to note that there are no randomized control trials demonstrating the efficacy of DCOs, regardless of the type of injury being treated. Given the nature of these types of problems encountered, there will almost certainly never be level one evidence proving the efficacy of these techniques.

When damage control strategies are appropriately applied, it is our strong belief that they may be life- or limb-saving, depending on the situation. However, these techniques present problems in and of themselves, including the potential of infection, life-limiting ventral hernias, and enterocutaneous fistula. Additionally, all will require at least one reoperation. As in all surgical situations, patients and their family must be made aware, when feasible, of the reasons for employing these radical but potentially lifesaving approaches.

One element of concern for us has been the potential overuse of techniques, such as abdominal packing. We have encountered patients transferred to us who have had gauze packing stuffed into their abdomen or chest, with no attempt made to definitively manage the problem. A review of records of some of these patients demonstrates that none of the hallmarks of the patient requiring a damage control procedure was initially present. As in all surgical procedures, the judgment required in these situations is a delicate balance between not doing enough and doing too much. When properly applied, damage control procedures are now one of the most important adjuncts for surgeons who take care of trauma and emergency general surgical patients.

Early Management of Pelvic Ring Disruption

J. Greg Mears, MD, and Greg M. Osgood, MD

Simply stated, early detection and appropriate basic early intervention can save a life. Pelvic fractures can bleed significantly; first responders can prompt life-threatening bleeding without sophisticated technology or advanced training. Appropriately managed, a patient with a complex pelvic fracture may not require intensive care unit (ICU) admission and may not place undue stress on a health system. In the past 20 years, improvements to understanding simple interventions and teaching these to front line providers have allowed primary emergency responders to care for prior to orthopedic consultation. For this reason, expanded dissemination of these techniques to all trauma responders is integral to improving trauma outcomes.

EARLY MANAGEMENT OF PELVIS FRACTURES

Early management of pelvic fractures involves detection of patients at risk of sustaining this injury, appropriate radiographic evaluation and fracture classification, and rapid assessment of patients with life-threatening patterns. This early triage aids in efficient utilization of resources and immediate intervention in the appropriate patients. Most pelvic fractures are not life threatening. Discerning the subset of patients with high-energy patterns with high degrees of morbidity and mortality within this diagnosis is imperative.

Mechanism of Injury in Pelvis Fractures

Pelvic fractures occur through both low energy and high energy mechanisms. The most common fractures of pelvic bones occur in falls from standing height. These fractures primarily occur in elderly people with osteopenic or osteoporotic bone. The mechanism of injury is a direct impact through the greater trochanter or iliac crest, placing a lateral compression (LC) force across the pelvis. Typically, this generates a compression fracture through the sacral alar area and a corresponding, more displaced, anterior pelvic ring fracture through the superior and inferior ramus (Fig. 1). This fracture type occurs because of significant osteopenia. Although these are low-energy fractures and are rarely life threatening, they may be devastating to the individual patient due to medical comorbidities and difficulty to mobilizing after the fracture.

In contrast, high-energy fractures to the pelvic ring occur through motor vehicle collisions, motorcycle injuries, falls from a height, and other mechanisms in which the pelvis is subjected to high velocity sudden impact. These fractures are characterized by larger degrees of displacement and generally occur in younger patients. They may involve LC, anteroposterior compression (APC), or vertical loading of the pelvic ring. Typically, these fractures occur through high energy direct impact to the symphysis or greater trochanter, or indirect loading through the femur and femoral head, although crushing mechanisms also occur. Associated injuries and significant bleeding characterize these fractures; a high index of suspicion for this injury is required when patient presents with high energy trauma to the abdomen and pelvic regions.

Relevant Patient History at the Time of Pelvic Trauma

Detection of pelvic trauma begins as the patient rolls into the trauma room. Pelvic trauma should be suspected after motor vehicle and motorcycle trauma, equestrian trauma, industrial injury, history of crushing mechanism, fall from a height, and other high-velocity injuries. The external signs of pelvic trauma include gross lower limb deformity, open wounds of the perineum and lumbosacral posterior torso (Fig. 2), bruising around the genitor trochanters and thighs, and subcutaneous swelling about the pelvis. Internal dysfunction or separation of the skin from underlying fascia, the Morel-Lavallée lesion, often occurs about the thigh at the time of pelvic trauma (Fig. 3). This can cause significant unrecognized blood loss and may also complicate surgery if not addressed appropriately. Compressive dressings are the first intervention when this associated injury is detected. Another common presenting complaint on immediate presentation is lower limb neurologic dysfunction. Motor and sensory loss below the hips should raise suspicion of lumbosacral trauma. The disturbing nature of this symptom to the patient makes it one of the first symptoms identified as the patient arrives at the trauma bay.

First responders should conduct a primary survey of the patient, assessing the ABCs of trauma response. Initial evaluation of the patient for sources of bleeding, the most common cause of hypotension in trauma, includes establishing whether there is pelvic and retroperitoneal bleeding. Bleeding from pelvic trauma occurs at lacerated vessels, but also from the large surface area of the fracture. Although providers often focus on arresting arterial blood loss, uncontrolled venous bleeding is a common source of hypotension. Veins do not contract or constrict, are thin walled, and are difficult to access; therefore venous bleeding is difficult to address directly without surgical intervention. Bleeding at fracture surfaces and venous bleeding can only be controlled by compression and stabilization of the fracture hematoma. Class III hemorrhage, with depression of systolic pressure, signifies a blood volume loss of 30%; in these cases, pelvic hemorrhage must be strongly considered. Focused abdominal sonography in trauma poorly identifies pelvic and retroperitoneal bleeding; therefore a high index of suspicion of this problem is indicated. Computed tomography (CT) and angiography may be required to identify discrete vascular sources of hemorrhage.

The events at the trauma scene are critical to patient outcome. Providers must know if there was associated external or perineal bleeding identified when the trauma occurred. In rushing to stabilize a patient with pelvic trauma, the clinician must identify all sources of external bleeding and open wounds as part of the initial survey; perineal and posterior wounds are often overlooked at the patient's peril (Fig. 4).

Prior to performing any surgical interventions, it is critical that the team assess the patient for prior abdominal and pelvic trauma, prior surgery to this area, prior laparoscopic or minimally invasive interventions, or radiation dosing to this area. These prior activities complicate all surgical procedures that address pelvic trauma.

IMMEDIATE ACTION SAVES LIVES: PRIMARY INTERVENTIONS

Advanced Trauma Life Support protocol mandates anteroposterior (AP) radiographs of the pelvis as part of the primary survey. Increasingly, CT of the body, and importantly the pelvis, is performed to identify life threatening injury. The primary responder to pelvic trauma therefore should have preliminary radiographic imaging that identifies a pelvic fracture, allows some important generalizations on patient hemodynamic status, and signals the need for orthopedic consultation. If the patient's history and emergency radiographs suggest pelvic trauma, fracture, or dislocation, orthopedic consultation is warranted. The specialist's experience with immediate interventions and knowledge of common protocols for management is important to decreasing mortality and morbidity.

The next step in intervention is identifying the patient at risk from life threatening hemorrhage from pelvic trauma. As stated, the combination of patient complaints, the history of the injury, and

FIG. 1 (A) Anteroposterior radiograph of stable minimally displaced lateral compression pelvic fracture. (B) Axial computed tomography image of sacrum shows left sacral alar compression fracture.

FIG. 2 Posterior lumbosacral abrasions related to pelvic trauma.

FIG. 3 Large Pelvic Cradle binder on the lateral thigh.

immediate visualization of the patient provide significant clues to this end. Radiographs that show gross displacement of the pelvis, gross asymmetry of pelvic bones, vertical shifting of the ilium on one side, and gross open book deformity of the pelvis warrant emergent placement of a circumferential pelvic sheet or binder; therefore efficient circumferential physical examination of the anterior and posterior lumbopelvic area and perineum (described later) is expedited and the compressive binder is applied. Rapid irrigation of large perineal wounds and packing improves the effect of a binder because large open wounds permit ongoing hemorrhage that cannot form a stable hematoma. The application of a pelvic compressive wrap or binder is lifesaving and should not be delayed (Fig. 3). It decreases the pelvic volume allowed for hemorrhage and applies a stabilizing compressive force at bleeding fracture surfaces and wounds. The technique of binder application is important to optimizing its effect and to minimizing the need for adjustment or reapplication.

Gentle realignment of the lower limbs with gross manual traction can improve binder effect. Bringing the feet together and internally rotating the lower extremities places the pelvis in optimal position. Commercially available binders attempt to simplify the steps of application; however, the principles of safe binder application must be followed. The first principle of binder application is centering the binder over the greater trochanters so that a compressive force is applied through toward force at the femoral heads. Improperly applied binders centered on the prominent iliac crest do not provide the best compression. The second principle is a wide, smooth surface of force application, roughly 20 cm in width, to distribute the required force over a large surface area of vulnerable skin. Wrinkles in sheets or binders must be avoided. Third, adequate compression should be applied; this often requires 2 to 3 responders to apply an effective binder when the patient is large. Two providers apply force at the greater trochanter, then one secures the binder. Finally, the patient

FIG. 4 Perineal wound associated with open fracture.

FIG. 5 Pelvic binder applied appropriately over greater trochanters and tightened.

with a binder must not be neglected. The skin beneath a binder is at risk due to initial trauma and then also due to binder compression.

There are few case reports of a binder causing or worsening a patient's injury. The question often arises if binders should be applied in the setting of LC injury, considering that the compressive force of the binder seems to only add to the internal rotation force of the patient's injury. If the patient's injury only involves internal rotation into hemipelvis (LC1 and LC2 injuries discussed later) the binder can be removed because it most likely does little to assist in hemorrhage control. If the patient's injury is a windswept pattern (LC3), the binder most likely can provide some benefit in stabilizing the pelvis and minimizing bleeding. A pelvic binder should always therefore be considered when pelvic fracture and hemorrhage is suspected as the source of hemorrhagic shock. Once the pelvic fracture pattern is appropriately identified, the binder may be removed if the provider determines it is not helping in the patient's care.

FIG. 6 Early skin breakdown is seen directly over the right greater trochanter 24 hours after binder application.

A binder may be left in place for 24 hours to allow fracture hematoma stabilization, but the skin must be checked around this time to assess for ongoing compromise. A binder may be left on after this point only if it is necessary for life-threatening injury. Prolonged application causes skin necrosis (Fig. 6) that can greatly affect surgical planning and patient outcomes.

A simple bed sheet is an effective universally available resource that all providers can learn to apply as a pelvic binder. Applied in this manner, it is referred to as a circumferential pelvic antishock sheet (CPAS). The same principles apply for sheet application: centering over the greater trochanters, wide surface of force application, effective compression and application, and tightness (Fig. 7A,B). When these principles are followed, pelvic hemorrhage can be effectively controlled on the scene wherever pelvic trauma occurs. Access for internal fixation can be obtained by strategically cutting windows in the sheet prior to surgical preparation (Fig. 7C).

Physical Examination vs Radiographs

The emergency imaging of the skeleton following high-energy trauma involves an AP pelvis radiograph, with or without axial CT of the pelvis. Although a great deal of information about a pelvic injury can be obtained through these standard radiographs, these images are merely snapshots of pelvic geometry that may belie the amount of pelvic instability and threat to the patient. A well-aligned pelvis on initial imaging may be the result of clothing, dressings, a compressive wrap or binder, or positioning at the time of radiograph, such as the cradling bed of the CT scanner. The pelvic injury and instability may be much greater than what appears on the films (Fig. 8). Stability of the pelvic ring should not be assumed when the history of injury suggests pelvic ring fracture, even when radiographs show a normal appearing pelvis. Therefore, a careful physical examination is critical.

Physical examination follows in a standardized manner, involving circumferential inspection, palpation, gentle motion of the extremities, and complete neurovascular examination including examination of both lower extremities.

In the setting of high-energy trauma, multiple caregivers should be recruited to safely logroll the patient to inspect the posterior spine and pelvic region. The perineal area must be inspected with great care, looking for small puncture areas where bony fragments may have perforated the skin. Additionally, open fractures can occur through perforation through the rectum and genitourinary system. For this reason, inspection and palpation of these sensitive areas is imperative,

FIG. 7 (A) Correct application of a circumferential pelvic antishock sheet. (B) A well-applied sheet secured with Kocher clamps compresses the pelvis. (C) Windows in the pelvic sheet allow access for conversion to anterior pelvic external fixation.

a speculum examination is warranted in women. Blood at the urethral meatus usually indicates urethral injury; this is best further investigated with retrograde urethrogram prior to Foley catheter insertion. The lower extremities should be inspected for subtle leg length inequality or abnormal rotational in either lower extremity. This may indicate significant displacement of one hemipelvis or upward displacement of one side of the pelvic ring, which allows limb shortening.

Palpation, specifically manipulative assessment of the pelvis, is important for these patients as well. AP compressive force is applied to patients in the supine position to detect subtle open book instability of the pelvic ring that is not identified on initial plain radiographs. In a similar manner LC, as the greater trochanters, detecting rotational instability of one hemipelvis, is essential. These maneuvers may disrupt pelvic hematoma, and therefore should not be executed repetitively. Gentle range of motion of the hips is indicated for these patients to detect fractures, soft tissue injury, or dislocation around the hip.

The neurovascular examination of a traumatized pelvis includes assessment of motor function and sensation from the waist down. Active hip, knee, ankle, and toe flexion and extension should be assessed. Lumbar and sacral roots must be tested for motor and sensory function. Rectal tone and perianal sensation should be tested at the time of rectal examination for open injury and hemostasis testing. Timely documentation of the neurovascular examination on presentation is important because the patient's examination may evolve after arrival.

Treatment of Open Pelvic Fracture Wounds

Open wounds may occur externally or rectally, as previously mentioned. Antibiotics are first and foremost in treatment of open wounds. Timely administration of antibiotics within 1 hour is essential in preventing infections at open fractures. First generation

FIG. 8. (A) Anteroposterior pelvis radiograph on presentation in a binder. (B) Fluoroscopic examination under anesthesia demonstrates approximated symphysis at rest. (C) A moderate anterior force is applied, displacing the left hemipelvis laterally.

cephalosporin should be administered for simple wounds; patients with large degloving injuries and wounds communicating with the bowel should also receive gram-negative coverage. External skin lacerations that do not extend to the abdomen, rectum, or vagina should be irrigated and closed, if small. Larger wounds may require operative exploration and treatment. Open wounds may allow significant ongoing bleeding. This may prevent stabilization of a pelvic hematoma. An open wound may also defeat the compressive forces of a pelvic binder, despite the binder's effect of decreasing the potential volume into which bleeding can occur. Bleeding may continue through the open wound if it is not examined. Careful emergency packing of open wounds should therefore precede application of the binder.

Traction Pins and Closed Reduction

Extremity traction can assist in stabilization of pelvic fractures by reducing and realigning anatomy and reapproximating surfaces that fit together. In the same manner, it can decrease the amount of bleeding at bony surfaces. Realignment and stabilization help to decrease patients' pain. Establishing normal anatomic relationships also helps in definitive treatment of the injury, considering that limbs will be more easily reassessed at the time of definitive fixation if traction has been in place.

Traction is most effective through application of skeletal traction pins through the distal femur, proximal or distal tibia, or calcaneus. Pin placement should be performed by skilled personnel only, considering that neurovascular structures are at risk in the locations of all properly placed pins. If skeletal traction is not possible, manual traction through the displaced extremity at the time of binder application, internal rotation of the extremities, and taping the toes together assist in accomplishing the previously stated goals. Although skin traction apparatuses exist, they are generally ineffective at maintaining length and may cause soft tissue compromise if not appropriately applied and vigilantly attended to.

Binder Removal

Although a CPAS or binder provides essential support in minimizing pelvic hemorrhage, continued use beyond 24 hours can be detrimental. It obscures femoral access points, may impede access to the abdomen, and puts sustained pressure on skin, which inevitably leads to necrosis. For this reason, the skin beneath the binder should be inspected after 24 hours of application and the position must be altered, if binder use is to continue.

Removal of CPAS or binder can exacerbate hypotension, so removal should usually be performed with supervision. This is easiest in the ICU setting, where the strap can be removed, and the immediate effect can be observed on continuous monitors. Outside of the ICU, the provider should be ready to measure vital signs a few minutes after removal, and then later detecting tachycardic response or hypotension in response to the decreased pelvic pressure and

FIG. 9 Angiogram of the patient shown in Figure 10 demonstrating small anterior right pelvic bleed.

increased volume. The binder is removed slowly and left in place beneath the patient, in case it needs to be rapidly reapplied. If the binder must be reapplied because of persistent initial hypotension, adjusting the binder to a slightly different position may decrease skin injury. External fixation placed in the operating room setting should also be considered at this point to provide adequate pelvic stabilization, compression of the pelvic hematoma, and to minimize external soft tissue injury. Documenting the condition of the skin beneath the binder assists the providers in the patient's continuity of care, to communicate the risk of ongoing soft tissue injury.

Role of Pelvic Angiography

The role of pelvic angiography is multifactorial in each trauma hospital. The availability of resources and the timing of availability are important factors in determining its use. Each trauma hospital must establish the potential role of angiography in treating pelvic hemorrhage. The success of pelvic binders in early management of hemorrhagic shock caused by gross pelvic hemorrhage has helped establish the role of angiography as an intervention that should be performed after the pelvic binder application, and after the emergency need for abdominopelvic surgery has been ruled out. Interventional radiography and specifically pelvic angiography have a role in addressing persistent arterial bleeding in patients who are persistently unresponsive to resuscitative efforts, who are already placed in a binder or external fixator, and who do not require surgical hemorrhage control (Fig. 9). Each hospital determines its decision tree or algorithm identifying the order of interventions and role of angiography based on available resources.

Role of Pelvic Packing in Emergency Control of Pelvic Hemorrhage

Some hospitals have access to surgeons educated in pelvic packing. When retroperitoneal hemorrhage is suspected as a source of hypotension and the patient is not responsive to binder application and primary resuscitative response with intravenous fluid and blood, pelvic packing can be considered. Especially in the setting in which exploratory laparotomy is underway for hemorrhage control, pelvic packing is a straightforward next step. The role of this step is predetermined, much the same as angiography, based on resources available within each institution. Understanding of the pathoanatomy of pelvic hemorrhage is critical for successful pelvic packing. Retroperitoneal veins in the space of Retzius and retroperitoneum are responsible for much of pelvic hemorrhage and this pathology is addressed with pelvic packing. These pads are forcibly packed against the hemorrhage on each side, along the pelvic brim and into the true pelvis, and posteriorly near the sacroiliac joint. The pelvis must be stabilized with a binder or an efficient pelvic external fixator for this method to succeed.

Systematic Radiographic Evaluation

The AP pelvis radiograph (Fig. 10A), when carefully inspected, reveals tremendous information about pelvic anatomy and pathology, its implications for instability and associated injury, and potential surgical challenges that can impede surgical stabilization. The first step in analysis is assessment of normal alignment of the body at the time of the radiograph. Central position of the sacrum proximate to symphysis and similar appearing pedicles in the lumbar spine are the best indicators that the alignment of the body is normal at the time of x-ray exposure. Gross asymmetry is easily perceived, when present. Subtle asymmetry must be searched for through critical comparison of density and clarity of the sacral ala at the sacroiliac joint, appearance of sacral foramen, area/volume of the iliac fossa, visibility of the sacral spine, density of the quadrilateral surface, the shape of the obturator foramen, and midline position of the pubic symphysis. When a subtle difference is detected on a well-centered film, small posterior fractures and displacements and hidden anterior fracture lines are more easily perceived and explained.

A systematic evaluation of the AP radiograph includes inspection of the lumbopelvic junction, the brim of the iliac crests, the brim of the true pelvis, the foramen of the sacrum, the quadrilateral surfaces, iliac spines and tuberosities, superior and inferior rami, and the pubic symphysis. The evaluator looks for blurring of bone and joints at the lateral sacrum near the sacroiliac joint, and vertical and transverse fracture lines in the front of the pelvis. On a well-centered pelvic radiograph, displacement of the pubic symphysis generally occurs away from the side of the posterior injury on an LC fracture. Soft tissue shadows, often unappreciated on plain radiography, may show thigh and retroperitoneal hematoma, bladder displacement, and intraperitoneal air.

The CT scan solidifies diagnoses and suspicions drawn from the AP radiograph. The same anatomic regions previously reviewed on plain radiographs must be inspected on axial or reconstructed views. Visualizing sequences of images assists in localizing and measuring pathological features. The bony volume of the sacrum and fixation corridors is best appreciated on CT. Fracture extensions into the lumbopelvic facet joints, that indicate increased lumbopelvic instability, are detected here as well. Three-dimensional reconstruction image quality is improving to the point that most features of pelvic fracture-dislocations can be clearly seen. It must be understood that most algorithms for reconstruction cause blurring of subtle fracture lines to the point of concealment. Soft tissues are further delineated with different contrast settings. Intravenous contrast medium that may have obscured plain radiography is better localized in CT planes. Despite the important information gleaned from the CT scan, advanced plain radiographs further assist the primary responder in quantifying risk of the injury to the patient and aid the orthopedic surgeon in operative planning.

The inlet pelvic radiograph (Fig. 10B) is performed by aiming the x-ray beam from anteroposterior to posteroinferior across the pelvis. The volume of the pelvis is best appreciated from this anterior cephalad viewpoint. This view best delineates the brim of the true

FIG. 10 (A) Anteroposterior pelvic radiograph. (B) Inlet radiograph of the pelvis. (C) Outlet radiograph of the pelvis.

pelvis. It demonstrates internal and external rotational deformities and anterior or posterior displacement of the pelvis at the time of injury. Evaluation of this radiograph, like the AP view above and outlet below, starts by assuring if the patient is well centered on the image. Visualization of compression fractures at the sacroiliac joint is improved from this perspective. Anterior pelvic fractures at the superior and inferior ramus and parasymphyseal region and their orientation (transverse to H, fractures, and cephalocaudad to APC fractures) are more easily understood.

The outlet pelvic radiograph (Fig. 10C) is performed by aiming the x-ray beam from anteroinferior to posteriosuperior across the pelvis. A true outlet superimposes the cephalad aspect of the symphysis over the S2 sacral body. Underappreciated on this view is the visualization of the sacral anatomy (necessary for surgical planning). Common features of sacral dysmorphism (accessory processes, crescent sacral foramen, persistent sacral disk disorder, and undulating sacroiliac joints). This view highlights the vertical displacement of one hemipelvis in relation to the other and the body during trauma. This can be measured by comparing the relative heights of the iliac crests, femoral heads, or ischial spines. Widening of the symphysis can be easily measured on this view. Appreciation of rotational deformity is also enhanced by comparing the symmetry of each obturator foramen oval.

The lateral sacral view or lateral reconstruction of the lumbosacral pelvic region from the CT scan may prove important in assessment of injury. This projection allows improved evaluation when sacral fractures or hemipelvic dissociations without pelvic ring disruption are suspected. U shaped and H shaped sacral fractures, among other isolated sacral patterns, and their associated sagittal plane (kyphotic) deformities are detected from this perspective.

Judet oblique radiographs, taken with 45-degree elevation of each hip, allow assessment of the acetabulum if fractures in the hip socket are detected on the AP projection. Fractures of the acetabulum can occur in combination with pelvic ring disruptions, most commonly when a lateral compressive or trajectory force is applied through the greater trochanter as the mechanism of injury. If a patient's pelvic fracture does not extend to the acetabulum, Judet projections do not add significantly to the diagnosis and treatment of pelvic ring injury.

Classification of Pelvic Fractures

Several pelvic fracture classifications have evolved in an effort to improve communication and decrease morbidity and mortality rate in patients. Unfortunately, no classification is complete; some pelvic ring injuries escape classification.

The best classification system in the emergency department (ED) setting and among all trauma team subspecialties is the Young Burgess classification of pelvic fractures (Table 1). This scheme correlates the trauma history and vector of force application against the pelvic ring to the radiographic findings of bony and soft tissue displacement on standard films. The force of displacement on the anatomy is linked to common patterns of fracture and dislocation. The classification

TABLE 1 Young-Burgess Classification of Pelvic Fractures

Category	Common Characteristic	Differentiating Characteristic
LC1	Anterior transverse fracture (pubic ramus)	Sacral compression on side of impact
LC2	Anterior transverse fracture (pubic ramus)	Crescent (iliac wing) fracture
LC3	Anterior transverse fracture (pubic ramus)	Contralateral open book (APC) injury
APC1	Symphyseal diastasis	Slight widening of pubic symphysis and/or sacroiliac joint, stretched but intact anterior and posterior ligaments
APC2	Symphyseal diastasis or anterior vertical fracture	Widened sacroiliac joint, disrupted anterior ligaments, intact posterior ligaments
APC3	Symphyseal diastasis or anterior vertical fracture	Vertical displacement anteriorly and posteriorly usually through sacroiliac joint, occasionally through iliac wing and/or sacrum
VS	Symphyseal diastasis or anterior vertical fracture	Vertical displacement anteriorly and posteriorly, usually through sacroiliac joint, occasionally through iliac wing and/or sacrum
CM	Anterior and/or posterior, vertical and/or transverse components	Combination of other injury patterns: LC/VS or LC/APC

From Burgess AR, Eastridge BJ, Young JW, Ellison TS, Ellison PS, Poka A, Bathon GH, Brumback RJ. Pelvic ring disruptions: effective classification system and treatment protocols. J Trauma. 1990;30:848–856.
APC, Anteroposterior compression; LC, lateral compression; VS, vertical shear.

disruption vectors in those from APC, LC, or forces causing vertical displacement of one side of the pelvis anatomy (vertical shear [VS]).

Certain injuries are associated with each vector of force application. APC injuries are commonly associated with severe life-threatening hemorrhage, especially in the elderly. LC injuries commonly have associated head and thoracic trauma.

APC and LC injuries are divided into three subsets of increasing severity. APC1 fractures have minimal anterior widening at the symphysis or anterior pelvis, with insignificant ligamentous or bony disruption; these do not require surgery. APC2 injuries can be identified by more than 2.5 cm of anterior symphysial widening. They have disruption of the bone ligaments of the pelvis (sacrospinous and sacrotuberous ligaments) and anterior sacroiliac ligaments, but the strong posterior sacroiliac ligaments are intact. It is important to confirm that the posterior sacroiliac ligaments are intact on advanced imaging. APC3 injuries have ruptured all anterior and posterior pelvic ligaments; they are grossly unstable at one or both hemipelvis, have significant intrapelvic hemorrhage, and require immediate intervention. A binder is indicated in the initial resuscitation of all APC injuries.

LC1 injuries have fractures through the sacral foramen or ala and corresponding anterior pelvic fractures of the superior and inferior rami, with internal rotation of one hemipelvis. This fracture is the most common pattern because it occurs when elderly fall from standing onto their hip. Young patients who sustain fractures in these anatomic regions, and therefore are classified as LC1, commonly have significant displacement and instability. Although elderly LC1 fractures are commonly stable and do not require surgery, young patients or those with good bone stock often have instability that can be confirmed on examination of the pelvis under anesthesia. LC2 disruptions have posterior fractures through the iliac wing and corresponding anterior rami fractures. LC3 patterns are fracture-dislocations known as the "wind swept" pelvis. They have the greatest instability due to internal rotation of one hemipelvis and external (APC type) rotation of the opposite hemipelvis. LC3 injuries also have appreciable hemorrhage and this is appropriately managed in the ED with a binder.

VS fractures are one large subset that demonstrates predominating vertical displacement of an entire hemipelvis proximally or distally. Distal displacement is very rare but it is associated with significant nerve injury and often vascular trauma. Proximal vertical displacement is associated with proportional vascular injury and soft tissue damage to the abdominal ligaments, anterior and posterior sacroiliac ligaments, and anterior pelvic ligaments. Associated vascular injury is common, especially with significant displacement. Therefore, longitudinal traction on the shortened limb and binder application aids in management of pelvic hemorrhage in these patients.

It is clear from the Young Burgess classification that APC, LC3, and VS patterns (Fig. 1) are at the greatest risk of hemorrhage in general. These patients respond best to early pelvic binder application. APC injuries have a clear indication for binder protocol until surgical management. LC3 and LC2 injuries, once appropriately confirmed, probably do not benefit significantly from prolonged binder application.

Role of External Fixation

External fixation was often applied in the ED for pelvic ring fractures. With the rapid acceptance of pelvic binders and CPAS, ED external fixation is obsolete. Compressive wraps are reliable initial treatment, sheets are universally available and inexpensive. External fixation therefore only has a significant role once 24 hours have passed. At this time, the patient is usually able to transport to the operating room for thoracoscopic imaging and controlled sterile technique. External fixation applied in this environment is much more reliable than a frame applied in the ED. Additionally, recent acceptance of supra-acetabular two pin external fixation as a stronger compressive frame makes this the frame of choice (Fig. 12A); it must, however, be placed under fluoroscopic guidance. Definitive treatment of anterior pelvic instability can be effectively accomplished with external fixation (Fig. 12B). This is usually done once the patient is stable enough for surgery. This mode of fixation is usually selected over internal fixation when prior surgery or radiation complicates anterior open approaches, when an open fracture or gross contamination contaminate the anticipated surgical approach, or when other surgical incisions make standard approaches difficult.

Need for Definitive Surgical Stabilization of Pelvic Fractures

Definitive fixation of pelvic fractures should occur when the patient is stable enough for the approaches that are required for fixation. If limited open or percutaneous techniques are utilized, surgery does not have to be delayed. Large open approaches, including

FIG. 11 (A) Anteroposterior compression 3 pelvic ring disruption. (B) Lateral compression 3 injury shows internal rotation of left hemipelvis and external rotation of right hemipelvis. (C) Vertical shear pattern.

FIG. 12 (A) Clinical example of how rotation signs accurately external fixation frame. (B) Definitive treatment radiograph of patient in figure 10 using external fixation.

lateral windswept iliac fixation approach, Pfannenstiel/Stoppa approach, and prone posterior open approach to the posterior ilium require consideration of other lines and tubes (diverting colostomy or chest tube) and the ability of the patient to be placed in the proper position for surgery. The patient should be adequately resuscitated, signified by a normalized lactate less than 2.5. Finally, stabilization of a complex pelvic injury may require more than one surgery as staged procedures to allow recovery from each component of surgical stabilization.

Hospital Admission in Pelvic Fracture

Although many pelvic ring fractures are indicated for surgery, minimally displaced fractures and fractures in relatively healthy individuals may not require hospitalization or operative fixation. Many LC1 and APC1 fractures can be observed briefly and discharged from the ED. Disposition to home requires that a patient have adequate assistance to mobilize out of bed, ambulate with some assistance, and accomplish activities of daily living. Pain must be adequately controlled and breathing should not be labored. Elderly patients often require brief social admissions to plan safe discharge and teach mobilization skills with physical therapy. Once a patient is appropriately dealing with the fracture discomfort and equipped to return home, he or she can be discharged.

Definitive Nonoperative Pelvis Fracture Care

Nonoperative care of a pelvic fracture requires demonstration that the fracture will not displace under physiologic loading during activities of daily living. Usually the injury AP, inlet, and outlet radiographs are repeated after the patient mobilizes out of bed. Most APC1 injuries allow bilateral lower extremity weight bearing as tolerated (WBAT) with crutches or walker. Most LC1 injuries can accommodate partial/foot flat weight bearing or WBAT on the injured side. The key to nonoperative management of pelvic fractures is serial radiographs demonstrating that minimal displacement occurs over the course of healing. This requires frequent office visits so that unacceptable displacement is detected prior to healing.

CONCLUSIONS

Management of pelvic fractures requires urgent recognition of life-threatening fracture patterns, which respond well to pelvic binder application in the setting of hypotension (APC2, APC3, LC2, VS). Many physical examination findings lead the clinician to suspect these injury patterns. The diagnosis is confirmed on systematic radiographic evaluation. Urgent gentle manipulative reduction and application of a compressive sheet or binder is accepted as the best first line defense against life threatening hemorrhage. The key to success in management of these injuries is a systematic approach to physical examination and patient evaluation, followed by expeditious use of resources to resuscitate the patient in anticipation of surgical stabilization.

UROLOGIC COMPLICATIONS OF PELVIC FRACTURE

Hunter Wessells, MD, FACS

"It is the urologist who will have to share with the patient, the burden of any residual disability when thoracic, abdominal, and/or the orthopedic aspects are long forgotten."

—RICHARD TURNER-WARWICK, UNIVERSITY COLLEGE HOSPITAL, LONDON, ONTARIO, CANADA, 1982[1]

Pelvic injuries cause a significant disease burden in the United States, representing 7.3% of all traumatic injuries. Nonfatal injuries, based on most recent estimates by the US Centers for Disease Control and Prevention, totaled 2.3 million annually in the United States, which translates to approximately 180,000 pelvic injuries every year. Patients with pelvic trauma are severely injured, the majority having injury severity scores exceeding 16. Significant mortality arises from associated head injury, genitourinary and gastrointestinal organ injury with pelvic fracture can cause acute life threatening complications as well as lifelong disability and reduced quality of life.

Pelvic trauma, as with many unintentional injuries, has a male preponderance, with approximately two thirds of injuries occurring in men. The proportion of patients with bladder and urethral injury differ between women and men as follows: overall, 6% experience bladder injuries, whereas, in men, 3% exhibit urethral injury and, in women, nearly 7% have injury to the bladder neck and urethra. Notably, these figures represent rates of injury at large trauma centers and may not be representative of the experience in community hospitals or centers without trauma designation.

The American Urological Association (AUA) developed Practice Guidelines for Urotrauma in 2014 that provide a systematic evidence review that allowed for evidence based recommendations for the diagnosis and treatment of lower urinary tract injuries after pelvic fracture. These build on prior Guidelines and Consensus Statements from other organizations.

BLADDER INJURY

Identification of pelvic fracture bladder injury requires a detailed history, physical examination, urinalysis, and appropriate imaging. A total of 95% of patients with a bladder rupture will have gross hematuria, and the remaining few with microhematuria can be detected during the initial trauma evaluation with appropriate algorithms. There is no clinical prediction rule to identify patients requiring cystography after pelvic fracture other than the degree of hematuria. Recent studies suggest that patients with microscopic hematuria are unlikely to suffer bladder injury. Thus, AUA Guidelines state that clinicians must perform retrograde cystography to image the bladder after any blunt trauma with gross hematuria. Similarly, clinicians should perform retrograde cystography in stable patients with pelvic ring fractures and clinical indications of bladder rupture. At our institution, this translates into imaging all patients with pelvic fracture and greater than 30 red blood cells per high power field on urinalysis. All penetrating trauma patients with any degree of hematuria and an injury in the pelvis require assessment of the bladder either with imaging or operative exploration. Fracture patterns associated with bladder and urethral injuries are similar, namely, diastasis of the pubis and obturator ring fractures. The greater the displacement of these fractures, the more likely a genitourinary injury.

Imaging is important because failure to recognize a bladder injury can lead to significant complications including urinary ascites, infection

lateral windswept iliac fixation approach, Pfannenstiel/Stoppa approach, and prone posterior open approach to the posterior ilium require consideration of other lines and tubes (diverting colostomy or chest tube) and the ability of the patient to be placed in the proper position for surgery. The greater the displacement of these fractures, the more likely a genitourinary injury.

Imaging is important because failure to recognize a bladder injury can lead to significant complications including urinary ascites, infection

FIG. 1. Computed tomography cystogram demonstrating extraperitoneal bladder rupture with two defects in the anterior bladder wall.

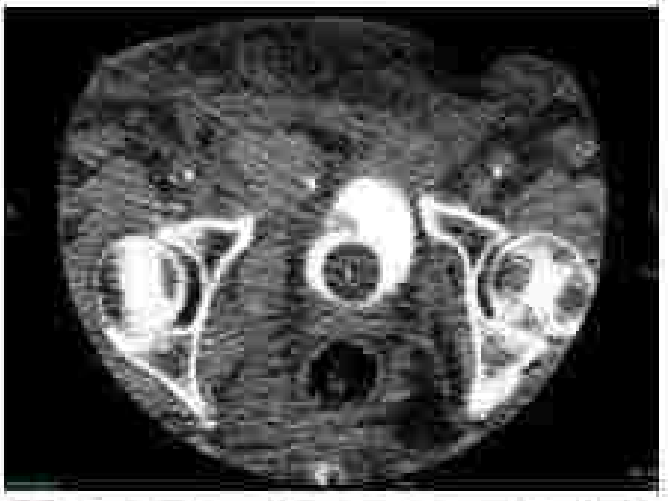

FIG. 2. Computed tomography cystogram demonstrating bony spicule in bladder lumen in a patient with unrecognized bladder injury.

of pelvic hematoma, chronic bladder dysfunction, and sepsis. Spiral computed tomography (CT) with 5-min cuts obtained after complete filling of the bladder will delineate all intra- and extraperitoneal bladder injuries. The degree of bladder filling is important and should be in the tolerance to a responsive patient. In the unresponsive patient, the contrast is hung at 40 cm of water and a volume of 350 mL infused. With CT, there is no need for scout or postevacuation imaging because the cross-sectional nature of the imaging identifies both anterior and posterior leaks. Conversely, with plain film cystography, scout and postevacuation films are required. Because of these differences, CT cystogram is more expedient and now the standard in most trauma centers.

The classic extraperitoneal bladder rupture, whether identified by CT or plain film cystography, will outline loops of bowel consistent with extraperitoneal location. Extraperitoneal bladder ruptures leads to extravasation of contrast in the retroperitoneum including the space of Retzius, the lateral pelvic regions, and into the groin and thigh. Typically, the dome defect in the bladder wall can be visualized with CT (Fig. 1). Combined intra- and extraperitoneal bladder ruptures can be missed when a large injury in one location makes it difficult to distend the bladder. These are rare, occurring in only 3% to 8% of all bladder ruptures.

The sensitivity and specificity of CT and cystography has been determined for blunt trauma and is 95% and 100%, respectively, using operative findings as a gold standard. CT of intraperitoneal rupture has a lower sensitivity, possibly because of the aforementioned confounding due to multiple sites of rupture.

Surgeons treat repair intraperitoneal bladder rupture in the setting of blunt trauma because the ruptures are large, and untreated can lead to ascites, azotemia, and sepsis. In contrast, management of extraperitoneal bladder injuries can be nonoperative with catheter drainage as long as the rupture is considered uncomplicated. These injuries do not involve open pelvic fractures, urinary infection, bony fragments (Fig. 2), or a foreign body to the bladder. Use of an appropriately sized catheter is essential to avoid obstruction by clots and poor bladder drainage. Other absolute indications for bladder repair include a bladder neck injury (Fig. 3), concomitant rectal injury, urethral injury, and major vaginal laceration. A relative indication for repair would be the need for open reduction and internal fixation of the pubis or anterior pelvic ring, to which case bladder exploration is often advocated.

Operative management of bladder rupture requires exposure based on whether the lesion is felt to be intra- or extraperitoneal. With extraperitoneal bladder rupture (Fig. 1), a lower midline or transverse Pfannenstiel-type incision provides sufficient access to the bladder and allows primary closure of injuries. The incision choice may be dictated by orthopedic or other considerations. For intraperitoneal bladder ruptures, which tend to be located at the dome, be midline in nature, and large, a midline incision slightly higher on the abdominal wall gives good access to the dome of the bladder.

Bladder exploration must be thorough to identify associated injuries to the genitourinary tract. Most common will be additional injuries to the bladder, including unrecognized or additional extraperitoneal injuries as well as bladder neck injuries. The bladder neck should be assessed by visual inspection, palpation, or endoscopic evaluation. Although ureteral injury is very uncommon in pelvic fractures, when the bladder is open, as long as visualization is adequate, assessment of the ureteral orifices is mandatory. This can be achieved by observing a jet of clear urine out of each orifice, intubation of the orifice with a feeding tube or other small (e.g., 3F/5) catheter, or administration intravenous indigo carmine and observing blue dye excreted in the urine.

Bladder lacerations should be repaired in a standard two-layer closure with running slowly absorbable suture such as 2-0 polyglycolic acid. The first layer incorporates the mucosa and the muscularis. The second layer incorporates the muscularis and overlying serosa. In the region of the bladder neck, where access to the urinary canal behind the pubis bone may be difficult, a single layer of well-placed interrupted absorbable sutures is sufficient to allow appropriate healing. When coordinating bladder exploration with other issues, it is advisable to explore and repair bladder neck injuries before orthopedic pelvic fracture fixation because exposure is worse after plating. In patients with multiple bladder lacerations, smaller lacerations can be fixed from within the bladder with a single layer of slowly absorbable suture. A closed suction drain is placed adjacent to the bladder to prevent collections. Urinary drainage after bladder repair may be carried out either with suprapubic cystostomy or usually with urethral catheter drainage alone. There is no evidence that suprapubic (SP) cystostomy improves outcomes compared to urethral catheterization alone, and the use of SP tubes is discouraged.

Follow-up imaging is required when nonoperative management by catheter drainage is selected, and after operative repair. Cystography (usually via plain film imaging) should be carried out 10 to 14 days after injury to confirm the integrity of the bladder before initiating voiding trials. This is true whether the patient has been under nonoperative management or underwent operative repair. Once bladder integrity has been confirmed, the catheter can then be removed based on patient's other injury status and mobility. If extravasation persists, repeat cystography is recommended at appropriate intervals until healing occurs. Overall, only a very small subset of patients with bladder injury will require re-operation or epiloyal closure.

URETHRAL INJURY

Pelvic fracture urethral injury (PFUI) is a rare but significant injury, associated with potential genitourinary morbidity including urethral stricture, urinary incontinence, sexual dysfunction, and chronic pain.

The signs and symptoms of these injuries are nonspecific and include blood at the urethral meatus; difficulty or inability to void after injury; a palpable bladder; butterfly perineal hematoma; high-riding prostate on digital prostate examination; fracture of the pubic symphysis; pelvic hematoma; or associated bladder injury. Thus, AUA Guidelines state that that patients with blood at the urethral meatus should undergo retrograde urethrogram (Fig. 1).

PFUI is suspected in cases of pelvic diastasis or fracture of the inferior pubic ramus. Such straddle fractures lead to a significantly greater odds of injury. Urethral injuries are classified using American Association for the Surgery of Trauma grades 1 to 5. Grades 1 and 2 (contusion and stretch injuries respectively) only need urethral catheter drainage until the patient recovers from other injuries. Grade 3 PFUI (partial disruptions) are easily managed with catheter realignment, whereas grades 4 and 5 complete disruptions with or without extensive separation or involvement of the prostate or vagina, may be treated with early endoscopic realignment or suprapubic cystostomy. There is debate as to the benefit of early endoscopic realignment, and suprapubic cystostomy remains the most commonly *elected* treatment nationwide.

Male urethral injuries after pelvic fracture are first delineated with retrograde urethrogram. However, when patients have blood at the urethral meatus and immediate catheter drainage is required, a single attempt at urethral catheterization may be considered. There is no strong evidence to suggest that this maneuver will convert a partial urethral injury to a complete injury. Nevertheless, in stable patients without immediate need for catheter drainage, retrograde urethrogram remains the recommended diagnostic modality. Cystoscopy can provide additional information, and may be performed in the emergency department, but overall it is not favored as a primary diagnostic modality. Female urethral and bladder neck injuries are more difficult to identify and diagnose compared with male injuries. These injuries may only be identified with intraoperative physical examination or incidentally in the intraoperative setting (40% of injuries). Thus, with all such patients, a thorough history and physical examination, laboratory studies, and imaging as indicated remain important.

The decision whether to perform suprapubic cystostomy or urethral realignment for PFUI depends on the patient's stability and associated injury status. Suprapubic cystostomy urinary diversion is appropriate as the initial step to securing prompt urinary drainage after PFUI, either in the emergency department or the operating room. AUA Guidelines state that clinicians may perform primary realignment in hemodynamically stable patients with PFUI. This may be deferred for up to 7 days, pending orthopedic coordination for ORIF, and does not need to be done in the middle of the night when equipment and support staff may be lacking. When attempting realignment, prolonged attempts at endoscopic realignment in patients should be avoided. Other rare indications for urethral realignment include the presence of a bladder rupture (which would complicate SP tube placement), rectal and vaginal lacerations, bladder neck injury, severe cephalad bladder displacement ("pie in the sky") and concomitant open reduction and internal fixation with the placement of orthopedic hardware.

Unfortunately, little evidence exists about the risk of bone or hardware infection in the face of suprapubic cystostomy, leading to discrepancy in expert opinion between urologic surgeons and their orthopedic colleagues. Our practice is to accommodate the preferences of our orthopedic colleagues when possible, preferentially realigning the urethra and thus removing the SP tube before pelvic fixation.

Stricture rates will be higher after suprapubic cystostomy compared with primary urethral realignment; realignment allows healing without strictures in 10% to 30% of patients versus less than 5% with suprapubic diversion. The standard approach for realignment uses two flexible endoscopes inserted per urethra and per SP tract, respectively. Typically, this requires two urologists skilled in flexible endoscopy, fluoroscopy, and coordination with orthopedic surgery. As long as SP cystostomy can temporize urinary drainage, realignment can be performed in an elective or semielective fashion when appropriate resources can be brought to bear, up to a week after injury.

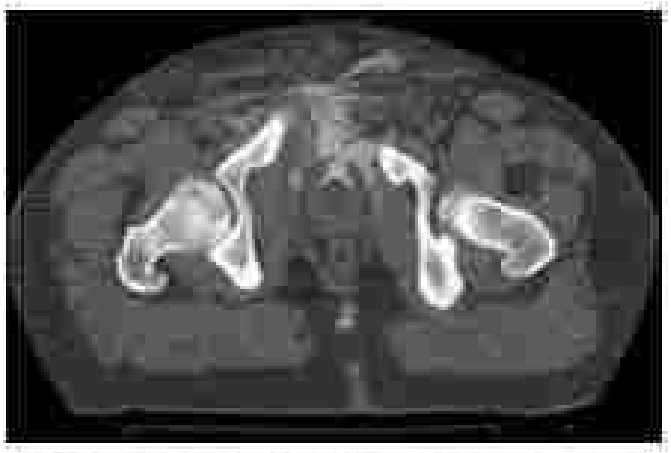

FIG. 1 Computed tomography cystogram demonstrating extravasation at level of catheter balloon consistent with a bladder neck injury.

FIG. 2 Retrograde urethrogram showing complete urethral disruption.

After urethral realignment, periurethral retrograde urethrogram is recommended at 4 weeks after injury to assess for persisting leak. If leaks persist, repeat imaging is required until healing. The impact and prevalence of urethral stricture, erectile dysfunction, and urinary incontinence after PFUI require close surveillance for at least 1 year after injury.

CONCLUSIONS

Immediate identification of acute genitourinary injuries and appropriate urinary drainage is essential to prevent early septic complications and to ensure subsequent normal organ function. Coordination with the trauma team early, and orthopedic surgery later, allows appropriate operative or nonoperative management based on the injury severity and presence of associated injuries. Continued controversy about

cost of urethral realignment after PFUI may be answered by trials currently under way through the American Association for the Surgery of Trauma. Close follow-up is required to identify bladder, urethral, urinary incontinence, and sexual dysfunction resulting from injury to the bladder, urethra, and pelvic vascular structures. Importantly, even in the absence of overt genitourinary organ injury, soft tissue and vascular damage may lead to delayed complications including urinary and sexual dysfunction and cause significant impairment of quality of life.

Spine and Spinal Cord Injuries

Khaled M. Kobashi, MD, FRCS, and Andrew Harris, BS

INTRODUCTION AND EPIDEMIOLOGY

The incidence of spinal cord injury (SCI) is between 25 and 50 cases per million in the United States, a rate that is higher than other developed countries. Among the general population, most cases of SCI are caused by motor vehicle accidents (40.8%), followed by acts of violence (12%), and sports-related injuries (9%). In those older than 65 years, however, falls are the leading cause of SCI. Recent trends show that overall, 55% of SCI cases occur in the cervical spine, with a rising predominance of upper cervical lesions (C1 to C3), that patients being discharged from the hospital as ventilator dependent. Current estimates suggest that 48.7% of SCI is neurologically complete at presentation, a number that has been decreasing slightly as the prevalence of gunshot related injuries decreases and falls in the elderly increases.

Although comparisons of affected age groups is complicated by differences in reporting, several predominant trends are clear. Men are the most commonly affected at approximately 80% of cases, and a 4:1 incidence ratio compared with women—a disparity that has remained constant over time. In addition, the highest risk age groups are the late teens and 20s, although recent data have shown that the mean age of patients affected by SCI is increasing in line with the increasing age of the US population.

INITIAL EVALUATION AND MANAGEMENT

Because of the magnitude of injury necessary to damage the spinal cord, SCI is commonly comorbid with multiorgan injury, which can complicate or even prohibit a thorough history and physical examination. Nonetheless, the initial evaluation of a patient with SCI is identical to other trauma patients in accordance with Advanced Trauma Life Support guidelines. Airway, breathing, and circulation are assessed as part of the primary survey, followed by complete evaluation in a secondary survey. Overt signs of SCI in the secondary survey include flaccid paralysis, hemodynamic instability with bradycardia, priapism, lack of response to painful stimuli to the lower extremities, and paradoxical breathing, all of which require prompt evaluation and application of appropriate algorithms to determine if imaging and/or surgical treatment is warranted.

Aside from the maintenance of airway, breathing, and circulation, the immediate chief concerns in patients with SCI are (1) avoiding movements that could worsen the condition by pathologic motion of displaced vertebral elements, and (2) minimizing deleterious effects of the secondary injury cascade by maximizing blood oxygenation and tissue perfusion. Within 2 to 3 hours after injury, disruption of arterioles by mechanical disruption and vasoconstriction causes ischemia in the gray matter of the cord. Following this result in fragile tissue of the central nervous system is the release of cytokines, inflammation, and apoptotic cell death primarily over the next 24 to 48 hours, although these processes can continue to cause damage for up to 3 weeks after injury.

In the acute phase of injury, maintaining an appropriate airway is essential to maintaining oxygen delivery to the damaged spinal cord. Patients with cervical spine injury are at increased risk of airway compromise both because of the risk of development of localized edema, neck hematoma, disruption of the innervation to respiratory musculature, and concomitant pulmonary injury. Thus throughout the acute evaluation, one should remain vigilant in monitoring for signs of acute respiratory failure and consider prompt intervention. Hypotension (<90 mm Hg systolic), even for brief periods of time, should be avoided as it is associated with significantly worse outcomes, although this can be especially difficult in the setting of neurogenic shock. Attention should also be given to transfer these patients to an appropriately specialized center that is equipped to treat patients with SCIs, as early transfers to such centers has been associated with improved outcomes and reduced complications.

cost of urethral realignment after PFUI may be answered by trials currently under way through the American Association for the Surgery of Trauma. Close follow-up is required to identify fistulae, strictures, urinary incontinence, and sexual dysfunction resulting from injury to the bladder, urethra, and pelvic vascular structures. Importantly, even in the absence of overt genitourinary organ injury, soft tissue and vascular damage may lead to delayed complications including urinary and sexual dysfunction and cause significant impairment of quality of life.

Spine and Spinal Cord Injuries

Khaled M. Kobashi, MD, FRCS, and Andrew Harris, BS

INTRODUCTION AND EPIDEMIOLOGY

The incidence of spinal cord injury (SCI) is between 25 and 50 cases per million in the United States, a rate that is higher than other developed countries. Among the general population, most cases of SCI are caused by motor vehicle accidents (40.8%), followed by acts of violence (13%), and sports-related injuries (9%). In those older than 45 years, however, falls are the leading cause of SCI. Recent trends show that overall, 55% of SCI cases occur in the cervical spine, with a rising predominance of upper cervical lesions (C1 to C3), thus patients being discharged from the hospital as ventilator dependent. Current estimates suggest that 48.7% of SCI is neurologically complete at presentation, a number that has been decreasing slightly as the prevalence of gunshot related injuries decreases and falls in the elderly increases.

