
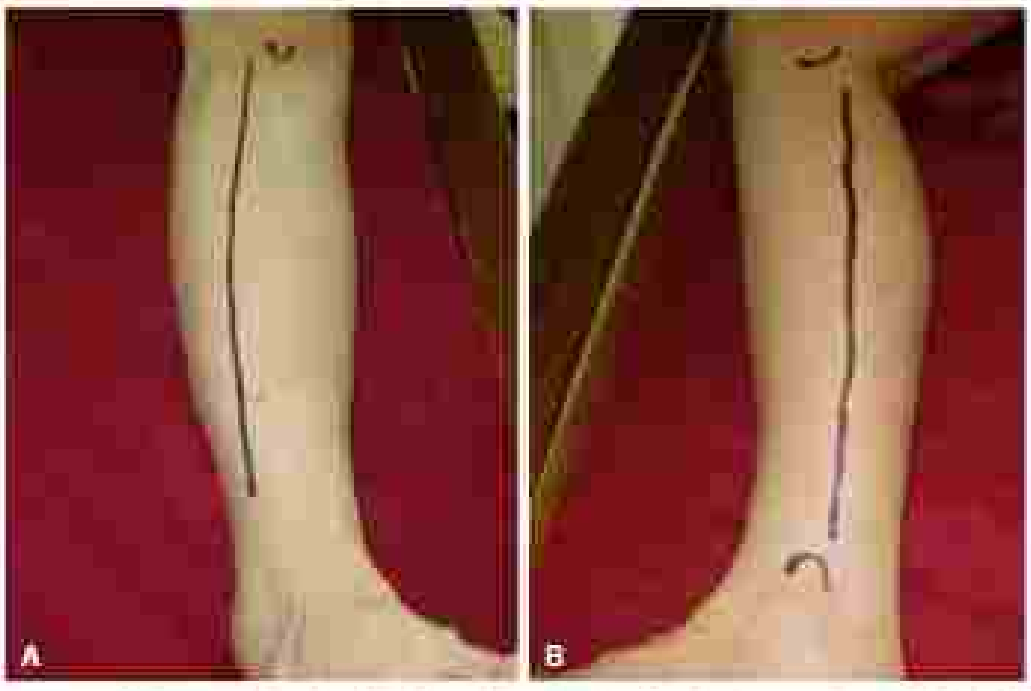

FIG. 9 (A) Four-compartment fasciotomy of the calf is achieved by making a lateral incision along the anterior margin of the fibula over the intermuscular groove separating the anterior and lateral compartments. (B) The medial incision is made just distal to the tibial condyle and extends between the superficial posterior muscle group and the tibia.

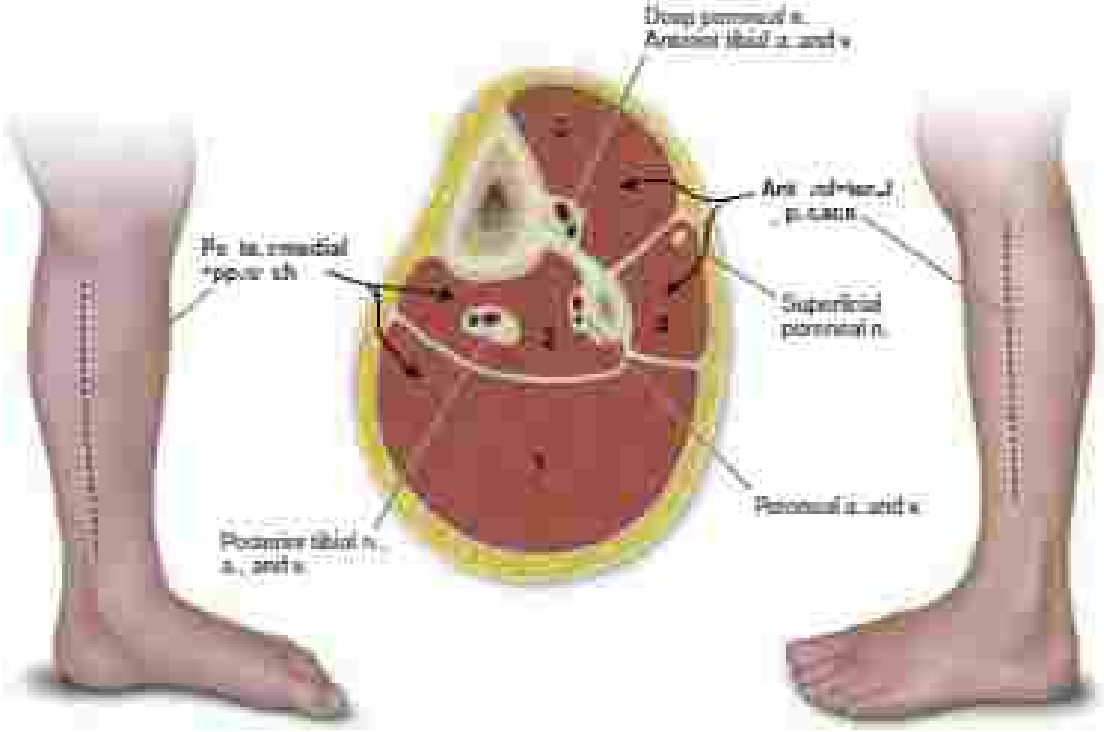

FIG. 10 Decompression of the anterior and lateral compartments through a lateral incision at the intermuscular groove exposes, with skin retraction, both the anterior compartment and lateral compartment muscles. Decompression of the deep posterior compartment through a medial incision exposes the gastrocnemius muscle, which is retracted medially along with the soleus muscle away from the tibia, providing access to the deep posterior compartment. Unless the soleus muscle is detached from the tibia, only a three-compartment fasciotomy has been performed. (From Herring JA, Tachdjian's Pediatric Orthopaedics from the Texas Scottish Rite Hospital for Children, 5th ed. Philadelphia: Elsevier; 2014.)

is needed. Selective compartment decompression is often the best approach to low-velocity injuries to arteries (Fig. 12).

ANTERIOR COMPARTMENT SYNDROME

The anterior compartment syndrome is an unusual single compartment syndrome of the calf. The patient uniformly gives a history of increased physical activity and exercise for an extended period. The patient describes how the anterior calf tightened and became extremely painful; massage did not help. The severe, constant pain is localized to the anterior compartment. The diagnosis is made clinically by noting a very hard and tender anterior compartment with excruciating pain on passive plantar flexion. This is a surgical emergency and requires immediate anterior compartment decompression by an incision from tibial tuberosity to just above the ankle in the midpoint of the anterior compartment muscle mass. Delay in operation may lead to muscle necrosis.

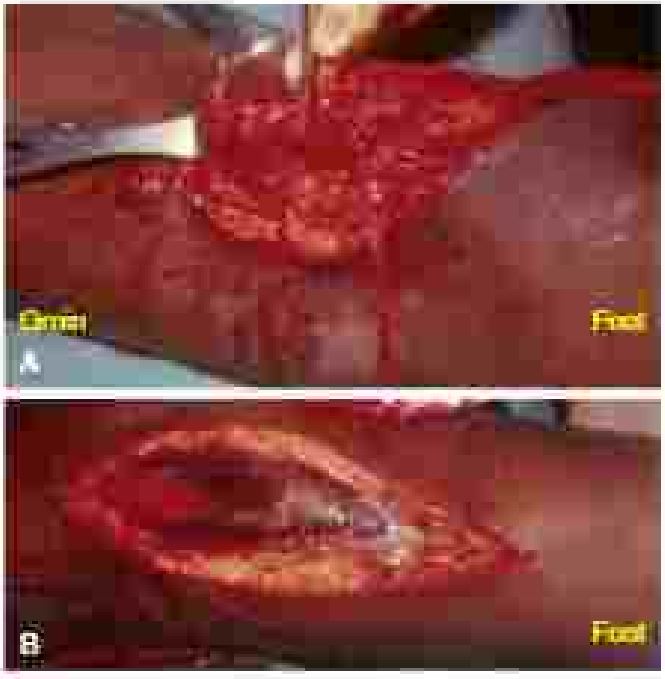

FIG. 11. This patient had a lumpectomy injury of the popliteal artery, which was repaired through a posterior approach. Decompression of the superficial posterior compartment was achieved by extending the distal portion of the operative incision inferiorly (A) whereas the lateral and anterior compartments were decompressed through a lateral fasciotomy (B).

HAND AND FOOT COMPARTMENT DECOMPRESSION

Decompression of the muscle compartments of the hands and feet is rarely needed. Such decompression may be needed with extensive burn, severe cellulitis, and industrial crush injuries. Whenever possible, incisions on the plantar surface of the foot or the volar surface of the hand should be avoided in that they impair function. Decompression of the hand compartments can be made by dorsal incisions over the second and fourth metacarpals, allowing for fasciotomy over the interosseous muscles on each side of the metacarpals (Fig. 13). Decompression of the muscle compartment of the foot, likewise, is made by dorsal incisions over the second and fourth metatarsals with a third incision made along the medial aspect of the arch muscles (see Fig. 13). When performing these dorsal incisions, one must recognize that both the dorsal and volar lymphatics of the hands and feet ascend dorsally, so that patients requiring compartment decompression will likely have extensive lymphedema, making hemostasis quite tedious.

POSTOPERATIVE MANAGEMENT

The extremities with open wounds can be dressed with dry gauze and a roll wrap and treated with elevation. A vacuum-assisted closure device can be applied if there is extensive drainage. A posterior splint of the low extremity is strongly recommended to prevent foot drop. Some fasciotomy incisions can be closed in 5 to 7 days with closure of the skin. One should avoid closing the fascial incision too soon as this may lead to recurrent compartment syndrome. If there is extensive muscle bulging precluding skin approximation, full-thickness skin grafts can be applied. Sometimes there is a delay to compartment decompression, which leads to superficial muscle necrosis. Functional

FIG. 12. The patient presented with a through-and-through gunshot wound to the proximal calf (A), as identified by the two markers (B); he had injury to the tibial peroneal trunk with a right calf necessitating bifocal fasciotomy in conjunction with resection and primary repair of the tibial peroneal trunk. Deep posterior compartment decompression was not needed.

FIG. 13 (A) Decompression of the hand muscles can be achieved through dorsal incisions over the second and fourth metacarpals, thus exposing the fascia of the interosseous muscles. (B) Decompression of the foot compartments is best made by dorsal incisions made over the second and fourth metatarsals with a third incision made along the medial aspect of the arch muscles. When possible, incisions made on the plantar surface of the foot or the volar surface of the hand should be avoided since these incisions compromise function.

BOX 1 Etiology of Compartment Syndrome

External Compartmental Compression

Cast/ACE wrap
Military antishock garments
Burn eschar

Internal Compartment Expansion

Ischemia and reperfusion
Arterial injury, thrombosis, hemorrhage
Burns, frostbite
Cellular insult and swelling
...rosis injury
Fracture, contusion, anterior leg compartment
Electrical injury/high voltage
Blood accumulation and edema
...ractures
Hemophilia
Anticoagulants
Venous occlusion
Miscellaneous
Intravenous infiltration
...rug injection, soft tissue

debridement should be conservative. The underlying ischemic muscle is compromised but usually survives and regains function. A superficial layer of necrotic muscle (but pericyte can be debrided at 2 to 3 days after compartment decompression (see Fig. 1). The patient must be monitored for myoglobinuria and, if present, treated aggressively with hydration, alkalinization, and careful diuresis to prevent renal failure.

Burn Wound Management

Guillermo Foncerrada, MD, MHS, Kara' D. Capek, MD, Celeste C. Finnerty, PhD, David N. Herndon, MD

Surgical treatment for burn injuries may involve emergency procedures such as escharotomy and fasciotomy that are limb- and life-saving. Early excision of all deep burns followed by durable wound closure is an important means to mitigate the systemic response to burn injury and has been demonstrated to offer significantly improved survival for patients under the age of 30 with burns of 30% or more of the total body surface area (TBSA). Burn surgery occurs in phases according to time post injury.

MAINTAIN PERFUSION

Burn shock can be optimized by precise resuscitation with fluids of requisite volume and composition to avoid end-organ damage or acute disturbance of the intracellular and extracellular constituents. Advanced monitoring, including central venous pressure, arterial pressure, serial echocardiography, ultrasound assessment of central venous caliber respiratory variation, pulse contour analysis, thermodilution lung water and cardiac output determination, and measurement of pulmonary arterial saturation/pressure and capillary wedge pressures, may guide therapy to select patients to optimal perfusion of jeopardized tissues. Adjunctive treatments can include cardiotonic and vasoactive medications tailored to the patient's hemodynamics and dominant clinical problem.

Compartment syndromes not infrequently complicate major burns. A compartment syndrome exists when there is sufficient increase in the tissue interstitial pressure (with respect to the capillary hydrostatic pressure—lower in systemic shock states) to critically reduce blood flow. This causes a cascade of tissue-level supply and demand mismatches, chiefly impaired tissue oxygenation. Progressive tissue death occurs, dependent on the severity of the flow decrement and the metabolic requirements of the involved tissue. Focused examination to detect the early manifestations of compartment syndromes should be performed, particularly in patients with high-voltage electrical injuries, circumferential burns, delayed resuscitation, or in the setting of high volume resuscitation. These syndromes typically evolve over 12 to 72 hours following burn and resuscitation. Indicated examination is dependent on the patient presentation, but a comprehensive examination would include palpation of the hands, feet, legs, forearms, abdomen, and eyes. This should be accompanied by an assessment of respiratory effort, oxygenation, and airway pressures. Neurologic (sensory, motor, and pupillary) examination should be carefully documented in those patients to identify acute nerve compression syndromes, including median, ulnar, tibial, peroneal, and optic nerves. When rhabdomyolysis occurs, urinary heme pigment can be seen grossly or as dipstick positive blood without red blood cells on microscopic examination. Serum creatine kinase and myoglobin levels can also assist in diagnosis, but do not supplant hands-on examination. Similarly compartment, bladder, airway, and intravascular pressure measurement may help as supportive tests to the setting of equivocal exam findings. Compartment syndromes remain clinical diagnoses, and because prompt treatment can be life-, limb-, and sight-saving, surgeons caring for burned patients need to be familiar with techniques of escharotomy and fasciotomy of the hands, including carpal tunnel and Guyon canal; the feet, including all three plantar compartments and the tarsal tunnel; forearms, including exploration of Parona space and the cubital tunnel; and legs. Additionally, chest escharotomy, peritoneal drainage/laparotomy, decompressive laparotomy, and lateral canthotomy may be indicated acutely after burn injury. These procedures are best performed in the operating room, but can be adapted to the intensive care unit, trauma room, or procedure suite if adequate equipment, preparation, lighting, and skilled staff are available. Escharotomy (Fig. 1) should be sufficient to alleviate compartment syndromes due to constricting burn eschar, but burn surgeons must maintain an adequate index of suspicion for true fascial compartment syndromes. Factors that increase the likelihood of a fascial compartment syndrome include high-voltage electrical injury, prolonged burn shock with delayed resuscitation, and high-volume resuscitation in excess of 10% of body weight.

OVERVIEW OF BURN ASSESSMENT

Burn wounds should be assessed in terms of size (percent of the TBSA involved) and depth (superficial, indeterminate-deep partial thickness, or full thickness injury). Superficial burns are expected to heal with hygiene, supportive topical treatments, and avoidance of infectious complications. Full thickness injuries benefit from prompt surgical excision and wound closure, usually with autograft. Burns that are indeterminate or deep partial thickness burns require careful assessment. In general, wounds that are expected to require more than 3 weeks for reepithelialization benefit from early surgical excision and grafting. Partial thickness scald burns, particularly in children, benefit from a trial of conservative treatment. This often results in a smaller area of excision/grafting without significantly increasing the risk of infectious complications or length of hospital stay. While the American Burn Association referral criteria (Box 1) identify patients who should be evaluated by accredited burn centers, they do not specifically identify the high mortality group that may benefit from care at a high acuity burn center. There are several calculations (see Capek et al) that provide an initial mortality estimate based on time of injury variables such as age, TBSA burned, TBSA full thickness, and the presence of inhalation injury. In the absence of prospective data, it is our consensus opinion that patients with a predicted probability of death of 20% or greater (1 in 19 odds) should ideally be stabilized and transferred to a high acuity burn center for definitive care.

OPERATIVE PLANNING AND THE LEVEL OF TISSUE REMOVAL

Except in first degree burns, there are usually necrotic tissues to be removed (excised) as part of burn wound treatment. In superficial second degree burns there is bullae (blister) formation at the intra- or subepithelial level. If either a layer of basal epithelial cells, or the basement membrane they reside upon, remains intact, rapid reepithelialization should occur within a few days, and should be complete within a week. When the basal epithelial cells are completely lost, reepithelialization is accomplished from two keratinocyte stem cell niches within the hair follicle. When the peculiar characteristics of the epithelial basement membrane are reformed (type IV collagen, laminin, integrin and other constituents), epithelial migration, proliferation, and wound closure are facilitated. Topical medications and coverage products may be employed to prevent bacterial overgrowth and facilitate the process of reepithelialization (Table 1). It is important that they do not impede epithelial proliferation/migration or exert toxic effects on the remaining proliferative cells.

Deep partial thickness burns are characterized by increasing depth of dermal necrosis. The dermis can be divided into the papillary dermis and the reticular dermis. The papillary dermis includes the rete ridges and terminal capillaries. The reticular dermis is the strength layer of skin and its components include densely packed collagen fibers and elastin fibers. At the level of burn injury associated necrosis deepens, proliferative and healing capacity is progressively

FIG. 1 Release of upper extremity burn eschar and associated compartment syndrome.

BOX 1. Criteria for Burn Center Transfer/Consultation

- Partial thickness burns greater than 10% TBSA
- Burns involving the face, hands, feet, genitalia, perineum, or major joints
- Third degree burns
- Electrical burns (including lightning)
- Chemical burns
- Inhalation injury
- Burns with preexisting medical conditions that may complicate patient management, prolong recovery, or affect mortality
- Burns with concomitant trauma, if the burn itself poses a significant risk of morbidity or mortality
- Burns in children without specialized personnel and equipment for the care of burned children
- Burns in patients with special social, emotional, or long-term rehabilitative needs
- Burns in the setting of suspected nonaccidental trauma

TBSA, Total body surface area.

but. Accordingly, as dermal necrosis approaches full thickness, the wound behaves progressively more like a full thickness ulcer and exhibits healing by deep tissue contraction and proliferation at the wound edges. Hypertrophic scarring is more frequent when the reticular dermis is involved.

Further complicating burn wound assessment and surgical treatment is the temporal evolution of the wound. Early after burn injury there is an ebb phase, characterized by high systemic vascular resistance, high catecholamines, and high endogenous thromboxane levels with relative vasoconstriction. During this phase, resuscitation is physiologically analogous to cardiac and cerebral vasospasm results in further reduction of blood flow to otherwise viable tissues. Deep partial thickness injuries may appear nonblanching (appear as full thickness) and may progress to full thickness injuries as the pressures of tissue expansion, vascular stasis dies, underlying coagulation necrosis. Adequate resuscitation, release of constricting eschar and compartment syndromes, and scrupulous avoidance of external pressure injury may help maximize the survival of at risk tissue. There are investigational pharmacologic adjuncts to mitigate the above described process.

Histologically, devitalized tissue demonstrates hemorrhagic necrosis. At excision, these same necrotic tissues can be recognized by a subtle pink hue, which represents microscopic hemorrhage into the tissues, rather than the pearl white color of intact/viable dermal collagen. Nonviable tissue also demonstrates a subtly blurred or dulled light reflection, whereas intact viable tissues typically show a sharp, crisp glistening light reflex. At excision, frankly necrotic tissues will not bleed, but often some bleeding can be observed at the level of microscopic necrosis described above.

In full thickness burns, the level of excision is below the dermis. It can be difficult to differentiate necrotic from viable subcutaneous adipose tissue, although here too the presence of microscopic hemorrhagic necrosis, seen as a subtle pink hue and dulled light reflex, may provide some guidance. However, the absence of bleeding generally identifies necrotic subcutis. In very deep burns and in the setting of burn wound infection, fascial excision may allow subsequent successful graft placement and wound healing. In the setting of true invasive burn wound infection with bacteria or mold, sometimes termed *ecthyma gangrenosum*, fascial excision is often combined with local or regional antibiotics; these cases experience a mortality rate approaching 50%. The surgical excision of compromised tissue should meet the extent to which the tissue is causing systemic

TABLE 1 Characteristics of Topical Burn Treatments

Product	Pros	Cons
Silver sulfadiazine (SSD) 1%	• Can be used on small, medium, and large surface area burns • Decreased colonization of wounds • Alleviates pain • Broad spectrum	• Limited evidence to support improved wound healing or reduction in bacterial wounds infection • May impair reepithelialization
Bacitracin ointment: 500 units/gram	• Can be used on small burns, face, ears, perineum, graft sites • Alternative agent if sulfa allergy • Ease of application and removal	• Bacterial resistance • No gram-negative coverage • May cause skin hypersensitivity
Combination antibiotic ointment (e.g., bacitracin, neomycin, and polymyxin B)	• Similar to bacitracin above, but with gram-negative coverage	• May have increased hypersensitivity or allergic reaction
Mupirocin ointment 2%	• Broad spectrum gram-positive activity • Resistant gram-positive organisms not described	• No gram-negative coverage • May cause hypersensitivity or allergic reaction
Mafenide 8.5% cream or 5% solution	• Can be used on ears and nose • Effective on dense bacterial proliferation • Excellent eschar penetration • Penetrates cartilage • Effective for gram-negative organisms including Pseudomonas	• Contraindicated in allergy to sulfonamides • Large treatment areas associated with metabolic acidosis due to carbonic anhydrase inhibitor effect
Foams (antimicrobial impregnated)	• Absorb fluid • Promote autolytic debridement • Maintain control • Conformability to wound bed • Can be used with moderate exudate • May reduce number of dressing changes	• Not effective for eschar • Not effective in the presence of high exudate • Limited opportunities for wound assessment due to extended interval between dressing changes
Honey	• Rehydrate wound bed • Promote autolytic debridement • Antimicrobial action • Can be used colonized wounds	• May cause "burning" pain (osmotic effect) • Known sensitivity • May encourage hypertrophic granulation • May cause maceration
Low adherent wound contact layer (silicone)	• Indicate to protect new tissue growth • Atraumatic to surrounding skin • Conformable to body contours	• May dry out if left in place for too long • Known sensitivity
Silver (active)	• Antimicrobial action • Useful for colonized wounds • Is available in combination dressings	• May cause discoloration • Known sensitivity • Requires maintenance of moist wound environment
Poly lactic acid sheets	• Decreased bacterial proliferation • Promotion of epithelialization • Possible decreased pain	• Increased cost, no clear benefit to reduced infections, wound complications, or faster wound healing
Hypochlorous acid	• Useful for wound rinse after local hygiene • Broad spectrum antimicrobial activity	• Limited activity (minutes) once applied to wound
0.5% Silver nitrate soaks	• Standard agent for reduction of bacterial growth in burn wounds and immediate postoperative graft dressings • Cost effective • Broad spectrum antimicrobial activity • Ease of ongoing wound assessment	• Requires q2h reapplication of soak • Discoloration of surrounding skin and materials • Known sensitivity • Higher frequency of dressing changes • May be associated with hyponatremia
Amniotic membrane	• May be associated with reduced pain, reduced scarring, and faster epithelialization, although definitive studies are lacking	• Cost • Need for donor screening, tracking, and tissue banking resources • Degrades quickly in inflammatory or infected wounds

Continued

TABLE 1 Characteristics of Topical Burn Treatments—cont'd

Product	Pros	Cons
Xenograft	• Useful in partial thickness wounds where sufficient regenerative capacity is retained, avoids autograft donor site	• Xenograft rejection possible • Incorporation and hypertrophic scarring possible • Not typically used in superficial burns
Nystatin powder (4 million units/gram strength)	• Sparingly sprinkled on wounds just before new dressing is applied • Useful to prevent fungal colonization of wounds • Useful as an adjunct in the treatment of fungal wound infections	• Hypersensitivity • Use often requires cooperation from local pharmacy • Off-label use requires physician discretion • Avoid use of lower concentration (100,000 units per gram) talc-admixed product, which creates a problematic exudate in burn wounds

dysfunction. Accordingly, invasively infected tissue with residual perfusion (analogous to wet gangrene) constitutes a threat to survival in patients with major burns.

ADJUNCTS TO DETERMINE BURN WOUND DEPTH

The search for technologies to more precisely diagnose burn depth surged when the benefits of early excision were recognized. Several noninvasive technologies have been proposed, such as thermography, nuclear imaging, pulse echo ultrasound, and photometry. Despite the higher level of technologic complexity, these techniques have not yet demonstrated superior efficacy when compared with serial assessment by a burn surgeon. Of these adjuncts, laser Doppler is best studied. Some reports suggest potential clinical benefit with the use of laser Doppler to indeterminate thickness burns. This technique provides a color perfusion map of the burn wound, and serial tests may be performed to follow up the progress of the burn. Although laser Doppler provides an objective measurement of burn perfusion, it remains an adjunct to the serial clinical assessment of the burn surgeon.

STRATEGY OF EXCISION; BLOOD LOSS AND OPERATIVE RISK

Particularly in children, optimal burn care includes early, complete excision of the burn wound. In the severely burned, this may require maximal perioperative and anesthetic resources. These include a warm, humidified operating room; several skilled assistants and often several anesthesiologists; a full-body surgical scrub and preparation; accommodation for multiple position changes including prone and side to side positioning while under anesthesia; accommodation for extremity elevation; upper and lower extremity tourniquets; wet pad electrocautery; harvest and graft preparation from all required donor sites; real time hemodynamic monitoring; rapid blood gas, electrolyte, and coagulation determinations; advanced rewarming equipment; capacity to provide rapid massive transfusion of blood and blood products; availability of sufficient skin bank resources to cover the wound; and a sufficiently staffed and experienced burn intensive care unit capable of reliably nursing patients through the postoperative period. Blood transfusion is usually needed for large burns, both due to losses from the wound as well from impaired hematopoiesis. Surgical blood loss can be estimated preoperatively based on the number of square centimeters of burned area to be excised, and the time elapsed since the burn. Within the first 72 hours after burn injury, blood loss should be less than 0.5 mL/cm^2 excised. Between days 3 and 16 postburn blood loss is expected to approximate 0.75 mL/cm^2 excised. Excision of infected wounds, while often necessary, is associated with higher blood losses (predictors range from 1–1.25 mL/cm^2). Blood volume can be estimated by 70 mL/kg (higher in infants and small children). In the setting of ideal skill, assistance, and resources, excision of burned areas predicted to incur losses of less than one blood volume (in boys, approximately 7% of adjusted body weight in kilograms for adults) may be planned. In less severe burns, or in a resource constrained setting where transfer cannot be arranged, a useful operative planning heuristic to spend no more than 2 hours operating, excise no more than 20% TBSA, and lose no more than 2 units of blood. If the wounds are clearly full thickness, we prefer to cover the posterior trunk and buttocks as rapidly as possible to better enable supine positioning later in the course of recovery. Coverage generally proceeds proximally to distally in major burn injuries where future amputation of at risk distal extremities remains a possibility. Based on the burn and patient characteristics if there is no expectation of hand or upper extremity amputation, an improved functional recovery can be achieved by autografting the dorsal surface of the hand and digits within the first 3 weeks after burn injury. Threatened sight due to ocular surface exposure, recognized by corneal epithelial defect or ulceration, may require urgent tarsorrhaphy placement and expeditious release and grafting of the eyelids to normalize eyelid function and preserve vision. The functional loss of one hand is associated with 24% whole person impairment, while loss of both hands is estimated to result in 79% whole-person impairment. Loss of sight in both eyes is associated with more than 80% whole person impairment. Prevention of functional losses and postburn disability should be individualized to each patient's needs, recognizing that hand function and sight are frequently at risk following burn injury. Timely surgical intervention can prevent or reduce resultant disability.

The postburn hematopoietic impairment is characterized as an erythropoietin resistant hypoproliferative anemia resulting from reprogramming of the common myeloid progenitors away from the erythroid lineage. It is associated with high levels of circulating erythropoietin and generally not responsive to exogenous erythropoietin.

Tangential Excision

Tangential excision is defined as the thorough removal of all burned skin by layers until reaching undurned tissue. Compared to fascial excision, tangential excision better preserves body contour. Investigators reported the procedure of tangential excision in detail, describing the procedure as the repeated excision of thin layers until reaching undurned tissue, followed by immediate application of split thickness autografts.

A variety of surgical instruments are available to accomplish the purpose of the tangential excision, including powered dermatomes, the Goulian knife, and the Watson knife. Partial thickness deep burns should be excised to uniformly viable tissue. In the case of full thickness burns, the excision should be done layer by layer, until the appearance of undurned subcutaneous tissue, which has a bright yellow color and a comparatively softer texture. If blood vessels with thrombosis, or tissue that exhibits a pink to purple discoloration or a dull yellow color are found, it should be excised because these findings are not consistent with viable tissue. Failure to excise these tissues prior to graft placement will impair graft take and impede wound healing.

Fascial Excision

Fascial excision is a procedure that entails the removal of all skin and subcutaneous tissue down to the fascia. The main indications for its use are to diminish blood loss in deep and extensive burns, and to remove invasive infection. The procedure limits excessive blood loss by avoiding the multiple capillaries located in and beneath the epidermis, while allowing for the direct control of the perforating vessels through exposure and ligation. If the subcutaneous tissue is burned or seriously infected, then fascial excision is a suitable option. Advantages may include increased graft take due to reliable perifascial blood supply and decreasing hemorrhage. Normal body contour and lymphatic function are generally lost after fascial excision, although this may be mitigated somewhat by preserving islands or a thin layer of viable deep adipose tissue superficial to the fascia.

Adjuncts to Minimize Blood Loss at Burn Excision

Adequate preparations should include blood bank requisition of autologous products, and blood products should be available to the operating room at the start of the excision proper. Strategies to decrease blood loss in the operating room include elevation, tourniquets (brief [<20 minute] inflation time) for the extremities, thrombin spray, and infiltration or topical spray with dilute epinephrine solutions and immediate compressive bandaging. The dilute epinephrine solutions can be prepared by adding 1.0 mL of 1:1000 epinephrine to 500 mL 0.45% saline solution for a final concentration 1:500,000 epinephrine. For small children, the amount of epinephrine can be reduced by half (0.8 mL). Tourniquets are particularly helpful when excising over hands and fingers. One potential pitfall is that the uniform pressure blanching that characterizes healthy tissue will not be visible. Other surrogates for tissue viability (see above) must be used in this setting.

The management of the larger blood vessels can be achieved either with ligation or electrocautery. For the smaller bleeding points, lap sponges soaked in dilute epinephrine solution can be applied topically and wrapped with elastic compressive bandages. In addition, elevation of the limb before, during, and after grafting will diminish venous bleeding and reduce hematoma formation.

The above described balanced salt solution and dilute epinephrine mixture, sometimes called Pitkin solution, works best if infiltrated before starting excision or donor site harvest. The anatomic areas that especially benefit from this subcutaneous injection are the face, the trunk, and the scalp. Epinephrine in the solution causes vasoconstriction, decreasing the amount of hemorrhage during excision. Another advantage of the infusion is that it creates an even surface that facilitates the tangential excision or donor harvest.

Reducing operating time reduces total blood loss, thus excision should be accomplished as quickly as safely possible and excised areas covered with gauze soaked in epinephrine solution, then bandaged with gauze and elastic materials. This approach uses the vasoconstrictive effects of epinephrine along with the pressure of the compressive bandage to achieve adequate hemostasis. Active hemorrhage localized to a blood vessel that persists despite the above techniques can be controlled with electrocautery.

DONOR SITE MANAGEMENT AND TECHNIQUES OF WOUND CLOSURE

Autograft donor sites are selected based on need, availability, healing characteristics, and patient preference (including ease of concealment of any donor site scar). The scalp heals rapidly and a perioperative scalp block can provide postoperative anesthesia. In general, burn wounds are closed with split thickness skin grafts (STSGs) harvested with a powered dermatome. For most body areas in large burns, a thin STSG is harvested at 0.008 to 0.01 inch. Note that most powered dermatomes have both an inch and a metric scale and the equivalent thickness is 0.1 to 0.2 mm. Slightly thicker grafts may be preferred to accomplish a specified reconstructive goal, such as increased range of motion at the hands and fingers, although the actual relationship between graft thickness and resulting contracture is often difficult to predict. As the donor site is a prototypic superficial wound, donor site dressings should be selected to facilitate reepithelialization, minimize toxicity, and prevent infection.

Skin autografts can be processed in several ways. They can be used as a sheet or meshed, and the meshing can vary from 1:1 to 6:1. Mesh ratio will be determined according to the patients' individual circumstances such as TBSA burned, area to be grafted, and availability of donor sites.

The decision of whether to mesh the graft depends on the surface to be covered. The ideal graft for small burns, and burns present on the face, neck and hands is a sheet graft. A nonmeshed graft provides the best cosmetic results. A possible complication that may arise when using sheet grafts is the occurrence of a hematoma under the graft. Making small "pie crust" incisions in the graft to allow the drainage of any remaining blood and or serum may occasionally prevent this complication and favor graft take. Postoperative assessment of the graft is important to evaluate for possible complications. If fluid (blood or serum) accumulates under the graft, this can be resolved by puncturing the graft with a needle and draining all fluid. The initial determinant for graft take is adherence between the wound bed and the graft. The optimal way to place the graft is perpendicular to the longitudinal axis of the extremity with the aim of preventing contracture. This consideration is especially important at major joints where contractures may impair flexion and extension and necessitate future surgery for scar release. On the forearm and on the dorsum of the hand it is acceptable to use longitudinal grafts.

The objective of meshing a graft is to expand it, and thus be able to cover a larger surface with viable proliferative epidermal units. Durable wound closure implies reconstitution of a stable self renewing epithelial layer, ideally with associated structures (innervation) and cells (melanocytes). Frequently used mesh ratios are 2:1 and 4:1, but these ratios can be expanded even more if the situation warrants. One advantage of the 2:1 ratio is that it is easier to handle and apply. A disadvantage of all meshed grafts is the pattern of scarring that results. If the burn is very large, the use of a 4:1 mesh ratio may be preferred to expand the coverage. 4:1 meshed autograft leaves large interstices open and the wound bed exposed in these areas. These exposed areas and the massive widely expanded autograft can be protected by placing a 2:1 meshed homograft over it. This is commonly known as sandwich or Alexander technique.

Additional methods include autograft techniques and local tissue flaps. The Meek technique, modified by Krizek, is occasionally a useful strategy to manage extensive burns. It consists of cutting the skin grafts into small squares and placing them uniformly over the wound bed. These small islands of skin promote epithelialization, although the healing process is lengthy and the cosmetic results are not favorable. The expansion ratios available for this technique vary from 3:1 to 5:1. Occasionally, local tissue flaps may be successfully incorporated in wound closure following burn excision. These acute flaps carry greater risk of failure than their reconstructive analogues and should only be employed by providers with specialized training in burn reconstruction in addition to acute burn care.

SPECIAL CONSIDERATIONS

Nonaccidental Trauma

Along with assessment and treatment of the burn wound, astute providers note the characteristics of the injury, signs of previous significant injuries, the nutritional, developmental, and psychologic state of the patient, and interactions between the patient and caregivers. These may raise suspicion for nonaccidental injury. Providers must follow state laws in addition to practice guidelines, in clinically investigating and reporting findings concerning for abuse or neglect to the appropriate authorities. It has been previously shown that abuse occurs in 10% of nonaccidental burn cases and is eventually accompanied by a 30% mortality rate. Each of these preventable deaths starkly emphasizes the importance of this aspect of burn management.

Chemical Injuries

It is important to identify and characterize the type of agent involved. A direct method for this is to obtain the Material Safety Data Sheet(s) (MSDS) on all potential agents involved in the exposure. Personal protective equipment suited to the potential agent(s) is essential for all providers. Solid particles of the burning agent should be brushed off gently. Although many chemical burns are aided by rapid and copious irrigation with water, the notable exceptions to this guideline are indicated on the agent-specific MSDS. For acid and alkali exposures, irrigation should be continued until the skin pH normalizes. It is advisable to wait 5 minutes after an initial normal reading, as additional irrigation is indicated if agent continues to leach back to the surface from deeper tissues. Chemical injuries of the eye can result in severe, irreversible vision loss and are an ophthalmologic emergency. When these are identified, immediate irrigation with water or saline should be initiated and continued until ophthalmology consultation can be obtained.

Toxic Epidermal Necrolysis, Stevens-Johnson Syndrome, and Blistering Skin Diseases

The skin lesions in these diseases are usually superficial partial-thickness injuries. Careful medication history may identify a potential pharmacologic trigger. Sulfa drugs, anticonvulsant drugs, and allopurinol are among the agents previously associated with development of these conditions. Care should be directed toward physiologic stabilization, avoidance of secondary infection or pharmacologic insult, and promoting reepithelialization. A number of temporary skin coverage products are available for this purpose. Maximal complications affect over half of survivors, chiefly corneal scarring, vision loss, and chronic dry eye. All of these patients require a detailed examination of the ocular surface to identify or exclude eye involvement at initial presentation, with follow-up if changes in condition are noted. Because early application of amniotic membrane grafts to the ocular surface has been shown to ameliorate these devastating complications, such patients require referral to centers capable of reliably and rapidly providing this treatment.

CONCLUSION

The phenomena of increased survival following severe burns is one of the great success stories of twentieth century surgical science, and a contemporary marker of medical progress. With increased survival, there is increased demand for prevention of disabling sequelae of burn injury. We have identified areas where prompt and indicated surgical intervention may mitigate disabling complications of the early postburn period. We want to again emphasize the importance of early excision and durable wound closure for full-thickness and near full-thickness burns. While advances in prevention, resuscitation, nutrition, care for inhalation injury, treatment of infection, and rehabilitation all benefit the burned patient, early excision of the burn wound followed by durable wound closure is the keystone. It potentiates these advances and actualizes the burn team in constructing an opportunity for increased survival following severe burn injury. Evidence also indicates that more rapid wound closure is associated with reduced hypertrophic scarring. Durable closure of burn wounds implies establishment of a stable self-renewing population of keratinocytes, thus closure of burn wounds either by native cells or autografts to be exercise in the skin organotypic culture. While short-term graft survival may reflect epithelial survival and proliferation, long-term success requires reconstitution of functional stem cell niches competent to maintain the epithelial layer indefinitely. The primary work of the burn surgeon is to optimize the conditions for this process to occur as rapidly and completely as possible.

Medical Management of the Burn Patient

Mayur Narayan, MD, MPH, MLP, MHPE, FACS, FCCM, EICS, Aakanksha Agrawal, MD, and Phillip S. Barie, MD, MBA, FIDSA, FACS, FCCM

Nearly 500,000 burn injuries were reported in the United States in 2016. According to the Healthcare Cost and Utilization Project National Inpatient Sample (2017 data), there were an estimated 40,000 hospitalizations related to burn injury, including 30,000 at hospital-based burn centers. Mortality after burn injury has decreased over the past 20 years, largely attributable to improved physiologic support of injury and a dedicated, multidisciplinary approach to the care of the burn patient. Of the 205,000 burns in the National Burn Registry from 2016, the mortality rate for all cases was 3.2%. Despite these successes, larger total body surface area (TBSA) burns still pose a high risk of mortality and morbidity.

The pioneering research (among many others) of Charles Baxter, Henry Harkins, David Hinshaw, Lloyd McLean, Francis Moore, Carl Moyer, Basil Pruitt, C. Tom Sisters, and Douglas Wilmore and the advances by their proteges (again, among many) Peter Cameron, William Cioffi, William Curtsinger, Robert Demling, Clem Gerbasio, David Herndon, Stephen E. Lowry, Ronald Tompkins, and Roger Yurt has established that the concept of burn shock results from extensive fluid shifts in both burned and nonburned tissue. Thermal injury activates the release of inflammatory and vasoactive mediators responsible for increased transcapillary permeability, local vasoconstriction, ischemia, coagulation, and hemostatic and microcirculatory derangements that together lead to tissue hypoperfusion. Release of histamine, prostaglandins, neuropeptides, and cytokines including oxygen-derived free radicals contributes to the local and systemic inflammatory response, exacerbating the microcirculatory dysfunction. This upregulation of innate immunity, compounded by downregulated adaptive immunity, which creates such a deranged host response to injury, can have profound organ-level effects that alter cardiovascular function, endocrine, gastrointestinal, hematologic, hepatic, neurologic, renal, and pulmonary function, leading eventually to multiple organ dysfunction syndrome (MODS) and death (Fig. 1). Fortunately, both the incidence and magnitude of MODS have decreased owing to better recognition of risk, improved resuscitative, timely metabolic, nutritional, and pharmacologic support, and timely source control and wound closure.

Chemical Injuries

It is important to identify and characterize the type of agent involved. A direct method for this is to obtain the Material Safety Data Sheet(s) (MSDS) on all potential agents involved in the exposure. Personal protective equipment suited to the potential agent(s) is essential for all providers. Solid particles of the burning agent should be brushed off gently. Although many chemical burns are aided by rapid and copious irrigation with water, the notable exceptions to this guideline are indicated on the agent-specific MSDS. For acid and alkali exposures, irrigation should be continued until the skin pH normalizes. It is advisable to wait 5 minutes after an initial normal reading, as additional irrigation is indicated if agent continues to leach back to the surface from deeper tissues. Chemical injuries of the eye can result in severe, irreversible vision loss and are an ophthalmologic emergency. When these are identified, immediate irrigation with water or saline should be initiated and continued until ophthalmology consultation can be obtained.

Toxic Epidermal Necrolysis, Stevens-Johnson Syndrome, and Blistering Skin Diseases

The skin lesions in these diseases are usually superficial partial-thickness injuries. Careful medication history may identify a potential pharmacologic trigger. Sulfa drugs, anticonvulsant drugs, and allopurinol are among the agents previously associated with development of these conditions. Care should be directed toward physiologic stabilization, avoidance of secondary infection or pharmacologic insult, and promoting reepithelialization. A number of temporary skin coverage products are available for this purpose. Mucosal complications affect over half of survivors, chiefly corneal scarring, vision loss, and chronic dry eye. All of these patients require a detailed examination of the ocular surface to identify or exclude eye involvement at initial presentation, with follow-up if changes in condition are noted. Because early application of amniotic membrane grafts to the ocular surface has been shown to ameliorate these devastating complications, such patients require referral to centers capable of reliably and rapidly providing this treatment.

CONCLUSION

The phenomena of increased survival following severe burns is one of the great success stories of twentieth century surgical science, and a contemporary marker of medical progress. With increased survival, there is increased demand for prevention of disabling sequelae of burn injury. We have identified areas where prompt and indicated surgical intervention may mitigate disabling complications of the early postburn period. We want to again emphasize the importance of early excision and durable wound closure for full thickness and near full thickness burns. While advances in prevention, resuscitation, nutrition, care for inhalation injury, treatment of infection, and rehabilitation all benefit the burned patient, early excision of the burn wound followed by durable wound closure is the keystone. It potentiates these advances and actualizes the burn team in constructing an opportunity for increased survival following severe burn injury. Evidence also indicates that more rapid wound closure is associated with reduced hypertrophic scarring. Durable closure of burn wounds implies establishment of a stable self-renewing population of keratinocytes, thus closure of burn wounds either by native cells or autografts is an exercise in the skin organotypic culture. While short-term graft survival may reflect epithelial survival and proliferation, long-term success requires reconstitution of functional stem cell niches competent to maintain the epithelial layer indefinitely. The primary work of the burn surgeon is to optimize the conditions for this process to occur as rapidly and completely as possible.

Medical Management of the Burn Patient

Mayur Narayan, MD, MPH, MBA, MHPE, FACS, FCCM, EICS, Aakanksha Gupta, MD, and Philip S. Barie, MD, MBA, FIDSA, FACS, FCCM

Nearly 500,000 burn injuries were reported in the United States in 2016. According to the Healthcare Cost and Utilization Project National Inpatient Sample (2017 data), there were an estimated 40,000 hospitalizations related to burn injury, including 30,000 at hospital-based burn centers. Mortality after burn injury has decreased over the past 20 years, largely attributable to improved physiologic support of injury and a dedicated, multidisciplinary approach to the care of the burn patient. Of the 205,000 burns in the National Burn Registry from 2016, the mortality rate for all cases was 3.2%. Despite these successes, larger total body surface area (TBSA) burns still pose a high risk of mortality and morbidity.

The pioneering research (among many others) of Charles Baxter, Henry Harkins, David Hinshaw, Lloyd McLean, Francis Moore, Carl Moyer, Basil Pruitt, G. Tom Shires, and Douglas Wilmore and the advances by their proteges (again, among many) Peter Cameron, William Cioffi, William Curtsinger, Robert Demling, Clem Gerbode, David Herndon, Stephen E. Lowry, Ronald Tompkins, and Roger Yurt has established that the concept of burn shock results from extensive fluid shifts in both burned and nonburned tissue. Thermal injury activates the release of inflammatory and vasoactive mediators responsible for increased transcapillary permeability, local vasoconstriction, ischemia, coagulation, and hemostasis and microcirculatory derangements that together lead to tissue hypoperfusion. Release of histamine, prostaglandins, neuropeptides, and oxidants including oxygen-derived free radicals contributes to the local and systemic inflammatory response, exacerbating the microcirculatory dysfunction. This upregulation of innate immunity, compounded by downregulated adaptive immunity, which creates such a deranged host response to injury, can have profound organ-level effects that alter cardiovascular function, endocrine, gastrointestinal, hematologic, hepatic, neurologic, renal, and pulmonary function, leading eventually to multiple organ dysfunction syndrome (MODS) and death (Fig. 1). Fortunately, both the incidence and magnitude of MODS have decreased owing to better recognition of risk, improved resuscitative, timely metabolic, nutritional, and pharmacologic support, and timely source control and wound closure.

Contemporary research inquiries in the management of the burn patient have focused largely on resuscitation to ameliorate burn shock, MODS, and the surge of inflammatory mediators to improve morbidity and mortality.

CRITERIA FOR TRANSFER TO BURN CENTER

Physicians caring for burn patients must have a working knowledge of when to transfer care of these patients to the appropriate care facility (usually, a regional burn center). The American Burn Association (ABA) has recommended that certain injuries and circumstances be considered for burn center referral after initial assessment and stabilization at an emergency department (Box 1).

Burn Classification

The physiologic impact of a burn is proportional to the extent of body surface area involved. Clinical examination remains the primary modality for burn depth estimation in the United States. The traditional classification of burns according to degree of injury (first through fourth) has been replaced by a system reflecting need for surgical intervention. Current designations of burn depth are superficial, superficial partial thickness, deep partial thickness, and full thickness (Table 1). A multitude of techniques have been developed to provide an objective estimate of burn depth and healing time. These include tissue biopsy, administration of radiopharmaceuticals, sonofluorescein and fluorescein dyes, thermography, photometry, liquid crystal (thermoindicating) film, nuclear magnetic resonance, pulse ultrasound, Doppler ultrasound, and laser doppler imaging (LDI). Outside the United States, LDI has been used increasingly to determine burn depth. In Fig. 2, the regions of interest are identified using two-dimensional clinical photos (Fig. 2, left). An outlined template is created from these regions of interest and applied to LDI and thermal imaging using anatomical and wound reference points. LDI has been shown to have several advantages: ease of use, it is noninvasive and noncontact, highly accurate (>90%) with low interoperator variability (kappa), can distinguish reliably between superficial and deep partial thickness burns, can be used as a prognostic tool to classify burns into three categories of healing time (<14 days, 14–21 days, and >21 days), and is the only modality approved currently by the US Food and Drug Administration. Cost of the device approximately $85,000 per unit, has been cited as the primary reason for the lack of more widespread adoption.

Estimation of TBSA

Accurate estimation of burn size is essential to determining when to transfer a patient and also to guide appropriate fluid resuscitation. Of note, superficial (first degree) burns are not included in percentage TBSA burn assessment. Several studies have shown underestimation of the size of large burns, especially in obese patients, and can lead to undertransfusion. Several methods have been described to estimate TBSA. These include the Rule of Nines, the Lund Browder chart, and the "palm" method. The Rule of Nines, first described by Pulaski and Tennison in the late 1940s and published by Wallace in the early 1950s, is in common usage for estimation of TBSA in adult patients. By contrast, the Lund Browder chart is considered a more accurate method for calculating TBSA in both adults and children but is cumbersome. The Lund Browder method accounts for the fact that children have proportionally larger heads and smaller lower extremities compared with adults. Finally, the single palm method, useful for patchy

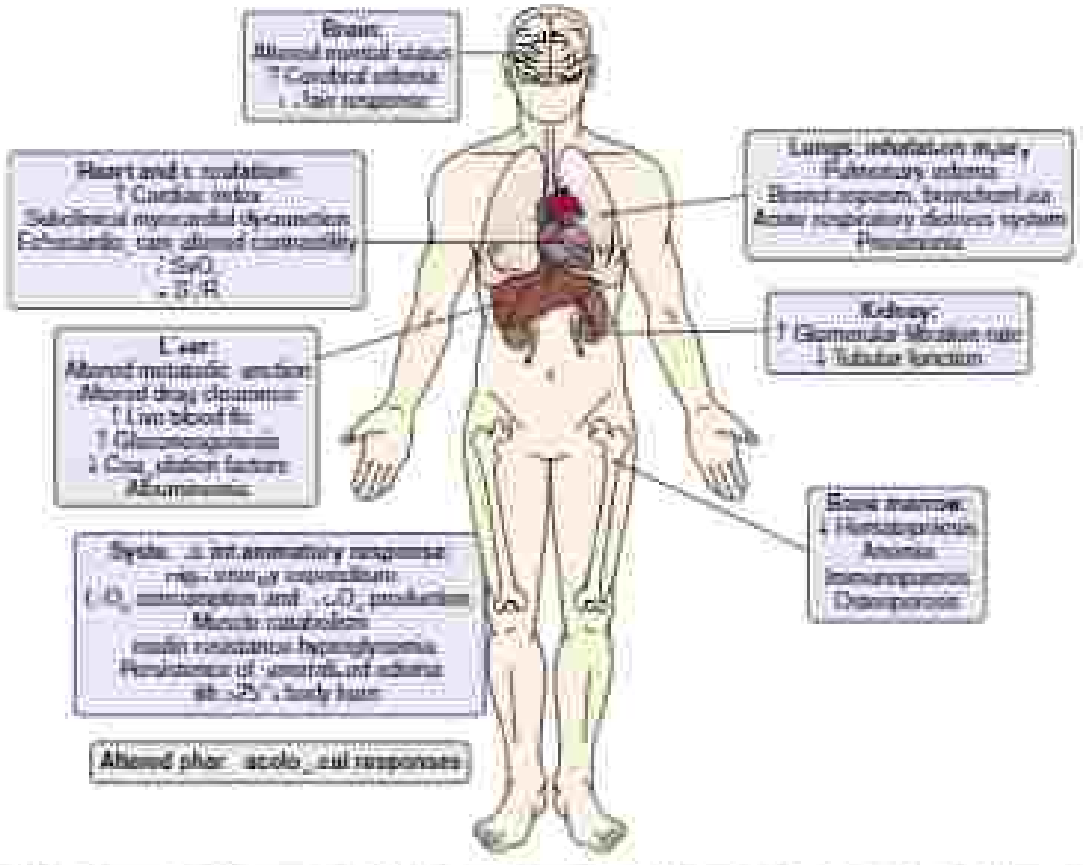

FIG. 1 . athophysiologic changes during hypermetabolic/hyperdynamic phase of burn (>48 hours). (Modified from Barret J.P., Herndon D.N., Wolfram D., et al. Acute and postacute care of the burn injured patient. In: endocrinology 2011;2720(1449-1464).

burn distribution, is calculated based on the patient's hand size. The palm of the patient's hand, excluding the fingers, is both children and adults is approximately 0.5% of TBSA, whereas the entire palmar surface including the fingers is 1% (Fig. 2).

RESUSCITATION

It is imperative to understand resuscitation tactics in the burn patient. All adult patients with burns involving more than 20% TBSA and pediatric patients with more than 10% TBSA should receive intravenous fluid resuscitation. Many formulas exist to estimate fluid requirements, some more popular than the Parkland Formula (4 mL/kg/%TBSA), with the first half of the calculated requirement given over 8 hours, starting from time of injury. It is necessary to catch up if initial resuscitation is delayed or inadequate. The remaining half is given over the next 16 hours. Resuscitation by the Parkland formula in the second 24 hours administers substantial amounts of 5% human serum albumin solution. Colloids can be given as 20% to 40% of calculated plasma volume. No crystalloids are used. Glucose in water is added to amounts required to maintain a urinary output of 0.5 to 1 mL/hr in adults and 1 mL/hr in children. Other formulas vary by fluid composition as well as rate of administration (Table 2).

A caution to providers tasked with the initial resuscitation of the burn patient. Patients with inhalation injury, delayed resuscitation, high voltage injuries, and extensive deep burns will likely require higher volumes than predicted by burn formula calculations. Resuscitation is then guided by usual parameters (e.g., sensation, urine output, cardiopulmonary function, arterial lactate clearance).

BOX 1 Considerations for Referral of a Burned Patient to a Specialized Burn Treatment Facility (American Burn Association)

I. Partial thickness burns greater than 10% total burn surface area
II. Burns involving the face, hands, feet, genitalia, perineum, or major joints
III. Full thickness burns of any location in any age group
IV. Electrical burns, including lightning injury
V. Chemical burns
VI. Inhalation injury
VII. Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
VIII. Any patient with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality. In such cases, if the trauma poses the greater immediate risk, the patient may be stabilized by a trauma center before being transferred to a burn unit. Physician judgment, first the outset in conjunction with regional medical protocols must guide decision making.
IX. Burned children in hospitals without qualified personnel or equipment for the care of children
X. Burn injury in patients who will require special social, emotional, or long-term rehabilitative support or intervention

USE OF COLLOIDS

The problem of "fluid creep" as a result of crystalloid resuscitation was one of the early drivers of the use of colloid resuscitation. In fact, the use of plasma for burn resuscitation was described in the early 1940s by Henry Harkins, who recommended 1 L of plasma for each 10% TBSA burned for patients with burns to more than 10% TBSA. The common hypothesis for the use of colloids was based on the observation of hemoconcentration after a major burn, and the deduction that this must have resulted from a loss of plasma volume; therefore, colloid solutions containing macromolecules would theoretically increase plasma colloid osmotic pressure and act as better intravascular volume expanders than crystalloid fluid alone. Unfortunately, measurement of colloid osmotic pressure and resuscitation based on these measurements proved unsuccessful in improving outcomes of many forms of shock, including major burn injury.

During the 1970s, resuscitation tactics using balanced salt solutions arose, leading to a shift away from early provision of colloids. Moyer and others conducted resuscitation studies with Lactated Ringer's solution and concluded that burn shock likely arose from an extracellular sodium deficiency that was best treated with balanced

TABLE 1 Classification of Burns by Depth of Injury

Depth	Level of Injury	Clinical Features	Usual Treatment
Superficial (first degree)	Epidermis	Dry, red, blanches, painful	Healing time 3–6 days, no scarring
Superficial partial thickness (superficial second degree)	Papillary dermis	Blisters, moist, red, weeping, blanches, severe pain to touch	Cleaning, topical agent, sterile dressing, healing time 7–21 days, hypertrophic scar rare, return of full function
Deep partial thickness (deep second degree)	Reticular dermis, most skin appendages destroyed	Blisters, wet or waxy dry, reduced blanching, decreased pain sensation to touch, pain present to deep pressure	Cleaning, topical agent, sterile dressing, possible surgical excision and grafting, scarring common if not surgically excised and grafted, earlier return of function with surgery
Full thickness (third degree)	Epidermis and dermis, all skin appendages destroyed	Waxy white to leathery dry and inelastic, does not blanch, absent pain sensation, pain present to deep pressure, pain present in surrounding areas of second degree burn	Treatment as for deep partial thickness burns plus surgical excision and grafting at earliest possible time, scarring and functional limitations more common if not grafted
Fourth degree	Involves fascia and muscle and/or bone	Pain to deep pressure, in the area of burn, increased pain in surrounding areas of second degree burn	Healing requires surgical intervention

salt solution. Baxter and Shires also found that extracellular sequestration of sodium and water resulting from decreased transmembrane potential, at the expense of decreased intracellular sodium and water occurred early in burn injury. They advocated successfully for resuscitation only with balanced salt solutions in the first 24 hours. Pruitt and others found that use of colloid early in burn resuscitation did not appear to augment intravascular retention of fluid because increased extracellular osmotic pressure caused by capillary leak syndrome of sufficient magnitude results in loss of membrane integrity; the membrane becomes permeable to albumin and other macromolecules until equilibrium is reestablished along the new concentration gradient that promotes transmembrane flux of albumin. Without treatment, the clinical consequences are hypovolemia and tissue edema that may persist until microcirculatory integrity is restored and the patient begins to mobilize and excrete the fluid administered for resuscitation. As a result of these works, colloid free resuscitation in the first 24 hours post burn injury became the standard of care in burn resuscitation.

Colloid use in burn resuscitation might have become obsolete had Pruitt not described the problem of fluid creep. The phenomenon refers to the consequences of aggressive crystalloid resuscitation. Edema related complications were noted, such as massive facial and airway swelling requiring prolonged endotracheal intubation, extremity compartment syndromes (including of unburned extremities), and respiratory and cardiac failure. Other resuscitation related complications now reported as consequential to overresuscitation include abdominal compartment syndrome and rarely permanent blindness (as a result of prolonged elevated intraocular pressure).

As a result of the lessons learned from the problem of fluid creep, colloid use in burn resuscitation is regaining popularity. Considering that early colloid administration is demonstrably methodical colloid is probably administered optimally after 12 to 18 hours postinjury, either as a routine supplement or as rescue treatment of fluid creep. A 2010 international survey conducted by the International Society of Burn Injuries and the ABA found that one half of respondents initiate colloids in the first 24 hours, with nearly equal preference for fresh frozen plasma (FFP) or albumin as the chosen colloid.

Albumin is a 67 kDa protein synthesized by the liver, with 40% being distributed in the extravascular space and 60% intravascular. Total body albumin is ~3.5 to 5.0 g/kg or about 250 to 300 g for a 70 kg person. A negative acute phase reactant (albumin synthesis) is downregulated by the innate immune response to injury in favor of protein synthesis of salutary to the host response (e.g., coagulation proteins), and thus unreliable to monitor as an acute biomarker; albumin has been used as a volume expander since the 1940s. However, a late 1990s Cochrane review found that the use of albumin was associated with a pooled increased absolute risk of death of 6% (95% confidence interval [CI], 3–9). More recent trials such as the Saline versus Albumin Fluid Evaluation study, the Early Albumin Resuscitation during Septic Shock study, and the ALBumin Italian Outcome Sepsis study, found no increase in mortality associated with albumin use when compared with crystalloid fluids, albeit not explicitly after burn injury. Although hypoalbuminemia is universally present in burn patients, and its correction has been studied in numerous critically ill patient populations, more research is needed to ascertain its utility in burn resuscitation. A recent meta-analysis by Ulrich et al. found that early use of albumin based resuscitation strategies demonstrated no impact on mortality in burn patients. They concluded that more research is needed to assess the effect of albumin based solutions on mortality in burn patients, but lacking evidence of superiority, the high cost of human serum albumin as compared with crystalloids should be taken into account.

The use of plasma in early burn resuscitation (as described by Harkins) was one of the first colloid administration tactics. FFP for burn resuscitation was first described by Oser et al. As the name implies, FFP is collected ("fresh") from a single unit of donated blood or by apheresis and then cryopreserved ("frozen") at −30°C and stored for up to 1 year. FFP is an important adjunct in the management of traumatic coagulopathy as part of a balanced resuscitation strategy. Its use in burn resuscitation has gained popularity with the development of the Slater formula. The formula starts with 2 L lactated Ringer's solution given over the first 24 hours after burn, plus 75 mL/kg/% for. Importantly, FFP is titrated to achieve urine output of 0.5–1.0 mL/kg per hour. Detractors have argued that its benefits should be

B BODY AREA

FIG. 3 Lund-Browder charts. (A) The Lund-Browder charts are somewhat more accurate than the rule of nines in estimating the total body surface area (TBSA) burned. (B) Proportion of TBSA of individual areas according to age. When compared with adults, children have larger heads and smaller legs. Other areas are relatively equivalent throughout life. The rule of nines is not accurate in determining the percentage of TBSA burned in children. (L, Left lower; L, left upper; R, right lower. [from Roberts et al. Roberts and Hedges' Clinical Procedures in Emergency Medicine and Acute Care, 5th ed. Philadelphia: Elsevier; 2010.])

weighed against the risk of disease transmission, transfusion-related lung injury (TRALI), and cost (double that of albumin). TRALI typically occurs within 6 hours of transfusion of blood products (usually after administration of packed red cell concentrates, but also reported after FFP administration). It is believed to occur as a result of either neutrophil priming or antibodies against recipient white blood cell antigens, activating an inflammatory cascade. Clinical presentation varies with rapid onset of dyspnea, tachypnea, and respiratory distress with noncardiogenic pulmonary edema characteristic of acute respiratory distress syndrome (ARDS). Saxe et al. conducted a retrospective review and found that whereas many patients with severe burns have preexisting acute lung injury on admission, the incidence of TRALI following FFP resuscitation from burn shock is low.

Nonprotein semisynthetic colloids, such as hydroxyethyl starch (HES) solutions, contain complex carbohydrate molecules derived from corn or potato starch. Although initial studies were promising in terms of volume expansion, larger randomized controlled trials among critically ill patients identified a significantly increased risk of renal dysfunction requiring renal replacement therapy, significantly more pruritus, and higher 90 day mortality when using HES compared with crystalloids for fluid resuscitation. Consequently, the US Food and Drug Administration has recommended against the use of HES in critically ill patients and therefore cannot be recommended for the resuscitation of burn patients at this time.

MARKERS OF RESUSCITATION

The primary goal of resuscitation is to restore and preserve tissue perfusion and metabolic homeostasis. Vital signs, including urine output, should be measured hourly. The ABA practice guidelines recommend that fluid infusion be titrated to achieve urine output of 0.5 to 1.0 mL/kg per hour. As a resuscitation endpoint, although

TABLE 2 Intravenous Fluid Burn Resuscitation Formulas

Formula	Fluid Solution	Volume in First 24 Hr	Rate of Administration
ADULT			
Parkland	Lactated Ringer's solution	2–4 mL/kg/% TBSA burn	First half over 8 hr, second half over 16 hr
Modified Brooke	Lactated Ringer's solution	2 mL/kg/% TBSA burn	First half over 8 hr, second half over 16 hr
PEDIATRIC			
Parkland	Lactated Ringer's solution	2–4 mL/kg/% TBSA burn plus maintenance fluids	First half over 8 hr, second half over 16 hr
Shriners Cincinnati	Lactated Ringer's solution plus 50 mEq sodium bicarbonate	4 mL/kg/% TBSA burn +	First 8 hr
	Lactated Ringer's solution	1500 mL/m² BSA	Second 8 hr
	Lactated Ringer's solution plus 12.5 g albumin 5%		Third 8 hr
Shriners Galveston	Lactated Ringer's solution	5000 mL/m² TBSA burn plus 2000 mL/m² BSA	First half over 8 hr, second half over 16 hr

From Warden GD: Fluid resuscitation and early management. In Herndon DN, ed: Total Burn Care, 4th ed. New York: Elsevier, 2012:115–124.
BSA, body surface area; TBSA, total body surface area.
Intravenous fluid resuscitation should be commenced in adult burns exceeding 20% TBSA and pediatric burns exceeding 10% TBSA. Pediatric patients following the Parkland formula should also receive maintenance fluids with dextrose 5% in half-normal saline at 4 mL/hr for the first 10 kg of body mass, 2 mL/hr for the second 10 kg of body mass, and 1 mL/hr for the remaining kilograms of body mass. Maintenance fluid requirements for the first 24 hours are already factored into the Shriners Cincinnati and Shriners Galveston formulas.

urine output is practical because of ease of measurement, it may be an imperfect marker, especially for patients with diabetes mellitus or those who have received a hyperosmotic medication such as mannitol or radiocontrast medium. Studies have shown that the correlation is poor between urine output and hemodynamic parameters or measures of oxygen transport or tissue perfusion. Furthermore, upon an hourly urine output in the burn patient has never been defined.

Laboratory markers of resuscitation are similar to those used in septic shock and trauma patients. They include pH, serum bicarbonate and lactate concentrations, and arterial base deficit (BD). Although not specific to burn injury, they are markers of global hypoperfusion and shock (Table 3). Multiple studies have shown that rapid correction of these indices leads to improved survival. Monitoring skin perfusion or gastric mucosal pH has not been proven to be advantageous in guidance for burn resuscitation.

Although no single laboratory parameter has been identified as perfect, serial lactate measurements early during resuscitation are an important factor in treatment for critically injured patients. Lactate, the byproduct of glycogenolysis via the lactate-pyruvate pathway, is a rapid, sensitive, and inexpensive marker of shock. Importantly, a high lactate concentration at the time of patient presentation predicts death in studies of burn, trauma, and sepsis. Dezman et al. showed that the inability to reduce lactate toward normal concentrations within the first 24 hours of hospitalization increases the risk of death.

Admission BD has long been recognized to be an excellent multifaceted predictor of mortality in trauma patients, having a good correlation with volume resuscitation. Carlson et al. found that patients with a nadir BD less than −6 mmol/L during the initial 24 hours after injury developed a more aggressive systemic inflammatory response on the first postburn day, had a higher incidence of MODS, and experienced more severe MODS. This did not appear to be related to the size of the burn, and occurred despite resuscitation to an acceptable level of urine output.

MONITORING

Initial monitoring includes standard measurements of heart rate, blood pressure, pulse oximetry, respiratory rate, and urine output (Table 1).

Central venous pressure (CVP) monitoring has served as an estimator for intravascular volume for decades because of the relative ease of data acquisition and interpretation, although invasive hemodynamic monitoring carries numerous risks. However, relationships among CVP, cardiac output (Q), and vascular resistance and capacitance are complex, making for interpretive complexity. Many factors can affect CVP measurements, including ventilation, hypervolemia, right ventricular failure, valvular heart disease, pulmonary hypertension, and mechanical ventilation. In patients ventilating spontaneously, CVP varies with the ventilatory cycle. Relative negative intrathoracic pressure in inspiration results in a decrease of measured CVP, whereas exhalation results in relatively positive intrathoracic pressure and an increase of measured CVP. These changes are considered normal respiratory variation of the CVP waveform. When patients in respiratory failure receive positive pressure ventilation from a mechanical ventilator, opposite effects are noted: delivery of a breath from a mechanical ventilator results in comparatively positive intrathoracic pressure, and elevation of measured CVP, whereas the expiratory phase leads to a decrease in measured CVP.

Use of a pulmonary artery catheter (PAC) to guide acute burn resuscitation has largely disappeared, beginning about 15 years ago. Recent studies found that this approach led to administration of excessive volumes of fluid. Invasive monitoring using a PAC provides no survival benefit and is not no longer routine. However, PACs may still be useful for carefully selected patients with underlying severe cardiac disease or acute kidney injury when renal replacement therapy is being considered.

Critically ill patients often receive extended hemodynamic monitoring with measurement or estimation of Q as an aid for guiding fluid and vasopressor therapy. With the introduction of the pulmonary artery catheter by Swan and Ganz in 1970, bedside measurement of Q by thermodilution became commonplace. However, routine use of the PAC has been questioned, owing to its invasiveness, difficulty in interpretation of results, and lack of benefit with respect to outcome.

Newer, less invasive monitoring approaches including transpulmonary thermodilution may be used to measure Q and determine volumetric measures of preload such as the global end-diastolic volume, the intrathoracic blood volume, and extravascular lung water. Arterial waveform pulse contour analysis yields real-time continuous

TABLE 3 Markers of Fluid Resuscitation

Index of Response	Normal (Target) Range
Vital signs	
HR (beats/min)	<140
BP (mm Hg)	>90/60
SaO_2 (%)	>98
Urine output (ml/kg/hr)	
Adults	0.5–1.0 (or 30–50 ml/hr)
Children	1.0
Base deficit (mM)	
Normal	−3 to 0
Target	< −6
Serum lactate (mM)	
Normal	0.5–2.2
Target	<4
Central venous pressure (mm Hg)	
Normal	2–6
Target	8–12
Mean arterial pressure (mm Hg)	>65
Bladder pressure (mm Hg)	
Normal	0–5
IAH	>12
ACS	>20
Intrathoracic blood volume index (ml/m²)	>800
Cardiac index (l/min/m²)	>3.5

From Kao KC, Mullins A, and Hedges JR: Important developments in burn care. Biol Resuscitation 2010;1:001(1):20–106.
ACS: Abdominal compartment syndrome; BP: blood pressure; HR: heart rate; IAH: intra-abdominal hypertension; Sa_{O_2}: oxygen saturation.

measures of Q, stroke volume (SV), stroke volume variation, pulse pressure, and pulse pressure variation.

Arterial pulse contour analysis measures and monitors SV on a beat-to-beat basis from the arterial pulse pressure waveform. Q is then calculated based on the pulse pressure being directly proportional to SV. Pulse pressure variability in relation to SV can be affected by positive pressure ventilation, and in hypovolemic patients whose right ventricular filling is decreased. There are several theoretical advantages of this technique when compared to the gold standard, bolus thermodilution technique. It is noninvasive, using already placed arterial catheters. In addition, the clinician can monitor changes in SV and Q on a continuous basis. A major limitation of pulse contour analysis is reduced validity in the setting of cardiac arrhythmias, aortic regurgitation, or peripheral vascular disease.

Point-of-care ultrasound has become an integral tool in management of critically ill patients, especially in determining volume status and cardiac function. Specifically, information about a patient's cardiac anatomy, assessment of cardiac function, ventricular volume, Q, ejection fraction, and inferior vena cava (IVC) diameter. IVC diameter is used to assess preload and volume responsiveness. Nevada et al. found that patients with IVC diameter <2 cm were more likely to be fluid responders (IVC diameter >2 cm after fluid bolus). Heldt et al. have described support-performed hemodynamic transesophageal echocardiography as a useful adjunct in burn resuscitation, for example, in determining whether additional fluid or vasopressors are required to treat hypotension. Potential disadvantages of point-of-care ultrasound and echocardiography are similar to any new learned technique that requires proficiency. It remains unclear how many procedures one needs to perform before proficiency is attained.

COMPLICATIONS OF BURN RESUSCITATION

Systemic complications of burn injury remain a substantial problem despite advances in burn resuscitation. Severity of complications correlates with percent TBSA, age, sex, and undertresuscitation.

ARDS is a pulmonary manifestation of the upregulation of innate immunity, resulting in systemic inflammation and clinical respiratory failure caused increased vascular permeability and impaired gas exchange and oxygen utilization. ARDS usually occurs in patients who already are critically ill from predisposing conditions such as sepsis, aspiration pneumonitis, pneumonia, burns, inhalation injury, and trauma. Burn injuries, especially those involving inhalation injuries, have the highest incidence of ARDS among all predisposing conditions. Carlson et al. found that nearly 40% of mechanically ventilated adult civilian burn patients develop ARDS. Management of the burn patient with ARDS is largely supportive with mechanical ventilation being the cornerstone of therapy. Lung protective ventilation to minimize the additive insult of volutrauma (formerly barotrauma) for example, the use of low tidal volumes of ~6 ml/kg, and the targeted achievement of lower plateau pressures (P_{plat} <30–35 cm H_2O), combined if necessary with permissive hypercapnia (allowance for a partial pressure of carbon dioxide >80 mm Hg as long as pH >7.20, absent a coexistent traumatic brain injury) has improved mortality.

ACS is a complication associated with aggressive fluid resuscitation of burns (Fig. 8). In large TBSA burns that require large volume resuscitation, measuring a baseline urinary bladder pressure on admission to the burn intensive care unit may assist in monitoring for the potential development of ACS. Burns can lead to ACS by several mechanisms. Circumferential burns of the lower torso with abdominal wall edema and eschar formation can cause reduced compliance of the abdominal wall. Large burns can lead to ischemic paralysis secondary to elevated mesenteric vascular resistance resulting from the release of vasoactive substances and inflammatory mediators from burned tissue. In addition, ascites and bowel edema secondary to massive fluid resuscitation, exacerbated by cardiovascular failure, can also lead to intraabdominal hypertension (IAH). Reed et al. showed that patients who received 12 L or more of intravenous fluid in the first 24 hours of resuscitation, or who received 200 ml/hr or intravenous fluids for more than four consecutive hours, were at risk for developing IAH and ACS, which is characterized by both respiratory and renal insufficiency. End-organ injury to the kidneys as evidenced by low urine output may be misinterpreted as requiring even more fluid resuscitation, leading to worsening of ACS. There is not consensus as to what degree of IAH should cause alarm. Intraabdominal pressure is normally 5 to 10 mm Hg. Pressure of 20 mm Hg or higher is clearly abnormal, whereas more than 30 mm Hg may require abdominal decompression to ensure homeostasis.

Severe burn injury can lead to dysfunction of the gastrointestinal system, primarily a result of loss of the gut barrier function and enteric bacterial translocation. Additionally, hypovolemia following a severe burn can result in a low-flow state of mesenchymal ischemia, further worsening gut mucosal integrity. Gut mucosal atrophy can also occur in the absence of enteral feeding, which should be instituted early after injury to promote anabolism, prevent trophic effects on gut mucosa. Early enteral nutrition, started 24 to 48 hours after burn injury, is one of the only therapies shown to decrease these complications. Moreover, abdominal wall burns or burns to the lower back can induce ileus, including the feared complication of colonic pseudo-obstruction (Ogilvie's syndrome), which usually can

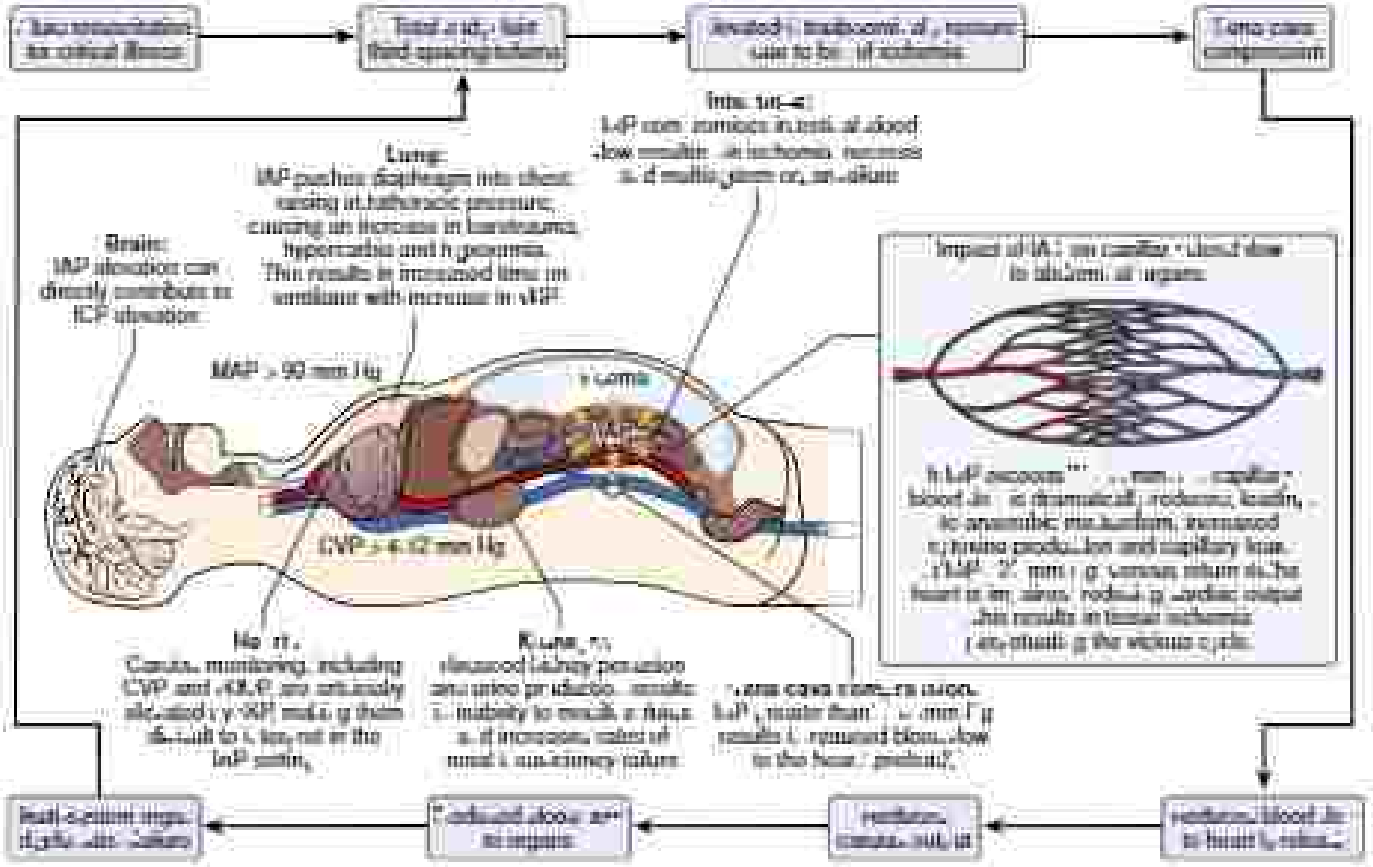

FIG. 4 Optimal use of the pathophysiologic processes leading to abdominal hypertension and abdominal compartment syndrome [illegible]

be reversed with a 2.8 mg bolus injection of neostigmine, but which may require surgical decompression in refractory cases owing to the risk of colon perforation.

Early onset acute kidney injury (AKI) results most commonly from reduced CO. Burn injury can cause hypovolemia and hypotension that stimulates a renal vasoconstrictive response via the renin-angiotensin-aldosterone axis, release of neurohormonal mediators of renal vasoconstriction, depressed myocardial contractility, a stress-related counterregulatory hormonal milieu, direct and indirect (from nephrotoxic medications) nephrotoxicity, and protein denaturation. This leads to an increase in vascular resistance and permeability and production of microthrombi in the glomeruli and renal tubules, leading to a further reduction of renal flow and tubular necrosis. The ABA has suggested avoidance of AKI using criteria such as stages of the Risk Injury Failure Loss End Stage or Acute Kidney Injury Network criteria. Early, judicious resuscitation to mitigate the innate immune response is key to preventing AKI in burn patients.

Burn wound infection and sepsis are common causes of morbidity and mortality in burn patients. Any rapid change in the burn wound appearance or the clinical condition of the burn patient may herald burn wound infection or sepsis. Categories of burn wound infection are based on clinical features and depth of invasion, which is determined through cultures and histopathology of tissue obtained by burn wound biopsy. Specific criteria that include, among other criteria, microbial invasion into adjacent normal tissue have been suggested by the ABA to define burn wound sepsis (Table 4).

Although not often discussed as part of burn resuscitation, the goals of transfusion of blood and blood products in burn management is worthy of consideration. A multicenter randomized prospective trial compared two standard transfusion tactics with hemoglobin goals of less than 10 g/dL compared with less than 7 g/dL in patients with burn injury more than 20% TBSA, and found that the restrictive protocol reduced transfusion volume without significant differences in blood stream infections, mortality, pneumonia, urinary tract infection, wound infection, hospital or intensive care unit length of stay, organ dysfunction, or wound healing. The findings of this trial confirm and extend the results of the historic Transfusion Requirements in Critical Care trial, in which restrictive transfusion was equally effective as was a liberal blood product administration protocol. These observations were confirmed subsequently in studies of hip fracture patients, cardiac surgery, and other critical care populations in addition to burn patients.

Thermal injury can occur to the upper or lower airway. Indications include singed facial hair, soot in the oropharynx, carbonaceous sputum, respiratory distress, hoarseness, persistent cough, or deep facial or circumferential neck burns. Inhalation injury of the upper airway can cause substantial swelling and subsequently complicate the securing of an artificial airway. The lower airway generates a substantial local and systemic inflammatory response mediated by the [illegible] present in smoke particles. In the lower airway, these antigens are in close proximity to large populations of airway macrophages and marginated neutrophils in the pulmonary microcirculation, and severe tissue injury can ensue, including an ARDS picture. Mucosal sloughing and carbonaceous deposits determine the grading of lower airway injury, mindful of the possibility that mucosal sloughing can lead precipitously to respiratory failure resulting from mucus plugging. Such airway debris can be managed by bronchodilators, pulmonary toilet including fiberoptic bronchoscopy, mechanical ventilation

TABLE 4 ABA 2007 Criteria of Sepsis in Burn Patients

	Children	Adults
Progressive tachycardia	≥2 SD age-specific norms (90% age-adjusted maximum heart rate)	≥110 beats/min
Progressive tachypnea	≥2 SD age-specific norms (90% age-adjusted maximum respiratory rate)	≥25 breaths/min (not ventilated) or ≥12 mm Hg (ventilated)
Thrombocytopenia (applicable only 5 days after initial resuscitation)	<2 SD age-specific norms	<100 × 10^3/μL
Hyperglycemia (without preexisting diabetes mellitus)	>200 mg/dL (without treatment) or insulin resistance >25% increase in insulin requirements in 24 hours	>200 mg/dL (without treatment) or insulin resistance >7 U/hr intravenous insulin
Inability to continue enteral feedings >24 hours	Abdominal distension, enteral feeding intolerance (residual > 50 mL/hr), uncontrollable diarrhea	Abdominal distension, enteral feeding intolerance (residual >½ feeding rate), uncontrollable diarrhea

ABA, American Burn Association; SD, standard deviation.

if needed, and careful surveillance for invasive pulmonary aspergillosis, which is common in this patient population. Inhalation injury is discussed in detail elsewhere in this issue of the *Clinics*.

Burn wound sepsis is the most common cause of late mortality in burn patients. Early excision and closure of the burn wound, topical antimicrobial therapy, and systemic antibiotics when indicated have significantly reduced the incidence of burn wound sepsis. Despite these advances, burn wound sepsis remains a significant cause of morbidity and mortality in burn patients. Early diagnosis of burn wound sepsis is difficult because the signs of sepsis, such as fever, hyperglycemia, and tachycardia, are also present in patients without sepsis. Furthermore, the presence of bacteria in the burn wound is universal, and quantitative cultures of tissue biopsy specimens are the gold standard for diagnosis of burn wound sepsis. However, the use of quantitative cultures is not widespread because of the time required to perform the test and the lack of availability in many burn centers. Therefore, most burn centers rely on clinical criteria to diagnose burn wound sepsis. Unfortunately, clinical criteria are not very specific for burn wound sepsis. Recently, the American Burn Association published consensus guidelines for the diagnosis of sepsis in burn patients (Table 4). These guidelines are based on the systemic inflammatory response syndrome criteria but have been modified to account for the pathophysiologic changes that occur after burn injury. Using these criteria, the diagnosis of sepsis can be made with greater accuracy. Treatment of burn wound sepsis includes surgical debridement of infected tissue, systemic antibiotics, and topical antimicrobial therapy. Topical antimicrobials are applied directly to the burn wound and include silver sulfadiazine, mafenide acetate, and silver-containing dressings. Mafenide acetate has the advantage of penetrating eschar, but it can cause pain and metabolic acidosis. Silver sulfadiazine is painless and has a broad spectrum of antimicrobial activity, but it does not penetrate eschar. Silver-containing dressings have the advantage of providing continuous antimicrobial therapy, but they are expensive and require frequent dressing changes. Systemic antibiotics should be used only when there is clinical evidence of burn wound sepsis, because prophylactic systemic antibiotics have been shown to increase the incidence of infection with multidrug-resistant organisms.

BURN METABOLISM AND NUTRITION SUPPORT

Severe burn injury results in a massive stress response that induces profound, protracted catabolism that sometimes can persist for years after the initial insult. Typically, patients with major burns have higher caloric/metabolic requirements when compared with patients with sepsis, multiple trauma, or head injury (Fig. 3).

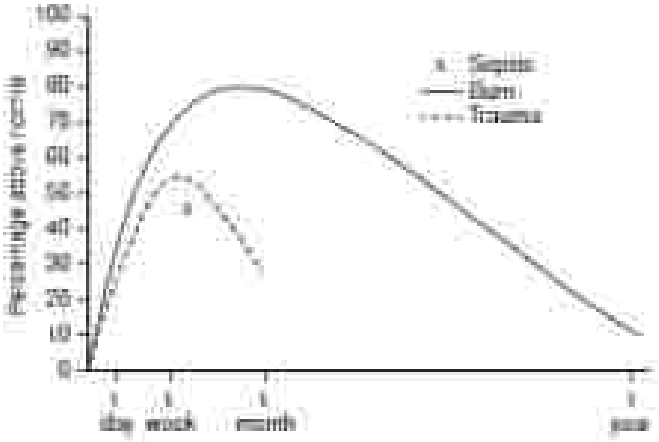

FIG. 3 Hypermetabolic response after severe burns, trauma, and sepsis. (Modified from Clowes GH Jr, Hirsch EF, Simeone FA. Nutrition and metabolism in burns. *Surg Clin North Am*. 1970;50:1251.)

The acute response to burn injury typically manifests two distinct states. The shock, or ebb phase, is typically brief in duration and is predominated by reduced cardiac function, decreased metabolism, and reduced tissue perfusion. This state can result in hypothermia, anuria and elevated lactate production.

Unlike the acute phase, the classic response to burn injury, or flow phase, is a hypermetabolic, catabolic state that may last days to months after initial burn injury. The metabolic rate and O_2 are markedly elevated, resulting in increased whole body oxygen consumption and energy expenditure (EE) above normal. The importance of adequate early nutritional support cannot be overstated in mitigating the stress response of burn injury. Failure to support full the metabolic needs of the burn patient can lead to loss of lean tissue, poor wound healing, sepsis, multiple organ failure syndrome, and death.

Early enteral nutritional support (within 24 hours of injury) attenuates the hypermetabolic/catabolic response to severe burn injury. The caloric requirements for burn patients can be estimated by a variety of formulas (Table 5). Regardless of which formula is used, the primary goal of nutritional support is to match the metabolic demand caused by the hypermetabolic state, while maintaining safety

TABLE 5 Common Formulas Used to Calculate Caloric Needs of Burn Patients

Adult Formulas	Equation	Comments
Harris Benedict	Men: 66.5 + 13.8 (weight in kg) + 5 (height in cm) − 6.76 (age in years) Women: 655 + 9.6 (weight in kg) + 1.85 (height in cm) − 4.68 (age in years)	Estimates basal energy expenditure; can be adjusted by both activity and stress factor; multiply by 1.5 for common burn stress adjustment
Toronto formula	−4943 + 10.5 (TBSA) + 0.23 (calorie intake in last 24 hr) + 0.84 (Harris Benedict estimation without adjustment) + 114 (temperature) − 4.5 (number of postburn days)	Useful in acute stage of burn care; must be adjusted with changes in monitoring parameters
Davies and Liljedahl	30 (weight in kg) + 70 (TBSA)	Overestimates caloric needs for large injuries
Curreri	Ventilated patients (208 − 11 (age in years) + 5 (weight in kg) + (244 if male) + (23 if trauma) + (804 if burn) Nonventilated patients (25 − 11 (age in years) + 25 (weight in kg) − (609 if obese)	Complex formula which integrates variables for ventilation and injury status
Cunningham	Age 1–55: 25 (weight in kg) + 40 (TBSA) Age >55: 20 (weight in kg) + 65 (TBSA)	Often overestimates caloric needs
PEDIATRIC FORMULAS		
Galveston	0–1 year: 2100 (body surface area) + 1000 (body surface area × TBSA) 1–11 years: 1800 (body surface area) + 1300 (body surface area × TBSA) 12–18 years: 1500 (body surface area) + 1500 (body surface area × TBSA)	Focuses on maintaining body weight

(principally, from either pulmonary aspiration of gastric contents/enteral feeding solution or use of a malpositioned tube) and avoiding overfeeding. The macronutrients in the formulation of burn nutrition solutions include carbohydrates, proteins, and lipids. Some research suggests that given the inhibition of lipolysis in the acute response to injury, lipids should be limited as a source of calories. Fatty acid deficiency is a rarity that takes weeks to develop even absent any intake of fat). Comparison of high carbohydrate and protein, low fat enteral formula with low carbohydrate and protein, high fat formula in a systematic way showed no clear benefit to either formula, although the risk of pneumonia may have been lower with the high carbohydrate formula. Arginine appears to be an essential macronutrient for wound healing, and protein requirements in burn patients may be 50% higher than in healthy individuals. Protein delivery should be 1.5 to 2 g/kg body weight daily.

Parenteral nutrition in burn patients is typically reserved for patients whose gastrointestinal function is impaired. Parenteral nutrition requires central venous access, is associated with higher rates of complications in critically ill patients (e.g., hepatic dysfunction, catheter-related blood stream infection), and does not support gut mucosa directly, as does enteral feeding.

Immunonutrition (use of micronutrients that modify the immune response during critical illness) has not gained popularity despite supporting evidence. Immunonutrients that have been administered to burn patients include omega-3 fatty acids (fish oil), arginine, and glutamine. Arginine is a conditionally essential amino acid that serves as a precursor to glutamine, promotes T cell proliferation, stimulates growth hormone and insulin secretion, and promotes wound healing. Glutamine is believed to be a conditionally essential amino acid that provides fuel for immune cells and enterocytes, serves as a precursor for the antioxidant glutathione, and potentially reduces insulin resistance. Whereas glutamine has shown promise as a nutritional supplement in the critical care population, a recent review of immunonutrition in the burn population found insufficient evidence to recommend its use. Evidence-based practice guidelines for the use of micronutrients in burn patients have not been developed. Intuitively, diminished gastrointestinal absorption, increased urinary losses, altered distribution, and altered carrier protein (e.g., albumin, lactoferrin) concentrations following severe burn will lead to a deficiency in many micronutrients if not supplemented. There is little evidence for pharmacologic doses of any micronutrient in burn patients. In fact, the majority of patients achieve the recommended supplemental micronutrients in sufficient amounts through standard nutritional therapy.

NEW TRENDS IN BURN INJURY MANAGEMENT

As described earlier, the burn-induced stress response stimulates secretion of catecholamines, glucocorticoids, and peptide hormone mediators that are believed to be the primary factors of hypermetabolism after severe burns. Nonspecific β-blockade with propranolol, a nonspecific beta-1, beta-2 adrenergic receptor antagonist, has shown good results in blunting the response to burn injury. Low-dose propranolol (0.5–1.0 mg/kg) in patients with severe burns reduces myocardial oxygen consumption without affecting oxygen transport adversely. Higher doses (2 mg/kg/day for 7 days) cause a 20% reduction in heart rate. Propranolol also decreases resting energy expenditure, hepatic steatosis, and sepsis. The benefit of propranolol lasts demonstrably for at least 12 months after injury.

Anabolic steroid production is decreased after severe burn injury and can remain below normal for up to 3 years postinjury. Restoring serum testosterone to severely burned patients can decrease lean tissue loss and improve protein synthesis. Oxandrolone, an analogue of testosterone, is well absorbed orally and is preferred to the authentic hormone for repletion of serum and supraphysiologic levels. In skeletal

muscle, oxandrolone binds to intracellular androgen receptors and stimulates anabolism via protein synthesis. Porro et al. demonstrated that oxandrolone 0.1 mg/kg by mouth twice a day for 1 year postburn provides benefits that persist for up to five years post injury with few deleterious side effects.

Other anticatabolic agents have also been used to improve muscle mass. Recombinant human growth hormone (rhGH) has shown promise as an agent for blunting catabolism. rhGH ameliorates the hypermetabolic response to major stress, and enhances immune function, protein synthesis, and wound healing, after burn injury. Unfortunately, Takala et al. found that rhGH increases mortality in critically ill adults. Concomitant use of rhGH and propranolol attenuated hypermetabolism, peripheral lipolysis, inflammation, and avoids the problematic effects of using rhGH alone. Insulin is a classic anabolic hormone, but stimulates weight gain primarily through increased fat stores.

Vitamin C (ascorbic acid) is an antioxidant that acts to quench oxygen free radicals that cause tissue injury via oxidation of cell membrane lipids. Much of the imbalance in predicted fluid requirements and required administration in burn patients has been attributed to lipid peroxidation and dysregulation of scavenging systems for reactive nitrogen species, altering endothelial integrity and metabolism as the result of endothelial cell injury. Several laboratory and clinical studies demonstrated that adjunctive ascorbic acid in burn resuscitation decreases the exogenous fluid volume needed to restore and maintain adequate perfusion. Tanaka et al. randomized 37 patients with more than 30% TBSA burns to receive isotonic crystalloid and colloid fluid resuscitation with or without high-dose intravenous vitamin C (66 mg/kg per hour) for the first 24 hours after admission. Patients who received ascorbic acid infusion in the first 24 hours post burn demonstrated improved partial pressure of oxygen in arterial blood/fraction of inspired oxygen with fewer ventilator days. Patients requiring escharotomies or fasciotomies were fewer in the ascorbic acid group.

Kahn et al. conducted a 3-year retrospective analysis of patients treated (2007–2009). The control group were resuscitated according to the Parkland formula, whereas the experimental group was resuscitated by the Parkland formula plus the volume required to administer an intravenous vitamin C dose of 66 mg/kg per hour. Twenty-four-hour fluid requirements were 25% less in the vitamin C–treated subjects. Although overall resuscitation volume was decreased, the study demonstrated no improvement in respiratory function or mortality.

Complications of high-dose vitamin C infusions include an increase in postburn AKI as a result of osmotic diuresis. This, in turn, leads to decreased fluid resuscitation requirements and worsening renal function without changing resuscitation endpoints. Additionally, oxalate nephropathy (obstructive uropathy secondary to crystalluria) has been described in postmortem examinations of burn patients treated with high-dose vitamin C infusion. Hyperoxaluria can worsen existing kidney injury or delay kidney recovery. More research is needed before widespread adoption.

SUMMARY

The medical management of burn resuscitation and continuing burn care has evolved over the past several decades. Judicious, balanced use of crystalloid fluid with colloid administration has resulted in minimizing "fluid creep" and its sequelae. Advances in monitoring and measurement of burn depth have also led to more precise estimation of fluid requirements. Adjuncts to care including nutrition support, prevention of complications, and the use of novel pharmacotherapies have all played a role in reducing the morbidity and mortality of burn injury.

MANAGEMENT OF FROSTBITE, HYPOTHERMIA, AND COLD INJURIES

Paul M. [illegible]

The several types of localized cold injuries may be classified according to the temperature that produces them: (1) nonfreezing or (2) freezing temperatures. Nonfreezing, immersion foot and trench foot, are produced by cold but not freezing temperatures. Frostbite is produced by freezing temperatures. Trench foot and immersion foot and hand are seen principally in military populations, whereas chilblains and frostbite are seen more commonly in civilian populations.

Further, cold injuries may be divided into (1) localized cold injuries (i.e., frostbite) and (2) generalized cold injuries (i.e., hypothermia). Frequently, localized cold injuries such as frostbite do not co-exist with systemic hypothermia.

Localized cold injuries have in common the fact that they are produced by exposure to cold stimuli and that they occur at the extremities of circulation. Localized cold injuries may be seen in the cheeks, nose, ears, and face but are seen primarily in the hands and feet. Cold injuries to the face tend to be superficial because of the blood supply. Serious cold injuries are confined almost exclusively to the extremities, in which there is a small margin of difference between the injuries that produce superficial versus deep injury.

TRENCH FOOT

Trench foot is usually seen in military populations and occurs with exposure to above-freezing temperatures, generally over a prolonged period of time. The presence of moisture is very important to its pathogenesis. Chronic symptoms produced after recovery from the acute injury are those of pain, paresthesia, and a particular susceptibility to further cold injury.

IMMERSION FOOT AND HAND

Immersion foot and hand are seen after prolonged exposure to cold but not freezing water. After recovery from the acute episode, major nerve paralysis may be seen in addition to chronic vasospastic cold sensitivity and pain. Pain in the affected area and paresthesias are commonly seen after all types of cold injury.

CHILBLAINS

Chilblains represent the mildest form of cold injury and occur after prolonged exposure to cold and wet conditions. The symptoms consist of burning and itching and are associated with a mild dermatitis. Vesicles and hemorrhagic lesions may be seen in the acute period.

The chronic condition is characterized by cold sensitivity, itching, paresthesias, and skin eruptions, which may be reddish lesions, vesicles, or superficial ulcers. The chronic condition may be treated by protection from cold and heat to avoid production of dermatitis symptoms and pain. The role of sympathetic denervation in the management of the chronic condition has been suggested but not established. Some feel it may be helpful in chronic, well-established symptoms that require treatment. Chilblains do not produce tissue loss, and thus they require no reconstruction.

FROSTBITE

Frostbite occurs from exposure to freezing temperatures. The period of exposure required for its production may be short or long, depending on environmental conditions, wind, and protection. Frostbite has been classified into degrees of injury depending on the depth of damage. Often several degrees of injury will be seen in the same extremity, with the damage increasing as injury progresses from proximal to distal.

First-Degree Frostbite

First-degree frostbite is a superficial skin injury characterized by numbness, edema, and erythema. The injury is similar to a

Management of Frostbite, Hypothermia, and Cold Injuries

Paul M. Hanson, MD

The several types of localized cold injuries may be classified according to the temperature that produces them: (1) nonfreezing or (2) freezing temperatures. *Trench foot, immersion hand and foot*, and *chilblains* are produced by cold but not freezing temperatures. *Frostbite* is produced by freezing temperatures. Trench foot and immersion foot and hand are seen principally in military populations, whereas chilblains and frostbite are seen more commonly in civilian populations.

Further, cold injuries may be divided into (1) localized cold injuries (i.e., frostbite) and (2) generalized cold injuries (i.e., hypothermia). Frequently, localized cold injuries such as frostbite do not co-exist with systemic hypothermia.

Localized cold injuries have in common the fact that they are produced by exposure to cold stimuli and that they occur at the extremities of circulation. Localized cold injuries may be seen in the cheeks, nose, ears, and face but are seen primarily in the hands and feet. Cold injuries to the face tend to be superficial because of the blood supply. Serious cold injuries are confined almost exclusively to the extremities, in which there is a small margin of difference between the injuries that produce superficial versus deep injury.

TRENCH FOOT

Trench foot is usually seen in military populations and occurs with exposure to above freezing temperatures, generally over a prolonged period of time. The presence of moisture is very important to its pathogenesis. Chronic symptoms produced after recovery from the acute injury are those of pain, paresthesia, and a particular susceptibility to further cold injury.

IMMERSION FOOT AND HAND

Immersion foot and hand are seen after prolonged exposure to cold but not freezing water. After recovery from the acute episode, major nerve paralysis may be seen in addition to chronic vasospastic cold sensitivity and pain. Pain in the affected area and paresthesias are commonly seen after all types of cold injury.

CHILBLAINS

Chilblains represent the mildest form of cold injury and occur after prolonged exposure to cold and wet conditions. The symptoms consist of burning and itching and are associated with a mild dermatitis. Vesicles and hemorrhagic lesions may be seen in the acute period.

The chronic condition is characterized by cold sensitivity, itching, paresthesias, and skin eruptions, which may be reddish lesions, vesicles, or superficial ulcers. The chronic condition may be treated by protection from cold and heat to avoid production of dermatitis symptoms and pain. The role of sympathetic denervation in the management of the chronic condition has been suggested but not established. Some feel it may be helpful in chronic, well-established symptoms that require treatment. Chilblains do not produce tissue loss, and thus they require no reconstruction.

FROSTBITE

Frostbite occurs from exposure to freezing temperatures. The period of exposure required for its production may be short or long, depending on environmental conditions, wind, and protection. Frostbite has been classified into degrees of injury depending on the depth of damage. Often several degrees of injury will be seen in the same extremity, with the damage increasing as injury progresses from proximal to distal.

First-Degree Frostbite

First-degree frostbite is a superficial skin injury characterized by numbness, edema, and erythema. The injury is similar to a

FIG. 1 First- and second-degree frostbite. Epidermal skin loss and peeling are seen.

first-degree burn in that it heals spontaneously (in terms of the epithelium) in 1 to 2 weeks. Superficial desquamation may occur, and regeneration is usually complete with decreased but adequate skin appendages (Fig. 1).

Second-Degree Frostbite

In second-degree frostbite, partial-thickness skin injury occurs that is characterized by numbness, edema, erythema, and vesiculation. The vesicles may be filled with either clear or bloody fluid. The partial-thickness skin injury heals in 2 to 3 weeks (Fig.). The quality of the regenerated skin depends on the depth of the injury to the dermis and parallels thermal burn injuries in that deep second-degree injuries heal with thin atrophic skin that has a reduced number of skin appendages.