Although comparisons of affected age groups is complicated by differences in reporting, several predominant trends are clear. Men are the most commonly affected at approximately 80% of cases, and a 4:1 incidence ratio compared with women—a disparity that has remained constant over time. In addition, the highest risk age groups are the late teens and 20s, although recent data have shown that the mean age of patients affected by SCI is increasing in line with the increasing age of the US population.

INITIAL EVALUATION AND MANAGEMENT

Because of the magnitude of injury necessary to damage the spinal cord, SCI is commonly comorbid with multiorgan injury, which can complicate or even prohibit a thorough history and physical examination. Nonetheless, the initial evaluation of a patient with SCI is identical to other trauma patients in accordance with Advanced Trauma Life Support guidelines. Airway, breathing, and circulation are assessed as part of the primary survey, followed by complete evaluation in a secondary survey. Overt signs of SCI in the secondary survey include flaccid paralysis, hemodynamic instability with bradycardia, priapism, lack of response to painful stimuli in the lower extremities, and paradoxical breathing, all of which require prompt evaluation and application of appropriate algorithms to determine if imaging and/or surgical treatment is warranted.

Aside from the maintenance of airway, breathing, and circulation, the immediate chief concerns in patients with SCI are (1) avoiding movements that could worsen the condition by pathologic motion of displaced vertebral elements, and (2) minimizing deleterious effects of the secondary injury cascade by maximizing blood oxygenation and tissue perfusion. Within 2 to 3 hours after injury, disruption of arterioles by mechanical disruption and vasoconstriction causes ischemia in the gray matter of the cord. Following this result in fragile tissue of the central nervous system is the release of cytokines, inflammation, and apoptotic cell death primarily over the next 24 to 48 hours, although these processes can continue to cause damage for up to 3 weeks after injury.

In the acute phase of injury, maintaining an appropriate airway is essential to maintaining oxygen delivery to the damaged spinal cord. Patients with cervical spine injury are at increased risk of airway compromise both because of the risk of development of localized edema, neck hematoma, disruption of the innervation to respiratory musculature, and concomitant pulmonary injury. Thus throughout the acute evaluation, one should remain vigilant in monitoring for signs of acute respiratory failure and consider prompt intervention. Hypotension (<90 mm Hg systolic), even for brief periods of time, should be avoided as it is associated with significantly worse outcomes, although this can be especially difficult in the setting of neurogenic shock. Attention should also be given to transfer these patients to an appropriately specialized center that is equipped to treat patients with SCIs, as early transfers to such centers has been associated with improved outcomes and reduced complications.

TABLE 1 American Spinal Injury Associations International Standards for Neurologic Classification of Spinal Cord Injury Impairment Scale

Grade	Classification	Motor	Sensory
A	Complete	No motor function	Complete deficit
B	Incomplete	No motor function	Incomplete deficit
C	Incomplete	Motor function is preserved—more than half of key muscles below the neurologic levels have a grade <3/5	Incomplete deficit
D	Incomplete	Motor function is preserved—more than half of key muscles below the neurologic levels have a grade >=3/5	Incomplete deficit
E	Normal	Normal motor	Normal

After completion of the primary and secondary survey, the National Emergency X-Radiography Utilization Study (NEXUS) criteria are commonly used to determine if radiographic imaging is warranted for patients with suspected cervical SCI. According to these criteria, patients who are alert and communicated, and who lack midline cervical pain, neurologic symptoms, or distracting injury do not require further imaging. The negative predictive value of these criteria is 99.8% for ruling out a cervical spine injury. No such validated criteria exist for ruling out the need for imaging in cases of suspected lumbar SCI; however, the same concepts can intuitively apply to the thoracolumbar spine as above the level of the spinal cord.

Patients with neurologic symptoms, or who fail the NEXUS criteria, will usually require imaging, which will be discussed later in this chapter. Symptomatic patients should also receive a thorough physical examination to identify motor and sensory deficits that can aid in localizing the injury. Detailing specific deficits in these patients is important and has shown to be associated with prognostic value and decreased complications. The American Spinal Injury Association (ASIA) classification system is widely used for classifying physical examination symptoms in these patients. This scale uses a 0 to 5 point scale to evaluate 10 different muscle groups bilaterally, and each of the resulting 20 scores are added to determine the total ASIA motor score. Sensation is also evaluated on a 0 to 2 scale in all dermatomes. Finally, the ASIA scale classifies SCI overall as complete SCI (A), sensory incomplete (B), motor incomplete (C and D), and normal (E) (Table 1). The combination of the ASIA impairment scale with the ASIA motor score comprises the best description of a patient's neurologic status after SCI.

Incomplete SCI is also commonly classified into syndromes based on the level of injury and neurologic tracts involved. Central cord syndrome is the most common, accounting for 9% of SCI overall. The defining characteristics of this syndrome include symptoms with arms weaker than the legs, and a variable amount of sensory loss that does not affect the face. Corticomedullary syndrome results from injury from the lower medulla to C4, and presents with respiratory difficulty, spinal shock, sensory deficit between C1 and C4, and facial sensory loss from damage to the ascending tract of the spinal trigeminal nerve. Space occupying lesions such as disk fragments, hematoma, or fractured vertebrae can cause anterior cord syndrome, which presents with complete paralysis owing to disruption of the corticospinal tract and preservation of vibration and light touch. Posterior cord syndrome is more rare and presents with tetraparesis and profound sensory loss with preservation of pain and temperature sensation. Brown-Séquard syndrome is another commonly described syndrome involving hemisection of the spinal cord, classically in patients with penetrating injury. The syndrome presents with ipsilateral paralysis, ipsilateral vibration and loss of light touch sensation, contralateral pain, and temperature loss. Conus medullaris syndrome can be caused by burst fractures of T12 or L1 and will result in paraparesis along with loss of bowel and bladder function, sensory loss in the legs, and sparing of perianal sensation. With lower third lumbar injury, cauda equina syndrome can also occur as a traumatic injury presenting with saddle anesthesia, bowel and bladder dysfunction. Of note, the prognosis for cauda equina syndrome caused by traumatic injury to the spinal column has a higher rate of recovery owing to the higher resistance to injury found in lower motor neurons. In addition to the classically described syndromes, SCI can also be caused by prolonged hypotension and watershed infarction. Although rare, SCI due to hypotension and ischemia can occur in the absence of cerebral ischemia and is best diagnosed by magnetic resonance imaging (MRI).

IMAGING

Computed tomographic (CT) scanning is the imaging modality of choice in acute SCI and has proven to be more sensitive and specific than radiographs in diagnosing vertebral column fracture or dislocation following blunt trauma. In patients who are found to have SCI at a single level, imaging of the entire spinal column should be obtained as 10% to 80% of patients will present with multiple noncontiguous fractures. In patients with cervical spine injury, if high-quality CT scans are available, three-view radiographs are not required; however, if high-quality CT is not available, level I evidence supports three-view radiographs (anteroposterior, lateral, odontoid views) as an additional test.

Performing MRI in trauma patients is challenging, time intensive, and not readily available at all centers. In patients who have clearly defined symptoms that correlate with CT findings, most would argue against the use of MRI in the acute setting. In patients who have neurologic symptoms without findings on CT scan, however, MRI may be useful to identify occult cord compression from dynamic pathologies such as critical disk herniation or epidural hematoma. Because MRI can accurately depict cord compression and signs of cord injury (hemorrhage, transection, edema, hemorrhage, ischemia), current recommendations suggest that MRI may be performed, when feasible, prior to surgical intervention for a potential addition to surgical decision-making, although evidence is weak to support this recommendation. In patients who have pain without neurologic findings, MRI may identify ligamentous injury as the cause of pain, although ligamentous injury does not necessarily imply spinal instability. MRI has also shown use in predicting long-term neurologic outcomes through a prognostication score when correlated with clinical symptoms, although the validity of these predictions have yet to be established.

SCI without radiographic abnormality (SCIWORA) is a syndrome that presents almost exclusively in children. The most accepted current definition of SCIWORA has come to encompass CT and radiographs only as cases of SCI almost always have pathologic findings on MRI. Nonetheless, both complete and incomplete SCI may present as SCIWORA, and surgeons should be aware of this presentation of SCI. Current recommendations involve up to 12 weeks of bracing, and MRI in this population of patients has been shown to hold prognostic value.

SELECTION OF SURGICAL CANDIDATES AND TIMING OF SURGERY

Disruption of musculoligamentous structures associated with the majority of SCIs has the potential to cause permanent neurologic impairment. Therefore the goal of surgical intervention in patients with SCI is to reduce compressive forces on the spinal cord and restore normal anatomic alignment. Although a variety of injury patterns may occur, we will describe the classic isolated injuries. Patients with multiple fracture patterns or cord compression present at multiple levels may warrant more complex treatment algorithms.

Cervical Spine

Injuries to the cervical spine can be classified as craniocervical (occiput to C2) or subaxial (C3-T1) injuries. The most cranial of these injuries is atlanto-occipital dislocations. Although usually fatal because of the level of the injury or associated vertebral artery injury, patients who survive this traumatic dislocation are treated with occiput to cervical fusion. Infrequently, these traumatic dislocations may also require decompression of associated damaged nerves. Unilateral fractures of the occipital condyle can be treated with a cervical collar for 6 to 12 weeks. C1 fractures commonly occur as a burst type fracture of the anterior and posterior arches, originally described as double fractures through each arch and known by the eponym Jefferson's fracture. Although other variations of C1 fractures exist, they are typically treated by halo vest immobilization for 6 to 12 weeks. C2 fractures are divided between those affecting the odontoid process and all other fractures. Type I odontoid fractures occur at the tip of the dens. Type II fractures occur at the base, and type III fractures occur at the body of the axis. Type I fractures are stable and can be treated with immobilization with a cervical collar. The management of type II odontoid fractures is somewhat controversial, as there is a high risk for nonunion without surgical treatment, but surgical treatment is both risky and invasive at this level. Current accepted indications for surgical management of type II odontoid fractures include patients with instability, cord compression with neurologic deficits, and high risk of nonunion (smoking, osteoporosis, etc.). Surgical treatment options include odontoid screw fixation and posterior atlantoaxial arthrodesis. Nonoperative management may be considered for patients without these symptoms and <5 mm displacement. Nonoperative treatment options include nonrigid orthosis (collar, cervicothoracic orthosis) or rigid cervical orthosis (halo vest). Type III odontoid fractures may be treated effectively with cervical collar immobilization. Hangman's fractures (HF) are bilateral fractures of the C2 pars interarticularis and are similarly classified into three types based on the degree of subluxation of C2 on C3 and angulation of the C2 vertebral body. Type I HF exhibit less than 3 mm translation and may be successfully treated with a cervical collar. Type II HF are defined as those with more than 11 degrees of angulation and more than 3 degrees of translation, and may require surgical fixation if deemed unstable, although the definition of stability varies between authors. There is no consensus. Type III HF are defined by severe angulation and facet dislocation of C2-C3, and generally require surgical fixation. Nonoperative management of these fractures include either cervical collar or halo vest, and surgical treatment options include anterior C2-C3 interbody fusion, posterior C1-C3 fusion, and bilateral C2 pars screw osteosynthesis (Table 2).

Subaxial cervical spine fractures can be classified using several classification schemes. The Arbeitsgemeinschaft für Osteosynthesefragen (AO) classification and subaxial cervical spine injury classification (SLIC) system are the most commonly used. The SLIC system is shown in (Table 3) and considers the morphology of the fracture, integrity of the discoligamentous complex, and neurologic status of the patient. Each of these domains are scored from 0 to 2/4 from intact to most severely damaged, and the decision to operate is dictated by the overall summative score. Overall score of less than 4 indicates nonoperative management, whereas overall score of more

TABLE 2 Craniocervical Fracture Types and Recommendations for Treatment

Fracture Location	Recommended Treatment
Atlanto-occipital dislocation	Occiput to cervical fusion
Unilateral occipital condyle fracture	Cervical collar for 6–12 weeks
C1 fracture	Halo vest immobilization for 6–12 weeks
C2 fracture:	
Odontoid (type I)	Cervical collar immobilization
Odontoid (type II)	Surgical vs nonsurgical treatment depending on displacement and patient comorbidities
Odontoid (type III)	Cervical collar immobilization
Hangman's (type I)	Cervical collar immobilization
Hangman's (type II)	Surgical fixation if unstable
Hangman's (type III)	Surgical fixation

TABLE 3 Subaxial Cervical Spine Injury Classification System

Characteristic	Points
MORPHOLOGY	
No abnormality	0
Compression	1
Burst	+1 = 2
DISTRACTION (E.G., FACET PERCH, HYPEREXTENSION)	
Rotation/translation (e.g., facet dislocation, unstable teardrop, or advanced-stage flexion compression injury)	4

Intact	0
Indeterminate (e.g., isolated interspinous widening, magnetic resonance imaging signal change only)	1
Disrupted	2
NEUROLOGIC STATUS	
Intact	0
Root injury	1
Complete cord injury	2
Incomplete cord injury	3
Continuous cord compression in setting of neurodeficit	+1
SCORE	
≤4	Nonoperative treatment
4	Operative vs nonoperative
≥5	Operative treatment

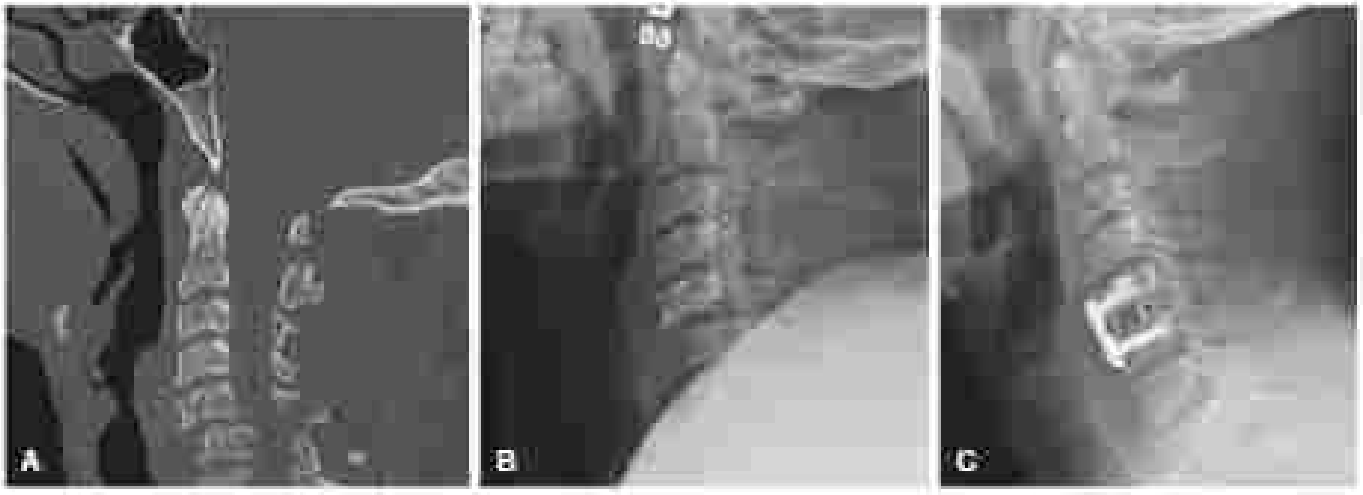

FIG. 1 Subaxial cervical spinal cord injury. This patient presented to the emergency department (ED) as a pedestrian versus motor vehicle accident. Computed tomography scan (A) and radiographs (B and C) demonstrated C5–C6 bilateral jumped facets with relative anterolisthesis of C5 on C6 with complete spinal cord injury at C6 level (American Spinal Injury Association score A). The injury was reduced in the ED using serial traction. Later that day, the patient had definitive fixation with a C5–C6 anterior cervical discectomy and fusion.

than 5 nonoperative operative treatment. Fractures with a score of 4 using the SLIC system may be treated operatively or nonoperatively. Nonoperative management of these fractures is similar to craniocervical fractures. When indicated, surgical fixation for subaxial fractures may be performed through an anterior, posterior, or combined approach, considering the need for decompression, stabilization, and reconstruction (Fig. 1).

Ideally, surgical decompression should be performed prior to 24 hours after injury in cases of cervical SCI. To date, the 2012 Surgical Timing in Acute Spinal Cord Injury Study (STASCIS) is the largest study to evaluate the effect of early surgical decompression after SCI on long-term outcomes. The results of the STASCIS showed that decompression prior to 24 hours was associated with a grade 2 improvement on the ASIA scale at 6 months. These findings are backed by a large amount of preclinical evidence supporting the advantages of early surgical decompression. When feasible, given the limitations of the treatment facility and comorbid injuries in these patients, the goal should be for surgical decompression to be performed in less than 24 hours.

Thoracolumbar Spine

Traumatic injury at the level of the thoracic spine is less common, owing to the added structural support of the ribs and sternum. Thus when injury at this level does occur, it is frequently severe and associated with neurologic deficits, and most thoracic injuries occur in the thoracolumbar junction. Isolated lumbar SCI is less common, mainly because the spinal cord typically ends between L1 and L2. Surgical decision making in thoracolumbar SCI is also dependent on the stability at the level of the injury.

The three-column model of the spine proposed by Denis in 1983 is the basis for conceptualizing variations in thoracolumbar injury and the resulting loss in mechanical stability (Fig. 2). The three-column model has subsequently been used to develop the AO classification of spinal injury (1994), and more recently, the Thoracolumbar Injury Classification and Severity Score (TLICS) (2005). Unlike the AO classification, thoracolumbar spinal injuries are classified as compression injury (group A), distraction injury (group B), and translation or rotation injury (group C) (Fig. 3). This classification system depicts increasing injury severity from category A to C and associated increased likelihood of requiring surgical stabilization. In general, type A injuries are limited to the anterior column and type B and C injuries affect two or three columns. Considering that type A injuries

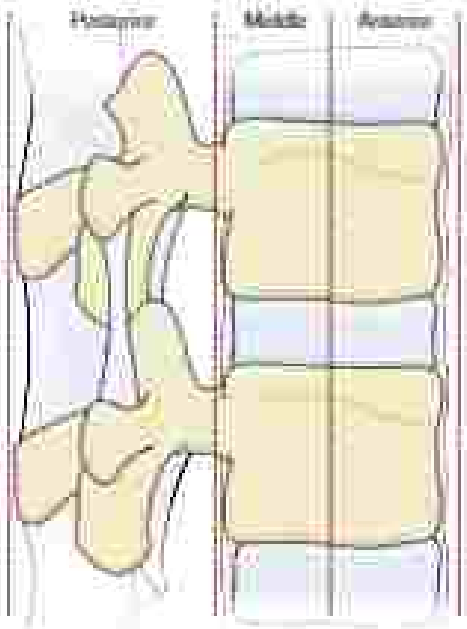

FIG. 2 Three-column model of Denis. The three-column model divides the spinal column into anterior, middle, and posterior columns. The anterior column is composed of the anterior portion of the annulus fibrosus, anterior annulus, and anterior portion of the vertebral body. The middle column is composed of the posterior portion of the vertebral body, posterior annulus, and posterior longitudinal ligament. The posterior column is composed of the posterior bony elements (pedicles, facets, spinous process, lamina) and interspinous ligaments.

are generally stable, they can be treated with a thoracic lumbar sacral orthosis (TLSO) brace, whereas type B and C injuries are inherently less stable and will usually require operative management. The TLICS score considers injury morphology, posterior ligamentous complex injury, and the patients' neurologic status. The score of each domain is added, with a higher score indicating more severe injury, and the total score determines if surgical versus nonsurgical management is warranted.

In stable fractures that are treated with TLSO bracing, patients are followed with radiographic imaging to ensure bony union across the

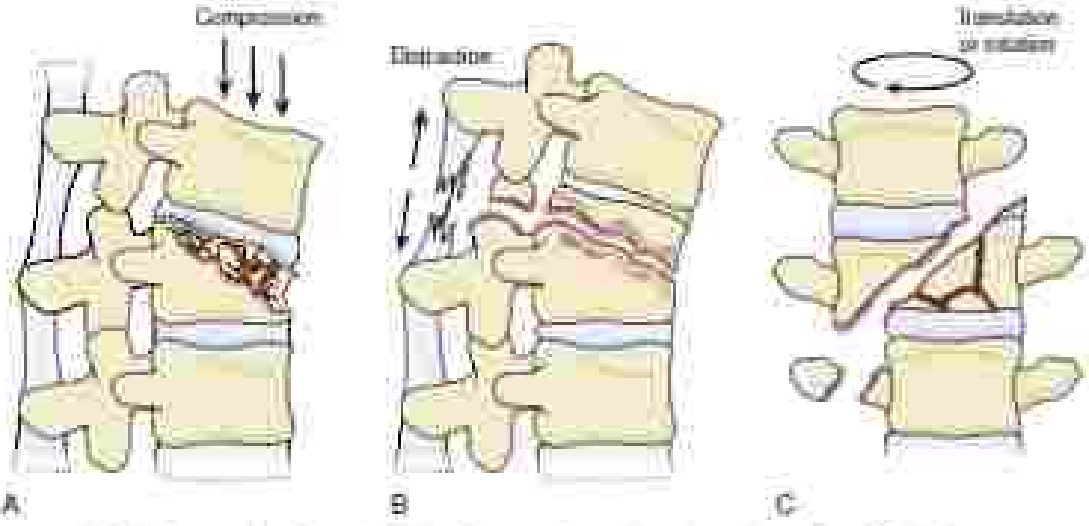

FIG. 2 Arbeitsgemeinschaft für Osteosynthesefragen (AO) classification of thoracolumbar spinal injury. The AO classification is semi categorical and evaluates the mechanism of compression (A), distraction (B), and translation or rotation in any (C).

fracture site. Follow-up visits should include surveillance of psychosocial issues, pressure ulcers, urinary tract infections, and bowel and bladder dysfunction. Patients should be screened for depression and suicidal ideation, and referrals to psychiatry should be made as needed. Patients should be educated on the importance of skin inspection and pressure relief, and should be instructed to perform self-catheterization if necessary. Patients should be screened for spasticity, and treatment should be initiated if it is interfering with activities of daily living or causing pain. Patients should be screened for neuropathic pain, and treatment should be initiated if it is interfering with activities of daily living or causing pain. Patients should be screened for bowel dysfunction, and treatment should be initiated if it is interfering with activities of daily living or causing pain. Patients should be screened for sexual dysfunction, and treatment should be initiated if it is interfering with activities of daily living or causing pain.

MEDICAL MANAGEMENT

Hemodynamic Support

Hypotension (SBP < 90 mm Hg) should be avoided in the acute setting of SCI. Hypotension can result from hemorrhagic shock and concomitant hemothorax, tension pneumothorax, cardiac tamponade, or sepsis, and all can contribute to hypotension. As such, substantial evidence supports the use of intravenous fluids and vasopressors to maintain MAP between 85 and 90 mm Hg for the first 7 days after injury. Intravenous fluids should be titrated judiciously, as these patients are at high risk of pulmonary edema, and early consideration should be given to vasoactive agents. Lactate has yet to be a preferred algorithm developed to guide fluid resuscitation in patients with SCI.

Corticosteroids

Among the most controversial topics within the field of SCI is the use of methylprednisolone sodium succinate (MPSS) in the treatment of acute SCI. MPSS is a synthetic glucocorticoid that exhibits anti-inflammatory effects through interference with cytokine signaling and arachidonic acid metabolites. The theoretical basis for its use in SCI comes from numerous studies in animal models that have shown enhanced neuron survival after the use of MPSS; however, high dose glucocorticoids come with increased risk of infection and gastrointestinal bleeding in patients with SCI. For many years, it was common practice to administer MPSS within 8 hours of SCI, but this has proven to be a complex issue that continues to be debated even when faced with several large randomized trials, and the subsequent debate has brought to light the heterogeneity of the population of SCI patients. The National Acute Spinal Cord Injury Study (NASCIS) has conducted three trials (NASCIS I, II, and III) spanning from 1.84 to 7, and the findings of these trials have served as the basis for other prospective studies and current guidelines. The most recent guidelines are the result of a joint statement between AANS, the American Academy of Neurological Surgeons, and the Congress of Neurological Surgeons published in 2013. These recommendations are to consider a 24 hour infusion of high dose MPSS within 8 hours of SCI (30 mg/kg bolus + 5.4 mg/kg per hour for 23 hours). In addition, the AANS/CNS recommendations are to avoid MPSS after 8 hours of SCI, and to avoid the 48 hour bolus infusions that were once recommended. These recommendations are based on evidence suggesting a small benefit in motor recovery when MPSS is administered within 8 hours of injury, and that the possible drawbacks (gastrointestinal bleeding, infection) outweigh the benefits after 8 hours and with 48 hour infusions.

Alternative Neuroprotective and Neuroregenerative Agents

Several alternative neuroprotective agents have been studied in SCI, including minocycline, riluzole, GM-1, 21, 1118, and Cethrin. Although there has been promising preclinical evidence, several phase III clinical trials have failed to demonstrate significant clinical benefit of these agents.

COMPLICATIONS AND REHABILITATION

Patients with SCI are at risk for a handful of short- and long-term complications, owing to both direct neurologic injury and concomitant injuries. In the subacute setting, patients may experience spinal shock, neurogenic shock, or respiratory failure that may require fluids, vasopressors, and/or mechanical ventilation. In the intensive care unit, common complications include dysphagia, venous thromboembolism, infections, and stress gastrointestinal ulcers—all of which are managed in line with standard medical therapy. Long-term complications include complications owing to immobility, pressure sores, hypokinesia, obesity,

Evaluation and Management of Facial Injuries

Michael P. Grant, MD, [illegible], PhD

Facial injuries consist of damage to bone and soft tissue and disruption of the attachments between the two. The facial injury may be isolated or part of a multiple system injury pattern. Multiple system injuries that include a facial injury often require a coordinated effort by general surgeons, trauma surgeons, and specialty teams. Even isolated high-energy maxillofacial injuries warrant a complete evaluation preferably by a trauma team.

EMERGENCY TREATMENT OF MAXILLOFACIAL TRAUMA

The presence of a facial injury implies a geographic (simultaneous) injury to the head, face, and neck, including the brain and cervical spinal regions. Evaluation for brain injury, skull fracture, and cervical spine injury is mandatory in any patient with a maxillofacial injury to exclude serious injuries to adjacent anatomic regions.

Maxillofacial trauma presents three life-threatening emergencies: (1) airway obstruction, (2) hemorrhage, and (3) aspiration.

Airway Obstruction

Airway obstruction is expected in patients with comminuted fractures of the upper and lower jaws and injuries that result in swelling or bleeding into the airway spaces (neck, pharynx, larynx, mouth, floor of the mouth, and nose). The onset of stridor, hoarseness,

denervation (spasticity, urinary retention, constipation, temperature dysregulation, autonomic dysreflexia, and orthostatic hypotension), and the development of psychiatric conditions (depression, anxiety, and sleep disorders). Rehabilitation goals are often complex and should be individualized to each patient. Physical and occupational therapists should be an integral part of caring for these patients even before transferring to the rehabilitation unit, and both patients and their families should be educated on the importance and goals of rehabilitation efforts on maximizing the potential for long-term recovery.

PROGNOSIS

Providing a reliable prognosis to patients and their families is an important component of caring for patients with SCI. The most important prognostic factors to consider are the level of neurologic injury, AIS impairment scale grade, age at injury, and appearance of the spinal cord on MRI—with early mortality seen in high cervical lesions, increased age, more severe neurologic deficits, and edema or hemorrhage on T2 MRI. A handful of disability measurement scales exist for categorizing patient's impairments and monitoring improvement, and the Spinal Cord Independence Measure (SCIM) is among the most common. The SCIM considers self-care (0 to 20 score), respiratory and sphincter management (0 to 40), and mobility (0 to 40) with the final score ranging from 0 to 100. The mortality rate of patients with SCI is difficult to generalize overall, with a large systematic review showing median survival between 35.4 days and 56.5 years. On average, however, the mortality associated with SCI is highest between 4 and 12 months after injury with the greatest threat being pneumonia and sepsis. It is estimated that 13% of patients are employed at 1 year following the initial insult. The average lifetime costs attributed to the care for patients with SCI vary from $1.1 million in elderly patients with less severe injuries to $4.8 million in younger patients with high cervical injuries.

EVALUATION AND MANAGEMENT OF FACIAL INJURIES

Michael P. Grant, MD, PhD, FACS, and Paul N. Manson, MD

Facial injuries consist of damage to bone and soft tissue and disruption of the attachments between the two. The facial injury may be isolated or part of a multiple system injury pattern. Multiple system injuries that include a facial injury often require a coordinated effort by general surgeons, trauma surgeons, and specialty teams. Even isolated high-energy maxillofacial injuries warrant a complete evaluation periodically by a trauma team.

EMERGENCY TREATMENT OF MAXILLOFACIAL TRAUMA

The presence of a facial injury implies a geographic (simultaneous) injury to the head, face, and neck (including the brain and cervical spine) regions. Evaluation for brain injury, skull fracture, and cervical spine injury is mandatory in any patient with a maxillofacial injury to exclude serious injuries to adjacent anatomic regions.

Maxillofacial trauma presents three life-threatening emergencies: (1) airway obstruction, (2) hemorrhage, and (3) aspiration.

Airway Obstruction

Airway obstruction is expected in patients with comminuted fractures of the upper and lower jaws and injuries that result in swelling or bleeding into the airway spaces (neck, pharynx, larynx, mouth, floor of the mouth, and nose). The onset of stridor, hoarseness,

drooling, inability to swallow, and noisy respirations should prompt an alert clinician to urgently intubate the patient or in some cases perform a tracheostomy. Cricothyroidotomy is an emergency maneuver to access the airway through the cricothyroid membrane. It should always be converted to tracheostomy as soon as feasible.

Life-Threatening Hemorrhage

Life-threatening hemorrhage results from several categories of injury. (1) facial and scalp lacerations, (2) closed fractures of the sinus and midface, (3) arterial injuries of the sinuses and skull base with internal carotid or venous sinus (cavernous sinus) hemorrhage.

Facial Lacerations

Bleeding from facial lacerations is usually the result of partially or fully transected major arteries. These are controlled by direct ligation, carefully avoiding branches of the facial nerve, which are many times adjacent to arteries. The partially transected artery cannot retract and will continue to bleed until effectively manually controlled.

Closed Fractures, Sinus Injuries, and Midface Injuries

Midface and orbital fractures produce hemorrhage from lacerations of arteries and veins in the walls of the sinus cavities or adjacent structures. In the majority of cases, manual repositioning of the maxilla or zygoma combined with intermaxillary mandibular fixation controls the bleeding. The maxilla is first placed at rest in intermaxillary fixation (IMF). Angiographic embolization is the usual method of control in those few patients (<5%) who continue to bleed. Selective embolization or ligation of the internal maxillary artery, accessed through the posterior wall of the maxillary sinus, or bilateral external carotid and superficial temporal artery ligation can be performed. These procedures are seldom necessary.

Aspiration

Aspiration of oral secretions, gastric contents, or blood frequently accompanies fractures of the middle and lower face, especially with cerebral injury or depressed mental status secondary to injury or drug or alcohol ingestion. Rapid, noisy respirations, low arterial oxygen content, and a decrease in pulmonary compliance are seen. Intubation prevents aspiration and should be performed urgently when it becomes evident that the airway is not being protected.

Occult and Ancillary Injuries

The possibility of occult injuries demands a thorough, multisystem examination in every patient. Observations of other organ systems must be continued throughout the entire period of facial injury treatment. In patients with multisystem injuries, the status of all injuries must be continuously assessed.

EARLY MANAGEMENT OF MAXILLOFACIAL TRAUMA

The early management of maxillofacial trauma comprises (1) clinical examination, (2) appropriate diagnostic imaging, and (3) definitive wound and/or fracture management.

Clinical Examination

The diagnosis of most facial injuries is accomplished by a thorough clinical examination, noting the pattern of contusion, bruises, discolorations, crepitus, pain, localized tenderness, numbness, paralysis, malocclusion, diplopia, visual acuity loss, facial asymmetry, deformity, and changes in eye position and facial contour. The care provider should assume that a fracture underlies any contusion bruise or laceration until proved otherwise. Any laceration or wound should be suspect for containing a foreign body.

The physical examination should be both sequential and direct, starting with an orderly examination of the facial structures in sequence from top to bottom, followed by a careful, sequential examination to those areas suspect or obviously injured. A digital examination of the critical areas is then performed. Palpation of all bony surfaces begins at the supraorbital rims, continues around the orbit, and extends to the infraorbital rims and nose, includes the zygomatic arches and molar prominences, and concludes with an examination of the maxilla and mandible, both intraorally and externally to position and movement. Any deformity, malocclusion, crepitus, bone irregularity, inability to bring the teeth together to occlusion, or tenderness is noted. It is essential to confirm the proper interrelation of the teeth in occlusion; any deviation to the expected pattern implies the possibility of a fracture/dislocation. Intraoral or extraoral lacerations or bleeding from a tooth socket imply the possibility of an accompanying fracture.

An evaluation of facial nerve (facial motoric muscle system) and trigeminal (sensory nerve and motor nerve) function compares the two sides of the face. Facial sensation is documented in the supraorbital, corneal, infraorbital, and mental distributions (anesthesia or hypoesthesia). A search for occult lacerations in the ear canal, nose, mouth, floor of mouth, and pharynx should be conducted. The occlusion of the jaws, the relation of the teeth to occlusion, and the stability of the teeth in sockets are noted, looking for irregular arch forms and abnormalities of interrelation of the teeth. Fractured or missing teeth, intraoral and gingival lacerations, bleeding tooth sockets and gaps or level discrepancies in the maxillary and mandibular dentition indicate the possibility of fractures. Lacerations of the lips, chin, floor of the mouth, and palate are accompany anterior jaw fractures.

Visual and sensory function should be evaluated in all patients with orbital, upper facial, or frontal bone trauma. Visual acuity and range of extraocular motility should be evaluated, and the presence of a relative afferent pupillary defect, visual field defect, diplopia, hyphema (bleeding in the anterior chamber), periorbital ecchymosis, or subconjunctival hemorrhage imply the possibility of an orbital fracture or globe injury. In a partially injured optic nerve, a light swinging back and forth between both eyes will cause the usually intact pupil to constrict, whereas the partially compromised optic nerve causes that pupil to paradoxically dilate while the contralateral pupil constricts.

Alginate impressions of the dentition are taken, and most models are set up prepared to provide a dental record. In the physical examination, any grossly displaced midfacial or mandibular fractures can be manually repositioned, which often stops bleeding, and if desired, IMF can be applied with wire loops between the teeth to temporarily stabilize jaw fractures. The airway must be protected at all times, and intubation is frequently the best technique.

Radiographs

Plain radiographs are of little value in the evaluation of facial injuries, except when they may be necessary to exclude the presence of a radiopaque foreign body. The ideal radiographic examination is computed tomography (CT). Multiply injured patients should not be transported for extensive radiographic evaluation, and such studies supplement, but do not replace, the findings of a physical examination. For most fractures, the best radiographic evaluation consists of images in three axes—axial, sagittal, and coronal plane CT scans, to include the frontal sinus, nasoethmoid, orbital, maxillary, and mandibular regions. Both bone and soft tissue windows should be obtained, so that all structures may be assessed. If the patient cannot be positioned for direct coronal images, coronal images may usually be reconstructed from the axial CT format. A rapid soft tissue window CT examination of the brain or skull does not replace the need for a specific maxillofacial CT because needed detail is not provided and soft tissue windows miss fractures.

WOUND AND FRACTURE MANAGEMENT

Soft Tissue Injuries

Soft tissue injuries include lacerations, bruises, contusions, and hematomas. Cutaneous wounds are inspected for foreign material and assessed for depth and direction to predict deep structure involvement (probing with a cotton tipped applicator, not sharp instruments) and to detect contamination or foreign material. Lacerations require inspection for damaged structures, followed by cleansing by scrubbing, gentle irrigation, and removal, judicious sharp debridement of the uneven, contused tissue edge before closure (and when tolerated by entire tissue). A millimeter or two is usually a sufficient edge resection of a laceration, and achieves a clean, even minimum-trauma margin. A layered repair achieves a flat wound, resulting in minimal scar formation. Antibiotics are indicated when a clean wound (defined by surgical debridement) cannot be created, especially in the presence of heavier contamination, such as an animal bite. Direct primary closure of facial wounds is always preferred, with second-look procedures at 48-hour intervals, when concern about infection, hematoma, or continued devitalized tissue is an issue, as in the case of large degloving or avulsive wounds. We use the benefits of second-look procedures frequently, obtaining the benefits of primary healing and early opportunities for detection of hematoma, infection, or devitalized tissue by secondarily opening a portion of the wound.

Open wound management is almost never used, with the possible exception of human bites, and second-look procedures are preferred. Debridement should be quite conservative in the region of the vermillion, oral commissure, eyelids, eyebrows, distal nose, and nostrils. All foreign material must be meticulously removed at the time of the initial examination and treatment, because it cannot be satisfactorily removed after healing. Postoperative wound laceration surface hygiene is accomplished four times daily with a 10-15 cc peroxide saline solution on cotton tipped applicators and the application of either a liberal lubricating ointment and or a topical antiseptic ointment such as bacitracin (facial sutures) or a combination steroid antibiotic ophthalmic ointment (Lacri-Lube) (periorbital sutures). Intraoral repairs are cleansed with mouthwash and standard oral hygiene three times daily. The toothbrush remains the best cleaning mechanism for the gums and the dentition.

Any localized facial hematoma should be drained by incision, and a soft compressive dressing should be applied. Localized hematomas most commonly occur in the ear region and may involve the forehead or buccal areas. Laceration of the lacrimal system should be suspected in any wound on the nasal aspect of the upper or lower eyelids. Eyelid or periorbital lacerations raise the possibility of globe rupture or penetrating injury, which must be excluded by direct palpation and thorough inspection and eye evaluation.

Lacerations of the facial nerve and parotid duct are managed by direct repair using loupe magnification. Parotid duct lacerations are diagnosed by inserting a No. 22 Angiocath sleeve (Becton Dickinson) into the duct orifice (opposite the second maxillary bicuspid tooth necessarily) after dilating it with a lacrimal punctum dilator and irrigating with saline. The presence of saline in the wound implies duct and or parotid gland laceration.

Because duct is a short structure that extends from the anterior margin of the parotid gland 1.5 inches anterior to the tragus on a line between the tragus and floor of the nostril, to the second maxillary bicuspid. Facial lacerations are usually accompanied by buccal branch facial paralysis because the two structures are adjacent. Nerve and duct transections should be repaired.

Cerebrospinal Fluid Rhinorrhea

Fractures involving the frontal or basilar skull may lacerate the dura, allowing cerebrospinal fluid (CSF) to exit from the nose (rhinorrhea), or fractures with dural lacerations may allow air to enter the intracranial area (pneumocephalus). Either condition permits entry of organisms through the meninges with the possibility of meningitis. Generally prophylactic antibiotics are used to a pulse rather than a prolonged course in these conditions; perioperative antibiotics will generally accompany operative treatment of either condition when indicated. CSF rhinorrhea is detected by the presence of clear fluid exiting from the nose or pharynx. Often CSF is mixed with blood, making its detection more difficult. The double ring sign, absorption of blood and CSF onto a paper towel, produces a small, central blood ring with a large, peripheral, clearer fluid ring surrounding it. A detailed CT scan is mandatory if CSF leak or pneumocephalus is suspected. Chemical tests confirming the CSF leak include beta transferrin and intrathecal fluorescein.

Definitive Fracture Management by Region

Nasal Fractures

Nasal fractures produce dislocation either laterally, posteriorly, or in combination. The diagnosis is suggested by epistaxis, bruising, swelling, and deformity: lateral deviation/dislocation, or recession, and flattening of the nose in frontal impact injuries of the nasal pyramid (Fig. 1). Intranasal inspection shows dislocation, deviation, or laceration of the mucous membranes or septum and possibly the turbinates with difficulty breathing because of blood, mucosal swelling, and the narrowed airway. Nasal and periorbital hematomas generally accompany nasal fractures, and at least one third have a small laceration over the nasal bridge. Nasal fracture hematomas do not observe the precise boundaries seen in orbital fractures, which are confined to the distribution and insertion of the orbital septum (Fig. 4.8).

Clinically, radiographic evaluation of nasal fractures consists of plain films, a nasal series, a Waters view, and sinus films. These are not very definitive, and a CT scan is the best examination, making plain radiographs of no utility. The value of nasal images to isolated low-energy injuries is both methodical and clinical. Injuries to adjacent bony structures are excluded, and the exact fracture extent and displacement of nasal structures, including the septum, nasal bones, and turbinates are identified.

Treatment

Closed reduction of the septum and nasal pyramid is performed under anesthesia; less ideally, an external field block and intranasal topical Afrin are used. Reduction maneuvers may occasionally create

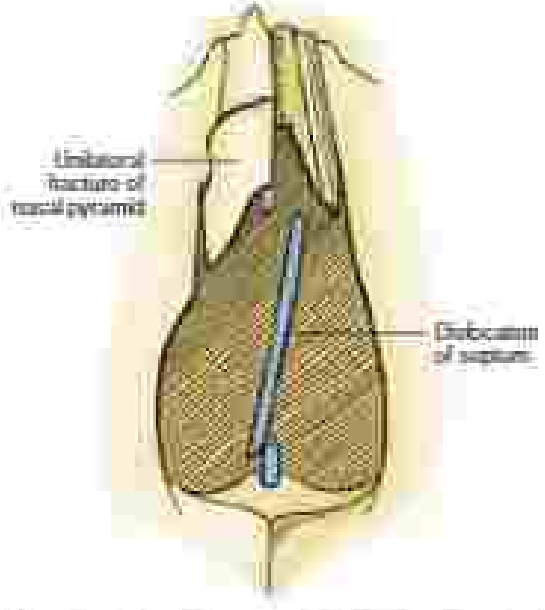

FIG. 1 Nasal fractures are characterized by lateral or posterior displacement, and sometimes both. Each displacement requires a specific reduction maneuver.

profuse nasal hemorrhage, and one must be prepared for this and protect the airway. Isolating patients when the airway is unprotected is not recommended.

Laterally deviated nasal fractures first have any greenstick components of the fracture completed by bilateral intranasal mobilization of the nasal pyramids laterally and the septum centrally, establishing them to the midline and supporting them with external and internal nasal splints. The septum is straightened and centralized with an Asch forceps and supported with antiprotic, laminated Doyle nasal splints. Frontal impact nasal injuries produce varying degrees of nasal retrusion and may require open reduction and bone or cartilage grafting to restore projection and achieve the nasal profile and support necessary to produce an adequate aesthetic result.

Zygomatic Fractures

The zygoma constitutes the malar prominence and forms the lateral and inferior walls and rims of the orbit. The zygoma has five attachments to adjacent structures: laterally to the temporal bone through

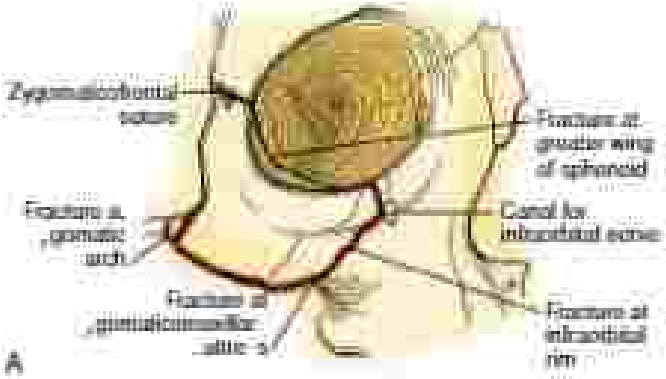

FIG. 1 (A) The zygomatic bone constitutes the lateral and inferior portions of the orbit and malar eminence. It attaches to the frontal bone superiorly, the temporal bone posteriorly, and the maxilla medially and inferiorly. In the orbit, the alignment of the orbital process of the zygomatic bone with the greater wing of the sphenoid provides an accurate clue to reduction. (B) The combination of a periorbital and subconjunctival hemorrhage implies a bone fracture somewhere; when the orbital periorbital hematoma is confined to the orbit by the insertion of the orbital septum,

the zygomatic arch, superiorly to the frontal bone through the frontal process, medially to the maxilla through the infraorbital rim, inferiorly to the maxillary alveolus through the zygomaticomaxillary buttress, and to the lateral orbit to the greater wing of the sphenoid through the orbital process of the zygoma (Fig. 1). The diagnosis of a zygomatic fracture is suggested by the combination of a periorbital and lateral subconjunctival hematoma (Fig. 1B). These are sensitive but nonspecific signs that may accompany any orbital fracture. If the frontal process of the zygoma is dislocated inferomedially, the lateral canthus is inferiorly displaced by its attachment to the lateral orbit at Whitnall's tubercle. Depression of the malar eminence accompanies posterior displacement of the body of the zygoma. Steps, or level discrepancies, may be palpated in the bone forming the inferior or lateral orbital rim or at the zygomaticofrontal suture. Intraorally, a hematoma is present in the upper buccal sulcus, and intraoral irregularity of the maxillary buttress may be palpated. Unilateral epistaxis is secondary to hemorrhage exuding through the ipsilateral maxillary antrum. If the zygoma is posteriorly or medially dislocated, difficult or painful chewing or difficulty bringing the teeth into occlusion may result from impingement of the zygomatic body or zygomatic arch on the coronoid process of the mandible, from bruising to the temporalis muscle, or from hemorrhage into the temporomandibular joint.

Orbital extraocular muscle entrapment symptoms (diplopia) result from the orbital floor fracture component and depend on the mechanism and degree of involvement of extraocular muscles, with restriction of their motion by actual muscle incarceration and/or entrapment of adjacent soft tissue in the fracture. Infraorbital nerve numbness accompanies most zygomatic fractures and is related to bruising or injury of the infraorbital nerve at the infraorbital foramen. In the case of a significant orbital fracture, globe dystopia, enophthalmos, and double vision may be present. The definitive radiographic examination of the zygomatic fractures is axial, sagittal, and coronal CT scans with bone and soft tissue windows.

Indications for surgery include the functional symptoms produced by bone displacement, which include deformity, enophthalmos, double vision resulting from incarceration of an extraocular muscle or its surrounding fat or fascia, vertical malposition of the globe, loss of malar prominence, anesthesia of the infraorbital nerve (in medially dislocated zygomatic fractures that compress the nerve at the infraorbital foramen), radiographically extensive orbital floor fracture, and interference with the excursion of the coronoid process by medial depression of the zygomatic arch or posterior depression of the body of the zygoma.

Treatment

Displaced fractures isolated to the zygomatic arch are treated by elevation through a Gillies approach. An incision in the temporal hair permits insertion of an elevator under the deep temporal fascia on the temporalis muscle to elevate the zygomatic arch. Because of periosteal continuity, medially displaced arch fractures are generally stable following closed reduction. Displaced zygomatic fractures not isolated to the arch are managed by open reduction and internal plate and screw fixation (Fig. 3). Incisions for zygomatic fracture reduction consist of lower eyelid incisions (subciliary, subtarsal, or transconjunctival), gingivobuccal intraoral sulcus incisions (the lateral limb of an upper blepharoplasty incision and, in extensive fractures, a coronal incision. Simple fractures with incomplete fractures at some buttresses may often be reduced with a single approach. Comminuted zygomatic fractures, especially those with lateral displacement of the zygomatic arch and body of the zygoma, require three incisions: coronal, intraoral, and eyelid.

Temporary alignment is initially achieved by placing interfragmentary wires at the zygomaticofrontal suture and infraorbital rim. The zygomaticomaxillary buttress, exposed through an intraoral gingivobuccal sulcus incision, is then stabilized by reduction and fixation. If the zygoma is laterally displaced, an open reduction of the zygoma, orbit, and arch are directly approached through a coronal incision. The orbital floor is explored through a lid incision and following

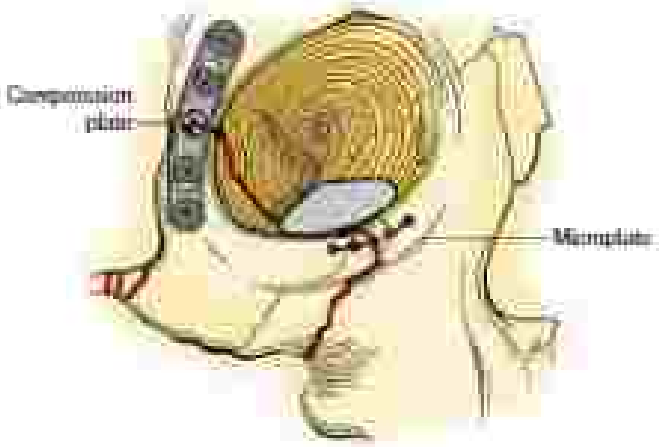

FIG. 1. Right internal fixation of a zygomatic fracture has been performed by applying plates and screws to the junction of the zygoma with the frontal bone and maxilla. The bone is manipulated into position and temporarily secured with interfragment wires before rigid internal fixation is applied.

retrieval of soft tissue contents of the orbit from the antrum, the orbital floor is reconstituted with either alloplastic materials (polyethylene or titanium) or a thin, curved bone graft such as a split rib, or the external table of the skull.

Nasoethmoid-Orbital Fractures

Nasoethmoid orbital fractures are comminuted fractures of the central upper midface: the nose and medial orbital rims. They result either directly from a blow to the glabella and upper nasal area that shatters the medial orbital rims, nose, and frontal sinus, or indirectly by the extension of other midface or frontal fractures (forehead or zygomatic/Le Fort's maxillary areas). One-third of these fractures are unilateral, one side of the nose and the medial orbital rim, and two-thirds are bilateral. One-third are isolated to the central midface alone (ipsilateral nose and medial orbital rim), and two-thirds are extended to other areas of the central midface or forehead. Commonly, a unilateral nasoethmoid fracture exists with a midface Le Fort's fracture. The *sine qua non* of this fracture is the presence of fractures that isolate the lower two-thirds of the medial orbital rim with its attached medial canthal ligament from adjacent bones, which allows migration laterally of the entire medial eyelid commissure (Fig. 3A).

The diagnosis of a nasoethmoid orbital fracture is suggested by the presence of a severely depressed, comminuted, frontal impact nasal fracture (Fig. 4B). Pain and tenderness are present with direct finger pressure over the medial canthal ligament. Unilateral or bilateral eyelid (spectacle) hematomas are usually present. Nasal lacerations are present in 50% of patients, and epistaxis is invariably accompanies this injury. A forehead contusion, depressed nose is usually accompanied by telecanthus, which is increased distance between the medial eyelid commissures. Crepitation is present on palpating the nose, and a CSF leak, pneumocephalus, or orbital emphysema may be present.

Traumatic telecanthus is measured by an increase in the distance between the medial commissures of the eyelids. This distance normally equals the length of a palpebral fissure. A high index of suspicion is necessary to confirm the diagnosis of traumatic telecanthus in patients with minimal displacement or impacted fractures. Mobility of the medial orbital rim may also be detected on bimanual examination with simultaneous intranasal-extranasal examination. A palpating finger placed externally against the bone bearing the medial canthal ligament attachment detects movement of the bone produced by the tip of a clamp placed in the nose directly under the canthal ligament. Movement of the medial orbital rim confirms the presence of a fracture that will require open reduction. The definitive radiographic examination consists of axial, sagittal, and coronal CT scans with bone and soft tissue windows (Fig. 4C).

Treatment

Treatment should generally be accomplished as soon as reasonably possible because of the possibility of an associated CSF leak, frontal sinus fractures with associated duct obstruction, and pneumocephalus. The fracture is exposed with three incisions: coronal, lower eyelid, and gingivobuccal sulcus incisions, so that the entire frontal-nasomaxillary fracture is visualized. Initially, fracture fragments are linked together with interosseous wires and then stabilized by plate and screw fixation (Fig. 5). Reconstruction of the majority of the internal orbit and nose are accomplished by inserting shaped bone grafts to the nose and either bone graft or alloplastic material to replace orbital wall defects. The repair will reconstitute the orbital volume, nasal height, contour, and projection of the central upper face. Bone grafts replace critical areas of structural bone loss. If the medial canthus is detached from the frontal process of the maxilla, it is reattached by trans-nasal canthopexy wires attached posttimed posterior and superior to the lacrimal fossa.

Frontosinus Fractures

Frontosinus fractures include fractures of the frontal bone, frontal sinus, supraorbital rims, and anterior cranial base (Fig. 6A). Anterior cranial base fractures often accompany frontal vault skull fractures and supraorbital, nasoethmoid, and frontal sinus fractures. High Le Fort's (II or III) fractures are often accompanied by a fracture of the frontosinus region.

The diagnosis of frontosinus fracture is suggested by frontal contusion and laceration, periorbital hematoma, or swelling (*question mark—sinus* [Fig. 6B], is a classic symptom of an anterior cranial base fracture), which also may include a dural tear and a CSF leak, pneumocephalus, frontal lobe injury symptoms (confusion, coma, and seizures), epistaxis, anosmia, and visual impairment. Hemotympanum occurs in middle cranial base fractures, and a Battle's sign (hematoma of the mastoid) occurs in posterior cranial fossa fractures. The definitive radiographic examination is an axial and coronal CT scan of the frontal bone, frontal sinus, and anterior cranial fossa and cranial base.

Frontal Sinus Fractures

The frontal sinus consists of two asymmetric cavities separated by one or more bony partitions. The size of the frontal sinus is quite variable, from almost nothing to pneumatization of the entire frontal bone and orbital roof. The most common symptoms of a frontal sinus fracture are lacerations, contusion, or bruises in the forehead area. Often, these are the only physical signs of a fracture, and their presence with tenderness should prompt a CT scan. Epistaxis is usually present. In severe cases, a deformity or depression of the glabellar area may be seen, especially after resolution of the swelling. A CSF leak, pneumocephalus, or orbital emphysema may be noted. Radiographic examination consists of axial and coronal CT scans.

Treatment

Nondisplaced anterior wall fractures without duct obstruction require only observation. Depressed fractures of the anterior wall that do not obstruct patency of the nasofrontal duct (Fig. 6A) can be treated by elevation and concentrative mucosal debridement. Fractures blocking the nasofrontal ducts are treated either by obliteration of the entire sinus with bone after thoroughly stripping the mucosa and plugging the nasofrontal duct with a bone graft, or cranialization of the sinus cavity after removing the mucosa and posterior wall. Posterior wall frontal sinus fractures imply the possibility of a dural laceration if there is more than several millimeters' displacement. Nondisplaced posterior wall fractures can be observed if duct obstruction is not present; however, posterior wall fractures displaced more than the thickness of the inner table may require surgical exploration. If the posterior wall of the frontal sinus is fractured and displaced more than several millimeters, the integrity of the dura must be confirmed.

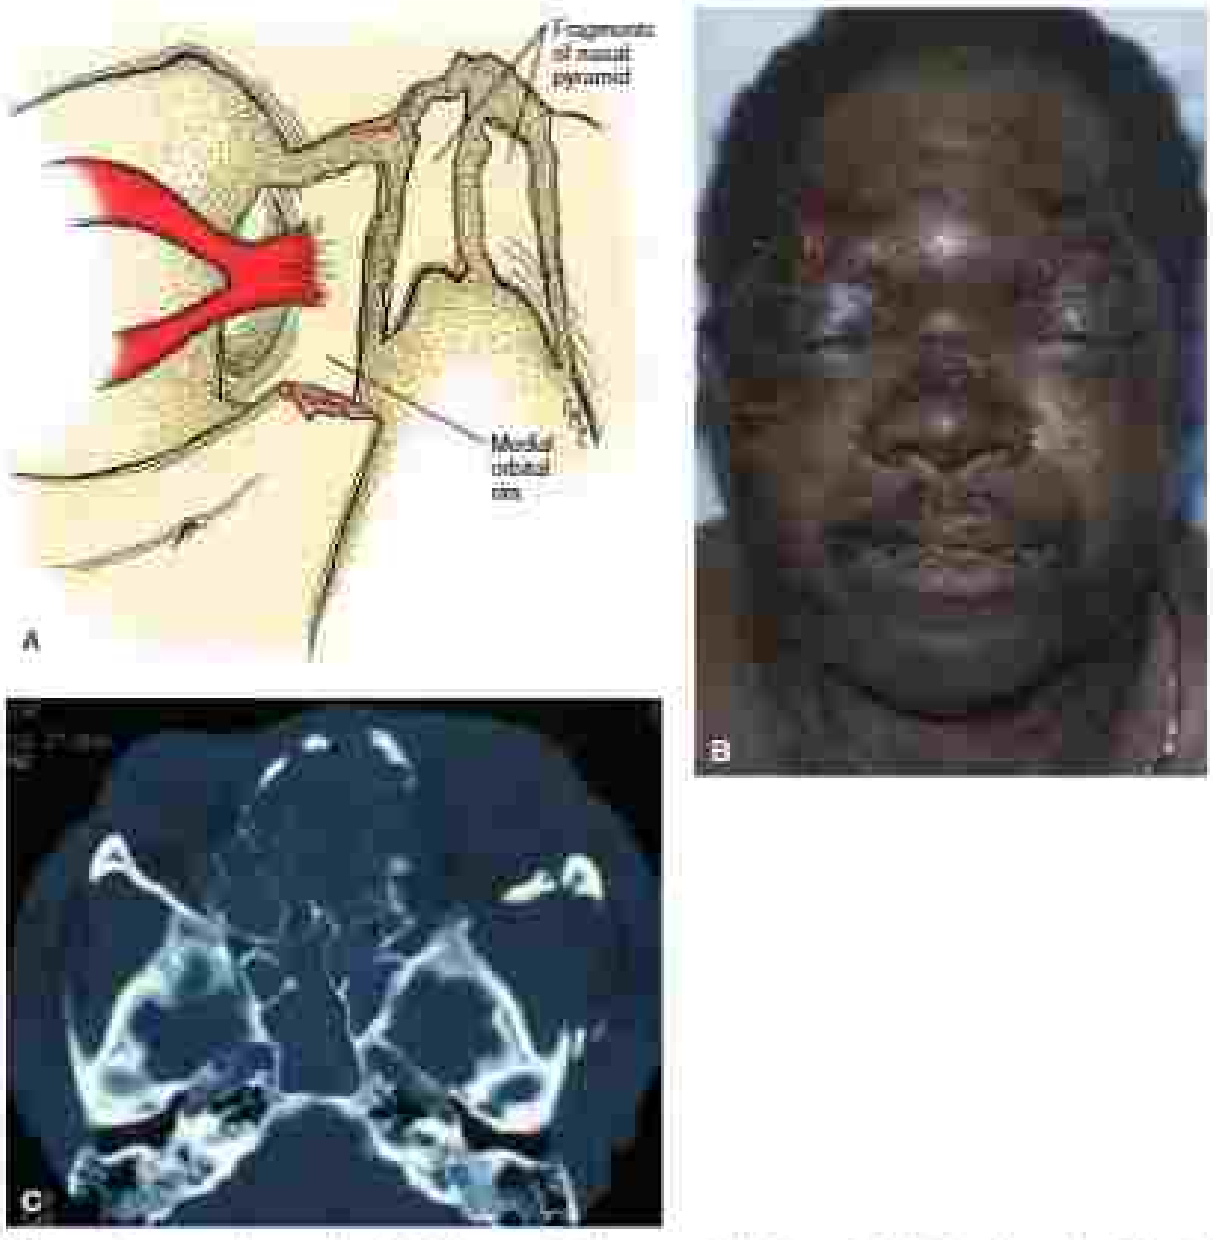

FIG. 8 (A) The central segment of a naso-orbital orbital fracture is the lower two-thirds of the medial orbital rim. Here, the medial canthal ligament attaches to the frontal process of the maxilla. Dislocation of the frontal process of the maxilla dislocates the entire canthal complex. (B) A patient with naso-orbital orbital and Le Fort III fractures. Flattening of the nose and bilateral periorbital hematomas are seen. (C) Radiograph computed tomography scan of the patient's nose in panel

When enough of the sinus is destroyed (and especially if the nasofrontal duct is not patent), the likelihood is that the sinus will not function and will form an abscess. Sinus mucosa may be removed both by stripping and light burring of the bony walls of the sinus cavity to eliminate microscopic invaginations of mucosal membrane into the bone. Both nasofrontal ducts are then plugged with fascia or fat or calvarial bone grafts. The remainder of the sinus may then be obliterated with bone shaving sinus obliteration. The procedure of cranialization implies more thorough removal of the frontal sinus and accompanying ethmoid sinus remnants, and osteoplasty of the anterior posterior wall, sealing the nasofrontal ducts with calvarial bone grafts following thorough removal of the mucosal membrane and posterior sinus wall, and reconstruction of the anterior wall. In effect, the procedure of cranialization converts the sinus to a portion of the intracranial cavity (Fig. 7). The anterior bony wall of the sinus may be reconstructed by bone replacement or grafts where appropriate.

Supraorbital Fractures

Supraorbital fractures are suggested by the presence of lesions or lacerations in the area, a depression of the supraorbital region, a downward and forward protrusion of the globe, ptosis, and possible components of the superior orbital fissure or orbital apex syndromes. In some cases, a superior gaze paresis that may mimic inferior rectus entrapment (Fig. 8). A step or fracture discontinuity may be palpated in the supraorbital rim, and numbness may occur in the distribution of the supraorbital or supratrochlear nerves. Radiographic examination consists of axial, sagittal, and coronal CT scans.

Treatment

The treatment of displaced supraorbital fractures involves confirmation of the integrity of the dura, replacement of bone pieces into their proper position, and direct stabilization by interosseous wiring or plate and screw fixation. Damaged segments of the orbital roof are

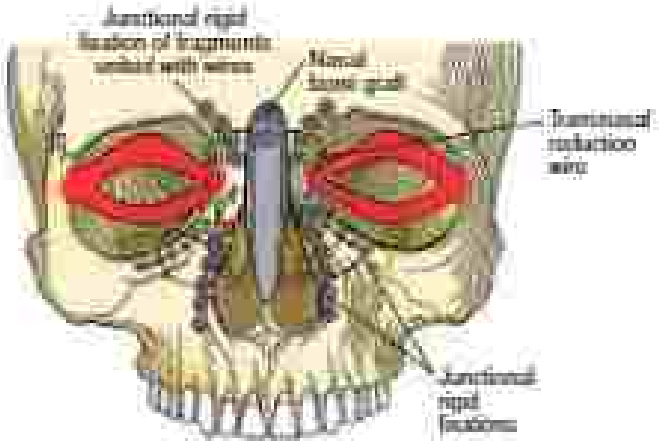

FIG. 5 Scheme for open reduction and internal fixation of a naso-orbital fracture. Initially the fracture fragments are maintained into position and temporarily held with transnasal wires. Plate and screw fixation is then applied. The two frontal processes of the maxilla are linked by a transnasal reduction wire and paired from one frontal process of the maxilla to the other at the posterior and superior edge of the lacrimal fossa.

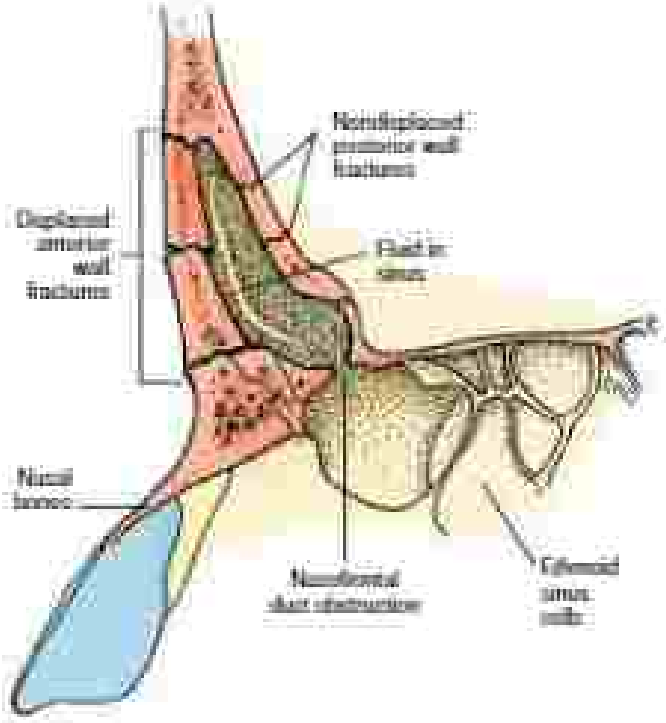
replaced by repositioning or substituted with a shaped bone graft. Frontal sinus involvement is frequent in supraorbital fractures and is managed as previously described. Exposure for operative reduction may occasionally be accomplished through a local laceration, but it generally requires a coronal incision.

Fractures of the Orbit

Isolated fractures of the internal portion of the orbit are accompanied by globe injury in 30% of patients. The minimal visual sensory examination consists of an assessment of visual acuity, pupillary reaction to light, confrontation fields, extraocular motility, examination of the anterior and posterior chambers, and a determination of intraocular pressure. The pupillary size and reaction must be assessed and compared bilaterally to exclude the presence of a relative afferent pupillary defect. Subtle physical signs of an optic nerve injury are a decreased red saturation test and decreased color vision, with more significant injuries, a relative afferent pupillary defect and a reduction in central visual acuity occur.

Orbital Floor Fractures

The diagnosis of an orbital floor fracture is suggested by periorbital and subconjunctival hemostasis. Anesthesia is invariably present in the infraorbital sensory nerve distribution, which produces cutaneous anesthesia of the ipsilateral nose, cheek, and upper lip and anesthesia of the anterior maxillary teeth on the affected side. Diplopia can be present in primary (central) gaze or in looking up or down or left or right, by virtue of contusion or entrapment of the fascial sheath of the rectus muscles. Enophthalmos is often present initially because of swelling, and it is followed by enophthalmos when enlargement of the bony orbital cavity allows extrusion of the globe into the enlarged orbit as the swelling resolves. Acute posttraumatic enophthalmos implies a significant orbital expansion injury that will require an early surgical repair. With orbital floor fractures, inferior and medial displacement of the globe accompanies posterior displacement. Orbital emphysema and ipsilateral epistaxis are usually present. Topical anesthesia, instilled into the conjunctival sac, allows the performance of a forced duction examination when indicated: the globe is manually rotated after grasping the insertion of the inferior rectus muscle through the conjunctiva with a forceps. Difficulty or absence of globe rotation implies incarceration of an extraocular muscle or its ligament system, which would often benefit from operative reduction and repair.



A

FIG. 6 (A) Depressed fractures of the anterior wall of the frontal sinus are created by alteration. Fractures blocking the duct are treated by obliteration of the sinus cavity because absence of duct function would create an abscess. Fractures of the posterior wall of the frontal sinus imply the possibility of a dural laceration. Generally, significantly displaced fractures of the posterior wall of the frontal sinus (>3–5 mm) require surgical exploration. (B) A spectacle hematoma is seen in the upper lid and implies a fracture of the frontal region: frontal bone, frontal sinus, or supraorbital area. The fracture hematoma is confined by the insertion of the orbital septum in the internal orbit with a sharp demarcation.

The radiographic examination consists of axial, sagittal, and coronal CT scans with soft tissue and bone windows. Indications for surgery are enophthalmos, entrapment of a muscle (diagnosed by restrictive strabismus producing double vision in a field of gaze controlled by the muscle), positive forced duction examination and/or CT confirmation of muscle or fascial entrapment, and vertical

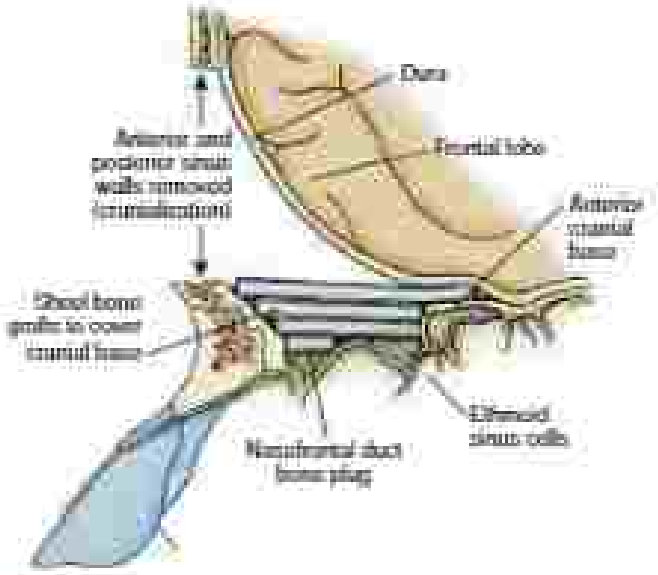


FIG. 7 The procedure of cranialization of the frontal sinus involves removal of the posterior sinus wall and all of the sinus mucosa, sealing the nasal frontal ducts with bone grafts, and using bone grafting to the defects in the anterior cranial fossa (floor of the frontal sinus) and anterior cranial fossa. In effect, the sinus is obliterated and converted to a portion of the intracranial cavity. The anterior wall of the sinus is then reconstructed, either with the preserved fracture fragments of the anterior wall or with bone grafts. Intracranial sinus is being cranialized with the reconstruction of the anterior wall to follow.

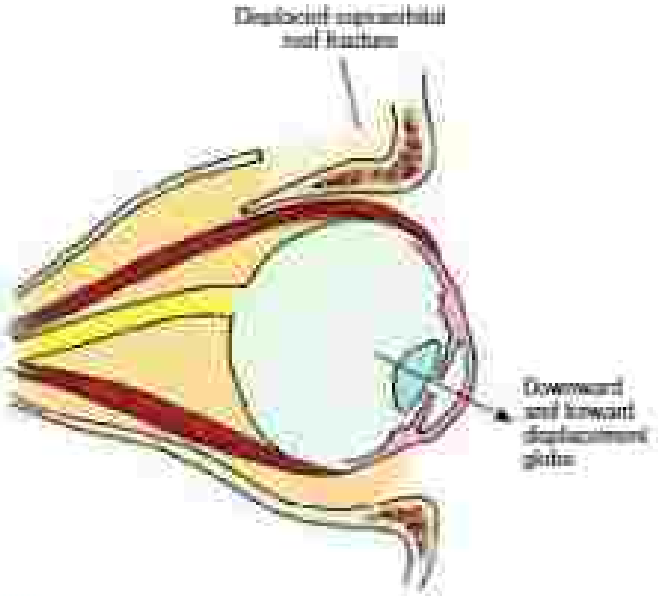

FIG. 8 Displaced supraorbital fractures produce a downward deformity of the superior orbital rim and orbital roof. The globe is dislocated downward and forward, producing exophthalmos; reduction of the fracture corrects the eye position.

or anterior posterior malposition of the globe. Anesthesia of the infraorbital nerve usually resolves without treatment. If significant destruction of an orbital floor is seen on CT scan in the absence of globe malposition, reconstruction of the orbit is indicated to prevent late globe malposition.

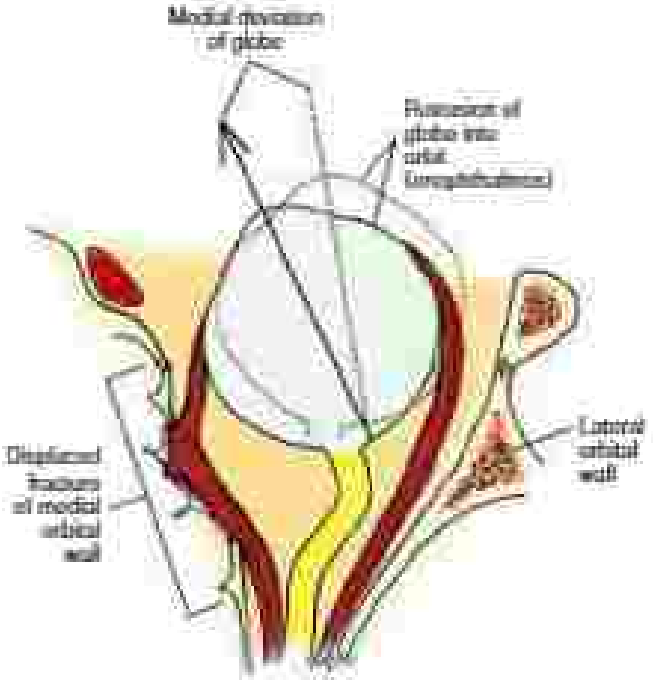

FIG. 9 Displaced fractures of the medial orbital wall crush the ethmoid sinus and expand the orbital volume. The surgical treatment consists of inserting bone grafts to narrow the volume of the orbit. The soft tissue is removed from its prolapsed position in the fracture site and replaced into the orbit and held in position by a bone graft or an orbital implant.

Treatment

Surgical treatment consists of an exposure of the defect through a lower eyelid incision (subciliary, subtarsal, or transconjunctival) with dissection of the orbital floor and removal of any incarcerated tissue from the fracture site or the maxillary sinus. The orbital floor is then reconstituted with alloplastic material (Supramid, Medpor) or carved bone grafts harvested from the calvarium, rib, or iliac region; the calvarium is often preferred, because the head is a self-contained reconstructive unit (after Tessier).

Medial Orbital Wall Fractures

Medial orbital wall fractures are suggested by the presence of periorbital and subconjunctival hematoma, diplopia when looking laterally or medially, orbital emphysema, epistaxis, enophthalmos, and medial displacement of the globe. The radiographic examination consists of axial and coronal CT scans with both bone and soft tissue windows.

The indications for surgery are radiographic entrapment of the medial rectus muscle with positive forced duction (impaired medial to lateral rotation of the globe) and the presence of enophthalmos, either on physical examination or the prediction of such an occurrence on the basis of radiographic evidence of an extensive volume-increasing medial orbital wall fracture displacement (Fig. 9).

Treatment

Surgical treatment is accomplished by a medial conjunctival or cutaneous incision with removal of incarcerated tissue from the crushed ethmoid sinuses and reconstruction of the medial orbital wall with alloplastic material or bone grafts. Patients with orbital fractures should refrain from forcefully blowing their noses for 1 month.

Le Fort's (Maxillary) Fractures

Le Fort's or maxillary fractures are classified according to a pattern described by Rene Le Fort in 1901 (Fig. 10A). A Le Fort I fracture is a horizontal or transverse maxillary fracture separating the maxillary

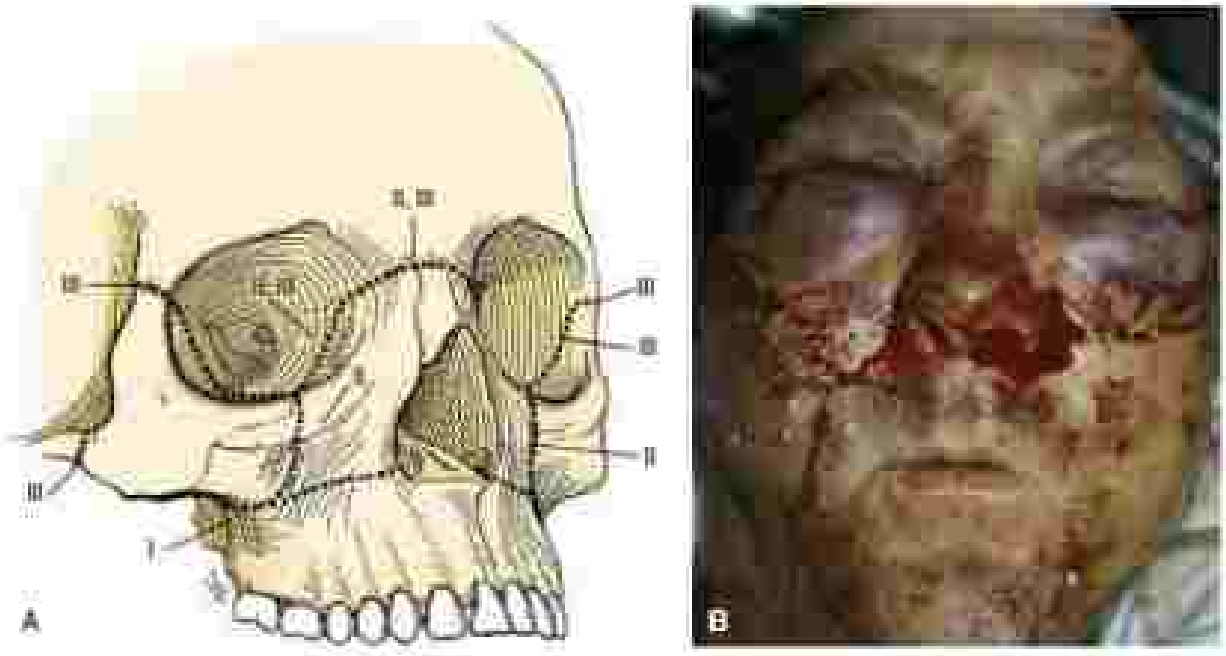

FIG. 10 (A) The Le Fort's maxillary fracture classification. A Le Fort I fracture is a horizontal fracture separating the maxillary alveolus from the upper midfacial skeleton. The *Le Fort II, or pyramidal fracture*, separates a central, pyramid-shaped nasomaxillary segment from the upper midfacial skeleton. The Le Fort III fracture is a craniofacial disjunction in which the midface is fractured *through the upper portion of the orbits*. Generally, Le Fort's II and III fractures do not exist as single segments but display combination. (B) Clinical appearance of a patient with a Le Fort's II–III fracture. The face is flattened and elongated and there are bilateral periorbital hematomas.

alveolus from the upper midfacial skeleton. A Le Fort II (pyramidal fracture) separates a central, pyramid-shaped nasomaxillary segment from the zygomatic and orbital portions of the facial skeleton. A Le Fort III fracture is a craniofacial disjunction separating the facial bones from the cranial skeleton through the upper portion of the nose and the lateral, floor and medial orbits.

Most Le Fort's II and III fractures are comminuted and consist of combinations of lesser Le Fort's fragments, such as simultaneous fractures at the Le Fort's I, II, and III levels. The injury is usually severe (many columns with multiple levels) on the side of the impact; commonly, a Le Fort III superior level fracture is seen on the donor side with a Le Fort II superior level fracture on the other. Single pure Le Fort's III fractures are unusual and frequently are accompanied by bilateral eyelid hematomas, no maxillary mobility, and a slight malocclusion (half cusp), reflecting the minimal displacement and incomplete character of the fracture. They are thus easily missed on physical examination. The *presence of bilateral eyelid hematomas* should always support the possibility of a Le Fort fracture. Also, if fluid is seen in both maxillary sinuses on CT scan, a Le Fort fracture should be suspected.

The physical diagnosis of a Le Fort fracture rests on the demonstration of malocclusion and mobility or displacement of the maxillary alveolus. This mobility is confirmed by grasping the maxillary alveolus and testing for its movement, holding the cranium stable with the contralateral hand. Crossbite (incomplete or impacted fractures that have no mobility). Upper Le Fort's fractures possess signs of zygomatic, orbital, nasal, and nasoethmoid fractures, depending on the level and extent of the injury (Fig. 10B). When Le Fort's fractures are not treated, midfacial proportions change, and midfacial elongation and retrusion generally follow. Profuse nasopharyngeal bleeding initially accompanies Le Fort's fractures; marked facial and eyelid swelling also occur. CSF leak, pneumocephalus, and orbital emphysema occur in Le Fort's II and III fractures, and 10% to 15% of Le Fort's fractures are accompanied by palatal alveolar fractures that divide the maxillary alveolus in an anteroposterior plane (sagittal fracture of the maxilla), making treatment more complicated. The radiographic examination consists of axial and coronal CT scans with bone and soft tissue windows.

Treatment

Treatment is accomplished by first placing the maxilla in IMF to occlusion with the mandible. Sagittal fractures of the maxilla are managed by plate and screw fixation to make a single one piece unit of the maxillary alveolus to the *roof of the mouth* and at the piriform aperture. The Le Fort I fracture is treated by plate and screw fixation at the four anterior buttresses of the maxilla (Fig. 11) through an intraoral gingival buccal sulcus incision. IMF may then be released preoperatively if rigid fixation has been used. Otherwise, the patient is kept in IMF for 4–6 weeks period to ensure bone healing.

The treatment of a Le Fort II fracture involves exposure through a lower eyelid incision (subciliary, subtarsal, or lower orbital rim), with a reduction of the orbital rim and floor or medial orbital wall components of these fractures and open reduction of the central midface and nasoethmoid area. A coronal incision may be required to upper Le Fort's II fractures for an open reduction and internal fixation of the nasofrontal area. Upper Le Fort's fractures are often accompanied by simultaneous fractures in the frontoethmoidal region.

Complex or Panfacial fractures

Panfacial fractures consist of combinations of frontal, midface, and mandibular fractures. The treatment consists of reconstructing the lower face as one unit and reconstructing the upper face as a separate unit, relating both units to the cranial base in their proper relationship. The upper face is then reconstructed to the lower face at Le Fort's I level, and both the horizontal and vertical portions of the mandible are stabilized with open reduction. The upper midface, the orbits and nasoethmoid area are stabilized to the frontal bone and cranial base and then linked to the stabilized lower face (mandible and Le Fort's I segment) at the Le Fort's I level. Previously,

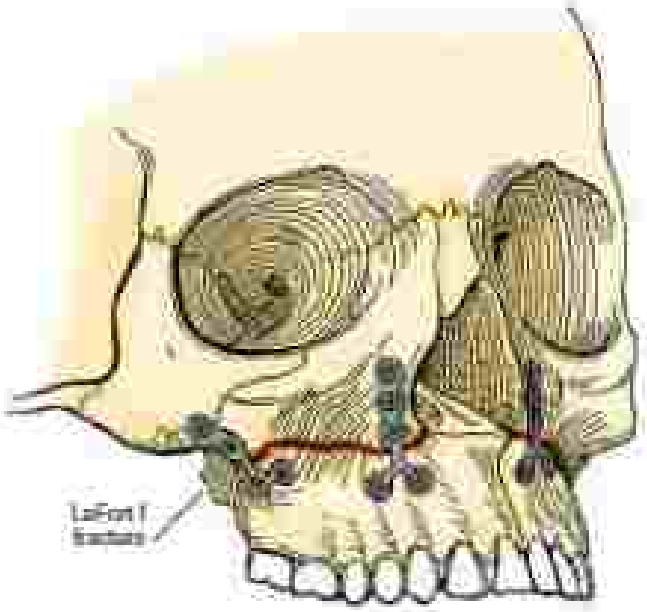

FIG. 11 A Le Fort I fracture has been treated by plate-and-screw fixation at the four anterior buttresses of the maxilla at the Le Fort's I level. The patient is initially placed in intermaxillary fixation. The fracture fragments are aligned, and fixation is applied to stabilize the reduction. Postoperatively, the intermaxillary fixation can be released because of the stability of plate and screw fixation.

as an initial step, the maxilla is aligned with the mandible and the dental arches through IMF.

Mandibular Fractures

Mandibular fractures are one of the most common facial injuries. In the horizontal mandible and the tooth bearing area, they are usually compounded into the mouth; less commonly, they are compounded through the skin. Fractured, loose, or broken teeth, bleeding from a tooth socket, and intraoral lacerations imply the presence of a mandible fracture. One third of mandible fractures occur in the condylar-subcondylar area, one third occur in the region of the angle, and the other third occur in the body, symphysis, and parasymphysis areas (Fig. 12A), which represent weaker areas of the mandible. The angle is weakened by the presence of the third molar tooth and, anteriorly, the parasymphysis by the long root of the canine tooth and the mental foramen.

The subcondylar area represents a thin region in the ramus. More than 50% of mandibular fractures are comminuted and multiple; therefore, the presence of a single mandibular fracture prompts a thorough search for a second or third fracture, often present contralaterally. Known combinations such as parasymphysis and contralateral subcondylar, parasymphysis and contralateral angle, or symphysis with unilateral or bilateral subcondylar fractures are frequent. The diagnosis of a mandibular fracture is suggested by pain, swelling, abnormal occlusion, numbness in the distribution of the mental nerve (lower lip), swelling, bruises, external or intraoral lacerations, bleeding from a tooth socket, fractured or missing teeth, trismus, or pain on moving the jaw (Fig. 13B). Inability to bring the teeth into occlusion, which may occur anteriorly, laterally, or bilaterally; abnormality or irregularity in dental arch form; malocclusion of the teeth; steps or level discrepancies in teeth or bone height or position; or gaps detected either in the dentition or by palpating the mandible are all indications of possible fracture. Bleeding from the ear canal implies the possibility of a condylar fracture/dislocation. In some cases, segments of the dental alveolus are separated from the lower portion of the mandible and constitute an alveolar fracture, which is defined by separation of the dental alveolus from the rest of the basal mandible. Dental (alveolar) fractures may occur as isolated fractures alone or in the presence of more extensive mandibular fractures by comminution. An unpleasant odor in the mouth is present soon after mandibular fractures occur.

The plain radiographic examination includes posteroanterior, lateral oblique, and Towne films of the mandible. Seldom now are plain radiographs taken, but a CT scan (Fig. 13D) for the condylar, coronoid, and ramus areas and horizontal portion of the mandible is routine. The Panorex examination is the one helpful plain film radiograph, but it requires a cooperative patient who is able to stand, and often it cannot be obtained urgently because they are available in dental departments. Occlusal and apical dental films are sometimes required to visualize specific areas of the teeth to examine for root fracture and apical or tooth root pathology which complicates mandibular fracture treatment and predisposes to infection.

Treatment

The treatment of mandibular fractures includes the application of arch bars to the teeth, placing the teeth of the mandible in IMF to occlusion with the maxilla. IMF is continued for 4 to 8 weeks depending on the fracture type. If plate and screw (rigid internal fixation) is used, the jaws are not wired together postoperatively, and immediate mobilization is permitted with a light diet. Closed reduction is appropriate for many condylar, coronoid, and ramus fractures and those stable fractures in the angle, body, or symphysis that are not displaced. Displaced fractures in the horizontal mandible require open reduction with plate and screw fixation. Exposure is obtained intraorally, the preferred exposure for the anterior portion of the horizontal segment of the mandible. Angle fractures may be treated intraorally if simple and extraorally if comminuted. Condylar and subcondylar fractures that require open reduction are those that would result in mechanical interference with mandibular motion or a loss of ramus height such as a dislocated condylar head, are exposed with a preauricular, retromandibular, or intraoral ramus incision for fixation.

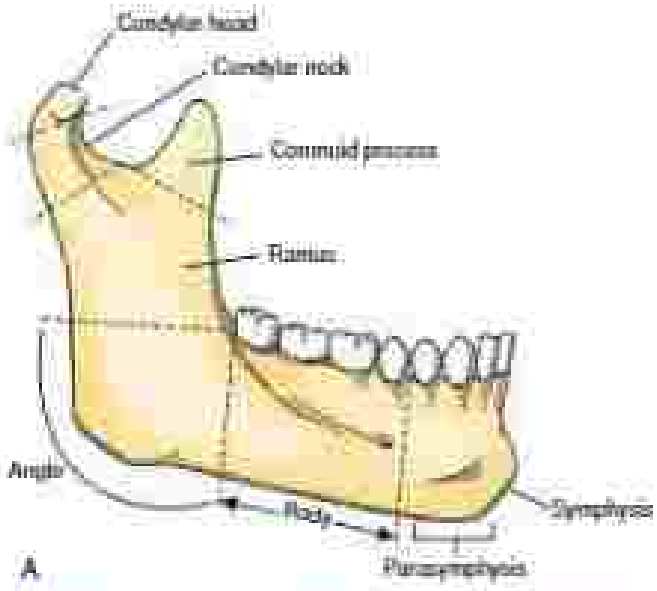
Patients who require IMF are given a soft, blenderized diet, and the average patient with IMF loses 15 to 20 pounds in 4 to 6 weeks. The use of rigid internal fixation (plate and screw fixation) allows many patients to immediately move the mandible, to have better oral hygiene, and to take a soft diet. Occlusion must be observed at least weekly in all patients to detect any displacement.

Gunshot and Shotgun Wounds

Gunshot wounds of low velocity may be managed as facial fractures with overlying lacerations. The soft tissue injury is carefully excised and closed. Fractures are repaired as in fractures with overlying lacerations.

High velocity gunshot or close range shotgun wounds produce extensive damage to, and loss of, soft tissue and bone. Zones of soft tissue and bone loss and separate zones of soft tissue and bone injury are identified and characterized. The bones are immediately stabilized in anatomic position in all regions where present by rigid internal fixation. Areas of bone loss are stabilized, preserving the length of bone defects with rigid fixation to achieve anatomic reconstruction of the bone architecture to normal dimensions. Soft tissue closure is obtained either by advancement or skin to mucosa closure after conservative debridement, with replacement procedures performed early for missing soft tissue replacement.

Serial second look procedures are required at 48 hour intervals until no further devitalized tissue is seen. Soft tissue reconstruction may then be completed, and distant flap transfer is usually required for intraoral lining defects and dead space or sinus obliteration and mucosal or cutaneous replacement. At the time of flap transfer, composite replacements of bone and soft tissue may be considered, or soft tissue reconstruction may be accomplished first and then bone reconstruction secondarily. The bone gaps resulting from missing bone are maintained by rigid internal fixation until bone grafting/replacement can be performed.



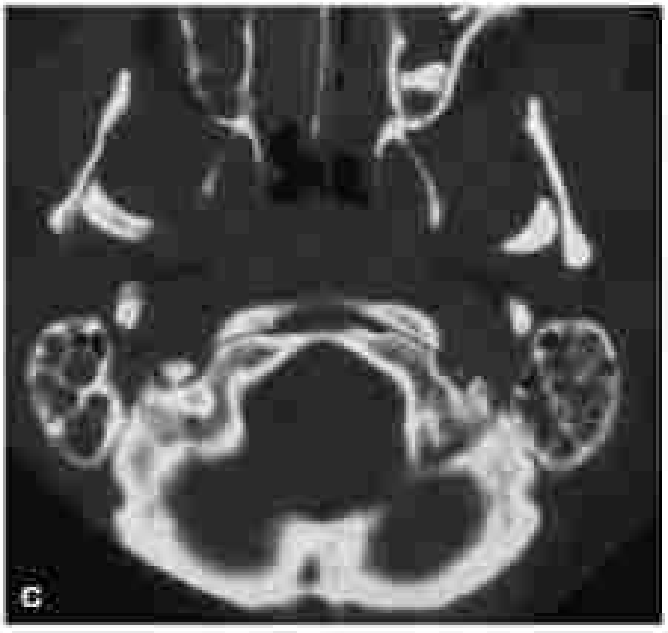


FIG. 11 (A) The anatomic regions of the mandible include the condylar and subcondylar areas and ramus posteriorly, the angle and the body laterally, and the symphysis and parasymphysis areas anteriorly. Weak areas are the subcondylar region, the angle, weakened by the third molar tooth, and the parasymphysis area, weakened by the long roots of the canine teeth. (B) A patient with anterior mandible, hemipalatal fractures, and a Le Fort I maxillary fracture. Computed tomography scan of (C) bilateral subcondylar and symphysis fractures of the mandible.

Late Scarring From Wounds

Generally, it takes 1 to 2 years for a cutaneous scar to fully mature. A red, raised scar that is initially quite prominent and shows some soft tissue contracture may resolve satisfactorily with time. Patients who understand the course of scar maturation can be encouraged to be accepting through the healing process. Early scar revisions are generally not indicated; in fact, they are discouraged except in the cases of obvious malalignment of tissues or contractures of the type that cause functional problems, such as ectropion and corneal exposure or oral incompetence.

SUMMARY

The face is of supreme importance in communication, nutrition, perception, and interpersonal relationships. The aesthetic attractiveness of an individual's facial features influences his or her personality and success. Although there are few facial emergencies, the literature has consistently underemphasized the advantage of prompt, definitive reconstruction of facial injuries and the contribution of early anatomic skeletal reconstruction to superior aesthetic results. It is not unusual for a victim of a multiple injuries to be principally concerned about residual facial deformity after other more life-threatening injuries have been resolved. The early definitive care of maxillofacial injuries is safe and possible and will repay the surgeon with superior results and grateful patients. A coordinated reconstruction is accomplished by interspecialty communication. All patients require counseling and rehabilitation, and psychological dividends result from these efforts.

Penetrating Neck Trauma

Cory R. Evans, MD, Katherine Santor, MD, and Timothy C. Hollier, MD

Penetrating neck trauma is a common presenting injury to civilian trauma centers. These injuries are usually the result of either stab wounds or gunshot wounds (GSWs). GSWs are much more likely to cause significant injuries requiring surgical repair. Recent data from the conflicts in Iraq and Afghanistan report injuries to the head, face, and neck accounting for 21% to 39% of all injuries, with 18.8% of these involving the neck. Mortality from penetrating neck trauma has been reported to be around 3% to 4% from recent military data. Civilian mortality ranges from 1% to 5%.

ANATOMY

Although the neck is divided into several triangles by the classic anatomist, in trauma, the neck is divided into three zones. Zone I spans the thoracic inlet (the clavicles) up to the level of the cricothyroid membrane. Zone II is the area between the cricoid and the angle of the mandible, and zone III is the angle of the mandible and above. The division of the neck in this manner assists the surgeon in thinking about what and where vital structures could be injured. More important, it helps guide what approach must be taken to repair them. With this in mind, these three incisions allow access to the neck: the anterior sternocleidomastoid, the collar incision, and the median sternotomy. These incisions are very versatile (in particular, the anterior sternocleidomastoid and the median sternotomy incisions) and can be extended into one another to assist with operative exposure. This is very important because missile tracts often cross zones, necessitating better exposure, not only for proximal or distal vascular control, but also for facilitating high-quality repair, and decreasing the rate of iatrogenic or missed injuries.

Initial Management

Initial management of a patient with a penetrating neck wound should begin with a standard trauma evaluation using the ABCDE format (Fig. 1). The airway is especially important given that injuries in this region are more likely to cause airway compromise, and the injury could also be to the airway itself. A low threshold for endotracheal intubation exists in these circumstances. Stridor, respiratory distress, or an expanding hematoma should trigger early intubation. For patients with difficult-appearing airways who are able to protect their airway with upright positioning, consider proceeding to the operating room for intubation in a more controlled setting.

As with all trauma patients, the major branch in the decision-making tree is whether the patient should go immediately to the operating room versus proceeding with further imaging. Historically, violation of the platysma was an indication for surgical exploration. This policy of mandatory exploration led to a number of nontherapeutic operations, upwards of 80% to 90%. Now the decision to operate immediately is based on the presence of hard signs of vascular or aerodigestive tract injury. Although there exists debate as to the definition of hard signs, we use hemodynamic instability, severe active bleeding, expanding or pulsatile neck hematoma, massive subcutaneous air, bubbling from the wound, neurologic deficits, and hematemesis. Although zone of injury will be important when deciding your surgical exposure, it should not influence your decision to operate. This no zone approach oversimplifies decision making and can lead to a lower rate of negative explorations. For GSWs, preoperative x-ray imaging is a useful adjunct to locate missiles. We have seen entrance wounds in the neck with bullets that have travelled to thorax and even abdominal locations. It is better to know this before ending up in the operating room with unexplained hypotension after a negative neck exploration.

As imaging technology has advanced, in particular the development of high-resolution computed technology, selective neck exploration has become the standard of care. For patients without hard signs, further diagnostic testing is indicated. Angiography used to be considered the gold standard for diagnosing vascular injury. However, this has been surpassed by computed tomography angiography (CTA) as initial imaging modality of choice. It has high sensitivity and specificity for detecting vascular injuries. Intravenous access should be opposite the side of suspected injury and contrast bolus should be given from the side opposite suspected injury. Doing this will decrease artifact from the venous contrast bolus and improve imaging quality. Ultrasound is growing in popularity as a diagnostic modality for vascular injury; however, it is limited in trauma patients because of overlying or surrounding soft tissue injury and has a lower sensitivity and specificity than CTA. If the CTA demonstrates a trajectory that is remote from vital structures, the need for additional studies may be eliminated. A limitation of CTA is streak artifact from retained bullets or metallic fragments. This may necessitate fine-cut axial angiography of the neck to completely rule out injury.

CTA also has the advantage of a high sensitivity to rule out aerodigestive tract injury. When emphysema exists in deep fascial planes or around aerodigestive structures, continued suspicion of esophageal injury should be maintained. Further diagnostic testing includes esophagogram, esophagoscopy, or both. Esophagram done with water soluble contrast will miss injuries, so should be repeated with barium if initially negative. Esophagoscopy is more practical for detecting injury in patients who are intubated, or intraoperatively if there is high suspicion of injury, but one cannot be located. It is also better at identifying hypopharyngeal injuries. For these reasons, esophagoscopy has largely replaced esophagram in many centers. For suspicion of laryngeal or airway injuries, consult with

Penetrating Neck Trauma

Cory R. Evans, MD, Katherine Santor, MD, and Timothy C. Fabian, MD

Penetrating neck trauma is a common presenting injury to civilian trauma centers. These injuries are usually the result of either stab wounds or gunshot wounds (GSWs). GSWs are much more likely to cause significant injuries requiring surgical repair. Recent data from the conflicts in Iraq and Afghanistan report injuries to the head, face, and neck accounting for 21% to 30% of all injuries, with 18.8% of these involving the neck. Mortality from penetrating neck trauma has been reported to be around 3% to 4% from recent military data. Civilian mortality ranges from 1% to 5%.

ANATOMY

Although the neck is divided into several triangles by the classic anatomist, in trauma, the neck is divided into three zones. Zone I spans the thoracic inlet (the clavicles) up to the level of the cricothyroid membrane. Zone II is the area between the cricoid and the angle of the mandible, and zone III is the angle of the mandible and above. The division of the neck in this manner assists the surgeon in thinking about what and where vital structures could be injured. More important, it helps guide what approach must be taken to repair them. With this in mind, these three incisions allow access to the neck: the anterior sternocleidomastoid, the collar incision, and the median sternotomy. These incisions are very versatile (in particular, the anterior sternocleidomastoid and the median sternotomy incisions) and can be extended into one another to assist with operative exposure. This is very important because missile tracts often cross zones, necessitating better exposure, not only for proximal or distal vascular control, but also for facilitating high-quality repair, and decreasing the rate of iatrogenic or missed injuries.

Initial Management

Initial management of a patient with a penetrating neck wound should begin with a standard trauma evaluation using the ABCDE format (Fig. 1). The airway is especially important given that injuries in this region are more likely to cause airway compromise, and the injury could also be to the airway itself. A low threshold for endotracheal intubation exists in these circumstances. Stridor, respiratory distress, or an expanding hematoma should trigger early intubation. For patients with difficult-appearing airways who are able to protect their airway with upright positioning, consider proceeding to the operating room for intubation in a more controlled setting.

As with all trauma patients, the major branch in the decision-making tree is whether the patient should go immediately to the operating room versus proceeding with further imaging. Historically, violation of the platysma was an indication for surgical exploration. This policy of mandatory exploration led to a number of nontherapeutic operations, upwards of 80% to 90%. Now the decision to operate immediately is based on the presence of hard signs of vascular or aerodigestive tract injury. Although there exists debate as to the definition of hard signs, we use hemodynamic instability, severe active bleeding, expanding or pulsatile neck hematoma, massive subcutaneous air, bubbling from the wound, neurologic deficits, and hematemesis. Although zone of injury will be important when deciding your surgical exposure, it should not influence your decision to operate. This no zone approach oversimplifies decision making and can lead to a lower rate of negative explorations. For GSWs, preoperative x-ray imaging is a useful adjunct to locate missiles. We have seen entrance wounds in the neck with bullets that have travelled to thorax and even abdominal locations. It is better to know this before ending up in the operating room with unexplained hypotension after a negative neck exploration.

As imaging technology has advanced, in particular the development of high-resolution computed technology, selective neck exploration has become the standard of care. For patients without hard signs, further diagnostic testing is indicated. Angiography used to be considered the gold standard for diagnosing vascular injury. However, this has been surpassed by computed tomography angiography (CTA) as initial imaging modality of choice. It has high sensitivity and specificity for detecting vascular injuries. Venous access should be opposite the side of suspected injury and contrast bolus should be given from the side opposite suspected injury. Doing this will decrease artifact from the venous contrast bolus and improve imaging quality. Ultrasound is growing in popularity as a diagnostic modality for vascular injury; however, it is limited in trauma patients because of overlying or surrounding soft tissue injury and has a lower sensitivity and specificity than CTA. If the CTA demonstrates a trajectory that is remote from vital structures, the need for additional studies may be eliminated. A limitation of CTA is streak artifact from retained bullets or metallic fragments. This may necessitate four vessel angiography of the neck to completely rule out injury.

CTA also has the advantage of a high sensitivity to rule out aerodigestive tract injury. When emphysema exists in deep fascial planes or around aerodigestive structures, continued suspicion of esophageal injury should be maintained. Further diagnostic testing includes esophagogram, esophagoscopy, or both. Esophagram done with water soluble contrast will miss injuries, so should be repeated with barium if initially negative. Esophagoscopy is more practical for detecting injury in patients who are intubated, or intraoperatively if there is high suspicion of injury, but one cannot be located. It is also better at identifying hypopharyngeal injuries. For these reasons, esophagoscopy has largely replaced esophagram in many centers. For suspicion of laryngeal or airway injuries, consult with

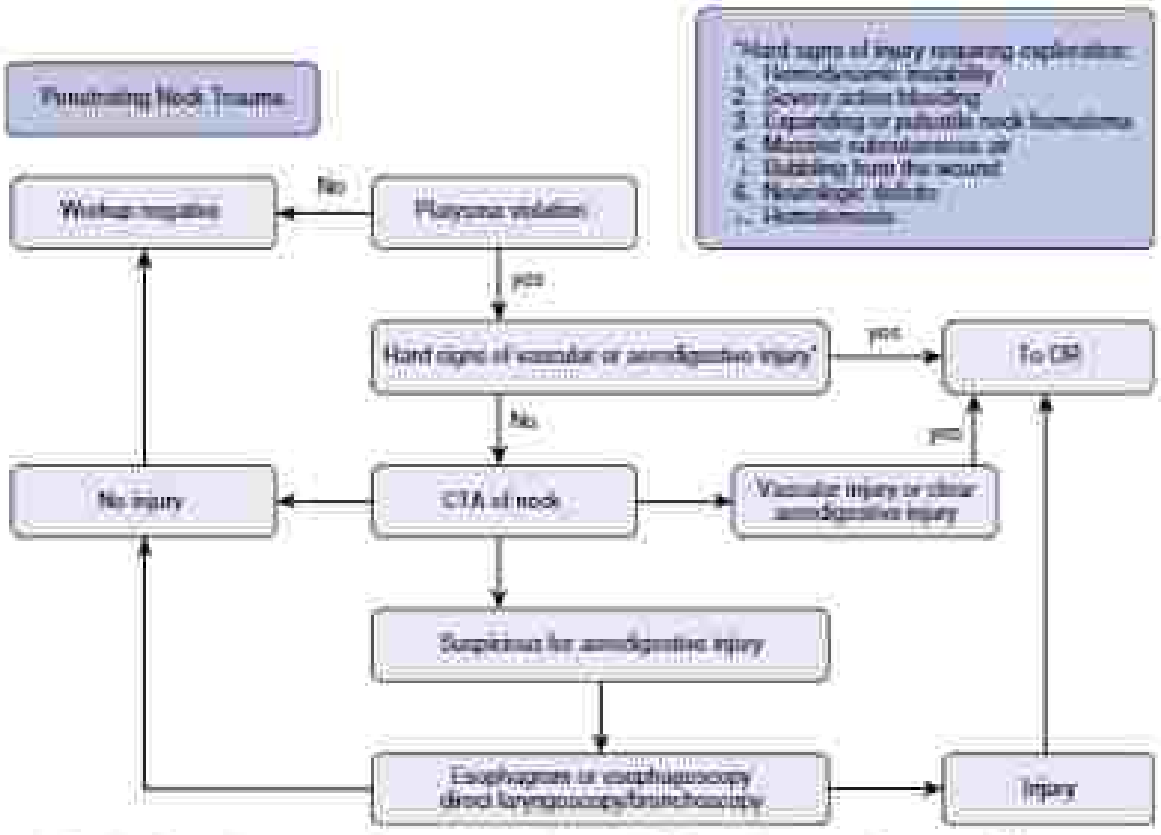

FIG. 1 Algorithm for initial management of penetrating neck trauma. CTA, Computed tomography angiogram; OR, operating room.

otolaryngology for direct laryngoscopy is the gold standard study. The American College of Radiology recommends direct visualization techniques for diagnosing aerodigestive injuries.