Third-Degree Frostbite

Third-degree frostbite represents full-thickness skin loss. After the injury, a insensible segment of full-thickness skin loss is observed; this may be seen initially as a gray-blue patch, or death of the skin may follow an initial period of reactive hyperemia after 24 to 72 hours. Eventually, a black eschar forms that generally separates slowly in 1 to 3 months unless infection occurs (Fig.).

Fourth-Degree Frostbite

Fourth-degree frostbite signifies necrosis of all deep tissue; pain down to and sometimes including bone, black, mummified tissues are present with the initial episode. If the mummified area becomes infected, it softens and becomes swollen and macerated at the margin with viable tissue.

Pathophysiology of Frostbite

Two pathophysiologic mechanisms account for the production of frostbite injury. One is vasoconstriction and damage to the microcirculation in the zone of vascular stasis, which results in progressive vascular thrombosis. The second is direct damage to the cells or cellular fluidity from freezing. Experts disagree on the importance of these two mechanisms and the importance of each mechanism varies according to the amount of tissue freezing that occurs and the local conditions, such as circulation.

Thawing Reaction

The body responds to cold with an alternating cycle of vasoconstriction and vasodilatation (called the thawing reaction) in an attempt to conserve heat loss from the skin. As the injury becomes worse, the cycle may involve actual freezing and thawing of tissue. Circulation virtually ceases as the vasoconstriction increases, causing marked ischemia of the tissue.

[illegible] to Cold

Freezing produces extracellular and then intracellular ice crystals. Extracellular ice crystals produce direct damage to cell walls and also cause a leaching out of electrolytes and water from the intracellular compartment, resulting in intracellular dehydration followed by cell death. Intracellular ice crystals produce direct damage to important cell structures.

[illegible] Thereafter

Frostbite produces progressive dermal ischemia, similar to the process seen in thermal burns or in the no-reflow phenomenon. The role of edema and endothelial injury in the subsequent arrest of dermal blood flow has implicated various inflammatory mediators such as thromboxanes, prostaglandins, histamine, and bradykinin; these observations have led to the use of inhibitors of these mediators in an attempt to ameliorate the harmful tissue reaction and improve tissue survival.

Tissue injury occurs both from direct damage to cells and from the vasoconstriction stasis, which results in vascular stasis and thrombosis. After the state of decreased circulation, a state of reactive hyperemia occurs, which may or may not be associated with a no-reflow phenomenon, in which capillary thrombosis occurs in the zone of stasis. The pathology of tissue repair is similar to that of burn injuries in that epithelium migrates to cover the wound from the surviving remnants of sweat glands, hair follicles, and margins of the healing wound. The quality of the skin produced is intimately proportional to the depth of damage. Deep injuries have necrotic nerve, muscle, and bone and are healed by scar after the shedding of dead tissue. Frequently, autoamputation occurs after ischemic necrosis and gangrene. Left untreated, the process is generally dry and progresses to autoamputation without infection over several months.

Environmental Influences

A number of behavioral and environmental factors may influence the production of cold injuries. Two of the most significant environmental factors are the ambient temperature and the wind.

The effects of temperature may be modified by wearing protective clothing, which provides insulation proportional to its thickness and weight. The effects of temperature are modified by the presence of wind and wet conditions, which accelerate heat loss. Wet conditions increase heat conduction to the environmental air, whereas wind accelerates the loss of heat in the air. Siple has developed a "wind chill index" to reflect the magnitude of the contribution of wind to heat loss. The heat loss would be the same at 20°F with a wind of 45 miles per hour as at −40°F with a wind of 2 miles per hour.

The mean outdoor temperature recorded in frostbite injury series is −20°C. Frostbite is seen isolated to the upper extremities in 10% of cases, isolated to the lower extremities in 47% of cases, in both upper and lower extremities in 31% of cases, and with an extremity involvement in only 3% of cases.

Clothes provide insulation proportional to their thickness (one-quarter of an inch equals one clothing unit) and weight. They should be light to allow activity and may act in multiple layers to be effective. Sweating wets the clothing, reducing the insulation value. The importance of light clothing permitting work (heat production) is emphasized. The proper use of protective clothing is important. In one study, 65% of those who suffered frostbite had inadequate protective clothing, whereas 21% had adequate clothing but were wearing it improperly. Only 15% of frostbite victims had adequate clothing and were wearing it properly. Moisture accelerates heat loss.

Behavioral factors also predispose to cold injuries. Alcohol and drug intoxication; smoking; accidents such as car, plane, skiing, and vehicular failure; homelessness; high altitude; and outdoor pursuits

FIG. 2 (A) Second-degree frostbite to the fingers. Vesicles and swelling are seen. (B) Second-degree frostbite to the feet. Vesicles and swelling are seen.

FIG. 3 Third- and fourth-degree frostbite with tissue death and demarcation beyond the metatarsophalangeal joint.

predispose to frostbite, as does a previous cold weather injury. Medical conditions that decrease circulation (peripheral arterial disease), neuropathy, and diabetes all decrease the body's ability to adapt to colder temperatures; psychiatric illness is observed much more frequently in patients who suffer frostbite. The average age of a frostbite victim is 30 to 40 years, with men outnumbering women by 10 to 1.

Prevention of Frostbite

There are two ways to prevent cold injury: (1) by increasing heat production and (2) by decreasing heat loss. Heat loss may be decreased by avoiding wetness or contact with metal (which accelerates heat loss) and by wearing adequate protective clothing. The extremities have a large surface to mass ratio, and thus represent prime sites for heat loss. Other factors may affect the circulation to extremities, such as the presence of arterial occlusive disease. Some feel that the presence of a frostbite injury should prompt an examination for an arterial occlusive lesion or conditions such as diabetic neuropathy, which do not permit reflex vasoconstriction and vasodilatation. The importance of inactivity and immobility in reducing heat production, producing orthostatic edema, and decreasing circulation has been emphasized in studies on military frostbite. Malnutrition, hemorrhage, anemia, and the use of tobacco and alcohol all have been implicated in the increased susceptibility to frostbite injuries. Acclimatization and cold tolerance probably occur. African Americans have increased susceptibility to cold injuries, probably because of less frequent waves of cold-induced vasodilatation, and thus less effective skin warming. Military experience has emphasized the importance of working and keeping active so as to increase heat production. The importance of avoiding sweating to avoid wetness and replacing wet with dry clothing also is emphasized.

Superficial Versus Deep Frostbite

Frostbite to the head and neck area is generally superficial. The face is not subject to the same vasoconstrictive phenomena as are the extremities. The drying potential of cold in the facial area is manifested in chapped lips, nose tip, ears, and mucous membranes. Facial frostbite is generally superficial, whereas serious frostbite usually is confined to the extremities.

Mills believes that the differentiation of frostbite into first-, second-, third-, and fourth-degree injuries is cumbersome and not clinically useful. He believes that one can only classify frostbite as superficial (tissue remains soft) or deep (tissue is hard). It is initially difficult to tell the depth of the injury, and differentiation can be accomplished only after rewarming and a period of observation. Cauchy (2003) believes that the extent of the initial lesion and the result of three-phase bone scanning can predict the ultimate result of the initial lesion is confined to the distal digit, the probability of amputation is 1%; the probability increases to 31% for the middle digit, 67% for the proximal phalanx, 98% for the metacarpal and metatarsal, and 100% for the carpal and tarsal areas. In the face, a small white patch of tissue may be seen, and this clears over the course of a week.

Medically, frostbite heals with no therapy, therapy with dressings alone, or surgical debridement, amputation and dressings. Twenty-one percent of patients with frostbite are seen more than 48 hours after the injury.

In the extremities, mild frostbite is manifested by pallor, paresthesias, and a dull yellow color of the skin. Ice crystals may be observed. The area is numb, and after rewarming a prickly, itchy sensation, or aching pain occurs. After rewarming, reactive hyperemia is observed superficially; in deeper injuries, hypersensitivity and paresthesias are observed. Deep frostbite is differentiated by the absence of circulation; on rewarming, the progression (progressive vascular thrombosis) to full thickness tissue loss (eschar formation) occurs. The tissue may remain insensitive after rewarming, presenting as a blue-gray patch with absent circulation. Burning pain, paresthesias, and thick-walled blisters containing blood may follow rewarming to full thickness tissue injury.

The history of the injury is important in predicting tissue loss. Important factors include duration of the exposure, temperature, protective clothing worn, contact with metal or moisture, and the presence of previous symptoms that would indicate reduced arterial

BOX 1 Therapy for Frostbite

- Correct systemic hypothermia (temperature <35°C)
- General measures (including detection of other injuries)
- Rapid rewarming of frozen extremities (15 to 30 minutes until a digital flush is observed) in a 104°F to 108°F agitated water bath and topical antiseptic
- Tetanus immunization ± antibiotics
- Aspirin: 325 mg every 4 hours for 72 hours (Robust)
- Open or light dressings
- Clear blebs debrided
- Hemorrhagic blebs, keep intact
- Topical aloe vera (Robson) and antibacterial agents
- Selected blisters: debride, antibiotics, antiseptics
- Functional splinting, elevation
- Twice daily cleanse with antiseptics
- Avoid macerating dressings
- Surgery
- Await clear demarcation
- Allow spontaneous epithelialization
- If within the first 24 to 48 hours
  - Consider regional sympathectomy in those with troublesome, persistent symptoms; normal or low vascular response after rewarming; arteriogram of magnetic resonance imaging or magnetic resonance angiogram evidence of vascular spasm and lack of complete flow (Robson)
  - Hyperbaric oxygen
  - Intra-arterial tissue plasminogen activator, initially 0.5 mg/hr, then decreasing daily
  - Heparin therapy
  - Steroids

circulation. These include claudication, Raynaud's phenomenon, and superficial phlebitis. It is important to assess if there is any contribution of underlying vascular disease to patients with frostbite.

Diagnosis of Hypothermia

Hypothermia must be excluded, and the management of frostbite should include general and specific measures (Box 1). Management of frostbite must include restoration of core body temperature. In patients with hypothermia (temperature <37°C), the hypothermic condition must be corrected before specific treatment of frostbite begins. Death may occur at a body temperature of 28°C.

Hypothermia is defined as a core body temperature below 35°C or 95°F. It is seen principally in the military or secondary to outdoor recreation, homelessness, or substance abuse. Hypothermia has been classified as the following: (1) mild (90°F to 94°F), (2) moderate (86 °F to 89°F), and (3) severe (< 86 °F).

In mild hypothermia, the patient is shivering, complains of being cold, and has mental confusion but is communicative. In moderate hypothermia, the patient becomes more confused and is often agitated, obstinate, or combative, and the shivering ceases. There is muscle spasticity, dilated pupils, and slow respirations. At this stage, mild myocardial irritability is encountered. In severe hypothermia, the patient becomes comatose, has a flaccid paralysis, and begins to develop apnea eventually this progresses to ventricular fibrillation and death.

The body physiologically responds to lowered temperatures by increasing cardiac output with tachycardia. Hyperventilation then follows, with apnea, bradycardia, and an increase in total peripheral vascular resistance with decreased cardiac output and an increase in mean arterial pressure. Cardiac arrhythmias and sudden death occur in this sequence and follow ventricular ectopy and atrial fibrillation. Cardiac standstill occurs with temperatures decreasing below 23 °C. The blood becomes more viscous with each drop in temperature, and hemoconcentration is seen related to cold diuresis. Shivering occurs in the peripheral vessels, and respiratory depression follows. Pulmonary edema accompanies rewarming. There is a decrease in the ability to clear bronchial secretions and a diminished cough reflex resulting in cold bronchorrhea. Metabolic acidosis follows rewarming. The cold diuresis results in hypovolemia.

Treatment of Hypothermia

When the victim is identified in the prehospital setting, removal of wet clothing and replacement with dry clothing should be performed. No massage, friction rubbing, or manipulation should be performed. Patients who have sustained cardiopulmonary arrest should undergo resuscitation according to standard protocols. Patients have been salvaged following rewarming in the field, only passive warming is undertaken because active rewarming can lead to myocardial arrhythmia and hypotension and can be managed only by person in hospital monitoring.

In the hospital, accurate recording of temperature and vital signs are imperative. Complete examinations of the blood, including complete blood cell count, electrolytes, liver function tests, coagulation, and arterial blood gas analysis, are performed urgently. The workup should include toxicology screens to assess the effect of alcohol or other sedatives. A Foley catheter is inserted with a urinometer, and urine volumes are monitored. Several large bore intravenous cannulas are inserted to combat the inevitable hypotension that occurs after rewarming. Continuous electrocardiographic monitoring and a chest x-ray or appropriate extremity radiographs for trauma are obtained. The intensive care setting is mandatory, with serial blood testing. Hypoglycemia should be excluded, as should narcotic overdose. Passive rewarming at the rate of 0.1°C to 2°C hourly results in a slow increase in body temperature. Oxygen that is warm and humidified is provided.

Therapy of Frostbite After Hypothermia Has Been Resolved

There is no place for vigorous rubbing of frostbitten tissue or the application of snow (treatments mentioned in the lay literature). This merely accelerates damage to skin. There is no place for slow thawing, rubbing the area, and especially application of snow or other measures that would increase tissue damage. A frozen part should not be thawed if refreezing is likely to occur.

The management of frostbite is divided into the following phases: (1) prehospital field care, (2) acute hospital rewarming, and (3) posthospital care.

Before reaching the hospital, the frostbitten part should be protected from mechanical trauma and splinted. Warming should not be attempted if refreezing is likely.

Management of frostbite is carried out in accordance with the guidelines popularized by Mills. The patient's general condition should be assessed, and other injuries detected and managed. Shelter should be obtained, wet garments removed, and the part wrapped in warm, dry covers or blankets, being careful to avoid trauma. The benefit of antibiotics has been difficult to establish, although some prescribe them as for burn injuries, others believe that they are not appropriate. Cultures should be done so that appropriate antibiotic treatment can be instituted if infection occurs. Long term care includes physical therapy, neurologic rehabilitation, psychological support, and counseling for management of specific localized injuries.

Patients with serious frostbite (i.e., frostbite of the extremities) should be hospitalized. On admission, the frozen areas should be rewarmed properly in an agitated water bath in which temperature is controlled precisely from 104°F to 108°F (40°C to 42°C) for 15 to 30 minutes. Rewarming should be continued for 15 minutes beyond recirculation.

The rewarming may be stopped soon after the digital flush signifying a hyperemic state of perfusion is observed. Rewarming is often painful, implying that a free radical reaction is present on reperfusion.

Excessive rewarming results in further tissue damage. The temperature is critical, as excessive temperatures (>45°C) cause heat damage and lower temperatures (<38°C) are ineffective. Rewarming should be continued for 1½ minutes beyond thawing. Rewarming may be painful, and narcotic analgesics may need to be given. The pain associated with rewarming is believed to be a reperfusion injury and secondary to free radical generation.

In general, it has been recommended that open treatment or light dressings be utilized, keeping the blisters intact and bathing (hydrotherapy) the affected area once or twice daily in an antiseptic solution.

Most affected areas heal spontaneously if infection is prevented. Compression dressings are not necessary.

Hands should be splinted in a functional position, as should feet. Nonadherent (petrolatum or Xeroform) dressings assist with gentle treatment of the skin areas. It has been our experience that ointments macerate the areas and may contribute to increased infection. Dry treatment is preferred when possible. The value of prophylactic antibiotics has not been shown, and they should be used only prophylactically for short durations, such as 48 to 72 hours.

Rubkin has shown that blisters contain increased amounts of thromboxane derivatives, which can accelerate production of progressive vascular thrombosis and dermal ischemia, similar to that observed in thermal injury. Therefore therapeutic advantage may be obtained from debriding the blisters. Rubkin differentiates between white and hemorrhagic blisters, debriding only the white blisters. Rubkin recommends treatment of affected frostbite areas with topical aloe vera (Dermaide Aloe), aspirin, and antibiotics. The effectiveness of this treatment has not been shown clearly.

Daily cleaning of affected areas should be performed in a 40°C water bath, using antiseptic skin cleansers. Plantigraphic wounds of progress should be taken at 2 day intervals. Tetanus prophylaxis is recommended on admission.

It is important that the affected part be elevated and splinted in a position of function according to the usual principles of treatment of significant extremity injuries. Gentle exercise and range of motion are important, as in physical therapy. Elevation decreases edema, which is part of the vicious cycle that contributes to decreased capillary circulation.

Surgical Intervention for Frostbite

There are two options for surgical treatment of frostbite: early surgical intervention and delayed (observation) treatment. Early surgical intervention is not necessary in the typical frostbite injury but may be necessary if acute progressive infection occurs. Full demarcation of dead tissue may take several weeks or 2 to 3 months, and the general recommendation is that the process of separation of tissue be allowed to progress spontaneously. Some believe that surgery may be appropriate at 3 weeks if the demarcation is clear. Unfortunately, there may be times when circumferential extremity constriction causes impaired circulation and occurs because of an unyielding third-degree eschar.

Assessing the Circulatory System and Early Surgical Intervention

There has been considerable interest in assessing the circulation, which has been done by arteriography but mostly by technetium imaging (three-phase bone scans) done on admission. This assessment results in the ability to predict tissue loss, which accurately reflects the ultimate degree of tissue loss. These scans should be done on the first day after injury.

The accuracy of magnetic resonance imaging and magnetic resonance angiography examinations for the same purpose also have been suggested. The hope that earlier surgical intervention could lead to earlier resolution of the injury for many patients after the use of these circulatory assessments generally has not been realized. Corleth and colleagues used this to aggressively debride the soft tissue, and ultimately probably salvaged digits that otherwise would have been lost with aggressive microsurgical reconstruction of digits destined to be amputated.

Therapy to Microcirculation

The damage to the microcirculation has been treated with anticoagulation, hyperbaric oxygen, and free radical scavengers. Agents such as heparin have been shown to slightly increase tissue survival in experimental frostbite (tissue injury), as have free radical scavengers. Clinical experience has not confirmed a definite advantage of these medications, obviously because of the critical time window in which they must be administered. It has been difficult to demonstrate the clinical effectiveness of agents such as low-molecular-weight dextran in preventing sludging, and although steroids have been recommended for the vasculitis, the evidence for their beneficial effect has not been confirmed clinically. Heparin and anticoagulants have not been shown to influence the ultimate degree of tissue loss. Ultrasound treatments have been suspected of increasing tissue damage.

Rubkin recommendations have been used by some to limit the progressive vascular thrombosis and include prostacyclin and thromboxin such as recombinant tissue plasminogen activator (rtPA). Hyperbaric oxygen may be of limited value but must be begun within 24 to 48 hours to be effective. Although many questions of effectiveness, several experimental studies demonstrate improved tissue salvage when hyperbaric oxygen is begun promptly, a number of case reports since 1987 suggest some effectiveness, but a true trial has not been conducted. Hyperbaric oxygen increases tissue oxygen concentrations, stimulates angiogenesis, reduces edema, improving the microcirculation, stimulates antiinflammatory process and antioxidant enzymes, and stimulates several wound healing mediators such as basic fibroblast growth factor, transforming growth factor β1, and platelet-derived growth factor.

Tissue plasminogen activator has shown some progress in ameliorating the microcirculatory injury and in improving circulation and tissue loss (30% compared with historical controls) of lesions destined to be amputated that did not receive treatment.

rtPA must be administered intraarterially within 24 hours after the injury, the earlier the better, therapy salvaged and the clinical reports are supported by some laboratory studies. The treatment must begin within the first 24 hours to be effective and is continued for several days if effective.

Sympathectomy

Regional sympathetic blockade has been utilized to decrease the pathologic vasoconstriction and sympathetic response. Based on the theory of the importance of progressive vascular damage to severe frostbite, several authors have advocated early surgical or chemical sympathectomy. At one time, we used intraarterial reserpine to regionally block the sympathetic nervous system (chemical sympathectomy). Arteriograms have demonstrated significant proximal vasospasm a considerable distance proximal to the clinically obvious area of frostbite (Fig. 4). Recently, Rakower has attempted to define the patient populations that benefited from sympathectomy according to Doppler ultrasound and digital plethysmographic examinations after rewarming. Patients had digital plethysmograms and Doppler ultrasound mapping of digital vessels, and three degrees of vascular response to cold were found. The most common was the hyperdynamic response, implying patent digital vessels; this response was clinically apparent as warm, red digital tissue. Regional sympathectomy was troublesome in these patients. Patients with a normal or hypodynamic response had evidence of vascular compromise at the digital, palmar, or pedal arch level and benefited from regional sympathectomy with chemical mechanisms. Patients with the hyperdynamic response did not have severe pain, whereas patients with a normal or decreased vascular response had ischemic pain, stiffness, and coldness in the digital areas. It therefore seems possible that sympathectomy may be utilized for a group of patients who could most benefit from it.

Those who support regional sympathectomy claim that it provides earlier cessation of pain, more rapid decrease of tissue inflammation and edema, tissue salvage, quicker demarcation, and earlier healing. In addition, there is some evidence that regional sympathectomy

FIG. 4 (A) Second-degree frostbite. Note the poor capillary perfusion of the nail bed of the middle finger. (B) Arteriogram of the patient in part A demonstrating loss of distal circulation secondary to intense vasoconstriction. The ulnar artery flow ceases in the forearm, and the palmar arch and digital vessels are not seen.

provides significant diminution of the late sequelae of frostbite: impaired circulation, hyperhidrosis, pallor and vasospastic and pain symptoms. It is claimed that extremities that have been subjected to a cold injury are able to perceive repeated significant cold injuries more accurately than extremities without sympathectomy.

Chronic Changes

The chronic sequelae of frostbite may benefit from sympathectomy in that sympathetic overactivity (hyperhidrosis and vasomotor tone) and cold sensitivity are reduced. The symptoms represent diminished circulation and reflect pallor and vasospastic and pain symptoms. Lubrication of atrophic skin and prevention from extreme temperatures are important. It is important that the parts affected be prevented from further cold exposure, as they are unusually more susceptible to cold injury. Platt has advocated digital artery sympathectomy for patients with troublesome digital symptoms.

Radiographic and Joint Changes

Degenerative joint disease may be seen in severe cases of frostbite, and stiff, painful joints with limited may be a sequela of moderately severe frostbite.

Intrinsic Muscle Atrophy

Platt has described intrinsic muscle atrophy and fibrosis in severe frostbite. It may be possible to minimize the intrinsic muscle damage of contracture with proper physiotherapy, splinting, and appropriate exercise.

INJURIES IN CHILDREN

Injuries to epiphyseal growth centers may result from even minor cases of frostbite in children, with joint changes being radiographically demonstrable even 6 months after injury. Bone changes may result in short digits, deviation of the digits, and osteoarthritis. Parents should be advised that these sequelae are possible despite appropriate therapy of frostbite during the period of injury.

Electrical Injury and Lightning Injuries

Cathleen M. Ryan, MD, Jeremy Gewertzman, MD,
Jun [illegible] MD, MPH, FACS, and La[illegible] P. [illegible], MD

Electrical injury is an unusual and devastating form of mechanical trauma. It is associated with significant mortality and a wide range of acute and long-term physical, psychological, and social disabilities. Understanding of the physics and pathophysiology of electrical injury lays the groundwork for treatment plans aiming to mitigate the morbidity and mortality caused by accidents involving electricity. This chapter aims to cover the specific aspects of this injury that are different or additive to standard trauma and critical care protocols.

There are approximately 1000 deaths per year in the United States attributed to electrical injuries, with the most frequent cause of death related to cardiac arrest. Approximately 400 electrical injury–related deaths are due to high-voltage electrical sources, whereas lightning causes an additional 50 to 300 deaths per year. There are also at least 30,000 nonfatal electrical injuries per year. In adults, these injuries occur mostly in occupational settings and are the fourth leading cause of workplace–related traumatic death, whereas, in children, electrical injuries occur most often at home. According to the National Burn Registry, patients with electrical injuries account for just less than 4% of burn center admissions. Of these, more than one half were work-related accidents, 3% of the electrical injury patients were attributed to lightning, and 11% of the electrical injuries were in children. Only percent of the electrical injuries reported to the National Burn Registry required operations.

The majority of electrical injuries in construction and utility workers are related to brief, high-voltage (>400–1000 volts) exposure. Up to 80% of serious electrical injuries are fatal. Two-thirds of these deaths occur in the workplace. Electrocution represents 5% to 6% of all work-related traumatic mortality, accounting for more than 500 deaths per year and making it the second leading cause of occupation-related deaths in the United States. Short-term and long-term morbidity in many electrical injury survivors is typically related to significant musculoskeletal and neurologic disability.

Electrical accidents can involve arc, flame, and direct current injuries as well as a variety of traumatic injuries and ordinary flame burns. In this chapter, we will focus on arc flashes and direct current injuries, as well as lightning strikes, a form of direct current injury.

An arc flash is a sudden release of energy through the air when a high-voltage gap exists and there is a breakdown between conductors. These injuries are typically seen with electricians working near an electrical box complicated by corrosion, a dropped tool, or a buildup of conductive dust. Although the arcs can be extremely hot, with temperatures up to 4000°C to 5000°C, their fleeting nature usually results in more superficial burns. They can be associated with an extremely bright light, sound pressure up to 160 dB, and a pressure wave that can hurl shrapnel and chunks of molten metal at speeds of 700 mph. Appropriate eyewear and personal protective clothing and equipment can mitigate many of the effects of this accident. Flame injuries can be caused if the arc ignites the individual's clothing. Deep contact burns can also occur from an arc heating of metal objects against the skin such as a coin or necklace.

Deep current injuries are a result of current passing through the body as the individual becomes part of the electrical circuit. Once the current passes through the body, the risk for internal burn exists as the current turns into thermal energy. In many of these cases, the current lingers in the bone, heating up the bone, and eventually cooking the muscle and tissue that invests the bone. Another destructive mechanism also becomes clinically important in electrical injury when the electrical current causes interference with coordinated electrical activity in the body such as heart rhythms or the brain respiratory center, often killing people at the scene. Finally, in the special case of lightning, the extremely short but very high-voltage electrical energy is associated with an electrical current flowing through or around the individual's entire body can produce a wide range of possible injuries via these mechanisms, blast, or other trauma mechanisms.

Any of these direct electrical injuries can be associated with indirect injury such as a fall associated with asystole or the blast from the initial trauma, severe muscle injury from tetany, or delayed complications such as multiple organ system failure from rhabdomyolysis, compartment syndrome, or infection.

PHYSICS AND PATHOPHYSIOLOGY OF DEEP CURRENT ELECTRICAL INJURY

The severity of direct electrical injury from deep current is determined by several critical factors:

1. Voltage (high or low)
2. Type of current (alternating or direct)
3. Intensity of current (amperage)
4. Pathway of the current through the body (vertical, horizontal, peripheral)
5. Duration of current exposure
6. Area of contact on the body
7. Resistance of the body tissues involved

An understanding of the physics of electricity provides insight into how electrical energy damages tissues.

ELECTRICITY BASICS

Current

Electricity is defined as the flow of electrons through a conductor. Electrical current (I) is the rate of flow of electrons in a conductor and is measured in amperes (A). Injuries result from current in several forms: alternating current (AC), direct current (DC), or pulse-type shocks such as lightning.

AC is the directional flow of current in a circuit that constantly is being reversed back and forth in a repetitive sinusoidal pattern. In general, it is a more efficient way of generating and distributing electricity than DC. Standard household current is AC at a rate of 60 (or 50) Hz (cycles per second) and is supported by 100 to 200 A. DC means that the direction of electrical current remains constant. It is found in automobile electrical systems, railway tracks, batteries, and lightning. High-voltage utility power lines may be either AC (most common, commercial) or DC.

There can be differences in the clinical presentation of an electrical injury related to the type of current exposure. DC provides unidirectionality to the current exposure, hence the classically termed entrance and exit point cutaneous wounds that identify potential current pathway. A high-voltage DC injury could produce a small cutaneous entrance wound and a small cutaneous exit wound associated with much more significant deep tissue injury in addition to the electrical current tissue effects. In contrast, the bidirectional flow of AC produces cutaneous burns known as contact points. Furthermore, DC does not produce the same contraction of muscles found with AC. The "let go" reaction occurs when the current through a hand and arm may cause the hand to involuntarily close and remain closed so that the energized conductor cannot be released. Although a 60 Hz theoretical current 0.5 mA is the threshold for a startle reaction, the let go threshold current intensity varies from 3 to 9 mA, depending on body size, and tetany occurs at 15 to 20 mA. DC shock thresholds are about three times higher than AC; however, there does not seem to be a let go phenomenon. An individual can let go of an energized circuit but there is an intense shock when the circuit is broken. Although AC is generally

lower voltage and produces less direct tissue injury, prolonged contact can alter the cardiac cycle, causing arrhythmias and cardiac arrest. Ventricular fibrillation occurs at 50 to 100 mA, and asystole occurs at more than 3 A. Finally, in lightning or pulse type shocks, shock energy and timing in relation to the cardiac cycle (particularly those that occur during a T wave) are related to the onset of ventricular fibrillation. Pulse shocks with an energy level of 50 J can be lethal while shocks below 0.25 J are annoying but not dangerous. For example, a typical shock from walking across a carpet is about 10 mJ. Again, high-current pulses cause asystole rather than ventricular fibrillation. Unlike ventricular fibrillation, a blow or fall may convert asystole to a normal heart rhythm in some cases. Keep in mind that although most providers speak about voltage, it is the current, or amperage, that kills.

Voltage and Resistance

By definition, voltage at a point must always be measured with respect to another point. The voltage difference between the two points is a factor in determining the current that will be in a given electrical path between two points. For instance, a classic example would involve a bare high voltage conductor (for example, 7200 V) with respect to the ground; a squirrel or bird running on the conductor would not be electrocuted because each of its feet would be the same voltage with respect to the ground (7200 V); however, the voltage difference across its body would be zero.

Voltage is the force that drives electrical current (I) across the potential difference and contributes critically to the intensity of the electrical injury. Historically in medicine, electrical injuries are classified as either high voltage (>1000 V) or low voltage (<1000 V). However, because the US National Electrical Code defines the difference between low voltage and high voltage/injury at 600 V, we should consider high voltage to be 600 to 1000 V. Typical voltage delivered in homes in the United States and Canada is 120/240 V, providing 240 V for appliances that require high power and 120 V for general use. Low voltage injuries tend to occur indoors and are almost exclusively AC. In the United States, the AC power system operates at 60 Hz, causing the current to reverse polarity 120 times a second. Voltage in high tension power lines tends to exceed 100,000 V and is most commonly AC in developed areas. High voltage mortality and amputation rates typically exceed low voltage rates twofold to threefold.

Resistance (R) is the hindrance to current flow and is measured in ohms. Resistance creates heat based on Joule's law. Joule heating is energy transfer that occurs when charged particles meet resistance and lose energy to tissues in the form of heat.

Joule's Law

$$\text{Power (P)} = I^2 \text{ (current) } x \text{ R (Resistance)}$$

Materials that are the best conductors (meaning that they facilitate current flow) have the least resistance. With increasing resistance, more energy is expended in the form of heat and results in thermal tissue damage.

Different tissues have notably different resistances and resistances vary under different conditions. Overall, resistance of a tissue depends on the surface area of contact, tissues in the current's pathway, pressure applied, duration of exposure, magnitude of current flow, and absence or presence of moisture. For example, dry skin has a much greater resistance (approximately 100,000 ohms) than moist skin (<2500 ohms).

The magnitude of average electrical resistance across body tissues is as follows:

Nerve<Blood Vessels<Muscle<Skin (Variable)<Tendon<Fat<Bone

The relationship between the forces discussed is described by Ohm's law:

$$I = \frac{V}{R}$$

where the current (I) is directly proportional to voltage (V) and inversely proportional to resistance (R).

PATHOPHYSIOLOGY

Injury to the affected tissue predominantly depends on the duration and intensity of electrical exposure. For example, brief exposure to current will conduct rapidly across low resistance tissues (Ohm's law), with low heat production and structural tissue damage but more electrophysiologic derailment of end organs (i.e., heart, central nervous system [CNS], and muscle).

If contact time is brief, nonthermal direct electrical damage to tissue occurs as the current disrupts the intracellular electrical gradient across cell membranes via electroporation and conformational changes in membrane proteins. Electroporation results in a significant increase in the electrical conductivity and cell plasma membrane permeability, leading to tissue edema and possible cell injury. Muscle fibers and nerves are the most susceptible. It can either induce cell necrosis or permanently, partially, or reversibly affect cell membrane function in the absence of joule heating. Damage will be relatively localized to the involved tissue cell membranes and result in functional disruption of tissue and organs dependent on coordinated electrical activity such as heart, brain, spinal cord, and muscle. These cell membrane effects may progress over time and partially explain some of the delayed clinical symptoms observed after electrical injury, such as vascular thrombosis and rupture, cognitive dysfunction, and late appearing spinal cord deficits.

When contact time is prolonged, heat damage will dominate because the entire cell is compromised. In general, the severity of the injury is inversely proportional to the cross sectional area of the body part, with the most severe injuries seen in the wrist and ankle and decreasing proximally. Deeper tissues and regions between two bones (tibia and fibula, ulna and radius) also create heat to a greater degree. Macroscopic and microscopic vascular injury can occur immediately and is often not reversible.

Identification of contact points often helps to establish the path that the current has taken. A path parallel or vertical to the axis of the body (craniocaudal) is most dangerous because it may affect all vital organs. A horizontal path (e.g., from hand to hand) may spare the brain but still be fatal because of its effect on the heart and respiratory muscles. A path with contact points confined to a single extremity may cause extensive local damage but not be lethal (Fig. 1). However, although identification of a potential pathway of current suggests that certain organs in the pathway might be more likely to be injured, it does not guarantee that injury to other organs or deep tissues has not occurred.

Immediate cardiac arrest and life threatening arrhythmias may occur with the conduction of current across the heart. AC tends to cause ventricular fibrillation, whereas DC tends to cause asystole. Actual injury to the heart or the metabolic effects from injury elsewhere in the body (e.g., hyperkalemia and rhabdomyolysis) may result in delayed cardiac arrhythmias and acute renal failure. Paralysis of the muscles of respiration can result in apnea. Effects on the spinal cord and brain can lead to immediate death or long term neurologic abnormalities. A list of potential effects of electrical injury is presented in Table 1. These do not include multitrauma injuries such as falls or blasts associated with the accident or respiratory failure resulting from inhalation injury. CNS abnormalities can be transient, permanent, or delayed based on gross and histologic anatomic structure injury.

MANAGEMENT

Patients with major electrical injury should be evaluated, treated, and followed long term in a burn center. Because of the traumatic, multisystem nature of electrical injury (including potential associated blunt or penetrating trauma injuries), these patients should be managed according to both trauma and burn guidelines for care. In the field, bystanders and first responders should establish safe access to the electrically injured patient. Be aware of victim's ongoing contact with the current source. The rapid electrical impulses produced by alternating current can provoke tetanic spasm in muscles causing the

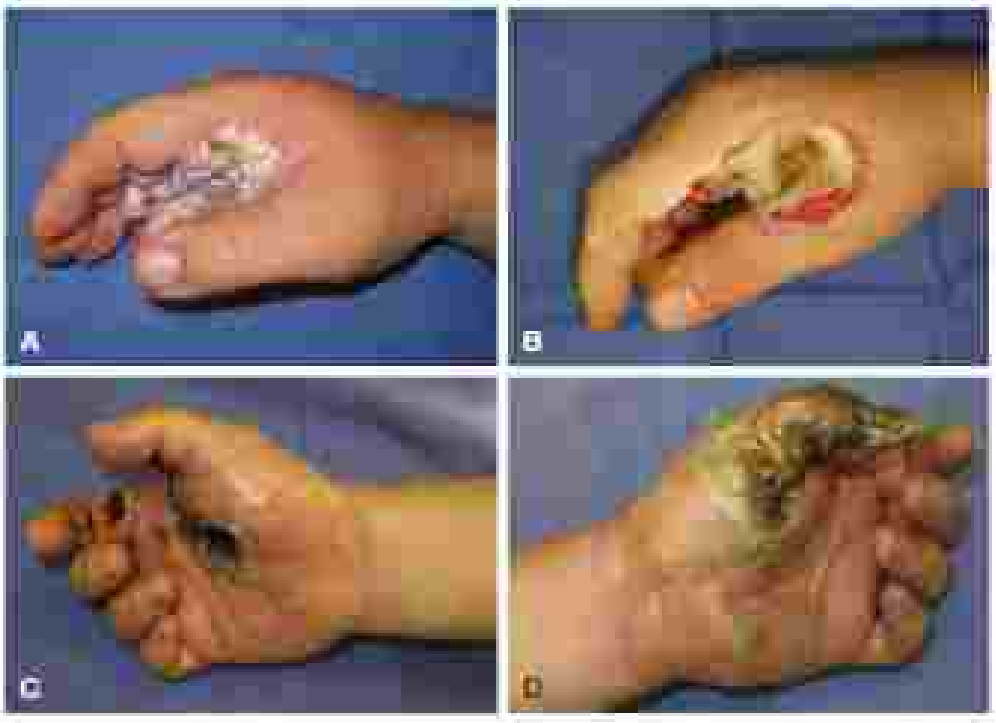

FIG. 1 (A) A farmer working in the field came in direct contact with a low-hanging wire (7000 V). (B) An electrician grabbed a cable (370 V, alternating current) overhead to avoid falling into a ditch. (C, D) A fireman touched a power line (7620 V, alternating current).

victim to close a vise-like grip on the electrodes. This phenomenon occurs because of simultaneous contraction of (stronger) forearm flexors and (weaker) forearm extensors. If still in contact, DO NOT TOUCH because specialized nonconductive equipment is necessary to safely recover these victims. Whether AC or DC, confirmation of disconnection from active, live electrical sources is needed. Avoid environmental conductors such as puddles of liquid, exposed metals, and wires. Victims of lightning injury may be treated immediately.

Rapidly assess the patient's airway, breathing, circulation, and disability (rapid neurologic assessment) and provide in-line immobilization of the entire spine (primary survey). In the event of a cardiac arrest, prolonged resuscitation is indicated if not initially responding. Treat life-threatening findings immediately: control threatened airway or ventilation, decompress tension pneumothorax or pericardial tamponade, control external hemorrhage, and manage potential core temperature heat loss (hypothermia). Establish intravenous access and continuously monitor vital signs (including temperature), neurologic examination, pulse oximetry, respiratory function, electrocardiogram (ECG), and urine output (urinary catheter). Ligature and cover thermal burn sites with clean, dry sheets or towels and then with appropriate topical dressing when at the hospital. Initiate fluid resuscitation with warmed, isotonic crystalloid intravenous fluids.

Once at the hospital, perform a complete trauma survey. In electrical injury, this includes defining the path of current through body and determining voltage of accident. Electricity usually flows from an electrical source, through the body to the ground. Although locating electricity contact points (formerly called entry and exit sites) can help suggest which organs could be damaged, this does not rule out damage to other organs or structures not in an obvious straight current path. Domestic accidents usually involve 110 V (US) or 220 V (EU). Other low voltage accidents occur related to workshops (380 V), subway third rails (600–750 V), or autos (960 V). High-voltage situations include high-tension wires (40,000 V–400,000 V), rail networks (25,000 V), and overhead lines (3500 V). If high voltage injury or if arrhythmia, ECG changes, or troponin elevation are present, check cardiac enzymes. Consider cardiac ultrasound, and possibly cardiac magnetic resonance imaging or cardiac angiogram if indicated. Pregnant females should have an obstetrical ultrasound, and patients with significant burns should be admitted to a burn center. Patients with initial loss of consciousness, cardiac anomalies, or high-voltage injury require hospital admission with continuous ECG monitoring for at least 24 hours. Otherwise, in those patients with a normal cardiac rhythm in the emergency department, a dysrhythmia is unlikely, and thus 24-hour monitoring is not needed. In those patients with cutaneous burns, calculate the total body surface area burned, assess compartment pressures, perform a complete neurologic examination including baseline vision (cataracts are long-term complications) and hearing (tympanic membrane rupture [perforation] examinations, and carefully record the history, source of the history, and all physical findings in the medical record because many of these cases will eventually find their way into the legal system.

The management of all trauma patients, including those with electrical injury (with or without external burns), is a standardized process per Advanced Trauma Life Support protocol with the addition and consideration of these additional caveats to consider: compartment syndromes and the need for decompression, cardiac arrhythmias and which patients require longer term cardiac monitoring, and the administration of fluid given the possibility of a massive injury that may or may not externally visible as well as the need for hydration to prevent acute kidney injury from rhabdomyolysis. In patients with significant burns, maintain fluids (lactated Ringer's solution) to target urine output of 0.5 mL/kg per hour if the patient has clear urine and is at low risk for rhabdomyolysis. If the patient has dark urine and is at risk for rhabdomyolysis, aim for a higher urine output of greater than 1.0 mL/kg per hour. Note that the fluid resuscitation amounts indicated in standard burn resuscitation formulas do not account for deeper tissue injuries that can occur in electrical injuries. Resuscitation should proceed as it would for any other trauma or injury, with the goal being to reestablish appropriate cellular perfusion and restore the oxygen deficit. Most commonly, this should be performed with the least amount of fluid required and global/regional parameters of perfusion are serially analyzed to evaluate effectiveness of resuscitation.

Although compartment syndrome from flame burns is associated with constriction of the tissue associated with burn eschar, the constricting tissue in electrical injury patients is the fascia due to deep tissue and muscle swelling resulting from heat energy caused by the current running through bone. Signs of compartment syndrome are not different from other causes of compartment syndrome; however, pain on passive extension and pain out of proportion to physical

TABLE 1 List of Potential Systems Involved in Electrical Injuries

Systems	Potential Injuries
Cardiovascular	Arrhythmias, including asystole, ventricular fibrillation, bradycardia, and electromechanical dissociation Heart muscle injury Thrombophlebitis
Respiratory	Respiratory arrest Paralysis of diaphragm Inhibition of brain control of respiration
Skin	Burns Infection Dehydration
Neurologic	Loss of consciousness Impaired recall Cognitive deficits Paralysis Spinal cord injury Sensory losses Weakness Chronic pain syndromes
Musculoskeletal	Fractures and dislocations Compartment syndrome Tetany Muscle necrosis Rhabdomyolysis Contractures
Renal	Myoglobin tubular necrosis Renal failure
Other	Cataracts Tympanic membrane injury Visceral injuries including perforations Cholelithiasis and cholecystitis Pancreatitis Posttraumatic stress disorder and other psychiatric disabilities

examination are early signs. Paresthesias and pulselessness are late signs indicating an advanced problem. In extreme cases, the patient might present with flexion contractures and mummification of the extremity, which will usually result in the need for amputation. Any absolute pressure greater than 30 or diastolic pressure–compartment pressure less than 30 indicates compartment syndrome. Fasciotomies should be performed in the presence of compartment syndrome, making sure to decompress all compartments affected. Debridement and ultimately surgical decompression of the hand and upper extremity should only be performed by those surgeons comfortable and familiar with this anatomy. This may include general, burn, plastic, or trauma surgeons.

When taking the patient to the operating room for debridement and grafting of electrical injuries, the surgeon should perform serial debridements and allow the tissue to completely declare itself. These injuries will often evolve with progressive muscle necrosis over time, thus early grafting (within the first week) is commonly unsuccessful. Experienced clinicians often perform conservative serial debridements with temporary wound vacuum-assisted closure or dressing changes that allow time (sometimes as long as 3 weeks) for the wound to completely declare itself before definitive wound closure. Thoughtful planning for functional amputation lengths and possible future surgical interventions such as flaps or transplants should be considered early in the acute course and appropriate consults undertaken. However, because many of these patients will have a significant necrotic tissue burden, limb preservation should not take precedence of preservation of life.

Long-term follow-up involves coordinated multidisciplinary care for these patients from onset of injury through injury recovery and rehabilitation. Complications such as chronic pain interfering with work, issues with amputations, contractures, and neurologic issues, ranging from paralysis to Guillain-Barré type syndromes, paresis, and transverse myelitis have been reported. Central manifestations including cognitive, emotional, and psychiatric changes can be seen. In patients with extensive burns including deep burns to the upper extremity and head and neck areas, lymphedema ambulation is a risk. Cataract formation is the most frequent ocular complication after electrical injury, occurring in 5% to 30% of electrically injured patients. Baseline and follow-up eye examinations are indicated because these cataracts can arise in a delayed fashion, several years after the injury. Auditory examinations are helpful, particularly in the case of an arc blast. Both cholecystitis and cholelithiasis are reported to be associated with electrical injury long term. Ideally, these patients should be followed in an outpatient burn center with capabilities for surgical reconstruction, access to psychiatric and psychological support services, as well as physical, occupational, vocational, and social therapists. Peer support and online resources are also useful.

SPECIFIC CLINICAL SITUATIONS

Lightning Injury

Lightning is one of the most dramatic examples of high-voltage direct electrical injury. Its injuries account for a small subset of electrical injuries, but lightning is responsible for an average of 409 injuries and approximately 90 deaths per year in the United States. The odds of being struck by lightning in a lifetime (estimated 80 years) are 1 in 3000. Estimated fatality from lightning is 30%, and 70% to 80% of survivors may have permanent disabilities.

In addition to tissue injury related to direct contact with an electricity source, injuries noted from the various lightning strike patterns include thermal burns through clothing or other heated material, ruptured tympanic membranes caused by shock wave from a thermoacoustic phenomenon (i.e., thunder), concussive or blast-type injuries secondary to the rapidly expanding air near a lightning strike, and injury caused by a subsequent fall.

Lightning injury can be minor, moderate, or severe.

1. Minor: often awake and alert, may have confusion or amnesia, dysesthesia, hearing or vision changes. Physical findings may be temporary, and complete recovery can occur.
2. Moderate: disorientation, confusion, unconsciousness, paralysis, skin swelling, hypotension, respiratory failure, secondary cardiac arrest. Physical symptoms may resolve over time. Long-term sequelae such as cognitive and sleep disorders, weakness, dysesthesia, and peripheral neuropathy can develop.
3. Severe / serious injury or death in 30% of victims. Blunt trauma, contusion from shock wave, cardiac dysrhythmias, cardiac arrest (primary or secondary), CNS dysfunction. Asystole may be transient, and spontaneous rhythm may recover because of cardiac automaticity. Hypoxia related to central apnea may lead to secondary cardiac arrest. Long-term sequelae such as cognitive and sleep disorders, weakness, dysesthesia, and peripheral neuropathy can develop without direct evidence of initial direct anatomic brain injury.

Keraunoparalysis is transient paralysis that can occur after a lightning strike and is characterized by signs and symptoms of motor and sensory loss (affecting lower limbs more than upper limbs), pulselessness, and pallor associated with vasospasm. Keraunoparalysis typically resolves within several hours after the injury

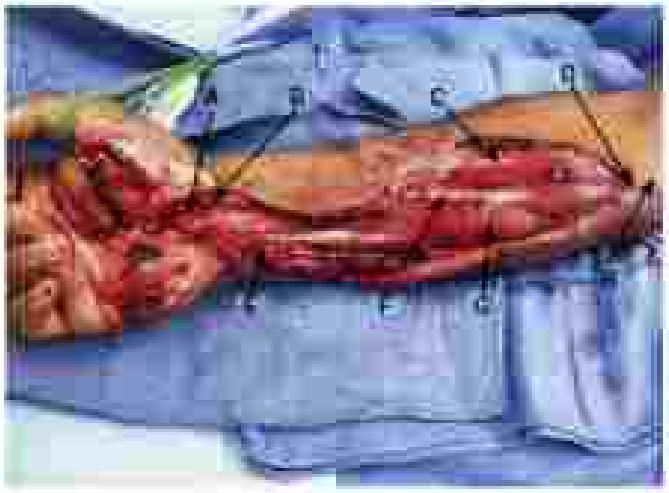

FIG. 3 Fasciotomy of right forearm and hand after electrical injury. (A) Median nerve. (B) Flexor retinaculum. (C) Flexor pollicis longus. (D) Proximal incision. (E) Ulnar nerve and artery. (F) Palmaris longus. (G) Flexor digitorum profundus. (H) Medial epicondyle.

but can mimic spinal cord injury and temporarily mask underlying musculoskeletal injury.

Unlike high-voltage electrical injuries, in which massive internal tissue damage may occur, lightning seldom causes substantial burns. Historically, most burns related to lightning are caused by other objects (moisture, metal on a belt, jewelry or coins in a pocket) being heated and causing a contact burn rather than by the lightning itself. The transformation of the electrical energy to heat can generate temperatures as high as 50,000°F. However, the duration of this transmission is only 1 to 2 milliseconds, as a result, the insulating properties of the skin do not have time to break down.

The two most common causes of death related to lightning injury are (1) cardiopulmonary arrest caused by an interruption of the cardiac cycle by the direct current, resulting in asystole; and (2) apnea from the direct current's interference with the brain's respiratory center, which if left untreated will result in hypoxia, arrhythmia, and secondary cardiac arrest. There is an estimated morbidity 5 to 10 times higher than for non-lightning related electrical injury. A pathognomonic fern-like pattern called keraunographic markings or Lichtenberg figure (Fig. 2) may appear on the skin of lightning strike victims. This is not a burn and often disappears within 24 hours.

Upper and Lower Extremity Compartment Syndrome

Most high voltage injuries are associated with deep tissue injury that is often more extensive than initially appreciated. Management of acute compartment syndrome involves immediate surgical decompression, primarily via fasciotomies of the involved compartment(s). Unlike external burn injuries, which result in a constrictive eschar as the cause of the compartment syndrome and therefore can often be decompressed with escharotomies, electrical injuries typically require fasciotomies because compartment edema from injury and fluid resuscitation is often the cause of the compartment syndrome.

Indications for surgical decompression for any extremity include progressive neurologic dysfunction, vascular compromise, increased compartment pressure, and systemic clinical deterioration from suspected ongoing myonecrosis. Delayed exploration and decompression in the compromised extremity can result in increased amputation rates as well as increased organ failure and mortality.

Fasciotomy of the Upper Extremity

Decompression of the upper extremity includes forearm fasciotomy and assessment of muscle compartment integrity. The decision to include carpal tunnel release should be made on a case by case basis. Initial fasciotomy should be performed in the areas of contact and conduction; for instance, carpal tunnel release should be considered if the injury occurs in the wrist.

There are four compartments in the forearm (superficial volar, deep volar, dorsal, mobile wad), and each should be released with a forearm fasciotomy. One classic technique for the forearm fasciotomy uses a lazy S incision (Fig. 3). The incision begins 1 cm proximal and 2 cm lateral to the medial epicondyle and is continued obliquely across the antecubital fossa toward the mobile wad. It then curves distally and ulnarly reaching the midline at the forearm at the junction of the mid and distal one-third of the forearm and then continuing distally just ulnar to the palmaris tendon and then distally incorporating Guyon canal and the carpal tunnel. The reason for curving the distal fasciotomy incision ulnarly is because the median nerve can give off a separate proximal branch in the thenar area, so by staying ulnarly it reduces the risk of injury. Volar release must include the pronator quadratus and deep flexor compartments as well.