Operative Exposure

The patient is placed supine with a shoulder roll and the neck extended if there is no concern for cervical spine injury. The head can be rotated away from the side of injury, however, keeping the head straight can facilitate a bilateral exploration if needed. The patient should be prepped from the earlobe to the umbilicus. This allows extension to the chest if needed. Prep a groin and thigh in case vein graft is required. The initial incision runs along the anterior border of the sternocleidomastoid muscle. For a bilateral exploration, consider a collar incision two fingerbreadths above the sternal notch. Alternatively, bilateral sternocleidomastoid incisions can be connected inferiorly. Sternocleidomastoid incisions can be extended into a sternotomy for additional exposure. For exposure superiorly, such as a high carotid injury, subluxation of the mandible anteriorly and division of the digastric muscle can allow for better exposure.

The incision will be carried through the platysma with cautery. Next, find the anterior border of the sternocleidomastoid and define it along the length of the incision. Continue the dissection through the connective tissue here until the internal jugular vein is encountered. The next step will be to dissect out the anterior border of the internal jugular vein. Along its course, you will encounter the facial vein. A key step in neck exploration is ligating and dividing the facial vein. Immediately underneath should be the bifurcation of the carotid artery. The major pitfall of this step is dividing and ligating the internal jugular vein at a branch point running posteriorly. Once the facial vein has been divided and the internal jugular vein is dissected free, locate the carotid artery by palpation. Sharply enter the carotid sheath immediately on top of the artery and continue dissection into the pretracheostomial plane. Staying directly on top of the vessel and in the pretracheostomial plane will help avoid injury to other structures. Identify and preserve the vagus nerve which usually runs lateral to the artery. The ansa cervicalis will be anterior to the carotid sheath. If possible, identify and preserve this as well.

To explore the esophagus, continue medially and deep to the carotid artery. Bluntly develop the filmy flow plane behind the esophagus and anterior to the vertebral bodies. Having no serosal layer, the esophagus may be hard to distinguish from the overlying strap muscles, especially in the austere environment of a trauma case. Placement of an esophagus tube and palpation of the tube can help identify the esophagus. Beware of the recurrent laryngeal nerve running in the tracheoesophageal groove. Instillation of air or methylene blue into a withdrawn nasogastric tube can help identify or locate esophageal injuries.

Operating in the neck of a trauma patient is not usually a painless environment. If a hematoma is present, begin your dissection proximally and distally. Try to obtain vascular control before entering the hematoma. If there is already active hemorrhage into the operative field, it is very important to follow your landmarks to avoid iatrogenic injury during your dissection.

Management of Specific Injuries

Veins

Isolated venous injuries will likely not require exploration and will frequently self-tamponade. However, when encountered intraoperatively, these can easily be controlled with finger pressure. Ligate pesky bleeding anterior and external jugular veins with impunity. Injuries to the internal jugular vein can be repaired or ligated. Repair the internal jugular vein with transverse venorrhaphy if possible. Complex repairs should be avoided, especially if the contralateral jugular is uninjured.

Arteries

Carotid arterial injuries should be managed with primary repair when possible. Repair with a patch can be used if the repair would

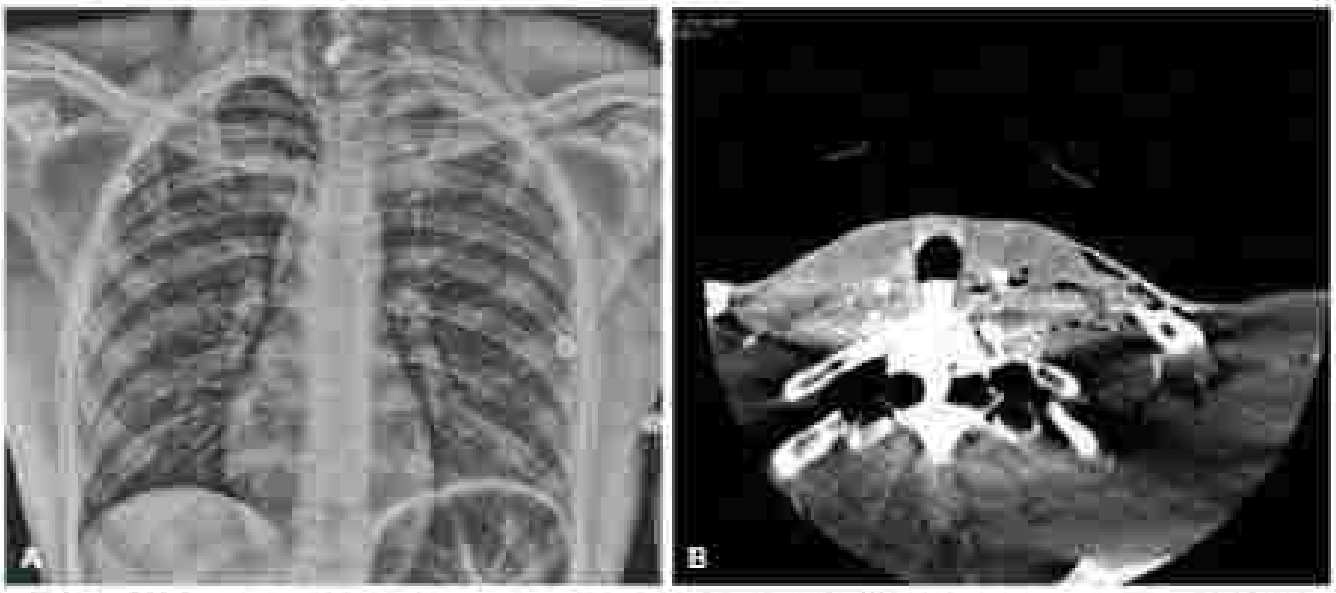

FIG. 2. A 24-year-old man presented with a single gunshot wound to the angle of his right jaw. He was hemodynamically normal, with no hard signs of vascular injury. However, he had sensory and motor deficits in his bilateral lower extremities. A, a chest radiograph, the bullet was seen in the proximity of C7–T1 vertebral bodies in the midline. He was electively intubated for airway protection because he was to be kept mostly flat for further studies. Computed tomography angiogram revealed a bullet lodged in the T1 vertebral canal, possible thyrocervical trunk injury and possible right vertebral artery injury. He underwent angiography that demonstrated traumatic occlusion of his thyrocervical trunk. Because of suspicion of aerodigestive injury, he underwent further investigation with both esophagoscopy and bronchoscopy. He was found to have a hypopharyngeal injury that was treated with a short course of antibiotics and nasogastric tube decompression. He was extubated on hospital day 2 after a cuff leak was detectable. A diet was started on hospital day 3, and the patient was discharged to a rehabilitation facility on hospital day 4.

result in narrowing of the vessel. Additional length can be gained by dividing the superior thyroid artery. Grafting seems to lead to more complications and there is an additional nature that to worry about; however, grafting is likely the best option if the defect is greater than 2 cm. If grafting is necessary, one of the saphenous vein is preferred to polytetrafluoroethylene or Dacron. A completion angiogram should be performed if grafts are used. Division and transposition of the proximal external carotid artery to the distal internal carotid artery may be an option for repair to avoid using a graft. The patient should be heparinized as soon as vascular control is obtained to prevent thrombus formation. Shunts may be a useful adjunct to maintain cerebral perfusion if a vein graft is to be obtained. Patients presenting with neurologic deficits should be repaired as this has been shown to lead to less morbidity and mortality. Comatose patients should likely be repaired as well because outcomes seem to be dismal regardless of approach.

Zone I carotid injuries may require median sternotomy for exposure with extension to an anterior SCM incision. Additionally, distal carotid artery injuries (zone 3) may require anterior mandible subluxation to reach the injury as well as division of the omohyoid and digastric muscles. The glossopharyngeal nerve lies inferior to these structures. If the distal portion of the injury is within the skull base the only option remaining is ligation. Intravascular techniques may be useful for zone 1 and zone 3 injuries that would be difficult to access surgically.

Vertebral artery injuries are difficult to manage. The vessels are either buried in bone or in direct contact with bone making ligation a technically demanding exercise. Initial vascular control may be maintained by inserting a Foley catheter into the wound and inflating the balloon. Some advocate for bone wax placement into the injury and compression. Vascular control could be obtained at the takeoff of the vessel from the subclavian artery; however, this necessitates an infraclavicular incision and a median sternotomy to expose the vessel at this point. Removal of the medial portion of the clavicle may facilitate this exposure. Temporary packing and referral to interventional radiology for embolization could be a more reasonable option.

Esophageal Injury

When an esophageal injury is identified, exposure of the entire injury is paramount. Debride injured esophageal tissue and expose the entire mucosal defect. Repair the injury primarily in two layers, with absorbable suture on the mucosa. Reapproximate the muscular injury with interrupted nonabsorbable sutures. Hypopharyngeal injuries can be repaired in a similar fashion. Beware the recurrent laryngeal nerve during exposure. A second esophageal injury is likely to be encountered, as completely mobilizing the esophagus or exploration from the contralateral side to surround unless clinical suspicion of a second injury is very low. The repair can be buttressed by mobilizing a strap muscle, or by mobilizing the sternal head of the sternocleidomastoid. This is especially important with concomitant tracheal injury. Strap muscles must be mobilized distally to preserve the blood supply. We do not advocate drainage following primary repair; however, if injuries are discovered in a delayed fashion, surgical debridement and drainage is the cluster of treatment. The tissue at this point will friable and repairs are likely to fail. A cervical esophagostomy can be created for large defects with gross contamination as a bailout option. Esophagram should be performed prior to resuming an oral diet.

Tracheal Injury

Tracheal injuries require exposure and debridement of injured tissue before repair. The repair can be done with interrupted absorbable sutures with the knots on the outside. Large injuries with extensive tissue damage may necessitate resection and primary reconstruction of the trachea. The endotracheal tube should be in place below the level of the injury. Early tracheostomy can be done if it is suspected the patient will require prolonged intubation. This predisposes the patient to increased risk of surgical site infection but does decrease mortality compared with prolonged intubation. Patients tend to fare

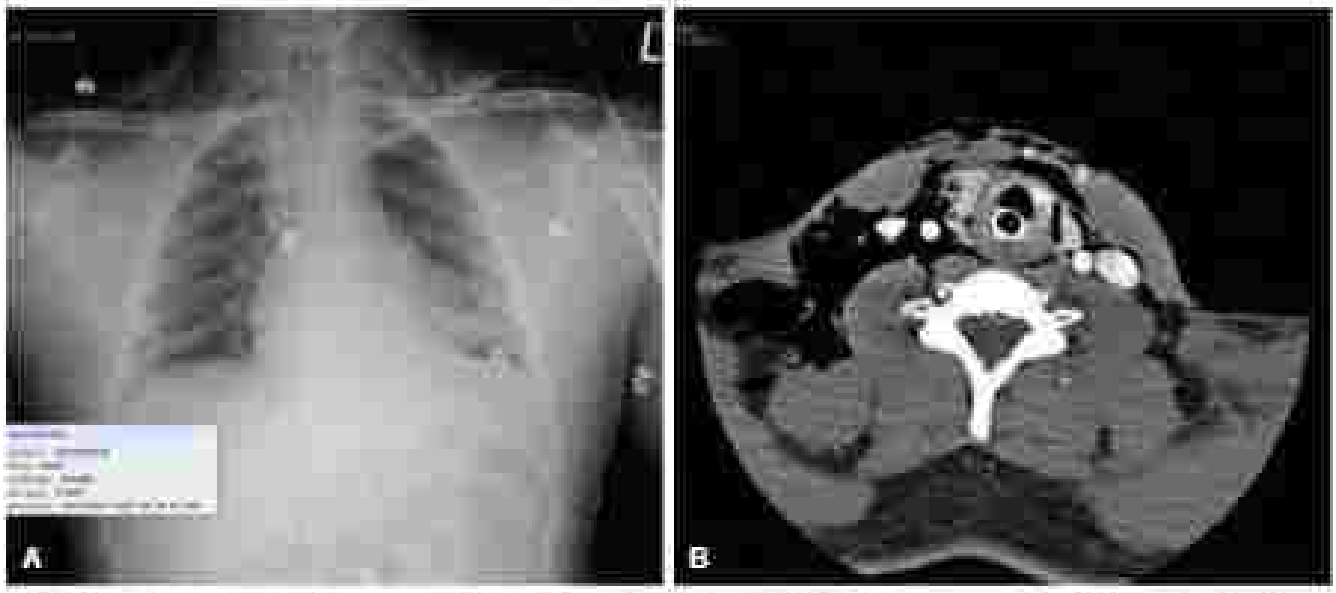

FIG. 1 A 29-year-old man sustained a gunshot wound to the anterior neck. He was noted to have air emanating from the wound with forceful coughing and talking. On chest radiograph, the bullet was seen to lie somewhere in the right mediastinum. He was electively intubated in the operating room in case an emergent surgical airway was necessary. Imaging revealed massive subcutaneous emphysema and mediastinal air. He was taken back to the operating room for bronchoscopy and esophagogastroduodenoscopy, which revealed injuries to both his trachea and his esophagus. His esophageal injury was approached via anterolateralmost incision and repaired with 3-0 PDS and buttressed with a portion of strap muscle. The tracheal injury was small and was not repaired. The patient was extubated and underwent an unremarkable upper gastrointestinal swallow study before initiation of a diet.

better with early intubation; however, this is largely dependent on concomitant injuries. It is wise to involve otolaryngology in the operative decision making to help manage postoperative complications should they arise. Otolaryngology can also help manage complex laryngeal injuries. Make sure to evaluate for combined esophageal injury. The esophagus is quite mobile compared with the trachea and associated esophageal injuries may not be immediately adjacent to the tracheal injury, especially if the head is turned to the side for operative exposure. In the instance of combined tracheoesophageal injury, it is especially important to buttress between the repairs with a muscle flap.

Blunt Cardiac Injury

Anna M. Ledgerwood, MD, and Charles E. Lucas, MD

Blunt cardiac injury (BCI) can occur in any patient who sustains a significant impact to the chest. Clinical manifestations may encompass a wide spectrum of injury patterns ranging from simple myocardial bruise to rupture of a ventricle and death. The myriad injuries include minor electrocardiogram (ECG) abnormalities, complex arrhythmias, cardiac failure, septal rupture, valve rupture, coronary artery thrombosis, pericardial rupture, and chamber wall rupture.

INCIDENCE

The incidence of BCI varies widely (0%–19%) due, primarily, to the lack of a gold standard for diagnosing BCI after major thoracic injury. The diagnosis of myocardial contusion was often suggested in patients who had blunt thoracic injury with sternal fracture and elevated cardiac enzymes. Most likely this was over diagnosing BCI in patients who had no cardiac symptoms. Autopsy series of injured patients who die at the scene, however, show a relatively high incidence of BCI from a ruptured heart and pericardial tamponade.

MECHANISM OF INJURY AND PATHOPHYSIOLOGY

BCI should be considered in any patient with a high speed impact to the thorax from a motor vehicle collision, bicycle, or motorcycle crash, falls greater than 10 feet, blast injuries, assaults, and crush injury to the chest. Any mechanism such as a direct precordial impact, a compression or crush between the sternum and spine, or a deceleration/tension force causing a cardiac tear at a fixed point such as between the right atrium and vena cava can cause BCI. Even an abrupt compression of the abdomen causing a significant and sudden rise in venous pressure that is transmitted to the right heart can result in cardiac rupture. This hydrostatic pressure can also produce rupture of the pericardium or its diaphragmatic attachments. Most patients with blunt thoracic injury, however, have no BCI. In contrast, most patients with cardiac chamber rupture die at the scene and seldom present alive to the emergency department.

CLINICAL DIAGNOSIS OF BCI

There are no signs or symptoms specific for BCI. The most common complaint is chest pain, which could be due to the associated thoracic injuries including rib fractures, sternal fractures, or chest wall contusions. The presence of associated thoracic trauma, however, should raise suspicion for BCI. Likewise, auscultatory findings of a thrill, murmur, or rub should raise suspicion for BCI, but they usually are not present. Hypotension may accompany BCI but is usually from other causes such as a tension pneumothorax, spinal cord injury, or hemorrhagic shock.

The use of ECG and cardiac enzymes to diagnose BCI in the emergency department has been extensively studied. Velmahos and coworkers determined that the combination of a normal ECG and troponin I level on admission and eight hours later rule out the diagnosis of significant BCI. They prospectively evaluated 333 consecutive patients with major blunt trauma and defined significant BCI as the presence of cardiogenic shock, arrhythmias requiring treatment, or posttraumatic structural deficits. They noted that all 131 patients with normal serial ECG and troponin I levels had no significant BCI. Only 48 patients (14%) had significant BCI and, of these, 94% had both abnormal ECG and troponin levels. They reported that 22% of their patients with only an abnormal ECG and 7% of their patients with only an abnormal troponin level developed a significant BCI. However, 43 of their 48 patients with significant BCI had an abnormal ECG on admission.

Testing for creatinine kinase-MB isoenzyme and the use of radionuclide angiography have not been helpful in diagnosing BCI. The initial chest radiograph is helpful in ruling out a tension pneumothorax and/or a hemothorax that may be a source of blood loss and hypotension. A careful physical examination confirming movement of the lower extremities and the presence of rectal tone prior to giving drugs for intubation rules out spinal cord injury as a cause of hypotension. The FAST examination helps determine whether there is any cardiac activity in the patient who presents without vital signs and identifies if there is fluid in the pericardial sac in patients who present with vital signs. A transthoracic echocardiogram or a transesophageal echogram is recommended on those patients who have abnormal ECGs on admission. These studies provide information regarding the cardiac function.

BCI INJURY SEVERITY

The American Association for the Surgery of Trauma has identified an organ injury scale for BCI. A grade I BCI is identified by ECG abnormalities, such as nonspecific ST or T wave changes, premature atrial or ventricular contractions, or persistent sinus tachycardia. Grade II BCI includes patients with heart block or ischemic changes without cardiac failure. Grade III injury includes patients with sustained arrhythmias, septal rupture, valvular incompetence, papillary muscle dysfunction, distal coronary artery occlusion without heart failure, or blunt pericardial laceration without cardiac herniation. Grade IV BCI includes patients with septal rupture, pulmonary or tricuspid incompetence, papillary muscle dysfunction, distal coronary artery occlusion with cardiac failure, rupture of the right or left atrium or the right ventricle, or aorta, or mitral valvular incompetence. Grade V BCI includes patients with proximal coronary artery occlusion, left ventricular perforation, or rupture of more than one chamber.

TREATMENT OF BCI

Grade I Injury

Patients with a grade I BCI will have only ECG abnormalities and should be observed by continual monitoring until the ECG abnormalities have corrected. This typically occurs within 24 hours. The treatment of associated injuries resulting from the blunt force has a higher priority.

Grade II Injury

Patients with grade II BCI have heart block and/or ischemic changes and need to be monitored until ischemic changes resolve and the ECG pattern returns to normal. Arrhythmias should be anticipated and treated promptly. Close monitoring and serial assessment of troponin levels should continue while associated injuries are treated. Resolution often occurs within 48 hours. Inotropic support is not needed unless the patient worsens and develops evidence of heart failure.

Grade III Injury

Patients who have BCI associated with ventricular arrhythmias with or without an anatomic defect such as septal rupture, papillary muscle dysfunction, or distal coronary artery blockade without heart failure need to be monitored closely for progression to cardiac

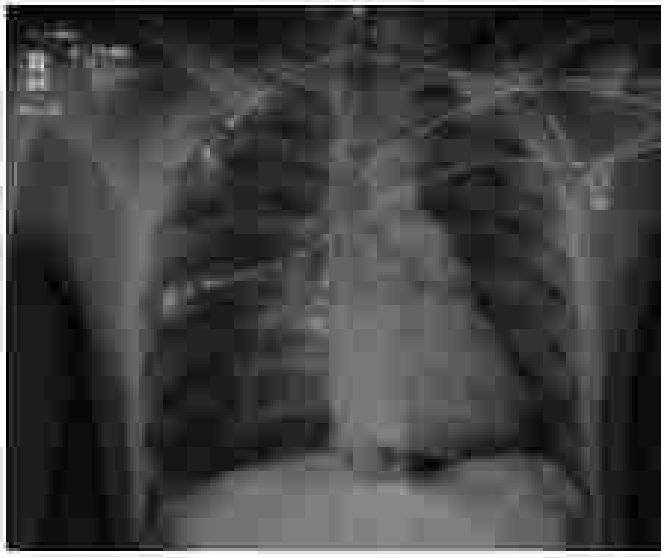

FIG. 1. Initial chest radiograph in a patient with grade 3 blunt cardiac injury demonstrated a small left pulmonary contusion but did not show significant hemothorax to explain his hypotension after arrival in the emergency department.

failure. Even patients who have a blunt pericardial rupture can be followed nonoperatively as long as this does not interfere with cardiac output and total body perfusion. If the patient with grade III injury has evidence of pericardial fluid, be careful to look for any evidence of pericardial tamponade and treat promptly with pericardiocentesis or, if necessary, open pericardiotomy. This type of nonpenetrating injury in patients with grade III BCI is potentially life-threatening and requires careful observation and seldom requires operative intervention.

This type of a grade III BCI was recently treated in a 23-year-old man who was found on the embankment of the freeway after ejection from the back seat of an SUV that struck a semi truck at high speed. He was awake and could answer questions but had a Glasgow Coma Score (GCS) of 12. His palpable systolic pressure was 100 mm. He had multiple abrasions and contusions but, on arrival to the emergency department, was moving all extremities. Shortly after arrival, he became hypotensive (80/57 mm Hg), tachycardic (145 beats/min), and tachypneic (22 breaths/min) with a GCS of 8. He was resuscitated, and his FAST examination of the chest and abdomen was negative. Initial chest radiograph suggested left lung contusion (Fig. 1). Subsequent computed tomography (CT) of the chest confirmed bilateral hemothoraces with small pneumothoraces, left pulmonary contusion, bilateral rib fractures, and nondisplaced sternal fracture (Fig. 2). He also had fractures of thoracic T12 vertebra, fracture of the transverse processes of L1–L3, and nondisplaced fracture at the base of the sacrum. The abdominal CT scan demonstrated a grade III liver injury and a grade II splenic injury (Fig. 3). Blood studies showed an arterial pH of 7.16, a lactate of 5.9 mmol/L, an alcohol of 165 mg/dL, and a troponin of 1.67 ng/mL. Bilateral tube thoracostomies yielded 750 mL of blood on the right and 150 mL on the left. The EKG showed sinus tachycardia with ST elevation.

Repeated episodes of hypotension in the intensive care unit were treated with blood and crystalloid solution, to which he responded. He gradually improved over the next 12 hours when his pH was 7.3, the troponin was 2.50 ng/mL, and the elevated liver enzymes began to normalize. The transthoracic echo examination showed "normal left ventricular size with slight increase in left ventricular wall thickness with mildly decreased left ventricular systolic function. He had global hypokinesis, and the left ventricular ejection fraction was 45%

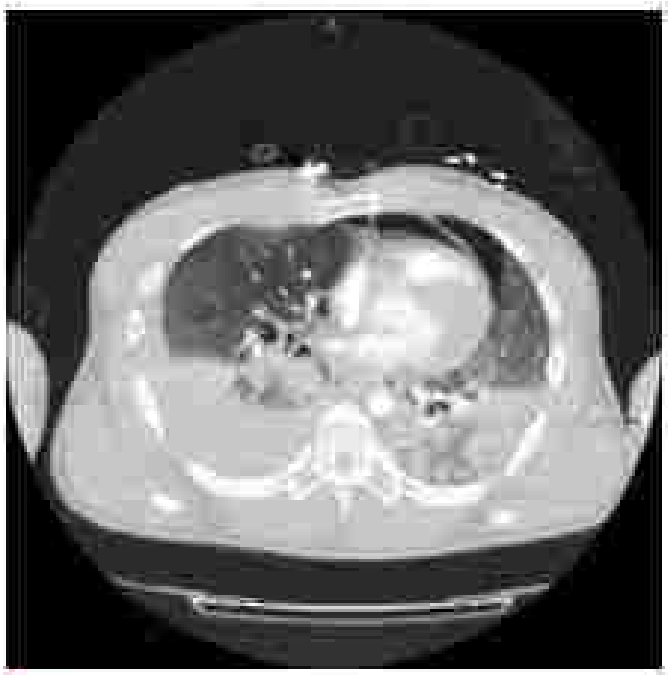

FIG. 2. Chest computed tomography scan in a patient with grade 3 blunt cardiac injury demonstrated a left pneumothorax, bilateral hemothorax and showed the pulmonary contusion.

FIG. 3. Abdominal computed tomography scan in a patient with grade 3 blunt cardiac injury showed a grade 3 liver injury and a grade 2 splenic injury but no obvious reason for the patient's hypotension.

to 50%. Throughout day 1 and on to day 2, he had a fever (39.2°C), remained tachycardic (135 beats/min), and required continued resuscitation with crystalloid, packed red cells, and fresh frozen plasma. By day 2, his troponin had risen to 2.53 ng/mL, and his abdomen was full and difficult to evaluate.

Laparotomy at this time revealed 9 .0 mL of blood. He underwent gastrostomy tube placement, tracheostomy, and bronchial alveolar lavage, which returned a gram-positive cocci and gram-negative coccobacilli, for which he was appropriately treated. He progressed to severe respiratory distress (partial pressure of oxygen/fraction of

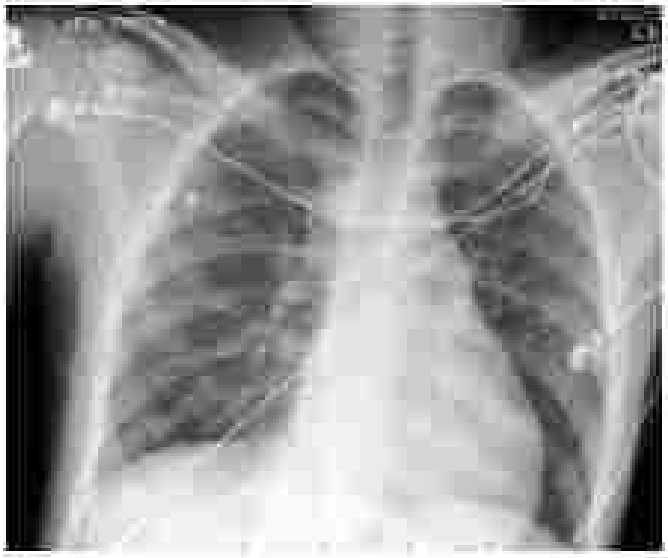

FIG. 4 Admission chest radiograph in a young man who developed a grade 4 blunt cardiac injury following a motor vehicle collision showed a globular heart.

required oxygen (100%) even though his troponins and liver enzymes normalized. He remained tachycardic for the next 10 days but, by day 14, his pH and blood gases normalized. Repeat transthoracic ECG (TTE) at this time showed normal left ventricular function with an ejection fraction of 60% to 65%; the right ventricular size and function were normal. He slowly improved, so that by day 30, his chest tubes, tracheostomy tube, and percutaneous endoscopic gastrostomy tube had been removed, and he was able to tolerate oral diet and he was transferred to the rehabilitation center. The long-term result was good. This example of grade III BCI, sometimes referred to as severe myocardial contusion, may produce prolonged tachycardia, ST segment changes, elevated troponin, and impaired cardiac function, but usually responds to supportive care while the associated injuries are treated.

Grade IV Injury

Grade IV BCI associated with septal rupture, valvular incompetence, or chamber rupture of the right ventricle, either atrium or the right atrial appendage often die at the scene; when arriving at the hospital alive, prompt diagnosis and therapy are needed. The diagnosis of valvular incompetence or papillary muscle dysfunction shows a reduced ejection fraction or dyskinesis. Likewise, patients with distal coronary artery occlusion will have evidence of cardiac ischemia and inotropic compromise, which can be documented by TTE. These patients tend to have myocardial support but usually do not require operative intervention unless there is chamber rupture. An example of a patient requiring operative intervention follows.

This young man was found outside his vehicle after an MVC. He was confused, drowsy, tachycardic (115 beats/min), and hypotensive (systolic blood pressure, 80 mm Hg). He was given Narcan with little immediate improvement in his drowsiness, but when he arrived in the emergency department, his pressure rose (140/100 mm Hg), but the tachycardia (120 beats/min) persisted. His GCS was 10. He moved all four extremities, thus ruling out spinal cord injury. His blood alcohol was 76 mg/dL, and he had a positive drug screen for benzodiazepine and cannabinoids. Chest radiograph demonstrated normal lungs, but a globular heart (Fig. 4). A CT of the chest showed pericardial effusion (Fig. 5), and CT of the abdomen showed hepatic inotropy with edema around the liver and gallbladder (Fig. 6). The troponin level on arrival was 0.052 ng/mL. Shortly after admission to the surgical intensive care unit, he became hypotensive (BP 60/40 mm Hg) and did not respond to a 1-L bolus. The arterial pH was 7.19. He was taken to the operating room for laparotomy and was found to have yellow, cloudy ascites with a very large, edematous, purple-looking liver of undetermined etiology. No specific treatment was done, and he returned to the intensive care unit, where a repeat troponin level was 1.56 ng/mL; the liver enzymes including bilirubin were normal. TTE demonstrated a large pericardial effusion, thus explaining his recurrent hypotension. A difficult transthoracic pericardial window was performed with return of a large amount of bloody exudate, which led to a sternotomy, pericardiotomy, and primary repair of a 4-mm hole in the right atrial appendage. Postoperatively, his troponin level was 3.97 ng/mL, but his vital signs stabilized, and the transient rise in his liver enzymes returned to normal. He had an uneventful recovery.

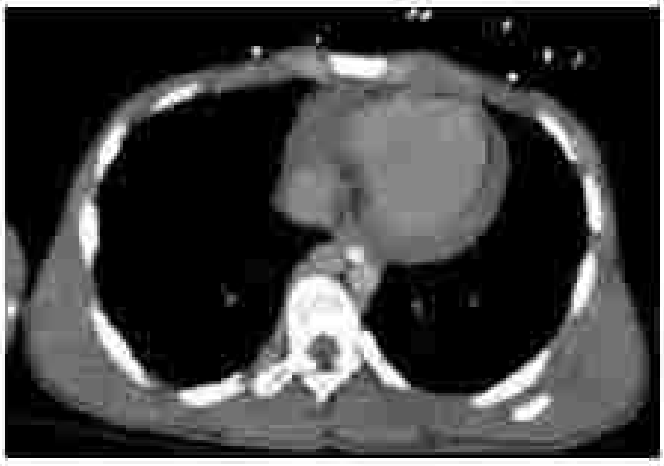

FIG. 5 Computed tomography scan of the chest in a young man with a grade 4 blunt cardiac injury demonstrated a pericardial effusion.

FIG. 6 Abdominal computed tomography in a patient with grade 4 blunt cardiac injury demonstrated significant hepatomegaly and edema around the liver.

The rarity of this type of BCI led to the delay in recognizing pericardial tamponade, which should have been detected on an initial FAST examination and confirmed on the CT scan. Definitive care should have included a transthoracic pericardiocentesis followed by

a prompt left anterior thoracotomy. The engorged purple liver in this patient was caused by impaired hepatic venous return because of the pericardial tamponade.

Grade V BCI

BCI associated with rupture of the left ventricle or more than one heart chamber is highly lethal. The vast majority of these patients (>80%) have been injured in motor vehicle collisions, hitting vehicles, motorcycle crashes, or pedestrian/vehicular mishaps; less common causes would include thoracic crush injury, falls from major heights, and other events that exert a great force on the chest. Chamber rupture is more likely to occur in the right atrium or ventricle (60%) followed by the left ventricle with few patients having rupture of more than one chamber. The lethality of this syndrome is reflected by the fact that most patients die at the scene or receive cardiopulmonary resuscitation at the scene only to be declared dead at the time of arrival in the emergency department. The force of the impact is so great that almost all such patients have major associated injuries and very high injury severity scores.

The typical scenario of BCI with chamber rupture was seen in a 21 year old restrained front seat passenger in a vehicle that struck a tree at 80 mph. She was unresponsive at the scene, was intubated, and had cardiopulmonary resuscitation during her 20 minute trip to the hospital. Upon arrival, she had pulseless electrical activity with no cardiac movement per ultrasound and was declared dead. Injuries identified at autopsy included fractures to the right humerus, left femur, 10 right ribs, six left ribs, in addition to atlanto occipital separation, bilateral pulmonary contusions, and rupture of the right hemidiaphragm, liver, and spleen. She had a 6.3 cm laceration of the apical portion of the right ventricle and numerous lacerations of the right atrium with bilateral hemothorax. This patient's mechanism of injury, attempted resuscitation by emergency medical services, and subsequent death are typical for patients with ventricular rupture, or rupture of more than one chamber.

COMMOTIO CORDIS

Commotio cordis is sudden death from cardiac arrest associated with no anatomic structural damage to the heart identified at autopsy. This condition occurs in young people typically after a blunt blow to the chest inflicted during competitive sporting activity. Direct impacts from a baseball or hockey puck have caused this sudden death. These patients have no underlying congenital cardiac disease, cardiomyopathy, or other preexisting abnormalities. This condition appears to be caused by the impact transmitted to the heart inducing ventricular fibrillation during a phase of ventricular excitability such as cardiac repolarization. This untoward event is most often refractory to cardiopulmonary resuscitation and defibrillation. These patients present to the hospital in cardiac arrest and the FAST examination will show no cardiac activity and no pericardial fluid.

LONG-TERM FUNCTION AFTER BCI

There have been few studies that have evaluated the long-term effects of BCI. The studies that have been done show that most of these patients do well and require no further treatment.

ALGORITHM FOR DIAGNOSIS AND MANAGEMENT OF BCI

Any patient who presents with blunt thoracic trauma should be suspected of having BCI despite its rarity (Fig. 7). The patient who presents without vital signs should have a FAST examination done to determine if there is cardiac activity. In the absence of cardiac activity nothing further should be done and the patient should be pronounced dead. The patient who presents unresponsive after blunt thoracic trauma should have a FAST examination done as part of the secondary survey. If the heart is beating and there is no pericardial fluid, the patient should have an ECG and troponin measurements. If both ECG and troponin are normal, no further tests or monitoring for BCI is indicated. However, if the ECG, and/or troponin is abnormal with findings such as tachycardia, arrhythmia, and/or ST elevation, the patient should be admitted to the intensive care unit and the ECG and troponin levels repeated in 6 hours. An echocardiogram should be done within that first 24 hours. These patients will usually remain stable and will have correction of their abnormal ECG and troponins within the first 24 to 48 hours. If the echocardiogram is abnormal, it should be repeated in 48 to 72 hours. Treatment of the BCI in this setting is supportive. The tachycardia is best treated with a β-blocker and any pulmonary injury is treated with ventilatory support.

The patient who presents with blunt thoracic trauma and is hypotensive presents a real challenge. The initial examination and chest radiograph should exclude spinal cord injury, a tension pneumothorax, or other sites of hemorrhage including the chest or fractures. The FAST examination is most helpful in determining whether there is fluid in the pericardial sac. If there is pericardial fluid and the patient is stable, a CT of the chest is recommended to determine whether the fluid resembles a serous pericardial effusion from an underlying medical condition or blood. Some patients may have a comorbid condition leading to pericardial fluid which is typically serous as occurs in renal failure. If the pericardial fluid has the appearance of blood, and the patient is stable, immediate operation is indicated. If the patient is unstable and has pericardial fluid, the patient should have pericardiocentesis on the way to the operating room. Recommended operation is a left anterolateral thoracotomy, which provides rapid access for pericardiotomy and repair of most BCI. We do not recommend a transabdominal pericardial window that, in the presence of BCI, leads to rather sudden blood loss and does not facilitate expedient repair. We recommend either a definitive median sternotomy or a left thoracotomy. The pericardium is then opened parallel to the phrenic nerve. The blood is evacuated and the heart examined for injury. Most of these patients will have a small injury involving the atrium or the atrial appendage. A simple primary repair including clamping of the atrial appendage followed by ligation, and control of the bleeding. Repair of the atrium and/or the ventricle can be done with a 3-0 silk suture on a noncutting needle. Bleeding is controlled with digital pressure while the sutures are being placed. Some surgeons prefer pledgeted sutures. The main objective is to control bleeding. If a left thoracotomy is done which limits access to the heart, the incision could be carried across the sternum into the right chest as a clamshell thoracotomy. Occasionally, there may be bleeding from the pericardial sac itself so that there is blood in the pericardial sac but no rupture of the heart. The pericardium should be approximated leaving the anterior part of the pericardial sac open for about 3 to 4 cm to permit egress of any postoperative pericardial blood. Successful therapy of BCI requires definitive management of the other injuries including the pulmonary injuries which are usually severe.

Injuries to the coronary vessels are very unusual and include coronary artery contusion or rupture. Rupture of a valve or papillary muscle may also occur. These injuries would probably be detected on an echocardiogram and would require cardiopulmonary bypass for repair. Cardiopulmonary bypass should be available for repair of any chamber ruptures but has not been found to be useful for cardiac support alone.

Abdominal Compartment Syndrome and Management of the Open Abdomen

Jennifer L. Hartwell, MD, and Rao L. Ivatury, MD, MPH

Abdominal compartment syndrome (ACS) is the end stage of a progression from a mild increase in intraabdominal pressure (IAP) to the development of intraabdominal hypertension (IAH). Once IAH occurs, there are negative effects on multiple organ systems. Intraabdominal hypertension occurs when the accumulation of bowel wall edema, retroperitoneal swelling from blood or edema, intraluminal gas, or a combination of these factors outstrips the compliance of the abdominal wall and diaphragm. Primary IAH occurs as a result of an intraabdominal injury or process. The classic presentation of primary IAH and subsequent ACS is a patient with an intraabdominal injury that results in hemorrhagic shock and large volume resuscitation with blood and crystalloid. The abdomen is closed at the index operation and the patient develops IAH and then ACS. Intraabdominal injury is not the only reason IAH and ACS occur. Primary IAH has been described in patients with gastrointestinal bleeding, liver transplantation, superior mesenteric vein thrombosis, pelvic fractures, and ruptured abdominal aortic aneurysm to name a few.

Secondary IAH occurs as a result of the need for a massive resuscitation from a cause other than a primary intraperitoneal injury or process. This form of IAH is a consequence of capillary leak leading to the accumulation of fluid in the bowel wall and retroperitoneum. The mechanisms behind the development of capillary leak are multifactorial, but the commonality is a systemic inflammatory response. Septic shock, burn wounds, and large volume soft tissue injury can all result in the need for high paced resuscitation with crystalloid, putting patients at risk for secondary IAH and ACS.

DIAGNOSIS

Clinically, ACS is diagnosed in the intensive care unit (ICU) in a patient who has required massive resuscitation and who develops worsening renal function, increased peak airway pressures (PAWPs) on the ventilator, worsening abdominal distention, and persistent hypotension. These signs occur in the end stage after the patient is suffering from the full effects of ACS. These particular signs occur as a result of the complex pathophysiology of IAH. Increased IAP causes decreased venous return resulting from compression of the intraabdominal portion of the vena cava. Cardiac output subsequently drops because of lower preload pressures. Additionally, the increased pressure in the abdomen causes collapse of the microvasculature supplying the intestines and abdominal organs leading to ischemia. Initially, blood pressure is maintained by increasing systemic vascular resistance until vasoconstriction can no longer keep pace with the reduction in preload. Renal function is impaired from the lower systemic blood pressure. Renal function is further compromised by direct pressure and compression of the kidneys because of their intraabdominal location. Increased intrathoracic pressure occurs from limitation on the excursion of diaphragm. As a consequence, pulmonary compliance is reduced and PAWP begins to rise. Intraabdominal hypertension can have effects on organs distant from the abdomen as well. Intracranial pressure is thought to increase in patients with a combination of a head injury and IAH to the point that decompressive laparotomy might be considered to reduce dangerously high intracranial pressures.

Recognition of rising IAH and impending ACS is important to prevent these potentially harmful complications from occurring. Risk factors for the development of IAH on arrival to the intensive care unit include a history of transfusion of more than 10 units of packed red blood cells, infusion of more than 7500 mL of crystalloid, the presence of a coagulopathy, or a pH of less than 7.2. In patients at risk for IAH, the physical examination is often unreliable to detect IAH; therefore, frequent monitoring of IAP is required. The World Society of Abdominal Compartment Syndrome developed guidelines for the diagnosis, management, and classification of IAH. Intraabdominal pressure should be measured using a trans-bladder approach with the patient in the supine position and at end expiration. Every effort should be made to ensure that the abdominal muscles are not contracting at the time of the IAP measurement, including the administration of short-acting neuromuscular blocking agents, if necessary. Manometry or continuous measurement can be used to determine IAP after instilling 25 mL of sterile saline through a catheter to the bladder. The World Society of Abdominal Compartment Syndrome defines normal IAP as 5 to 7 mm Hg in critically ill adults and IAH begins at 10 mm Hg. Intraabdominal hypertension is graded from I to IV (Table 1). It is important to be aware that continuous bedside monitors in use in the ICU often measure pressures in cm H_2O instead of mm Hg. The corresponding cm H_2O are also given in Table 1. Abdominal compartment syndrome is defined as a sustained IAP of greater than 20 mm Hg that is associated with new organ dysfunction or failure.

THERAPY

Management of Intraabdominal Hypertension

Once IAP begins to climb in a patient at risk for the development of ACS, it is important to aggressively treat IAH. In patients with grade I and grade II IAH, medical management strategies are used as primary treatment modalities. Treatments for IAH are aimed at improving abdominal wall compliance, reducing intraluminal volume, removing intraabdominal fluid, maintaining sedation, and supporting at-risk organs, including the pulmonary system. These strategies are used in a multimodal manner to maximize reductions in IAP. Once IAH is identified and treatments started, IAP should be measured at least every 4 hours to determine the effectiveness of the treatments used to reduce IAP.

To improve abdominal wall compliance, it is important to ensure adequate sedation and analgesia. Although easy to overlook, removal or loosening of abdominal dressings or release of abdominal eschars in the setting of a burn can also help to increase abdominal wall compliance. The reverse Trendelenburg position can be helpful if the patient can tolerate a change in position. If these maneuvers do not result in adequate reduction of IAH, consider the use of neuromuscular blockade as a last resort.

There is sufficient evidence to suggest that after the IAP reaches 15 mm Hg that there is a logarithmic rise in IAP. Thus, small changes in intraabdominal volume may have profound effects on IAP once above this threshold. Placing a nasogastric or nasoenteric tube and use of a rectal tube can reduce intraluminal pressure and subsequently IAP. The use of prokinetic agents can also help to reduce IAP. Minimizing enteral nutrition, colonoscopy, decompression, and enema administration to evacuate a large stool burden can be considered in cases where there is persistent IAH. Reducing space occupying lesions in the abdominal cavity may also be an option. This is particularly helpful if the patient has ascites that can be easily identified with ultrasound and drained at the bedside.

The use of a balanced resuscitation strategy in patients with hemorrhagic shock with a near 1:1 plasma to packed red blood cell ratio is associated with fewer episodes of IAH and ACS. Once the initial resuscitation is complete, maintaining euvolemia with goal directed fluid resuscitation strategies are important in the setting of IAH. In

TABLE 1 Grade of Intraabdominal Hypertension and Corresponding Pressure Measurements

Grade	Bladder Pressure	
	mm Hg	cm H_2O
I	10–15	13–20
II	16–25	21–35
III	26–35	36–47
IV	>35	>48

the critically ill patient, it is easy to allow fluids to begin to accumulate at a rapid rate because of the need for drips for sedation and blood pressure maintenance, antibiotics, and maintenance fluids. Once the initial resuscitation is complete, which is usually after the first 48 hours, one should attempt to achieve a zero fluid balance. If the patient's situation allows, diuresis and negative fluid balance should be continued. In severe cases, hemodialysis or ultrafiltration should be considered to achieve zero balance. Another way to reduce IAP is to reduce intrathoracic pressure. Use of lower than normal tidal volumes and the use of ventilator strategies that allow for lower mean airway pressures can also lead to reductions in IAP.

Intervention for ACS

Once a patient has sustained IAP of greater than 20 mm Hg and evidence of at least one organ system dysfunction or failure, then abdominal decompression is the treatment of choice. Decompression is achieved via a generous midline laparotomy from the xiphoid to the pubis. A large incision allows for the abdominal viscera to extrude from the abdominal cavity and for any intraabdominal fluid to escape. If the ACS is severe or has been prolonged, there is a chance that the patient will suffer from the effects of rapid reperfusion and washout of accumulated lactic acid and potassium. To reduce the chance of catastrophic cardiac collapse, we protect patients with bicarbonate prior to or at the time of abdominal decompression. Subcostal and paramedian incisions should be avoided because they do not allow for adequate decompression of the abdominal cavity and these incisions are much more difficult to manage in the open abdomen stage.

Initial Management of the Open Abdomen with Temporary Closure

The ideal temporary closure technique should protect the intraabdominal viscera, allow egress of intraabdominal fluid, minimize damage to the abdominal wall tissues, be easy to apply, and be loose enough to prevent ACS from developing again. Techniques that are now mostly of historical interest do not meet all of these criteria. The Bogota bag, first described by surgeons in Colombia, repurposes a 3 L urologic irrigation bag or an x-ray contrast cover. The bag or cover is cut to size and sutured to the patient's skin with a running heavy nylon stitch. Closed suction drains are placed around the open abdominal wound and an adhesive dressing can be placed over the drains and the bag to control fluid egress from the abdominal cavity. Although effective, this technique damages the skin, takes time to complete, and risks injury to the bowel while suturing the bag in place. Perforating towel clips can be placed approximately 2 cm apart to bring the skin of the abdominal wall together. The main disadvantages of this technique are that the towel clips can damage the skin and that the towel clips are radiopaque, which can complicate subsequent radiographic studies of the abdomen. Another disadvantage is that the closure is sometimes too tight and IAH can redevelop. One scenario to which a higher pressure might be helpful, however, is when the liver is packed in the upper abdomen. Towel clip closure of the upper one third of the abdomen may help with achieving tamponade of packed liver injuries.

FIG. 1 Open abdomen managed with Barker Vac Pac dressing.

In the modern era, there are two widely used strategies that meet the ideal temporary abdominal closure criteria. In 2000, Barker and colleagues published the results of their vacuum pack technique of temporary abdominal closure. In the originally described technique, a 10–10 polyethylene sheet is perforated with scissors or a scalpel. The sheet is placed under the abdominal fascia. A moist surgical towel is placed under the fascia but above the polyethylene sheet. Two No. 10 flat Jackson Pratt drains are placed on the bowel and connected to wall suction via a T-connector. Alternatively, two nasogastric tubes can be used for the same purpose. The entire wound is then covered with a plastic polyester adhesive drape, also known as an Ioban drape. The suction must be on and the skin should be as dry as possible before placing the Ioban. The use of benzoin can aid in the adherence of the Ioban to the skin. A modification of this technique is to avoid use of the surgical towel and to ensure that the holes in the polyethylene drape are not large enough to allow the Ioban to stick to the underlying bowel. Using a scalpel to perforate the 10–10 drape is the best way to ensure the holes are small enough to protect the underlying bowel (Fig. 1). More recently, commercially available products have been developed that are similar to the Barker vacuum pack technique; these products can also be effective at temporary abdominal closure. Commercially available negative pressure wound therapy systems are rapid to apply and aid in the removal and quantification of fluid from the peritoneal cavity.

Management of the Patient with an Open Abdomen in the ICU

Patients who develop abdominal compartment syndrome are often in extremis from overwhelming trauma or shock and require ongoing aggressive resuscitation. However, after the initial resuscitation phase has passed, attention should rapidly be turned to other management priorities such as administration of nutrition, antimicrobial management, and ventilator weaning strategies.

Nutrition

Patients with an open abdomen will require repeated operations for a second look, washout, and attempts at definitive closure. With every surgery, the question should be asked, "Is it appropriate to feed this patient enterally? If so, through what access?" Contraindications to early enteral nutrition (EN) include bowel discontinuity, ongoing massive resuscitation, and high dose vasopressor requirements. Consideration should be given to placing temporary feeding access, such

as a small bore nasogastric, or more preferably, a nasojejunal feeding tube while in the operating room because direct palpation of the tube passing through the stomach and into the small bowel ensures accurate placement and mitigates the need for this procedure to be done blindly in the ICU setting. Once access has been established, tube feedings can safely be started if the patient no longer requires massive blood product transfusion or large volumes of fluid, bearing in mind that tube feeding formulations are not appropriate to be used for resuscitation. Although it may cause some apprehension on behalf of the surgeon, early EN in patients with open abdomens has not only been demonstrated to be safe, but also to provide significant benefit for the patient. A recent multiinstitutional trial sponsored by the Western Trauma Association determined that early EN is associated with earlier fascial closure, decreased complications, and decreased mortality. The choice of enteral tube feeding formula should be discussed with the dietitian, taking into consideration the volume of the feedings, the patients' existing medical conditions (such as renal or hepatic failure), and protein needs. Patients with an open abdomen have large insensible volume losses and an increased protein sink while serous fluid is being sequestered from the peritoneal cavity. As such, patients with an open abdomen routinely require 2 to 2.5 g/kg per day of protein to meet nutritional goals. Recent data from our institution in a retrospective review of 217 critically injured trauma patients revealed that those who meet their protein goals within 4 days of admission have fewer complications, such as infections and delayed wound healing, than patients who do not achieve protein goals, further emphasizing the benefit of early protein rich nutrition.

At the definitive operation for either primary fascial closure or definitive closure with a mesh product, consideration should be given to placement of durable enteral access such as a gastric tube or jejunal tube. These translocal feeding tubes should not be placed before the definitive operation because their ultimate abdominal wall location will migrate with gradual reduction of bowel edema and reclamation of abdominal domain when initial resuscitation is over.

Medications

Patients managed with an open abdomen require no specific antibiotic prophylaxis. Routine perioperative antibiotic dosing per institutional guidelines is sufficient. The routine use of chemical deep vein thrombosis prophylaxis is encouraged if not otherwise contraindicated by ongoing bleeding or injuries such as intracranial hemorrhage. Standard protocols for gastrointestinal bleeding prophylaxis are appropriate but no additional gastrointestinal medications are indicated in the patient with an open abdomen.

Fluid Management

Strict measurement of all fluid intake and output is essential in the management of patients with an open abdomen. Large volume serosanguinous drainage from the abdomen must be measured. The fluid balance should be monitored daily and day over day accumulated balance should be calculated. Patients can rapidly fall behind in their fluid balance, with large volume losses from the peritoneum and other sources such as nasogastric tube, ileostomy, urine output (especially diabetic insipidus in a head injured patient), or chest tube drainage. Occasionally, replacement of large volume losses to a 1:1 or 1.5:1 mixture with crystalloid will be required to maintain euvolemia. Judicious use of fluids during the resuscitation phase may help minimize massive bowel edema and promote efforts toward fascial closure. Ultimately, the goal is for the patient to maintain euvolemia and evidence of adequate end organ function.

Additional methods used to support adequate perfusion of the intestine may also be used. One such technique is direct peritoneal resuscitation as described by Weaver and Smith. This technique involves the instillation of hypotonic fluid into the abdomen while ongoing intravenous resuscitation is occurring, which promotes dilution of the electrolytes supplying the bowel and reducing ischemia. Animal studies using this technique are promising and reveal improvements in bowel edema, increased organ blood flow, and a reduction in inflammatory serum markers. Direct peritoneal resuscitation used in the clinical setting has shown encouraging results in terms of earlier fascial closure and a reduction in abdominal complications.

Ventilator Management

It is not mandatory that patients with an open abdomen remain ventilated. Patients who otherwise meet criteria for extubation and have a contained, well dressed abdominal covering, such as a commercial negative pressure vacuum device, can safely be extubated between abdominal washout procedures. It is, however, important to consider each patient's individual risk factors for complications if extubated and no longer sedated. Combative or head injured patients may not be able to comply with dressing changes or may increase their abdominal pressure to the point of disrupting the abdominal dressing with coughing or pulling at tubing connected to a vacuum device. Ventilated patients have the benefit of continuous monitoring of PAWP as a signal of the degree of intraabdominal pressure. During sequential tightening of temporary closure devices, as described in the following section, PAWP can provide guidance as to the tolerance of advancements toward closure. Rapid and large increases in PAWP during attempts at closure are indicative of a high risk for ACS and ultimate failure of the closure.

Wound Care

Regardless of the choice of technique chosen to manage the open abdomen, general wound care principles apply. The wound is not considered sterile and once the bowel is covered with mesh or a sponge and direct access to the peritoneum is eliminated, dressing changes do not need to take place in the operating room or under strict sterile conditions. Routine barrier precautions are all that is required of the personnel caring for the patient.

Closure of the Open Abdomen

Definitive fascial closure is the goal for any patient with an open abdomen to avoid early and late complications. For patients who rapidly resolve the injury or derangement necessitating an open abdomen and are able to tolerate primary fascial closure at a subsequent operation, we recommend a tension free closure of the fascia and forgoing staged skin closure to mitigate the risk of infection. The open skin can be treated with wet to dry dressings in the traditional manner or a commercial vacuum closure device can be placed. In many patients, however, this straightforward closure is not possible. The presence of multiple descriptions of techniques to achieve definitive fascial closure in the literature indicates that this goal may remain elusive in some patients. However, several important concepts in the management of patients with an open abdomen that may help to improve rates of definitive fascial closure include: (1) controlling the underlying physiology and aggressively managing fluid balance; (2) preventing the adherence of the abdominal viscera to the abdominal wall; (3) preventing the loss of abdominal domain by using dynamic tension on the abdominal wall; and (4) attempting to cycle the fascia at regular intervals and at least every 48 hours.

We have experience with two techniques for closure of the abdomen that adhere to these stated principles. The group at Denver General Hospital described a technique in which white sponges are placed on the bowel and mated under the fascia. If more than one white sponge is required, the sponges are cut to fit and stapled together. Once the white sponges are in place, single interrupted heavy nonabsorbable sutures are placed approximately 5 cm apart to pull continuous traction on the fascia and to prevent the fascia from laterally retracting. A black VAC sponge is placed on top and the wound is covered with adhesive dressing and vacuum applied. The

patient returns to the operating room at least every 48 hours. If the abdomen can be closed, then the fascia is closed with a running heavy monofilament absorbable suture. If the fascia cannot be completely closed, interrupted figure of 8 fascial sutures are placed inferiorly and superiorly in a sequential fashion until fiery tension precludes the placement of further interrupted sutures. The white sponges are replaced and the interrupted fascial bridging sutures are replaced and tightened. The rest of the dressing is replaced as previously described.

Two potential disadvantages to using the technique described are that the fascia is violated by repeated suture placement and there is the potential that the bridging fascial sutures will put pressure on the underlying bowel, even though there is a white sponge between the bridging sutures and the bowel. Miller and colleagues at Wake Forest described a technique that avoids these two potential disadvantages. In this technique, a perforated 10–18 polyethylene drape is placed over the abdominal viscera but below the fascia, preferably to the parietal gutters on both sides. Next, the black sponge is placed over the top of the covered abdominal contents. A heavy nylon suture is used to approximate the skin to the sponge. The suture is placed using full thickness bites of skin from inside out on both sides and in a running fashion taking 3- to 4 cm bites along the length of the wound. This helps to preserve abdominal domain and to limit additional injury to the fascia.

Other techniques to achieve fascial closure that have been described include the use of commercially available Velcro closure devices that can be used to close the abdomen by serially tightening the Velcro closure until the fascia is reapproximated. Another option is to perform an early definitive repair using a component separation technique or by bridging a fascial defect with a biosynthetic mesh. The use of prosthetic mesh in the acute setting is not recommended due to the high risk for infection. Enthusiasm for early definitive repair, although potentially appealing, should be tempered by the fact that many patients with an open abdomen remain catabolic and in a poor nutritional state. Thus, these patients are at significant risk of wound healing issues and dehiscence. If the patient's metabolic state is not conducive to early definitive repair, other techniques should be used to manage the abdominal wound until such time that the patient is metabolically optimized for a definitive repair.

There is no definitive time frame in which attempts at fascial closure become futile. There are reports of successful closure out to more than 40 days. However, if fascial closure is not achieved within 2 weeks, it is unlikely that definitive closure will be possible and other techniques for wound coverage should be considered. It is our practice that once the decision is made that further attempts at fascial closure are futile, a piece of polyglycolic acid (Vicryl) mesh is placed over the abdominal contents and sutured to the fascial edge if possible or the skin edge if the fascial edge is not able to be safely used. The wound is allowed to granulate and then a split thickness skin graft (STSG) is placed. The polyglycolic mesh does not need to be removed to place the STSG as long as there is adequate granulation tissue. It is important to cover the granulation tissue as soon as practical. The large abdominal wound acts as a metabolic sink and prevents the patient from converting from a catabolic state to an anabolic one. The longer the abdominal viscera remain uncovered, the higher the likelihood of formation of an entero-atmospheric fistula. Once the bowel is covered with an STSG, a white sponge can be placed over the graft and then covered by a black sponge and an adhesive dressing and suction can be applied. We leave this dressing in place for 5 days and then remove it to examine the underlying STSG. If the STSG has taken, we use Xeroform or petroleum jelly gauze to cover the graft and then change the dressing every 48 hours until it is healed (Fig. 2).

The patient can then return in 6 to 12 months for definitive repair. Typically, it takes 6 months for the STSG to separate from the underlying abdominal viscera. We have found that waiting much past 9 months does not usually result in further loosening of the STSG and there can be an additional loss of abdominal domain with added waiting time. For definitive repair, we use the Memphis modification of the standard 'component' separation technique described by Ramirez. Using standard components separation, it is possible to obtain approximately 5 cm of length for fascial closure on each side. The Memphis modification allows for up to 10 cm of length on both sides if the fascia is fully intact. The steps of the operation are outlined in Table 2.

FIG. 2. Partial fascial closure with granulating wound managed with split thickness skin graft. Note the lateral placement of an ostomy in the left lower quadrant to facilitate dressing changes and delayed fascial closure.

There are two factors that may influence preoperative decision making at the time of definitive repair. The presence of an ostomy complicates the acute and delayed management of an open abdomen. Placing the ostomy in a more lateral position and outside of the rectus sheath, while increasing the potential for a parastomal hernia, preserves the tissue planes needed for definitive repair. Another factor to consider is the amount of skin available for coverage once the fascia is approximated. For large defects or in cases where there has been loss of skin resulting from the original injury, it may be necessary to place tissue expanders in the weeks before definitive repair to have adequate skin for closure (Fig. 3).

Complications

The most feared complication from an open abdomen is an entero-atmospheric fistula. The American Association for the Surgery of Trauma Open Abdomen Study Group published the results from their accumulated experience with entero-atmospheric fistula formation in the setting of an open abdomen. They found that cryocolloid administration of more than 5 L in the first 24 hours, the number of reoperations, and the presence of a bowel anastomosis were all associated with entero-atmospheric fistula formation. Interestingly, the type of temporary closure that was used was not related to fistula formation. Once a fistula forms, it can be devastating for the patient, so prevention is paramount. Early definitive closure, using the measures to protect the underlying bowel, meticulous wound care and limiting reoperations can all help to reduce the risk of fistula formation. If a fistula does occur, it is unlikely that the fistula will close on its own, and operative repair will be needed; however, it is often not possible to operatively repair the fistula in the acute setting. It is important to determine the location of the fistula if possible. More distal fistulas are easier to manage and may allow enteral nutrition to continue and avoid the need for total parenteral nutrition for prolonged periods. One of the most difficult issues when confronted with a fistula in the setting of an open abdomen is controlling the output from the fistula. There is no perfect strategy and creativity is paramount. If possible, performing an STSG as early as practical can aid in the ability to manage the fistula. If the output from the fistula can be temporarily reduced or controlled by suturing the fistula closed, placing a Malecot tube, or by some other means, it is possible to place

TABLE 2 Delayed Repair of the Abdominal Wall Using the Memphis Modification of the Components Separation Technique

Step	Description
1. Remove split-thickness skin graft	It is easiest to start the operation over the liver in the right upper quadrant. Once access to the peritoneal cavity is gained, the STSG can be removed from the underlying bowel.
2. Raise full-thickness skin flaps on either side of the defect	The correct anatomic plane is avascular and just above the abdominal wall fascia. Flaps should be raised to just beyond the insertion of the external oblique fascia into the lateral rectus sheath.
3. Release of the external oblique component of the anterior rectus fascia	The release is started by incising the anterior fascia approximately 3 cm lateral to the rectus. The release extends from the costal margin to the pubic symphysis. The serratus anterior can be divided to obtain more length at the midline.
4. Dissection of the posterior sheath	After incising the medial portion of the rectus sheath the posterior sheath is dissected free from the rectus muscle.
5. Release of the internal oblique component of the anterior fascia	After identifying the lateral border of the rectus muscle by placing the hand under the muscle but above the posterior rectus sheath, the anterior fascia is incised and the internal oblique is the medial from the arcuate line superiorly to the costal margin. Be careful to preserve the integrity of the posterior rectus sheath.
6. Translocation of anterior fascia and muscle	At this point, the medial border of the posterior rectus sheath can be sutured to the lateral border of the anterior fascia using interrupted figure-of-8 nonresorbable heavy absorbable suture.
7. Close the midline	The midline is closed with a running heavy nonresorbable absorbable suture. If there is tension in the midline, it is preferable to place a bridging piece of biologic mesh.

FIG. 3 In cases with a large abdominal wall defect, consider placement of tissue expanders before definitive fascial closure to ensure there is adequate skin to cover the repair.

an STSG in this setting. By stopping or controlling output for 5 to 10 days, it may be possible to get enough of an STSG to take that placement of an ostomy appliance becomes much simpler. If an STSG does not take or if it is not possible to place one, then using a combination of white sponges, black sponges, adhesive dressings, negative pressure therapy, and an ostomy appliance may make it possible to control fistula output. However, the dressing must be changed every 48 hours to prevent wound-related complications.

SUMMARY

Early detection and treatment of rising IAP using multimodal treatment strategies may help to prevent ACS and the need for a decompressive laparotomy and subsequent open abdomen. If an open abdomen is required, meticulous attention to detail is needed at every stage in management. Although knowledge of several management options is helpful in achieving fascial approximation, it is more important to become proficient with one or two strategies and to learn the benefits and pitfalls associated with these strategies. Ultimately, one must develop an algorithm for the management of these complicated patients to have the best outcome possible.

Coagulation Issues and the Trauma Patient

John B. Taylor II, MD, and Bryan A. Cotton, MD, MPH

Even with dramatic advances over the last 2 decades, trauma continues to be the leading cause of death in individuals aged 0 to 44 years. Although traumatic brain injury persists as a leading cause of death from injury, hemorrhage is still considered to be responsible for more than 40% of trauma deaths and the number one *potentially* stable cause. The purpose of this chapter is to review the current understanding of hemorrhage owing to trauma and identify evidence-based therapies for treating the hemorrhaging trauma patient.

NORMAL COAGULATION

Hemostasis is a complex process designed to limit bleeding and hemorrhage following injury. Although the main physiologic parts of the cascade (local vasoconstriction, platelet plug formation, fibrin deposition, and fibrinolysis) occur in a sequential manner, there is extensive redundancy with the system (Fig. 1). Without vascular injury or trauma to the system, blood remains in a steady state system in which its purpose is to deliver oxygen to and remove carbon dioxide from tissues. Once normal coagulation is exposed to trauma and endothelial injury, the coagulation system begins the process of cessation of hemorrhage.

Hemostasis starts with constriction of injured vessels and is most pronounced in those with smooth muscle within their media layer. The release of arachidonic acid leads to thromboxane A2 (a potent constrictor of smooth muscle). The subsequent release of serotonin and endothelin from injured vessels and platelets results in further vasoconstriction and platelet aggregation. Platelet aggregation leads to formation of a hemostatic plug and the generation of thrombin. Platelet degranulation follows with a release of adenosine diphosphate, calcium, thromboxane, and other substances, and formation of fibrinogen (cleaved into fibrin strands) that helps to serve as a bridge for platelets and the injured endothelium (via glycoprotein receptors IIb/IIIa). Initiation of coagulation occurs from exposure of tissue factor following endothelial injury. Clot propagation begins with tissue factor binding to an activated factor VII, and following through a sequence of enzymatic reactions, resulting in activation of factor X. Thrombin is then formed, converting fibrinogen to fibrin, with the redundancy of the system resulting in further activation of factors V, VII, VIII, XI, and XIII.

Balance in the hemostatic system is maintained by the actions of endogenous anticoagulants (such as antithrombin, protein C, and protein S), whose role is to downregulate fibrin formation and thrombin generation. This balance is also maintained by the actions of prostacyclin and nitric oxide that function to inhibit platelet aggregation. Finally, the fibrinolytic system works to breakdown clot that is made after injury. In the uninjured patient, the coagulation system works in a delicate balance to maintain homeostasis; major trauma, however, throws this balance off. Trauma-induced coagulopathy (TIC) is the byproduct of severe tissue injury, hypoperfusion, and the profound inflammatory and hemostatic processes that can lead to death if not addressed in a timely fashion.

TRAUMA-INDUCED COAGULOPATHY

TIC is an overall failure of the coagulation system to maintain adequate hemostasis after major trauma and hemorrhage as a result of endothelial level injury, shock, and poor resuscitation support. TIC progresses rapidly in response to tissue injury and hemorrhagic shock resulting in hypocoagulation and hyperfibrinolysis. This process will continue unabated and will be exacerbated by ongoing bleeding, hemodilution, acidemia, and hypothermia. Brohi and colleagues have elucidated some of the mechanisms behind TIC, demonstrating that endothelial injury (mediated through shock and hypoperfusion), along with anatomic injury (mediated through actual tissue trauma) activates the protein C pathway. Activation occurs as a result of thrombomodulin exposure to thrombin (via endothelial injury and glycocalyx disruption), with thrombin then binding, thereby preventing cleavage of fibrinogen (and formation of fibrin). This thrombomodulin–thrombin complex activates protein C, which then inhibits factors V and VIII, thus preventing further thrombin generation. This reduction in fibrin formation leads to decreased clot strength and, as a result, increased bleeding. Endothelial injury lead activation of protein C also consumes plasminogen activator inhibitor-1 (PAI-1). PAI-1 serves as the major antagonist of tissue plasminogen activator, when considered as a whole, the activation of protein C leads to decreased clot formation by direct factor inhibition and promotion of clot breakdown (fibrinolysis).

Hypothermia

The presence of hypothermia will potentiate the effects of TIC. The creation of clot occurs during a series of enzymatic reactions that are temperature sensitive. For every drop in the body temperature by 1°C, there is a 10% reduction in coagulation factor activity. Hypothermia is categorized as mild (temperatures <32°C to 36°C), moderate (28°C to 32°C), or severe (20°C to 28°C). Studies have shown that temperatures less than 33°C will reduce the coagulation factor activity below 33%, and will also alter the fibrin kinetics. Hypothermia also functions to directly inhibit the interaction of platelet surface proteins with von Willebrand factor, as well as reducing the rate of thromboxane B2 production. It is paramount that all traumatically injured patients are warmed to normal temperature in a timely fashion. Expedited removal of wet clothing, prophylactic placement of warming blankets, and maintaining a warm trauma bay/resuscitation room will help to mitigate the influence of hypothermia on TIC.

Acidosis

Acidosis is another factor that will accelerate the negative effects of TIC. Metabolic acidosis is the result of tissue hypoperfusion (shock) and the subsequent oxygen debt in tissues. Therefore the mechanisms and pathways responsible for coagulopathy after injury are also responsible for acidosis, which markedly worsens the coagulation insult. At a pH of 7.2, the activation of thrombin is reduced by 50%, and at a pH of 6.8, it is reduced by 90%. Because of changes to the platelet structure at a pH of less than 7.1, platelet aggregation is impaired by 50%. Restoration of pH to normal or near normal levels allows the patient's own homeostatic mechanisms of acid base regulation to again assume their vital function.

In situations of severe acidosis, some authors have advocated the use of acid buffers such as tris(hydroxymethyl)aminomethane (THAM) and sodium bicarbonate. THAM is a weak base providing a temporary buffer to the extracellular fluid through the acceptance of hydrogen ions. Unlike sodium bicarbonate, its effects are observed even when carbon dioxide elimination is impaired. THAM rapidly restores pH and acid base regulation, resulting in reversal of acidosis-related coagulopathy and cardiac dysfunction. Sodium bicarbonate, whereas also effective in rapidly changing a patient's pH, generates free CO_2 and paradoxically aggravates acidosis when CO_2 elimination from tissues or lungs is hindered (e.g., hemorrhagic shock). Although administration of bicarbonate or THAM will both increase the pH in the traumatically injured patient, neither addresses the underlying cause of acidosis. Given these limitations and knowing that early correction of the underlying cause of the acidosis is paramount to slow

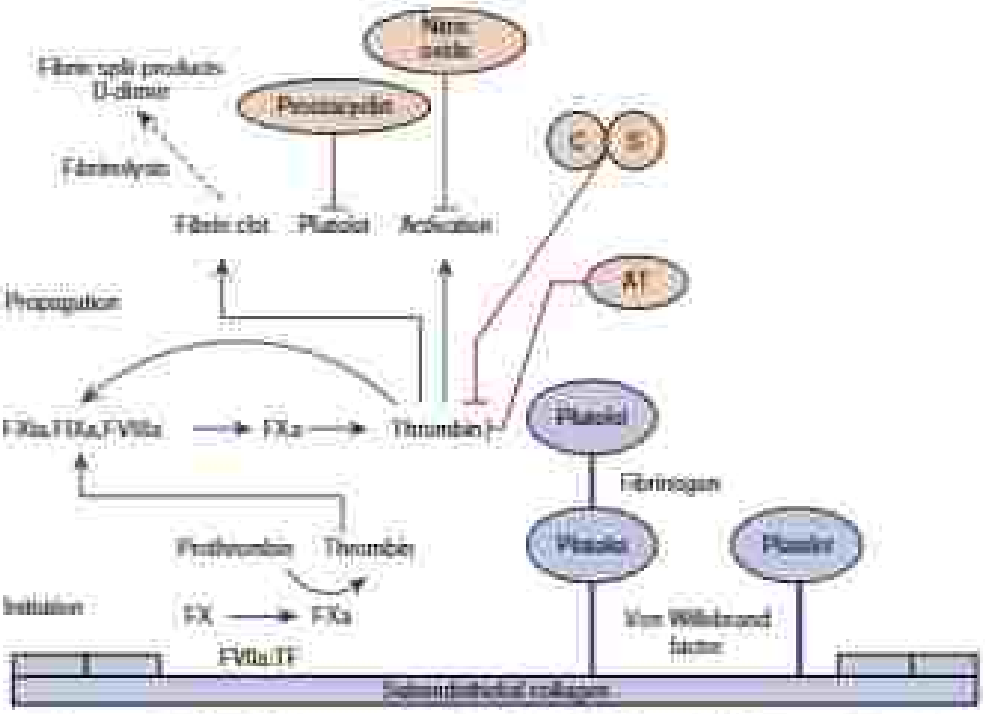

FIG. 1 Normal hemostasis. Hemostasis is initiated by the exposure of subendothelial collagen, which initiates activation of the coagulation cascade through tissue factor (TF) and factor VIIa (FVIIa). Subsequent production of small amounts of thrombin results in propagation and amplification of the coagulation response, leading to fibrin clot formation and platelet activation. Collagen exposure also triggers platelet adhesion and aggregation through interactions with von Willebrand factor (adhesion) and fibrinogen (aggregation). The endogenous anticoagulants protein antithrombin (AT) and the protein C (C)/protein S (S) complex, inhibit thrombin activity and generation, and prostacyclin and nitric oxide inhibit platelet function. The fibrinolytic system degrades fibrin clot, into fibrin degradation products such as D-dimers. FVIIa, Activated factor IX; FVIIIa, activated factor VIII; FIX, factor IX; FIXa, activated factor X; FXa, activated factor Xa.

the progression of TIC owing to acidosis, plasma is the ideal resuscitation fluid to correct both acidosis and coagulopathy. Plasma is an excellent buffer solution with a fivefold higher buffering capacity than crystalloids. In addition to its high citrate content (which makes it ideal for the resuscitation of severe acidosis from shock), plasma contains all necessary clotting factors and countless microparticles, and has been shown to protect and reestablish endothelial vascular integrity by stabilizing the endothelial glycocalyx, limiting coagulopathy progression (Fig. 2).

Hypocalcemia

Calcium functions as a cofactor in the enzymatic regulation of coagulation factors II (prothrombin), VII, IX, and X, facilitating the binding of these factors to the membranes of activated platelets. Calcium also plays a direct role in the stabilization of clots, the polymerization of fibrin, and platelet aggregation and activity. A lack of calcium will lead to impaired clot formation and propagation of TIC. The goal ionized calcium for resuscitating trauma patients is greater than 0.9 mmol/L. The presence of citrate in both fresh frozen plasma (FFP) and packed red blood cells (PRBCs) will also deplete calcium stores. To adequately resuscitate traumatically injured patients, one must maintain normal levels of calcium to facilitate hemostasis.

DIAGNOSIS OF TRAUMA-INDUCED COAGULOPATHY

Conventional Coagulation Tests

Classically, there were five plasma-based conventional coagulation tests (CCTs) that were utilized to identify TIC: international normalized ratio (INR), prothrombin time (PT), activated partial thromboplastin time (aPTT), platelet count, and fibrinogen levels. PT and partial thromboplastin time (PTT) were originally developed and validated to evaluate and treat patients with hemophilia and those who were on anticoagulant therapy. PT directly reflects the extrinsic pathway, specifically the activity of factor VII, whereas PTT assesses the intrinsic pathway, analyzing the activity of factors XI, IX, and VIII. The activity of factors X, V, and II, otherwise known as the common final pathway, is reflected by both the PT and PTT. Classically, an INR greater than 1.2 and/or an aPTT longer than 30 seconds was associated with TIC. The group out of Denver has shown that for patients requiring massive transfusion (>10 RBCs/first 6 hours), 2% had a prolonged INR (>1.3), 13% had an elevated aPTT (>30 sec onds), and 72% had combined abnormalities of INR and aPTT. Interestingly, 13% of these patients had normal INR and aPTT.

The benefit to CCTs is that physicians are familiar with ordering them and are comfortable interpreting their results. However, there are countless flaws when evaluating and treating TIC. First, these tests were never developed with TIC in mind; they were developed to guide therapy for patients with hemophilia and those anticoagulated with heparin or warfarin. Guidelines that were developed for resuscitation based on CCTs were targeted toward management of elective general surgery patients, rather than severely injured trauma patients. Timely intervention for TIC is necessary to prevent further complications, and the turnaround time to get results from CCTs is prolonged. One can only resuscitate based on clinical evaluation when waiting for the results from CCTs, flying blindly until the labs are run. Moreover, as these tests are typically run on a machine remote from the patient, the results reflect where the coagulation status was some time ago, rather than where the patient's coagulation is now. With respect to platelet count and fibrinogen count, these tests simply provide a quantitative assessment of each component, and do not tell the surgeon about the functional status (which is what determines performance of each in clot formation) of the patient's platelets and fibrinogen. Finally, these

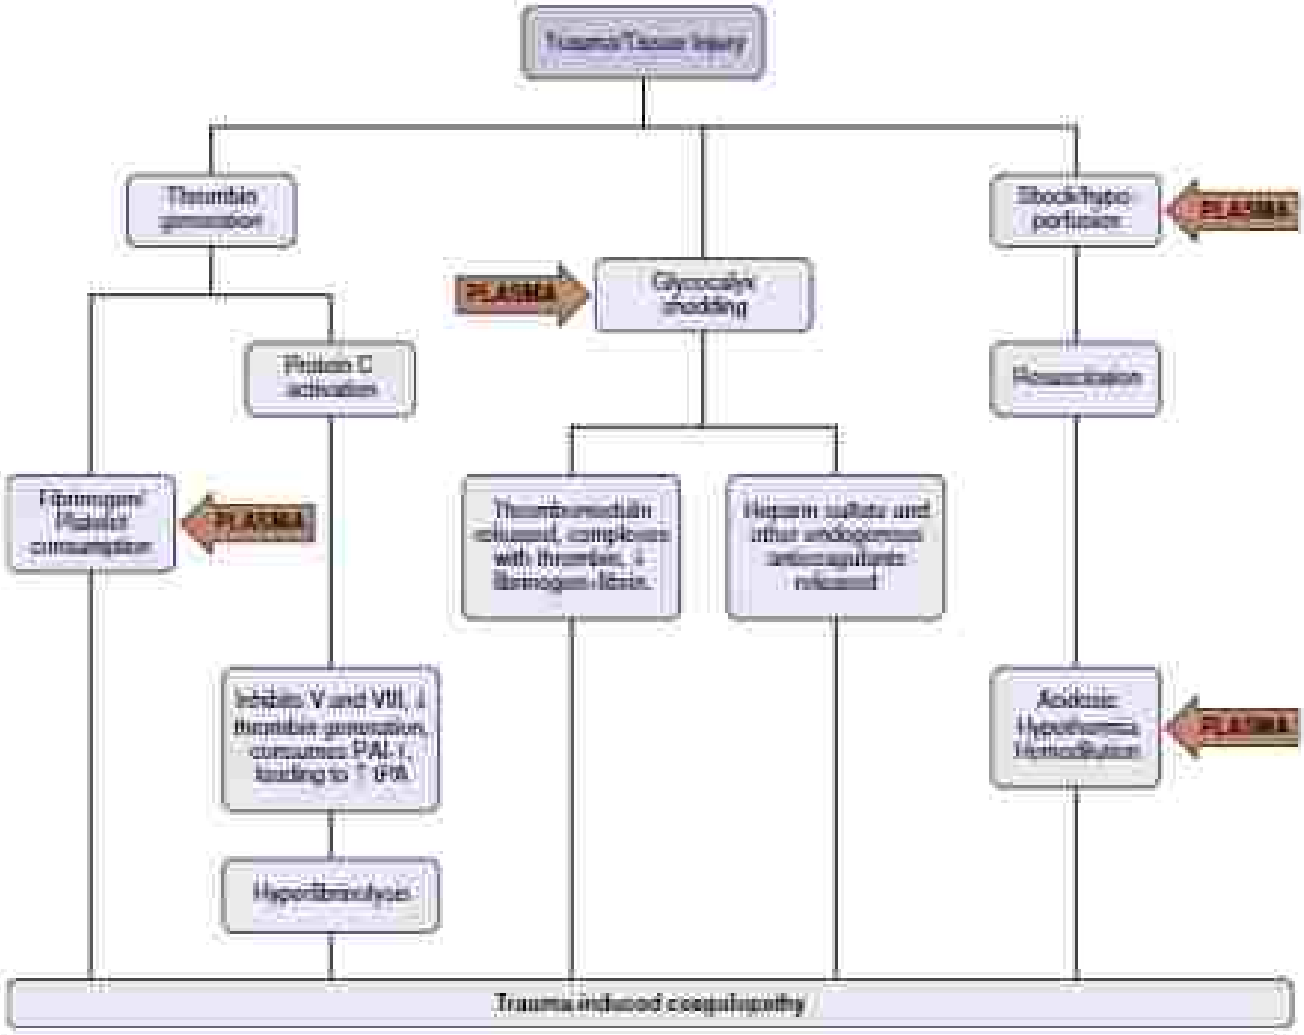

FIG. 2 Development of trauma-induced coagulopathy (TIC) through initial tissue insult, hypoperfusion, consumption, and activation of endogenous anticoagulants. The red arrows demonstrate points along the pathway where early transfusion of plasma can resuscitate the patient from shock, reinstitute the endothelial glycocalyx, prevent consumptive coagulopathy, and address severe acidosis, all of which may improve/reverse TIC. PAI-1, Plasminogen activator inhibitor-1; tPA, tissue plasminogen activator.

test are run down on specimens that have been spun down, generating a plasma only sample for which to assess clotting function. Given the contribution of the other blood components (RBCs, platelets, etc.), these plasma only specimens fail to account for the true hemostatic potential and deficits of the patient's blood in a bleeding scenario. Although moderate prolongations to the INR and aPTT are associated with TIC, there are better qualitative and quantitative evaluations of the coagulation system of the traumatically injured patient.

Thromboelastography

Thromboelastography (TEG) was initially conceived in Germany in 1948 and was applied in Europe during the 1950s to evaluate the coagulation system during liver transplantation. The first article published in the United States using TEG was from 1958 by Henry Swan at the University of Colorado characterizing the effects of hypothermia and cardiopulmonary bypass during cardiac surgery. TEG functions by taking a whole blood (WB) sample, approximately 360 µL, placing it in a cylindrical plastic cup and having the cup oscillate while a pin on a torsion wire is suspended in the sample. As the fibrin strands of the clot develop, the resistance built up couples the pin to the motion of the cup. As clot strength increases, more rotation energy is transmitted to the wire and detected by the electromagnetic transducer. The signal from the transducer is then interpreted by the TEG software, which then characterizes the development of the clot. The strength of the clot is reflected by the distance to the limit on the tracing, reflecting the firmness with which the cup is bound to the pin. Once the clot is broken down, or undergoes lysis, the tracing reflects the subsequent decrease in amplitude as the binding of the cup to the pin. TEG software allows for real time interpretation of clot dynamics as the clot develops and subsequently breaks down (Fig. 3).

Conventional (standard) TEGs are run with the addition of kaolin to start the clotting process (calcium is also added to recalcified samples). Rapid TEGs (rTEG) are an accelerated version that uses both kaolin and tissue factor to activate the clotting process. The inclusion of tissue factor accelerates the development of the clot and allows for earlier analysis of clot formation, and mimics the exposure of the clotting system to injured endothelium and tissue factor. For standard TEG, the traditional reaction time (R time) is the time to clot initiation, representing the status of clotting factors and/or the effects of anticoagulants. Normal values for the R time with standard TEG are 4 to 8 minutes. TEG ACT is the activated clotting time (CT) for the rTEG, with normal values ranging from 88 to 120 seconds. The K time (normal range, 1 to 2 minutes with rTEG and 1 to 3 minutes with standard TEG) is the time needed to reach 20 mm clot strength; this is generally increased in states of

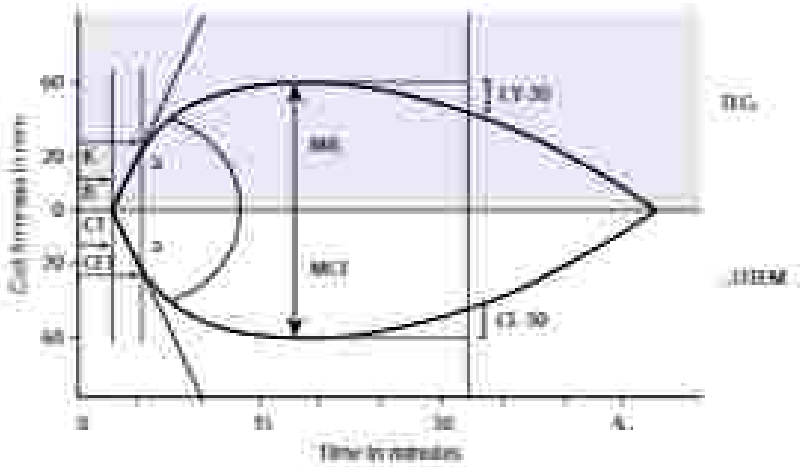

FIG. 3 A side-by-side comparison of the overlapping features of thrombelastography (TEG) and rotational thromboelastometry (ROTEM). Although nearly all values are describing the same coagulation defect, their names differ with respect to some variables. The initial clot formation is represented as R time for kaolin TEG, activated clotting time for rapid TEG (rTEG), and clotting time (CT) for ROTEM. Clot kinetics assessed as time to clot firmness of 20 mm are represented as K time for TEG and rTEG and clot formation time (CFT) for ROTEM. Acceleration of clot formation and fibrinogen contribution are expressed as α angle for all three tests. The maximal firmness of the clot and assessment of platelet function (and fibrinogen to a lesser degree) are represented as maximal amplitude (MA) for TEG and rTEG and maximal clot firmness for ROTEM. The lysis of the clot assessed as percent reduction 30 minutes after achieving MA or maximum clot firmness is expressed as lysis at 30 (LY30) and clot lysis at 30 (CL30).

hypofibrinogenemia. The α angle (normal range 53 to 78 degrees) is the slope of the tracing that represents the rate of clot formation. The α angle is decreased with hypofibrinogenemia or platelet dysfunction. The maximal amplitude (MA; normal range, 54 to 69 degrees) is the greatest amplitude of the tracing and reflects platelet contribution to clot strength. Low MA values correspond with states of platelet dysfunction or hypofibrinogenemia. The G value (normal range, 5kIII to 10,900 dynes/cm^2) is a global measure of the absolute clot strength (both enzymatic and platelet contributions) and is decreased in hypocoagulable states. Lysis index 30 (LY 30) (normal range, 0 [0%–2.5% to rTEG and 0%–15% to standard] is the percent amplitude reduction at 30 minutes after MA, and when elevated reflects a state of hyperfibrinolysis. CCT are unable to assess fibrinolysis and this aspect is one of the keys to the superiority of TEG over CCT for diagnosis and treatment of TIC.

The superiority of TEG over CCT was documented by Cotton and colleagues starting in 2011, in which they showed that over a 5-month period evaluating 272 trauma activations that when comparing CCT to TEG, TEG provided real time results available in minutes, was able to predict who was going to need massive transfusion and was predictive of who would need blood product transfusion. The same group then showed that the change for rTEG was similar to the five CCTs ($317 vs $786) but gave faster, more accurate results. They concluded that admission CCTs can be replaced with rTEG.

Rotational Thromboelastometry

Rotational thromboelastometry (ROTEM) provides similar information to TEG when used to diagnose and treat TIC, yet the mechanism and graphs of ROTEM differ in those from TEG (Fig. 3). ROTEM, like TEG, provides information on the time to clot initiation, the kinetics of clot growth, clot strength, and breakdown of the clot. Similar to TEG, a timed sample is placed in a cup into which a pin is introduced. ROTEM differs from TEG in that the pin rotates through an angle of 4.75 degrees, whereas with TEG the cup rotates. The rotating pin then initiates the clot formation process, and the ROTEM software produces the functional clotting graphs. The TEG produces just one tracing for the clot; ROTEM, however, produces five: intrinsic activation (INTEM), extrinsic activation (EXTEM), fibrin component of the clot (FIBTEM), aprotinin addition (a fibrinolysis inhibitor used with EXTEM) (APTEM), and the HEPTEM (includes the addition of heparinase to remove the influence of heparin on the clot). Each of these four graphs provides an insight into the development of the clot. The INTEM corresponds to the activation of the intrinsic clotting pathway, utilizing ellagic acid addition as the activator for clot formation. EXTEM corresponds to the activation of the extrinsic clotting pathway utilizing tissue factor as the activator to activate clot formation. Both tests by default evaluate the common final pathway too. The purpose of the FIBTEM is to isolate fibrinogen function via the addition of cytochalasin D, a potent platelet inhibitor. This leaves only the clotting proteins to identify the contribution of functional fibrinogen to clot formation. APTEM excludes the influence of fibrinolytic proactivity via the addition of aprotinin. The addition of heparinase to the HEPTEM allows for identification of coagulopathy when a patient is fully heparinized. The utility of the HEPTEM for trauma is minimal, unless the patient is actively being heparinized.

CT corresponds to the patient's ability to generate thrombin resulting in the onset of clot formation, normal if less than 80 seconds. Clot formation time reflects the time from initiation of clotting until a clot firmness of 20 mm is detected. This represents the fibrin polymerization and stabilization of the clot, normal if 30 to 110 seconds. The α angle is the angle at which the clotting curve achieves 2 mm off of its baseline, representing the initial development of clot. Normal value for the α angle is 70 to 83 on INTEM, and 63 to 83 on EXTEM. Amplitude 10 (A10), amplitude 20 (A20), and maximum clot firmness (MCF) reflect the firmness and stability of a clot owing to the interaction of platelets, fibrin, and factor XIIIa. Normal A10 and A20 is 44 to 71 mm. Normal MCF is 50 to 72 mm. LY 30 is a representation of clot lysis after 30 minutes from CT. More useful is the maximum lysis (ML), which is the percentage of maximum breakdown of clot. ML less than 15% is considered to be normal fibrinolysis. ML greater than 15% reflects hyperfibrinolysis.

The majority of the literature supporting the use for ROTEM in the treatment and diagnosis of trauma is from Europe. Multicenter studies have been undertaken showing the ability of diagnosing and treating TIC using ROTEM; however, they suffer from lack of patients enrolled. The superiority of TEG versus ROTEM has not specifically been studied; however, the volume of literature with TEG is large and founds greater than ROTEM.

Treatment of Trauma-Induced Coagulopathy

Thrombelastography-Guided

Paramount to the identification of and treatment of TIC is obtaining a TEG at the time of admission. The rTEG allows for identification of coagulopathy in less than 5 minutes, however, standard TEG will also do this but in 10 minutes. Either way, a prolonged ACT longer than 120 seconds or R time longer than 9 minutes reflects prolonged factor deficiency or severe hemodilution (Table 1). Do treatment for this is resuscitation with FFP. A prolonged K time greater than 2.5 minutes reflects the lack of fibrinogen or platelet dysfunction, requiring resuscitation with plasma and/or cryoprecipitate. A depressed α angle (<50) is associated with lack of fibrinogen and/or platelet dysfunction. Correction of this requires transfusion of cryoprecipitate. A decreased MA less than 55 mm is associated with platelet dysfunction and is an indication for transfusion of platelets. Hyperfibrinolysis is suggested by an LY 30 greater than 3%, which is treated with tranexamic acid (TXA) if identified in less than 3 hours from the time of injury. Standard kaolin TEG value thresholds are similar to those of rTEG, yet do require some modification (Table 1). Once abnormalities are identified, they should be corrected and repeat rTEG or TEG needs to be undertaken after resuscitation to ensure correction of coagulopathy.

Rotational Thromboelastometry-Guided

When using ROTEM to guide the identification of and treatment of TIC, specific aspects of the graphs that are produced are useful. Prolongation of the CT, more than 240 INTEM and more than 100 EXTEM, is an indication for transfusion of FFP. As with the ACT or R time, this is a reflection of prolonged factor deficiency or severe hemodilution. A depressed α angle is associated with lack of fibrinogen and/or

TABLE 1 Recommended Thresholds for Treatment of Thrombelastography Values in the Injured Patient Among Different Institutions and Different Thrombelastography Formats

Value	Interpretation	Treatment
rTEG PARAMETERS AT THE RED DUKE TRAUMA INSTITUTE		
ACT >120 seconds	Prolonged with factor deficiency, severe hemodilution	Plasma
K time >2.5 minutes	Prolonged in hypofibrinogenemia + platelet dysfunction	Plasma + cryoprecipitate
α angle <65 degrees	Decreased in hypofibrinogenemia or platelet dysfunction	Cryoprecipitate/fibrinogen concentrate
Maximal amplitude <55 mm	Decreased with platelet dysfunction + hypofibrinogenemia	Platelets + cryoprecipitate
LY 30 >3%	Increased with accelerated fibrinolysis	Tranexamic acid
nTEG PARAMETERS AT DENVER GENERAL/DENVER HEALTH		
ACT >120 seconds	Prolonged with factor deficiency, severe hemodilution	Plasma
α angle <65 degrees	Decreased in hypofibrinogenemia or platelet dysfunction	Cryoprecipitate
Maximal amplitude <55 mm	Decreased with platelet dysfunction + hypofibrinogenemia	Platelets
LY 30 >3%	Increased with accelerated fibrinolysis	Tranexamic acid
STANDARD KAOLINTEG PARAMETERS AT THE RED DUKE TRAUMA INSTITUTE		
R time >9 minutes	Prolonged with factor deficiency, severe hemodilution	Plasma
K time >2 minutes	Prolonged in hypofibrinogenemia + platelet dysfunction	Plasma + cryoprecipitate
α angle <60 degrees	Decreased in hypofibrinogenemia or platelet dysfunction	Cryoprecipitate/fibrinogen concentrate
Maximal amplitude <52 mm	Decreased with platelet dysfunction + hypofibrinogenemia	Platelets + cryoprecipitate
LY 30 >8%	Increased with hyperfibrinolysis	Tranexamic acid
ROTEM PARAMETERS AT THE UNIVERSITY OF ARKANSAS FOR MEDICAL SCIENCES		
INTEM CT ≥240 or EXTEM CT ≥100 seconds	Prolonged with factor deficiency, severe hemodilution	Plasma
FIBTEM A10 <10 mm	Decreased in hypofibrinogenemia or platelet dysfunction	Cryoprecipitate/fibrinogen concentrate
FIBTEM A10 >10 mm and EXTEM A10 <46 mm	Platelet dysfunction	Platelets
EXTEM ML >15%	Increased with hyperfibrinolysis	Tranexamic acid

ACT, activated clotting time; CT, clotting time; EXTEM, extrinsic activation, FIBTEM, fibrin component of the clot; INTEM, intrinsic activation; LY 30, lysis index 30; ML, maximum lysis; rTEG, rapid TEG; ROTEM, rotational thromboelastometry; TEG, thrombelastography.

or platelet dysfunction. Correction of this requires transfusion of cryoprecipitate and platelets. A depressed A10, A20, or MCF identified on INTEM, EXTEM, or FIBTEM reflects dysfunctional platelets. A20 less than 40 on INTEM or EXTEM requires the transfusion of platelets. If the corresponding FIBTEM A10 less than 7, that equates to dysfunctional platelets as well as fibrinogen, requiring transfusion of platelets and cryoprecipitate. Hyperfibrinolysis is reflected by an ML greater than 15% on INTEM, EXTEM, or FIBTEM. If identified in less than 3 hours from the time of injury, the use of TXA is indicated. As with TEG-based resuscitation, repeat ROTEM is necessary to ensure correction of coagulation abnormalities.

Conventional Coagulation Test–Guided

Resuscitation of TIC based on CCTs, while still done today, is less precise, takes more time, and is unable to identify hyperfibrinolysis. Clinically, the threshold of INR greater than 1.2 was an indication for resuscitation with plasma, as was an aPTT longer than 30 seconds. Based on complete blood count evaluation, platelet count less than 100,000 for diffuse bleeding and less than 50,000 for microvascular bleeding were indications for platelet transfusion. Hypofibrinogenemia (< 229 mg/dL) was identified as the threshold at which to transfuse cryoprecipitate. Cryoprecipitate contains 150 to 250 mg of fibrinogen in a 15- to 20-mL unit. Each unit of cryoprecipitate should raise the fibrinogen level by 10 mg/dL. There is no CCT for the evaluation of hyperfibrinolysis, but some centers use D-dimer as a surrogate and/or give antifibrinolytics empirically when TEG or ROTEM are not available. Conventional wisdom would suggest that continued bleeding in light of adequate resuscitation and bleeding control may be owing to hyperfibrinolysis. If less than 3 hours from the time of injury, TXA could be used to potentiate the hyperfibrinolysis. However, extreme caution should be used in the early care of coagulopathic trauma patients as TXA has been shown to be harmful when administered more than 3 hours from the time of injury.

PRODUCTS AND ADJUNCTS FOR TREATING TRAUMA-INDUCED COAGULOPATHY

Whole Blood

WB was first implemented successfully during World War I, with over 1 million units of WB transfused when factoring in all the conflicts since then, including the Global War on Terror. Similarly, WB was the go-to product for civilian hemorrhagic shock resuscitation until the mid-1970s, when, alongside dramatic advances in blood component separation, blood centers were able to supply hospitals with individual components and the availability of WB decreased rapidly. Unfortunately, this occurred without any data supporting downgrading resuscitation products from WB to component-based therapy in hemorrhagic shock. In recent military conflicts, the transfusion of fresh, warm WB was associated with increased 24-hour and 30-day survival when compared with balanced component therapy. As well, a randomized trial from Cotton and colleagues demonstrated that civilian trauma patients resuscitated with WB achieved better hemostasis and required less blood products than those resuscitated with even 1:1:1 component therapy (plasma/platelets/RBCs). When patients are bleeding, they are bleeding WB, not just random ratios of components. Resuscitation with WB is superior in light of the fact that each 500 mL unit has a hematocrit of 38% to 50%, 150,000 to 400,000 platelets per microliter with full activity, and 100% activity of clotting factors (Table 2).

With the development and implementation of cold-stored WB programs in the military at several United States centers, the safety and efficacy of low-titer group O (LTO) WB is being demonstrated. With this new universal product alternative, an increasing number of trauma centers and aeromedical programs have adopted LTO-WB into their early resuscitation of hemorrhagic shock. Given our previous evidence of clinical utility, hemostatic benefit, and safety, our institution implemented a cold-stored LTO-WB program in 2017. We currently keep WB on our trauma bay and on our aeromedical transport services.

TABLE 2 Comparison of Component Therapy and a Single Cold-Stored Whole Blood Unit With Respect to Content and Volume

	Component Therapy (1:1:1)*	Whole Blood
Hematocrit (%)	29%	39%
Platelet count	80,000 to 96,000 per μL	150,000 to 250,000 μL
Coagulation factor activity (%)	≤30% to ≤35%	85% to 100%
Fibrinogen	240 to 400 mg	1000 mg
Total volume	625 mL	450 mL

*1 unit plasma, 1 unit platelets, 1 unit red blood cells.

We limit the transfusion of LTO-WB to 4 units, unless we are able to demonstrate the blood type and Rh status of the individual. Following these units, non-group O patients are transitioned to type-specific component therapy. Any patient who receives LTO-WB has a daily hemoglobin panel obtained for the first 48 hours postadmission. If this panel suggests hemolysis or clinical transfusion reaction is identified, a direct antiglobulin test is ordered and performed by the blood bank.

With respect to whether to administer Rh− or Rh+ product to patients initially, much of this has to do with concern of the rare but potentially fatal isoimmunization risk in women of childbearing age. The current practice of most centers and the recommendations of the AABB are for the use of Rh− in women younger than 50 years (and often male children as well) and Rh+ in men. However, as with RBC transfusions, the risk of hemolytic transfusion reaction and Rh-related complications are likely overstated and much less common than that observed in the nontrauma, nonbleeding setting. First, approximately 85% of patients are Rh+, and 70% of trauma patients are male (and many female trauma patients are older than 50 years). In addition, the 10% to 40% immunization reported from Rh isoimmunization in the nontrauma setting is only 20% to 30% risk in the severely immunosuppressed setting of trauma and hemorrhagic shock. Moreover, the conversion rate (development of anti-D antibodies from Rh incompatibility) varies in the literature from 3% to 30%, and options exist for lowering this even further in women of childbearing age (Rh immunoglobulin therapy and/or exchange transfusion therapy). Therefore the risk/benefit ratio appears to favor using Rh+ products in all patients, regardless of age or sex.

Red Blood Cells

RBCs are generally considered the initial product of choice in the bleeding trauma patient (as with gastrointestinal bleeds, obstetrical hemorrhage, etc.). However, the majority of trauma patients are not extremely anemic on presentation and the oxygen-carrying capacity of most individuals is initially adequate. Therefore in centers without WB immediately available, we would recommend beginning resuscitation with plasma, then adding RBCs to the regimen after the first 2 to 3 units are transfused (or simultaneously with RBCs when using a rapid infuser). That said, RBCs do improve tissue perfusion and oxygenation and do actively contribute to the coagulation cascade. The surface of RBCs expresses phosphatidyl serine that assists in the process of thrombin generation. In addition, through elongation, RBCs displace platelets to the periphery of the vessel, increasing contact with the injured vessel and exposed tissue, thereby facilitating adhesion and the subsequent interactions of platelets, glycoproteins, and endothelium.

With respect to anemia, transfusion of RBCs is necessary, and although lower hemoglobin values are recommended in the nonbleeding patient, most would transfuse RBCs to keep the patient's hemoglobin at 10 g/dL while actively bleeding. This transfusion of RBCs is usually begun with universal, uncrossmatched product to

the form of group O blood. Current guidelines recommend using Rh– in women younger than 50 years (and male children as well) and Rh+ in men. As soon as the patient arrives, a type and screen should be sent along with the activation of the massive transfusion protocol. Type specific blood can be made available in 10 minutes, whereas fully crossmatched blood may take 40 minutes or more to prepare.

Plasma

As stated earlier, plasma may be the ideal resuscitative agent in the absence of WB. Plasma is a strong acid–base buffer (fivefold higher capacity than crystalloids, fivefold higher than albumin), an excellent volume expander (smooth, quiet, and contains all necessary clotting factors and numerous involved immunoparticles. In addition, it has the potential to reverse or attenuate endothelial injury from shock.

There are two critical logistical considerations to making this nearly ideal transfusion product more immediately available. First, many centers do not keep this product ready for immediate transfusion. It is often kept frozen until requested, and then thawed. This process can take between 20 and 40 minutes to be made available for transfusion. Understanding that time is critical to saving the lives of bleeding patients, many centers have begun to keep thawed plasma available in their emergency departments or blood banks. However, once thawed, the product only has a 5 day shelf life. To address this, some centers have transitioned to liquid (never frozen) plasma. In addition, to the absence of temperature injury to plasma proteins, this product has a 21- to 24-day shelf life. Second, although blood group AB plasma is the universal donor for emergency settings, several investigators have demonstrated that plasma with low anti-B titers can be safely used as a universal product while awaiting delivery of type specific plasma. As such, both of our centers currently employ low titer group A liquid plasma as our emergency release, universal plasma option.