In the hand, all 10 compartments (8 dorsal interossei, 3 palmar interossei, hypothenar, thenar, and adductor pollicis) can be accessed through 4 separate incisions: 2 incisions along the second and fourth dorsal meta-carpal, and 1 each on junction of the glabrous-nonglabrous skin of the thenar and hypothenar eminence (Fig. 3). Additionally, carpal tunnel release is often performed at the same time using a standard carpal tunnel incision. The landmark for the distal portion of the carpal tunnel is the intersection of a line between the ulnar border of the fourth fully abducted (Kaplan cardinal line) and the ulnar border of the middle finger. This can be done as a separate incision 2 to 3 cm in length or continued to join the forearm fasciotomy incision of the forearm.

The fingers have no true fascial compartment, and thus a fasciotomy is not indicated. In the rare instance an escharotomy is needed for the fingers, it can be performed between the extensor tendon and neurovascular bundles. Sometimes one release is sufficient, but on other instances releases are needed dorsal to both neurovascular bundles.

Fasciotomy of the Lower Extremity

Diagnosis of compartment syndrome in the lower extremity is similar to diagnosis in the upper extremity. There are four compartments in the lower extremity: superficial posterior, deep posterior, lateral, and anterior. These compartments can be released through a double-incision fasciotomy with one incision centered between the fibular

FIG. 4 Oral commissure burn resulting from contact with a household electrical wire. Associated complication: labial artery rupture may occur 7 days after burn.

shaft and the crest of the tibia overlying the intramuscular septum between the anterior and lateral compartments. After the skin is incised, subcutaneous flaps are developed medially and laterally to expose the fascia of the intramuscular septum and fascia of the anterior and lateral compartments. Care must be taken to avoid injury to the peroneal nerves. The medial incision is placed 2 cm medial to the tibia between the anterior intramuscular septum and tibial crest, taking care to avoid the saphenous vein and nerve. The superficial posterior compartment is decompressed by incising the gastrocnemius fascia, and the deep posterior compartment is decompressed by dividing the attachments of the soleus to the tibia, providing access to the posterior tibialis muscle.

Pediatric Commissure Burns

Commissure burns typically occur in the young patient and commonly result from biting or kissing on a household appliance cord. Although considered a relatively low voltage (120–240 V) injury, this soft tissue injury can be devastating and lead to significant tissue loss (Fig. 4). The burn is a result of the saliva permitting the local conduction and arcing of electricity. The electrical energy is primarily concentrated to the oral commissure and the anterior tongue. As with any trauma, the initial management follows Advanced Trauma Life Support guidelines, but these are usually isolated injuries that rarely require intubation.

The contact burn wound, often a grayish white eschar, should be cleansed gently and dressed with an ointment of choice. On examination of the vestibule of the mouth, digital palpation may reveal a "woody," indurated buccal mucosa as far posterior as the maxillary pillars. Early surgical intervention can lead to loss of potentially salvageable tissue that may be necessary for the reconstructive surgery and thus should be avoided. The goal of early treatment is to maintain a clean, moist environment that allows tissue to heal, while ensuring that the airway is not compromised. The child should be encouraged to eat and drink. Involvement of a speech pathologist can be of significant help from the onset. The use of custom-made splints can help reduce contracture and should be initiated early after injury (within 2 weeks if possible). The eschar will demarcate and slough within 7 to 21 days. Based on the proximity of the labial artery to the oral commissure, vessel rupture can be expected to occur in about 10% patients. Parents and caregivers should be educated that should labial artery rupture bleeding occur, compression of the site between the index and thumb should be performed to minimize the hemorrhage, and they should immediately return to the hospital. Seldom do these need surgical intervention for ligation.

The continued healing from the burn can result in tissue scarring and contracture. Contracture can interfere with normal vocalization, facial expression, eating, and oral hygiene (including dental care), not to mention the psychologic sequelae of the trauma. Long-term burn injuries to the mouth can result in microstomia. Contracture of the angle of the mouth is generally treated approximately 1 year after the burn injury has occurred because it takes at least 1 year for the burn to become stable because of the spherocytal action of the orbicularis oris muscle. Subsequent reconstruction of the oral commissure is best addressed with Z-plasty, V-Y flaps, trapezoid flaps, or cervical tongue flaps.

Large Cranial Defects

Deep, large electrical burns to the scalp are often some of the most challenging reconstructive cases in surgery. Necrotomy, decompression, aggressive debridement, and attempts at skin grafting are often insufficient to adequately close the wounds. Often, areas of unstable bone and other significant challenges complicate these wounds. Early involvement of plastic reconstruction services for consideration of major rotation flap and free flap planning is warranted.

Preoperative and Postoperative Care

Fluid and Electrolyte Therapy

Alessandro Fichera, MD, FACS, FASCRS, and Theodoros J. Pu [illegible] MD

F[illegible]ow and the [illegible] of its movement [illegible] a critical c[illegible]p must be tak[illegible] care of [illegible]th a medical and surgical pati[illegible]. The clinical [illegible]pe[illegible]ment that [illegible]ows [illegible]ssessment and understanding of fl[illegible]uid and el[illegible]ctr[illegible]ytes [illegible]ehavior in cellular and s[illegible]ystemic level. [illegible]nderstanding the clinical implications of [illegible]mechanisms and [illegible]ssessment [illegible]apy in the [illegible]urgical patient. This [illegible]apter discusses fluid and electrolyte distribution in the [illegible]body, normal [illegible]ns and [illegible]s as well as [illegible]ssessment and [illegible]ppropriate therapy of fluid and electrolyte disorders.

Fluid [illegible]ompartments and Electrolytes

[illegible]ater [illegible]ounts for [illegible]pproximately [illegible]% of an adult human's total body [illegible]ght and is referred to as total body water (TBW). Adipose tissue [illegible]ater content [illegible]muscle. Therefore, individuals have a lower TBW as a percentage of body [illegible]ght. In addition, [illegible]s tend to have a greater lean muscle [illegible]ass as a percentage of total body weight, resulting in TBW accounting for approximately [illegible]% of total body weight in [illegible]ale patients and [illegible]% in females.

TBW is distributed throughout multiple body [illegible]partments, with the [illegible]ajority residing within the cellular [illegible]partment, as shown in Fig. 1. These percentages [illegible]ange depending on the status of illness and inflammation, but a healthy adult can approximately [illegible]ook at fluid resides in the intracellular space and [illegible]/3 resides in the extracellular space. The extracellular compartment is subdivided into [illegible]nterstitial and intravascular or plasma compartments. The latter is [illegible]/4 of fluid within the extracellular compartment, [illegible]or a healthy 70-kg male patient this would amount to 3 L (one-fourth of 12 L). The interstitial volume is 8 L (two-thirds of 12 L) and the intracellular volume [illegible]s the third TBW.

The balance of TBW is dictated by a complex interplay between membranes and solutes. Membranes separating intracellular and extracellular compartments are freely permeable to water such that the osmolality of the intracellular, interstitial and intravascular compartments remains equal. This is the guiding principal that dictates TBW balance. However, [illegible]ifferential permeability to different solutes [illegible]ists, resulting in a non-[illegible]qual distribution of solutes. These impermeable solutes are known as effective osmoles. They have the ability to create osmotic forces that direct the movement of water across membranes. Water moves across membranes via intracellular junctions or transcellular pores. Lipid rich cell membranes result in the diffusion of water, whereas [illegible]ransmembrane water channels known as aquaporins are [illegible]ndicated in cell membranes. [illegible]ese channels [illegible]ovement

[illegible]apillary membranes are freely permeable to [illegible]ost small solutes (less than 30 kDa) including sodium, potassium, glucose, and low molecular weight proteins. As a result these small solutes have [illegible]ittle to no effective osmolarity in the setting of capillary fluid movement. Movement of water across capillary membranes is dictated by competing forces as described by Starling's law. Transcapillary water movement is the result of the balance between osmotic pressure (an effective osmole) and hydrostatic pressure from blood flow. Osmotic pressure is exerted by plasma proteins [illegible]arge to cross the capillary wall. Starling's law states that net filtration is the difference between the hydrostatic and osmotic pressures of both the interstitial and the capillary fluids. Plasma proteins provide osmotic pressure that tends to draw fluid into the intravascular space, whereas the hydrostatic pressure is thought to push fluid out of the interstitial space. On the arteriolar end of a capillary bed, intravascular hydrostatic pressure exceeds osmotic pressure, resulting in net outward fluid movement. The opposite occurs at hydrostatic pressure decreases along the length of the capillary bed, resulting in net fluid influx into the intravascular compartment near the venous side.

Although most solutes do not contribute to water movement across capillary membranes, they do function as osmotic agents that direct water movement between the intracellular and extracellular spaces across cell membranes. Sodium (Na^+) and potassium (K^+) are the principal determinants of extracellular tonicity and intracellular osmolality, respectively. Na^+ and K^+ are unable to pass freely across the lipid membrane, [illegible]ntrations maintained and maintained by the Na^+–K^+ adenosine triphosphatase (ATPase) pump mechanism. This [illegible]ransmembrane transport exchanges three Na^+ molecules for [illegible]ecules, generating a net negative charge potential. Manipulation of either of these ions results in water movement [illegible]ross [illegible]ts [illegible]ctive osmolality compartment in order to reestablish equilibrium. For example, administration of hypertonic

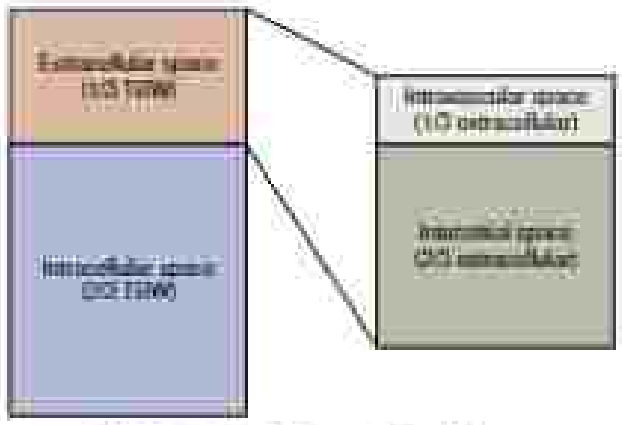

FIG. 1 Body fluid [illegible]ns [illegible]ns [illegible]ns and [illegible]ir [illegible]ns

solution (e.g., 0.25% NaCl solution) results in decreased extracellular osmolality as water moves from the extracellular space to the intracellular space, resulting in cellular swelling. In contrast, administration of a hypertonic solution (e.g., 3% NaCl solution) results in increased extracellular osmolality, as water moves from the intracellular space to the extracellular space, resulting in cellular dehydration.

Serum osmolality is maintained within a narrow range through osmoregulation and is calculated using the following formula:

$$\text{Serum osmolality} = 2 \times (\text{Na} + \text{K}) + \frac{\text{BUN}}{2.8} + \frac{\text{glucose}}{18}$$

where BUN is blood urea nitrogen and mOsm/kg is serum osmolality. Normal serum osmolality ranges from 275 to 290 mOsm/kg, with a threshold of 1% to 2% variation before activation of mechanisms to restore normal levels. Variations in serum osmolality are detected by osmoreceptors within the hypothalamus. Increases in plasma osmolality result in stimulation of thirst along with antidiuretic hormone (ADH) secretion from the posterior pituitary gland. ADH release results in upregulation of aquaporin channels in the luminal membrane of distal collecting tubules in the kidney, promoting free water reabsorption down its established gradient. As a result of increased aquaporin insertion, urine osmolality increases, with variations from 100 to 1,400 mOsm/kg depending on the serum osmolality. ADH secretion is also triggered by central baroreceptors that detect decreased plasma volume. The result of ADH secretion is free water reabsorption in the body's attempt to restore normal osmolality and maintain homeostasis.

Osmoregulation can be viewed as a separate but related process from volume regulation. Changes in osmoregulation result in sodium shifts. Hormones that influence total body sodium content are the principal mediators of volume regulation. The renin-angiotensin-aldosterone (RAA) axis promotes volume expansion. Renin is secreted by the juxtaglomerular cells in response to renal hypoperfusion or low sodium concentration in the macula densa region of the distal tubule. Renin secretion promotes formation of angiotensin from angiotensinogen and the eventual production of aldosterone, which promotes sodium reabsorption. Contrary to the RAA axis, atrial natriuretic peptide (ANP) results in net diuresis. ANP is a hormone released in response to cardiac atrial stretch and results in increased renal blood flow through dilation of the afferent glomerular arteriole and inhibition of sodium reabsorption in the kidney.

Fluid Status and the Management of Volume: The Data

Assessment of Fluid Status

In the immediate postoperative period, patients may have fluid deficits resulting from preoperative or intraoperative fluid losses. Continued fluid losses in the extended postoperative period from urine, skin, and the gastrointestinal (GI) tract are common. Fluid management requires close assessment of fluid status and selection of an appropriate type and rate of fluid replacement. It should be recognized that intravenous (IV) fluids are a therapy capable of providing benefit when utilized appropriately but also able to cause harm when used inappropriately.

Commonly seen in the postoperative period, inflammatory states result in a low effective intravascular volume despite an overall positive fluid balance due to cytokine-induced permeability, which increases extracellular volume. Common signs and symptoms of low effective circulatory volume include abnormal mentation, excessive thirst, dry mucous membranes, poor skin turgor, tachycardia, hypotension, orthostatic changes in vital signs, and oliguria. Daily weights, serum and urine electrolyte levels, acid-base balance, and invasive monitoring can be used to assess a patient's volume status and the adequacy of resuscitation. Urine output is an excellent measure of volume status; adults should produce at least 0.5 mL/kg/hr, whereas children should produce nearly 1 to 2 mL/kg/hr. However, in the setting of renal insufficiency, those receiving diuretics, or those in hyperglycemic states, urine output may be an inaccurate measure of volume status and resuscitation.

Additional indicators of intravascular depletion include an elevated hematocrit, low serum bicarbonate level with a base deficit, blood urea nitrogen/creatinine ratio greater than 20:1 (prerenal azotemia), and a fractional excretion of sodium (FE_{Na}) of less than 1%. Elevated urine osmolality may suggest intravascular hypovolemia, but in the setting of renal insufficiency or use of diuretics it is not an accurate measure. The equation for fractional excretion of sodium is as follows:

$$FE_{Na} = \frac{(\text{Urine Na} \times \text{Plasma Cr})}{(\text{Plasma Na} \times \text{Urine Cr})} \times 100$$

...milar to urine output and urine osmolality assessments, in the setting of renal dysfunction or use of diuretics FE_{Na} is not a useful indicator of volume status. Instead, fractional excretion of urea (FE_{Urea}) provides a useful tool. FE_{Urea} is calculated in the same fashion as FE_{Na}:

$$FE_{Urea} = \frac{(\text{Urine urea} \times \text{Plasma Cr})}{(\text{Plasma urea} \times \text{Urine Cr})} \times 100$$

FE_{Urea} less than 35% is suggestive of a prerenal condition.

Forms of IV Fluid Therapy

IV fluid therapy in the broadest sense is divided into two categories based on its composition and overall goal. Maintenance fluids are used to replace normal and insensible losses. They typically contain dextrose to maintain plasma osmolality and prevent glucagon depletion. Resuscitative, or replacement fluids, replace abnormal or excessive losses and correct for any water or electrolyte deficits. These are utilized in the immediate postoperative period, dehydration, sepsis, and other situations with large fluid deficits.

Maintenance Fluids and Daily Electrolyte Requirements

Sensible losses can be quantified and occur primarily in urine (~800 to 1500 mL daily) and stool (~250 mL daily). Insensible losses are unable to be quantified and include cutaneous losses from the skin (75%) and upper respiratory tract (25%). Insensible losses alone are quantified roughly at 8 to 12 mL/kg per day. Sensible and insensible losses vary greatly in different physiologic states and pathologic conditions, including fever, hyperventilation, burns, tachycardia, and other hypermetabolic states. Cutaneous insensible losses increase by 10% per day for each 1°C increase in body temperature above 37.1°C. Laparotomy and thoracotomy increase insensible losses from the operative site at rates that approach nearly 1 L/hr.

Daily maintenance fluid administration in both pediatric and adult populations can be calculated for a 24-hour period utilizing the 100-50-20 rule or hourly utilizing the 4-2-1 rule (Table 1-3). By definition, maintenance fluids contain dextrose. Their electrolyte composition is variable and allows for replacement of these lost from insensible and sensible losses but these levels should be closely monitored in perioperative patients. In general, the most common postoperative maintenance fluid for adults consists of 5% dextrose in one-half normal saline (D5 ½NS) with 20 mEq/L KCl. In children the standard maintenance fluid is D5 ¼NS or D5 lactated Ringer's solution (LR). This is to avoid hyponatremia, which has been shown to be of critical significance in the pediatric population. Children younger than 2 years usually receive D5 ¼NS, with 20 mEq/L. The reason for this is that until age 2 years, the kidney has a glomerular filtration rate (GFR) that is one-quarter the adult level, and the distal nephrons are unable to effectively concentrate the urine, leading to a difficulty in excreting high sodium loads.

TABLE 1 Electrolyte Composition (mEq) of Parenteral Fluids

Fluid	Na^+	K^+	Cl^-	Ca^{2+}	HCO_3^-	Lactate	pH	Osmolality
Extracellular fluid	142	4	103	5	27	0	7.4	280
Lactated Ringer's solution	130	4	109	2.7	28	0	6.5	275
Normal saline (0.9% NaCl)	154	0	154	0	0	0	4.5	308
One half normal saline (0.45% NaCl)	77	0	77	0	0	0	4.5	154
One quarter normal saline (0.22% NaCl)	34	0	34	0	0	0	4.5	77
3% Saline	513	0	513	0	0	0	4.5	1026
5% Dextrose in water	0	0	0	0	0	50g	5.0	278
5% Albumin	145	0	0	0	0	0	7.4	290
Normosol	140	5	98	0	0	0	6.6	294
Plasma-Lyte	140	5	98	0	0	0	7.4	294

Ca^{2+}, Calcium; Cl^-, chloride; HCO_3^-, bicarbonate; K^+, potassium; Na^+, sodium.

TABLE 2 Electrolyte Composition (mEq) of Gastrointestinal Fluids

Source	Daily Production (mL)	Na^+	K^+	Cl^-	HCO_3^-
Saliva	1000	30–80	20	20	30
Gastric	1000–2000	60–80	15	100	0
Pancreas	1000	140	5–10	60–90	80–100
Bile	1000	140	5–10	100	80
Small bowel	2000–3000	140	20	100	25–60
Large bowel	200–1500	75	30	30	0

Cl^-, Chloride; HCO_3^-, bicarbonate; K^+, potassium; Na^+, sodium.

When administering maintenance fluids, utilizing a 4-2-1 dosing regimen in a 70 kg male (110 mL/hr) results in a total sodium load of 203 mEq in a 24-hour period, which is greater than the required 1 to 2 mEq/kg/day. Although patients with normal kidney function are able to excrete the excess sodium load, caution should be utilized in patients with underlying renal dysfunction, cardiac failure, or other serious comorbidities to not cause iatrogenic hypervolemia. In general, maintenance fluids should be reassessed at least daily to ensure that correct electrolyte and fluid volume needs are met but not exceeded.

Resuscitative Fluids

Resuscitative fluids are most commonly used the immediate postoperative period, after injury, and in the setting of hypotension. The rate of fluid administration is determined by the severity of the existing deficit, presence of ongoing losses, and the patient's comorbidities. NS and LR closely approximate the composition of extracellular fluid and therefore are the most commonly used resuscitative fluids. The composition of various resuscitative fluids is shown in Table 1. LR has a pH of 6.5 and provides 28 mEq of bicarbonate (HCO_3^-) per liter, making it preferential in the setting of acidosis. NS, at a pH of 4.5, does not contain HCO_3^- but has a greater concentration of Na^+ and Cl^- (154 mEq/L making it preferential in patients with a metabolic alkalosis. However, it can create hyperchloremic metabolic acidosis in the setting of high volume resuscitation. Severe fluid losses resulting in hemodynamic instability should be replaced with isotonic resuscitative fluid boluses of 0.9% sodium chloride (NS solution) or LR solution at volumes of 10 to 20 mL/kg, with boluses repeated until adequate resuscitation is reached. Colloid solutions, such as 5% albumin, theoretically provide an advantage when restoring intravascular volume because of the oncotic pressure afforded by the protein content. However, clinical use of colloid solutions is less cost effective and has not demonstrated improved patient outcomes in randomized studies.

ENHANCED RECOVERY AFTER SURGERY (ERAS) PROTOCOLS AND FLUID MANAGEMENT

Enhanced recovery after surgery (ERAS) programs are evidence-based multidisciplinary pathways designed to accelerate postoperative recovery and shorten time to discharge from the hospital without compromising patient safety. The basic hallmarks of ERAS programs are evidence-based, standardized, preoperative assessment and teaching, as well as intraoperative and postoperative management. One of the basic tenants of colorectal ERAS programs focuses on minimizing both intraoperative and postoperative IV fluids. Balanced fluid administration to provide intraoperatively through goal directed therapy that utilizes vasopressors in addition to fluids and closely monitors hemodynamic parameters. Excessive IV fluid in the perioperative period has been linked to delayed return of bowel function and increased postoperative complications. In addition to fluid restriction, data supports restricting sodium intake in attempt to avoid hyperchloremia, which has been associated with renal dysfunction. The data on this field is likely to grow as the number of ERAS programs expand and the literature accumulates.

DIAGNOSIS AND TREATMENT OF ELECTROLYTE DISORDERS

Sodium

Hemostasis and Cl- and Na+ Balance

Sodium is the principal determinant of serum osmolality and free water balance. Sodium is predominately located in the extracellular space and its normal physiologic range is 135 to 145 mEq/L. It functions as an effective osmole, stimulating free water movement across cellular membranes secondary to cell wall impermeability to sodium. Recognizing volume status and osmolarity is vital in the safe and effective treatment of sodium abnormalities.

Hypernatremia

Hypernatremia is defined as a serum sodium concentration greater than 145 mEq/L. It can be subdivided further into mild, moderate, or severe (> 160 mEq/L). Symptoms of severe hypernatremia are related primarily to central nervous system depression as a result of cellular dehydration and include muscle weakness, restlessness, insomnia, lethargy, and coma. Unlike hypovolemia, in which mild to moderate similar states can exist, hypernatremia is always associated with a hypertonic state but can be seen in hypervolemic, euvolemic, and hypovolemic states. Assessment of volume status is the key to successfully understanding the etiology and proper management of hypernatremia.

The most common cause of hypervolemic hypernatremia is seen in patients in dehydrated states and with uncontrolled fluid losses. Older patients, infants, and patients with end stage liver disease are particularly vulnerable. Patients with diarrhea from nasogastric suction, vomiting, diuretics, or lactulose administration are particularly at risk and can become dehydrated quickly. Iatrogenic hypernatremia must often occurs due to inappropriate urinary loss of free water (inappropriate low urine osmolality) seen with neurogenic or nephrogenic diabetes insipidus (DI). In the setting of head injury, pituitary surgery, or cerebral hemorrhage, iatrogenic DI should be suspected for patients who exhibit persistent hypernatremia. A significant response (50% increase in urine osmolality) after administration of desmopressin (DDAVP) in the setting of DI suggests a neurogenic origin. Treatment of nephrogenic DI is more difficult as the kidney responds inappropriately to DDAVP. Finally, hypervolemic hypernatremia is usually iatrogenic in nature, resulting from fluid resuscitation with hypertonic solutions. Other medical causes include mineralocorticoid excess, such as with Conn's or Cushing's syndrome.

Treatment of hypernatremia begins with calculation of the free water deficit:

$$\text{Free water deficit: (L)} = 0.6 \times \text{weight (kg)} \times \left[\frac{\text{Serum Na}}{140} - 1\right]$$

Patients with severe hypernatremia (>160 mEq/L) or symptomatic hypernatremia should undergo treatment with IV water replacements. Those with mild or moderate hypernatremia can be corrected utilizing isotonic NS. *Rate of correction* is critically important and is influenced by the rate in which hypernatremia developed. Those with acute development (<24 hours) should be replaced more rapidly, whereas those with chronic hypernatremia (48 hours) should be approached cautiously. Acute hypernatremia should be corrected at an initial rate of 2 to 3 mEq/L per hour but should not exceed a maximum correction of 12 mEq/L per day. Chronic hypernatremia should be corrected at a rate not to exceed 0.5 mEq/L per hour, with a total change of 8 to 10 mEq/L per day. Serum sodium measurements should be obtained every 2 hours until the patient is neurologically stable.

Hyponatremia

A commonly accepted definition of hyponatremia is a serum sodium concentration lower than 135 mEq/L. Hyponatremia can be subdivided further into mild (130–135 mEq/L), moderate (120–130 mEq/L), or severe (<120 mEq/L). It is estimated that approximately 1% of postoperative patients develop moderate to severe hyponatremia, with upward of 20% of these cases deemed clinically significant. Severe hyponatremia or acute changes in serum sodium concentrations can result in cellular edema and cerebral swelling, leading to clinical manifestations of headaches, lethargy, seizures, and coma. Clinical manifestations of hyponatremia are related to the rate in which the derangement develops. Significant hyponatremia can remain asymptomatic if chronic, as in the case of cirrhosis or heart failure, as the nervous system can adapt. Conversely, patients with acute mild hyponatremia may manifest with symptoms. Additionally, previous work has demonstrated the roles of gender (females worse than males), age (young worse than old), and the presence of hypoxia (worse with hypoxia) as factors that influence the severity of hyponatremia symptoms.

To guide corrective therapy, calculation of the sodium deficit is required utilizing the patient's TBW estimate:

$$\text{Na deficit} = [140 - \text{Serum Na}] \times \text{TBW}$$

TBW is estimated utilizing 0.6 times total body weight for males and 0.5 times total body weight for females. When correcting hyponatremia, the rate of correction is important, as rapid corrections can lead to central pontine myelinolysis (CPM) with potential for permanent spastic quadriparesis and pseudobulbar palsy. Patients with liver disease are particularly susceptible to demyelination. In patients with severe liver disease, the upper limit for a safe rate of correction is unknown. In the majority of patients, serum sodium correction should not exceed 0.25 mEq/L per hour or 9 mEq/L per day. Severe manifestations of hyponatremia (active seizures, respiratory failure, etc.) require immediate treatment with the goal of raising the serum sodium by 2 to 4 mEq/L through a 100 mL bolus of 3% saline over a 10 minute period. If the clinical manifestations do not improve, repeat bolus is indicated. For those patients with less severe manifestations of hyponatremia but who demonstrate hyponatremic encephalopathy (recent seizure, altered mental status, headache, nausea, emesis, etc.), infusion of 3% saline given at a rate of 1 mL/kg per hour is recommended. As a general rule, infusion of 3% saline at a dose of 1 mL/kg provides a serum sodium increase of 1 mEq/L.

In the setting of asymptomatic hyponatremia or as an adjunct to hypertonic saline, furosemide reduced diuresis can aid in a more gradual correction of serum sodium. Treatment of asymptomatic hyponatremia requires assessment of serum osmolality, as it can occur in high, normal, or low serum osmolality states. Aside from osmotic variations, hyponatremia can be present in hypovolemic, euvolemic, or hypervolemic states. Assessment of serum osmolality and volume status is extremely important when determining the appropriate corrective therapy. In the postoperative period, abnormalities in volume status are most common.

Hypovolemic hyponatremia: hyponatremia is the most common form of hyponatremia in the perioperative setting. When hypovolemia is suspected, urine sodium levels less than 20 mmol/L suggest hyponatremia secondary to sequestration of isotonic fluids in the extracellular space or loss from the GI tract or skin. Contrary to treatment of hypervolemic or euvolemic hyponatremia, fluid restriction in the setting of hypovolemia will worsen the clinical picture. Thus, mild to moderate cases are treated utilizing isotonic saline solution.

Hypervolemic hyponatremia is the least common type in the postoperative period, as it is most commonly the iatrogenic result of excessive hypotonic fluid administration. To avoid hypervolemic hyponatremia, hypotonic fluid administration should be reserved primarily for correction of free water deficits in the setting of hypernatremia. Treatment for hypervolemic hyponatremia can be accomplished easily with a combination of water restriction and gentle diuresis. Euvolemic hyponatremia is uncommon in the perioperative period, as it is often the result of syndrome of inappropriate ADH secretion (SIADH), hypothyroidism, or excessive water intake (psychogenic polydipsia). In the postoperative period, transient increases in ADH as the result of pain, stress, narcotic medications, and volume depletion promote free water reabsorption, but not typically at a level sufficient to create a hyponatremic state. SIADH occurs in the setting of traumatic brain injury, pulmonary malignancies (carcinoma and small cell), and lung infections. Diagnosis of SIADH usually is made on findings of high urine osmolality (>150 mmol/kg) and high urine sodium (>25 mmol/L). The absence of hypokalemia helps to differentiate SIADH from adrenal insufficiency. In the setting of SIADH, administration of isotonic saline often worsens hyponatremia, as the sodium is diluted out with reabsorption of free water. Treatment for

euvolemic hyponatremia consists of fluid restriction (<1 L/day) for gradual correction of serum sodium levels.

Assessment of osmolality in addition to volume status is important. Hyperosmolar states can occur in the setting of hyponatremia; however, in the setting of hypertonic hyponatremia it is important to evaluate serum BUN and glucose levels. Elevations in BUN or glucose create increased extracellular osmotic pressure, resulting in an influx of water into the extracellular space, resulting in a relative hypervolemic state. The first step in assessment of hypertonic hyponatremia is to determine the true serum sodium level. In the setting of hyperglycemia, for every 100 mg/dL increase in glucose over 100 mg/dL, 2 mEq/L should be added to the reported sodium.

$$\text{Corrected Na} = \text{Na (mg/dL)} + \left[\frac{\text{glucose}\left(\frac{\text{mg}}{\text{dL}}\right) - 100}{100}\right]$$

Factitious hyponatremia, also known as pseudohyponatremia is rarely seen anymore, as it is now often corrected for by most laboratories. It is caused by elevated chemicals such as proteins and triglycerides, resulting in a false lowering of the serum sodium measurement. Finally, hypotonic hyponatremia occurs most commonly in the setting of a hypervolemic state resulting from expanded extracellular and interstitial volumes with relative intravascular depletion resulting in ADH release. This is seen most commonly in the settings of congestive heart failure, chronic renal insufficiency, nephrotic syndrome, cirrhosis (often in the setting of hepatorenal syndrome), and hypoalbuminemia. Treatment of hypotonic hyponatremia most commonly includes sodium (1500–2000 mg/day) and fluid (<1 L/day) restriction.

Potassium

Homeostasis and Clinical Significance

Serum potassium levels are maintained in a narrow range (3.5–5 mmol/L) via tight regulation at the level of the kidney. The renin-angiotensin-aldosterone system is the body's major feedback system for maintaining potassium homeostasis. Aldosterone acts on the distal renal tubule to cause secretion of potassium. Approximately 98% of the body's potassium is sequestered within the intracellular compartment. Given the relative lack of potassium in the extracellular space, transcellular shifts in potassium are the primary culprit for the development of potassium abnormalities.

Metabolic acidosis, and less commonly lactic acidosis, results in influx of potassium into the extracellular space in exchange for intracellular movement of hydrogen (H^+) ions in an attempt to buffer serum pH. On the contrary, insulin and β-receptor stimulation result in an influx of potassium intracellular.

Hyperkalemia

Hyperkalemia is defined as K^+ above 5.5 mEq/L. Hyperkalemia is cardiotoxic and can lead to ventricular arrhythmias and death. Electrocardiographic (EKG) findings include, in order of progression, peaked T waves, QRS widening, shortened QT intervals, and ventricular ectopy. Hyperkalemia develops through two distinct mechanisms; total body excess or translocation of extracellular potassium into the extracellular space. Acute rises in potassium are not well tolerated, but chronic elevations as seen in chronic renal failure are fairly well tolerated. Notable causes of acute hyperkalemia include acidosis, rhabdomyolysis, cell lysis, and insulin deficiency. A unique surgical cause includes ischemia reperfusion injuries, where revascularization after 4 to 6 hours of ischemia, severe systemic hyperkalemia may occur. Many surgeons utilize prophylactic bicarbonate administration before reperfusion. Additional patients in whom the risk of hyperkalemia is increased include those with profound atrophy (often secondary to prolonged bed rest), neuralgia, denervation syndromes, severe burns, or muscular trauma. Additionally, some medications such as spironolactone and succinylcholine can cause iatrogenic hyperkalemia.

Treatment of hyperkalemia is multifaceted and the degree to which it is treated depends on the presence or lack of symptoms. Treatment consists of promoting either intracellular shift of potassium or overall excretion of potassium from the body. For patients in whom cardiac instability is detected on EKG, the FIRST step in treatment is administration of intravenous calcium gluconate 1 to 2 g over 2 to 3 minutes with continuous cardiac monitoring. This step stabilizes cardiac membranes to prevent arrhythmias but has no effect on serum potassium levels. If EKG changes remain, calcium bolus may be repeated. To quickly affect serum potassium concentration, intracellular shift of potassium can be achieved by administering 10 units of regular insulin IV plus 1 ampule of 50% dextrose (D50) to prevent hypoglycemia and/or administering an ampule of sodium bicarbonate ($NaHCO_3$) and/or administering a β_2 agonist (albuterol). Intracellular shifts temporizes the situation, but ultimately excretion of excess potassium from the body is accomplished with administration of loop diuretics or cation exchange resins (hypernatremia). Exchange resins can be given orally or as a retention enema (contraindicated with immunosuppression) with sorbitol but have an associated risk of colonic ischemia. In critically ill patients, hemodialysis can be utilized to reduce serum potassium.

Hypokalemia

Hypokalemia is defined as serum K^+ below 3.5 mEq/L and is commonly encountered in the perioperative period. It is often the result of renal and GI losses and can be see with loop diuretics, vomiting, diarrhea, and nasogastric suctioning. Signs and symptoms of hypokalemia include generalized fatigue, weakness, atrial arrhythmias, and ileus. EKG findings include flattening of T waves or the formation of prominent U waves. As stated previously, 98% of total body potassium is stored within the intracellular compartment; thus, small changes in serum K^+ reflect large changes in total body stores. Low potassium frequently is associated with hypomagnesemia and acidosis. Magnesium first must be replenished before K^+ is corrected to achieve adequate serum K^+ levels. In patients who are both hypokalemic and acidemic, potassium administration should precede correction of acidemia with bicarbonate because increasing pH will cause an intracellular shift of potassium and overall decrease in serum potassium. Potassium can be replenished via oral or IV routes. Treatment of mild hypokalemia should be accomplished via oral replacement, however, oral therapy often is poorly tolerated. Given the high oral bioavailability of KCl, IV administration should be reserved for patients who do not tolerate the oral form or for those who have severe hypokalemia. Severe hypokalemia should be treated utilizing IV KCl at a rate of 10 to 20 mEq/hr with simultaneous replacement of any magnesium deficits. Given the large total body deficit reflected by serum abnormalities, serial replacements often will be necessary.

Calcium

Homeostasis and Clinical Significance

Calcium is the most abundant electrolyte in the body, with the vast majority found in bone stores. The normal range of serum calcium is 8.5 to 10.5 mg/dL. Serum concentrations are tightly maintained by processes that increase serum calcium via bone demineralization and intestinal absorption and decrease serum calcium via urinary excretion and bone formation. This homeostasis is regulated through complex hormonal regulation, with the majority via parathyroid hormone and calcitriol. Nearly 50% of calcium exists in a biologically active ionized state; the other 50% exists in a minimized inactive state bound to albumin. With such a large portion of circulating calcium bound to albumin, serum calcium measurements must be adjusted for serum albumin levels by the following equation:

$$\text{Corrected calcium} = (0.8 \times (\text{Normal albumin} - \text{Patient's albumin})) + \text{measured calcium}$$

Although this correction generally is utilized, true measurement of ionized calcium in critically ill patients is necessary for patient care and is readily available in all laboratories.

Hypercalcemia

Hypercalcemia is defined by total calcium level greater than 10.4 mg/dL or ionized concentration greater than 5.6 mg/dL. It most commonly is seen with malignancy (breast cancer most common) or in hyperparathyroidism. Other causes include thiazide diuretics, lithium, familial hypocalciuric hypercalcemia, excess intake, vitamin A and D overdose, and immobilization. Symptoms of hypercalcemia include headache, nausea, emesis, altered mental status, lethargy, myalgias, arthralgias, polyuria, and abdominal flank pain secondary to renal stones.

Treatment should be sought for all individuals with total serum concentration greater than 14 mg/dL or those with symptoms. The initial step in treatment includes volume expansion with normal saline (rate of 200 to 300 mL/hr) to dilute circulating calcium and increase renal excretion of calcium. Noninvasive diuretics such as furosemide given IV is used to increase renal excretion of calcium and assist with excess fluid removal to prevent volume overload. An additional treatment for severe or symptomatic hypercalcemia includes calcitonin (4 IU/kg), which will acutely inhibit bone resorption and inhibit renal resorption of calcium. Bisphosphonates, such as zoledronic acid (4 mg IV over 15 minutes) and pamidronate (60 to 90 mg IV over 4 hours) are the best choice for long-term calcium control and for hypercalcemia from enhanced bone resorption. They inhibit osteoclast-induced bone resorption, providing prolonged control with onset of action between 24 and 48 hours.

Hypocalcemia

Hypocalcemia is defined as total serum concentration below 8.4 mg/dL or ionized calcium concentration below 4.5 mg/dL. Causes of hypocalcemia are broken into two broad categories: increased efflux from the extracellular space or decreased influx into the extracellular space. Common causes include hypoparathyroidism and vitamin D deficiency. Additionally, alkalosis increases albumin affinity for calcium and severe pancreatitis results in saponification of calcium intracellular, both resulting in a hypocalcemic state. Hyperphosphatemia and hypomagnesemia also alter calcium homeostasis. In the postoperative period, large volume resuscitation or rapid transfusion of blood products before removal of citrate from blood can result in hypocalcemia.

Symptoms of hypocalcemia include perioral numbness and tingling, hyperreflexia when mechanically stimulating the facial nerve (Chvostek's sign), muscle spasm of the hand and forearm with inflation of a blood pressure cuff proximally (Trousseau's sign), and prolonged QT and arrhythmias on ECG. Treatment should be pursued in the setting of symptoms, (corrected) total serum calcium below 7.0 mg/dL, or ionized calcium below 3.0 mg/dL. Treatment with IV calcium gluconate or calcium chloride should be reserved for cases of severe hypocalcemia or cases with serious symptoms, including overt tetany, laryngospasm, and seizures. Treatment with 10% calcium chloride provides three times as much elemental calcium as 10% calcium gluconate but this requires central venous access. Additionally, administration of calcium chloride requires a monitored setting to avoid associated bradycardia or hypotension. Oral replacement for chronic hypocalcemia in adults can be done through either calcium carbonate or calcium gluconate (1 to 2 g Ca/day). Resistant or severe hypocalcemia may require concurrent vitamin D_3 supplementation. As with hypokalemia, replacement of magnesium concurrently is critical when replacing calcium.

Magnesium

Homeostasis and Clinical Significance

Magnesium is essential for energy metabolism, protein synthesis, calcium homeostasis, and potassium homeostasis. Magnesium primarily is stored intracellular, with less than 1% contained in the extracellular compartment. Normal serum magnesium level is 1.8 to 2.0 mEq/L.

Hypermagnesemia

Hypermagnesemia is a rare event usually seen with burns, trauma, or long-term hemodialysis. Symptoms are uncommon unless serum magnesium levels reach 4.0 mg/dL or greater, with the most common symptom being lethargy. Treatment usually consists of normal saline to expand plasma volume and decrease serum concentration with loop diuretics to reduce renal excretion. Severe hypermagnesemia is treated with IV 10% calcium gluconate (10–20 mL given over 10 minutes).

Hypomagnesemia

Hypomagnesemia often is seen in the postoperative period secondary to dilution. Patients at high risk for hypomagnesemia include alcoholics and critically ill patients. Alternatively, hypomagnesemia may occur as a result of poor intake or GI losses, including diarrhea and biliary and enteric fistulae. Signs and symptoms rarely occur unless serum levels are below 1.0 mEq/dL. Postoperative monitoring is necessary, as severe hypomagnesemia may cause ventricular arrhythmias such as torsades de pointes. Magnesium can be replaced with IV therapy in the form of magnesium sulfate ($MgSO_4$) and is well tolerated. Oral magnesium oxide is an alternative replacement option but it can cause diarrhea, which should be taken into consideration in the postoperative patient.

Phosphorus

Homeostasis and Clinical Significance

Normal serum phosphate ranges from 2.2 to 4.7 mg/dL and it is important in many of the basic cellular processes within the body. Given phosphate's role in cellular metabolism, levels often are altered in critically ill individuals and in the postoperative setting. Individuals who have a poor nutritional status, including critically ill individuals, may experience deficient phosphate levels. Approximately 80% of body stores for phosphate reside within bone, with less than 1% within the intravascular compartment. The renal system is crucial to homeostasis, as thyroid hormone and insulin favor reabsorption of phosphate, whereas parathyroid hormone plays a role in the excretion of excess phosphate. Reabsorption is principally at the proximal tubule through NPT2 sodium/phosphate transporters.

Hyperphosphatemia

Hyperphosphatemia is defined as serum phosphorus levels above 5.0 mg/dL but rarely occurs in the postoperative period. Typically, hyperphosphatemia is seen in patients with renal insufficiency and is the result of a deficiency in 1,25-dihydroxyvitamin D production. Typically, these patients also experience hypocalcemia from increased precipitation resulting from the elevated phosphate levels. The predominant symptoms associated with hyperphosphatemia are mostly those associated with the hypocalcemic state. Treatment of hyperphosphatemia includes plasma volume expansion with normal saline followed by renal stimulation with acetazolamide. In patients with extremely poor renal function or in severe cases, hemodialysis provides corrective therapy. For those with chronic renal failure with chronic hyperphosphatemia, treatment with phosphate binders such as aluminum hydroxide is standard.

Hypophosphatemia

Hypophosphatemia is defined as the serum phosphate level below 2.5 mg/dL and symptoms include arrhythmias, platelet dysfunction, abnormal glucose metabolism, and cardiopulmonary arrest. Hypophosphatemia is much more common in the postoperative period and among individuals in the intensive care unit. Causes of hypophosphatemia include internal redistribution, deficient intake, or excessive loss. Internal redistribution is the result of increased insulin secretion, epinephrine, acute respiratory alkalosis, or bone hunger

TABLE 3 Signs, Symptoms, and Treatment of Electrolyte Disorders

Disorder	Neurologic	Cardiovascular	Gastrointestinal	Renal	Therapy
Hypovolemia	Confusion, seizures, coma	Hypotension, hypertension	Salivation	Oliguria	Fluid resuscitation 0.9% NaCl Hypertonic saline + diuretic
Hypernatremia	Confusion, seizures, coma	Fluid overload	Thirst		Free water 0.45% NaCl
Hypokalemia	Fatigue, weakness	Atrial arrhythmias, flat T waves or U waves	Ileus	Nephrotoxicity	Oral/IV potassium Magnesium replacement
Hyperkalemia	Confusion, paralysis, arrhythmia	Ventricular arrhythmias, peaked T waves, prolonged PR, wide QRS	Nausea, vomiting, abdominal pain		Insulin + 50% dextrose 10% Calcium gluconate
Hypocalcemia	Paresthesia, perioral tingling, carpopedal spasms, Chvostek's sign	Ventricular arrhythmias, prolonged QT interval			IV calcium gluconate 1,25-Dihydroxyvitamin D
Hypercalcemia	Confusion, fatigue, coma	Shortened QT	Abdominal pain	Renal stones, nephrogenic DI (long term)	0.9% NaCl Furosemide
Hypomagnesemia	Weakness, cramping, hyperreflexia	Atrial ventricular arrhythmias (torsades de pointes)	Dysphagia		IV magnesium Magnesium sulfate
Hypermagnesemia	Sedation, paralysis, areflexia	Atrial, ventricular arrhythmias	Diarrhea		0.9% NaCl Furosemide
Hypophosphatemia	Confusion, seizures, weakness	Heart failure, respiratory failure			Sodium or potassium phosphate
Hyperphosphatemia	Symptoms of hypocalcemia				0.9% NaCl Diuretics *Acetazolamide*

DI, Diabetes insipidus; *IV*, intravenous; *NaCl*, sodium chloride.

Dietetic intake can result from intestinal malabsorption (phosphate-binding medications, GI tract surgery), vitamin D deficiency, or starvation and chronic diarrhea. Increased excretion can result from diuretic therapy (acetazolamide), hyperparathyroidism, and acute hepatic reaction.

Refeeding syndrome is a potentially life-threatening condition that occurs when chronically nutritionally depleted individuals receive nutrition. Carbohydrate administration triggers an insulin surge that causes redistribution of phosphate intracellular, further lowering serum phosphate levels. This leads to depletion of adenosine triphosphate and can cause respiratory failure and death. Phosphate levels need to be closely monitored when chronically malnourished individuals are given nutrition.

Hypophosphatemia can also be seen postoperatively after large hepatic resections. Emerging evidence suggests that hypophosphatemia in the setting of liver resection is not the result of increased use by the regenerating liver, but rather a transient hyperphosphaturia secondary to deranged hepatorenal signaling. These patients should have close monitoring and replacement of phosphate postoperatively.

Appropriate treatment of hypophosphatemia should include assessment of the etiology for hypophosphatemia and the cause is often clinically apparent. For cases of symptomatic or severe hypophosphatemia (<1.0 mg/dL), treatment with IV phosphate should be utilized until serum levels exceed 1.5 mg/dL, followed by oral therapy. One millimole (mmol) of phosphate equals 31 mg of phosphorus. IV dosing varies, but for most cases 0.25 to 0.50 mmol/kg given over 8 to 12 hours with a maximum dose of 80 mmol is recommended. Oral therapy, administered as a sodium or potassium salt, usually is dosed at 1 mmol/kg of elemental phosphorus (maximum dose of 80 mmol) divided into 3 doses over 24 hours. In cases where serum phosphate levels are between 1.0 and 1.9 mg/dL, treatment with oral therapy alone is sufficient. Given that only 1% of total body phosphate resides in the intravascular compartment, continuous therapy with phosphate for 5 to 7 days is often indicated. Replacement in patients with renal failure should be done judiciously given the significant risk for development of hyperphosphatemia.

SUMMARY

Fluid status and electrolyte disorders (Table 3) are complex clinical problems that require frequent assessment and correction in critically ill patients. It should be recognized that both IV fluids and electrolytes are therapies capable of providing benefit when utilized appropriately, but also able to cause harm when used inappropriately.

Optimizing Perioperative Care of the Older Adult

Thomas N. ... MD, MS, FACC ... and ... A. ... MD, FACS, ... Michael A. ... MD, FACS

The demographic inevitability of the aging population requires surgeons to acquire basic understanding of geriatric specialty care issues related to the perioperative needs of older adults. Currently, nearly 40% of all inpatient operations in the United States are performed on individuals aged 65 years and older. Older adults are physiologically unique from younger adults.

Surgical quality programs rely on implementation of hospital-wide processes to improve perioperative care. To date, surgical quality programs have focused on certain surgical specialties (e.g., bariatrics, trauma) or individual complications (e.g., infections, readmissions). There are currently no surgical quality programs directly targeting the frail elderly—the population that most commonly undergoes operations and is the most vulnerable to adverse outcomes.

The purpose of this chapter is to provide an overview of the hospital-wide processes required to provide high quality surgical care across the entire perioperative period to frail older adults. The framework of the described care plan for the oldest old is based on the current National Surgical Quality Improvement Program (NSQIP) Coalition for Quality in Geriatric Surgery initiative. Four major clinical domains describe the areas of concentration for optimal perioperative care of the oldest old: function, cognition, goals of care, and nutrition/hydration. Fig. 1 provides an overview of geriatric specialty across the surgical phases of care.

PREOPERATIVE CARE OF THE OLDER ADULT

Risk Screening and Modification

Surgical risk for older adults requires geriatric specialty assessment. For nongeriatric adults, uncomplicated single organ disease (e.g., coronary artery disease) and multimorbidity are used to define risk. Older adults may have a unique surgical risk termed frailty. By definition, a frail older adult is disproportionately at higher risk for adverse healthcare outcomes including disability, major morbidity, and death. Characteristics necessary to quantify the frail vulnerable older adult include cognition, function, mobility, nutrition, and social vulnerability (Fig. 2). Identification of positive characteristics of the frail older adult should trigger geriatric specialty assessment and risk modification prior to the operation. The following characteristics of the frail older adult should be screened for and addressed if present.

Cognition

Cognition describes a patient's thinking, or mental function. Dementia is a chronic decline in mental function (particularly memory) that can lead to inability to live independently. Because older adults have reduced brain function, their brain is more vulnerable to acute brain dysfunction, or delirium, which is the most common postoperative complication in older adults. Delirium is associated with adverse surgical outcomes of death, major morbidity, prolonged hospitalization and institutionalization. Cognition screening tools include the Mini-Cog Test (combination of a three-item recall and clock draw) and the Montreal Cognitive Assessment (MoCA) tool. Positive screens should trigger postoperative delirium prevention bundle ordering (see section on inpatient delirium and Table 1) and counseling on the increased risk of poor postoperative outcomes.

Function

Function describes an older adult's ability to live independently and is typically measured by the ability to perform six activities of daily living (ADLs): bathing, grooming, dressing, feeding, toileting, and transferring. Major operations and hospital stays promote functional disability, an adverse outcome, which studies have shown, that older adults specifically want to avoid. Screening for functional impairment include assessing ADLs and instrumental activities of daily living (IADLs). Older adults screened negative are independent in all activities. Older adults who screen positive are classified as partially dependent or fully dependent. Adults who screen positive should be considered for preoperative exercise therapy, need postoperative physical therapy consultation and require counseling of increased risk of adverse events (notably risk for institutionalization) following an operation.

Mobility

Mobility describes an individual's ability to ambulate. Impaired mobility is reflected by an older adult's need to use walking aids or a slowed walking speed. Major operations result in impaired postoperative mobility. Screening tools to detect impaired mobility include the timed up-and-go (a timed test of rising from a chair, walking 10 feet, turning around and returning to a seated position in the chair), gait speed test (measuring time to walk a ¼ in distance), or use of a mobility aid. Older adults screening positive should be considered for preoperative physical therapy for mobility training and should be counseled of their increased risk of adverse postoperative outcomes, including worsening mobility and increased fall risk.

Malnutrition

Physiologic anorexia occurs in frail older adults resulting in weight loss, decreased lean muscle mass, and poor nutrition. The frailty literature terms this phenomenon as "shrinking." The Mini Nutritional Assessment tool screens for malnutrition. Older adults who screen positive for malnutrition should be considered for preoperative nutritional supplementation, require postoperative nutrition support and should be counseled of the increased risk of poor postoperative outcomes.

Polypharmacy

Taking multiple medications simultaneously makes older adults at high risk because polypharmacy is a surrogate for multimorbidity, increases risk of drug-drug interactions and is associated with adverse drug events. There is not universally agreed upon number of medications that defines polypharmacy. Older adults taking 10 or more medications should undergo medication review prior to their

Optimizing Perioperative Care of the Older Adult

Thomas N. Robinson, MD, MS, FACS, Ronnie A. Rosenthal, MD, FACS, and Michael A. Zenilman, MD, FACS

The demographic inevitability of the aging population requires surgeons to acquire basic understanding of geriatric specialty care issues related to the perioperative needs of older adults. Currently, nearly 40% of all inpatient operations in the United States are performed on individuals aged 65 years and older. Older adults are physiologically unique from younger adults.

Surgical quality programs rely on implementation of hospital-wide processes to improve perioperative care. To date, surgical quality programs have focused on certain surgical specialties (e.g., bariatrics, trauma) or individual complications (e.g., infections, readmissions). There are currently no surgical quality programs directly targeting the frail elderly—the population that most commonly undergoes operations and is the most vulnerable to adverse outcomes.

The purpose of this chapter is to provide an overview of the hospital-wide processes required to provide high quality surgical care across the entire perioperative period to frail older adults. The framework of the described care plan for the oldest old is based on the current National Surgical Quality Improvement Program (NSQIP) Coalition for Quality in Geriatric Surgery initiative. Four major clinical domains describe the areas of concentration for optimal perioperative care of the oldest old: function, cognition, goals of care, and nutrition/hydration. Fig. 1 provides an overview of geriatric specialty across the surgical phases of care.

PREOPERATIVE CARE OF THE OLDER ADULT

Risk Screening and Modification

Surgical risk for older adults requires geriatric specialty assessment. For nongeriatric adults, uncomplicated single organ disease (e.g., coronary artery disease) and multimorbidity are used to define risk. Older adults may have a unique surgical risk termed frailty. By definition, a frail older adult is disproportionately at higher risk for adverse healthcare outcomes including disability, major morbidity, and death. Characteristics necessary to quantify the frail vulnerable older adult include cognition, function, mobility, nutrition, and social vulnerability (Fig. 2). Identification of positive characteristics of the frail older adult should trigger geriatric specialty assessment and risk modification prior to the operation. The following characteristics of the frail older adult should be screened for and addressed if present.

Cognition

Cognition describes a patient's thinking, or mental function. Dementia is a chronic decline in mental function (particularly memory) that can lead to inability to live independently. Because older adults have reduced brain function, their brain is more vulnerable to acute brain dysfunction, or delirium, which is the most common postoperative complication in older adults. Delirium is associated with adverse surgical outcomes of death, major morbidity, prolonged hospitalization and institutionalization. Cognition screening tools include the Mini-Cog Test (combination of a three-item recall and clock draw) and the Montreal Cognitive Assessment (MoCA) tool. Positive screens should trigger postoperative delirium prevention bundle ordering (see section on inpatient delirium and Table 1) and counseling on the increased risk of poor postoperative outcomes.

Function

Function describes an older adult's ability to live independently and is typically measured by the ability to perform six activities of daily living (ADLs): bathing, grooming, dressing, feeding, toileting, and transferring. Major operations and hospital stays promote functional disability, an adverse outcome, which studies have shown, that older adults specifically want to avoid. Screening for functional impairment include assessing ADLs and instrumental activities of daily living (IADLs). Older adults screened negative are independent in all activities. Older adults who screen positive are classified as partially dependent or fully dependent. Adults who screen positive should be considered for preoperative exercise therapy, need postoperative physical therapy consultation and require counseling of increased risk of adverse events (notably risk for institutionalization) following an operation.

Mobility

Mobility describes an individual's ability to ambulate. Impaired mobility is reflected by an older adult's need to use walking aids or a slowed walking speed. Major operations result in impaired postoperative mobility. Screening tools to detect impaired mobility include the timed up-and-go (a timed test of rising from a chair, walking 10 feet, turning around and returning to a seated position in the chair), gait speed test (measuring time to walk a ¼ mi distance), or use of a mobility aid. Older adults screening positive should be considered for preoperative physical therapy for mobility training and should be counseled of their increased risk of adverse postoperative outcomes, including worsening mobility and increased fall risk.

Malnutrition

Physiologic anorexia occurs in frail older adults resulting in weight loss, decreased lean muscle mass, and poor nutrition. The frailty literature terms this phenomenon as "shrinking." The Mini Nutritional Assessment tool screens for malnutrition. Older adults who screen positive for malnutrition should be considered for preoperative nutritional supplementation, require postoperative nutrition support and should be counseled of the increased risk of poor postoperative outcomes.

Polypharmacy

Taking multiple medications simultaneously makes older adults at high risk because polypharmacy is a surrogate for multimorbidity, increases risk of drug-drug interactions and is associated with adverse drug events. There is not universally agreed upon number of medications that defines polypharmacy. Older adults taking 10 or more medications should undergo medication review prior to their

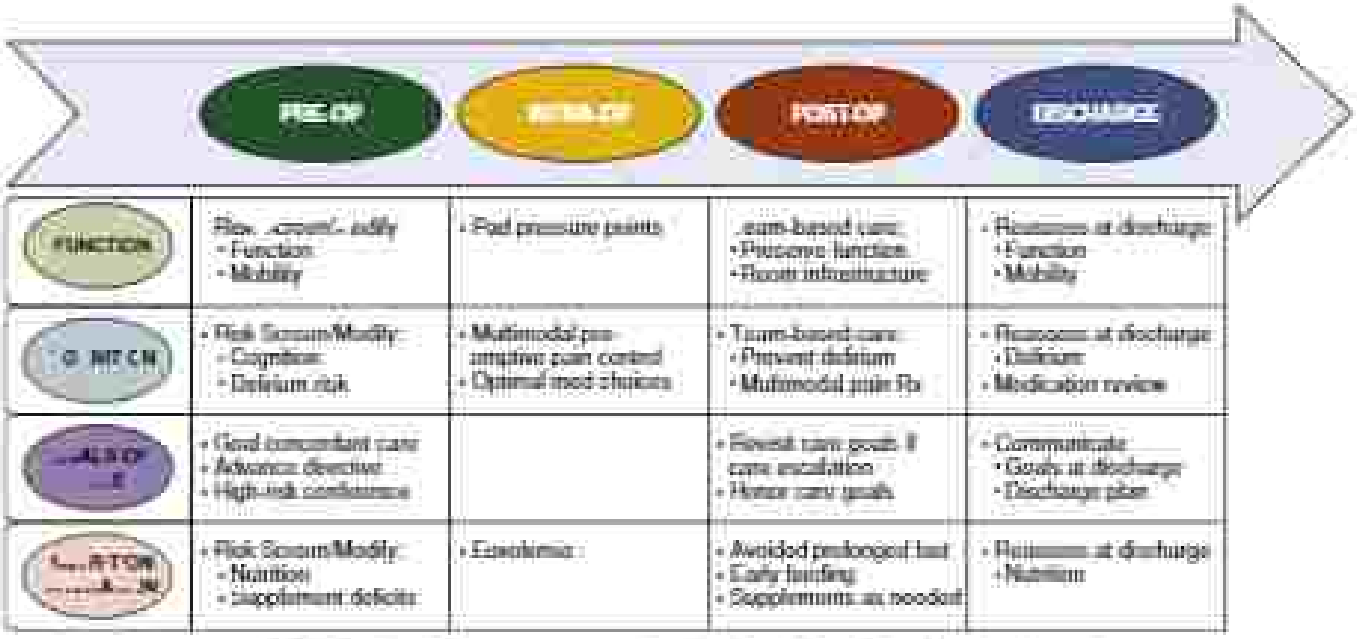

FIG. 1 Overview of the process necessary for optimal surgical care of the vulnerable older adult.

FIG. 2 Clinical characteristics used to identify the frail older adult.

operation. Unnecessary drugs may should be eliminated prior to the operation, including over the counter products.

Goal Concordant Surgical Decision Making

An older adult's values and preferences should guide surgical decision making with the goal of aligning the patient's surgical plan with the anticipated outcomes most valued by the patient. Historically, quantity of life has dictated surgical care plans. This strategy needs to be reconsidered in older adults with limited lifespan who often value quality of life over quantity of life for their remaining lifespan. Surgical decision making should incorporate both forecasted health span (the period of life during which one is healthy and active) and lifespan (life expectancy or chronologic survival) (see Fig. 1). Surgical decision making needs to allow the older adult to discuss overall health goals (ones relating to issues beyond the current condition related to the proposed operation), treatment goals related to the current condition, and the impact of both surgical and nonsurgical treatments on anticipated long-term outcomes. The four outcomes that need to be addressed in addition to those specific to the disease related to the proposed operation include long-term symptoms, function, living location, and survival. The surgeon is responsible for aligning the treatment plan with the patient's overall healthcare goals. Because of the complexity of the information provided to the elderly patient and the substantial potential impact on his or her life, the decision to undergo a major surgical intervention should be revisited sometime between the preoperative consultation and the operation to ensure that the surgical plan is aligned with the patient's goals.

Multidisciplinary High-Risk Conference for Older Adults

A multidisciplinary conference designed to review surgical decision making in at-risk older adults provides valuable insight from a variety of specialists into surgical decisions. Analogous to a tumor board conference, which provides a multidisciplinary approach to cancer management, a high-risk older adult conference provides a multidisciplinary approach to decisions and management of surgical care for vulnerable older adults. Regular attendees at this meeting include geriatrics, surgical leadership, primary surgical team, palliative care, geriatrics, anesthesia, hospital medicine, critical care, and social work. Geriatric high risk committee membership may vary at individual institutions. The overarching goal of this conference is to move the surgical decision making in the most vulnerable older adult from a single provider's recommendation to a more systematic, multidisciplinary approach. As a minimum, the geriatric surgery high risk conference should review all patients 75 years and older undergoing inpatient operations. Older adults who have high mortality risk (e.g., >5% 30-day mortality) based on surgical risk calculator results (https://riskcalculator.facs.org/RiskCalculator/) also have particularly high benefit from being presented at this multidisciplinary conference.

Advance Care Planning

Preoperative planning for adverse perioperative events is essential. The elderly patient's treatment goals should be elicited and an approach to life-threatening problems should be outlined that are consistent with the patient's values and preferences. At a minimum, an older adult's healthcare representative, surrogate, or proxy must be clearly identified with both the name and contact information documented in the medical record prior to all elective operations. If advance directives exist, the existing advance directives must be revisited preoperatively in the context of the proposed operation. For an older adult with planned postoperative admission to the intensive care unit, the extent of the

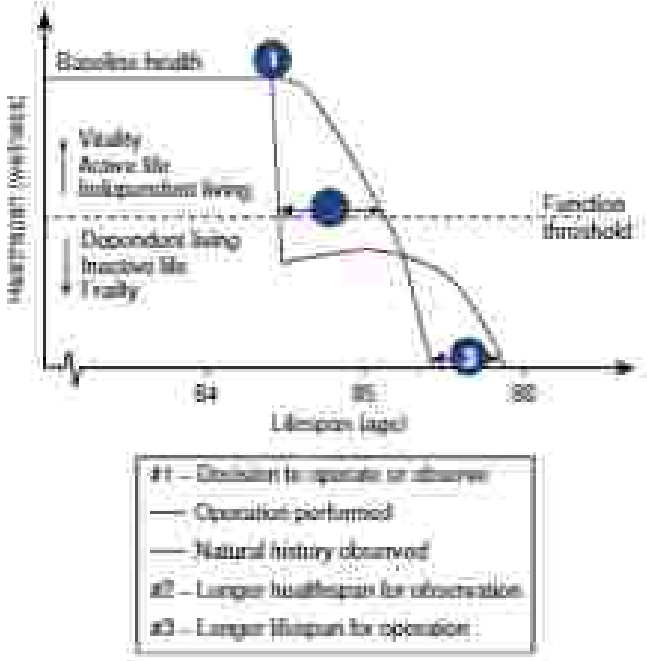

FIG. 3 Conceptualizing health gain versus lifespan in the context of [illegible]

advance directive discussions needs to expand to specifically delineate the patient's preferences for life-sustaining measures including cardiopulmonary resuscitation, mechanical ventilation, feeding tubes, renal replacement therapy, and blood transfusion. It is not mandated that the patient sign and his or her do not resuscitate (DNR) order prior to the operating room or for the intraoperative phase of care. However, the proposition of an elective operation should trigger reconsideration of an existing DNR order.

The advance directive orders established prior to the operation need to be communicated and followed in the postoperative setting. Processes to ensure advance directives are followed postoperatively (e.g., unique wrist bands, prominent documentation in the electronic medical record) should be implemented. Postoperatively, established goals of care must be revisited upon events leading to an escalation of care and for unintended intensive care unit stays of longer than 3 days.

INTRAOPERATIVE CARE OF THE OLDER ADULT

The recommended intraoperative care of the older adult does not significantly differ from the care of other adults. Specific management strategies important for older adults include:

1. To take extra care in padding during patient positioning to prevent skin breakdown, which older adults are particularly susceptible.
2. To use preemptive nonopioid multimodal preventive pain management strategies (e.g., regional blocks, acetaminophen 1000 mg, gabapentin 300 mg) prior to the incision to decrease anesthesia medications during the operation and postoperative pain.
3. To avoid prescribing high-risk medications in the immediate pre- and intraoperative phases of care (e.g., routine use of high-risk antiemetic medications). For a list of commonly prescribed high-risk medications in the perioperative setting see Table 1.

TABLE 1 Common Perioperative Medications With High Risk of Adverse Events in Older Adults

Medications	Comments
PAIN MEDICATIONS	
Meperidine (Demerol)	Related to postoperative delirium
Indomethacin (Indocin)	NSAID with most CNS side effects
Pentazocine (Talwin)	Associated with hallucinations and confusion
Ketorolac (Toradol)	Increased risk of GI bleeding and peptic ulcer disease
GI STRESS ULCER PROPHYLAXIS	
Cimetidine (Tagamet)	Anticholinergic properties predispose delirium
Famotidine (Pepcid)	Anticholinergic properties predispose delirium
Ranitidine (Zantac)	Anticholinergic properties predispose delirium
NAUSEA MEDICATIONS	
Scopolamine	Anticholinergic properties predispose delirium
Promethazine (Phenergan)	Anticholinergic properties predispose delirium
INSOMNIA MEDICATIONS	
Benzodiazepines	CNS toxicity, increase fall risk and fracture
Zolpidem (Ambien)	Increase risk of delirium and falls
OTHER MEDICATIONS	
Diphenhydramine (Benadryl)	Anticholinergic properties predispose delirium
Cyclobenzaprine (Flexeril)	Drowsiness, confusion
Metoclopramide (Reglan)	Extrapyramidal effects

POSTOPERATIVE INPATIENT CARE OF THE OLDER ADULT

Multidisciplinary Inpatient Care Team

The foundation of high-quality postoperative inpatient care of older adults depends on daily rounding of a multidisciplinary team that focuses on geriatric specialty care issues. The surgical and medical teams charged with the hospitalized care of elderly patients disproportionately focus their efforts on the primary disease process leading to the current hospitalization. In contrast, the multidisciplinary geriatric team will focus their efforts on issues central to optimal recovery of the older adult—functional preservation, delirium prevention,

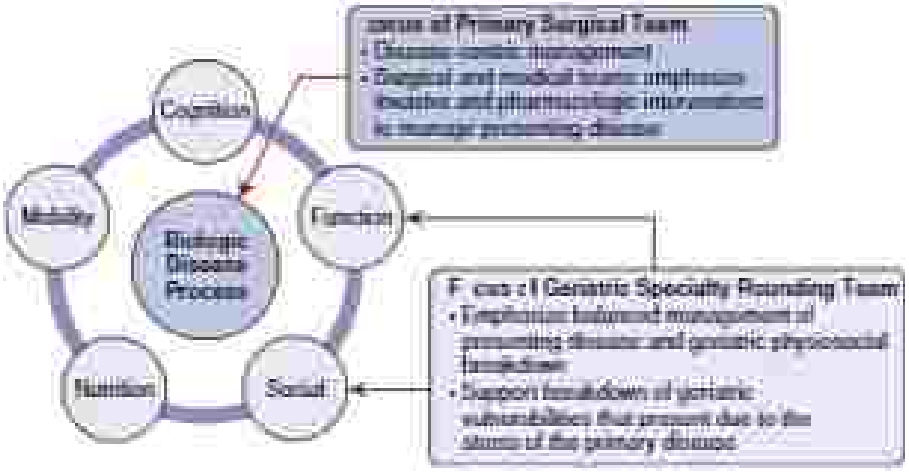

FIG. 4 Uniting the paradigm of hospitalized surgical care of the older adult. The unique vulnerability of the older old requires a paradigm shift in hospitalized care. Traditionally surgical teams focused on the primary disease process alone and disproportionately relied on medical and pharmacologic interventions to manage the presenting disease. In contrast, the frail older adult requires a balanced approach between treating the primary disease and proactively addressing the vulnerability unique to the older adult that lead to postoperative functional, mental and social decline.

nutritional support and discharge transition planning (See Fig. 4). Emphasis on both primary disease management and support of geriatric specialty issues is necessary for optimizing recovery. The composition of the multidisciplinary team may include surgery, geriatrics, hospital medicine, social work, physical therapy, occupational therapy, nutrition, pharmacy, and discharge planner/utilization management.

While rounding may be simultaneous or separate, the care provided by the multidisciplinary team requires direction and coordination. The leadership responsibility of coordinating the care of all these teams will typically be held by a nurse or advance care provider (e.g., physician assistant or nurse practitioner), but could also be managed by a physician team member (e.g., surgeon, hospitalist, geriatrician) depending on the institution. Daily rounds by the team focused on the geriatric vulnerabilities unique to the elderly compliment the primary surgical team, which focuses on surgery specific recovery pathways and avoidance of major morbidity. Existing hospital care models that exemplify this geriatric centric care model include the Hospital Elder Life Program (HELP) and the Acute Care Elderly (ACE) program.

Delirium Prevention

Delirium represents acute brain dysfunction and is the most common postoperative complication in hospitalized older adults. Delirium is closely associated with the adverse outcomes of serious morbidity, prolonged length of stay, need for institutionalization, death, and increased healthcare costs (Box 1). Delirium is an ideal candidate for quality improvement programs because delirium is common and deleterious. One-third of cases of delirium are preventable by simple supportive protocols.

Interventions to prevent delirium include bedside supportive protocols including re-orientation, mobilization, sleep hygiene, and sensory deficit support (Table 2). Delirium prevention "bundles" are constructed in the electronic medical record and should be ordered on all high-risk patients. A common threshold to order the delirium prevention order set bundle is on all patients 75 years and older undergoing an inpatient operation. Targeting this population versus a larger group to start the delirium prevention quality program allows the nursing staff to focus their efforts on a limited, truly high-risk population of inpatients. Prior to launching the delirium prevention order sets, nursing education programs aimed to teach the bedside interventions included in the bundled delirium prevention order set must occur.

In addition to bedside supportive measures to prevent delirium, there are iatrogenic promoters of hospitalized delirium that need to be addressed to allow a more comprehensive delirium prevention program. The clinical team can also target uncontrolled pain, postoperative infections, and use of deliriogenic medications (see next section and Table 1 for high-risk medications) as strategies to reduce delirium rates.

BOX 1 Important But Less Common Drivers of Delirium

Hypotension
Acute blood loss anemia
Myocardial infarction
Pyrexia
Abnormal sodium
Hypoxia
Hypercarbia
Pulmonary embolus
Dehydration
Metabolic acidosis
Urinary retention
Constipation
Stroke
Malnutrition

Postoperative pain control should include multimodal opioid-sparing pain regimens. These pain regimens should include ice packs, massage, standing acetaminophen (1000 mg tid), liberal use of regional blocks and finally opioids. This strategy utilizing opioids as the last line therapy is different from traditional postoperative pain management in which opioids are first line therapy. An important concept is that the delirium risk of uncontrolled pain is far greater than the delirium risk of opioids. Therefore, opioid use is superior than leaving an older adult with uncontrolled pain.

Function Preservation

Functional decline from baseline to discharge occurs in 40% of adults 65 years and older undergoing inpatient operations and in nearly two-thirds of hospitalized 90 year olds. To avoid functional decline, proactive processes to avoid deconditioning must be employed. Avoiding deconditioning requires more than simply mobilizing the patient from the bed to a chair or performing passive range of motion therapy. Early in-hospital physical rehabilitation interventions typically focus on strength, mobility, and balance training. The intensity and duration of physical rehabilitation should increase with ongoing therapy. For example, strength exercises progress in terms of numbers of repetitions and sets, and walking (mobility) exercises can increase in both distance and time. These interventions have been shown to improve physical function

TABLE 2 Modifiable Causes of Postoperative Delirium

Delirium Promoter	Management Strategy
Disorientation	Orient to person, place, time three times daily minimum* Encourage family presence at bedside*
Disrupted sleep	Sleep hygiene: awake during daytime, uninterrupted sleep overnight* Windows allowing natural light in room*
Immobility	Early ambulation: walk in hallway minimum three times daily* Avoid tethers, minimize catheters, tubes, lines that discourage walking*
Sensory deficits	Vision: wear glasses* Hearing: hearing aids/pocket talker*
Uncontrolled pain	Nonpharmacologic pain adjuncts (e.g., ice, massage)† Opioid sparing multimodal pharmacologic pain management†
Medications	Avoid anticholinergic medications and Beers list medications Avoid starting multiple new medications simultaneously
Infection	Avoid iatrogenic infections Diagnose source and actively treat infections

*Commonly used in bedside delirium prevention bundle order sets.

at discharge, decrease need for nursing home disposition, and reduce length of stay.

Appropriate Medication Usage

Medications are a major source of adverse events in hospitalized older adults. Potentially inappropriate medications for older adults should not be used as first line pharmacologic treatment. Vulnerable older adults are more sensitive to medication side effects, have less robust metabolism, and have altered pharmacokinetics. Multiple medications, a phenomenon termed polypharmacy, is both common and deleterious due to drug–drug interactions. For example, starting five new medications puts an older adult at a threefold delirium risk. The Beers list is a medication list considered the gold standard reference for pointing out which medications to avoid in older adults. Table 3 reviews a subset of medications from the Beers List that are relevant to the perioperative setting.

Nutrition and Hydration

Close attention to the nutritional status of vulnerable older adults is important to optimize surgical outcomes. In the postoperative setting, an initial bedside screening for swallowing dysfunction is important to prevent aspiration. Resumption of oral diet should occur as soon as clinically indicated. Inclusion of a nutritional supplementation beverage with meals is a common strategy to increase postoperative caloric intake. Common reasons that limit an older adult's ability to consume food include missing teeth, lost dentures, and lack of appetite due to the normal physiologic anorexia of aging. Ongoing evaluation of adequate food intake should occur throughout the hospital stay.

POSTDISCHARGE CARE OF THE OLDER ADULT

Older adults' physiosocial vulnerability makes them especially vulnerable to hospital readmission and other adverse postdischarge outcomes. Core issues include a poor understanding of what actually happened during the hospital stay, noncompliance with the recommended discharge medical regimen, and a lack of communication with outpatient primary care providers.

Optimizing safe discharge practices requires:

- Clear discharge instructions: Clear review of discharge medical instructions with particular attention paid to newly prescribed medications.
- Written instructions: Written documents reviewing hospital course and potential post discharge adverse events including the occurrence of potential geriatric syndromes including delirium and falls.
- Communication: Written communication sent to the older adult's outpatient primary care provider(s) including operation performed and postoperative course, as well as laboratory and diagnostic test results.
- Follow up: Prearranged follow up with both surgical team, primary care provider, and any new consultants relevant to inpatient stay.

PROGRAM MANAGEMENT TO OPTIMIZE GERIATRIC SURGICAL CARE PROCESSES

Infrastructure to support the optimal surgical care of the older adult is necessary to optimize a continuous quality improvement program aimed to improve the care of vulnerable older adults. The program support necessary is similar to that of trauma or cancer programs.

Personnel

Personnel include a geriatric surgery director (a practicing surgeon with additional expertise in geriatric care) and geriatric surgery manager (a registered nurse with managerial experience and with additional geriatric training).

Clinical Data Collection

Measurement of geriatric specialty care variables (e.g., delirium, function) in addition to traditional 30 day mortality and morbidity variables is necessary to allow assessment and subsequent improvement of outcomes important to older adults perioperatively.

Committee Oversight

A Geriatric Surgery Quality Committee must oversee system wide processes, implement care plans, and actively work to improve surgical quality as dictated by outcomes measurements.

education

All healthcare professionals involved in perioperative care need basic education on the aspect of aligning healthcare goals, cognitive prevention, functional mobility, and nutrition/hydration relevant to older adults.

SUMMARY

Surgical care of older adults requires system wide processes to support the physiosocial vulnerabilities unique to the older adult. This chapter has outlined care plans in all phases of surgical care required to optimize the surgical care of the high risk, frail, older old patient. Knowledge of specialty care topics relevant to geriatric patients is the responsibility of all surgeons.

Perioperative Optimization

John R. Montgomery, MD, and Mich . el J. Englesbe, M.D

The perioperative period from initial office visit to after surgical recovery represents a significant period in a patient's life. Patients are uniquely engaged in their health and attentive to improving their wellbeing. Perioperative optimization can not only improve surgical outcomes and decrease costs but also improve health outcomes long after the operative procedure. This chapter focuses on eight high-yield domains of perioperative care and provides evidence-based recommendations for optimization.

PERIOPERATIVE CARE MANAGEMENT DOMAINS

Smoking Cessation

According the Centers for Disease Control and Prevention, smoking is the leading cause of preventable death in the United States, with over 480,000 deaths annually. On average, smokers die 10 years earlier than nonsmokers. In the perioperative period, smoking is linked to poor wound healing, surgical site infections, increased inflammatory response, pneumonia, respiratory failure, cardiovascular events, and mortality. In the long term, it increases the risk of stroke, myocardial infarction, emphysema, stomach ulcers, periodontal disease, blindness, infertility/impotence, multiple cancers, and death. The scheduling of elective operations presents an optimal time for smoking cessation counseling and intervention.

Potential barriers to cessation include patient belief that quitting is not important, lack of confidence that attempted smoking cessation will be successful, high perceived cost of intervention methods, lack of social support, and lack of engagement or urging by the surgical team. Evidence-based measures to increase chance of smoking cessation include direct physician advice, prescription of approved medication(s), structured counseling sessions, and plans for follow-up. Approved medications include varenicline, bupropion, and nicotine replacement therapy. There is no evidence for superiority of any of these medications over the others in the perioperative period. Contrary to previous belief, inclusion of nicotine replacement therapy in perioperative care is not linked to inferior surgical outcomes. Compliance with smoking cessation can be assessed with measurement of urine cotinine levels, which are not influenced by nicotine replacement therapy.

Of note, smokers have a better chance of successful smoking cessation in the perioperative period than at other time points. Furthermore, longer periods of nonsmoking preoperatively are associated with increased chances of remaining nonsmoking postoperatively. Therefore, early and direct patient counseling with inclusion of approved medication(s) is crucial to the perioperative and long-term health of the surgical patient.

Recommendations

- Surgeon should urge all patients to quit smoking prior to surgery
- Smoking cessation intervention for all smokers, ideally 2–6 weeks before surgery
- Urine cotinine testing if clinically indicated
- Further postoperative follow-up with primary care provider to decrease chance of recidivism

Frailty

Frailty is an emerging concept used to describe generalized poor functional status and reduced physiologic reserve that results in increased vulnerability to adverse outcomes. Although more prominent in elderly populations, it can also be found in younger patients who suffer from chronic illness, persistent inflammatory states, poor nutrition, or sedentary lifestyle. In the general population, it is independently associated with accelerated progressive functional decline, loss of independence, need for hospitalization, and all-cause mortality. These risks are compounded in the perioperative period due to the stresses of surgery, akin to a debilitated person attempting to run a marathon with no previous physical training. Frail patients are particularly prone to in-hospital mortality, 1-year mortality, pneumonia, infection/sepsis, longer hospital length of stay, higher costs of care, hospital readmission, and need for discharge to rehabilitation center.

Frailty should be evaluated before considering major elective surgery. Common clinical assessments include questionnaires such as the Modified Frailty Index (MFI) and Clinical Frailty Scale (CFS), although numerous additional indices exist. Often, these questionnaires are augmented with objective data such as 6-minute walking distance (6MWD) or hand-grip strength test. Improvement in these objective measurements over time has been shown to improve outcomes.

If a patient screens positive for frailty, enrollment in a "prehabilitation" program to improve functional status and endurance is recommended. These programs take many forms but often include elements of aerobic/anaerobic exercise and nutritional optimization. Prehabilitation has been shown to reduce postoperative complications, decrease hospital length of stay, lower healthcare costs, and increase health-associated quality of life. Even if patients screen negative for frailty, it is still important to encourage preoperative physical activity, as this has been associated with improved postoperative outcomes and patient empowerment. After surgery, these activities should be continued and be incorporated into the lifestyle changes in partnership with the primary provider.

Recommendations

- Every patient should train for surgery by intentionally increasing his or her activity levels.

Perioperative Optimization

John R. Montgomery, MD, and Michael J. Englesbe, MD

The perioperative period from initial office visit to after surgical recovery represents a significant period in a patient's life. Patients are uniquely engaged in their health and attentive to improving their wellbeing. Perioperative optimization can not only improve surgical outcomes and decrease costs but also improve health outcomes long after the operative procedure. This chapter focuses on eight high-yield domains of perioperative care and provides evidence-based recommendations for optimization.

PERIOPERATIVE CARE MANAGEMENT DOMAINS

Smoking Cessation

According the Centers for Disease Control and Prevention, smoking is the leading cause of preventable death in the United States, with over 480,000 deaths annually. On average, smokers die 10 years earlier than nonsmokers. In the perioperative period, smoking is linked to poor wound healing, surgical site infections, increased inflammatory response, pneumonia, respiratory failure, cardiovascular events, and mortality. In the long term, it increases the risk of stroke, myocardial infarction, emphysema, stomach ulcers, periodontal disease, blindness, infertility/impotence, multiple cancers, and death. The scheduling of elective operations presents an optimal time for smoking cessation counseling and intervention.

Potential barriers to cessation include patient belief that quitting is not important, lack of confidence that attempted smoking cessation will be successful, high perceived cost of intervention methods, lack of social support, and lack of engagement or urging by the surgical team. Evidence-based measures to increase chance of smoking cessation include direct physician advice, prescription of approved medication(s), structured counseling sessions, and plans for follow-up. Approved medications include varenicline, bupropion, and nicotine replacement therapy. There is no evidence for superiority of any of these medications over the others in the perioperative period. Contrary to previous belief, inclusion of nicotine replacement therapy in perioperative care is not linked to inferior surgical outcomes. Compliance with smoking cessation can be assessed with measurement of urine cotinine levels, which are not influenced by nicotine replacement therapy.

Of note, smokers have a better chance of successful smoking cessation in the perioperative period than at other time points. Furthermore, longer periods of nonsmoking preoperatively are associated with increased chances of remaining nonsmoking postoperatively. Therefore, early and direct patient counseling with inclusion of approved medication(s) is crucial to the perioperative and long-term health of the surgical patient.

Recommendations

- Surgeon should urge all patients to quit smoking prior to surgery
- Smoking cessation intervention for all smokers, ideally 2–6 weeks before surgery
- Urine cotinine testing if clinically indicated
- Further postoperative follow up with primary care provider to decrease chance of recidivism

Frailty

Frailty is an emerging concept used to describe generalized poor functional status and reduced physiologic reserve that results in increased vulnerability to adverse outcomes. Although more prominent in elderly populations, it can also be found in younger patients who suffer from chronic illness, persistent inflammatory states, poor nutrition, or sedentary lifestyle. In the general population, it is independently associated with accelerated progressive functional decline, loss of independence, need for hospitalization, and all-cause mortality. These risks are compounded in the perioperative period due to the stresses of surgery, akin to a debilitated person attempting to run a marathon with no previous physical training. Frail patients are particularly prone to in-hospital mortality, 1-year mortality, pneumonia, infection/sepsis, longer hospital length of stay, higher costs of care, hospital readmission, and need for discharge to rehabilitation center.

Frailty should be evaluated before considering major elective surgery. Common clinical assessments include questionnaires such as the Modified Frailty Index (MFI) and Clinical Frailty Scale (CFS), although numerous additional indices exist. Often, these questionnaires are augmented with objective data such as a timed walking distance (6MWD) or hand-grip strength test. Improvement in these objective measurements over time has been shown to improve outcomes.

If a patient screens positive for frailty, enrollment in a "prehabilitation" program to improve functional status and endurance is recommended. These programs take many forms but often include elements of aerobic/anaerobic exercise and nutritional optimization. Prehabilitation has been shown to reduce postoperative complications, decrease hospital length of stay, lower healthcare costs, and increase health-associated quality of life. Even if patients screen negative for frailty, it is still important to encourage preoperative physical activity, as this has been associated with improved postoperative outcomes and patient empowerment. After surgery, these activities should be continued and be incorporated into the lifestyle changes in partnership with the primary provider.

Recommendations

- Every patient should train for surgery by intentionally increasing his or her activity levels

- Clinical assessment of poor physical activity levels and frailty for all major elective surgery patients
- Formal prehabilitation programs should be used for patients who screen positive for frailty

Nutritional Status

Optimization of nutritional status is an integral component of perioperative care. Malnutrition is a significant predictor of adverse postoperative outcomes including infection, renal/cardiac complications, gastrointestinal fistula formation, poor wound healing, increased hospital length of stay, higher healthcare costs, and death. Interestingly, obesity is not protective from malnutrition, and it is possible for overweight patients to have micro- and macronutrient deficiencies. Therefore, it is important for all patients to be screened for malnutrition before inpatient and some outpatient elective operations.

Multiple validated risk questionnaires exist for malnutrition screening, including the Nutritional Risk Score 2002 and Malnutrition Screening Tool. Historically, certain laboratory values have been used to support a diagnosis of malnutrition (i.e., albumin, prealbumin, or transferrin); however, reliance on these values in isolation is inadequate and can be misleading. While screening for malnutrition, the surgeon must consider the overall clinical presentation with recent weight changes and healing progress. Presence of chronic inflammatory conditions such as diabetes mellitus, rheumatoid arthritis, and Crohn's disease should heighten concern for malnutrition.

Positive screening necessitates a full nutritional assessment, usually via referral to a registered dietitian. A dietitian can also assist with individualized supplementation of micronutrients and/or macronutrients (e.g., selenium, glutamine) that have been shown to decrease postoperative infectious complications. The surgeon must be aware of the differences between a dietitian and nutritionist in the community setting. A dietitian is legally considered an expert in nutrition after having received a bachelor's degree or higher, completed an internship, passed standardized examinations, and maintained ongoing credentials in the field. A nutritionist is not required to have any formal education or licensing. Once diagnosed, malnutrition should be aggressively managed with early intervention and frequent monitoring to minimize risks of postoperative complications.

Recommendations

- Balanced diet for all surgical patients
- Preoperative screening for malnutrition to allow for referral to dietitian and immediate intervention if screening positive

Cardiac Disease

Heart disease is the leading cause of death for both men and women in the United States and is a significant risk factor for morbidity and mortality in the perioperative setting. In particular, postoperative myocardial infarction is one of the most common causes of increased mortality. Risk assessment requires interrogation of patient-specific risk factors, surgery-specific risk factors, and exercise tolerance. The Revised Cardiac Risk Index is the most commonly used and broadly validated tool for predicting major cardiac complications; a score of 3 or greater confers an 11% chance of major postoperative cardiac event. The American College of Cardiology and the American Heart Association (ACC/AHA) have published extensive clinical practice guidelines regarding the perioperative work-up and management of cardiac disease. The complete guidelines can be found in published documents from the ACC/AHA (http://my.americanheart.org/professional/StatementsGuidelines/_y.xpx).

Recommendations

- Preoperative screening and management of cardiac disease as per the most recent ACC/AHA guidelines

Alcohol Use

According to the 2015 National Survey on Drug Use and Health, 6.2% of adults ages 18 and older have alcohol use disorder and 26.9% of adults engaged in binge drinking within the last month. Furthermore, an estimated 88,000 people die from alcohol-related deaths annually, making alcohol the third leading preventable cause of death in the United States. For the surgical patient, chronic alcohol use poses significant risks in the postoperative period including withdrawal, delirium tremens, pneumonia, and increased wound infection rates. Symptoms of withdrawal can range from mild tremors, confusion, and fever to severe electrolyte abnormalities (hyponatremia, hypokalemia, hypocalcemia, hypophosphatemia, hypomagnesemia), hemodynamic instability, seizures, and death.

Screening tools for alcohol use disorder include the CAGE questionnaire and Alcohol Use Disorders Identification Test (AUDIT-C). If positive, the patient should undergo assessment and treatment by their primary care provider before elective surgical intervention. Laboratory monitoring for chronic heavy alcohol use is available and includes the serum carbohydrate-deficient transferrin and ethyl glucuronide levels. Abstinence for 8 weeks prior to surgery has been shown to decrease postoperative complications from 74% to 31%.

If surgery is needed in an urgent fashion, patients with known alcohol use disorder should be systematically monitored for evidence of withdrawal. Utilization of an institutional protocol for withdrawal monitoring and treatment should be implemented. At our institution, the Michigan Alcohol Withdrawal Severity (MAWS) Assessment Scale is both a scoring and a treatment protocol that utilizes frequent patient assessment for signs and symptoms of withdrawal, including central nervous system excitation, adrenergic hyperactivity, and delirium. Nearly all prescribed patients are initiated on thiamine and folate supplementation with the addition of benzodiazepines or haloperidol based on MAWS and clinical assessment. It is strongly encouraged to quickly transfer patients to higher level care centers if symptoms of withdrawal worsen.

Recommendations

- Preoperative screening for alcohol use disorders via questionnaires such as CAGE and AUDIT-C
- Multimodal abstinence in partnership with addiction professionals is recommended prior to elective surgery
- Monitoring and prompt treatment for withdrawal in perioperative period

Chronic Narcotic Use

Preoperative narcotic use and addiction are increasingly common phenomena in the setting of a nationwide opioid epidemic. In 2015, an estimated 2 million Americans had an opioid use disorder involving prescription pain medications and 591,000 had a substance use disorder involving heroin. The next year, narcotics killed more than 42,000 Americans, with 80% of those deaths coming from prescription narcotics. Preoperative narcotic use is linked to increased hospital length of stay, postoperative ileus, and increased readmission rates. Poor postoperative pain control is also common given the frequent association of chronic narcotic use with hyperalgesia. There is growing evidence for opioid-induced immunosuppression and increased infectious complications, especially in cancer and total joint arthroplasty patients.

In the preoperative period, a multidisciplinary approach should be pursued to minimize narcotic use. This process should include the patient's primary care provider and possible referrals to an anesthesia pain clinic, physical therapist, and mental health professional. Inclusion of nonnarcotic pain medications such as acetaminophen, nonsteroidal antiinflammatory drugs, gabapentinoids, selective serotonin reuptake inhibitors, tricyclic antidepressants, and steroid injections should be considered based on the etiology of the pain and the patient's particular comorbidities. In Michigan, the Overdose Risk

Score is commonly used to estimate the risk of unintentional opioid death. Developed from a large case series of over 5000 unintentional overdose deaths, this score incorporates 12 variables, including number of pharmacies visited per unit time, maximum morphine milligram equivalence prescription in the last year, number of opioid prescriptions in the last 2 years, and various signs of opioid and sedative use to compute a score from 000 to 999. Using 000 to 199 as a reference point, every 100 point increase is associated with an approximate double in risk of unintentional opioid death (Table 1). This score can then be used to provide recommendations on patient counseling and interventions (Table 2).

The physician who principally cares for the patient's pain must be involved in the perioperative care. Narcotic weaning is possible before planned surgical intervention, but total narcotic abstinence can be difficult to achieve. Although narcotic cessation may be beneficial, there is a paucity of evidence to show that total abstinence results in improved outcomes. Patients should not be precluded from surgery if total abstinence is not obtained. In the early perioperative period, a multidisciplinary approach with inclusion of nonnarcotic medications should be utilized to return patients to preoperative narcotic use or lower as quickly as possible. Discharge prescriptions should not exceed a 1-week supply for most operative procedures, and providers should consider addition of an opioid antagonist prescription (e.g., naloxone) and teaching for patients at increased risk of overdose.

Recommendations:

- Pain planning and involvement of pain specialists prior to surgery
- Utilize multidisciplinary approach for preoperative narcotic weaning with inclusion of nonnarcotic medications
- Incorporation of risk calculators to identify patients at risk of unintentional overdose and guide interventions appropriately

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) is now recognized to affect between 25% and 30% of Americans, with up to 90% of those being undiagnosed. Mild symptoms include excessive daytime sleepiness, impaired work performance, and decreased health-related quality of life. More serious associations include systemic hypertension, pulmonary hypertension, cardiac arrhythmias, myocardial injury, stroke, depression, metabolic syndrome, and sudden death. In the perioperative period, OSA is also associated with increased incidence of cardiac arrest, cardiac shock, respiratory failure, need for reintubation, and longer hospital length of stay.

Clinical screening tools for OSA include the Berlin questionnaire, American Society of Anesthesiologists checklist, STOP-Bang questionnaire, and Sleep Apnea Clinical Score. Any patient who screens positive for OSA should have an informed discussion with the surgeon about the perioperative risks of OSA and options for preoperative referral to a sleep specialist. Previous studies have shown that preoperative initiation of continuous positive airway pressure (CPAP) therapy for severe OSA patients decreases the risk of perioperative cardiovascular complications by >50%. However, there is insufficient evidence to support postponing an operation for patients with untreated OSA or CPAP noncompliance so long as other major comorbidities and problems with ventilation or gas exchange are optimized (i.e., hypoventilation syndrome, severe pulmonary hypertension, and resting hypoxemia).

In the perioperative period, anesthesiology should be notified of the patient's OSA status so that the anesthetic plan can be optimized.

TABLE 1 Opioid Risk Score and Odds Ratio of Unintentional Death

Risk Score	Odds Ratio
000–199	1
200–299	10
300–399	32
400–499	75
500–599	44
600–699	86
700–799	141
800–899	194
900–999	329

*Opioid Risk Score from 0–0 to 999 is used as reference point.

TABLE 2 Overdose Risk Score Clinical Guidance*

Overdose Risk Score	Approximate CDC MED Equivalent	Recommended Clinical Guidance
<400	<50 MED	Consider other sources of overdose risk outside of ORS data.
400–599	50–89 MED	Consider naloxone prescription.
≥600	≥90 MED	Consider naloxone prescription. Review use patterns for unsafe conditions. If multiple providers involved in unsafe prescribing, discuss concern with patient and consider contacting other providers directly. If multiple pharmacies involved in unsafe prescribing, discuss concern with patient and consider pharmacy lock-in program. If overlapping medications of same or different type, discuss concern with patient and consider taper to lower dose and/or discontinuation of potentiating medications. If patient has evidence of a substance use disorder, consider inpatient admission or referral for outpatient evaluation and treatment.

From www.cms.hhs.gov/Medicare/Fraud-and-Abuse/Physician-Self-Referral/Publications-and-Guidance-Advisory-Opinions.html. [accessed 5/6/23]. Opioid Risk Score.

*The recommended clinical guidance points have not been independently validated and should not supplant individualized clinical decision making.

CDC, Centers for Disease Control and Prevention; MED, morphine equivalent dose; ORS, overdose risk score.

Occasionally, choice of local block or spinal anesthesia can be selected if safe and feasible. Patients who use CPAP should also be encouraged to bring their own machine into the hospital for use. Finally, choice of multimodal and narcotic minimizing analgesia to mitigate risks of opioid-induced respiratory depression should be considered.

Recommendations

- Clinical screening for OSA in all patients, as majority of cases are undiagnosed.
- If screening positive, informed discussion of risks and benefits of proceeding with surgery versus sleep specialist referral.
- Inform anesthesia colleagues of OSA status before operation so anesthetic plan can be optimized.

Diabetes Mellitus

Type 2 diabetes mellitus is an increasingly common condition affecting 30.3 million or 9.4% of the US population according to the American Diabetes Association. Of these, 7.2 million are undiagnosed. For surgical patients, hemoglobin A_{1c} (HbA_{1c}) greater than 8% is associated with postoperative infectious complications such as pneumonia, surgical site/wound infection, and sepsis. Additionally, diabetics usually have longer hospital lengths of hospital stay. Diabetics are also more likely to have other comorbidities such as cardiovascular disease, obesity, and renal disease.

For patients with known diabetes, HbA_{1c} should be drawn within 3 months of the planned operation. If this value is greater than 8%, the patient should be referred back to their managing clinician for medication optimization. If hyperglycemia is discovered on routine preoperative labs, showing a HbA_{1c} and referred to primary care physician or endocrinologist for management is warranted. There is no evidence for routine blood glucose level screening independent of the procedure specific preoperative labs for average risk patients.

In the immediate postoperative period, glucose levels should be closely monitored for diabetic patients. Goal blood glucose levels are less than 140 mg/dL for stable patients and less than 180 mg/dL for critically ill patients. Given the stresses of surgery and periods of fasting, blood glucose levels can vary widely. Therefore, most clinicians will convert oral medications to a sliding scale insulin for inpatient and reduce long acting insulin doses. The exact changes are dependent on the anticipated postoperative course and patient-specific factors. Before discharge, patients should be converted back to their baseline diabetic medications unless otherwise contraindicated. Management of patients with type 1 diabetes is beyond the scope of this chapter. Expert consultation is recommended if the surgical team is not familiar with management of this condition.

Recommendations

- Referral of surgical patient to primary care physician or endocrinologist for glycemic optimization if preoperative HbA_{1c} greater than 8%.
- Perioperative goal blood glucose level less than 180 mg/dL in stable patients and less than 180 mg/dL in critically ill patients.

CONCLUSION

The perioperative period provides an unparalleled opportunity to impact the overall health of the surgical patient. Interventions at this time should be geared to not only optimize the chance of short term operative success but also facilitate durable changes to the patient's life. Surgeons must recognize their pivotal role in this process and reach out to other providers for multidisciplinary action on comorbid conditions. The aforementioned domains of care provide eight high-yield areas for perioperative optimization; however, this list is not all inclusive and care must be personalized to each individual patient. Unfortunately, most care pathways and policies do not support perioperative medicine as a key component of durable population health interventions. Comprehensive efforts to optimize patients should be supported by providers, policymakers, and payers.

IS NASOGASTRIC TUBE NECESSARY AFTER ALIMENTARY TRACT SURGERY

Travis J. Webb, MD, MHPE

The nasogastric tube (NGT) historically has been used in the postoperative period for patients undergoing surgery on the alimentary tract. The long standing belief held by many surgeons has been that nasogastric decompression allows the bowel to rest, prevents air and fluid accumulation, decreases postoperative nausea and vomiting, prevents abdominal distention, and protects the patient from aspiration, pneumonia, anastomotic leak, and fascial dehiscence. Pervasive use of NGTs coincided with significant advances in the administration of anesthesia, the development of germ theory and aseptic technique, and improvements in hemostasis that revolutionized surgery at the turn of the twentieth century and allowed surgeons to successfully operate in the abdomen. However, evidence has accumulated over the past 40 years repeatedly demonstrating that prophylactic NGT use after alimentary tract surgery is not necessary and may contribute to increased morbidity and hospital length of stay (LOS).

HISTORICAL PERSPECTIVE

Originally described by John Hunter in the eighteenth century as oil skin wrapped around whalebone, the NGT initially was used to feed liquid nutrients to the sick. The first description of a flexible

Occasionally, choice of local block or spinal anesthesia can be selected if safe and feasible. Patients who use CPAP should also be encouraged to bring their own machine into the hospital for use. Finally, choice of multimodal and narcotic minimizing analgesia to mitigate risks of opioid-induced respiratory depression should be considered.

Recommendations

- Clinical screening for OSA in all patients, as majority of cases are undiagnosed
- If screening positive, informed discussion of risks and benefits of proceeding with surgery versus sleep specialist referral
- Inform anesthesia colleagues of OSA status before operation so anesthetic plan can be optimized

Diabetes Mellitus

Type 2 diabetes mellitus is an increasingly common condition affecting 30.3 million or 9.4% of the US population according to the American Diabetes Association. Of these, 7.2 million are undiagnosed. For surgical patients, hemoglobin A_{1C} (HbA_{1C}) greater than 8% is associated with postoperative infectious complications such as pneumonia, surgical site/wound infection, and sepsis. Additionally, diabetics usually have longer hospital lengths of hospital stay. Diabetics are also more likely to have other comorbidities such as cardiovascular disease, obesity, and renal disease.

For patients with known diabetes, HbA_{1C} should be drawn within 3 months of the planned operation. If this value is greater than 8%, the patient should be referred back to their managing clinician for medication optimization. If hyperglycemia is discovered on routine preoperative labs, drawing a HbA_{1C} and referral to primary care physician or endocrinologist for management is warranted. There is no evidence for routine blood glucose level screening independent of the procedure-specific preoperative labs for average-risk patients.

In the immediate postoperative period, glucose levels should be closely monitored for diabetic patients. Goal blood glucose levels are less than 140 mg/dL for stable patients and less than 180 mg/dL for critically ill patients. Given the stresses of surgery and periods of fasting, blood glucose levels can vary widely. Therefore, most clinicians will convert oral medications to a sliding scale insulin formulation and reduce long-acting insulin doses. The exact changes are dependent on the anticipated postoperative course and patient-specific factors. Before discharge, patients should be converted back to their baseline diabetic medications unless otherwise contraindicated. Management of patients with type 1 diabetes is beyond the scope of this chapter. Expert consultation is recommended if the surgical team is not familiar with management of this condition.

Recommendations

- Referral of surgical patient to primary care physician or endocrinologist for glycemic optimization if preoperative HbA_{1C} greater than 8%
- Perioperative goal blood glucose level less than 140 mg/dL in stable patients and less than 180 mg/dL in critically ill patients

CONCLUSION

The perioperative period provides an unparalleled opportunity to impact the overall health of the surgical patient. Interventions at this time should be geared to not only optimize the chance of short-term operative success but also facilitate durable changes in the patient's life. Surgeons must recognize their pivotal role in this process and reach out to other providers for multidisciplinary action on comorbid conditions. IS NASOGASTRIC TUBE NECESSARY AFTER ALIMENTARY TRACT SURGERY?