Platelets

Although they are usually a late transfusion consideration, platelets are critical to hemostasis and to nearly every component of the coagulation cascade. In the setting of noncranial coagulopathy, absolute platelet counts less than 100,000/μL have been identified as thresholds below which diffuse or "medical" bleeding occurs. However, from a quantitative rather than qualitative standpoint, it is usually at much lower counts (<50,000 to 40,000/μL) that one sees such diffuse bleeding in the trauma setting. However, as with hemoglobin thresholds in the actively bleeding patient, we would recommend maintaining platelet counts in the hemorrhagic shock patient at or near 100,000/μL, especially in those with concurrent traumatic brain injury. Platelet transfusions should be part of a center's massive transfusion protocol and should be employed early, alongside that of plasma and RBCs. In fact, some have argued that the immediate transfusion of platelets in both arms of the PROPPR (Prospective, Randomized Optimal Platelet and Plasma Ratios) trial resulted in the nonstatistically significant findings. A standard dose of apheresis platelets contains ≥ 6 to 8×10^{11} platelets and will typically increase the platelet count by 30,000 to 60,000/μL. However, our centers primarily utilize viscoelastic testing (MA in TEG and MCF in ROTEM) to guide platelet transfusions.

Fibrinogen/Cryoprecipitate

Historically, hypofibrinogenemia has been common in patients with massive blood loss, regardless of trauma, obstetrical, or gastrointestinal origin. Although much of this may have been related to poor resuscitation techniques (large volume crystalloid and RBCs early, with plasma late), some of this is because of the consumption of fibrinogen in patients with severe hemorrhage. Also, as with platelets, the function of available fibrinogen is likely more important to hemostasis than the actual fibrinogen value. That said, fibrinogen values less than 200 in the bleeding patient are associated with significant increases in mortality. The qualitative state, or fibrinogen function, can be monitored using conventional laboratory assays such as the Clauss fibrinogen assay or with viscoelastic testing (TEG or ROTEM). Fibrinogen as a product is available in plasma (approximately 800 mg per unit dose), in cryoprecipitate (1500 mg or more per dose), or in fibrinogen concentrate. Cost has made cryoprecipitate the product of choice in the United States, whereas transfusion related complications have made fibrinogen concentrate (virally inactivated human fibrinogen) more common in Europe. Cryoprecipitate is usually delivered in a 10 unit dose, delivering 1500 mg per bag. Many recommendations suggest 10 to 20 units in standard sized adults to increase the fibrinogen level by 100 to 200 mg/dl.

Tranexamic Acid

TXA is a synthetic antifibrinolytic that blocks plasminogen from binding fibrin, and thus inhibits dissolution of the fibrin clot. The initial data from the CRASH 2 (Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage 2) trial showed that implementation of 1 g of TXA over 10 minutes, followed by 1 g TXA infused over 8 hours, was associated with increased survival when administered to traumatically injured patients or those with suspected hemorrhage. However, a more in-depth look at this trial shows the following: (1) the difference in bleeding related mortality was less than 1%, however, in a study with 20,000 patients, this was statistically significant (but perhaps not clinically meaningful; (2) the patients who most benefitted from TXA were with penetrating trauma, with severe hypotension (<75 mm Hg), and who received the drug within 1 hour of injury; and (3) patients receiving the drug after 3 hours were harmed by administration of TXA.

In the absence of empiric administration of TXA, identification of hyperfibrinolysis requires the implementation of ROTEM or TEG. Centers with experience with these viscoelastic tests generally use lysis of 3% to 5% as a trigger to administer TXA to their patients. The implementation of TEG and ROTEM, and deeper study into its use and measurements, has provided insight into the three distinct phenotypes of fibrinolysis: (1) hyperfibrinolysis (LY 30: >3%); (2) physiologic (LY 30: 0.08%–3.0%); and (3) shutdown (LY 30: <0.8). The majority of these data come from the work of groups in Denver, Miami, and Houston. Their works have shown that although the highest mortality rates are associated with hyperfibrinolysis, the shutdown group was associated with delayed death due to organ failure due to proinflammatory mechanisms.

When considering the use of TXA, it is important to take pause prior to empiric dosing. Given the three distinct fibrinolysis phenotypes, and specifically that the shutdown groups mortality was due to prothrombotic events, one can surmise that empiric use of a medication that will enhance thrombosis may lead to more deaths in the shutdown group. Mature trauma systems in which hemorrhage control can be achieved in a timely manner, and implementation of TEG or ROTEM to identify TIC and specifically the fibrinolysis phenotype, are the ideal places to optimize the use of TXA based on fibrinolysis status. Further research is necessary to identify whether or not empiric use of TXA is associated with worse outcomes. In light of all this, for the traumatically injured patient who is far from a center where hemorrhage control can be achieved, the empiric use of TXA, when given less than 3 hours from injury, may lead to improved outcomes.

Massive Transfusion Protocols

Protocolization of an institution's massive transfusion policy and delivery system has been shown to be as critical to improving survival as is the contents of that protocol. In fact, the PROPPR trial demonstrated that every 60 second delay in delivery of the initial massive transfusion cooler (from time of activation) was associated with a 3% increase in mortality, regardless of the ratio of products delivered. Therefore the ability to predict, early, who will require a massive transfusion is key to successful resuscitation and prevention of TIC. Current military casualty management utilizes the presence of *hostile* mental status, in the absence of head injury, and a normal radial pulse as two factors that are most predictive of need for transfusion and lifesaving intervention. The ABC (assessment of blood consumption) score was developed in a civilian trauma center, and

utilizes immediate vital signs and ultrasound to predict who will need massive transfusion. One point is given for the presence of each of the following: (1) positive FAST, (2) penetrating mechanism, (3) systolic blood pressure less than 90 mm Hg, and (4) heart rate greater than 120 beats/min. When considered, a score of 2 or greater, although having a tendency to overactivate the massive transfusion protocols (MTP), misses less than 5% of massive transfusion or substantial bleeding scenarios. This score has been validated in a multicenter trial and is a key component to identification of who will need MTP when ultrasound is available. The ABC score is used by our prehospital aeromedical personnel to trigger transfusion en route, by our hospital-based team to activate our institutional MTP, and has been used in multiple randomized trials as inclusion into those studies of hemorrhagic shock patients. Other centers utilize the shock index, which is calculated by dividing the heart rate by the systolic blood pressure. This is another useful tool to help facilitate early prediction of who will need MTP. For those patients with a shock index greater than 1, there is a high likelihood that they will need MTP. The key difference is that the shock index does not require the individual calculating the score to need an ultrasound. Anyone in the care team, be it prehospital or in the resuscitation bay, can calculate the shock index. A recent analysis by Dutton and colleagues showed that although the sensitivity of the ABC score for predicting the need for MTP was greater, both were successful at identifying patients who were at risk for needing MTP.

The breakdown of product allocation for massive transfusion continues to be a source of variation, although the PROPPR trial would suggest that 1:1:1 (plasma, platelet, RBC) is most likely to achieve hemostasis and have lower bleeding-related mortality. The PROPPR trial compared 1:1:1 versus 1:1:2 for patients predicted to need MTP. Although there was no overall difference in mortality, bleeding-related mortality (death from exsanguination) was less in the 1:1:1 group. As with previous studies, the majority of deaths owing to hemorrhage in either arm occurred in the first 3 hours from arrival. As such, the authors believe that en route resuscitation and early care should mimic the transfusion of WB and include products in a 1:1:1 ratio. Moreover, these products (WB, plasma, RBCs) should be immediately available in the emergency department and should be utilized and transfused as the hospital's MTP is being rushed for delivery to the patient.

Damage Control Resuscitation

Damage control resuscitation (DCR) is a strategy that focuses on three tenets: limiting crystalloids, delivering WB or high ratios of plasma and platelets, and maintaining permissive hypotension. This concept was first described in 2006, by a multidisciplinary team who endeavored to reduce morbidity and mortality from hemorrhage among injured soldiers. They set out to achieve this by replicating WB with higher ratios (and later using fresh, warm WB), avoiding "popping the clot," and minimizing the harm associated with crystalloid-based resuscitation. Recent research has shown that large volume crystalloid resuscitation is associated with worsening hypoxia, acidosis, and hypothermia. Crystalloid exacerbates the effects of TIC by diluting out the clotting factors and creating acidosis. The protective effect of permissive hypotension is the byproduct of randomized control trials that confirmed that delaying resuscitation to a normal blood pressure until after operative control of bleeding in both blunt and penetrating trauma was associated with improved mortality. A strict no prehospital fluid practice was also shown to increase survival in patients with penetrating trauma presenting with a systolic blood pressure less than 90 mm Hg. Those patients treated with permissive hypotension by delaying resuscitation had improved survival compared with those with immediate fluid resuscitation. The positive outcomes shown in both military and civilian trials of MTP using 1:1:1 in the final tenet of DCR.

The implementation of DCR has been associated with an almost 50% reduction in crystalloid use in certain centers. Other studies have shown a profound decrease in the morbidity from abdominal compartment syndrome, infection, organ failure, and death from hemorrhage in centers where DCR is practiced. The implementation of the three tenets of DCR is necessary to prevent the development of TIC and prevent mortality from hemorrhage.

Antiplatelet and Anticoagulant Management

The use of antiplatelet and anticoagulant agents continues to become increasingly common throughout the United States and around the globe. Moreover, their use is made even more apparent as the surgeon as the aging trauma population continues to grow rapidly. Although the bleeding associated with these agents do not technically result in TIC, their use in a patient who sustains injury may make the life-threatening bleeding unstoppable and quickly fatal. Available

TABLE 3 Agents to Restore/Improve Hemostatic Function in Patients Taking Antiplatelet and Anticoagulant Drugs

Reversal agent	Drug Indication	Mechanism of Reversal	Dosing
Platelet transfusion	Aspirin, clopidogrel, prasugrel	Provides unbound platelets to potentially restore function	Aspirin: 1 to 2 aphaeresis platelets Clopidogrel: 2 to 4 aphaeresis platelets
Desmopressin	Aspirin, clopidogrel, prasugrel	Improves platelet binding by stimulating release of vWF/FVIII from endothelium	One-time dose of 0.3 μg/kg
Vitamin K	Warfarin	Bypass warfarin's inhibition of vitamin K dependent coagulation factors	10 mg of vitamin K IV (infuse no faster than 1 mg/min)
Prothrombin complex concentrates	Warfarin	Replacement of vitamin K dependent coagulation factors	INR <4: 25 IU/kg INR 4 to 6: 35 IU/kg INR >6: 50 IU/kg
Prothrombin complex concentrates	Rivaroxaban, apixaban	Replacement of unbound factors II, VII, IX, and X	35–50 IU/kg
Idarucizumab	Dabigatran	Antibody binds, inactivates dabigatran	5 g IV (dosed in two 2.5 g infusions, 5 to 15 minutes apart)
Andexanet	Rivaroxaban, apixaban	Antibody binds, inactivates rivaroxaban, apixaban	Apixaban: 400 mg bolus, then 480 mg infusion/2 hours Rivaroxaban: 800 mg bolus, then 960 mg infusion/2 hours

INR, international normalized ratio; vWF, von Willebrand factor.

treatment (possible several agents) for bleeding issues in this patient population is illustrated in Table 1.

RECOMMENDED APPROACH TO TRAUMA-INDUCED COAGULOPATHY

Traumatically injured patients should be expedited to the nearest trauma center. Early evaluation for those at risk for needing MTP by either the ABC score or shock index is critical to stay ahead of and prevent or attenuate TIC. Adoption of and implementation of MTP that mimics WB in a 1:1:1 ratio is key to reducing filtered translusion and minimizing TIC. Utilization of the principles of DCR by limiting the use of crystalloid, allowing permissive hypotension, and balanced resuscitation of blood products will lead to a greater chance of survival. Warming fluids, warming resuscitation bays, and liberal use of warm blankets will go far to limit the influence of hypothermia on the development of TIC. Early identification of coagulation abnormalities within minutes of arrival via ROTEM or TEG is key to resuscitating and preventing the development of TIC. Serial evaluations of the coagulation via ROTEM or TEG for ongoing bleeding will tailor the resuscitation of blood products and/or cryoprecipitate to the treatment of TIC. Early hemorrhage control in either the operating or interventional radiology suite will prevent the development of further coagulopathy and minimize unnecessary transfusions.

The Abdomen That Will Not Close

Heidi N. Overton, MD, and Kent A. Stevens, MD, MPH

The principle of damage control has changed the practice of surgery dramatically over the past 2 decades and has become one of the central and dominant practices in trauma and acute care surgery. As a result, the morbidity and mortality associated with abdominal compartment syndrome (ACS), abdominal coagulopathy, hypothermia, acidosis, and a myriad of other resuscitative complications have been reduced dramatically. However, with all significant advances come new challenges. With the widespread practice of damage control surgery (DCS) and abbreviated laparotomy, surgeons must be prepared to manage an open abdomen with a temporary abdominal closure (TAC) as well as the abdomen that will not close.

This chapter reviews TAC techniques, management of patients with an open abdomen (OA), subsequent definitive closure of the abdomen, and long-term reconstruction options in patients who develop hernias resulting from OA management.

INDICATIONS FOR LEAVING THE ABDOMEN OPEN

Initially described by trauma surgeons, DCS is among the most common reasons for leaving an abdomen open. It was originally reserved for a traumatically injured subset of patients, defined as those with (1) at least one major vessel injury (e.g., inferior vena cava), (2) at least two visceral injuries, and (3) profound shock. Early results from DCS were very impressive, survival for such traumatically injured patients jumped from 11% to 77%, and use of DCS subsequently spread to less severely injured patients. However, many now believe that the pendulum has swung too far and, in some cases, the risks associated with leaving the abdomen open outweigh the benefits. Thus, patient selection is vital. In general, there are five distinct groups of patients in whom the abdomen should be acutely left open.

1. **Patients with or at risk of intraabdominal hypertension (IAH) and subsequent ACS.** This group includes patients undergoing major elective operations as those who will require massive resuscitation are at risk for primary ACS. Similarly, patients who require substantial resuscitation because of severe medical illness or trauma that requires abdominal decompression are at risk for secondary ACS and are included in this group.
2. **Patients after non-DCS.** This group includes patients undergoing DCS for massive abdominal trauma, such as a patient with a gunshot wound through a major vessel (e.g., renal artery), a solid organ (e.g., kidney), and multiple segments of bowel. Once the major vessel injury and solid organ injury have been controlled and spillage from the bowel injury contained, the patient may be too unstable for reconstruction of the bowel and closure of the fascia. In this case, DCS allows rapid truncation of laparotomy before the patient enters the "lethal triad" of hypothermia, acidosis, and coagulopathy. Once the damage has been controlled, the patient can be taken to the intensive care unit (ICU) for resuscitation and stabilization. It is important to decide on the need to perform DCS early on in the operation. Predictors of a patient's need for DCS include: temperature below 34°C, pH less than 7.2, estimated blood loss greater than 4 L, transfusion requirement of more than 10 units of packed red blood cells, systolic blood pressure less than 70 mm Hg, lactate levels greater than 5 mmol/L, base deficit greater than −6 in patients older than 55 years or greater than −15 in patients younger than 55 years, and/or prothrombin time greater than 1.6. DCS may also be required in patients undergoing elective general surgery with overwhelming blood loss or unexpected intraoperative findings that require further stabilization/resuscitation.
3. **Patients whose fascia cannot be closed.** This category includes patients who may be physiologically stable but have swollen abdominal contents from an ongoing resuscitation (e.g., DCS) or loss of fascial domain such that they cannot be closed primarily. Fig. 1 depicts a patient who required TAC while waiting for bowel edema to resolve. The latter example must be kept open until the patient is ready for a definitive closure with mesh or other modalities.
4. **Patients with severe intraabdominal infections or necrotizing fasciitis of the abdominal wall.** This includes patients with necrotizing pancreatitis, a soft tissue infection, or a large amount of purulent material in the abdomen requiring repeated washouts.
5. **Patients having a planned repeat exploration or second look surgery.** These are patients with intraabdominal pathology that require another laparotomy in the next 48 to 72 hours. For example, a vascular surgery patient with mesenteric ischemia who undergoes a small bowel resection, and 48 hours later needs to be reexplored to check for additional bowel ischemia.

treatment (possible several agents) for bleeding issues in this patient population is illustrated in Table 1.

RECOMMENDED APPROACH TO TRAUMA-INDUCED COAGULOPATHY

Traumatically injured patients should be expedited to the nearest trauma center. Early evaluation for those at risk for needing MTP by either the ABC score or shock index is critical to stay ahead of and prevent or attenuate TIC. Adoption of and implementation of MTP that mimics WB in a 1:1:1 ratio is key to reducing filtered translation and minimizing TIC. Utilization of the principles of DCR by limiting the use of crystalloid, allowing permissive hypotension, and balanced resuscitation of blood products will lead to a greater chance of survival. Warming fluids, warming resuscitation bays, and liberal use of warm blankets will go far to limit the influence of hypothermia on the development of TIC. Early identification of coagulation abnormalities within minutes of arrival via ROTEM or TEG is key to resuscitating and preventing the development of TIC. Serial evaluations of the coagulation via ROTEM or TEG for ongoing bleeding will tailor the resuscitation of blood products and/or cryoprecipitate to the treatment of TIC. Early hemorrhage control in either the operating or interventional radiology suite will prevent the development of further coagulopathy and minimize unnecessary transfusions.

The Abdomen That Will Not Close

Heidi N. Overton, MD, and Kent A. Stevens, MD, MPH

The principle of damage control has changed the practice of surgery dramatically over the past 2 decades and has become one of the central and dominant practices in trauma and acute care surgery. As a result, the morbidity and mortality associated with abdominal compartment syndrome (ACS), abdominal coagulopathy, hypothermia, acidosis, and a myriad of other resuscitative complications have been reduced dramatically. However, with all significant advances come new challenges. With the widespread practice of damage control surgery (DCS) and abbreviated laparotomy, surgeons must be prepared to manage an open abdomen with a temporary abdominal closure (TAC) as well as the abdomen that will not close.

This chapter reviews TAC techniques, management of patients with an open abdomen (OA), subsequent definitive closure of the abdomen, and long-term reconstruction options in patients who develop hernias resulting from OA management.

INDICATIONS FOR LEAVING THE ABDOMEN OPEN

Initially described by trauma surgeons, DCS is among the most common reasons for leaving an abdomen open. It was originally reserved for a maximally injured subset of patients, defined as those with (1) at least one major vessel injury (e.g., inferior vena cava), (2) at least two visceral injuries, and (3) profound shock. Early results from DCS were very impressive, survival for such maximally injured patients jumped from 11% to 77%, and use of DCS subsequently spread to less severely injured patients. However, many now believe that the pendulum has swung too far and, in some cases, the risks associated with leaving the abdomen open outweigh the benefits. Thus, patient selection is vital. In general, there are five distinct groups of patients in whom the abdomen should be acutely left open.

1. **Patients with or at risk of intraabdominal hypertension (IAH) and subsequent ACS.** This group includes patients undergoing major elective operations as those who will require massive resuscitation are at risk for primary ACS. Similarly, patients who require substantial resuscitation because of severe medical illness or trauma that requires abdominal decompression are at risk for secondary ACS and are included in this group.
2. **Patients undergoing DCS.** This group includes patients undergoing DCS for massive abdominal trauma, such as a patient with a gunshot wound through a major vessel (e.g., renal artery), a solid organ (e.g., kidney), and multiple segments of bowel. Once the major vessel injury and solid organ injury have been controlled and spillage from the bowel injury contained, the patient may be too unstable for reconstruction of the bowel and closure of the fascia. In this case, DCS allows rapid truncation of laparotomy before the patient enters the "lethal triad" of hypothermia, acidosis, and coagulopathy. Once the damage has been controlled, the patient can be taken to the intensive care unit (ICU) for resuscitation and stabilization. It is important to decide on the need to perform DCS early on in the operation. Predictors of a patient's need for DCS include: temperature below 34°C, pH less than 7.2, estimated blood loss greater than 4 L, transfusion requirement of more than 10 units of packed red blood cells, systolic blood pressure less than 70 mm Hg, lactate levels greater than 5 mmol/L, base deficit greater than −6 in patients older than 55 years or greater than −15 in patients younger than 55 years, and/or prothrombin time greater than 1.6. DCS may also be required in patients undergoing elective general surgery with overwhelming blood loss or unexpected intraoperative findings that require further stabilization/resuscitation.
3. **Patients whose fascia cannot be closed.** This category includes patients who may be physiologically stable but have swollen abdominal contents from an ongoing resuscitation (e.g., DCS) or loss of fascial domain such that they cannot be closed primarily. Fig. 1 depicts a patient who required TAC while waiting for bowel edema to resolve. The latter example must be kept open until the patient is ready for a definitive closure with mesh or other modalities.
4. **Patients with severe intraabdominal infections or necrotizing fasciitis of the abdominal wall.** This includes patients with necrotizing pancreatitis, a soft tissue infection, or a large amount of purulent material in the abdomen requiring repeated washouts.
5. **Patients having a planned repeat exploration or second-look surgery.** These are patients with intraabdominal pathology that require another laparotomy in the next 48 to 72 hours. For example, a vascular surgery patient with mesenteric ischemia who undergoes a small bowel resection, and 48 hours later needs to be reexplored to check for additional bowel ischemia.

FIG. 1 AbThera VAC system (Kinetic Concepts, Inc.) features a foam that controls exudate laterally to assist in volume removal. (Courtesy KCI, an Acelity Company.)

Once the decision has been made to leave the patient open, a TAC is performed and the patient transported to the ICU for further management. In some situations, such as with massive liver injury, the abdominal viscera may be packed with laparotomy pads for direct pressure to control bleeding prior to a TAC. As stressed previously, the practice of closing the fascia under tension must be avoided to prevent IAH and ACS and to prevent wound complications that arise from ischemia and pressure such as infection and dehiscence. For hemodynamically stable patients who present challenges to primary abdominal closure during the index case, several options to achieve a tension-free abdominal closure exist, some of which are highlighted later in this chapter.

TEMPORARY ABDOMINAL CLOSURE

Once the decision to leave the abdomen open has been made, the most optimal TAC technique as allowed by local resources should be used. The ideal method for TAC should prevent loss of domain, limit contamination, allow egress of peritoneal fluid, and avoid adhesion formation. Many TAC techniques have been described in the 20 plus years since Bjorcke and Schwab coined the term *damage control surgery*, and all share the following attributes:

- Easily encompasses the bowel and abdominal viscera
- Allows enlargement of the abdominal cavity in situations of massive bowel, tissue, or retroperitoneal edema without inducing IAH and while preventing ACS
- Is expansible but also sturdy enough to permit the tamponade effect of packing the liver or other bleeding surfaces
- Does not damage the fascia and prevents fascial retraction
- Contains and quantifies fluid loss
- Prevents adhesions formation between viscera and abdominal fascia
- Promotes removal of infectious materials
- Is quick to apply and remove
- Has a good primary fascial closure rate (>50% in a systematic review of trauma-only series by van Hensbroek et al.)

Options can be divided into skin approximation techniques (towel clip closure, the Bogota bag, the slip technique), fascial closure techniques using an interposition graft material sutured to the abdominal fascia (e.g., the Wittmann Patch), or negative pressure wound therapy (NPWT) (Barker's vacuum pack, commercially available vacuum-assisted closure [VAC] devices). Table 1 compares the most common methods of TAC.

Although the earliest forms of TAC, the towel clip and Bogota bag closures, are mentioned in the table, these have largely been replaced with improved techniques. The 2014 International Consensus Conference on Open Abdomen in Trauma recommends NPWT whenever feasible. These devices create a negative pressure silo that contains the abdominal contents, is somewhat expansible, and enables measurable fluid removal. The negative pressure is applied medially up through the open abdomen, minimizing fascial retraction and loss of abdominal domain. These dressings are also very quick and easy to apply and they can be used in situations of massive bowel swelling. Although several variations of the negative pressure TACs exist, most include the following key features:

1. Semipermeable (fenestrated), nonadherent inner membrane: The innermost layer of fenestrated plastic or plastic-coated sponge acts to protect the viscera from the overlying suction device and simultaneously permit evacuation of intraabdominal fluid.
2. Sponge inlay: The middle layer of the VAC device consists of a porous sponge, often made of polyurethane, placed in an inlay position between the fascial edges and flush with the level of the skin. This layer transmits the suction effect onto the inner viscera to remove intraabdominal fluid. Suction effect on the inlay sponge also produces wound contraction and gentle fascial edge approximation over time.
3. Adhesive impermeable outer layer: The outer layer of the VAC dressing is an adhesive, impermeable layer used to create a seal around the edges of the wound and to anchor the dressing to the periwound skin and allow gentle tension or wound contraction.
4. Suction device or machine: Finally, the suction device or machine typically connects to the dressing via an adaptor placed overtop an intentionally created defect in the impermeable outer layer to allow transmission of negative pressure directly onto the middle sponge layer.

Figs. 1–3 illustrate the AbThera VAC device (Kinetic Concepts Inc.). Fig. 4 illustrates the Barker dressing, which uses materials readily available in the operating room to create a vacuum pack dressing. The World Society of Emergency Surgery also recommends NPWT with continuous fascial traction as the preferred method for TAC but acknowledges that TAC without negative pressure (e.g., Bogota bag) can be applied in low-resource settings accepting a lower delayed fascial closure rate and higher intestinal fistula rate.

Practical Tips for Use of VAC Closure Dressing as Temporary Abdominal Closure

Maximally Lateralize the Inner, Visceral Protective Layer

To prevent viscera from sucking out at the edges of the inlay sponge, it is important to maximally lateralize the inner, visceral protective layer. This also prevents adhesions of the viscera to the undersurface of the abdominal wall, which could make eventual abdominal closure more difficult. It can be helpful to take down the falciform ligament as well as any secondary adhesions to the anterior abdominal wall. One technique is to use an abdominal wall retractor to facilitate adequate placement.

Place Intestinal Anastomoses Deep in Abdominal Cavity

The previously mentioned 2014 International Consensus Conference on Open Abdomen in Trauma found that GIA and NPWT do not harm intestinal anastomoses as long as they are buried deep within the pelvis or central abdomen under multiple loops of bowel or tucked laterally under the abdominal wall.

Avoid Leaks

Air leaks, typically at the edges of the wound or at skin creases and ostomy sites, are the Achilles heel of VAC therapy. Using an appropriate overlap of adhesive is important, as is intraoperative leak testing before leaving the operating room. The use of ancillary liquid

TABLE 1 Various Methods of Temporary Abdominal Closure

Closure Technique	Description	Advantages	Disadvantages
SKIN APPROXIMATION			
Towel clip closure	Serial application of towel clips or sutures	Rapid	Does not prevent IAH, may interfere with radiography or angiography
Bogota bag	IV bag, Steri-Drape, Silastic bag, plastic bag attached to skin	Inexpensive, quick, semiadherent	Risk of evisceration, loss of abdominal domain, risk for IAH, fluid losses difficult to quantify
FASCIAL CLOSURE			
Absorbable mesh	Suturing of absorbable mesh to fascial edges	Can be applied directly over bowel, allows for drainage of peritoneal fluid	Rapid loss of tensile strength (in the setting of infection), potentially large volume late ventral hernia, risk for bowel fistula, damage to fascial edges limits repeated suturing
Wittmann patch (Star Surgical)	Suturing of artificial burr (e.g., Velcro) to fascia, staged abdominal closure by application of controlled tension	Good tensile strength, allows for easy reexploration and eventual fascial closure	Poor control of third space fluid, adherence of bowel to abdominal wall, potential for fistulae
NEGATIVE-PRESSURE WOUND THERAPY			
Barker's vacuum pack	Bowel covered with plastic sheet and towel or laparotomy pads, that drains attached to wall suction and outer adhesive layer	Inexpensive, uses available materials, moderate control of fluid, suction provides constant medial traction, preventing loss of domain, high success in fascial closure	Difficult to quantify suction, unknown whether full benefits of negative-pressure therapy are realized
VAC Abdominal Dressing System	Reticulated polyurethane foam dressing over the plastic covering of the bowel; negative pressure is controlled with a computer-controlled vacuum pump that applies a constant, regulated pressure to the wound surface and a sensing device to prevent uncontrolled fluid (e.g., blood) drainage	Increase in blood flow, a reduction in abdominal wall tension, reduction in size of the abdominal wall defect, decreased bowel wall edema, and potential removal of inflammatory substances that accumulate in the abdomen during inflammatory states; edema and third space losses are controlled	Expensive, not available in all institutions or in all low-resource settings; mechanisms of action not fully understood, but also lead to hypersensitization; full relationship to fistula needs further study

IAH, intra-abdominal hypertension; IV, intravenous; VAC, vacuum abdominal closure.

FIG. 2 Placement of foam pad layer for the ABThera VAC (Kinetic Concepts, Inc.), which combines with an embedded foam that lies on laterally making it easier to apply and also assists in bowel parietal fluid and effluent removal.

FIG. 3 Vacuum-assisted closure dressing on patient in the surgical intensive care unit. This dressing was easily applied despite an enormous bowel and massive retroperitoneal bulging.

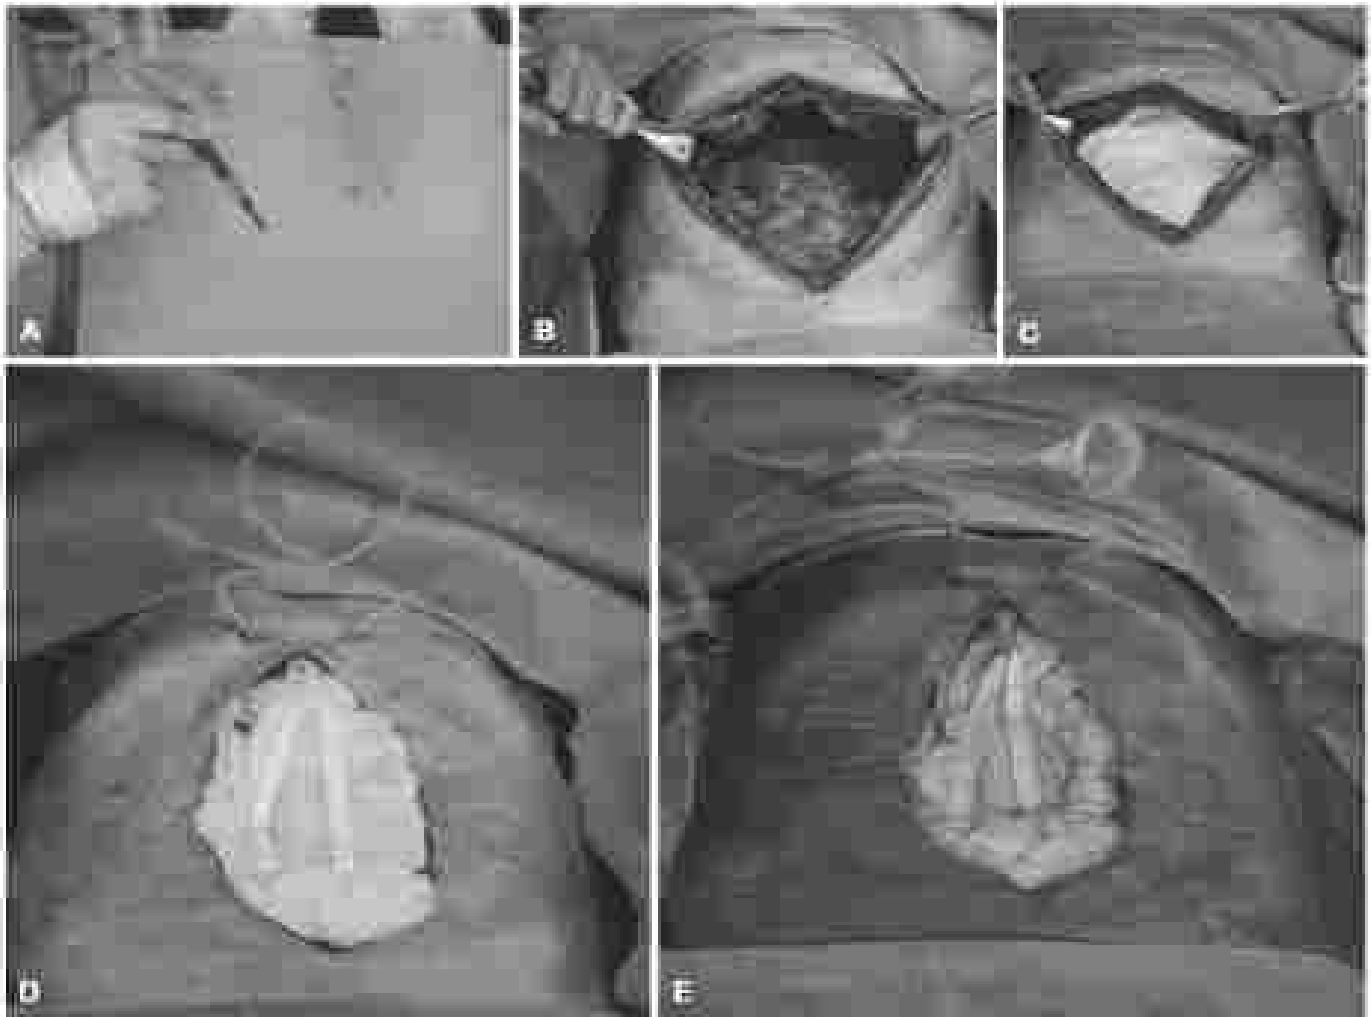

FIG. 8 Barker vacuum pack technique. (A) The polyethylene sheet is perforated multiple times with a scalpel blade. (B) The sheet is placed over viscera and beneath the parietoumbilical wall. (C) A moist towel is placed over the polyurethane and positioned below the skin edges. (D) Suction drains are placed. (E) An outer adhesive dressing is applied and the drains are hooked up to wall suction. (Courtesy Donald H. Barker, MD, Department of Surgery, University of Tennessee, Chattanooga.)

adhesives, such as tincture of benzoin or Mastisol can facilitate a good seal, especially in difficult areas for adhesion. Pulling and placing the outer dressing under tension should be avoided as it can lead to epidermal blistering leading to long-term skin problems.

Staples for Skin-Sponge Approximation

Polyurethane sponge damages the epidermis when direct contact is made under negative pressure; however, the inlay sponge must come to a flush approximation with the skin edge to maximize the effectiveness of the dressing. One solution is to use skin staples to temporarily affix the inlay sponge to the edges of the wound during dressing application and initial suction, although this is not a necessary step. These staples then are removed at the next VAC dressing change.

Overlap Outcomes With Adhesive Outer Layer

VAC therapy in the presence of an ostomy creates a very difficult problem for wound management. If the ostomy is close to the wound or if the patient has an enteric atmospheric fistula in the middle of the wound, there are other possible solutions to ensure a good seal of the VAC dressing. With the ostomy appliance off, a sheet of adhesive outer layer can be placed over the stoma site, with a small hole cut to allow the stoma to pass through. The ostomy appliance then is reapplied on top of the adhesive layer and simply changed every 48 hours with the dressing.

Appropriate Hole for Vacuum Device

Although simple, the use of an appropriately sized hole in the outer adhesive layer is a critical step. At least a 3 × 3 cm hole is appropriate and allows efficient transmission of negative pressure.

Amount of Negative Pressure Depends on Clinical Condition

The optimal therapeutic amount of negative pressure that maximizes tissue growth is approximately 125 mm Hg, with some flexibility based on clinical conditions and time of management. If active bleeding caused by coagulopathy is suspected, the pressure level should be lower, approximately negative 75 mm Hg, to decrease risk of hemorrhage.

OA POSTOPERATIVE CARE

After DCS, patients require management in a critical care unit with aggressive hemodynamic monitoring. The immediate postoperative period should consist of rewarming, correction of coagulopathy,

acidosis, and metabolic derangements, and likely ongoing resuscitation. During this early "fluid seeking" phase, patients should not be restricted in terms of fluid administration because of concerns about bowel edema or ultimate fascial closure. Hypertonic crystalloid solutions for both infusion and bolus therapy during the resuscitative phase may provide durable volume expansion while restricting edema to a certain degree. All patients who sustain penetrating abdominal wounds should receive a preoperative dose of prophylactic, broad-spectrum antibiotics. In the presence of a hollow viscus injury, the literature supports use of prophylactic antibiotics for not more than 24 hours. However, there is a lack of evidence regarding the need to continue antibiotics solely in patients with an OA. If the patient is thought to have sepsis, however, broad-spectrum antibiotics should be initiated and narrowed as appropriate based on culture results and clinical course. It should be recognized that OA patients are in a hypermetabolic condition and adequate nutritional support is mandatory. Early enteral nutrition is preferred if the gastrointestinal tract is intact and viable. Further goals for resuscitation are well delineated in the DCS literature as well as in the chapter on damage control in this text. In brief, we believe patients should receive judicious sedation and return to the operating room every 24 to 72 hours for abdominal washout and evaluation for abdominal closure.

Subsequent Take-Backs to the Operating Room

At 1- to 3-day intervals, the patient should be returned to the operating room to irrigate the abdomen, change the abdominal VAC dressing, and perform the necessary therapeutic maneuvers (e.g., bowel anastomosis, drainage of purulent collections) and to evaluate for abdominal closure. At our institution, abdominal VAC dressing changes are only done at the bedside if the patient is unstable and cannot tolerate a trip to the operating room. Close collaboration between the critical care team and the surgical team will allow for early closure of eligible patients, and in turn, earlier abdominal closure. Data suggest that patients who remain open at day 8 are unlikely to have a primary closure and are at increased risk for serious complications, including wound infections and fistulas. Alternative closure techniques should be undertaken in these patients unless there is some compelling reason to keep the abdomen open, such as the continued need for fascial debridement.

Definitive Closure of the Abdomen

Once the patient is ready for abdominal closure, the best-case scenario is primary fascial closure. We generally place heavy, interrupted, absorbable sutures in figure-of-8 fashion. In a setting of colonic perforation or heavy contamination, the skin should be left open. Some authors suggest the use of retention sutures, but we do not routinely place them. Retention sutures do not prevent fascial dehiscence but can help prevent bowel evisceration should dehiscence occur. Additionally, they can be placed when wound infection and subsequent dehiscence is a concern. It must be reiterated that the fascia must not be closed under tension as this may lead to IAH and ACS.

Research on OA management has found that direct closure is usually possible when the fascial edges are approximately 3 to 7 cm apart. When this cannot be achieved, different surgical techniques must be considered. Skin flaps can be raised to gain some medial length to the fascia. The fascia can also be advanced by releasing the lateral obliques; however, a full component separation is not recommended for the acute closure of an open abdomen. For patients who need mesh to bridge a gap between fascial edges, the options include biologics such as human acellular dermal matrix (HADM), absorbable mesh such as Vicryl (Ethicon), and composite meshes. Two possible techniques for management at this stage are outlined in the following section.

If the fascia cannot be closed but the skin of the abdominal wall is lax enough to close at the midline, an underlay biologic mesh can be placed to bridge the fascial defect. The overlying skin can then be closed to provide coverage for the mesh. In this situation, the method of skin closure or reapproximation can be assisted by VAC therapy. The underlay of biologic mesh typically is placed in an intraperitoneal position and affixed to the abdominal wall using transfascial suture techniques.

Where neither fascia nor skin has the capacity for midline closure, we routinely default to a temporary Vicryl (polyglactin) mesh closure with delayed placement of a split thickness skin graft. This temporary absorbable mesh then is placed in an underlay, intraperitoneal position. Standard saline moist to dry dressings are placed twice daily for about 2 to 4 weeks until satisfactory granulation tissue has appeared in the wound bed. At this time, a split thickness skin graft can be placed to cover the wound. The patient should be advised to avoid strenuous activity and heavy lifting during the several months of convalescence, and an abdominal binder can be considered for external support. Although this technique is neither novel nor aesthetically or functionally appealing, it is a time tested strategy to avoid OA catastrophes. With the advent of modern abdominal wall reconstruction techniques, these patients now can be offered a genuine and fairly reliable opportunity for restoration of abdominal wall continuity, albeit at a later date once they have completed convalescence for their acute illness. Usually this is accomplished after a minimum of 6 to 12 months, allowing for softening of intraabdominal adhesions and recovery from what is likely an extended stay in the ICU, hospital, and rehabilitation center. The benefit of this approach is that the native abdominal wall musculature is not violated and remains intact, allowing a number of possible internal definitive closure techniques. Fig. 1 describes an algorithm for managing an open abdomen.

Transfascial Tension-Bearing Closure Techniques

A distinct alternative to standard closure for management of the OA is a group of techniques collectively referred to as transfascial tension bearing closure techniques. Typical examples of such closures include the standard Wittmann Patch of hook and loop (Velcro) sheets and the Canica ABRA system. The guiding principle in all such techniques is to redistribute abdominal wall tension to a position lateral to the rectus sheath rather than to the medial portion of the abdominal wound, where the tension is highest in a standard closure. In doing so, these techniques are postulated to produce myofascial release by gradually lengthening the retracted oblique and transversus abdominis myofascial groups to regain abdominal domain.

The most recently described application of this technique has been popularized by the trauma and acute care surgical group at Cook County Hospital in Chicago and is known as the transabdominal wall traction (TAWT) method (http://www.stanmorepal.com). The TAWT technique takes advantage of a variation on the original Wittmann Patch whereby the same hook and loop (Velcro) sheets are used but are affixed lateral to the rectus sheath using heavy sutures passed through all layers of the abdominal wall and tied externally by a multicolored layer. The excess beneath the hook and loop sheets are protected by a semipermeable plastic adhesive barrier. The sutures then can be tightened gradually during serial abdominal washouts and adhesion barrier changes every 48 hours. The group at Cook County Hospital reports great success with this technique and has a near 100% rate of eventual abdominal closure, with only a relatively small number on average of tightening and washout procedures. A standard vacuum suction dressing is applied on top of the wound between tightening procedures. Once a midline tension-free closure can be obtained with the TAWT system, a layered closure can be performed either primarily or via a retromuscular approach. The retromuscular space is developed and the posterior sheath is closed primarily. Then a mesh can be placed in the retromuscular position before closure of the anterior sheath and vacuum assisted management of the open cutaneous portion of the wound (Figs. 6 through 8).

LONG-TERM MANAGEMENT AND DEFINITIVE ABDOMINAL WALL RECONSTRUCTION

The development of a significant ventral hernia is common in long-term survivors of OA management. Although hernia development is a risk factor regardless of the closure technique chosen for acute management of an OA, a hernia is expected in patients closed with an absorbable mesh and overlying skin graft. Careful planning is required before attempting to repair these hernias, and the patient must be completely recovered from the initial illness. The patient should also be well nourished and physiologically optimized.

Another important aspect is to allow sufficient time for remodeling of any adhesions that may have occurred between the mesh or fascia and viscera. In the case of Vicryl mesh and subsequent skin graft, one indicator of remodeling is the ability to pinch the mesh/skin graft structure away from the underlying abdominal contents. This separation indicates that the patient is ready for repair of the ventral hernia. Many general surgeons will request assistance from plastic surgeons, especially if tissue expanders or complex tissue rearrangement is required. The steps to reconstruction are:

1. Assess overlying skin and place tissue expanders, if necessary, before surgery.
2. Excise the skin graft and any previously placed mesh.
3. Perform extensive lysis of adhesions to release viscera from underlying fascia.
4. Reapproximate fascia, which may require one or all of the following:
   a. Raise large skin flaps and dissect skin and subcutaneous tissue from anterior fascia.
   b. Perform component separation, in which the aponeurosis of the external oblique muscle is transected longitudinally bilaterally, allowing the fascia to be pulled medially; the posterior sheath of the rectus may be similarly transected to gain further length.
   c. Use of mesh: if the fascia does not come together, mesh can be placed as an underlay (retrorectus position, above the posterior rectus fascia or intraperitoneally with fascia overlay) or as an interposition (bridging the fascial defect) graft; most authors suggest the use of ITALOM or other biologics for this purpose.
5. Onlay mesh on top of the fascia for reinforcement. If a ITALOM underlay or interposition has been placed, we may also apply a polypropylene mesh as an overlay. If no underlay was required, a polypropylene may be placed as an onlay mesh to reinforce the fascia.
6. Before skin closure drains can be placed in the subcutaneous space to draw off accumulated fluid.
7. Standard primary skin closure with staples or a hybrid skin VAC system as described by Soares and colleagues.

SUMMARY

In the appropriately selected patient, an OA can serve as a lifesaving component of an overall damage control strategy. Techniques to achieve eventual closure of the OA should include balanced resuscitation with crystalloid minimization, regular returns to the operating room, and a carefully selected approach to closure based on patient, surgeon, and institutional factors. Ongoing improvement in abdominal wall reconstructive techniques will continue to improve mortality and quality of life for patients who require damage control surgery or for those with ACS.

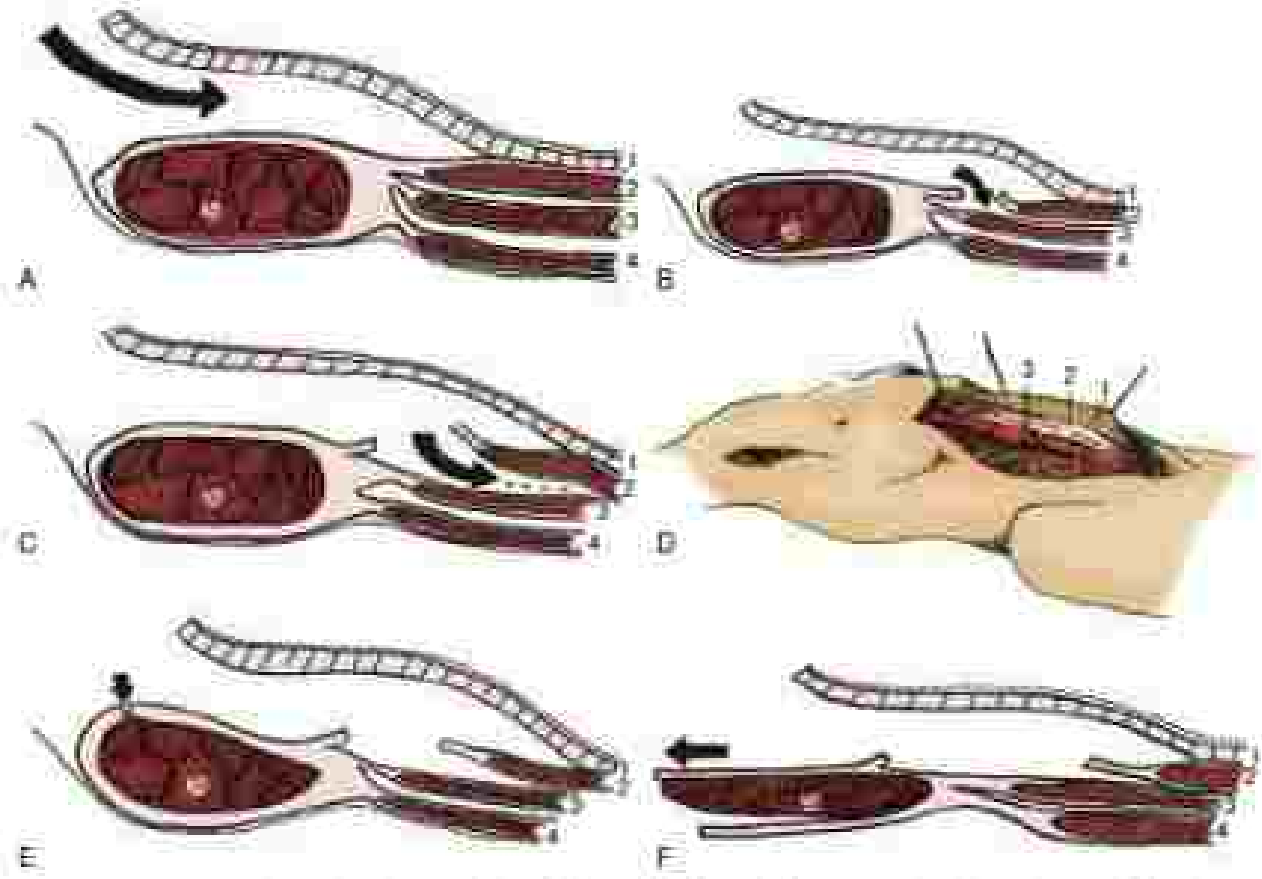

FIG. 1 Component separation technique for the repair of large abdominal wall hernias. After entering the abdominal cavity, the bowels are dissected free from the ventral abdominal wall. (A) The skin and subcutaneous fat (1) are dissected free from the anterior sheath of the rectus abdominis muscle (3) and the aponeurosis of the external oblique muscle (2). (B–C) The aponeurosis of the external oblique muscle (2) is transected longitudinally about 2 cm lateral from the rectus sheath, including the muscular part on the thoracic wall, which extends at least 5 to 10 cm cranially of the costal margin. (D) The external oblique muscle (2) is separated from the internal oblique muscle (3) as far laterally as possible. (E–F) If primary closure is impossible with undue tension, a further gain of 2 to 4 cm can be reached by separation of the posterior rectal sheath from the rectus abdominis muscle (5). Care must be taken not to damage the blood supply and the nerves that run between the internal oblique and transverse muscles (6) and enter the rectus abdominis muscle in the posterior side. Management of Vascular Injuries

Andrew Schulick, MD, MBA, FACS

The management of vascular injuries is determined by both the location and the nature of damage as well as the presence of associated trauma. Despite advances in care, major vascular injuries remain associated with significant morbidity and mortality. The general principles of trauma resuscitation are addressed elsewhere in this book. This chapter will focus on evaluation and management issues specific to injuries of major blood vessels of the neck, chest, abdomen, pelvis, and extremities.

INITIAL EVALUATION

Hard signs of vascular injury include (1) pulsatile bleeding, (2) expanding hematoma, (3) the presence of a bruit or thrill, and (4) evidence of ischemia, including the six P's (pain, pallor, paresthesias,

Management of Vascular Injuries

Andrew Schulick, MD, MBA, FACS

The management of vascular injuries is determined by both the location and the nature of damage as well as the presence of associated trauma. Despite advances in care, major vascular injuries remain associated with significant morbidity and mortality. The general principles of trauma resuscitation are addressed elsewhere in this book. This chapter will focus on evaluation and management issues specific to injuries of major blood vessels of the neck, chest, abdomen, pelvis, and extremities.

INITIAL EVALUATION

Hard signs of vascular injury include (1) pulsatile bleeding, (2) expanding hematoma, (3) the presence of a bruit or thrill, and (4) evidence of ischemia, including the six P's (pain, pallor, paresthesias,

BOX 1 Signs of Vascular Injury

Hard Signs

Pulsatile bleeding
Expanding hematoma
Presence of a thrill or bruit
Evidence of ischemia including (for a PI) (pain, pallor, paresthesia, poikilothermia, paralysis, pulselessness)

Soft Signs

History of significant hemorrhage
Injury in proximity to a major vessel
Nonexpanding hematoma
Diminished or asymmetric pulses
Unexplained hypotension or tachycardia

poikilothermia, paralysis, pulselessness). These hard signs are present; however, in the minority of patients with vascular injury limited, evidence of injury may present more subtly, as soft signs, which include (1) a history of hemorrhage in the field, (2) injury in proximity to a major vessel, (3) nonexpanding hematoma, (4) diminished or asymmetric pulses, and (5) unexplained hypotension or tachycardia. Failure to recognize these signs can result in delays to diagnosis, so a high index of suspicion, based on history and the mechanism of injury, is warranted (Box 1).

Vascular injuries often occur in association with musculoskeletal injuries. Common patterns are listed in Table 1, and the presence of associated injuries should prompt a thorough vascular evaluation. Many vascular injuries, especially penetrating wounds of the extremities, can be diagnosed and managed based on physical examination alone. Because computed tomography angiography (CTA) can be obtained rapidly and allows diagnosis of associated injuries, it has become the first line test in the investigation of vascular trauma and has largely supplanted conventional angiography for this purpose. Other useful diagnostic tests include segmental pressure measurements and duplex ultrasonography, neither of which require intravenous contrast, and both of which can be performed at the bedside without the need for patient transport. The utility of these tests, however, is highly operator dependent.