Travis P. Webb, MD, MHPE

The nasogastric tube (NGT) historically has been used in the postoperative period for patients undergoing surgery on the alimentary tract. The long-standing belief held by many surgeons has been that nasogastric decompression allows the bowel to rest, prevents air and fluid accumulation, decreases postoperative nausea and vomiting, prevents abdominal distention, and protects the patient from aspiration, pneumonia, anastomotic leak, and fascial dehiscence. Pervasive use of NGTs coincided with significant advances in the administration of anesthesia, the development of germ theory and aseptic technique, and improvements in hemostasis that revolutionized surgery at the turn of the twentieth century and allowed surgeons to successfully operate in the abdomen. However, evidence has accumulated over the past 40 years repeatedly demonstrating that prophylactic NGT use after alimentary tract surgery is not necessary and may contribute to increased morbidity and hospital length of stay (LOS).

HISTORICAL PERSPECTIVE

Originally described by John Hunter in the eighteenth century as eel skin wrapped around whalebone, the NGT initially was used to feed liquid nutrients to the sick. The first description of a flexible

tube (Levin tube) used to decompress the gastrointestinal (GI) tract after surgery was in 1921 by American gastroenterologist Dr. Abraham Louis Levin. In 1926 Meltzer hypothesized that postoperative abdominal distension resulted from swallowed air, which could be prevented by an indwelling NGT. Despite the lack of scientific evidence to support the benefit of routine prophylactic NGT use after GI tract and abdominal surgery, it remained common practice into the twenty first century. Cuthbert and colleagues were the first to challenge prophylactic NGT use in 1958 when they published results showing that in their cohort of 600 patients with postoperative ileus, the half managed without an NGT had lower morbidity and mortality as well as fewer respiratory tract complications. Their data were nonrandomized but started the conversation that perhaps NGTs were not mandatory postoperatively. The first prospective randomized trial comparing patients with ulcers, anastomoses was published in 1084, and although it showed no difference in complication rates between patients with and without NGTs, it was limited by small sample size and too much heterogeneity.

Cheatham and colleagues published the first meta analysis on the topic in 1995. Their study included 26 clinical trials (3968 patients) that compared the use of selective versus routine NGT decompression after elective laparotomy. Routine use was defined as an NGT placed preoperatively or intraoperatively that remained in place until an unspecified point in the patient's postoperative course (usually return of bowel function, flatus, or decreased output). Selective use was defined as either no NGT used or an NGT placed intraoperatively but removed in the operating room or in the recovery room and replaced only if the patient developed the need for decompression clinically in the postoperative course. The authors demonstrated a significantly lower rate of overall complications as well as a decreased incidence of postoperative pneumonia, aspiration, and fever. There was no significant difference between groups in the incidence of anastomotic leak, wound infection, wound dehiscence, or LOS. The authors reported that 30.5 patients could be spared nasogastric decompression for every 1 patient who required NGT reinsertion postoperatively. The main limitation of their meta analysis was that it included a large number of nonrandomized studies.

In the 20 years since that first meta analysis, numerous randomized controlled trials and subsequent meta analyses have repeatedly shown that prophylactic NGT decompression after surgery on the abdomen does not afford the benefits ascribed to it by surgical dogma. In fact, the majority of studies indicate that the liberal use of an NGT prolongs hospital postoperative LOS and actually increases the risk of certain complications, especially respiratory complications. A 2010 Cochrane review excluding laparoscopic abdominal surgery identified 27 studies (3211 patients) and showed that prophylactic NGT decompression is ineffective at (1) hastening return of bowel function, (2) decreasing risk of aspiration and subsequent pulmonary complications, (3) improving patient comfort by lessening abdominal distension, (4) protecting intestinal anastomoses from leakage, and (5) shortening hospital LOS. The use of NGTs also is associated with significant morbidity related to both placement and prolonged use, as well as significant patient discomfort.

Evidence based medicine has transformed all aspects of patient care, including surgical decision making, which traditionally was highly subjective, individualized, and primarily emulated the practice of prior master surgeons. The historical practice of prolonged bed rest, NGT decompression, and delay of oral intake to allow the alimentary tract time to heal and recover has been refuted repeatedly in the scientific literature. The 1980s and 1990s saw significant advances in perioperative pain control and minimally invasive surgical techniques that aimed at other outpatient or reduced LOS surgery. The Danish surgeon Henrik Kehlet pioneered the idea of fast track surgery in the 1990s, with the intent of developing a multidisciplinary approach to reduce surgical stress and achieve a smoother and faster recovery. This move toward streamlining care has proven successful and beneficial to patients, providers, and society. One of the cornerstones of surgical care to be eliminated by fast track pathways is the prophylactic use of NGTs.

COLORECTAL SURGERY AND ENHANCED RECOVERY AFTER SURGERY

Fast track surgery, as described by Kehlet, perhaps has been most successfully translated into colorectal surgery, specifically elective surgery for colorectal cancer (CRC). Enhanced recovery after surgery (ERAS) pathways significantly reduce postoperative morbidity and decrease LOS and healthcare expenditures. Consensus ERAS Society guidelines developed in 2005 and updated most recently in 2017 have become the standard of care for colorectal surgery. The current guidelines include 24 recommendations for preoperative, perioperative, and postoperative care. The elements included in ERAS for colorectal surgery focus on ensuring appropriate preadmission counseling, utilizing prehabilitation, avoiding prolonged fasting, providing carbohydrate loading, using appropriate antibiotic and thromboembolic prophylaxis, using short acting anesthetic agents and optimal analgesia, maintaining euvolemia with balanced resuscitation, preventing nausea and vomiting, and using postoperative early mobilization and nonopioid analgesia. In addition, the use of laparoscopic or laparoscopic assisted technique should be the first choice when appropriate.

Another critical component of ERAS is early resumption of oral nutrition by offering patients a regular diet immediately after surgery. A 2010 publication titled "The Evidence Against Prophylactic Nasogastric Intubation and Oral Restriction" reviews the current literature surrounding prophylactic NGT decompression in colorectal surgery. The study provides evidence that prophylactic NGT decompression (1) does not improve time to return of bowel function or LOS (in some studies it prolongs time to flatus and LOS); (2) does not reduce the incidence of anastomotic leak, wound infection, dehiscence, or incisional hernia; (3) does not prevent pulmonary complications of fever, atelectasis, or aspiration pneumonia and likely promotes pulmonary complications; and (4) does not prevent abdominal discomfort as measured by nausea, vomiting, or distension (and NGT reinsertion rates are low). The study also argues that early feeding, which is tolerated by 80% to 90% of patients within 24 hours after colorectal surgery, (1) enhances recovery time and decreases LOS; (2) reduces the risk for any type of postoperative infection; (3) decreases the risk for hyperglycemia; and (4) results in no difference in duration of ileus, although it does increase risk for vomiting.

For ERAS pathways to realize the expected benefits on patient outcomes there must be significant collaboration, buy in, and communication between all members of the healthcare team—surgeon, anesthesiologist, patient, nurses, and others. Compliance with the steps of the pathway cannot be assumed, and studies have found that adherence rates drop over time without repetitive education of staff. A web based survey of colorectal and general surgeons found that only about 30% were actively following a perioperative protocol for elective bowel resections. With regard to NGT removal, 61% reported avoidance of NGT completely and 15% reported removal of NGT on postoperative day zero. Another study found that despite the development of a multidisciplinary fast track protocol and training sessions for all staff, only 3 of the 7 key elements of the pathway met 80% compliance after implementation. The authors hypothesized that more time is needed to overcome the deep seated beliefs taught by tradition. This study and others highlight the need for continued monitoring of compliance with ERAS pathways and evidence based medicine.

FOREGUT AND PANCREATIC SURGERY

Whereas ERAS pathways after colorectal surgery have become widely utilized, the introduction of fast track protocols for upper GI

tract and pancreatic surgery has only gained traction over the past few years. As expected, there is often hesitation by surgeons regarding early removal of NGTs and earlier oral feeding after an esophagectomy, gastrectomy, or pancreaticoduodenectomy (Whipple's procedure). This is because of concern over the integrity of the anastomosis as well as the duodenal stump and, especially in the case of pancreaticoduodenectomy, the fact that multiple enteric anastomoses are involved. Traditional surgical training has taught that an NGT is necessary after an esophagectomy to prevent overdistention of the gastric conduit, protect the esophagogastric anastomosis from dehiscence, and prevent vomiting and aspiration. Surgeons also harbor concern that feeding too early after a pancreaticoduodenectomy will increase the risk of pancreatic leak and fistula formation.

Recently, a number of studies examining ERAS programs after elective esophagectomy have been published. In most of these studies the NGT is removed on postoperative day 2, and some studies forego NGTs altogether. A 2017 review of the literature and meta-analysis including 7 studies and 688 patients found no significant difference in rates of anastomotic leak, pulmonary complications, or mortality. Included in this meta-analysis was one study that found no difference in complication rate or in admission rate when comparing an ERAS study group of 103 patients, in which the NGT was removed on postoperative day 2, with a historical control group of 78 patients. Furthermore, another study that compared early removal (postoperative day 2) with delayed removal (postoperative days 6 to 10) found no difference in pulmonary complications, anastomotic leak rates, need for reintubation, mortality, or LOS between groups. The authors did note that patient discomfort scores were higher in the delayed removal group and that only about 10% of patients required NGT reinsertion for postoperative ileus, with no complications from reinsertion despite the fresh anastomosis. They concluded that early removal is safe and affords two-thirds of patients relief of NGT discomfort early in the postoperative course.

The ERAS Society has published official consensus guidelines for fast track care after gastrectomy for gastric cancer (2016) and after pancreaticoduodenectomy (2013). The guidelines after gastrectomy are based on nine randomized controlled trials and two meta-analyses and present strong evidence against the routine use of NGTs. The cited studies repeatedly have shown no difference in time to flatus, anastomotic leaks, pulmonary complications, morbidity, or mortality, and many demonstrated a longer LOS in patients with routine NGT decompression compared with those without an NGT postoperatively. The guidelines after pancreaticoduodenectomy also recommend against routine NGT decompression. The most common complication after a pancreaticoduodenectomy is delayed gastric emptying (DGE), which occurs in up to 30% of patients. Multiple studies comparing a fast track program with historical controls actually have demonstrated that DGE rates are higher when routine NGT decompression is used.

EMERGENCY SURGERY AND NASOGASTRIC TUBES

The data for fast track protocols and use of NGT in emergency abdominal surgery are sparse, however, in the absence of bowel obstruction or the need for NGT for gastrointestinal access there is no evidence to support routine use of NGT. One single institution study of emergency abdominal surgery randomized 367 patients to early oral feeding (soft diet given within 24 hours) and left to a traditional care pathway. The traditional care group of patients was further stratified as high risk (evidence of peritonitis, GI tract obstruction or perforation, or an anastomosis) and placed on nothing by mouth status for 3 days postoperatively or as low risk (none of the high risk criteria) and given liquids and then a soft diet once they passed either flatus or stool. The authors found no difference between the early and traditional groups in complication rate, LOS, or need for reoperation. The early feeding group did experience a significant increase in postprandial vomiting; however, there was no difference in the need for NGT reinsertion between any of the groups.

Another institution performed a prospective randomized trial to evaluate the safety and efficacy of ERAS pathways after emergency laparoscopic surgery for perforated peptic ulcer disease (excluded if ulcer >10 mm). The 21 patients assigned to the ERAS group had their NGT removed in the operating room and were given liquids on postoperative day 1. The control group had their NGT removed only after the output was less than 300 mL a day. The study demonstrated no difference in morbidity or mortality and a significantly shorter LOS for the ERAS group (5.8 vs 8.9 days). However, the exclusion criteria were numerous—American Society of Anesthesiologists class 3 or 4, evidence of septic shock, conversion to an open procedure, and others—which limits the generalizability of the results. Finally, a study in Nepal randomized 115 patients after emergency laparotomy for perforation with peritonitis, intestinal obstruction, or abdominal trauma to two groups with or without an NGT postoperatively. The authors found no difference in the rate of wound complications, gastric ileus, respiratory complications, anastomotic leaks, or NGT reinsertions. Similarly, they demonstrated a shorter LOS in the group managed without an NGT.

COMPLICATIONS OF NASOGASTRIC TUBES

Avoiding unnecessary morbidity from NGT complications is another matter to urge routine NGT decompression. Complications can occur during the placement of an NGT or as a result of prolonged NGT use. Some adverse effects, such as patient pain and discomfort, sinusitis, epistaxis, and pharyngeal pain, are likely under-recognized and under-reported. Despite the seemingly simple technique for insertion, serious complications can arise from misplaced NGTs. Pneumothorax, even a tension pneumothorax, can occur from inadvertent tracheobronchial intubation. Pharyngeal, esophageal, duodenal, and other GI tract perforations have been reported. Intracranial placement of NGTs also has been observed; thus, care must be taken when inserting an NGT in a patient with basilar skull fractures or significant maxillofacial trauma.

Prolonged use can lead to esophageal strictures, nasal ulcerations, and NGT syndrome—ulceration and infection in the posterior cricoid region that causes vocal cord dysfunction and may seriously compromise a patient's airway. Other described complications include middle ear effusions, phlebitis, hypesthesia, aspiration, bleeding, esophageal obstruction from a tangled NGT, incarceration of an NGT into a GI tract anastomosis, reflux, tracheal rupture, arteroesophageal fistula, tracheoesophageal fistula, intramural esophageal dissection, cleft nose deformity, and retropharyngeal infected hematoma.

WHY ARE SURGEONS STILL ROUTINELY USING NASOGASTRIC TUBES?

Despite the preponderance and strength of the scientific evidence against routine NGT decompression after alimentary tract surgery, it is still relatively common for surgeons to leave NGTs in place after a variety of abdominal surgeries. Why is this the case? The answer is likely multifactorial. Perhaps there is a lack of awareness of the current evidence among practicing surgeons. Possibly surgeons are aware of the evidence but do not believe that the results are generalizable to their patient population. It is also likely that many surgeons, even today, tend to base their clinical practice and decision making on the anecdotal experience of their senior teachers or partners rather than on scientific evidence. However, in the absence of bowel obstruction, ileus, or the need for enteral feeding access, the use of NGTs is unnecessary and likely detrimental to optimal outcomes.

CONCLUSION

Routine prophylactic NGT decompression of the GI tract after surgery is not supported by data and is not recommended. Many studies have now demonstrated the safety and efficacy NGT removal immediately post-operatively and initiation of early feeding. The NGT remains an important tool in the surgeon's armamentarium as therapy in the setting of a bowel obstruction or postoperative ileus with vomiting and as a conduit to provide medications and enteral nutrition. Although much progress has been made in the past several years, further work is needed to decrease the utilization of routine NGT use.

SURGICAL SITE INFECTIONS

Jaime A. Espinosa, MD, and Robert Sawyer, MD, FACS, FIDSA, FCCM

Surgical site infections (SSIs) are common postoperative complications, with an annual incidence of approximately 300,000 to 750,000 in the United States alone. They are an expensive burden on the world's economy. It is estimated that in the United States approximately $10,000 to $25,000 dollars are spent per SSI, leading to over $7 billion per year being spent on their management. Thus, within the past few years the Centers for Disease Control and Prevention (CDC), the American College of Surgeons (in conjunction with the Surgical Infection Society), and the World Health Organization (WHO) have published guidelines/recommendations on preventative strategies against surgical site infections based on evidence-based medicine. These are an update from previous recommendations, which were mostly based on expert opinion.

EPIDEMIOLOGY

SSIs occur in approximately 1% to 5% of patients worldwide. However, the incidence is likely underestimated as a large number of SSIs are diagnosed in the outpatient setting. The bacterial pathogens causing SSIs are closely monitored by the CDC via the National Healthcare Safety Network (NHSN). The NHSN is a surveillance system that was created in 2005 to closely track healthcare-associated infections, including antibiotic susceptibility. Interestingly, for SSIs, the percentage of Staphylococcus aureus that was oxacillin, methicillin, and/or cefoxitin resistant (i.e., methicillin-resistant Staphylococcus aureus) was relatively unchanged from 2011 to 2014 (~ 42.7% resistance in 2011 and 43.6% in 2014), while the percent of vancomycin resistant Enterococcus species went down from 68% to 58.4%. The most common bacteria isolated from SSIs from 1990 to 2014 are given in Table 1.

DEFINITION

SSIs are most commonly defined based on CDC definitions, which divide cases into superficial incisional, deep incisional, and organ space infections (Fig. 1 and Table 2).

RISK FACTORS

Risk factors for SSIs have been extensively studied and identified. They include both patient related factors and non-patient related factors as seen in Table 3.

CLASSIFICATION

Surgical wounds are assessed based on the classification system listed below, which was created by the CDC in 1999 (Table 4). Previous data suggested a much higher risk of surgical site infection with surgical wounds, with class IV (dirty) wounds having greater than 27% risk of becoming infected. However, more recent data have displayed a much lower risk, with class IV (dirty) wounds having a 5.1% to 8.5% risk of SSI.

PREVENTION

The increasing number of surgical procedures and the fact that perhaps 60% of SSIs are avoidable has increased the focus on SSI prevention. Thus, the CDC, the WHO, and the American College of Surgeons (in conjunction with the Surgical Infection Society) have recently published guidelines on preoperative, intraoperative, and postoperative recommendations for SSI prevention. The GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) system was used to evaluate the validity and strength of the CDC and WHO published guidelines (Tables 5 and 6).

TREATMENT

All surgical wounds with clinical evidence of infection (calor [heat], dolor [pain], rubor [redness], and/or tumor [swelling]), as first described by the Roman encyclopedist Aulus Cornelius Celsus, should be opened, debrided, cultured, and packed with a wet to dry or vacuum-based dressing. The wound should be fully explored for underlying abscesses, fluid collections, necrotizing infection, debris, and enteric contents. In addition, all necrotic and infected tissue should be meticulously debrided down to healthy bleeding tissue, and the wound should be thoroughly irrigated with normal saline.

The use of oral and intravenous antibiotics is recommended based on the United Kingdom's National Institute for Health and Care Excellence (NICE) surgical site infection guidelines. These antibiotics should be tailored based on wound cultures and local/regional

CONCLUSION

Routine prophylactic NGT decompression of the GI tract after surgery is not supported by data and is not recommended. Many studies have now demonstrated the safety and efficacy NGT removal immediately post-operatively and initiation of early feeding. The NGT remains an important tool in the surgeon's armamentarium as therapy in the setting of a bowel obstruction or postoperative ileus with vomiting and as a conduit to provide medications and enteral nutrition. Although much progress has been made in the past several years, further work is needed to decrease the utilization of routine NGT use.

The bacterial pathogens causing SSIs are closely monitored by the CDC via the National Healthcare Safety Network (NHSN). The NHSN is a surveillance system that was created in 2005 to closely track healthcare-associated infections, including antibiotic susceptibility. Interestingly, for SSIs, the percentage of Staphylococcus aureus that was oxacillin, methicillin, and/or cefoxitin resistant (i.e., methicillin-resistant Staphylococcus aureus) was relatively unchanged from 2011 to 2014 (~42.7% resistance in 2011 and 43.6% in 2014), while the percent of vancomycin resistant Enterococcus species went down from 68% to 58.4%. The most common bacteria isolated from SSIs from 1990 to 2014 are given in Table 1.

DEFINITION

SSIs are most commonly defined based on CDC definitions, which divide cases into superficial incisional, deep incisional, and organ space infections (Fig. 1 and Table 2).

RISK FACTORS

Risk factors for SSIs have been extensively studied and identified. They include both patient related factors and non-patient related factors as seen in Table 3.

CLASSIFICATION

Surgical wounds are assessed based on the classification system listed below which was created by the CDC in 1999 (Table 4). Previous data suggested a much higher risk of surgical site infection with surgical wounds with class IV (dirty) wounds having greater than 27% risk of becoming infected. However, more recent data have displayed a much lower risk, with class IV (dirty) wounds having a 5.1% to 8.5% risk of SSI.

PREVENTION

The increasing number of surgical procedures and the fact that perhaps 60% of SSIs are avoidable has increased the focus on SSI prevention. Thus, the CDC, the WHO, and the American College of Surgeons (in conjunction with the Surgical Infection Society) have recently published guidelines on preoperative, intraoperative, and postoperative recommendations for SSI prevention. The GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) system was used to evaluate the validity and strength of the CDC and WHO published guidelines (Tables 5 and 6).

TREATMENT

All surgical wounds with clinic evidence of infection (calor [heat], dolor [pain], rubor [redness], and/or tumor [swelling]), as first described by the Roman encyclopedist Aulus Cornelius Celsus, should be opened, debrided, cultured, and packed with a wet to dry or vacuum based dressing. The wound should be fully explored for underlying abscesses, fluid collections, necrotizing infection, debris, and enteric contents. In addition, all necrotic and infected tissue should be meticulously debrided down to healthy bleeding tissue, and the wound should be thoroughly irrigated with normal saline.

The use of oral and intravenous antibiotics is recommended based on the United Kingdom's National Institute for Health and Care Excellence (NICE) surgical site infection guidelines. These antibiotics should be tailored based on wound cultures and local/regional

TABLE 1 Percentage Distribution of Most Common Bacteria to Cause Surgical Site Infections Based on National Healthcare Safety Network Data

	2006–2008	2009–2010	2011–2014
Staphylococcus aureus	30%	30.4%	20.7%
Escherichia coli	9.6%	9.8%	13.2%
Coagulase-negative staphylococci	13.7%	13.2%	7.9%
Enterococcus faecalis	11.2%	11.6%	7.5%
Pseudomonas aeruginosa	5.6%	5.5%	5.3%
Klebsiella (previously Enterobacter) species	3%	4%	4.7%
Enterococcus species	4.2%	5%	4.4%

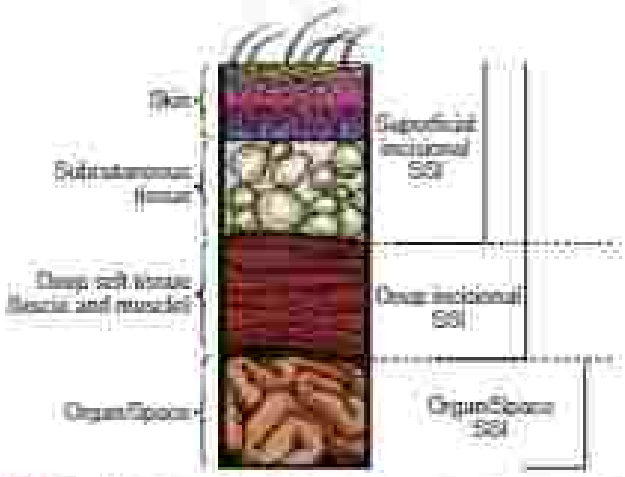

FIG. 1 Pictorial depiction of surgical site infections [illegible]

TABLE 2 Surgical Site Infection (SSI) Definitions

	Definition
Superficial incisional SSI	Infection that occurs within 30 days of surgery and includes only the skin and subcutaneous tissue of the incision. Plus at least ONE of the following: • Purulent drainage, with or without laboratory confirmation, from the superficial incision • Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision • At least one of the following signs/symptoms of infection and superficial incision is deliberately opened by the surgeon (unless incision is culture negative or not cultured) • Pain, tenderness, localized swelling, redness, or heat • Diagnosis made by surgeon or attending physician The following are not considered superficial incisional SSIs: • Stitch abscess (minimal inflammation and discharge confined to the points of suture penetration) • Infection of an episiotomy or newborn circumcision site • Infected burn
Deep incisional SSI	Infection that occurs within 30 days after the operative procedure if no implant is left in place or within 1 year if implant is left in place and the infection appears to be related to the operative procedure and infection involves deep soft tissues (i.e., fascial and muscle layers) of the incision, and at least one of the following is present: • Purulent drainage from the deep incision, but not from the organ/space component of the surgical site • A deep incision spontaneously dehisces or is deliberately opened by a surgeon when the patient has at least one of the following signs or symptoms: • Fever (>38°C), localized pain or tenderness, unless culture of the incision is negative • An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination • Diagnosis made by surgeon or attending physician
Organ space SSI	Infection that occurs within 30 days after the operative procedure if no implant is left in place or within 1 year of implant is left in place and the infection appears to be related to the operative procedure and infection involves any part of the anatomy (i.e., organs or spaces) other than the incision, which was opened or manipulated during the operation and at least one of the following is present: • Purulent drainage from a drain that is placed through a stab wound into the organ space • If the area around a stab wound becomes infected, it is NOT a SSI. It is considered a skin or soft tissue infection, depending on its depth. • Organisms isolated from an aseptically obtained culture of fluid or tissue from the organ space • An abscess or other evidence of infection involving the organ space on direct examination, during reoperation, or by histopathologic or radiologic examination • Diagnosis made by surgeon or attending physician

*Implant, nonhuman-derived implantable foreign body (i.e., prosthetic heart valve, nonhuman vascular graft, mechanical heart, or hip prosthesis) that is permanently placed in a patient during surgery.

From Horan TC, Gaynes RP, Martone WJ, et al. CDC definitions of nosocomial surgical site infections, 1992: a modification of CDC definitions of surgical wound infections. Infect Control Hosp Epidemiol. 1992;13(10):606–608.

TABLE 3 Surgical Site Risk Factors

	Risk Factors
Patient related • Nonmodifiable • Modifiable	Older age, recent radiotherapy, history of skin or soft tissue infection Diabetes, obesity, alcoholism, current smoker, immunosuppression, total bilirubin >1.0 mg/dL, preoperative albumin <3.5 mg/dL
Non patient related • Preoperative • Facility related • Procedure related	Inadequate antibiotic choice, timing, or dosing, inadequate skin preparation, glycemic control, surgical scrub, or hair removal method Inadequate ventilation, increased operating room traffic, nonsterile equipment Emergent procedure, complex procedure, high wound classification, long procedure, blood transfusion, breach in asepsis, poor glycemic control

Modified from Sun RA, Ishani IP, Carango G, et al. American College of Surgeons and Surgical Infection Society surgical site infection guidelines, 2016 update. J Am Coll Surg. 2017;224:59-74.

TABLE 4 Surgical Wound Classification

	Definition	Examples	Risk of Infection (1991)	Risk of Infection (2014)
Class I: clean	Surgical wound in which there is no breach of the respiratory, GI, GU, or genital tracts, and no inflammation is encountered.	Hernia repair (inguinal, femoral, ventral, incisional) Thyroidectomy CABG Mastectomy Laminectomy Total knee replacement Total hip replacement Port placement Axillary lymph node dissection	1%–5%	1.8%–2.4%
Class II: clean contaminated	Surgical wound in which there is a controlled entrance of the respiratory, GI, GU, or genital tracts without a major break in sterile technique.	Small bowel resection Lobectomy (lung) Hysterectomy Colectomy Colostomy reversal Roux en Y gastric bypass Whipple procedure Laryngectomy TURP	3%–11%	4.8%–6.7%
Class III: contaminated	Surgical wound that is open, fresh (less than 4 hours old), and/or accidental with a major break in sterile technique and/or uncontrolled gross spillage from the GI tract. Surgical wound in which acute, nonpurulent inflammation is met.	Cholecystectomy for acute cholecystitis Appendectomy for nonperforated appendicitis Nonsterile equipment or debris found on operative field Small bowel resection for infarcted or necrotic bowel	10%–17%	5.6%–8.6%
Class IV: dirty/infected	Surgical wound that is old (>4 hours old), and/or accidental/traumatic with a major break in sterile technique and/or uncontrolled gross spillage from the GI tract.	Peritonitis Appendectomy for perforated appendicitis Repair of perforated gastric ulcer Repair of perforated small bowel Open fracture repair	>27%	8.5%–13.8%

GI, Gastrointestinal; GU, genitourinary; TURP, transurethral resection of the prostate.

TABLE 5 ACS/SIS, CDC, and WHO Guidelines for Surgical Site Infection Prevention

Recommendation	Agency	GRADE
Administer preoperative antibiotics only when indicated based on published clinical practice guidelines and timed such that a bactericidal concentration is established in the serum and tissues when the incision is made. Refer to guidelines in Table 4.	ACS, CDC, WHO	Strong recommendation Low-quality evidence Accepted practice
Administer prophylactic IV antibiotics within 120 minutes before the incision while considering the half-life of the antibiotics. Antibiotics with a shorter half-life such as penicillin and cefazolin should be administered closer to incision time (within 60 minutes).	ACS, WHO	Strong recommendation Moderate-quality evidence
Administer prophylactic IV antibiotics prior to skin incision in all cesarean sections.	CDC	Strong recommendation High-quality evidence
Do not administer additional prophylactic IV antibiotics in clean and clean-contaminated cases after the incision has been closed, even in the presence of a drain. Also applies to prosthetic joint arthroplasty.	ACS, CDC, WHO	Strong recommendation High-quality evidence
Do not administer additional prophylactic IV antibiotics because of the presence of a wound drain. No evidence was found regarding optimal timing for drain removal.	WHO	Conditional recommendation Low-quality evidence
Do not apply antimicrobial agents to the surgical incision for SSI prevention (i.e., ointments, solutions, or powders). In addition, do not irrigate surgical wounds intraoperatively with antibiotic solutions (can lead to antibiotic resistance, WHO).	ACS, CDC, WHO	Strong recommendation Low-quality evidence
Administration of autologous platelet-rich plasma is not necessary for SSI prevention.	CDC	Weak recommendation Moderate-quality evidence
Consider the use of triclosan-coated sutures for SSI prevention.	ACS, CDC, WHO	Weak recommendation Moderate-quality evidence
Glycemic control: Implement perioperative glycemic control protocols in both diabetic and nondiabetic patients. CDC recommends blood glucose levels <200 mg/dL. ACS recommends blood glucose levels between 110 and 150 mg/dL. Except in cardiac surgery (goal <180 mg/dL). The WHO does not have an optimal target concentration, instead they recommend intensive protocols to prevent hyperglycemia (which has been shown to also increase morbidity and mortality).	ACS, CDC, WHO	Strong recommendation High- to moderate-quality evidence
Normothermia: the use of warming devices to maintain perioperative normal body temperature is recommended for SSI prevention.	ACS, CDC, WHO	Strong recommendation High- to moderate-quality evidence
Patients with normal pulmonary function undergoing general anesthesia with endotracheal intubation for surgical procedures should receive 80% FiO_2 (hyperoxia) intraoperatively and in the immediate postoperative period.	ACS, CDC, WHO	Strong recommendation Moderate-quality evidence
Full-body shower or bath with soap (antimicrobial or nonantimicrobial) is advised on at least the morning before the operative day.	CDC, WHO	Strong recommendation Moderate-quality evidence Accepted practice
Perform intraoperative skin preparation with an alcohol-based antiseptic solution (based on chlorhexidine gluconate is recommended by the WHO), unless contraindicated.	ACS, CDC, WHO	Strong recommendation High- to moderate-quality evidence
Application of a microbial sealant immediately after intraoperative skin preparation is NOT necessary for SSI prevention.	CDC, WHO	Weak recommendation Low-quality evidence
Plastic adhesive drapes with or without antimicrobial properties should not be used for SSI prevention.	CDC, WHO	Weak recommendation High- to moderate-quality evidence

TABLE 5 ACS/SIS, CDC, and WHO Guidelines for Surgical Site Infection Prevention—cont'd

Recommendation	Agency	GRADE
Consider intraoperative surgical wound irrigation with an aqueous iodophor povidone-iodine solution. Intraperitoneal lavage with aqueous iodophor solution is not recommended (CDC).	CDC, WHO	Weak recommendation Moderate quality evidence
It is not recommended to withhold transfusion of necessary blood products in an attempt to prevent SSI.	CDC	Strong recommendation Accepted practice
Normovolemic maintenance of adequate circulating blood volume via goal-directed fluid therapy is recommended.	WHO	Conditional recommendation Low quality evidence
Either sterile disposable nonwoven or sterile reusable woven drapes and surgical gowns may be used in surgery to prevent SSI.	WHO	Conditional recommendation Moderate- to low-quality evidence
Consider the use of wound protector devices (wound edge protectors) intraoperatively in clean contaminated, contaminated, and dirty abdominal surgeries to prevent SSI.	ACS, WHO	Conditional recommendation Very low-quality evidence
Consider the use of ciNPWT on primarily closed surgical incisions in high-risk wounds (bleeding, hematoma, intraoperative contamination, dead space, decreased blood flow, or skin or soft tissue damage) in order to prevent SSI.	WHO	Conditional recommendation Low-quality evidence
Laminar airflow systems should not be used to reduce SSI for patients undergoing total arthroplasty surgery.	WHO	Conditional recommendation Low- to very low-quality evidence
Advanced dressings, such as hydrocolloid, hydrogels, vapor-permeable films, etc., are NOT recommended over standard dressings on primarily closed surgical wounds.	WHO	Conditional recommendation Low-quality evidence
Do not discontinue immunosuppressive agents prior to surgery.	WHO	Conditional recommendation Low-quality evidence
Consider the use of oral or enteral multiple nutrient-enhanced formulas (arginine, glutamine, omega-3 fatty acids, and nucleotides) to underweight patients undergoing major surgeries for SSI prevention.	WHO	Conditional recommendation Very low-quality evidence
For orthopedic and cardiothoracic surgery patients, it is recommended that all patients who are known carriers of *Staphylococcus aureus* should receive perioperative intranasal applications of mupirocin 2% ointment with or without chlorhexidine gluconate body wash. Consider same treatment to patients who are known carriers and are undergoing other types of surgery. Conditional recommendation on moderate evidence (WHO).	ACS, WHO	Strong recommendation Moderate quality evidence
Preoperative oral antibiotics should be given with a MBP to adult patients undergoing elective colorectal surgery. MBP should NOT be used alone (without oral antibiotics) in these patients.	ACS, WHO	Strong recommendation Moderate quality evidence
Patients undergoing any surgical procedure should either not have their hair removed OR if absolutely necessary the hair should be removed using a clipper. Shaving is STRONGLY discouraged at all times, whether preoperatively or in the operating room.	ACS, WHO	Strong recommendation Moderate quality evidence
Surgical hand preparation should be done by either scrubbing the hands with antimicrobial soap and water or an alcohol-based hand rub solution prior to donning sterile gloves. Neither is superior to the other (ACS).	ACS, WHO	Strong recommendation Moderate quality evidence

ACS, American College of Surgeons; CDC, Centers for Disease Control and Prevention; FiO_2, fraction of inspired oxygen; N_2, nitrogen; MBP, mechanical bowel preparation; ciNPWT, prophylactic negative-pressure wound therapy; SSI, surgical infection society; WHO, World Health Organization.

TABLE 6 Recommendations for Antibiotic Prophylaxis Based on Surgical Procedure

Surgical Procedure	Recommended Antibiotic	Alternative for Patients With β-Lactam Allergy
Cardiac • Coronary artery bypass • Cardiac device insertion procedures (i.e., pacemaker) • Ventricular assist devices	Cefazolin or cefuroxime	Clindamycin or vancomycin
Thoracic • Lobectomy, pneumonectomy, thoracotomy, etc. • VATS	Cefazolin or cefuroxime	Clindamycin or vancomycin
Vascular	Cefazolin	Clindamycin or vancomycin
Gastroduodenal • Procedures involving entry into the GI tract (e.g., bariatric, Whipple procedure) • Procedures not involving entry into the GI tract (e.g., Nissen, vagotomy) for high-risk patients	Cefazolin	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone
Biliary tract:		
Open surgery	Cefazolin or cefotetan or cefotetan or cefuroxime or ampicillin-sulbactam	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone
Laparoscopic, elective	None	None
Laparoscopic, elective, high risk	Cefazolin or cefotetan or cefotetan or cefuroxime or ampicillin-sulbactam	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone
Small bowel:		
Nonobstructed	Cefazolin	Clindamycin + aminoglycoside or aztreonam or fluoroquinolone
Obstructed	Cefazolin + metronidazole or cefotetan or cefoxitin	Metronidazole + aminoglycoside or fluoroquinolone
Colorectal	Cefazolin + metronidazole or cefotetan or cefotetan or ampicillin-sulbactam Or cefotetan + metronidazole or erythromycin	Clindamycin + aminoglycoside or aztreonam or fluoroquinolone Or metronidazole + aminoglycoside or fluoroquinolone
Appendectomy for uncomplicated appendicitis	Cefotetan or cefoxitin or cefazolin + metronidazole	Clindamycin + aminoglycoside or aztreonam or fluoroquinolone Or metronidazole + aminoglycoside or fluoroquinolone
Hernia repair	Cefazolin	Clindamycin or vancomycin
Head and neck:		
Clean	None	None
Clean with placement of prosthetic (excludes tympanostomy tubes)	Cefazolin or cefuroxime	Clindamycin
Clean-contaminated with exception of tonsillectomy and functional endoscopic sinus procedures	Cefazolin + metronidazole Or cefuroxime + metronidazole or ampicillin-sulbactam	Clindamycin
Neurosurgery		
Elective craniotomy and CSF shunting procedures	Cefazolin	Clindamycin or vancomycin
Intraocular prosthesis implantation	Cefazolin	Clindamycin or vancomycin
Cesarean section	Cefazolin	Clindamycin + aminoglycoside

TABLE 6 Recommendations for Antibiotic Prophylaxis Based on Surgical Procedure—cont'd

Surgical Procedure	Recommended Antibiotic	Alternative for Patients With β-Lactam Allergy
Hysterectomy (vaginal or abdominal)	Cefazolin or cefoxitin or cefotetan or ampicillin sulbactam	Clindamycin Or vancomycin + aminoglycoside or aztreonam or fluoroquinolone Or metronidazole + aminoglycoside or fluoroquinolone
Ophthalmic	Topical neomycin polymyxin B gramicidin or fourth-generation topical fluoroquinolone	None
Orthopedic:		
Clean cases of hand, knee, or foot without implantation of foreign materials	None	None
Spinal procedures with or without instrumentation	Cefazolin	Clindamycin or vancomycin
Hip fracture repair	Cefazolin	Clindamycin or vancomycin
Implantation of internal fixation devices (i.e., nails, plates, screws)	Cefazolin	Clindamycin or vancomycin
Total joint replacement	Cefazolin	Clindamycin or vancomycin
Urologic:		
Lower tract instrumentation with risk factors for infection (includes transrectal prostate biopsy)	Cefazolin or fluoroquinolone or TMP/SMX	Aminoglycoside + clindamycin
Clean with entry into urinary tract	Cefazolin	Fluoroquinolone or aminoglycoside + clindamycin
Clean without entry into tract	Cefazolin	Clindamycin or vancomycin
Involving implanted prosthesis	Cefazolin + aminoglycoside Or cefazolin + aztreonam or ampicillin sulbactam	Clindamycin + aminoglycoside Or aztreonam Or vancomycin + aminoglycoside
Clean-contaminated	Cefazolin + metronidazole or cefoxitin	Fluoroquinolone Or aminoglycoside + metronidazole or clindamycin
Heart transplantation	Cefazolin	Clindamycin or vancomycin
Lung transplantation	Cefazolin	Clindamycin or vancomycin
Liver transplantation	Piperacillin tazobactam or Cefotaxime + ampicillin	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone
Pancreas transplantation and pancreas kidney transplantation	Cefazolin + fluconazole (for patients at high risk of fungal infection)	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone
Plastic surgery, clean with risk factors or clean-contaminated	Cefazolin or ampicillin sulbactam	Clindamycin or vancomycin

CSF, Cerebrospinal fluid; GI, gastrointestinal; "MRSA", methicillin-resistant Staphylococcus aureus; VATS, video-assisted thoracic surgery.
Based on guidelines developed by the American Society of Health-System Pharmacists (ASHP), the Infectious Diseases Society of America (IDSA), the Surgical Infection Society (SIS), and the Society for Healthcare Epidemiology of America (SHEA).

antifungal agents. Of note, the NICE recommends against the use of topical antibiotics for prevention and treatment of surgical site infections. The most appropriate duration of antimicrobial use is unclear and is frequently based on the severity of local and systemic inflammation.

The use of negative pressure wound therapy (NPWT), also known as a wound vacuum, is now considered an effective treatment to promote healing in open wounds. NPWT decreases local edema by extracting fluid out of the wound and promotes angiogenesis by promoting blood flow to the region. Within the last 20 years, NPWT has become a popular commodity for the treatment of infected wounds. Previously, NPWT was used mostly after the wound was clean and sutured; nowadays, however, the use of NPWT with instillation (NPWT-i) of normal saline, sodium hypochlorite, or 0.5% polyhexanide plus 0.1% betaine is commonly used for the acute treatment

of open abdominal SSIs. NPWT-i works by instilling one of these solutions into the wound, allowing the solution to dwell in the wound for a certain amount of time (called the dwell time), and finally removing the fluid with negative pressure. Much of the published literature on NPWT-i recommends the use of 0.1% polyhexanide plus 0.1% betaine based on its broad spectrum antibiotic activity. However, Kim et al. recently showed in a prospective, randomized effectiveness study that normal saline can work just as effectively, with a shorter time to a final surgical procedure.

SUMMARY

Surgical site infections are the commonest postoperative complication and the most expensive healthcare associated condition in the United States today. Diagnosis is frequently made on clinical grounds, and treatment should be prompt. Due to the importance of SSI, several evidence based prevention guidelines have recently been published. Future progress in the prevention and management of this condition will depend on optimizing the host immune response and understanding and controlling the bacterial pathogens that are frequently involved.

MANAGEMENT OF INTRA-ABDOMINAL INFECTIONS

Mahreen T. Khan, MD, MS, and Adil H. Haider, MD, MPH, FACS

CLASSIFICATION

Intraabdominal infections (IAIs) result from contamination and invasion of microorganisms into the sterile abdominal cavity. IAIs were traditionally categorized as primary, secondary, and tertiary infections. Primary IAIs occur due to invasion of the peritoneal cavity from a distant source or direct bacterial inoculation. This is commonly seen in patients with cirrhosis and ascites or immunocompromised hosts. Most of these infections are monomicrobial and do not require surgery. Secondary IAIs are seen in patients with perforation or severe inflammation of an intraabdominal organ such as appendicitis or diverticulitis. These can also occur due to contamination caused by perforation of hollow viscus or anastomotic leak. Most of these infections are polymicrobial and generally need to go to the operating room. Thus, secondary IAIs require prompt attention of a surgeon. Tertiary IAIs are due to persistent or recurrent infections and are usually seen in immunocompromised patients. These are most commonly sequelae of previous operative attempts to treat secondary IAIs. Tertiary IAIs are less well understood, are polymicrobial, and usually do not require surgery.

The new recommendations by the Surgical Infection Society (SIS) task force encourage differentiating patients with community-acquired intraabdominal infections (CA-IAI) from those with healthcare/hospital acquired intraabdominal infections (HA-IAI), to select appropriate treatment strategies. Within the CA-IAI group, patients should be divided into low risk and high risk categories. Identifying patients at high risk takes into account patient age, comorbid conditions, and physiologic derangements. There are scoring systems to differentiate between low risk and high risk patients. However, for individual patients, clinical judgment is equivalent to a scoring system. An example of a low risk patient is a 20 year old man with no comorbid conditions with perforated appendicitis. A high risk patient is defined as a patient who is at risk of treatment failure. Older age, comorbidities, immunosuppression, and presence of malignancy make a patient high risk (Fig. 1). Patients with HA-IAI are at an increased risk for infection with resistant or opportunistic organisms. The SIS has also developed criteria for identifying patients with healthcare- or hospital-acquired intraabdominal infection (see Fig. 1).

Classifying patients into one of these groups (low risk CA-IAI, high risk CA-IAI, or HA-IAI) helps optimize selection of antimicrobial therapy.

DIAGNOSIS

Presentation

Diagnosis of IAI should be suspected in any patient presenting with sepsis and gastrointestinal and/or genitourinary dysfunction. Obtaining a detailed history and physical examination are key. Patients can present with variable symptoms, most commonly with abdominal pain and fever. Other symptoms include nausea, abdominal distention, obstipation, and diarrhea. Past surgical history, especially recent interventions such as bowel resection and anastomoses are important to elucidate from the patient.

Physical examination can be challenging, as it is often nonspecific. Particular findings on examination may give clues for the underlying pathology. Pain out of proportion with physical exam is suspicious for ischemic bowel. Pain can be localized to a particular quadrant, such as the left lower quadrant, in uncomplicated diverticulitis of the sigmoid colon, or generalized when the infection has progressed, such as an anastomotic leak. Patients may also present with an unreliable physical examination, such as those with an altered mental status or an immunosuppression. In these patients, one should consider IAI if the patient presents with evidence of infection from an unknown source.

Vital signs may be within normal limits in a patient with localized infection. However, when the host's ability to contain the infection is overcome and the infection continues to progress, the patient may quickly progress to sepsis or septic shock.

of open abdominal SSIs. NPWT works by instilling one of these solutions into the wound, allowing the solution to dwell in the wound for a certain amount of time (called the dwell time), and finally removing the fluid with negative pressure. Much of the published literature on NPWT recommends the use of 0.1% polyhexanide plus 0.1% betaine based on its broad spectrum antibiotic activity. However, Kim et al recently showed in a prospective, randomized effectiveness study that normal saline can work just as effectively, with a shorter time to a final surgical procedure.

SUMMARY

Patients may also present with an unreliable physical examination, such as those with an altered mental status or an immunosuppression. In these patients, one should consider IAI if the patient presents with evidence of infection from an unknown source.

Vital signs may be within normal limits in a patient with localized infection. However, when the host's ability to contain the infection is overcome and the infection continues to progress, the patient may quickly progress to sepsis or septic shock.

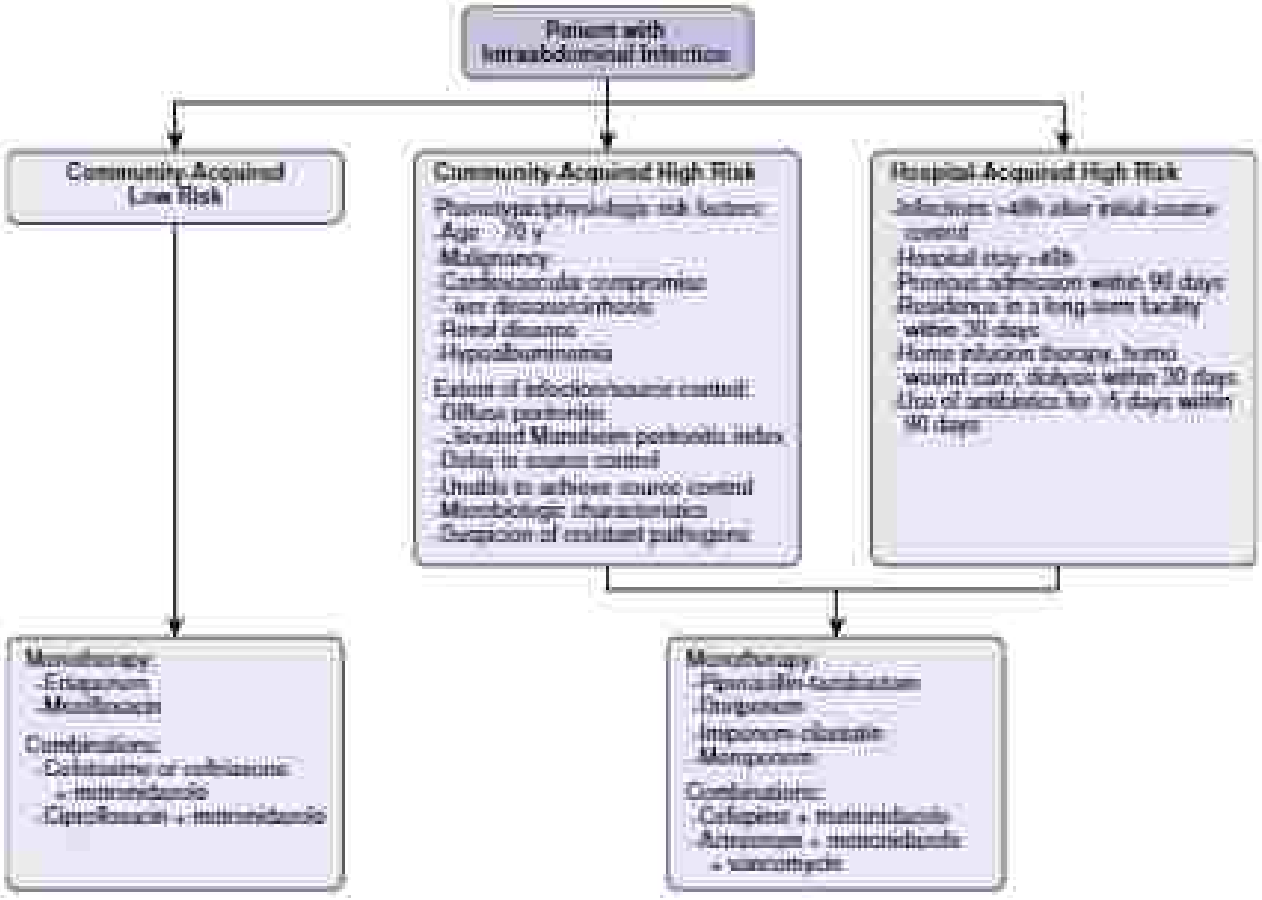

FIG. 1 Classification of intraabdominal infections and empirical antimicrobial regimens for community-acquired (low risk and high risk) and hospital-acquired IAIs. (Modified from Solomkin JS, Mazuski JE, Bradley JS, et al. Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America. Surg Infect (Larchmt). 2010;11(1):79–109.)

Diagnostic Workup

Laboratory tests such as complete blood count (CBC) and serum electrolyte levels are beneficial to determine potential bleeding and metabolic derangement. Liver function tests, amylase and lipase may be added if there is clinical suspicion of hepatobiliary or pancreatic pathology. In patients with sepsis, serum lactate levels need to be assessed. Blood, urine, and any catheter cultures should be obtained, but pending culture results should not delay therapy or treatment.

In a patient presenting with peritonitis, chest and abdominal radiographs may be the only tests needed before proceeding to the operating room for exploration. For example, in a patient with hollow viscus perforation, upright films are useful for identifying free air under the diaphragm.

Computed tomographic (CT) scan of the abdomen and pelvis with contrast is helpful in identifying the potential source of infection as well as in planning a potential surgical or radiologic intervention. Oral contrast helps to differentiate between bowel loops and intra-abdominal fluid collection. For example, in patients with perforated diverticulitis with an abscess, it can help delineate the abscess and guide subsequent drainage procedures. Intravenous (IV) contrast helps characterize inflammation, necrosis (such as liver or pancreas), and abscess wall. CT is also helpful in identifying small areas of pneumoperitoneum due to hollow viscus perforation, which may not be seen on plain films.

It is not necessary to perform a CT scan on every patient with IAI and different imaging modalities may be more beneficial in certain instances, such as acute biliary disease. In patients presenting with right upper quadrant (RUQ) pain, workup should include a RUQ ultrasound scan to evaluate the gallbladder. Biliary disease may require further imaging modalities such as magnetic resonance imaging. For female patients with right lower quadrant pain, a pregnancy test should be added to the diagnostic tests.

MANAGEMENT

The principles of treatment of IAIs are resuscitation, antimicrobial treatment, and source control. It is very important to recognize and manage IAIs aggressively, as delays in treatment can cause IAIs to progress to sepsis, shock and death. A thorough workup for identification of potential source and antimicrobial treatment should be pursued simultaneously. It is important not to withhold antimicrobial treatment while waiting for diagnostics such as microbial cultures as this may result in worse outcomes for the patient.

Resuscitation

This is a critical step in the management of IAI. Patients with IAI are susceptible to intravascular volume depletion. This can be assessed based on history and physical examination. For example, patients with appendicitis may present with nausea and vomiting causing metabolic alkalosis. Patients presenting with fever or increased respiratory rate have increased insensible fluid losses. In addition, patients with peritonitis have local and systemic fluid sequestration, which further contributes to intravascular volume depletion. High risk patients or those patients who appear to be decompensating should be managed in the intensive care unit. IV lines should be established. A Foley catheter should be placed to monitor and ensure adequate perfusion. If necessary, central venous access should be established to ensure appropriate resuscitation.

Nasogastric tubes should be considered in patients who are at risk of aspiration or have small bowel obstruction. If there is strong suspicion of a perforated gastric or duodenal ulcer, care should be taken when placing the tube. Placement of arterial lines may be beneficial in patients who require active titration of vasoactive substances or those in need of serial laboratory tests.

The 2016 Surviving Sepsis Campaign (SSC) Guidelines recommend the following goals for the first 3 hours after presentation: (1) measuring serum lactate levels, (2) obtaining blood culture, and (3) resuscitating with 30 mL/kg crystalloid for patients with hypotension or serum lactate levels 4 mmol/L or higher. The new sepsis guidelines also emphasize the following strategies for the first 6 hours after presentation: (1) frequently reassessing volume status and tissue perfusion in patients with persistent hypotension and/or initial lactate of 4 mmol/L or higher, (2) adding vasopressors for patients with persistent hypotension (mean arterial pressure <65 mm Hg), and (3) remeasuring lactate.

Antimicrobial Therapy

Antimicrobials should ideally be initiated within 1 hour of diagnosis of sepsis, according to the SSC Guidelines. Empirical broad-spectrum antimicrobials should be administered. The SIS and the Infectious Disease Society of America published recommendations on antibiotic choice for management of IAI in 2010. Since then, new challenges have arisen in the management of patients with IAIs, such as an aging population, sicker patients, increase in resistant bacteria and fungi, and the SIS revised their guidelines in 2017 to meet these needs. Categorizing patients with IAIs into low risk community acquired, high risk community acquired, or healthcare/hospital acquired groups can guide choice of antibiotics.

Within patients with CA IAI, low risk patients can be empirically treated with a single antimicrobial agent or combination therapy. Appropriate single agents are ertapenem and moxifloxacin. Options for combination therapy for low risk patients are metronidazole with cefazolin, cefuroxime, or ciprofloxacin. These antimicrobial agents have activity against microorganisms usually associated with these infections, including gram-negative Enterobacteriaceae, aerobic streptococci, and obligate anaerobes. The routine use of additional agents to provide antipseudomonal, antienterococcal or antifungal coverage is not recommended.

High risk CA IAI can also be empirically treated with single agent or combination therapy. Appropriate single agents are piperacillin-tazobactam, doripenem, meropenem, ceftazidime, moxifloxacin. Options for combination therapy for high risk patients are cefepime or combination with metronidazole or aztreonam in combination with metronidazole and vancomycin (in patients with a severe reaction to β-lactam agents). The flora of high risk patients with CA IAI is similar to those of lower risk patients. However, some high risk patients are infected with *Enterobacter* spp., *Pseudomonas aeruginosa*, and *Bacteroides* spp. These organisms are resistant to narrower-spectrum antimicrobials used in low risk patients. Thus, it is recommended to use broader spectrum empirical antimicrobial agents (see Fig. 1). The use of ampicillin or vancomycin for empirical antimicrobial treatment should be considered in high risk patients not being treated with piperacillin-tazobactam or meropenem-vaborbactam. The use of antifungal agents for empirical treatment is not recommended. It should be considered for critically ill patients with an upper gastrointestinal source.

Patients with HA IAI are at risk for infection from resistant or opportunistic organisms. At minimum, patients with HA IAI should be empirically treated with broader spectrum therapy recommended for CA IAI high risk patients. Each patient should also be assessed for their risk of infection with *Enterococcus* spp., methicillin-resistant *Staphylococcus aureus*, resistant gram-negative bacilli, and *Candida* spp., and empirical treatment provided accordingly. It is also important to know the local trends of antimicrobial susceptibility to help guide treatment of HA IAIs. Appropriate single agents are piperacillin-tazobactam or a broad-spectrum carbapenem. Options for combination therapy are cefepime plus metronidazole, ceftolozane plus metronidazole, or aztreonam plus metronidazole plus vancomycin. Other agents should be added to this basic regimen based on individual patient's assessment for resistant gram-positive, resistant gram-negative, or fungal pathogens.

The duration of antibiotics is debatable. New data support limiting antimicrobial treatment to 4 days in patients who have had adequate source control. In patients who have not had definitive source control, antimicrobial treatment can be continued for 5 to 7 days. Antimicrobial therapy should be changed based on culture results in selected patients. For low risk CA IAIs, antimicrobial therapy does not need to be changed in patients who have had a good clinical response to source control and empirical treatment. For high risk CA IAIs, antimicrobial therapy should be deescalated once culture results are available.

Source Control

The basic principles of source control are to eliminate infectious foci, control ongoing peritoneal contamination and restore anatomic and physiologic function. Majority of IAIs require an intervention in addition to antimicrobial treatment. The exception is patients with clinical problems for which there is evidence that nonintervational approach is associated with better outcomes. Source control should be achieved by the least invasive approach in a patient with IAI.

The use of percutaneous drainage to achieve source control results in significantly less physiologic alterations for the patient and can possibly eliminate or reduce the need for a surgical intervention. CT guided percutaneous drainage is useful in perforated appendicitis with an abscess or complicated diverticulitis. It is important for the surgeon to be involved in the care of the patients with IAI, even when patients are treated with percutaneous drainage initially, as additional therapy may be needed if repeat imaging shows worsening collections or the patient decompensates. In such patients, laparotomy may still be necessary for source control.

Surgical intervention should ensure complete removal of affected tissue. Any infected fluid collection or abscess should be completely evaluated. Necrotic tissue should be debrided until viable tissue is seen. If there is an anastomotic leak, a diversion should be considered. An abbreviated laparotomy and temporary abdominal closure should be done in critically ill patients if closing the abdomen results in significant intraabdominal hypertension, if the patient is hemodynamically unstable, if source control cannot be achieved in the index operation, or if a second look laparotomy is planned in patients with mesenteric ischemia. Routine planned reoperations should be avoided if source control is adequate. Thus, patients should be treated with on-demand instead of scheduled reoperations.

CONCLUSION

IAIs occur due to contamination and invasion of microorganisms into the sterile abdominal cavity. IAIs should be evaluated for risk of adverse outcomes to guide resuscitation, selection of antimicrobial therapy, and source control. Early intervention improves outcomes.

Epidemiology, Prevention, and Management of Occupational Exposure To Bloodborne Infections

Ethel D. Weld, MD; and Samuel Shoham, MD

Each year, there are 600,000 to 800,000 reported cases of occupationally related percutaneous injuries among US healthcare workers. Human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV) are by far the most important bloodborne pathogens to which healthcare workers (HCWs) might be exposed. At one academic medical center, on the general surgery service, 20% to 30% of operative cases were found to involve patients infected with HBV, HBV, or HCV. This chapter will focus on these three viruses. With careful attention to the epidemiologic risks at hand, knowledge of current guidelines, and timely evaluation by clinicians with expertise on the topic, the harm from such exposure can be minimized or averted entirely. Major gains have been made over the past several decades in prevention of occupational bloodborne infection transmission. Safer medical equipment has reduced sharps injuries, robust universal HBV vaccination programs have reduced the number of occupationally acquired cases of HBV from 17,000 annually in 1983 to 263 cases in 2010, and occupationally transmitted HIV has been all but eliminated. Nonetheless, occupational exposures remain a common problem, and it is estimated that each year over 300,000 HCWs sustain a percutaneous sharps injury. Moreover, complacency on the part of HCWs and facilities must be avoided to avoid preventable harm to HCWs.

While exposure can happen in virtually any site where health care is delivered, there are certain scenarios where risk is particularly high. Sharps injuries are twice as common at teaching hospitals compared with nonteaching facilities; the operating room and postanesthesia units are the highest risk settings. Nurses are at highest risk, accounting for nearly half of cases, followed by residents, fellows, and attending surgeons. Junior clinicians with less experience and/or who are fatigued are more likely to be exposed. The annual rate of percutaneous exposure for trainees is ~20% and nearly all (99%) surgical residents sustain at least one needlestick injury by the end of their training, with the mean of 7.7 total injuries sustained by the fifth postgraduate year.

Victims of such exposure frequently feel a range of emotions including anxiety, posttraumatic stress disorder, fear, embarrassment, anger, and even a sense of betrayal by the profession to which they have devoted themselves. This is further compounded by rates of reporting of such exposures of approximately 50%. Fear of being reprimanded, concerns regarding confidentiality of the process, and time constraints have been identified as possible reasons for this. Out of concern for both employee health and patient safety, institutions must ensure that their staff and trainees are knowledgeable about what to do in case an exposure has happened and that there are practical mechanisms in place to help them access postexposure care in a timely and efficient fashion. In addition, occupational health practices that interface with surgeons directly in or immediately outside of operating rooms are a practical stepping measure while working to change a surgical culture that strongly discourages scrubbing out of cases at the time of needlestick. The champions for improving the safety of surgical trainees can and should include attending surgeons at the highest levels, particularly those present in the operating room at the time of a needlestick injury.

Complacency about risks of bloodborne disease after percutaneous or mucocutaneous exposure must be vigilantly guarded against, both from an employee safety and patient safety perspective. It is true that the rate of perioperative transmission of HBV and HCV is low across populations of HCWs, but this is only true because of decades of concerted effort and policy to safeguard the occupationally exposed. Furthermore, a HCW facing an accidental needlestick or other percutaneous injury should rightly be far less concerned with population health statistics than with the individual particulars (ie, of the exact source patient and viruses) involved, some of which can escalate that HCW's risk dramatically over that estimated in epidemiologic trends. It is also true that HBV cannot be transmitted to HBV immune individuals, which is reassuring in the era of universal HBV vaccination for HCWs. However, 10% to 20% of vaccinated individuals are immune nonresponders (by some estimates, even higher), often without being aware of this, and these individuals are at risk of occupational transmission of HBV—also a chronic, incurable, and deadly disease. Of paramount importance is that the decision about reporting and managing exposures should be taken out of the hands of the exposed individual, who is likely to be in the throes of numerous external stressors.

EPIDEMIOLOGY

Assessment of an occupational exposure to bloodborne infection should start with an assessment of the level of risk of the individual exposure. Knowledge of the relative risk of infectious transmission after an exposure can often be reassuring to the exposed individual (Figures 1 and 2).

The following factors are critical determinants of whether transmission will occur after exposure to a bloodborne pathogen (see also Box 2):

- The pathogen: HBV is by far the most transmissible bloodborne pathogen, with rates of developing clinical hepatitis in unvaccinated individual being as high as 30% and serologic evidence of HBV infection that are twice those (Fig. 1). This far exceeds those of HCV and HIV, which are as low as 0.2% and 0.3%, respectively, for percutaneous exposures.
- The inoculum (determined by the following factors):
  - Amount of circulating virus in the source patient's body
    - Among individuals who have detectable HBV e antigen in serum (a sign of significant viral replication) the percutaneous risk of transmission is 22% to 31%, and risk for developing serologic evidence of HBV infection is 37% to 62%.

BOX 1 Factors That Increase the Risk of Transmission of all Infectious Bloodborne Pathogens

- *High-risk exposure:* percutaneous, mucous membranes exposed, nonintact skin exposed, bites with blood exposure, visible blood on device, deep injury, large volume, hollow needles, blood from vessel
- *High-risk body substance:* Blood, bloody fluid, potentially infectious tissue
- *High-risk source patient:* hepatitis B virus surface antigen (HBsAg)+, HBeAg+, HCV Ab+ with HCV RNA PCR at high levels, HIV Ab+, HIV RNA PCR at high levels, noncompliant drug user, clinical or epidemiologic risks, advanced disease (likely a proxy for high viral load in HIV)

On the other hand, if exposure is to blood from HBeAg-negative source, the risks of developing clinical hepatitis is 1% to 6%, and the risk for developing serologic evidence of HBV infection is 23% to 37%.

BOX 2 Relative Average Risk of Infection Transmission After a Percutaneous Exposure to Blood (Based on Aggregate Data)

By source patient correlates

HBV (HBsAg+): risk varies according to e antigen positivity (chronic infectiousness)
- HBeAg+: 37%–62% transmission risk per exposure
- HBeAg−: 23%–37% transmission risk per exposure

HCV: Historically risk of transmission after percutaneous exposure has been reported as 1.8%, newer data suggests risk is much lower (0.2%)
- HIV coinfection in source patient may increase risk of HCV transmission
- One study *only* found transmission (1.2%) with hollow bore needles

HIV: 0.33% transmission risk for a percutaneous exposure (1 in 300)
- 0 cases reported after intact skin exposure
- 0.23%–0.3% transmission risk from needlestick injury
- 0.09%–0.09% transmission risk for a mucocutaneous exposure (~ 1 in 1000)

- Patients with advanced HIV infection and high viral loads are more likely to transmit virus than are those whose viral loads are undetectable. However, transmission is still possible even when source patient is on antiretroviral drugs.
- Amount and identity of the source fluid.
  - Blood has the highest concentrations of transmissible bloodborne viruses and is by far the most important fluid for transmission of bloodborne pathogens.
  - Semen, vaginal fluid, cerebrospinal fluid, breast milk, pericardial fluid, synovial fluid, and pleural fluid can also transmit HIV, but these are far less common in the healthcare setting.
  - Unless visibly bloody, other body fluids (e.g., saliva, urine, vomitus, feces, nasal or respiratory secretions, sweat, and tears) will not transmit HIV and rarely transmit HBV or HCV. For the special scenario of Ebola, which is also considered a bloodborne infection, it is worth noting that the disease can be transmitted through exposure to feces and vomitus as well as blood, and while live virus has been isolated from saliva and tears as well, though studies of transmissibility via these latter two routes are limited by their small size.
- Mechanism of injury/exposure. Needlestick injuries with hollow bore needles that had been placed within the vein or artery of a source patient carry the highest risk for transmission.
- Site of exposure.
  - The most important site is percutaneous, particularly with deep tissue injury. However, bloodborne infections can also be transmitted following exposure to mucous membrane and across nonintact skin barriers.

Healthcare personnel status	Postexposure testing		Postexposure prophylaxis		Postvaccination serologic testing[†]
	Source patient (HBsAg)	HCP testing (anti-HBs)	HBIG[*]	Vaccination	
Documented responder[§] after complete series (≥ 3 doses)	No action needed				
Documented nonresponder[¶] after 6 doses	Positive/unknown	—[**]	HBIG ×2 separated by 1 month	—	No
	Negative	No action needed			
Response unknown after 3 doses	Positive/unknown	<10 mIU/mL[††]	HBIG ×1	Initiate revaccination	Yes
	Negative	<10 mIU/mL	None		
	Any result	≥10 mIU/mL	No action needed		
Inactivated/incompletely vaccinated or vaccine refusers	Positive/unknown	—[**]	HBIG ×1	Complete vaccination	Yes
	Negative	—	None	Complete vaccination	Yes

FIG. 1 Postexposure management of healthcare personnel after occupational percutaneous and mucosal exposure to blood and body fluids by healthcare personnel hepatitis B vaccination and response status and, as appropriate to hepatitis B surface antigen (HBsAg) status of source patient. *HBIG*, hepatitis B immune globulin; *HBsAg*, hepatitis B surface antigen; *HCP*, healthcare personnel. [*]HBIG should be administered intramuscularly as soon as possible after exposure when indicated. The dose of HBIG is 0.06 mL/kg. [†]Should be performed 1 to 2 months after the last dose of the HepB vaccine series (and 4–6 months after administration of HBIG to avoid detection of passively administered anti-HBs) using a quantitative method that allows detection of the protective concentration of anti-HBs (≥10 mIU/mL). [§]A responder is defined as a person with anti-HBs ≥10 mIU/mL after ≥3 doses of HepB vaccine. [¶]A nonresponder is defined as a person with anti-HBs <10 mIU/mL after ≥6 doses of HepB vaccine. [**]If HCP titer was anti-HBs <10 mIU/mL or who are unvaccinated or incompletely vaccinated and sustain an exposure to a source patient who is HBsAg positive or has unknown HBsAg status, should undergo baseline testing for hepatitis B virus infection as soon as possible after exposure, and follow-up testing again 6 months later. Ideally 6 months after initial baseline tests consist of total anti-HBc testing in approximately a 6 months duration of HBsAg and total anti-HBc. (From Jatla N, Gilbert C, Spiegel ... *et al*. Recommendations for Prevention of Hepatitis ... after Exposure to the Clinical Guidelines Recommendations of the Advisory Committee on Immunization Practices, MMWR 1991 ... Recommendations Rep. 2001;50(RR-11):1–42.)

- In the scenario of a human bite, it is imperative to consider that both the biter and the victim may have been exposed to bloodborne pathogens.
- The HCW's level of protective immunity
  - Immunocompromised HCWs are at higher risk for acquisition of bloodborne pathogens.
  - Immunocompetent HCWs who have received three or more doses of the HBV vaccine series and have achieved anti-HBs levels of ≥10 mIU/mL (vaccine responders) are protected against infection.
    - This vaccine is mandatory for all HCWs, and approximately 90% of HCWs attain seroprotective levels with vaccination. However, there do wane over time.

At the time of exposure, it is not always known whether the source patient is infected with HBV, HIV, or HCV. Exposure to blood or infectious fluids of a patient with known HIV or hepatitis is one situation, the management of which is discussed later in the chapter. Exposure to blood or infectious fluids of a patient whose infectious status is unknown is a separate scenario in which the risk of transmission of infectious illness reflects the risk of undiagnosed infection in the general population, and the particular population that a given hospital or healthcare setting serves.
The following statistics are relevant in that regard:

- In the general US population, an estimated 1.1 million people are living with HIV, of whom 15% are unaware that they have HIV. In the youth population, among 13- to 24-year-olds, 54% of those with HIV are unaware that they have HIV.
- Transmission of HIV to occupationally exposed individuals is increased when the virus is detectable in the source patient's blood; therefore, it is highly relevant that only 49% of the US population living with HIV have achieved and sustained viral suppression.
- In the United States, 862,000 people are chronically infected with HBV. It is estimated that about one fifth of those infected with HBV in the United States are unaware of it. HCV infects 3.5 million persons in the United States, of whom approximately 50% are unaware of their infection.

Efforts to increase diagnosis of all these infections in the general population are underway. Routine screening of all individuals between 13 and 65 for HBV and all individuals born between 1945 and 1965 (or in other age groups but with HCV risk factors) for HCV is now recommended by the Centers for Disease Control and Prevention and the US Preventive Services Task Force.

PREVENTION

In general, robust efforts at prevention of occupational exposures to bloodborne infections should include universal HBV vaccination for all HCWs, personnel education and protection with universal precautions including the use of eye shields and gloves (and double gloves when necessary), rigorous procedure training, eliminating needle recapping, and minimizing exposure to sharps. Interventions that enable this include vigilant use and regular emptying of sharps containers, and engineering fixes such as needleless devices, automatic retracting needles, and safety knives, among others.

MANAGEMENT OF ANY EXPOSURE TO BLOODBORNE INFECTION

Postexposure Immediate Care

Cleansing Affected Area

Once an occupational exposure has occurred, facilitate local wound care should be performed as follows:

- Clean wounds (scrub, with soap and water, in a prolonged, thorough fashion).
- Use alcohol-based agents on exposed area.
- Flush any exposed mucous membranes with water.
- Flush eyes with water if exposed.
- Avoid use of bleach or caustic products, which can further irritate and abrade skin.
- No evidence that squeezing or milking the site helps.
- As mentioned, after a percutaneous injury that occurs through a surgical glove, surgeons should duplicate and replace, and follow standard protocols for when sterility is breached.

Management of a Human Immunodeficiency Virus Exposure:

Testing the Source Patient

- Rapid HIV-1 and -2 testing should be performed on the source patient's serum (rapid tests on oral secretions or blood are often available that have a less than 20-minute turnaround time).
- Window period of detection of HIV is 2 weeks after acute infection (fourth-generation HIV Ag/Ab testing may be followed with HIV RNA polymerase chain reaction [PCR] if source patient is high risk or had a recent high-risk exposure).
- The recent history and clinical picture of the source patient should be investigated, with particular attention to whether there is any recent syndrome that could be consistent with acute HIV (such as fever, sore throat, rash, headache, fatigue, enlarged cervical lymph nodes, etc.) If yes, *HIV RNA PCR should be ordered.*
- Negative predictive value >99% for negative rapid HIV test.
- In cases where there is incomplete or missing data on the source patient, the exposed person should be actively involved in the decision-making process. Sometimes postexposure prophylaxis (PEP) is withheld in situations of epidemiologic low risk. However, often in these scenarios of incomplete information, the exposed person chooses to proceed with taking PEP, as the potential benefits likely outweigh the risk, even in situations of low risk.

Postexposure Prophylaxis

The evidence for the efficacy of PEP of HIV rests on animal transmission models, retrospective observational human data, and the analogies with the efficacy of prevention of maternal to child transmission and perinatal prophylaxis. Retrospective case control studies in exposed individuals given zidovudine (azidothymidine [AZT]) PEP demonstrate an 81% reduction in transmission; the regimens of today are far better tolerated and far more potent, and if taken properly should reduce the risk of transmission to virtually zero (Table 1).

For effective prevention of transmission, both the timing of initiation and the duration of therapy matter (Fig. 2). The initiation of PEP should take place within 1 to 2 hours of exposure; efficacy drops off after 24 hours and is negligible after 72 hours, so initiation of PEP is not recommended if 72 hours have elapsed (see Tables 1 and 2). The exposed HCW should be counseled to abstain from or practice safe sex until the source patient's HIV serology returns negative. The CDC-recommended acceptable regimens for PEP are displayed in tabular form in Box 3. The guidelines no longer recommend an assessment of risk of HIV transmission to determine whether to initiate a two drug or three drug regimen, and instead recommend a three drug antiretroviral therapy regimen in all cases where PEP is initiated. This is largely because the available three drug regimens in the current era are exceedingly well tolerated. If the source patient is HIV positive with a virus that is known to be resistant to certain antiretrovirals, it is advisable to choose PEP regimens that are active against the source patient's virus. For guidance with the time sensitive initiation of PEP, the PEP line is a telephone hotline that can be a valuable resource: 888-448-4911 or http://www.nccc.ucsf.edu/.

Failures of Multidrug Postexposure Prophylaxis Reported to Centers for Disease Control and Prevention Through 2005

All were older regimens such as PEP and all were with follow-lists results.

Exposed source patient

- Pregnancy does not alter the calculus for PEP (high risk of transmission to fetus during acute infection, so the benefits outweigh the risk)
- Medications used in PEP are safe in pregnancy (AZT/3TC + lopinavir has most safety data in pregnancy)
- Discontinue breastfeeding during acute (postpartum)
- Consult with experts in obstetric infection

TABLE 1 Effect of Zidovudine (Azidothymidine [AZT]) on Prevention of Occupationally Acquired HIV in Humans

Human Study*	Cases (n = 33)	Controls (n = 479)
No AZT	24 (73%)	455 (95%)
AZT	9 (27%)	244 (36%)

*Adjusted odds ratio for acquisition of HIV after AZT postexposure prophylaxis: 0.2 (0.1–0.3).

From Cardo DM, Culver DH, Ciesielski CA, Srivastava PU, Marcus R, Abiteboul D, et al. A case-control study of HIV seroconversion in health care workers after percutaneous exposure. *N Engl J Med.* 1997;337(21):1485–1490.

Monitoring

Follow-up testing for HIV is recommended at 6 weeks, 12 weeks, and 6 months postexposure.

Management of Hepatitis B Virus Exposure

There is a 90% protective response to the three-vaccine series for HBV immunization, and those who have had natural infection with HBV in the past should also be considered immune to reinfection. HCWs at risk of HBV acquisition after an exposure are those who have not been vaccinated or who have had inadequate response to vaccine. The highest concentration of HBsAg is found in blood. HBsAg is also found in CSF, saliva, semen, and breast milk, but most other body fluids do not contain infectious levels of HBsAg. Therefore, exposures to blood are highest risk for HBV transmission.

***Prevention: Hepatitis B Virus Vaccination** (See Figs. 1 and 2 for "Vaccination Algorithms")*

- Now two-dose HEPLISAV-B(Hyun Vac) HBV vaccine granted Food and Drug Administration approval in 2017 is more effective (95%) than older vaccines, increases completion rate as it is only 2 doses separated by 1 month, and should be considered for unvaccinated or nonresponder HCWs exposed to a patient with HBV.
- Older HBV vaccines (Recombivax HB, Engerix-B, Heplisav-B, Twinrix-B, etc.) are administered in a three-dose series at 0, 1, and 6 months.
- Anti-HBs titers decline to less than 10 mIU/mL in 30% to 50% of adults 8 to 10 years after immunization.
- Despite this, immune memory to nonresponders remains intact for at least 20 years after immunization.
- Very rare for prior responders (+ anti-HBsAb after vaccination) to acquire chronic HBV infection.

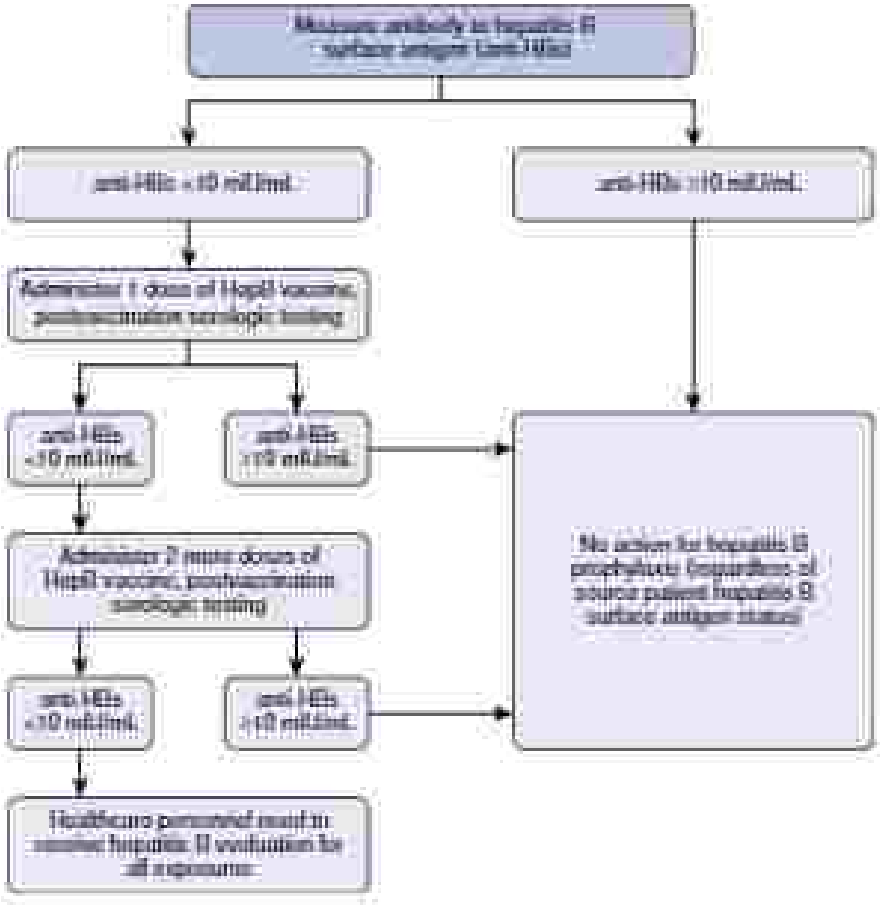

FIG. 1 Postexposure evaluation for healthcare personnel previously vaccinated with complete, 3-dose HepB vaccine series who have not had postvaccination serologic testing. Testing should be performed 1 to 2 months after last vaccine dose using quantitative method (e.g., enzyme-linked immunosorbent assay) to detect protective concentrations of anti-HBs (also known as anti-HBsAb). (Modified from Schillie S, Vellozzi C, Reingold A, et al. Prevention of hepatitis B virus infection in the United States: Recommendations of the Advisory Committee on Immunization Practices. *MMWR Recomm Rep.* 2018;67(RR-1):1–31.)

TABLE 2 Timing to Tenofovir (PMPA) Postexposure Prophylaxis Initiation and Duration of Treatment Both Affect Efficacy of Prevention of HIV Transmission of SIV in Macaques

TDF Treatment		
Initiation Delay (Hours)	Treatment Duration (Days)	No. HIV Infected
–	–	10/10
48	28	8/10
8	28	6/8
24	28	6/9
48	28	2/4
72	28	2/4
24	10	5/9
24	5	3/4

HIV, human immunodeficiency virus; TDF, tenofovir disoproxil fumarate.
Data from Tsai CC, Follis KE, Sabo A, Beck TW, Grant RF, Bischofberger N, et al. Prevention of SIV infection in macaques by (R)-9-(2-phosphonylmethoxypropyl) adenine. *Science*. 1995;270(5239):1197–1199.
Tsai CC, Emau P, Follis KE, Beck TW, Benveniste RE, Bischofberger N, et al. Effectiveness of postinoculation (R)-9-(2-phosphonylmethoxypropyl) adenine treatment for prevention of persistent simian immunodeficiency virus type 1 infection depends critically on timing of initiation and duration of treatment. *J Virol*. 1998;72(5):4265–4273.

- Important to check anti-HBs response after completing 3-vaccine series (5%–10% do not seroconvert after).
- Booster doses of HBV vaccine are recommended for seroresponders who do not become HBsAb positive.
- Booster doses of HBV vaccine among known prior responders are not recommended.

Immediate Management of Occupational Exposure to Hepatitis B Virus

1. Verify HBsAb status of exposed HCW
   - Ask HCW if he or she has been vaccinated against HBV
   - If HCW gives permission, look up anti-HBsAb status in medical record
   - If HCW is positive for HBsAb (i.e., has antibody titers anti-HBs ≥10 mIU/mL), then STOP. No need for further intervention regardless of HBsAg status of source patient.
2. If HCW is unvaccinated, ascertain HBV serologic status of source patient.
   - Ascertain previous HBsAg and anti-HBcAb for source patient and proceed as follows:
     - HBsAg unknown: send HBsAg from source patient
     - HBsAg positive
       - Immediately administer both HBIG 0.06 mL/kg IM × 1 and HBV vaccine to HCW
       - Optional: draw HBsAg from source patient to get a sense of the magnitude of transmission risk
     - HBsAg negative
       - Optional: initiate HBV vaccination series in source patient.
3. If HCW vaccinated, but seroresponse is unknown (i.e., no anti-HBs available)
   - Test HCW for anti-HBsAb
   - Determine HBsAg status of source patient
     - HBsAg positive: administer HBIG × 1 plus vaccine booster to HCW
     - HBsAg unknown: test source patient for anti-HBs
       - If source patient anti-HBs positive, no treatment needed
       - If source patient anti-HBs negative: administer vaccine booster to HCW and check titer in 1 to 2 months
     - HBsAg negative: no treatment necessary
4. If HCW vaccinated against HBV but is a known nonresponder after vaccination (HBsAb-negative, anti-HBs <10 mIU/mL)
   - Determine HBsAg status of source patient
     - HBsAg positive: administer HBIG × 2 (separated by 1 month) and HBV vaccine
     - HBsAg unknown
       - Test source patient for anti-HBsAb
       - If source patient anti-HBsAb positive, no treatment needed
       - If high risk, treat as though HBsAg positive
     - HBsAg negative: No treatment needed

BOX 3 Centers for Disease Control and Prevention Recommended Regimens for Postexposure Prophylaxis (PEP) of Human Immunodeficiency Virus*

Preferred

Tenofovir disoproxil fumarate (TDF)-emtricitabine (FTC)* 300 mg/200 mg daily + dolutegravir (DTG) 50 mg PO daily

or

Tenofovir disoproxil fumarate (TDF)-emtricitabine (FTC)* 300 mg/200 mg daily + raltegravir (RAL) 400 mg PO BID

Alternatives

Elvitegravir (EVG)-cobicistat-TDF-FTC* 150 mg/150 mg/300 mg/200 mg daily

or

TDF-FTC 300 mg/200 mg* + pharmacologically boosted† protease inhibitor (darunavir [DRV] or atazanavir [ATV]) daily*

or

Rilpivirine (RPV)-TDF-FTC* 25 mg/300 mg/200 mg daily with food

PEP should be started within 1 to 2 hours from the exposure, and transmission blocking efficacy drops off significantly after 24 hours. PEP should be administered for a total duration of 28 days. In the United States, the PEP Hotline is a useful resource when making decisions surrounding PEP: telephone 888-448-4911.

*For patients with glomerular filtration rate (GFR) ≥30 mL/min, dose adjustment of TDF and FTC will be necessary and single-tablet coformulations cannot be used.
†Available as single-tablet coformulations.
‡EVG should not be prescribed to women of childbearing potential who are sexually active and not using a >99% effective method of contraception, nor should it be prescribed to individuals in the early first trimester of pregnancy (within 8 weeks since last menses), pending further data.
§With cobicistat 150 mg or ritonavir 100 mg, to increase levels of protease inhibitor. DRV dose 800 mg daily. ATV dose 300 mg daily. DRV should not be prescribed to individuals with sulfa allergy but ATV may be.
¶Regimens containing both cobicistat and TDF should not be prescribed to anyone with CrCl <70 mL/min.

Management of Hepatitis C Virus Exposure

Because 20% to 30% of cases of acute HCV spontaneously clear, it is important that HCV Ab positivity be followed by HCV RNA PCR to confirm that the source patient indeed has chronic HCV rather than spontaneously cleared HCV with residual antibody positivity.

Appropriate management of HCV exposure depends on the status of the source patient, as follows.

If HCV Ab positive

- Check to see if HCV RNA has previously been ordered, to determine chronicity.
- If no HCV RNA available, order HCV RNA PCR.

If HCV RNA is undetectable

- Source patient previously treated and cleared infection, attaining sustained virologic response,
  or
- Source patient independently spontaneously cleared HCV
- HCW not at risk for acquiring HCV

If HCV RNA detectable

- Source patient is at risk for transmitting HCV to HCW.

If source patient is of unknown HCV status

- Draw HCV Ab.
- HCV Ab should be followed by HCV RNA PCR if positive.
- If high risk patient, can draw HCV RNA PCR with initial draw.

If source patient has chronic HCV (HCV Ab and HCV RNA positive), exposed HCW should have:

- HCV Ab test and LFT at baseline (time of exposure) and at 6 months post exposure.
- HCV RNA at 4 to 6 weeks postexposure.

Because of the high rates of spontaneous clearance of acute HCV by 6 months, there is some variance in recommendations on timing of treatment. The American Association for the Study of Liver Diseases and Infectious Disease Society of America joint guidelines on acute HCV recommend that the patient and their clinician jointly decide whether a delay in treatment initiation while monitoring for spontaneous clearance is favored, and even if the decision is instead to initiate treatment during acute infection, monitoring HCV RNA first for a minimum of 12 to 16 weeks before starting treatment is recommended. In such cases, the same HCV regimens used for chronic HCV are used for acute HCV, are safe and well tolerated, and are >90% likely to result in cure. However, we advocate immediate treatment of acute HCV for HCWs who are found to have HCV RNA positive at 4 weeks postexposure. Risk benefit ratio favors this, especially with regard to the availability of safe, well tolerated, and highly effective treatment regimens with acceptable cost, which minimize the impact on the HCW, their potentially exposed family, and their patients over the period of high HCV viral load.

No preexposure or postexposure prophylaxis for HCV is currently recommended.

1. Immune globulin not recommended by CDC
   - Little evidence that humoral response critical in clearance
   - No efficacy in chimpanzees to prevent infection
2. Interferon (IFN) ± ribavirin not recommended
   - Trials:
   - IFN may only be effective to established infection
   - No effect in (underpowered) Japanese study
   - Early identification and treatment of infection offers best course of action currently for occupationally acquired HCV.

Antifungal Therapy in the Surgical Patient

Ashley D. Meagher, MD, MPH, and Heather L. Evans, MD, MS

Nosocomial fungal infections are an increasing problem in hospitalized surgical patients. These infections are frequently seen in critically ill surgical patients, with bloodstream infection the most common etiology. The most commonly seen infections are caused by *Candida* species. Other significant fungal pathogens in surgical patients include *Aspergillus*, *Cryptococcus*, mucormycosis, and emerging pathogens such as *Fusarium*. Superficial fungal infections are rarely dangerous, but invasive fungal infections continue to be associated with serious complications and a high mortality. Surgical patients frequently have many of the risk factors associated with invasive fungal infection, including critical illness, recent abdominal surgery, solid organ transplantation, exposure to broad-spectrum antibiotics, as well as any additional immunocompromised states. Identification and diagnosis of infection can be difficult, which frequently delays initiation of appropriate antifungal therapy. Surgeons may be involved in the care of patients with invasive fungal infections in many settings, from debridement of infected tissue to treatment in a critical care unit. This chapter summarizes fungal infections typically encountered, with special emphasis on the use of antifungal therapy as treatment (Table 1).

Appropriate management of HCV exposure depends on the status of the source patient, as follows.

If HCV Ab positive

- Check to see if HCV RNA has previously been ordered, to determine chronicity.
- If no HCV RNA available, order HCV RNA PCR.

If HCV RNA is undetectable

- Source patient previously treated and cleared infection, attaining sustained virologic response,
  or
- Source patient independently spontaneously cleared HCV
- HCW not at risk for acquiring HCV

If HCV RNA detectable

- Source patient is at risk for transmitting HCV to HCW.

If source patient is of unknown HCV status

- Draw HCV Ab.
- HCV Ab should be followed by HCV RNA PCR if positive.
- If high risk patient, can draw HCV RNA PCR with initial draw.

If source patient has chronic HCV (HCV Ab and HCV RNA positive), exposed HCW should have:

- HCV Ab test and LFT at baseline (time of exposure) and at 6 months post exposure.
- HCV RNA at 4 to 6 weeks postexposure.

Because of the high rates of spontaneous clearance of acute HCV by 6 months, there is some variance in recommendations on timing of treatment. The American Association for the Study of Liver Diseases and Infectious Disease Society of America joint guidelines on acute HCV recommend that the patient and their clinician jointly decide whether a delay in treatment initiation while monitoring for spontaneous clearance is favored, and even if the decision is instead to initiate treatment during acute infection, monitoring HCV RNA first for a minimum of 12 to 16 weeks before starting treatment is recommended. In such cases, the same HCV regimens used for chronic HCV are used for acute HCV, are safe and well tolerated, and are >90% likely to result in cure. However, we advocate immediate treatment of acute HCV for HCWs who are found to have HCV RNA positive at 4 weeks postexposure. Risk benefit ratio favors this, especially with regard to the availability of safe, well tolerated, and highly effective treatment regimens with acceptable cost, which minimize the impact on the HCW, their potentially exposed family, and their patients over the period of high HCV viral load.

No preexposure or postexposure prophylaxis for HCV is currently recommended.

1. Immune globulin not recommended by CDC

Identification and diagnosis of infection can be difficult, which frequently delays initiation of appropriate antifungal therapy. Surgeons may be involved in the care of patients with invasive fungal infections in many settings, from debridement of infected tissue to treatment in a critical care unit. This chapter summarizes fungal infections typically encountered, with special emphasis on the use of antifungal therapy as treatment (Table 1).

TABLE 1 Patient Types and Treatment Options for Fungal Infections

Infection	Patient Type	Primary and Alternative Treatments	Duration of Therapy	Comments
Candidemia	Critically ill, abdominal surgery, cancer chemotherapy, vascular access, burns, parenteral nutrition	Primary Caspofungin 70 mg × 1, then 50 mg/day IV Anidulafungin 200 mg × 1, then 100 mg/day IV Micafungin 100 mg/day IV Fluconazole 800 mg × 1, then 400 mg/day IV or PO Alternative Deoxycholate AmB 0.7–1.0 mg/kg/day IV Lipid AmB 3–5 mg/kg/day IV Voriconazole 6 mg/kg BID × 2 doses, then 4 mg/kg BID	14 days after clearance of blood cultures Longer if ocular involvement. If possible, can switch to oral agent to complete therapy once patient has stabilized.	Remove vascular access devices, if possible. Do not use fluconazole for critically ill patients. Evaluate for ocular involvement with funduscopic examination.
Candiduria/UTI	Urinary catheter, DM, kidney transplant recipients	Primary Fluconazole 200–400 mg/day IV or PO	14 days	Patients with asymptomatic candiduria do not routinely need to be treated. Exceptions are neutropenia or planned instrumentation.
		Alternative Deoxycholate AmB 0.5–0.6 mg/kg/day IV	1–7 days	
		Flucytosine 25 mg/kg QID PO	7–10 days	
Oropharyngeal candidiasis	Immunocompromised, radiotherapy, ill-fitting dentures	Primary Clotrimazole 10 mg 5 times/day PO Nystatin suspension (100,000 U/mL) 4–6 mL QID PO Fluconazole 100–200 mg/day PO Alternative Fluconazole solution 200 mg/day PO Posaconazole 400 mg BID × 2 days, then 400 mg/day DID PO Voriconazole 200 mg BID PO Caspofungin 70 mg × 1, then 50 mg/day IV Anidulafungin 200 mg × 1, then 100 mg/day IV Micafungin 100 mg/day IV Deoxycholate AmB oral suspension 100 mg/mL QID PO or 0.3 mg/kg IV daily	7–14 days	Use topical therapy for mild disease; relapses more common with echinocandins.
Esophageal candidiasis	Immunocompromised	Primary Fluconazole 200–400 mg/day PO or 400 mg/day IV Alternative Micafungin 150 mg/day IV Caspofungin 70 mg × 1, then 50 mg/day IV Anidulafungin 200 mg/day IV Deoxycholate AmB 0.5–0.7 mg/kg/day IV Posaconazole 200 mg/day PO Voriconazole 200 mg BID IV or PO Posaconazole 400 mg BID PO	14–21 days	Relapses may be more common with echinocandins.

TABLE 1 Patient Types and Treatment Options for Fungal Infections—cont'd

Infection	Patient Type	Primary and Alternative Treatments	Duration of Therapy	Comments
Vulvovaginal candidiasis	Antibacterial therapy, DM	Topical therapy (e.g., clotrimazole, nystatin, miconazole) Fluconazole 150 mg × 1 PO	Schedules vary by agent	Vulvovaginal candidiasis, even if recurrent, usually does not result from an immunocompromised state.
Aspergillosis	Abnormalities of neutrophil number or function, structural lung abnormalities, burns	Primary Voriconazole 6 mg/kg IV/1 × 2, then 4 mg/kg/day × others Caspofungin 70 mg × 1, then 50 mg/day IV Posaconazole 800 mg/day in 2–4 divided doses IV or PO	Length of treatment not clear	Consider monitoring voriconazole and posaconazole levels to help guide therapy.
Mucormycosis	Systemic immunosuppression, burns, trauma, near drowning, neutropenia, DM, deferoxamine use	Primary Lipid AmB 5–7.5 mg/kg/day + posaconazole	Length of treatment not clear	Debridement and excision are often needed. If patient is stable, consider switching to posaconazole after 3 weeks AmB.

AmB, Amphotericin B; BID, twice daily; DM, diabetes mellitus; IV, intravenously; PO, orally; QID, four times daily; UTI, urinary tract infection.

SPECIFIC FUNGI

Candida

Candida species are the most common fungal pathogens in surgical patients, comprising approximately 80% of fungal nosocomial infections. These fungi are commensals of the human gastrointestinal (GI) tract, genital tracts, and skin. Infections are almost always of endogenous origin, particularly when host defenses break down or are breached. Patients with a central venous catheter, prolonged exposure to broad-spectrum antibiotics, or those who have had a recent operation, particularly when there has been GI contamination, are at greater risk for candidiasis. Iatrogenic spread between patients by healthcare workers can affect fungal colonization patterns and subsequent infecting species, as can exposure to antifungal agents.

There are at least 15 species of *Candida* identified; however, more than 90% of invasive infections are caused by *C. albicans*, *C. parapsilosis*, *C. glabrata*, *C. tropicalis*, and *C. krusei*. There are increasing infectious complications with other *Candida* species such as *C. dubliniensis*, *C. lusitaniae*, and *C. auris*. *C. albicans* still comprises approximately one half of infections, and the prevalence of non-*albicans* species vary based on geographic location and special populations. *Candida* is the third most common bloodstream pathogen, and accounts for 9% to 10% of all bloodstream infections in hospitalized patients. Awareness of non-*albicans* species is crucial because they frequently have reduced susceptibilities or intrinsic resistance to common antifungal therapies.

Infection resulting from *Candida* can be broadly divided into mucosal and systemic disease. Mucocutaneous infections are generally benign and limited to local overgrowth. These are mediated by changes in local flora. Oropharyngeal and candidal esophagitis generally occur in immunocompromised patients, including those with human immunodeficiency virus (HIV), those receiving chemotherapy, or being treated with corticosteroids. Cutaneous and vulvovaginal candidiasis are sometimes triggered by antimicrobial use, poor glycemic control, or may be spontaneous.

Surgical patients at elevated risk for invasive candidiasis are frequently critically ill with need for central venous catheter, broad-spectrum antibiotics, hemodialysis, or total parenteral nutrition. In addition, surgical diseases, such as perforation of the gastrointestinal tract, intestinal anastomotic leak, or pancreatitis, increase the risk for invasive candidiasis. Most frequently, invasive infection is in the form of candidemia; however, peritonitis, endocarditis, mediastinitis and meningitis may occur in certain postsurgical patient populations. Approximately 50% of blood cultures fail to demonstrate candidemia, so critically ill patients with the risk factors of upper gastrointestinal perforation, prolonged broad-spectrum antibiotic treatment, or known *Candida* colonization should be empirically treated with antifungal therapy.

Other Fungi

Other invasive fungal infections, once rare, are on the rise, likely secondary to the increasing number of immunocompromised patients. Patients with advanced malignancy, hematologic disease, HIV, as well as organ transplant recipients and those with autoimmune conditions are at increased risk for invasive fungal infection. *Aspergillus* is the most common species encountered. Patients with abnormal lung anatomy or function, such as with cystic fibrosis, chronic lung disease, lung transplantation, or prolonged mechanical ventilation may be chronically colonized with *Aspergillus* or other molds. These may progress to invasive or saprophytic disease. Invasive aspergillosis most commonly manifests as a progressive, cavitary pulmonary infection that can result in hemoptysis. Cavitary lesions usually are seen on chest radiograph or computed tomography of the chest. Cutaneous infection may occur after a break in the skin barrier, either because of burn injury or after an operation in a severely immunocompromised patient. *Mucormycosis*, *Cryptococcus*, and infection with endemic fungi (*Coccidioides*, *Blastomyces*) are rarely seen in primary surgical patients outside of organ transplantation or following burn or traumatic injuries contaminated by soil. These infections may

be reactivated with initiation of immunosuppressive medications or in severe critical illness.

ANTIFUNGAL AGENTS

Azoles

The azoles are a commonly used class of antifungal agents with activity against a broad range of fungi. These drugs inhibit ergosterol biosynthesis, thereby impairing formation of the fungal cell membrane. Azoles are available in oral, intravenous (IV), or topical forms, depending on the specific agent. Azoles have the potential for multiple drug interactions via the cytochrome P450 system, and care must be taken when they are administered at the same time as other drugs metabolized by these mechanisms.

Fluconazole

Fluconazole is the predominant azole used to treat fungal infections in surgical patients. It is effective against most species of *Candida* and is used often as first-line therapy. It is available in oral and IV formulations and is generally well tolerated. Fluconazole has excellent activity against *C. albicans* but has variable activity against *C. glabrata*, which can account for up to 25% of candidal infections. It is inactive against *C. krusei*. Fluconazole is a first-line agent for oropharyngeal and esophageal candidiasis as well as for urinary tract infections resulting from *Candida*. It also has a role in cases of invasive candidiasis in moderately ill, nonneutropenic patients, although dosing needs to be significantly higher (800–900 mg/day). Dose adjustment is required with renal dysfunction. The use of fluconazole has been associated with hepatic toxicity, GI upset, rashes, and drug interactions. Resistance to fluconazole is on the rise, so sensitivity testing should be performed in high-risk patients.

Voriconazole

Voriconazole is effective against most species of *Candida* and *Aspergillus* and multiple other filamentous fungi. It is available in oral and IV formulations. Voriconazole is the first-line treatment for invasive aspergillosis and can be used in cases of invasive candidiasis. It has excellent bioavailability, allowing for oral administration. Steady-state levels are reached more rapidly with IV loading doses of 6 mg/kg every 12 hours for 2 doses, followed by 4 mg/kg IV every 12 hours or 200 mg orally every 12 hours. Patients with renal dysfunction should receive the oral form of voriconazole for maintenance because the cyclodextrin carrier used in the IV formulation can accumulate and may damage the kidneys. Patients with hepatic impairment should receive the standard loading dose, but the maintenance dose should be decreased by 50%. Voriconazole is associated with multiple adverse reactions, most commonly visual changes such as photophobia, reduction in visual acuity, and blurred vision. Routine monitoring of drug levels is not recommended; however, monitoring can be helpful when there are concerns about efficacy or toxicity. Like fluconazole, voriconazole is associated with multiple drug interactions.