Before definitive treatment of injury to specific blood vessels, resuscitation is continued and is based on the principles of damage control. The goal is not necessarily to restore normotension, which may actually promote increased bleeding, but to maintain adequate organ perfusion while averting the deadly triad of hypothermia, coagulopathy, and acidosis. As a rule of thumb, this means maintaining systolic blood pressure in the 80 to 90 mm Hg systolic range, and liberally transfusing warmed blood products in preference to crystalloid, both to maintain oxygen carrying capacity (red blood cells) and to combat coagulopathy (fresh frozen plasma and platelets). Associated brain trauma, in which increased cerebral perfusion pressure is required, is an exception to the strategy of permissive hypotension. Refractory bleeding resulting from coagulopathy may be improved by the administration of factor VIIa and can be considered in extreme circumstances of refractory bleeding. Use of tourniquets, topical hemostatic agents, as well as pressure bandages and garments may all have a role in the initial management of vascular trauma, and should be familiar to and available for providers.

BASIC PRINCIPLES OF MANAGEMENT

After initial assessment and resuscitation of the trauma victim, the most important decision is to determine, based on the patient's condition, the type of intervention required. In the setting of a normal examination and physiologic stability, minor vascular injuries identified on physical examination and imaging studies can be followed serially, with intervention reserved for deterioration. Vascular injuries that may be safely followed include noncircumferential intimal flaps, nonflow limiting stenoses, small false aneurysms, and arteriovenous fistulae. The minority of these injuries will produce complications that require intervention, and most interventions, when necessary, can be safely deferred until more pressing, associated injuries are addressed.

In the severely injured patient, operative intervention often requires the coordination of multiple medical and surgical specialists, as well as early involvement of the blood bank. In the setting of damage control, which prioritizes physiologic stability over all else, definitive repair of extremity injuries may not be possible, especially if concomitant severe head, abdominal, or thoracic injuries are present. In these circumstances, temporary shunting or ligation of extremity injuries may be required for the sake of patient survival. In extreme cases, initial primary amputation may be necessary.

Operating rooms are ideally outfitted for both endovascular and open surgical procedures (hybrid operating room). Endovascular intervention has evolved into a robust complement to conventional surgery in the treatment of vascular injuries. Catheter-based interventions have highest utility to torso and proximal extremity injuries, as well as zone 1 and 3 injuries of the neck (see the following section). Endovascular techniques can also be used as an adjunct to open surgery to help control bleeding from vessels that are difficult to expose. Resuscitative endovascular balloon occlusion of the aorta (REBOA) is a high profile example. As is usual in all vascular surgical operations, wide preparation of the patient is mandatory, with an emphasis on access to autologous conduit for reconstruction. Polytetrafluoroethylene (PTFE) may be used if vein is not available or is not indicated. An operative approach with extensile exposure is preferred. Systemic heparin should be avoided if severe multiple injuries are present, including head, spinal cord, and torso. In these circumstances, local heparin can be administered to avoid operative thrombosis. Finally, decompression fasciotomy should be considered in extremity trauma to avoid the sequelae of compartment syndrome.

OPERATIVE TREATMENT

Neck

For management of penetrating trauma, the neck is classically divided into three anatomic zones (Fig. 1). Zone 1 is located below the clavicles and encompasses the thoracic outlet. Zone 2 is the region between the clavicles and the angle of the mandible. Zone 3 lies between the angle of the mandible and the base of the skull. Zone 2 is the most common zone for vascular injury. Because of the high density of critical structures in the neck, associated injuries are common. Management of vascular neck injuries is determined by presentation. Overtly symptomatic patients who present with major hemorrhage or asphyxiation require urgent airway control followed by immediate exploration for bleeding in the operating room. Asphyxiation in these patients may be due to airway or lung injury or tracheobronchial compression related to hematoma. Initial control of bleeding in zone 2 is often effectively achieved with manual pressure. For zone 3 injuries uncontrolled with manual pressure, an occlusive balloon can be gently advanced into the bleeding tract and inflated to give temporary control; alternatively, the opening and tract can be tightly packed with sterile gauze on the way to the operating room. Victims with less acute presentations undergo diagnostic evaluation referable to the suspected injury. The vascular system is most expeditiously evaluated with CTA. Evaluation of the aerodigestive system may include endoscopy and swallowing studies. For penetrating injuries of zone 1, echocardiography should be strongly considered to evaluate for pericardial effusion, suggestive of cardiac injury.

In terms of operative approach, penetrating zone 1 injuries may require either a median sternotomy for right sided or medial left sided injuries or a high anterolateral thoracotomy for left sided injuries. Incisions can be extended or combined into "clamshell" or "trap door" combinations for more extensile exposure. Exposure of zone 3 generally requires mandibular subluxation and division of the digastric muscle. In a bloody field, the exposure can be hazardous. Zone 2

TABLE 1 Patterns of Associated Musculoskeletal and Other Structures With Specific Vessel Injury

Vessel	Musculoskeletal	Other
Carotid artery	Cervical spine Mandible, Le Fort II/III facial fracture Skull base	Vertebral vein Carotid artery Trachea, esophagus
Vertebral artery	Cervical spine (vertebral foramina) Skull base	Jugular vein Carotid artery
Subclavian artery or vein	Clavicle Sternum, manubrium	Thoracic duct (left) Brachial plexus, recurrent laryngeal nerve
Axillary artery or vein	Shoulder, proximal humerus	Brachial plexus, axillary nerve
Brachial artery or vein	Midhumerus Biceps, triceps	Ulnar nerve Median nerve
Radial or ulnar artery	Elbow fracture or dislocation Radius, ulna, wrist Forearm and hand flexor tendons	Distal radial nerve (sensation) Ulnar nerve
Thoracic great vessels	Sternum, manubrium	Innominate vein Recurrent laryngeal nerve
Descending aorta	Thoracic spine Posterior rib fracture or dislocation Diaphragm	Esophagus Lung Left subclavian vein (blunt)
Abdominal aorta or vena cava Suprarenal Infrarenal	Thoracic or lumbar spine T12, L2 (with or without spinal cord) L2, sacral fractures	Zone 3 retroperitoneal hematoma Stomach, transverse colon, pancreas Duodenum, small bowel
Portal vein or Superior mesenteric vein	Lumbar spine fracture or ligament injury Rib fractures	Zone 1 retroperitoneal hematoma Duodenum (second or third portion), head of pancreas Portal triad (hepatic artery, common bile duct)
Renal artery or vein	Lumbar spine Posterior rib fracture or dislocation	Zone 2 retroperitoneal hematoma Kidney, proximal ureter, adrenal or gonadal vessels
Iliac vessels	Pelvic fracture Sacral fracture Sacroiliac joint disruption	Zone 3 retroperitoneal hematoma Cecum (right), sigmoid colon (left) Bladder, ureters
Femoral artery or vein	Pelvic fracture Acetabulum Proximal to mid-femur	Femoral nerve, sciatic nerve (rare) Inguinal ligament Spermatic cord
Popliteal artery or vein	Dislocated or "floating" knee Distal femur, proximal tibia	Tibial nerve Calf compartment syndrome
Tibioperoneal trunk	Tibia, fibula Ankle fracture or dislocation	Tibial nerve, peroneal nerve (foot drop) Calf compartment syndrome

From Cronenwett JL, Johnston KW, Rutherford's vascular surgery, 8th ed. Philadelphia: Saunders; 2014:2622.

injuries are generally explored via incisions along the anterior border of the sternocleidomastoid muscle, but transverse incisions may also be indicated.

Once control and exposure have been achieved, and the extent of injury determined, a decision is made regarding the mode of repair. Clean arterial lacerations may be primarily repaired. Jagged disruptions may require interposition grafting. In general, autogenous saphenous vein is the preferred conduit. Because of the difficulty of exposure in zones 1 and 3, hybrid endovascular techniques can be extremely helpful to control, and in some cases are the preferred approach to management. Covered stent graft placement is especially useful for internal carotid artery injuries high in zone 3 and for the treatment of subclavian artery injuries.

Blunt cervical injuries may be a result of a direct cervical blow, basilar skull fracture, flexion extension or rotational forces, or clothesline type trauma. Screening should be performed for all patients with signs and symptoms of injury, and for those who present following high-energy mechanisms. CTA has largely supplanted contrast angiography as the diagnostic test of choice in a patient sustaining blunt cervical trauma and has proven to be highly accurate in detection of clinically significant vascular injuries. Blunt carotid injuries are most commonly classified using the grading scale developed in Denver by Biffl: grade 1, luminal irregularity or dissection with less than 25% narrowing; grade 2, dissection or intraluminal hematoma with 25% or greater narrowing, intraluminal thrombus or raised intimal flap; grade 3, pseudoaneurysm; grade 4, occlusion; and grade 5, transection with free extravasation (Box 2).

To prevent stroke, grade 1 to 4 injuries are treated with anticoagulation or antiplatelet agents. Recent reports have demonstrated equivalence between the two classes of drugs in stroke prevention. Since

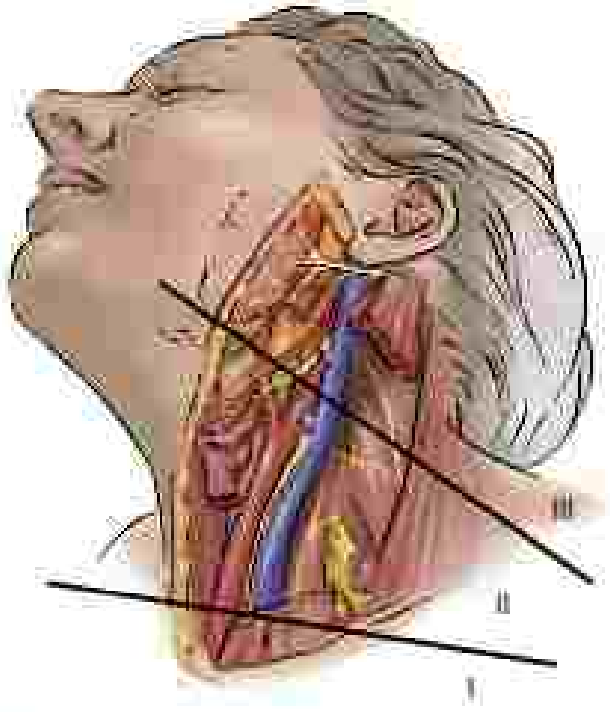

FIG. 1. Anatomic zones of the neck. Zone I is the thoracic outlet from the sternal notch to the cricoid cartilage. Zone II extends from the cricoid cartilage to the angle of the mandible. Zone III extends from the angle of the mandible to the skull base. *(From Rutherford, R., ed. Vascular trauma. In: Vascular surgery. 5th ed. Philadelphia: Saunders; 1996.)*

BOX 1 Grading Scale for Blunt Carotid Artery Injuries

- Grade 1: Intimal irregularity with <25% narrowing
- Grade 2: Dissection or intramural hematoma with >25% narrowing
- Grade 3: Pseudoaneurysm
- Grade 4: Occlusion
- Grade 5: Transection and extravasation

grade 3 lesions and progressing grade 2 lesions should be considered for treatment with endovascular stents, especially if associated with new neurologic events. Grade 1 lesions in poorly accessible locations are treated with endovascular stents if feasible, otherwise, open surgical repair is indicated.

Vertebral artery injuries are uncommon and are generally the result of penetrating trauma. The V1 segment (origin through the transverse foramen of C6) is surgically accessible, and injuries can be directly addressed either with reconstruction or ligation. The second (V2, in the bony foramina of the cervical spine) and third (V3, C2 to dural) vertebral artery segments are surgically hazardous and are best treated *either* by endovascular means (stent or embolization) *or* via open ligation of the V1 segment.

Chest

Thoracic great vessel injuries may occur after either penetrating or blunt trauma. The majority of injuries resulting from penetrating trauma result from gunshots and stabbings. Blunt vascular trauma is often associated with multisystem injury. Most victims with severe chest injuries die in the field. Those who are successfully transported generally arrive in the emergency department in hemorrhagic or cardiogenic shock. In selected cases, emergency resuscitative thoracotomy is indicated and is performed through a left anterolateral thoracotomy positioned at the fourth interspace. For right-sided injuries, the incision is extended across the sternum in a clamshell fashion. Evaluation entails inspection of the left lung and cross-clamping the hilum if necessary. Alternatively, after mobilization of the inferior pulmonary ligament, the lung can be torqued 180 degrees around the hilum to gain temporary control of bleeding. The pericardium is entered anteriorly to avoid the phrenic nerve. Cardiac injuries are controlled with mattressed nonabsorbable sutures such as 3-0 prolene; large needles are preferred. The descending aorta can then be cross-clamped to augment cerebral and coronary perfusion, and bimanual cardiac massage initiated. Absence of an intrinsic rhythm may warrant intracardiac administration of epinephrine as well as direct defibrillation. Mortality remains high.

For stable patients with penetrating trauma, physical examination and plain radiographs may provide evidence of major vascular injury and may aid in localizing missile fragments and their likely trajectories. CTA has rapidly become the first line test for screening for major injuries after chest trauma. Penetrating injuries revealed on screening evaluations generally require operative repair, with the surgical approach determined by the location of the injury. The ascending and transverse aorta, as well as the innominate artery and left common carotid artery are approached via a median sternotomy. The descending aorta and left subclavian artery are best approached via a left anterolateral thoracotomy. Endovascular approaches are increasingly used for definitive treatment. Utility of these less invasive approaches is determined by the location injury, the presence of associated trauma, and patient stability.

Following blunt chest trauma, the likelihood of major vascular injury is determined by the mechanism of injury, and the nature of damage is diagnosed with a combination of physical examination and imaging studies, typically chest radiography and CT scanning. The most common vessel injured in the aorta at the isthmus and is usually the result of rapid deceleration. The majority (80%) of victims of blunt aortic injury die at the scene. The majority of patients who arrive at the hospital have contained injuries, either intramural hematomas or false aneurysms at risk for free rupture. The risk of free rupture and exsanguination is decreased by prompt control of blood pressure and heart rate. Definitive repair in stable patients can be deferred up to 24 hours to allow adequate evaluation, resuscitation, and treatment of other life-threatening injuries. The exception is with concomitant major brain injury in which higher blood pressure is warranted. In these patients, aortic repair should proceed immediately.

Thoracic endovascular aortic repair (TEVAR) is the preferred approach for blunt aortic injury in anatomically suitable candidates (Fig. 2). Conventional open thoracotomy is associated with higher mortality and increased morbidity, including paraplegia, stroke, nephropathy, and pulmonary dysfunction. To increase the proximal seal zone with TEVAR, the left subclavian artery can be covered, if necessary, in the acute setting. Revascularization of the left subclavian (and vertebral), if required, can generally be deferred until the patient is more stable. A significant problem with TEVAR in young trauma victims is inadvertently undersizing of the stent graft in a hypotensive aorta, which can result in prior seal and graft migration. Use of intravascular ultrasound, which allows assessment of dynamic aortic diameter, has been useful to more accurately assess. Major thoracic venous injuries are generally treated with lateral venorrhaphy or, if necessary, ligation. Treatment of intrathoracic inferior vena cava (IVC) injuries may require cardiopulmonary bypass.

Abdomen and Pelvis

Abdominal vascular injury refers to trauma of large intraperitoneal or retroperitoneal vessels of the abdomen or pelvis. Most abdominal vascular injuries are penetrating in nature, either from gunshots or stab wounds, but major blood vessel can suffer damage after blunt trauma as well. The majority of patients with significant injuries

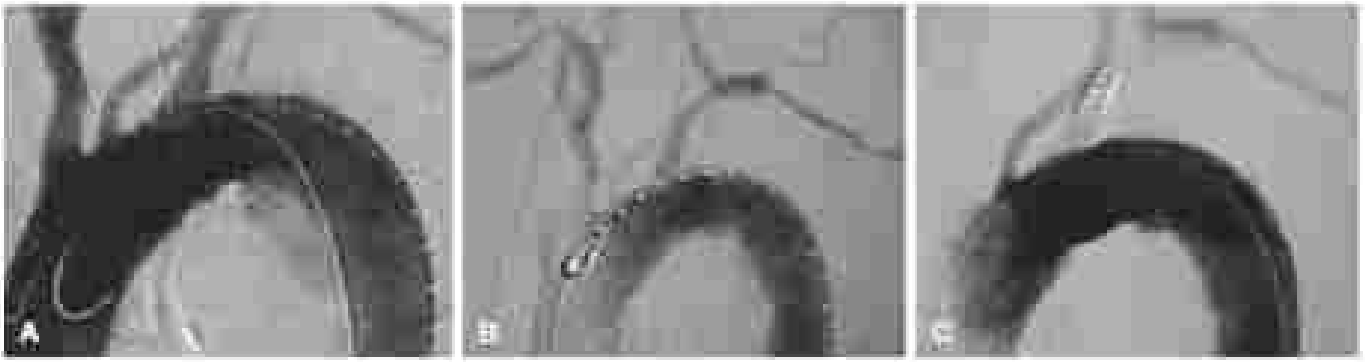

FIG. 2 Summit thoracic aortic rupture resulting from blunt trauma. (A) Contained pseudoaneurysm caused electively. (B) Intentional coverage of the subclavian artery after carotid-subclavian bypass to gain additional proximal landing zone. (C) Coil embolization to prevent endoleak from the proximal landing zone. (From Moore WS, Ahn SS: Endovascular Surgery. 4th ed. Philadelphia: Elsevier, 2013.)

arrive in the emergency room in profound hemorrhagic shock. Approximal patients may require resuscitative thoracotomy for survival. Use of REBOA as an endoluminal aortic cross-clamp to treat infradiaphragmatic exsanguination, has demonstrated utility, and has been used with success in some trauma centers (Fig. 3). In both stable and unstable patients, a rapid, surgeon performed ultrasound is useful in detecting tamponade or hemothorax.

Anatomically, abdominal vasculature is divided into three zones (Fig. 4). Zone 1 is central, zone 2 is lateral, and zone 3 is pelvic. Some authors distinguish a zone 4 encompassing the porta hepatis and the retrohepatic IVC. Most of the large vessels subject to injury are located in the retroperitoneum, making them difficult to quickly assess during exploration. As such, an organized approach based on mechanism of injury and location is required to optimize outcomes.

Abdominal vascular injury may present in one of three ways, including hemorrhage, as a contained hematoma, or with distal thrombosis. Patients present with either evidence of ongoing hemorrhage, or as physiologically stable. Unstable patients and those with injuries due to penetrating trauma generally require urgent operative exploration. In stable patients, CTA continues to prove its utility in localizing bleeding. This may be especially useful in stable blunt trauma victims in which CT findings may warrant further evaluation with angiography or operative exploration.

At exploration, active bleeding is controlled with direct compression or packing; compression of the aorta at the diaphragmatic hiatus is also an option. For proximal aortic injuries, control via a left thoracotomy may be required. The abdomen is explored systematically, and intraabdominal injuries are addressed or temporized for later repair. The approach to exploration of retroperitoneal hematomas depends on the mechanism of damage, hematoma location, and suspected vascular injury. Injuries resulting from penetrating trauma require exploration, an exception to the lateral zone 2 injury that has been adequately evaluated and characterized on preoperative imaging. Blunt injuries to zones 2 and 3 should be explored if the hematoma is pulsatile or expanding. Another indication for exploration of zone 3 hematomas are those associated with absent femoral pulses.

Injuries to the aorta, celiac artery, superior mesenteric artery, or left-sided zone 2 injuries are best exposed via a left medial visceral rotation (Fig. 5). The disadvantage is the time it takes to perform the maneuver. Infrarenal aortic injuries may be more quickly exposed akin to elective infrarenal AAA repairs. Limited aortic injuries are amenable to lateral repair. Larger injuries may require patch repair or grafting. The celiac axis and inferior mesenteric artery may be ligated if necessary. The superior mesenteric artery should be either repaired, bypassed, or shunted because ligation is not tolerated. Bleeding from the IVC or right-sided zone 2 injuries are best approached via a right medial visceral rotation (Fig. 6). Most IVC injuries can be repaired primarily. IVC ligation can be considered as a last resort, but results in significant morbidity. For zone 2 renal artery injuries not amenable to lateral repair, stable patients may require interposition grafting. The magnitude of the renovascular injury, warm ischemia time, and the patient's physiologic state will dictate if nephrectomy is the best option. Confirmation of a functioning contralateral kidney is required before nephrectomy. For zone 3 vascular injuries in which the bleeding vessels cannot be easily identified, the technique of total pelvic vascular isolation can be used by cross-clamping the abdominal aorta, IVC, and the external iliac vessels. Repair or bypass can then be performed as indicated. The common and external iliac arteries should be preserved to maintain limb viability; maintenance of perfusion is especially important in the hypovolemic patient to avoid limb ischemia. The hypogastric artery can be ligated with little consequence. Iliac vein injuries are often amenable to lateral repair. Analogous reconstruction can be considered in stable patients. For large injuries or in the unstable patient, the iliac veins can be ligated.

In damage control situations, the aorta can be shunted with an intraluminal large bore chest tube or equivalent; other bleeding is either controlled with gauze packing or with selective vessel ligation and shunting. When reasonable hemostasis is achieved, the abdomen may be closed temporarily for tamponade effect or may be covered with a wound VAC. The patient is brought back to the intensive care unit for further resuscitation before definitive intervention. When vascular reconstruction is required in a contaminated field, autologous vein is preferred although use of PTFE is acceptable. With severe enteric contamination, extraanatomic bypass such as axillofemoral or femoral-femoral bypass grafting is preferred.

Although most abdominal vascular injuries are managed surgically, indications for endovascular interventions continue to expand. In stable patients with localized, anatomically suitable, vascular injuries, the endoluminal approach avoids the morbidity of open surgery and minimizes potential exposure to contaminants. The techniques are particularly useful in major aortic branch vessels such as the renal arteries, especially when the injury involves flow limiting intimal flaps, false aneurysms, or fistulae (Fig. 7).

Bleeding associated with pelvic fractures deserves special consideration. Hemorrhage is due primarily to vascular shear injury, and is often primarily venous. Optimal treatment involves orthopedic stabilization of the pelvic ring, followed by angioembolization to treat arterial bleeding, and allowing venous bleeding to tamponade in the retroperitoneum (Fig. 8). Surgical exploration of these hematomas is not advised. In damage control situations or where bleeding persists, the pelvis can be packed. The technique of preperitoneal packing with or without laparotomy has also been described to augment hemostasis, and is performed via an extraperitoneal lower midline incision (Fig. 9).

Extremities

Most extremity vascular injuries can be diagnosed with a combination of physical examination and arterial pressure index measurement.

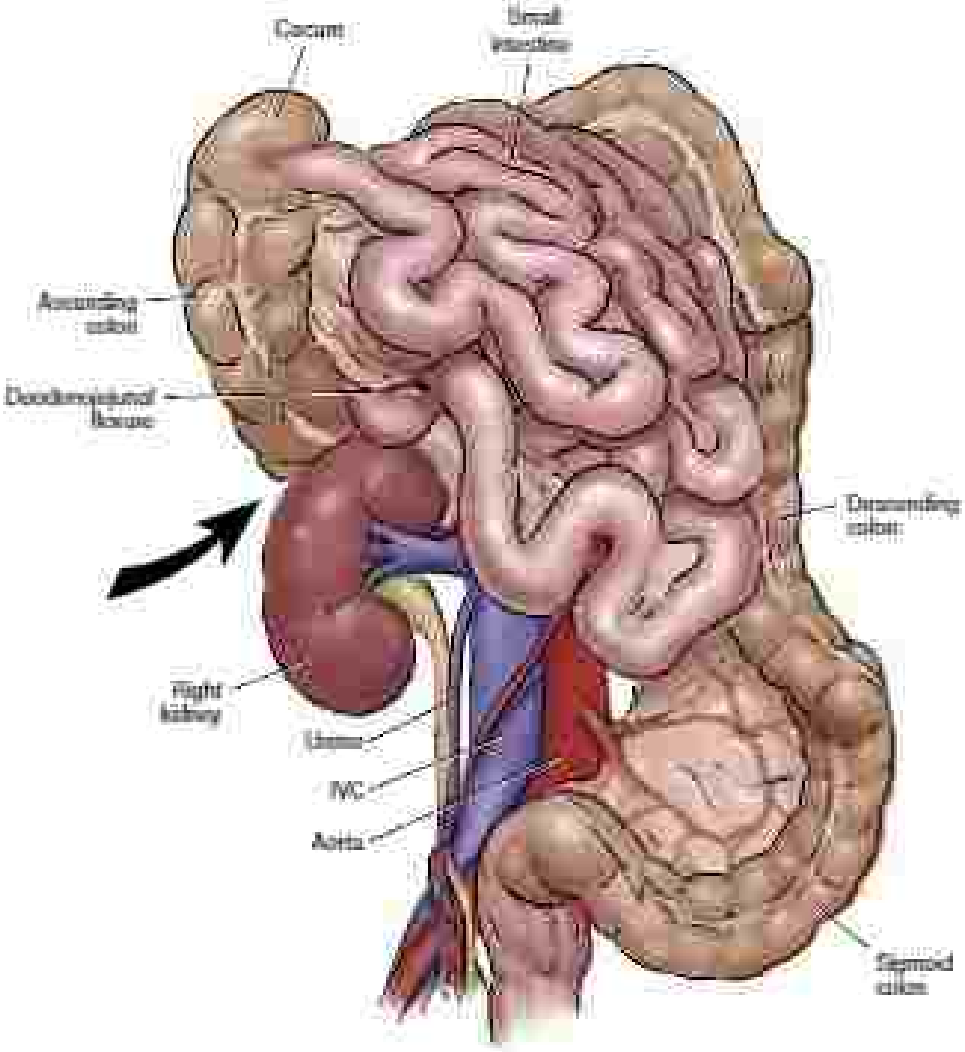

FIG. 6 Right medial visceral rotation to expose right-sided zone 2 and zone 3 vascular structures. Includes the Kocher and Cattell-Braasch maneuvers. IVC, inferior vena cava. (From Rasmussen TE, Tai NRM, Vascular Trauma, 1st ed. Philadelphia: Elsevier; 2015.)

The presence of hard signs of vascular injury, except arteriovenous fistula, mandates urgent operative intervention. Presentation with an ischemic limb should prompt consideration for systemic heparinization, which should be given in the absence of contraindications. The presence of an arteriovenous fistula itself, soft signs of arterial injury, or an arterial pressure index lower than 0.9 should prompt further investigation with CTA.

If possible, surgery should be performed in hybrid operating rooms, allowing endovascular interventions to be performed if needed. Temporary shunting may be indicated in some circumstances, to allow initial orthopedic stabilization of the badly fractured limb, to allow distal perfusion of an ischemic limb during reconstruction, and in the damage control situation to allow time for physiologic recovery prior to definitive repair (Fig. 10). Shunts may also be used as a bridge to replantation.

As a general rule, easily accessible arterial injuries should be addressed surgically. Once proximal and distal control is obtained, the injury can be assessed. If the injury results in little or no loss of vessel length, the defect can be closed in a transverse fashion with prolene sutures. For more substantial lesions, patch angioplasty or segmental interposition grafting may be required. In the heavily contaminated field, ligation and extra-anatomic bypass grafting may be indicated. In general, saphenous vein from an amputated extremity is the preferred conduit. PTFE is an acceptable alternative. Repairs and reconstructions should be covered with viable soft tissue to prevent anastomotic blowout.

Endovascular interventions are generally reserved for treatment of arterial injuries that are difficult to expose. Stent grafts are particularly useful in treating subclavian artery injuries, as well as some iliofemoral injuries. Angioembolization has become a useful adjunct in the treatment of some tidal vessel injuries when other central vessels are shown to be patent. Extremity venous injuries can be treatment with ligation, however vein preservation is preferred when possible. Compromised venous outflow will predispose to shunt thrombosis and the development of compartment syndrome.

Brachial Artery

The brachial artery is the most commonly injured upper extremity artery, and damage is most frequently the result of penetrating trauma. Supracondylar fracture of the humerus is the most common associated orthopedic injury. The brachial artery is explored through a medial longitudinal incision positioned in the groove between the biceps and triceps muscles. Through the antecubital fossa, a gentle S-shaped incision is used. For more distal brachial artery injuries, proximal control can be quickly obtained with a temporary upper arm tourniquet. Lateral repair or saphenous vein interposition grafting is performed as required. Venous injuries are ligated. Forearm fasciotomy may be required for prolonged ischemia.

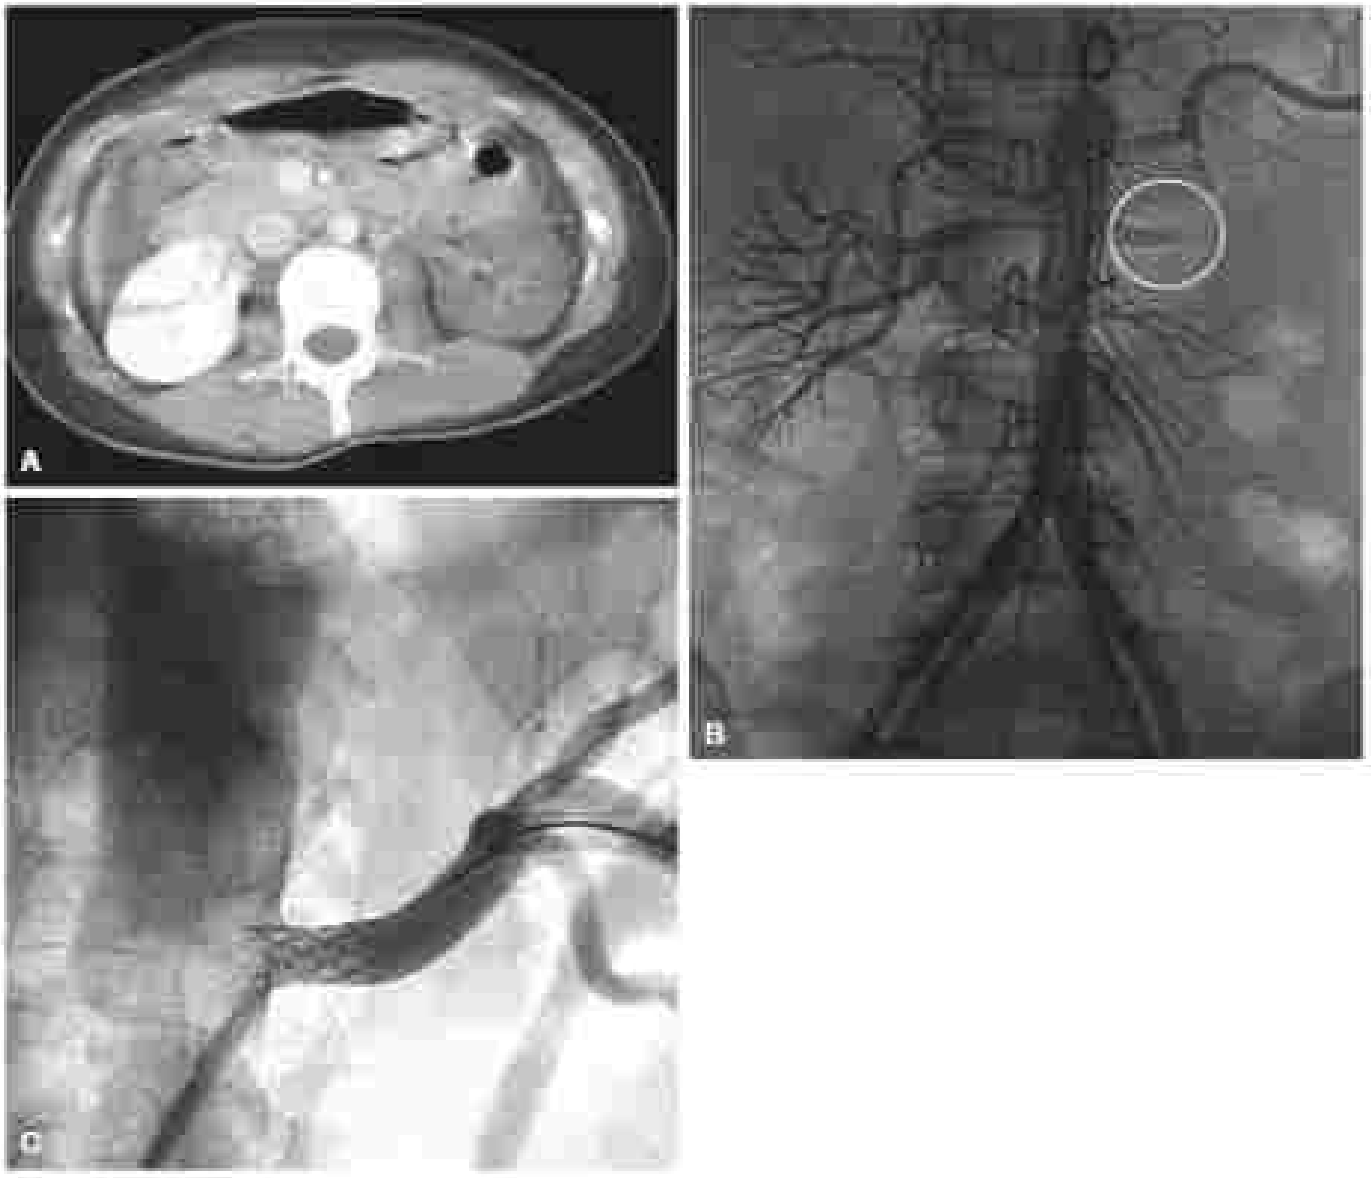

FIG. 1 Blunt injury to the left renal artery. (A) Computed tomography scan showing a nonfunctioning left kidney after a traffic injury. (B) Angiography shows complete occlusion of the renal artery (*circle*). (C) Revascularization with an endovascular stent. (From Salim AM, Perry RA. Endovascular surgery and percutaneous therapy. In: *Trauma*. 8th ed. Philadelphia: Elsevier; 2017.)

Forearm Arteries

Penetrating injuries are most common. An isolated radial or ulnar artery injury can be ligated before sacrifice, adequate collateral flow through the remaining vessel must be verified, usually by physical examination or pencil Doppler probe. Combined injuries of the radial and ulnar artery mandates repair of at least one of the vessels. The ulnar artery is generally larger and is the dominant vessel in the majority of individuals. The size difference is less pronounced in the distal forearm, so with distal injuries, repair should be performed on whichever vessels is less injured.

Femoral Arteries

The superficial femoral artery is the most commonly injured lower extremity artery, with the vast majority of injuries demonstrating hard signs of arterial damage. Common femoral artery injuries may require supra-inguinal retroperitoneal exposure of the external iliac artery for control. Exposure is accomplished via a transverse lower quadrant incision located just above the inguinal ligament. Common femoral vein injuries should be repaired when possible. The superficial femoral artery is exposed in a plane in front of the anterior edge of the sartorius muscle. In obese individuals, where landmarks are obscured, exposure is accomplished along a line extending from the anterior superior iliac spine to the tibial tuberosity. Most injuries require interposition grafting. The superficial femoral vein can be ligated if necessary but should be repaired if feasible. Consideration should be given to calf fasciotomy when ischemia is prolonged, especially in the circumstance of major venous ligation.

Popliteal and Tibial Arteries

The relatively fixed position of the popliteal artery, from the adductor canal to the gastrocnemius distally, make it prone to injury after posterior knee dislocation. In hyperextension, the popliteal artery is splayed across the tibial plateau, resulting in traction injury or vessel disruption. Pulse examination is often misleading and benign, and a

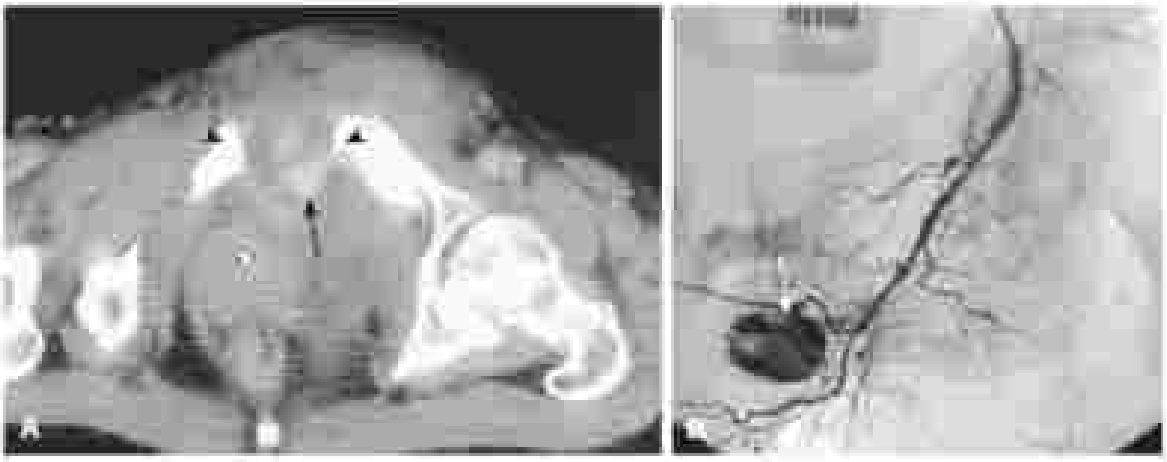

FIG. 8. "Open book" pelvic fracture with arterial bleeding treated with orthopedic stabilization and embolization. (A) Axial CTA demonstrating diastasis of the pubic symphysis (*arrowheads*) and extravasation (*arrow*) of contrast into a pelvic hematoma. FIG. 9. Preperitoneal pelvic packing technique. (A) Lower midline incision; (B) blunt dissection of preperitoneal space; (C), packing the preperitoneal space; (D), postprocedure computed tomography scan demonstrating packs in situ. (*A–C, from Cothren CC, Osborn PM, Moore EE, et al. J Trauma. 2007;62:834–839; D, from Saadiyan A, Madura J, Skupa NL, et al. Extraperitoneal pelvic packing as salvage procedure to control massive traumatic pelvic hemorrhage. J Trauma. 2007;62:1004–1005.*)

high index of suspicion is required to avoid missing an injury. CTA is reasonable in a patient suspected of having sustained a traumatic knee dislocation. Bypass grafting is generally required for arterial reconstruction. Contralateral vein is generally preferred, but for a short interposition graft across the knee, PTFE is acceptable. Fasciotomy should be considered, especially when associated venous injury is present.

An individual tibial artery can be sacrificed if the remaining vessels are proven to be patent. Evaluation is aided with Doppler interrogation or angiography. If multiple tibial arteries are injured, vein interposition grafting is performed to the one best supplying the foot, as long as it is also amenable to soft tissue coverage at the site of the anastomosis.

Fasciotomy

Victims of vascular extremity trauma are at risk for developing compartment syndrome. If not diagnosed promptly, compartment syndrome results in significant morbidity and potentially in limb loss. History and examination features suggestive of compartment syndrome include: (1) hypotension in the field or continued hypotension with resuscitation, (2) delay in extremity reperfusion of

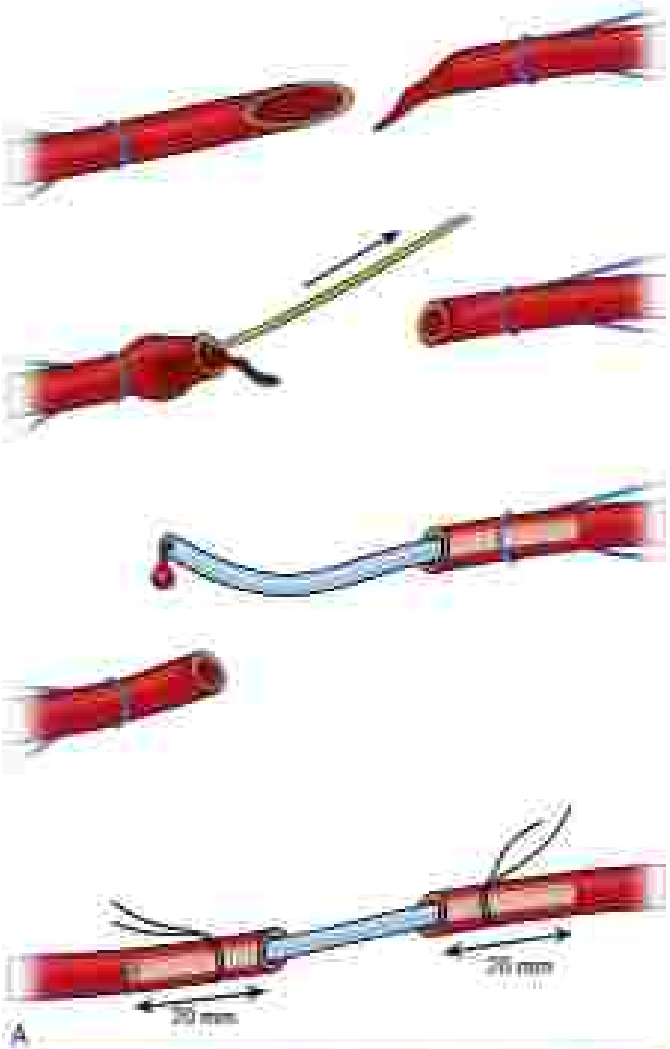

FIG. 10 (A) Sequential steps in management of a temporary vascular shunt. (1) proximal and distal control of the artery; (2) sharp debridement of injured vessel to healthy tissue; (3) shunt insertion; (4) secure tight fit after shunt placement. (B) Shunt in situ in a humeral vascular injury. (From Stannard A, Eliason JL, Rasmussen TE. Endovascular and open management of vascular injuries. Surg Clin North Am 2010;90:1211–1230.)

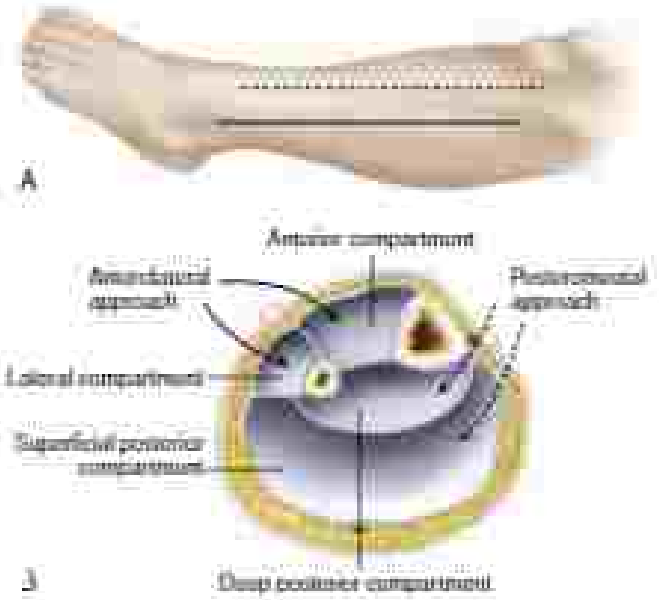

FIG. 11 Two incision approach to four compartment calf fasciotomy. A long anterolateral incision is made over the septum separating the anterior and lateral compartments. A separate but parallel posteromedial incision is made behind the tibia allowing access to the superficial and deep posterior compartments. (A) Bar axis view. (B) Cross sectional view. (From Schreiber MA, Aarabi S, Beekley AC, Operative Techniques: Orthopaedic Trauma Surgery. Philadelphia: Saunders; 2010.)

more than 3 to 4 hours, (3) limb pain out of proportion to the apparent injury; and (4) extremity swelling without significant injury. Extremity crush injuries and injuries involving both the artery and vein, especially in instances in which the vein requires ligation, are especially prone to developing compartment syndrome. There is an argument for performing fasciotomy in response to any of the high risk scenarios, the adage "if you think about doing a fasciotomy, do it" generally applies. When clinical context and examination are not clear cut, compartment pressure can be measured using a modified arterial line set up or using commercially available manometers. In general, compartment pressure greater than 30 mm Hg, or a difference between compartment pressure and diastolic blood pressure less than 30 mm Hg warrants decompression fasciotomy. Calf compartments require fasciotomy most commonly (Fig. 11).

SUMMARY

Because of the varied ways that vascular injuries can present, management can be complex, especially in the context of concomitant severe orthopedic, organ, or soft tissue injury. When presentation is subtle and the examination relatively benign, accurate management requires a high index of suspicion, with signs, mechanism of injury, and suggestive history should prompt further investigation, usually with CTA. The presence of hemorrhagic shock or hard signs of arterial injury (except intermittent bruits) are usual indications for prompt surgical intervention.

Patients in shock should be treated using the principles of damage control, permissive hypotension and liberal use of blood products are cornerstones of management and use of shunts are an important operative adjunct. For all vascular trauma patients, surgery should be performed in hybrid suites when possible. The patient should be prepped and draped for extensile exposure, with access to autogenous conduit if needed. Fasciotomy should be liberally used to prevent complications of unrecognized compartment syndrome.

The use of endovascular procedures in trauma has grown. [illegible] an adjunct for hemorrhage control [illegible] endovascular [illegible]

ENDOVASCULAR MANAGEMENT OF VASCULAR INJURIES

Joseph A. Lee [illegible], DO; Sabina Fakhoury, DO

With a rise in the use of endovascular techniques, both in surgical training and in practice, the extension of this technique to the treatment of traumatic vascular injuries is not surprising. Endovascular techniques are now being used to treat some of the most dangerous traumatic vascular injuries encountered. This newer technology can assist with quick control of difficult injuries and lead to improved outcomes in trauma patients, especially when combined with traditional open techniques.

Endovascular options provide a less invasive approach to injuries that otherwise may require large, morbid exposures. In addition, the prospect of using a familiar endovascular approach to an arterial tree avoiding a difficult or rarely encountered open exposure is attractive to many surgeons, especially those with limited trauma experience. While it may be enticing to utilize a familiar elective approach to a trauma situation, it is important to remember that trauma alters normal anatomy in unpredictable ways. Often the best approach to a traumatic vascular injury is a combination of endovascular and open techniques, and any surgeon treating these complex injuries should be prepared to use a combination tool best suits each patient.

PRE-PARE PROCESS

The first step to a successful endovascular repair of a traumatic injury happens long before the injury itself occurs, with the creation and stocking of a hybrid suite. As previously stated, the best approach to most vascular trauma includes a combination of open and endovascular techniques. Although some of the following techniques can be performed in any operating suite with a traditional C-arm, a true hybrid operating suite, capable of both endovascular and open repairs, is invaluable.

Inventory including a wide variety of wires and catheters, stents and stent grafts provides necessary options in challenging cases with variable anatomy. As many trauma patients are younger than the average vascular patient, injury due to often smaller as well. This creates a need for stents and stent grafts in smaller diameter sizes. A well-stocked endovascular trauma suite may have a much different inventory than that which we use for the average vascular patient.

In addition to a hybrid suite and a well-stocked trauma inventory, having properly trained staff available at all times is important for any program that wishes to successfully treat traumatic vascular injuries in a hybrid manner. Nurses and technicians familiar with endovascular products and techniques are an essential part of any vascular trauma team. With a combination of the appropriate staff, inventory, and operating suite, all manners of vascular injuries can be treated successfully.

MANAGEMENT OF BLUNT THORACIC AORTIC INJURIES

Blunt thoracic aortic injury (BTAI) is one of the most common and most deadly injuries encountered in trauma patients. Identification requires a high grade of clinical suspicion, as many patients with BTAI present without [illegible] dynamic instability, and films of the chest are used to assess for gross aortic abnormalities during the initial trauma evaluation. Traditionally, abnormalities, including changes in the contour of the aortic knob or widening of the mediastinum, prompted further investigation with invasive aortography. Today, however, computed tomographic angiography (CTA) is used to evaluate any patients with a high suspicion for injury.

Grading of injuries is one of the guiding principles of management. The most widely used classification scheme, first proposed by Azizzadeh et al, includes four grades of BTAI: grade I (intimal tear), grade II (intramural hematoma), grade III (pseudoaneurysm), and grade IV (rupture) (Fig. 1). These grades can help make decisions regarding treatment strategies and timing in order to optimize results.

Most grade I injuries heal spontaneously. Serial imaging with repeated control is, therefore, a reasonable treatment plan. Imaging on or near the third post-trauma day confirms stability or regression of the lesion in the majority of patients. Nonoperative management is supported by the Society for Vascular Surgery (SVS) guidelines. Grade IV injuries, which rarely survive initial injury and transport to the hospital, have a similarly simple treatment algorithm. These patients should all proceed immediately for repair.

Grade II and III patients, however, present more challenging management decisions. For each patient, two main questions must be answered: (1) Is repair required? and (2) If so, what is the optimal timing of intervention? Although the 2010 SVS guidelines recommend

The use of endovascular procedures in trauma has grown. Translational interventions, such as REBOA, are being used enthusiastically as an adjunct in trauma resuscitation. Stent grafts have demonstrated utility in the definitive treatment of injuries that would otherwise be difficult or morbid to approach surgically. It is likely that indications for endovascular therapy will continue to expand.

Endovascular Management of Vascular Injuries

Joseph V. Lombardi, MD, and Marissa Farmakes, DO

With a rise in the use of endovascular techniques, both in surgical training and in practice, the extension of this technology to the treatment of traumatic vascular injuries is not surprising. Endovascular techniques are now being used to treat some of the most dangerous traumatic vascular injuries encountered. This newer technology can assist with quick control of difficult injuries and lead to improved outcomes in trauma patients, especially when combined with traditional open techniques.

Endovascular options provide a quick, minimally invasive approach to injuries that otherwise may require large, morbid exposure. In addition, the prospect of using a familiar endovascular approach to an arterial tree, avoiding a difficult or rarely encountered open exposure, is attractive to many surgeons, especially those with limited trauma experience. While it may be enticing to utilize a familiar elective approach to a trauma situation, it is important to remember that trauma alters normal anatomy in unpredictable ways. Often, the best approach to a traumatic vascular injury is a combination of endovascular and open techniques, and any surgeon treating these complex injuries should be prepared to use a combination that best suits each patient.

PREPAREDNESS

The first step to a successful endovascular repair of a traumatic injury happens long before the injury itself occurs, with the creation and stocking of a hybrid suite. As previously stated, the best approach to most vascular trauma includes a combination of open and endovascular techniques. Although some of the following techniques can be performed in any operating suite with a traditional C-arm, a true hybrid operating suite, capable of both endovascular and open repairs, is invaluable.

Inventory including a wide variety of wires and catheters, stents, and stent grafts provides necessary options in challenging cases with variable anatomy. As many trauma patients are younger than the average vascular patients, injury size is often smaller as well. This creates a need for stents and stent grafts in smaller diameter sizes. A well-stocked endovascular trauma suite may have a much different inventory than that which we use for the average vascular patient.

In addition to a hybrid suite and a well-stocked trauma inventory, having properly trained staff available at all times is important for any program that wishes to successfully treat traumatic vascular injuries in a hybrid manner. Nurses and technicians familiar with endovascular products and techniques are an essential part of any vascular trauma team. With a combination of the appropriate staff, inventory, and operating suite, all manners of vascular injuries can be treated successfully.

MANAGEMENT OF BLUNT THORACIC AORTIC INJURIES

Blunt thoracic aortic injury (BTAI) is one of the most common and most deadly injuries documented in trauma patients. Identification requires a high grade of clinical suspicion, as many patients with BTAI present without hemodynamic instability. Plain films of the chest are used to assess for gross aortic abnormalities during the initial trauma evaluation. Traditionally, abnormalities, including changes in the contour of the aortic knob or widening of the mediastinum, prompted further investigation with invasive aortography. Today, however, computed tomographic angiography (CTA) is used to evaluate any patients with a high suspicion for injury.

Grading of injuries is useful to guide future management. The most widely used classification scheme, first proposed by Azarbal et. al., includes four grades of BTAI, grade I (intimal tear), grade II (intramural hematoma), grade III (pseudoaneurysm), and grade IV (rupture) (Fig. 1). These grades can help make decisions regarding treatment strategies and timing in order to optimize results.

Most grade I injuries heal spontaneously. Serial imaging with aspirin control is, therefore, a reasonable treatment plan. Imaging on or near the third post-trauma day confirms stability or regression of the lesion in the majority of patients. Nonoperative management is supported by the Society for Vascular Surgery (SVS) guidelines. Grade IV injuries, which rarely survive initial injury and transport to the hospital, have a similarly simple treatment algorithm. These patients should all proceed immediately for repair.

Grade II and III patients, however, present more challenging management decisions. For each patient, two main questions must be answered: (1) Is repair required? and (2) If so, what is the optimal timing of intervention? Although the 2011 SVS guidelines recommend

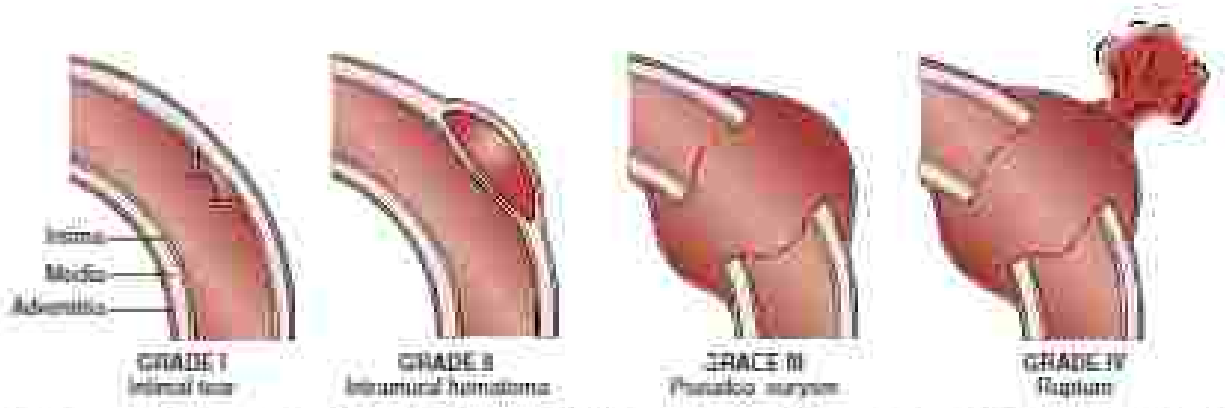

FIG. 1. Classification of traumatic aortic injury (from Cowan AR, Gleason TG, Eskandari MK, et al. Endovascular repair of traumatic thoracic aortic injuries: clinical experience and follow-up outcomes from the first multicenter registry. J Vasc Surg 2008;47:1008–13; discussion 1013–4).

intervention for all grade II and III patients, recent evidence is challenging this recommendation and deserves special review.

Several studies have reported the relative safety of nonoperative management in patients with grade II injuries. The infrequency of a true grade II injury has led several authors to group these patients together with grade I patients, reporting combined outcomes and further complicating the data. Other proposed classification schemes even group these two grades together initially. The true nature of disease of these intramural hematomas, however, remains unclear. Although it is likely that observing grade II injuries is safe, it is unclear and currently unsupported by official societal guidelines. Any observation mandates close follow up and careful impulse control.

Nonoperative management of aortic pseudoaneurysms (grade III BTAI) is also controversial. One review of 8 patients with grade III BTAI reported a 0% early aortic related mortality in patients treated with nonoperative management. A large systematic review of published reports revealed a less than 3% aortic specific mortality in patients treated nonoperatively but follow up was poor and results reporting was not standardized. All reports suggesting feasibility of nonoperative management document the need to perform this strategy only in "select patients." Unfortunately, predictors of failure have not been identified, and therefore choosing the correct patients, at this time, is impossible. In addition, continued follow up, an absolute necessity in patients with higher grade injuries managed nonoperatively, is famously impossible to achieve routinely, especially in trauma patients. A 1–3% risk of need for surgical repair in grade III patients has been reported, proving the importance of continued, reliable follow up. With an early risk of potentially preventable fatality, and a high risk of failure to follow up, the danger in observing grade III injuries is unacceptably high.

The above data suggest, however, that delaying intervention on grade II and III injuries while polytrauma patients are optimized is likely a safe option. A delay before thoracic endovascular aortic repair (TEVAR) has become increasingly common nationwide and is associated with improving national outcomes for BTAI patients. Close observation with impulse control and serial imaging is necessary, as an important caveat is that of the traumatic brain–injured patient. When purposeful hypertension is necessary to maximize cerebral perfusion, the principles of care are often at odds with the impulse control necessary to safely observe a BTAI. In these specific and not infrequent cases, we often elect to proceed with early TEVAR, allowing for permissive hypertension and the optimal treatment of any concomitant neurologic injuries.

Once intervention is deemed necessary, a surgical approach must be chosen. Traditional open repair has been compared with endovascular repair in several studies. TEVAR has been shown to decrease both mortality and morbidity, including spinal cord ischemia and renal failure, in patients with BTAI. For these reasons, endovascular repair is recommended over open repair whenever anatomically feasible, including in pediatric patients. National trends reflect these recommendations, with a sharp decrease in the number of patients with BTAI treated with open surgery being reported over time.

Several devices have been proven to be safe and effective in the endovascular treatment of BTAI. Percutaneous femoral access is the preferred method of access when suitable, although femoral cutdown or iliac conduit may be required in patients with diseased access vessels. Obtaining wire access across an injury can be challenging, especially in cases of transection. In these cases, careful use of a glidewire is often the best way to cross a lesion. Access into the true lumen of the healthy, proximal aorta can be confirmed with intravascular ultrasound or transesophageal echocardiogram, although in practice often a good angiogram is sufficient.

Landing in healthy aorta with at least 20 mm of neck proximal and distal to the aortic injury is an important tenet of endovascular repair. This often requires coverage of the left subclavian artery (LSA). In most patients, routine revascularization of the LSA is unnecessary and not recommended. However, in patients with stenotic or absent right vertebral artery or prior left internal mammary artery cardiac bypass, early revascularization should be performed. As the risk of spinal cord ischemia in BTAI patients is low, routine use of spinal fluid drainage is not recommended, although close postoperative evaluation of neurologic exam is important.

The ideal timing of surveillance after TEVAR for BTAI is unclear. Multiple studies have reported extremely low rates of reintervention following TEVAR for BTAI, suggesting low utility in frequent imaging. Problems leading to re-intervention predominantly occur early, usually within 3 months, for these reasons, several authors have suggested a decreased frequency of surveillance after stable scans at 1 year. Patient noncompliance is historically low in all trauma patients, and clear discussions with the patient and family are necessary to ensure any surveillance program is followed.

PENETRATING AXILLOSUBCLAVIAN INJURIES

Penetrating injuries to the axillary or subclavian artery are rare, but carry a high mortality. Open surgical repair is difficult and exposure is often time consuming. Endovascular therapy is gaining popularity as a first therapeutic treatment option for these unstable patients. Small studies have demonstrated superiority of endovascular repair to penetrating axillosubclavian injuries, with lower mortality and morbidity when compared with open surgical repair. A larger review of contemporary data from 11 large centers, however, points out the importance of patient selection, as in real-life experience endovascular repair is often used in more stable patients with less severe injuries. Endovascular repair is certainly an important tool that can assist in both control and repair of these challenging injuries.

brachial access to offer the quickest way to cross an innominate injury. This method can be performed percutaneously, although in practice a brachial cutdown is often the preferred method of choice. Brachial access avoids traversing the aortic arch prior to crossing the injury, a step that can be time consuming in patients with difficult arch anatomy. A combination of femoral and brachial access may be necessary for patients with difficult lesions, tortuosities, or small brachial arteries. Covered self expanding stents or balloon-expandable stents can be used, and a 10% to 20% oversizing is recommended.

Close postoperative evaluation with frequent physical exams is necessary, as this patient population is at particularly high risk for stent thrombosis. When appropriate, antiplatelet therapy should be initiated.

ENDOVASCULAR REPAIR OF TRACHEOINNOMINATE ARTERY FISTULA

tracheoinnominate fistula (TIAF) is a rare but feared complication of tracheotomy. Caused by pressure of the trachea from the tracheostomy tube tip or cuff against the overlying crossing innominate artery, TIAF is thought to be more common in patients where the cuff or edge of the tube reaches this area. This may be secondary to a low tracheostomy, a long tracheostomy tube, or patient anatomy.

The first important step in treating a TIAF is diagnosis. Although some patients initially present with overt hemorrhage, a herald bleed that stops spontaneously often precedes this event. TIAF should be suspected in any patient with a new episode of bleeding from their tracheostomy, especially if the tracheostomy was placed more than 3 days prior to the episode. Bronchoscopy remains the diagnostic test of choice, as CTA is rarely diagnostic. A lesion on the anterior tracheal wall adjacent to the pulsation of the crossing innominate artery is highly suggestive of fistula and should prompt repair. As the time between a herald bleed and overt hemorrhage is unpredictable, evaluation should be obtained emergently after any episode of bleeding.

Patients who present in extremis with active bleeding present a unique challenge. The first maneuver attempted should be to overinflate the tracheostomy balloon. If this is ineffective, digital compression of the innominate against the manubrium (the Chevy maneuver) can be attempted by placing a digit into the pretracheal plane, usually through the tracheostomy after orotracheal intubation. Throughout all attempts at control, the operating room (OR), preferably a hybrid suite, should be readied for emergent use.

The high mortality plaguing open repair of TIAF has led to many attempts at endovascular repair of these difficult lesions. Although the TIAF is considered a contaminated lesion, postoperative infectious complications occur in a minority of cases. It is therefore reasonable to attempt endovascular repair, with close postoperative follow up and lifelong antibiotic therapy. It should also be noted that the patient population experiencing TIAF is often fraught with comorbidities and the documented survival after these events, even after successful repair, is low. This has led many authors to compare endovascular TIAF repair to a palliative procedure.

Although coil embolization of the innominate has been suggested, stent graft placement across the lesion is usually considered first line therapy. Wire access across the lesion can be obtained via femoral approach, although carotid cutdown is often preferred as it allows for protection against distal embolization and easy access across the lesion without navigating the arch. The length and size of the innominate artery often makes graft selection for this area difficult, with thin grafts often being the most appropriate choice. Type II endoleak from a patent subclavian artery can be problematic (Figs. 2 and 3). In this case, a supraclavicular approach to the right subclavian allows for proximal ligation of the artery and subsequent carotid subclavian bypass (Fig. 4).

RESUSCITATIVE ENDOVASCULAR BALLOON OCCLUSION OF THE AORTA

Injury causing hemorrhage from a noncompressible vessel in the abdomen or pelvis is notoriously difficult to control quickly and can lead to significant morbidity and mortality in trauma patients. In the past, noncompressible torso hemorrhage leading to hemodynamic collapse was treated with resuscitative thoracotomy (ie, ED) and cross-clamping of the descending thoracic aorta. An effort to improve upon this maximally invasive approach led to the development of resuscitative endovascular balloon occlusion of the aorta, or REBOA.

In REBOA, a balloon inserted through the common femoral artery is used to occlude the aorta either above the celiac artery or below the renal arteries, depending on the suspected location of bleeding. Aortic occlusion not only assists with control of hemorrhage, but also aims to increase cardiac and cerebral perfusion.

Insertion and use of REBOA requires several steps (Box 1). Each step has several guidelines, which, when followed, can help prevent complications. Step 1 requires accessing the common femoral artery. Traditionally, a femoral cutdown was required for safe cannulation; however, more recently, percutaneous access has been used with increasing frequency. The location of arterial access is important in the prevention of complications. A high stick can lead to retroperitoneal hemorrhage, while a low stick can lead to occlusion of the vessel by the device sheath and thrombosis. Accidental vasopuncture can cause iatrogenic arteriovenous fistula. The precise location for safe arterial access can be difficult to find, especially in a hypotensive, noncontrasted patient in the high stress environment of the trauma bay. Fortunately, ultrasound, a familiar tool readily available in the trauma bay, has been shown to significantly decrease the incidence of access complications after percutaneous arterial cannulation. In the hands of a skilled user, ultrasound decreases the time to cannulation, and should be used in all cases of REBOA placement.

BOX 1 Stepwise Approach to Implementation of Resuscitative Endovascular Balloon Occlusion of the Aorta

Step 1: Arterial access
Step 2: Positioning of the balloon
Step 3: Balloon inflation
Step 4: Management of hemorrhage
Step 5: Balloon deflation
Step 6: Device and sheath removal

Once the common femoral artery is safely accessed, the Seldinger technique is used to place an appropriately sized sheath. Although historically a number of different balloons and devices have been used, there is currently one Food and Drug Administration–approved device, the ER-REBOA (Prytime Medical). This device is inserted through a 7Fr sheath.

In step 2, the ER-REBOA device is advanced blindly into position with no fluoroscopic guidance or guidewire. This should occur without resistance. Preexisting arterial pathology or malpositioning may prevent easy safe passage of the device, and resistance should prompt abandonment of the technique. Other devices and balloons use a guidewire for positioning. Fluoroscopy or radiography is used to confirm zone positioning of the balloon, after which it is inflated. Many catastrophic complications have been documented secondary to poor balloon positioning. Therefore, it is important for practitioners to be familiar with the device they are using and the proper placement of any radio-opaque markers on that specific device.

After balloon inflation, all efforts should be made to quickly repair the patient's source of hemorrhage and subsequently deflate the balloon. Longer aortic occlusion times portend poor outcomes. There is some evidence that the hemodynamic stability provided by REBOA and the minimally invasive nature of the femoral sheath create a decreased sense of urgency, with some reports even documenting patients who have had CTAs performed during REBOA. Patients with an inflated balloon should be considered unstable and should be treated just as a patient after ED and aortic cross-clamping.

Once a patient has been stabilized, the balloon can be deflated. This maneuver should always be performed with the full awareness of the entire team, including anesthesia. Volume shifts and metabolic abnormalities can lead to hypotension after balloon deflation. Temporary partial or complete reinflation of the balloon can be helpful to augment blood pressure. If no drop in blood pressure occurs after deflation of the balloon, distal embolization or thrombosis should be suspected. After balloon deflation, the device is removed through the sheath. Again, any resistance should raise high suspicion for complications.

Finally, removal of the sheath can occur. In a patient with normal coagulation, the 7Fr sheath used for the ER-REBOA can be removed safely with manual pressure held for approximately 20 minutes. Basic postcatheterization care will assist in the prevention and identification of complications, including 4 hours of bed rest after sheath removal and close evaluation of the groin and distal pulses for at least 24 hours. Larger sheaths or any sheath in a coagulopathic patient may be unsafe for basic manual removal. In these cases, and any case when the location of initial puncture is unknown or erroneous, femoral cutdown with direct arterial repair is the safest option.

Reports in the literature regarding complications of REBOA are sparse. The Aortic Occlusion for Resuscitation in Trauma and Acute Care Surgery (AORTA) registry, a multiinstitutional database capturing REBOA use since 2013, reported only 9 complications after 83 uses. However, anecdotal reports from high-volume centers suggest

FIG. 3 Bilateral lower extremity ischemia requiring amputation and inferior mesenteric artery occlusion requiring colectomy.

that a multitude of vascular complications can, and do, occur. In our institutional experience, an IR-REBOA positioned in a dissection plane was advanced into the subrenal aorta and inflated, leading to bilateral lower extremity ischemia requiring amputation and bilateral mesenteric artery occlusion requiring colectomy (Fig. 3). Like any surgical procedure, understanding and evaluating the possible complications of REBOA are paramount to its safe and effective use. Notification of the vascular surgical team is included by some groups as an important early step in the REBOA process, helping to prevent, identify, and correct complications. This step is highly recommended.

Some small studies and the AORTA registry have documented improved outcomes after REBOA use when compared with RT. REBOA has also been shown to be an effective bridge to definitive hemostasis after severe pelvic trauma. However, questions remain regarding the safety and utility of this newly adopted technology. For example, the lack of documented complications in the literature compared with a high number of anecdotal complications is concerning, and suggests that the safety of this technique is not yet known. While in a dying patient, attempting a new or unproven technique may be justified, the literature currently does not support the safe extension of this technology to stable patients. This technique, therefore, should never be used as a replacement for traditional proximal control in open trauma or vascular cases.

ENDOVASCULAR MANAGEMENT OF INADVERTENT ARTERIAL PLACEMENT OF LARGE-BORE CATHETERS

Accidental arterial catheterization is an infrequent complication of a common procedure. Although in the femoral artery catheters can often be removed safely with manual pressure applied, accidental cannulation of the carotid or subclavian artery proves more difficult to manage. The subclavian artery is impossible to compress manually due to its anatomic location. For accidental carotid cannulation, there is an added risk of stroke due to thrombus formation on the catheter that may be dislodged upon removal. Also, as most internal jugular (IJ) venous cannulations are now performed under ultrasound guidance, accidental carotid cannulations frequently involve through and through I injuries that are not amenable to percutaneous closure.

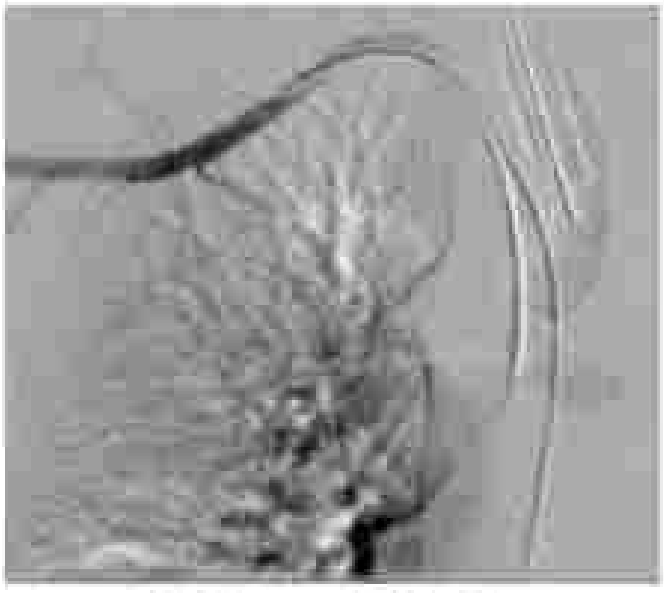

FIG. 4 Femoral approach to vessel.

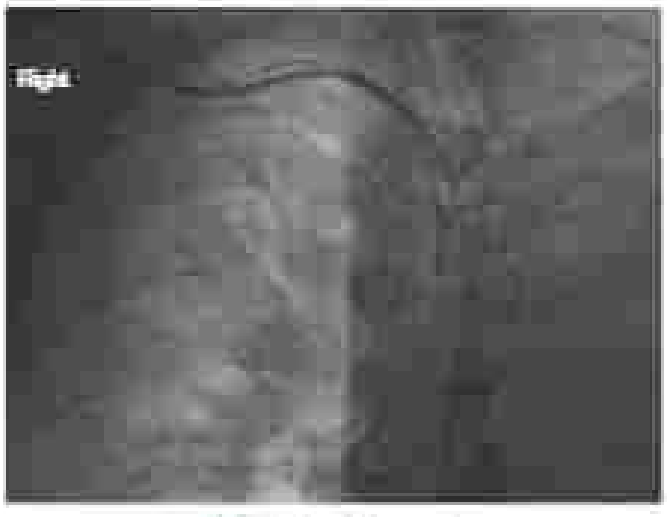

FIG. 5 Balloon placement.

Using a percutaneous closure device after accidental sheath placement has been evaluated and noted to be safe, even for carotid artery cannulations. If the accidental cannulation is identified early, before thrombus can form on the catheter tip, this is likely a reasonable approach. To prevent thrombus formation, if it were to heparinize any patient with a subclavian or carotid line as soon as it is identified. For additional safety, it is recommended that closure be performed in an OR or hybrid suite. It is our practice to obtain access to the vessel in question via a femoral approach (Fig. 4). A balloon can then be placed proximal to the injury in case proximal control is necessary (Fig. 5). The catheter is then removed and the closure device is deployed. After placement of the closure device is complete, a completion angiogram is performed to rule out any extravasation (Fig. 6). This is especially important for subclavian injuries, as manual compression is not possible in this location.

If a pseudoaneurysm or arteriovenous fistula is present at the cannulation site, placement of a covered stent over the area may be the best approach. Both self-expanding and balloon-expandable stents

FIG. 8 Completion angiogram.

have been successfully used in this manner. In cases of accidental carotid puncture, the high likelihood of concomitant venous injury makes use of a covered stent superior to closure device as a treatment strategy. It is important to remember, however, that embolization during stent deployment to the carotid circulation is a risk. Each case must be individualized and open operative repair is often the safest approach for carotid injuries for this reason.

Management of Extremity Compartment Syndrome

Charles E. Lucas, MD, and Anna M. [illegible]ood, PA-C

A compartment syndrome develops from excessive swelling of soft tissue within a confined space. This resultant tissue hypertension may exceed capillary hydrostatic pressure (25 mm Hg), thereby compromising oxygenation of muscle, nerve, and vessels, ultimately causing necrosis. Bywaters and Beall, in 1941, reported a lethal compartment syndrome during the World War II London Blitz. Following extrication of their neighbors with crushed limbs, the horse drawn drays transported them to nearby hospitals; those initially stable and oriented patients deteriorated that evening from extravasation of fluid into the crushed limb, tissue hypertension, muscle necrosis, rhabdomyolysis with myoglobinuria, renal failure, and death. Prevention of this fatal outcome requires an understanding of the basic pathophysiology. Elevated tissue pressure results from increased interstitial and intracellular fluid associated with ischemia/reperfusion, crush injury, or from external compression from a cast. The subsequent pathophysiology is comparable. The venous system develops outflow obstruction when tissue pressure rises. This compromises the lymphatic emptying into nearby veins, thus increasing interstitial fluid pressure, which impedes egress of intracellular fluid. This impairs nutrient flow from the capillaries, leading to cellular hypoxia and producing cellular ischemia, acidosis, muscle necrosis, myoglobinuria, renal failure, and death. Ultimately extensive debridement or amputation may be necessary.

Causes of Compartment Syndrome

Compartment syndrome may be caused by either external compression, internal tissue expansion, or a combination of both (Table 1). The classic scenario for increased external compression occurs when a tightly placed plaster cast or wrap is applied soon after long bone fracture. This external compression fails to allow for the expected soft tissue swelling, which typically follows injury. Any patient complaining of pain in this setting must have the cast bivalved or the wrap cut to relieve the pain. Masking the tissue hypertension with narcotics is potentially disastrous. This type of preventable tissue injury should never occur.

Most compartment syndromes result from an internal compartment expansion (see Table 1). The classic example is the ischemia/reperfusion injury. Artery occlusion due to injury, thrombosis, or prolonged application of a tourniquet leads to cellular ischemia with extensive tissue expansion once flow is restored. Patients with injury involving the femoral artery trifurcation or the popliteal artery are especially prone to severe distal ischemia when vascular reconstruction is delayed beyond 6 hours. The likelihood for compartment syndrome increases when the ischemic insult is combined with severe soft tissue injury typically associated with long bone fractures and/or venous injury requiring ligation. Other examples of the tissue ischemia/reperfusion syndrome occur in patients undergoing urgent abdominal aorta aneurysmectomy when there is technical difficulty reestablishing flow to one of the limbs, difficult reconstruction of the popliteal artery after severe injury (Fig. 1), and patients with arterial injury in a military setting where temporary shunting is practiced in preparation for vascular reconstruction. Prophylactic compartment decompression is routine when these soldiers have to be transferred to a higher level of care. Extensive combined injuries of bone, vessels, and soft tissues are seen after pedestrian motor vehicle collisions, high velocity rifle wounds, and close range shotgun wounds (Fig. 2).

FIG. 8 Completion angiogram.

have been successfully used in this manner. In cases of accidental carotid puncture, the high likelihood of concomitant venous injury makes use of a covered stent superior to closure device as a treatment strategy. It is important to remember, however, that embolization during stent deployment to the carotid circulation is a risk. Each case must be individualized and open operative repair is often the safest approach for carotid injuries for this reason.

Management of Extremity Compartment Syndrome

Charles E. Lucas, MD, and Anna M. Ledgerwood, MD

A compartment syndrome develops from excessive swelling of soft tissue within a confined space. This resultant tissue hypertension may exceed capillary hydrostatic pressure (25 mm Hg), thereby compromising oxygenation of muscle, nerve, and vessels, ultimately causing necrosis. Bywaters and Beall, in 1941, reported a lethal compartment syndrome during the World War II London Blitz. Following extrication of their neighbors with crushed limbs, the horse drawn drays transported them to nearby hospitals; those initially stable and oriented patients deteriorated that evening from extravasation of fluid into the crushed limb, tissue hypertension, muscle necrosis, rhabdomyolysis with myoglobinuria, renal failure, and death. Prevention of this fatal outcome requires an understanding of the basic pathophysiology. Elevated tissue pressure results from increased interstitial and intracellular fluid associated with ischemia/reperfusion, crush injury, or from external compression from a cast. The subsequent pathophysiology is comparable. The venous system develops outflow obstruction when tissue pressure rises. This compromises the lymphatic emptying into nearby veins, thus increasing interstitial fluid pressure, which impedes egress of intracellular fluid. This impairs nutrient flow from the capillaries, leading to cellular hypoxia and producing cellular ischemia, acidosis, muscle necrosis, myoglobinuria, renal failure, and death. Ultimately extensive debridement or amputation may be necessary.

Causes of Compartment Syndrome

Compartment syndrome may be caused by either external compression, internal tissue expansion, or a combination of both (Table 1). The classic scenario for increased external compression occurs when a tightly placed plaster cast or wrap is applied soon after long bone fracture. This external compression fails to allow for the expected soft tissue swelling, which typically follows injury. Any patient complaining of pain in this setting must have the cast bivalved or the wrap cut to relieve the pain. Masking the tissue hypertension with narcotics is potentially disastrous. This type of preventable tissue injury should never occur.

Most compartment syndromes result from an internal compartment expansion (see Table 1). The classic example is the ischemia/reperfusion injury. Artery occlusion due to injury, thrombosis, or prolonged application of a tourniquet leads to cellular ischemia with extensive tissue expansion once flow is restored. Patients with injury involving the femoral artery bifurcation or the popliteal artery are especially prone to severe distal ischemia when vascular reconstruction is delayed beyond 6 hours. The likelihood for compartment syndrome increases when the ischemic insult is combined with severe soft tissue injury typically associated with long bone fractures and/or venous injury requiring ligation. Other examples of the tissue ischemia/reperfusion syndrome occur in patients undergoing urgent abdominal aortic aneurysmectomy when there is technical difficulty reestablishing flow to one of the limbs, difficult reconstruction of the popliteal artery after severe injury (Fig. 1), and patients with arterial injury in a military setting where temporary shunting is practiced in preparation for vascular reconstruction. Prophylactic compartment decompression is routine when these soldiers have to be transferred to a higher level of care. Extensive combined injuries of bone, vessels, and soft tissues are seen after pedestrian/motor vehicle collisions, high velocity rifle wounds, and close range shotgun wounds (Fig. 2).

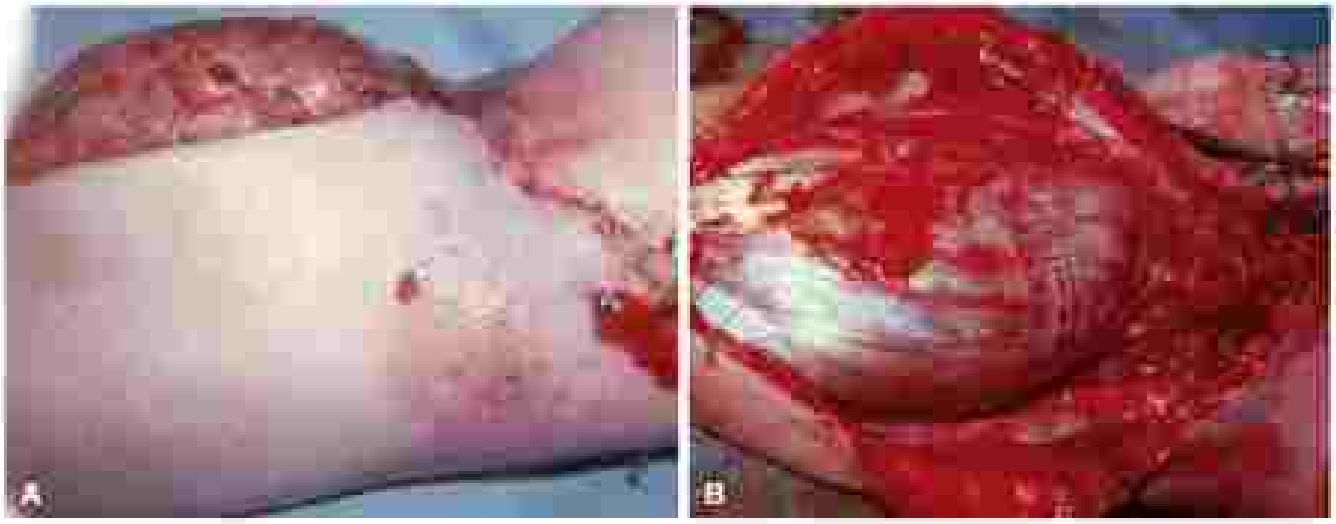

FIG. 1 (A) A delay in fasciotomy after repair of a popliteal artery injury and ligation of the adjacent vein results superficial muscle necrosis. (B) These areas of muscle ischemia and superficial death were minimally debrided and the underlying muscle gradually improved with frequent dry dressing changes over the next 3 weeks. Aggressive early debridement leads to loss of muscle fibers that would have survived.

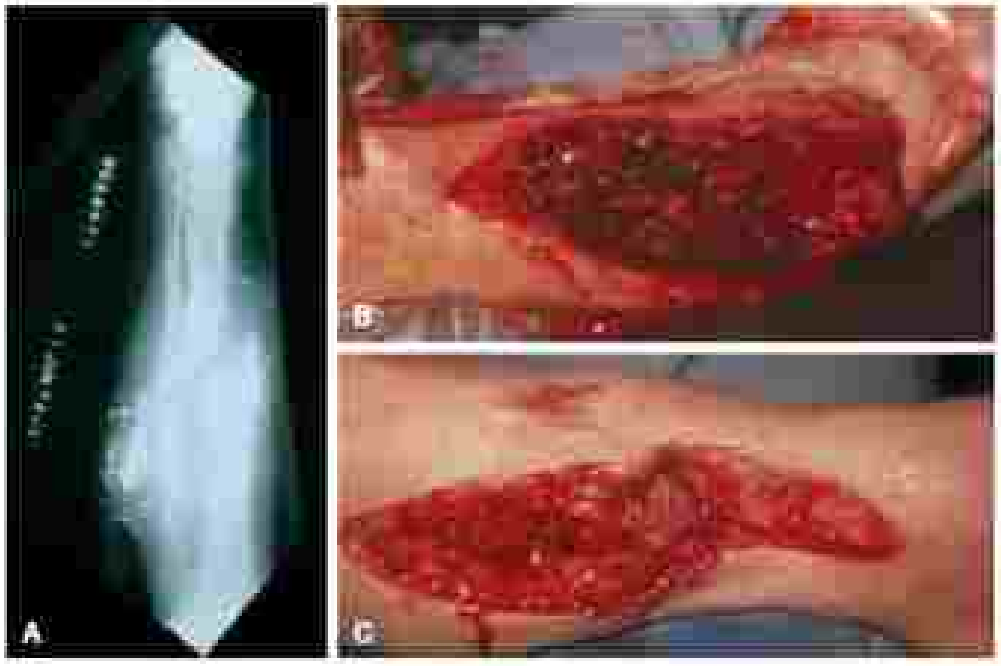

FIG. 2 (A) This 1-year-old patient had a close-range shotgun blast to the calf causing tibia and fibula fractures and extensive tissue damage with disruption of the peroneal and posterior tibial arteries. A split graft was recruited through the anterior compartment and extensions of the wounds (B) and a rent (C) wounds provided good compartment decompression. The wound was allowed to heal by second intent and by 3 weeks good granular tissue was present. He later received a skin graft and had a good long-term result.

Arterial shunting, external fixation of fractures, rapid vascular reconstruction, and extensive fascia decompression are often needed to salvage the involved limb.

Classic examples of both external compression and internal expansion include crush injury most commonly seen today in an industrial accident, a patient with circumferential burn of the extremity requiring intensive crystalloid resuscitation in association with a constrictive eschar, and vascular direct cellular insult from a high voltage electrical injury of muscle. Burns without eschar, limiting without circumferential swelling, and generalized sepsis rarely increase tissue pressure beyond hydrostatic pressure.

Venous occlusion due to thrombosis or impaired venous return from external pressure may lead to compartment syndrome (Fig. 3). The latter may occur when an intoxicated or even unconscious patient lies on the extremity for a prolonged period. Rhabdomyolysis with renal failure often accompanies this insult. Unusual causes of compartment syndrome include intramuscular or subcutaneous injection of illicit drugs causing abscess formation, extensive cellulitis, and tissue ischemia. This is commonly seen with soft tissue injection of "mixed jive" heroin, where attempted venipuncture is errant. Extensive debridement may be indicated (Fig. 4).

DIAGNOSIS

A thorough history directs the examiner to the diagnosis of compartment syndrome. The alert and cooperative patient should be assessed for the six P's, namely, pain, pressure, passive extension pain, paresis, paralysis, and pulselessness. Pain is usually described as throbbing

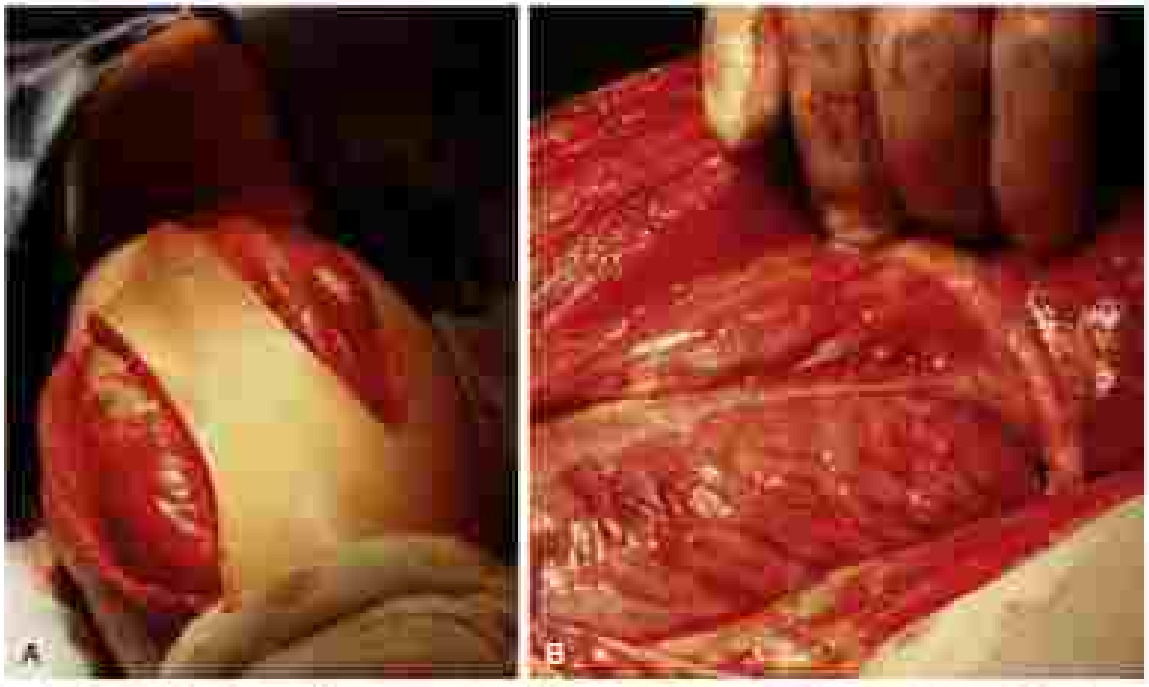

FIG. 3 This patient, admitted for a drug overdose, was seen in the critical care unit for a swollen right thigh, which was hard and tense and associated with neurapraxia. Medial and lateral thigh fasciotomies (A) revealed pale muscles, which rapidly pinked up with compartment decompression. (B) He went on to develop acute renal shutdown and required dialysis for 3 weeks, but all muscle group survived and he had good function following split thickness skin grafting.

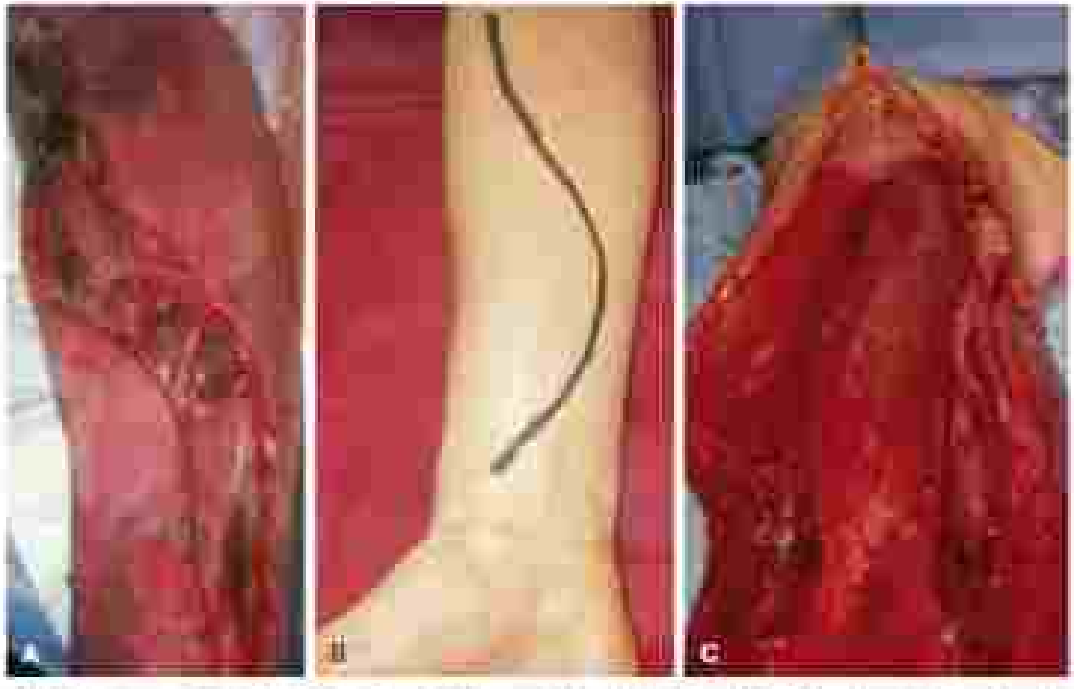

FIG. 4 (A) Injection of contaminated "mixed gas" heroin into the forearm subcutaneous tissues led to extensive soft tissue necrosis involving the forearm and distal arm with associated compartment syndrome. (B) Extensive soft tissue debridement and excision of the forearm fasciotomy incision proximal to include the anterior compartment of the arm (C) resulted in limb salvage and long-term reasonable function.

FIG. 3 The Stryker pressure monitoring system is a hand-held, solid-state transducer device that can be used to directly measure muscle tissue pressure. The syringe and manometer are contained in the special chamber and the directions for use are engraved on the back of this chamber.

and unrelenting. Pressure, the earliest objective finding, reflects the swollen, hard, and tender muscle. Passive stretch of the involved muscles increases the pain but is difficult to assess if there is an associated fracture. Paresis, or muscle weakness, is due to nerve compression and is a reliable finding with anterior compartment syndrome of the leg. The deep peroneal nerve, in the anterior compartment, innervates the web space of the great toe; paresis in this area suggests an anterior compartment syndrome. Paralysis indicates worse neural compromise. Pulselessness represents the end stage of compartment syndrome when the tissue pressure occludes a major artery, many patients with compartment syndrome still have a peripheral pulse.

Objective confirmation of a compartment syndrome in the unpaired patient requires direct tissue pressure monitoring. Compartment decompression, therefore, is usually performed on the basis of clinical examination without the need for tissue pressure manipulating. Patients under anesthesia or impaired by alcohol, street drugs, or head injury require tissue pressure monitoring. The direct needle puncture with a hand-held, solid-state transducer device (STIC catheter, Stryker Surgical) permits repeated measurements before and after decompression is provided (Fig. 3). Alternatively, a central venous pressure manometer filled with sterile saline and attached to an extension tube and an 18-gauge needle can be inserted into the muscle. The manometer is set at 40 cm H_2O and placed at the same level as the muscle when the stopcock is opened. The water column will either rise or fall. When the column rises, fasciotomy is needed; if the column falls, observation can be continued. A water column pressure of 40 cm H_2O is the same as 30 mm Hg.

COMPARTMENT DECOMPRESSION

Established compartment syndrome requires release of the constricting tissue; nonoperative therapies have no role. Release of the constricting tissue requires a long incision, which releases the skin, subcutaneous tissues, and underlying fascia. Subcutaneous fascial edges to be avoided. Debridement of ischemic muscle should be conservative since many muscle fibers that appear necrotic will survive, and the detrimental systemic effects of ischemic muscle will be avoided once the compartment is decompressed and the products of dead muscle can escape into the dressing (see Fig. 1). Nerve debridement should be avoided.

ARM COMPARTMENT DECOMPRESSION

The arm has two compartments, namely, the anterior compartment containing the deltoid and biceps brachii and the posterior compartment containing the triceps. Anterior compartment syndrome may occur after the inadvertent subcutaneous injection of heroin into

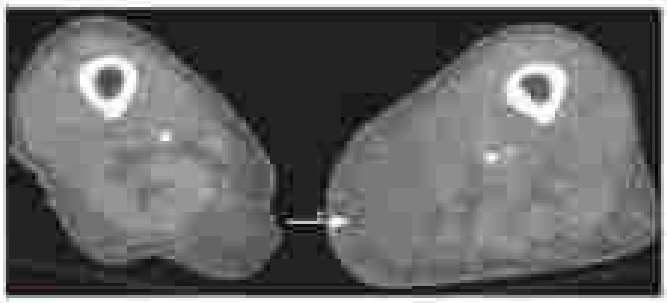

FIG. 4 This patient had severe sepsis, which was associated with myonecrosis of the gracilis and adductor muscle group. The left gracilis (right) is much smaller than the right gracilis (left). A long medial fasciotomy provided immediate relief of symptoms and allowed the underlying ischemic muscles to survive.

during attempted venipuncture. The resultant extensive cellulitis spreads rapidly, necessitating a long incision beginning just distal to the deltoid and extending over the biceps across the antecubital fossa in a curvilinear manner to the lateral portion of the forearm to the wrist. Compartment hypertension of both the anterior and posterior arm compartments more likely occurs with crush injury or long-term venous occlusion due to the patient sleeping on the arm while intoxicated. The posterior incision extends over the triceps muscle to the midline to about 3 cm proximal to the elbow. If necessary, decompression of the deltoid muscle can be achieved by extending the anterior incision proximally to the anterior cuff (see Fig. 4).

FOREARM COMPARTMENT SYNDROME

The forearm has three muscular compartments, the volar compartment contains the wrist and hand flexors, while the dorsal compartment contains the extensors; the lateral compartment contains the brachial radialis and extensor carpi radialis longus and brevis. Isolated volar compartment syndrome occurs after subcutaneous street drug injection, extravasation of intravenous infusions, or insect bites. Decompression of the volar compartment is achieved through an incision that begins at the lateral part of the elbow and descends medially in a curved manner for the proximal half of the forearm and then curves laterally down to just above the wrist (see Fig. 2). This incision also decompresses the lateral compartment. When all three forearm compartments are compromised, after severe burns or extensive trauma with long bone fracture and ischemia necessitating vascular reconstruction, a posterior decompression should be added. This incision extends from the radial head medially to the midportion of the arm and then laterally to the wrist (see Fig. 4).

THIGH COMPARTMENT SYNDROME

A thigh compartment syndrome is rare but may occur from crush injury, venous outflow occlusion, or extensive bone and soft tissue disruption from explosions or high-velocity rifle wounds (see Fig. 4). The thigh has three compartments with the anterior compartment containing the sartorius and the quadriceps femoris, the medial compartment containing the gracilis and adductor muscles, and the posterior compartment containing the biceps femoris, semimembranosus, and semitendinosus. Compartment syndrome of the thigh is likely to involve all three compartments requiring total decompression. Decompression of the anterior and posterior compartments can be achieved with an incision extending from the greater trochanter posterior laterally to just above the knee. The fascia overlying the vastus lateralis is identified so that the anterior compartment can be decompressed through an incision anterior to the intermuscular septum and the posterior compartment decompressed through another longitudinal incision posterior to the septum. Decompression of the medial compartment is achieved by a medial incision, which runs posterior to Hunter's canal and opens the fascia over the gracilis and the adductor muscles (Fig. 5).

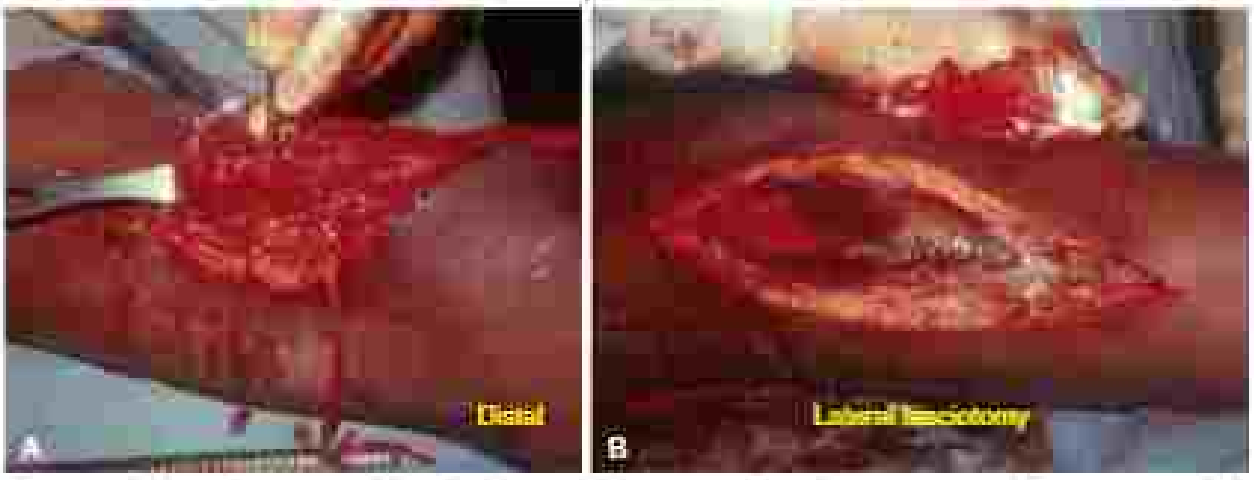

FIG. 7 The patient had a car bumper injury of the popliteal artery which was repaired through a posterior approach. Decompression of the superficial posterior compartment was achieved by extending the distal portion of the incision inferiorly (A), whereas decompression of the anterior and lateral compartments was achieved through a lateral fasciotomy (B).

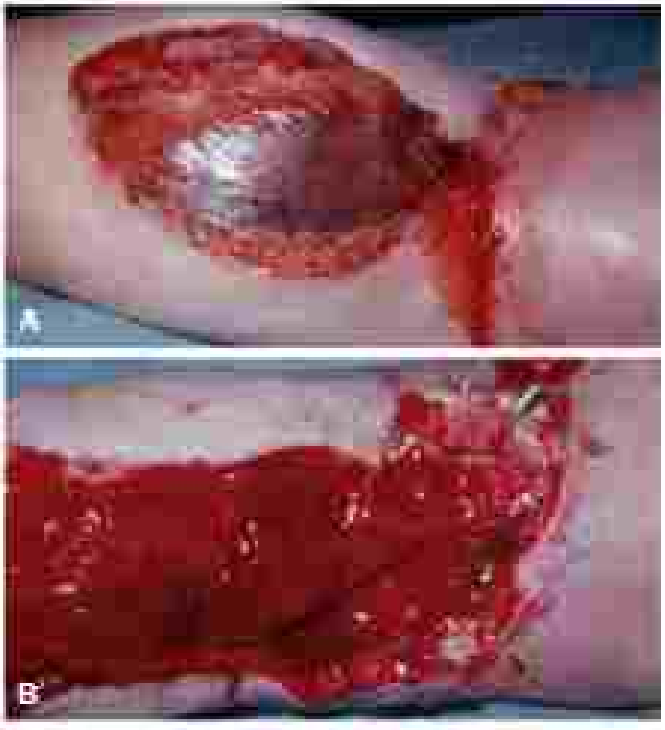

FIG. 8 The patient had primary repair of the popliteal vein and vein graft interposition of the popliteal artery following a crush injury. The skin was closed primarily leading to compartment syndrome, which shows marked bulging of the gastrocnemius (A) with superficial necrosis (B) necessitating resection or debridement of about half of the gastrocnemius. Following combined injury of the popliteal artery and vein, prophylactic compartment decompression is recommended.

CALF COMPARTMENT DECOMPRESSION

Most compartment syndromes occur in the calf and are due to ischemia/reperfusion injury associated with elective or emergency vascular reconstruction after crush injuries or combined fractures and soft tissue injury (Fig. 7). The calf has four compartments. These include the anterior compartment containing the tibialis anterior, the extensor hallucis longus, the extensor digitorum longus, and a portion of the peroneus tertius, the lateral compartment containing the peroneus longus and brevis, the superficial posterior compartment containing the soleus, gastrocnemius, and plantaris, and the deep posterior compartment containing the flexor hallucis longus, tibialis posterior, flexor digitorum longus, and popliteus. Although the lateral compartment contains the superficial peroneal nerve, the peroneal artery courses in the deep posterior compartment along with the posterior tibial artery and the deep peroneal nerve. Patients with popliteal artery injury, especially in association with popliteal venous injury, are especially prone to develop compartment syndrome. With these injuries, it is better to err on the side of being too aggressive rather than being too conservative (Fig. 8).

FOUR-COMPARTMENT DECOMPRESSION

The most common technique for decompressing the four compartments of the calf is to use bilateral incisions (Fig. 9). The medial incision is made just distal to the medial tibial condyle and extends inferiorly to about 5 cm posterior to the posterior ridge of the tibia (see Fig. 5A). The incision should divide the fascia overlying the gastrocnemius, the anterior superficial muscle fibers of the gastrocnemius and soleus are separated from the posterior periosteum of the tibia, thus giving access to the deep posterior compartment (Fig. 10). The lateral and anterior compartments are decompressed by a lateral skin incision along the anterior margin of the fibula between the muscle fibers of the lateral compartment and the lateral fibers of the anterior compartment. The skin must be retracted anteriorly to expose the fascia of the anterior compartment muscles and then posteriorly to expose the fascia overlying the lateral compartment; both fascial planes are incised the full length of the incision (Fig. 11). When there is extensive soft tissue damage with vascular disruption, the technique for fascial decompression may be modified.

SELECTIVE COMPARTMENT DECOMPRESSION

Occasionally, decompression of three of the four leg compartments will lower the pressure in the deep posterior compartment. For example, one patient with pressures of 70 cm H_2O in the anterior, lateral, and superficial posterior had three compartment decompression through medial and lateral incisions, which reduced the three compartment pressures to 5 cm H_2O. The deep posterior was then measured and was 7–8 cm H_2O. When tissue pressures can be obtained after three compartment fasciotomies and the deep posterior compartment pressure is below 20 mm Hg, no further decompression