Posaconazole

Posaconazole is effective against a broad range of fungi, including most species of *Candida* and *Aspergillus* and many filamentous fungi, including the zygomycetes. It is available in oral suspension, delayed-release tablets, and IV formulations. Oral suspension or delayed-release tablets are indicated for prophylaxis of invasive *Aspergillus* and *Candida* infections in patients at high risk of developing these infections because of being severely immunocompromised (e.g., recipients of hematopoietic stem cell transplant with graft-versus-host disease, those with hematologic malignancies with prolonged neutropenia from chemotherapy). Attainment of steady-state levels can take a week or longer, and for this reason it generally is not recommended as first-line therapy for established infections. The dose for invasive fungal infections varies depending on the formulation used, and it is imperative that this be taken into account. As with voriconazole, IV dosing should be reduced in patients with renal impairment because of toxicity from accumulation of the associated vehicle. Side effects of posaconazole are common and include fever, nausea, diarrhea, headache, hypokalemia, and thrombocytopenia. Long QT syndrome and hepatotoxicity are less common but serious complications. Posaconazole also is associated with multiple drug interactions similar to those with other azoles.

Itraconazole

Itraconazole's spectrum of activity is similar to that of fluconazole. It is active against *Candida* but also against some filamentous and dimorphic fungi, including *Aspergillus*, *Blastomyces*, and *Histoplasma*. It also can be used to treat onychomycosis. In some countries, itraconazole is available for IV therapy. Itraconazole has been of limited use in surgical patients because of the erratic bioavailability of the oral capsule, which has improved with the oral cyclodextrin solution. Additional factors limiting its use include the need for drug-level monitoring, GI upset (particularly with the cyclodextrin solution), hepatic toxicity, and negative inotropic cardiac effects that can cause or worsen congestive heart failure.

ECHINOCANDINS

The echinocandins (caspofungin, micafungin, and anidulafungin) are an important class of antifungal agents, and they have emerged as a preferred treatment class for many fungal infections. They act by inhibiting fungal cell wall formation and have fungicidal activity against almost all *Candida* species. Echinocandins are most widely for the treatment of invasive candidiasis, especially in critically ill and neutropenic patients. They also are used for empiric antifungal therapy in immunocompromised patients with neutropenic fever. Echinocandins are first-line therapy against invasive candidiasis because they are fungicidal against a variety of *Candida* species, including fluconazole-resistant *C. glabrata* and *C. krusei*. Treatment failures have been reported with *C. parapsilosis*, which has some innate resistance to the echinocandins. Under selective pressure, other species of *Candida* may develop resistance. They are not ideal for cases of oropharyngeal and esophageal candidiasis. The echinocandins inhibit growth of *Aspergillus*, but they are not fungicidal against this species. There may be a role for their use as salvage therapy in refractory *Aspergillus* infections, but should be used in combination treatment. Experience suggests that this class is among the safest and best tolerated of the antifungals available. They are available via the IV route only.

Polyenes

Polyene antibiotics are a class of antimicrobial compounds that bind to ergosterol, the main sterol in the fungal cell membrane, and cause depolarization. This increases membrane permeability and leads to leakage of intracellular cations causing cell death. Amphotericin B and nystatin are examples of polyene antimycotics. Amphotericin B deoxycholate, which was the standard drug for the treatment of candidiasis for decades, demonstrates rapidly fungicidal in vitro activity against most species of *Candida* but is associated with significant nephrotoxicity. Because of this adverse effect, it is rarely used. Instead, most physicians use a lipid-based amphotericin B formulation, either liposomal amphotericin B or amphotericin B lipid complex, when selecting a polyene agent. These lipid-based compounds have much less toxicity than amphotericin deoxycholate, but are significantly more expensive. Because of this, amphotericin B is now primarily used in salvage therapy of the most refractory invasive fungal infections. Nystatin is frequently used to treat mucocutaneous candidiasis in a powder, cream, or oral liquid form.

COMMON FUNGAL INFECTIONS

Mucocutaneous Disease

Mucocutaneous fungal infections are very common, and their risk factors, including diabetes mellitus, obesity, treatment with antibiotics or steroids, and inflammatory skin diseases, are found frequently in surgical patients. These infections can cause significant discomfort but are rarely dangerous. Typical sites of infection include the skin, oropharynx (thrush), genitalia, and esophagus. Patients with symptomatic superficial infections should be treated, but because *Candida* species normally exist on the skin and mucosal surfaces as commensals, culturing the organism from a superficial surface in the absence of symptoms is not an indication for treatment.

Cutaneous Candidiasis

Cutaneous candidiasis is almost always caused by *C. albicans* and may occur anywhere on the body but typically involves intertriginous areas (candidal intertrigo). Warm, moist, and macerated skin sites, such as inframammary crease, large abdominal folds, the axillae, or the groin, are common sites of involvement and must be examined and treated. Open incisions, wounds, or decubitus ulcers being treated with moist dressings are also at risk for infection. The affected area may be ruby red and moist. The skin can be eroded with scalloped scaling at the borders. Satellite lesions just beyond the border of the grossly affected area are common.

Diagnosis generally is based on clinical appearance. Superficial candidiasis can be treated with topical therapy. For moist macerated skin, an antifungal powder formulation is preferable because of its drying properties. Nystatin (100,000 units/g) and miconazole (2%) are available as either a powder or a cream. A variety of other antifungal creams are also available, such as ketoconazole (2%) and clotrimazole (1%). More extensive infections may require oral azole drugs in conjunction with topical treatments.

Candidal Vulvovaginitis

Candidal vulvovaginitis is common, and most women will have at least one episode during their lifetime. Most infections are caused by *C. albicans* and represent a patient's own organisms. Risk factors include antibiotics, diabetes mellitus, and pregnancy. Vulvovaginitis may be seen with local irritation, itching, erythema, thick white vaginal discharge, dysuria, and dyspareunia. Patients often make a self-diagnosis of "yeast" vaginitis. This can be confirmed by identifying *Candida* elements (pseudohyphae and blastoconidia) on microscopic evaluation of a 10% potassium hydroxide–treated sample. Fungal cultures are usually neither necessary nor helpful.

There are multiple intravaginal treatment options, including oral nystatin tablets (100,000 units/tablet), various topical azole creams and vaginal suppositories (e.g., miconazole 2%, butoconazole 2%, clotrimazole 1%, terconazole 0.4% and 0.8%, tioconazole 6.5%, miconazole cream 2% and 4% or suppositories at 100 and 200 mg) and oral fluconazole (150 mg as a single dose). The duration of treatment varies with different agents and concentrations. Most infections can be treated with a single dose of oral medication or a 1- to 3-day course of topical therapy. Some patients with recurrent or severe disease require longer treatment with either 7 to 14 days of topical azole or 150 mg of fluconazole in two sequential oral doses (second dose 72 hours after initial dose).

Oropharyngeal Candidiasis

Oropharyngeal candidiasis mainly presents in immunosuppressed patients, particularly after organ transplantation and in those with advanced HIV. Additional risk factors include extremes in age, poorly controlled diabetes mellitus, nutritional deficiencies, inadequately fitting dentures, systemic or inhaled steroids, radiotherapy, and cytotoxic chemotherapy. Presentation of oropharyngeal candidiasis in a patient without risk factors should spark a search for underlying disease. This may be the first manifestation of advanced HIV. Clinical manifestations include thrush, which is characterized by curd-like, white patches on multiple surfaces of the oral mucosa, and erythematous candidiasis (acute atrophic candidiasis), which occurs by itself or in association with the white patches. Symptoms include local pain, burning, and changes in taste perception. Microscopic examination of scrapings of the involved area may help with the diagnosis if it is doubtful.

Oropharyngeal candidiasis is almost always caused by *C. albicans* and usually responds to topical treatments such as clotrimazole troches, 10 mg 5 times daily, or nystatin suspension (nystatin "swish and swallow"). Systemic antifungal medication such as fluconazole 100 to 200 mg daily, or itraconazole 200 mg daily, may be necessary for oropharyngeal infections that do not respond to topical therapy. Treatment is typically for 7 to 14 days but may need to be extended, depending on response to therapy.

Esophageal Candidiasis

Esophageal candidiasis usually occurs in patients with a highly compromised immune system. Additional risk factors include advanced liver disease and inhaled steroids. Usual symptoms include odynophagia, dysphagia, and retrosternal pain. Concurrent oropharyngeal candidiasis is common but not always present. Infection is generally limited to the mucosa. Complications include dehydration and malnutrition resulting from poor oral intake, esophageal strictures, and even esophageal perforation.

Treatment is with oral fluconazole 200 to 400 mg daily. If the patient is unable to tolerate oral therapy, fluconazole 400 mg daily should be delivered intravenously. Therapy is typically for 14 to 21 days, depending on patient response. Oropharyngeal and esophageal candidiasis refractory to fluconazole occasionally may develop in patients who are highly immunosuppressed or those previously treated with an azole and have developed resistance. Alternative oral options include voriconazole solution 200 mg/day, posaconazole 200 mg twice daily, and posaconazole 400 mg twice daily. These regimens are more and are potentially more toxic than fluconazole. Treatment may be ineffective if resistance has developed to the entire azole class. IV antifungal therapy with echinocandins (micafungin 150 mg daily, caspofungin 70 mg loading dose, then 50 mg daily, and anidulafungin 200 mg daily) can be effective, but use is associated with higher relapse; therefore, recommended dosages are higher. Systemic amphotericin B deoxycholate or lipid formulations are another option, but can be associated with substantial toxicity. Patients at significant risk for oropharyngeal and esophageal candidiasis, such as those receiving cytotoxic chemotherapy or high-intensity immunosuppression or those who have advanced HIV, should be treated with prophylaxis. Topical agents such as nystatin or clotrimazole are generally effective. Systemic fluconazole 400 mg by mouth or IV daily also may be effective as suppressive therapy in cases of recurrent infection.

Candiduria

Candiduria is a common finding in hospitalized surgical patients, or those with long-term indwelling urinary catheters. This may represent a spectrum of clinical scenarios, from colonization and cystitis to more serious conditions such as upper urinary tract infection or disseminated disease. It is often difficult to distinguish true urinary infection from mere colonization, particularly in patients with indwelling urinary catheters. The decision to treat should be based on the clinical scenario and not solely on the presence of yeast in urine cultures.

Treatment is indicated in patients who are symptomatic, neutropenic, have renal allograft, or those with urologic manipulation. Removal or exchange of urinary catheters may be helpful in clearing candiduria. Oral fluconazole (200 mg or 3 mg/kg daily) for 7 to 14 days is recommended for the treatment of cystitis resulting from *Candida*. Alternatives include systemic amphotericin B deoxycholate or oral flucytosine, although the latter frequently results in the rapid development of resistance. Bladder irrigation with amphotericin B

deoxycholate may be useful in cases of refractory cystitis from azole-resistant strains. Lipid formulations of amphotericin B should be avoided because they do not achieve adequate concentrations in the urinary system. Patients with persistent candiduria and additional risk factors should be evaluated for presence of a fungus ball or renal parenchymal disease.

FUNGAL BLOODSTREAM INFECTIONS

Fungi are the fourth most common pathogen isolated in bloodstream infections overall and the third most common pathogen in intensive care units in the United States. The majority of cases are attributed to *Candida* species, in particular *C. albicans*. Candidemia occurs more commonly at the two extremes of age. Despite advances in pharmacologic agents, fungal bloodstream infections continue to carry an associated mortality rate of between 40% and 60%.

As with other candidal infections, risk factors include prolonged antibiotics treatment, total parenteral nutrition, neutropenia, immunosuppression, hemodialysis, previous fungal colonization, presence of an intravascular catheter, major surgery, and burns. Prolonged critical illness increases the risk of colonization with *Candida*, which then increases the risk of bloodstream infection. It is believed that once colonization occurs, *Candida* obtains access to the bloodstream via translocation across the mucosal barrier in the GI tract, IV catheter, or from an invasive localized infection. Blood cultures remain the gold standard for diagnosis; however, sensitivity of blood cultures is less than 50%. Newer diagnostic assays, including polymerase chain reaction, beta-D-glucan, and T2Candida, are still undergoing investigation and are not widely used. *C. glabrata* has been increasing and now comprises about one fourth of bloodstream isolates. This organism has an increased likelihood of resistance to azoles and potential for multidrug resistance. Sensitivity testing should be performed on all candidal bloodstream isolates.

Treatment recommendations vary for specific patient populations, taking into consideration recent drug exposure and risk factors for infection due to resistant strains. Fluconazole remains a reasonable option for noncritically ill patients who have no previous exposure to azoles and lack additional risk factors for *C. glabrata* (e.g., advanced age, malignancy, diabetes mellitus). Fluconazole should be given with an initial loading dose of 800 mg (12 mg/kg), followed by 400 mg (6 mg/kg) daily. Echinocandins are preferred for treatment of patients with greater risk factors, including neutropenic patients, and those at risk for infection with *C. glabrata* or *C. krusei* isolates. Echinocandin dosing recommendations include caspofungin at a loading dose of 70 mg, then 50 mg daily; micafungin 100 mg daily; or anidulafungin at a loading dose of 200 mg, then 100 mg daily. First-line therapy in neutropenic patients remains echinocandins; however liposomal amphotericin B formulations (3–5 mg/kg daily) also may be used. Patients should have blood cultures drawn every 1 to 2 days to monitor for clearance. Treatment should continue for 2 weeks after the first documented negative blood culture.

Central venous catheters should be removed as early as possible in patients with candidemia because it may be primary source of infection or become infected secondarily. Retention of the catheter may be considered in patients with implanted access devices and candidemia in the setting of cytotoxic chemotherapy and neutropenia. All patients with candidemia should have a dilated funduscopic examination by an ophthalmologist within the first week after diagnosis to evaluate for chorioretinitis or endophthalmitis.

Intraabdominal Fungal Infections

Intraabdominal fungal infections occur as a result perforation of the upper gastrointestinal tract, as a complication of an intraabdominal operation or, less commonly, from disseminated disease. *Candida* is the most commonly isolated species, and mortality rates range from 20% to 40%. Risk factors for *Candida* intraabdominal infections include pancreatic necrosis, recurrent abdominal operation, upper gastrointestinal tract perforation, anastomotic breakdown, and multifocal colonization. Patients should be classified as low or high risk, based on the presence of these risk factors.

Diagnosis of an intraabdominal fungal infection should be based on culture results from intraoperative samples or by percutaneous aspiration. Intraoperative fungal cultures or percutaneous aspiration should be obtained for patients at high risk of intraabdominal fungal infection to identify the presence of resistant organisms and to guide antimicrobial therapy. The presence of yeast in samples obtained from an existing surgical drain may simply represent colonization and not necessarily an intraabdominal infection. The Surgical Infection Society recommends against empiric antifungal treatment in low-risk patients, as well as most high-risk patients. However, patients with upper gastrointestinal perforation who are critically ill seem to be at even higher risk; so empiric antifungal therapy should be considered in this specific population.

Early source control is essential in managing these infections. Antifungal treatment with fluconazole is appropriate for most patients with infection due to *C. albicans*. An echinocandin should be used for critically ill patients and those with isolates likely to be resistant to the azoles. The optimal duration of treatment is unclear. A recent multinational expert panel recommended treatment for 10 to 14 days for intraabdominal *Candida* infections. However, the Surgical Infection Society's Study to Optimize Peritoneal Infection Therapy evaluated the duration of treatment for patients with complicated intraabdominal infections and demonstrated that 4 days of treatment following adequate source control resulted in similar outcomes compared with patients who received a longer course of therapy. Although patients with fungal infections were included in that study, it is unclear whether these recommendations apply to this group. The current Infectious Diseases Society of America guideline for management of candidiasis recommends that duration of treatment be determined by the adequacy of source control and clinical response.

FUNGAL SURGICAL SITE INFECTIONS

Approximately 3% of surgical site infections (SSIs) are fungal, with *C. albicans* being the most common fungal pathogen. Although infrequent, these infections are important to recognize because there have been case reports of *C. albicans* causing necrotizing infections at a surgical or central line site. Certain patient populations, such as those suffering from traumatic injuries, burns, or secondary or tertiary peritonitis are at higher risk of developing fungal SSIs.

Burn patients are at particularly high risk, with fungus responsible for approximately 20% to 25% of burn wound infections, often as one isolate of a polymicrobial infection. Fungal wound infections in this population typically occur approximately 2 weeks after burn injury and have been associated with a greater mortality. It is unclear if fungal SSIs are the direct cause of death or simply represent a more severe disease state in these patients. Diagnosis of a fungal wound infection in burn wounds requires histopathologic evidence of fungal invasion into viable tissue. The presence of fungi in necrotic tissue is considered to represent colonization. These patients require both surgical debridement as well as systemic antifungal therapy.

Both *Candida* and *Aspergillus* have infrequently been implicated in posttransplantation wound infections, including osteomyelitis and mediastinitis. The mainstay of treatment is surgical debridement and several months of antifungal therapy.

FUNGAL PULMONARY INFECTIONS

Fungi represent only a small fraction of pathogens responsible for pulmonary infections, but they are important to recognize in light of the growing population of immunosuppressed patients. Opportunistic organisms most commonly cause fungal pneumonias, whereas pulmonary infections due to endemic fungi are rare in surgical patients.

Candida

Candidal pneumonia is very rare, despite *Candida* being a common organism found in respiratory secretions. Most cases are related to disseminated *Candida* infection arising from distant sites and usually occur among patients with additional risk factors. As with most *Candida* infections, prolonged antibiotic use, hematologic malignancies, and other immunocompromised states are the primary risk factors. Definitive diagnosis of *Candida* pneumonia is based on isolating the organism from lung tissue samples because growth of *Candida* from respiratory secretions generally indicates asymptomatic colonization and should not be treated. There are no clear guidelines for treatment of primary *Candida* pneumonia. Most cases have been treated with amphotericin B deoxycholate or lipid formulations, although milder cases have been treated successfully with fluconazole. Disseminated disease should be treated similarly to candidemia.

Aspergillus

Invasive aspergillosis is an increasingly important problem in surgical patients, particularly the immunocompromised patient. It remains an uncommon disease but carries significant mortality. Early epidemiologic studies in the United States have estimated its incidence to be 12 cases per 1 million people per year.

Invasive aspergillosis is most commonly seen as a progressive, cavitary pulmonary infection that can result in hemoptysis. Common symptoms include fever, dyspnea, cough, and pleuritic chest pain. However, one third of patients are asymptomatic initially. Cavitary lesions are usually identified on plain radiographs or computed tomography of the chest. Other radiologic findings such as the "halo" sign and "air crescent" sign are highly suggestive of *Aspergillus* pneumonia but nonspecific. Diagnosis can be difficult because of the relative insensitivity of microscopy and culture to detect *Aspergillus*. A definitive diagnosis requires both histopathologic evidence of infection and culture of the organism from a sterile site. Galactomannan antigen detection, beta-D glucan detection, and polymerase chain reaction are additional laboratory studies that may improve detection in certain high-risk populations. Voriconazole remains the treatment of choice; amphotericin B is second line if voriconazole is not available. Echinocandins (alone or in combination) should be reserved as salvage therapy. Surgical resection of a pulmonary lesion may be indicated in patients with hemoptysis, bacterial superinfection, or as salvage in refractory infection; however, many patients with this level of disease are too ill to safely undergo surgery.

Mucormycosis

Mucormycosis, also referred to as zygomycosis, is another very rare infection caused by one of the organisms belonging to the order Mucorales, most commonly *Rhizopus* spp. or *Mucor* spp. It has an incidence of less than 2 per 1 million people per year.

Although this infection typically affects immunocompromised patients, it may also be seen after traumatic injuries, near drownings, or burns. Additional risk factors include poorly controlled diabetes mellitus, malignancy, and treatment with the iron chelator deferoxamine. Because of its invasive nature, this infection carries significant morbidity, with mortality rates greater than 50%. The most common sites of mucormycosis include the sinuses, respiratory tract, and skin. Less commonly, the GI tract may be involved. Infection is commonly locally invasive to adjacent structures such as the orbits, brain, and blood vessels, leading to extensive tissue destruction. Vascular invasion may result in serious complications such as massive hemorrhage. Pulmonary mucormycosis is characterized by angioinvasion and a high degree of tissue necrosis leading to rapidly progressive pneumonia, development of cavitations, and hemoptysis. Reversed "halo" signs may be an early radiographic finding but is nonspecific and also may be seen in aspergillosis. Symptoms of pulmonary infection are nonspecific, with patients typically having fever and hemoptysis.

Definitive diagnosis of mucormycosis requires histologic evidence of tissue invasion, but bronchoalveolar lavage is helpful in making a diagnosis. Management of this disease requires a multidisciplinary approach. This includes correction of metabolic abnormalities, reduction of immunosuppression medications, and excision or debridement of infected tissues. Aggressive surgical debridement is key to preventing further invasion. This is particularly important if there is angioinvasion or necrosis. Liposomal amphotericin B at doses of at least 5 mg/kg per day is recommended. Posaconazole may be used in combination with liposomal amphotericin B in refractory cases or for chemoprophylaxis and suppression. Echinocandins have not been shown to have in vitro activity against this species and are therefore not recommended.

Use of Opioids in the Postoperative Period

Richard J. Barth Jr, MD

CURRENT OPIOID EPIDEMIC

Opioid overdose is now the leading cause of injury-related death in the United States. There were 42,600 deaths from opioid overdose in 2016 compared to 37,000 deaths from motor vehicle crashes. Unfortunately, young people are most afflicted by this problem—20% of all deaths in persons between the ages of 24 and 35 were due to opioids. The death rate from prescription opioid overdose has quadrupled between 2000 and 2016. In addition, deaths from heroin and fentanyl are skyrocketing; the vast majority of people who use these drugs start with prescription opioids.

The rise in opioid overdose deaths has been temporally linked to rising rates of opioid prescriptions, which have similarly quadrupled between 2000 and 2015. In 2012 in the United States, 82 opioid prescriptions were written per 100 persons. Over 5 million Americans report current opioid abuse (within 30 days), and 18 million report abuse during their lifetime.

Candida

Candidal pneumonia is very rare, despite *Candida* being a common organism found in respiratory secretions. Most cases are related to disseminated *Candida* infection arising from distant sites and usually occur among patients with additional risk factors. As with most *Candida* infections, prolonged antibiotic use, hematologic malignancies, and other immunocompromised states are the primary risk factors. Use of Opioids in the Postoperative Period

Richard J. Barth Jr, MD

CURRENT OPIOID EPIDEMIC

Opioid overdose is now the leading cause of injury-related death in the United States. There were 42,600 deaths from opioid overdose in 2016 compared to 37,000 deaths from motor vehicle crashes. Unfortunately, young people are most afflicted by this problem—20% of all deaths in persons between the ages of 24 and 35 were due to opioids. The death rate from prescription opioid overdose has quadrupled between 2000 and 2016. In addition, deaths from heroin and fentanyl are skyrocketing; the vast majority of people who use these drugs start with prescription opioids.

The rise in opioid overdose deaths has been temporally linked to rising rates of opioid prescriptions, which have similarly quadrupled between 2000 and 2015. In 2012 in the United States, 82 opioid prescriptions were written per 100 persons. Over 5 million Americans report current opioid abuse (within 30 days), and 18 million report abuse during their lifetime.

Surgeons play an important role in this epidemic. Surgeons are responsible for a significant number of opioid prescriptions, and a substantial number of overdose deaths can be linked to opioid prescriptions written by surgeons. Although it was previously taught that prescribing opioids to patients for acute pain rarely resulted in long-term opioid use, recent studies have shown that 5% to 10% of opioid-naïve patients prescribed an opioid after surgery become long-term users. Furthermore, the size of the prescription matters. In one study, patients given a 1-day prescription had a 6% chance of being on opioids at 1 year after surgery, compared to a 13% chance if given an 8-day prescription. Thus, surgeons expose their patients to the risk of becoming long-term opioid users when they prescribe opioids for postoperative pain. Another problem arises when opioids are over-prescribed, excess pills can be diverted to others who were not the recipients of the original prescription. It is estimated that over 70% of chronic opioid users receive their medications through methods of diversion.

IN-HOSPITAL OPIOID-RELATED ADVERSE EVENTS

In addition to the risk of death from outpatient opioid overdose, the use of opioids in the inpatient setting is also associated with significant morbidity. Although opioids are effective analgesics, opioid-related adverse drug events occur in 5% to 10% of surgical patients. These adverse events include respiratory depression, ileus, nausea and vomiting, confusion, delirium, and dependence. Patients experiencing adverse opioid effects have a higher rate of inpatient mortality, length of stay, and cost of hospitalization.

NONOPIOID PAIN MANAGEMENT PLANS

Several alternatives to opioids are available for use in comprehensive pain management strategies and are implemented in enhanced recovery protocols. Pain from many operations can be decreased through the use of regional blocks. Regional blocks are highly effective in relieving pain and in decreasing opioid requirements, and have little morbidity. Regional blocks are well described for many operations, from mastectomies to hernia repairs to hemicolectomies. The use of epidural anesthetics to provide analgesia in the postoperative period for major abdominal surgery has also been shown to have several advantages, including decreased need for opioids. Infusion of local anesthetic into the wound prior to incision and the use of transdermal lidocaine patches should also be considered as part of the perioperative pain management plan.

Studies of patients with acute pain from surgery have indicated that ibuprofen and acetaminophen are more effective pain relievers than opioids. Meta-analyses by the Cochrane Database of Systematic Reviews have evaluated the effectiveness of various analgesics to determine the proportion of patients who achieved at least a 50% reduction of acute pain for 4 hours. They found that the combination of ibuprofen 400 mg and acetaminophen 1000 mg relieved pain in 79% of patients. Ibuprofen 400 mg alone relieved pain in 52% of patients. In contrast, oxycodone 5 mg alone relieved pain in only 23% of patients, similar to the 17% of patients whose pain was relieved by placebo. Randomized trials of emergency room patients with acute pain from extremity injuries have also shown that combinations of acetaminophen and ibuprofen are as effective as acetaminophen plus opioids. Most patients undergoing elective surgery have no contraindications to the use of acetaminophen and ibuprofen. Liver toxicity is very rare if acetaminophen is dosed correctly. Ibuprofen needs to be carefully used in patients with renal dysfunction. A meta-analysis has shown that the intraoperative use of ketorolac does not result in increased bleeding rates. The use of these medications can enable many patients to use less opioids and especially in the outpatient setting can enable some to avoid opioid use completely.

A wealth of studies have also demonstrated that the preoperative use of gabapentin can also decrease pain and decrease postoperative opioid use.

Studies in cognitive psychology have shown that establishing the expectation with patients that their pain is going to be relieved by the proper and acetaminophen is likely to contribute to the success of this approach. Indeed, discussing with patients prior to surgery what level of pain is expected, and what the pain management strategy is going to be, lets them know that their surgeon cares about their discomfort and has a thoughtful plan about how to both manage their pain and minimize complications from excessive opioid use.

APPROPRIATE OPIOID PRESCRIBING

The problem for surgeons is that they must balance their desire to adequately relieve their patients' postoperative pain with a responsibility for their patients' long-term wellbeing and for overall population health. The goal of appropriate opioid prescribing is to prescribe the optimal number of opioid pills so that patients' pain is adequately relieved and leftover pills are minimized.

Several recent studies that have queried patients about how many opioids they actually used have documented that opioids are being overprescribed for most operations. These studies have shown that only 25% to 40% of opioids that are prescribed are actually consumed by patients. Over three-quarters of patients have unused opioids left over after surgery. Why are surgeons overprescribing? Several factors probably come into play. Primarily, it is likely due to a lack of knowledge regarding how many opioids were required for adequate pain control; until recently data on postoperative opioid use was lacking. Indeed, most studies on overprescribing also report wide variations in the number of opioids prescribed by different providers, reflecting a lack of evidence-based data to guide decisions. Lacking knowledge, surgeons might just choose the default number of pills that appears on an electronic medical record prescription, which in some cases is quite high. Until recently, opioids could not be electronically prescribed, so surgeons prescribed an excess to prevent patients from having to return to the clinic to obtain opioid refills. Surgeons may be concerned that if they do not adequately treat patients' pain they themselves will be negatively impacted by poor provider satisfaction scores on patient surveys of postoperative patients. All of these factors are being addressed by recent initiatives.

Emerging data on actual opioid use has enabled clinicians to form guidelines for appropriate opioid prescribing. Once the median and range of opioid use is known, guidelines can be developed that satisfy a certain proportion of patients' needs. For example, after establishing opioid usage for several outpatient general surgery operations, we set a guideline to fulfill the opioid usage of 80% of our patients. As shown in Fig. 1, we initially observed that a median of 30 5-mg oxycodone pills were being prescribed to laparoscopic cholecystectomy patients, with a range of 0 to 100 pills. We established a guideline recommendation of 15 pills, as this would satisfy the opioid usage of over 80% of our patients. When this guideline (which called for 50% reductions in the number of opioids we had previously been prescribing) was implemented, we were concerned that we would be undertreating 20% of our patients. We observed, however, that this was not a problem: fewer than 1% of patients required a refill prescription. Why were we able to satisfy almost all patients' opioid needs despite targeting only 80%? We queried the outlier patients who took more than our guidelines recommended, and found that over half of their opioid usage was for reasons other than surgical pain. We also found that some patients took more than the guideline number because they were initially prescribed more than the guideline and patients dutifully thought they were supposed to take all that they were prescribed. In fact, once we routinely set patient expectations, maximized use of local anesthetics and pre- and postoperative nonopioid analgesics, we have found that patients are using far less than our initial guidelines called for. Although we recommended 30 5-mg opioid pills after

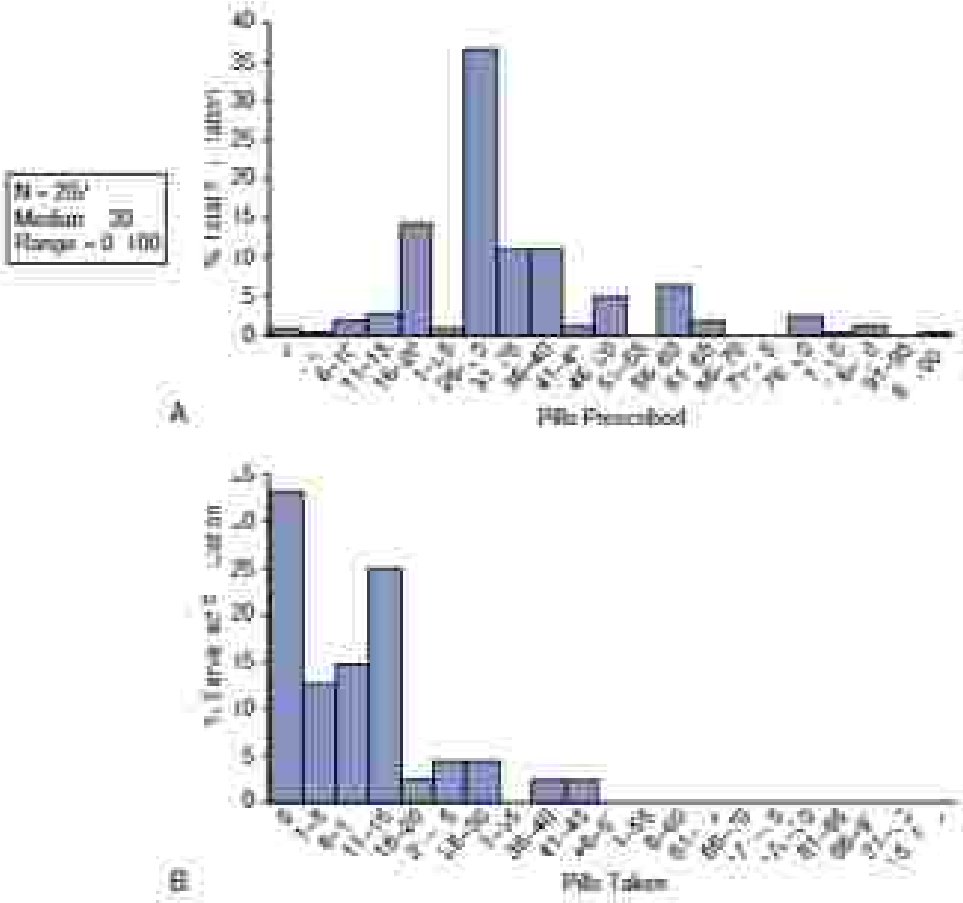

FIG. 1 Frequency of opioid pills prescribed and taken after laparoscopic cholecystectomy.

partial mastectomy and sentinel node excision in our initial guideline formulation, with the use of preoperative acetaminophen and gabapentin, intraoperative local anesthetic and ketorolac, and postoperative acetaminophen and ibuprofen, it is rare now for any of our partial mastectomy sentinel node patients to require an opioid.

The Mayo Clinic guidelines (http://links.lww.com/SLA/B67) are based on their observations of opioid use for several operations and were designed to supply enough pain medications for 80% of the middle two quartiles of patients (Tables 1 and 2). Procedure specific guidelines, based on evidence from usage studies, have also been made available by the University of Michigan (https://michigan.qures.org/prescribing-recommendations/). Opioid potency is expressed in oral morphine milligram equivalents (MME). For ease of conversion, a 5 mg tablet of oxycodone is 7.5 MME; 2 mg hydromorphone is 8 MME; 5 mg Vicodin is 5 MME; 30 mg codeine is 4.5 MME, and 50 mg tramadol is 5 MME.

Some guidelines, like the Mayo and Michigan guidelines, are procedure specific. This is particularly appropriate for outpatient procedures, some are just more painful than others and may require more opioids. These guidelines also give procedure specific recommendations for how many opioids to prescribe when patients undergoing a particular procedure are discharged after an inpatient stay. We have found, in multivariate analysis, that the best predictor of opioid use after a procedure that required an inpatient stay was the number of opioid pills taken the day prior to discharge. In our study of surgical inpatients, the particular operative procedure did not predict opioid usage post discharge. This allowed us to formulate an easy to remember guideline for discharge opioid prescriptions (Table 3). For patients discharged on postoperative day 2 or later, the discharge prescription is based on the number of pills taken the day prior to discharge: zero pills the day prior to discharge are prescribed none, 1 to 3 pills the day prior to discharge are prescribed 15, and 4 or more pills the day prior to discharge are prescribed 30. (1 pill = 5 mg oxycodone = 7.5 MME). In addition to its simplicity, another advantage of this guideline is that it takes individual variability in response to pain into account.

Several factors influence opioid usage after discharge. Patients who are opioid naive, older, have lower pain scores and who take few opioids while admitted are much less likely to require postoperative opioids than patients who are chronic opioid users, younger, have higher pain scores and who take more opioids in the hospital. Recognition of these factors is built into the Mayo Clinic guideline, which delineates low and high dose recommendations in addition to the standard, procedure specific dose (see Table 1).

PATIENT EDUCATION

Now that we have data on postoperative opioid use we can have a data driven discussion with patients preoperatively regarding the level of pain that they should expect after surgery and the methods (opioid and nonopioid) that we plan to use to minimize their pain. Those who are prescribed opioids should be clearly instructed on the risks of use, including both short term adverse events and the risks of becoming a long-term user. Clear instructions should be given to all about Food and Drug Administration (FDA) compliant forms of opioid disposal.

ASSESSMENT OF RISK OF OPIOID ABUSE

It is particularly important to prescribe the appropriate number of opioids to patients who have a high risk of becoming long term opioid users/abusers. At this point, we do not have molecular markers that will predict which patients, when prescribed opioids for surgery, are at risk of becoming long term opioid users. Certain patient characteristics, however, can be used to predict risk. The Webster Opioid Risk Calculator, for example (Table 4), takes into account family and personal history of abusing alcohol, illegal or prescription drugs, age,

and psychologic disorders like bipolar disease, depression, schizophrenia, and attention deficit disorder obsessive compulsive disorder to determine risk levels for long term opioid use. At some hospitals, risk calculators have become required elements for opioid prescribing through the electronic medical record. Several states have made it mandatory for surgeons to do a Physician Drug Monitoring Program (PDMP) search prior to prescribing opioids. The concept is that patients who have "doctor shopped" for opioids can be identified prior to surgery. However, even when one identifies a patient as high risk due to a high opioid risk calculator score or a suspicious PDMP record, these patients are still going to have pain from their surgery and are likely to require at least as many opioids as patients who are at low risk or have clear PDMP records. For surgeons it is likely that the most efficient use of our time would be to use the PDMP selectively for patients requesting refills after their initial prescription.

POSTOPERATIVE OPIOID PRESCRIBING FOR CHRONIC OPIOID USERS

Patients who are chronic opioid users are tolerant of opioids and therefore pose a particular challenge for perioperative pain management. With over 5 million such patients in the United States, it is not uncommon to have to manage their perioperative pain. Optimal management of chronic opioid users is not well defined. For patients requiring elective operations, innovative perioperative programs that utilize the expertise of both pain medicine physicians and psychiatrists may be beneficial. Some patients may be able to have depression or anxiety medications optimized, allowing them to be weaned off high dose opioids prior to surgery. Close collaboration between pain physicians and surgeons in the perioperative period is likely to lead to optimal results.

TABLE 1 Mayo Clinic Surgical Outcomes Program Recommendations for Adult Discharge Opioid Prescriptions (Number of Tabs of 5 mg Oxycodone or 50 mg Tramadol)

	Low Dose[a]	Standard Dose[a]	High Dose
GENERAL SURGERY			
Endoscopy (± PEG)	NSAID/acetaminophen only	NSAID/acetaminophen only	NSAID/acetaminophen only
Muscle biopsy or excisional biopsy			5 tabs oxycodone or 6 tabs tramadol
MIS cholecystectomy or appendectomy MIS inguinal hernia repair (TAPP or TEPP) Open inguinal hernia repair MIS bariatric, hernia repair, or adrenal surgery		8 tabs oxycodone or 12 tabs tramadol	20 tabs oxycodone or 30 tabs tramadol
SURGICAL ONCOLOGY			
Wide local excision or lumpectomy ± SLN	NSAID/acetaminophen only	5 tabs oxycodone or 10 tabs tramadol	10 tabs oxycodone or 15 tabs tramadol
Simple mastectomy only ± SLN		10 tabs oxycodone or 15 tabs tramadol	15 tabs oxycodone or 25 tabs tramadol
Mastectomy with tuboabdominal reconstruction ± SLN/ALND		20 tabs oxycodone and 40 tabs tramadol	40 tabs oxycodone and all tabs tramadol
Mastectomy with submuscular reconstruction ± SLN/ALND (recommend diazepam 2mg tabs every 6 hours, dispense #40)		30 tabs oxycodone and 80 tabs tramadol	60 tabs oxycodone and 60 tabs tramadol
MIS abdominal solid organ resection (e.g., kidney, spleen, or liver wedge)		15 tabs oxycodone or 25 tabs tramadol	25 tabs oxycodone or 40 tabs tramadol
Open major abdominal resection (e.g., Whipple, esophagectomy, or liver resection)		30 tabs oxycodone or 60 tabs tramadol	50 tabs oxycodone or 80 tabs tramadol
CRS			
MIS or open bowel resection (colon or small bowel) (rectal surgery, resection w/ ostomy, larger incisions, concurrent surgery, and major MIS cases may require higher dose)	NSAID/acetaminophen only	15 tabs oxycodone or 25 tabs tramadol	30 tabs oxycodone or 45 tabs tramadol

TABLE 1 Mayo Clinic Surgical Outcomes Program Recommendations for Adult Discharge Opioid Prescriptions (Number of Tabs of 5 mg Oxycodone or 50 mg Tramadol)—cont'd

	Low Dose*	Standard Dose†	High Dose‡
VASCULAR, THORACIC, AND ENDOCRINE			
Bronchoscopy or upper endoscopy (+ ablation)	NSAID/acetaminophen only	NSAID/acetaminophen only	NSAID/acetaminophen only
Percutaneous endovascular or vascular access procedures (cut-downs, complex endovascular, and AV superficialization may require additional opioids)			5 tabs oxycodone or 10 tabs tramadol
Carotid endarterectomy			8 tabs oxycodone or 12 tabs tramadol
Thyroid/parathyroid surgery, mediastinoscopy, or POEM		5 tabs oxycodone or 10 tabs tramadol	10 tabs oxycodone or 15 tabs tramadol
VATS procedure (pulmonary or mediastinal)		20 tabs oxycodone or 30 tabs tramadol	40 tabs oxycodone or 60 tabs tramadol
Thoracotomy (pulmonary, pleural, or chest wall)	5 tabs oxycodone or 8 tabs tramadol	30 tabs oxycodone or 90 tabs tramadol	60 tabs oxycodone or 100 tabs tramadol

*Prescribing a combination of tramadol and oxycodone is accepted as described, but the total number of pills should be reduced. For example, if 20 tabs oxycodone or 30 tabs tramadol is recommended from prescribing 10 tabs of oxycodone and 15 tabs of tramadol would be appropriate. However, prescribing a total of 50 tabs would be more than the patient would be expected to need. In addition, patients receiving opioids should still be encouraged to use NSAID/acetaminophen, if not contraindicated, and these should be taken around the clock with opioids being used only as needed for breakthrough pain.

†**Consideration for low-dose opioid dosing.** When collecting patients for low-dose opioid dosing it is important to note that prospective survey data on opioid use at mine suggests that a significant proportion of patients do not need any opioids after discharge. However, consideration should be made for anticipated intensity of pain associated with the patient's condition, patient access to clinical follow-up, and the extent to which nonopioid analgesics may be utilized for adjunct. For pain management (e.g., patients with contraindications to NSAID/acetaminophen) may require a prolonged level of opioids. Also consider using regional analgesia/anesthesia techniques in patients going home without opioids. It is also important to note that while providing refills requires extra care and time to providers, internal data somewhat strongly supports that patients found it easy to get a refill after discharge when needed. Prescribing higher opioids to avoid the inconvenience of a refill should be avoided.

‡**Consideration for standard opioid dosing.** If opioids are deemed appropriate to manage postoperative pain, the prescription should be for the lowest possible strength of a short acting opioid for the shortest duration of time based on anticipated pain, with a goal to taper as healing progresses. The recommended amounts in this group exceed self-reported use of 75% of patients; however, many patients use only 0 to 5 pills. Prescribing less opioids has not been shown to increase refill rates. Recommendations are for patients with no preoperative opioid use.

§**Consideration for high opioid dosing.** Preoperative opioid users should in general be included in these groups. Patients who are taking high doses of opioids, long-acting opioids, or have a pain management contract preoperatively fall outside of these recommendations and a postoperative pain management plan should be developed before surgery in coordination with their primary prescriber. When prescribing high doses of opioids it is important to discuss the risk of opioids, including respiratory depression and addiction, with the patient.

¶**Counseling.** Patients should be instructed before the procedure about their anticipated healing time, and that pain is a normal and expected part of the recovery process. Patients should be instructed on the expected duration of needing opioids, and that most patients should be off opioids 5 to 7 days after discharge. All patients should be instructed on the use of nonopioid pain medications if they are not contraindicated, regardless of dosing group selected. Patients should be instructed on the risk of opioids, including the risk of addiction. Very few patients dispose of unused opioids appropriately. Providers should instruct patients on the safe disposal of opioids.

ALND, Axillary lymph node dissection; BMI, body mass index; CRS, cytoreductive surgery; LOS, length of stay; NSAIDs, nonsteroidal anti-inflammatory drugs; POEM, per oral endoscopic myotomy; SLN, sentinel lymph node; TAPP, transabdominal preperitoneal; VATS, video assisted thoracoscopic surgery.

TABLE 2 Factors Shown to Influence Opioid Usage After Discharge

Less Use	More Use
Opioid naïve	Preoperative opioid users
Older age, lower BMI, longer length of stay	Younger age
Lower pain score at discharge	Higher pain score at discharge
Less in-hospital opioid use	High in-hospital opioid use

From Webster LR, Webster R. Predicting aberrant behaviors in opioid-treated patients: preliminary validation of the opioid risk tool. Pain Med 2005;6(6):432.

This tool should be administered to patients upon an initial visit prior to initiating opioid therapy for pain management. A score of 3 or lower indicates low risk for future opioid abuse, a score of 4 to 7 indicates moderate risk for opioid abuse, and a score of 8 or higher indicates a high risk for opioid abuse. ADD, Attention deficit disorder; OCD, obsessive compulsive disorder; Rx, prescription.

DISPOSAL OF EXCESS OPIOID PILLS

Appropriate disposal of excess opioids is a critical issue because when opioids are overprescribed, many patients will have left over pills and excess pills are then available for long-term use by the patient, or for diversion to others. Two methods of opioid disposal are approved by the FDA. One may return excess pills to drop boxes, which are commonly located at police stations and fire departments. Alternatively, one may dissolve pills in water in an unlabeled plastic bag to which dirt or cat litter is added and dispose of the bag in the trash. Several studies have shown that 10% or less of patients dispose of excess opioids in an FDA compliant manner. Even with intensive patient education about the dangers of excess opioids, compliant disposal rates of only 20% were achieved. Potential interventions to improve the proportion of pills disposed in a compliant fashion are under active investigation.

EFFECTIVENESS OF METHODS TO DECREASE OPIOID PRESCRIBING

In recognition of the link between opioid overprescribing and soaring death rates from overdose, many states have instituted legislation limiting the amount of opioid pills that can be given to patients for acute or chronic conditions. In general, these efforts have been based on expert and legislative opinion rather than rigorous evidence. Massachusetts and several other states have recently passed legislation that limits new opioid prescriptions for acute pain to "not more than a 7-day supply." This type of legislation, however, raises questions in its application. Does a 7-day supply mean 84 opioid pills (if 2 pills are taken every 4 hours), or 21 pills (if 1 pill is taken every 8 hours while awake)? Does one assume that the patient will slowly wean off the pills, thereby requiring less over time? Is a 7-day supply the appropriate duration for opioid pain control, or is it 5 days, or 10 days? Guidelines that are based on empirical data on patient opioid consumption, whether it be procedure based, or based on inpatient usage on the day prior to discharge, as described above, bring evidence-based precision to postoperative opioid prescribing decisions. There is some evidence that educational interventions about the dangers of opioid overprescription and providing surgeons with evidence-based prescription guidelines can dramatically change prescribing practices, without state legislative enforcement.

CONCLUSION

The epidemic of opioid overdose deaths and morbidity from adverse events from opioid use demands that surgeons use alternative methods to control postoperative pain and to responsibly prescribe appropriate amounts of opioids to their patients.

SURGICAL PALLIATIVE CARE

Geoffrey P. Dunn, MD, FACS

S[illegible] the pr[illegible] under [illegible] work for [illegible] [illegible] the [illegible] [illegible] treatment.

[illegible] In 2006, the National Quality Forum published its *National Framework and Preferred Practices for Palliative and Hospice Care* based on consensus guidelines authored by the leading hospice and palliative care organizations. In 2006, the Accreditation Council for Graduate Medical Education recognized hospice and palliative medicine as a subspecialty of 11 parent Boards including the American Board of Surgery.

PRIMARY PALLIATIVE CARE AND REFERRAL TO PALLIATIVE CARE SERVICES

The indication for palliative care in surgical practice is the seriously ill patient's desire for relief of distress in any of its forms as well as promotion of quality and promise of life regardless of diagnosis or prognosis. The choice of therapy is based on the ability of the treatment to meet the agreed upon goals of care, not its impact on the underlying disease process. Even highly invasive surgical treatments can be consistent with the purview of palliative care if shared decision making has adequately determined the relevance of the treatment. To date the majority of situations in surgical care for which palliative care would be appropriate do not trigger the services of palliative care teams or specialists. This has necessitated the concept of *primary palliative care*, the minimum deliverables of palliative support that can be secured by a surgeon and surgical team. These include (1) skilled communication about goals of care, unwelcome news, prognosis, and code status; (2) acute and uncomplicated chronic pain management; (3) management of common nonpain symptoms such as dyspnea, nausea, vomiting, anorexia, delirium, and anxiety; (4) recognition of syndrome of imminent demise; (5) appropriate and timely referral to specialty palliative care and hospice services. Palliative care consultation should be considered for patients with serious illness even when the surgeon has addressed the basic problems germane to palliation.

Shared decision making has become the preferred method for healthcare choices (including palliative care consultation) in situations attended by significant risk and uncertainty. Shared decision making is a collaborative process in which both the patient's preferences based on personal physical, socioeconomic, psychologic, and spiritual needs are aligned with the surgeon's presentation and explanation of available treatment options. It is not to be confused with informed consent, which is primarily an instructive, not a collaborative process. The operational platform for shared decision making is the family conference, which in the intensive care unit setting should occur within the first 5 days of admission, even in the absence of palliative care specialists. The primary nurse for the patient, social worker, and others active in the care of the patient (e.g., chaplain), should be invited to attend. During the meeting patients or their surrogates can identify the personal parameters for medical intervention while the clinician shapes a treatment recommendation, based on the prognosis, values, and priorities of the individual patient. In cases of doubtfully beneficial treatments the time-limited trial of therapy with a follow-up meeting is an invaluable maneuver that offers the chance but fires the warning shot. In the joint assessment of risk and benefit of operative intervention for seriously ill older patients the outcomes to be considered should go beyond the obvious and immediate (prolonged institutional care, burdensome symptoms, life support dependency) and include social and psychologic concerns such as being a burden, prolonged functional dependency, loss of personhood, and death away from home.

Palliative care consultation services, which are increasingly available in hospital and outpatient settings in the United States, have been shown to improve symptom control, enhance patient and family satisfaction, lower costs, and even improve survival. Triggers (see Box 2) for referral to specialty palliative care services have been proposed though may be of limited utility in resource poor settings or when consultation would duplicate primary palliative care.

BOX 1 Statement of Principles of Palliative Care

- Respect the dignity and autonomy of patients, patients' surrogates, and caregivers.
- Honor the right of the competent patient or surrogate to choose among treatments, including those that may or may not prolong life.
- Communicate effectively and empathically with patients, their families, and caregivers.
- Identify the primary goals of care from the patient's perspective, and address how the surgeon's care can achieve the patient's objectives.
- Strive to alleviate pain and other burdensome physical and nonphysical symptoms.
- Recognize, assess, discuss, and offer access to services for psychologic, social, and spiritual issues.
- Provide access to therapeutic support, encompassing the spectrum from life-prolonging treatments through hospice care, when they can realistically be expected to improve the quality of life as perceived by the patient.
- Recognize the physician's responsibility to discourage treatments that are unlikely to achieve the patient's goals, and encourage patients and families to consider hospice care when the prognosis for survival is likely to be less than 6 months.
- Arrange for continuity of care by the patient's primary and/or specialist physician, alleviating the sense of abandonment patients may feel when "curative" therapies are no longer useful.
- Maintain a collegial and supportive attitude toward others entrusted with care of the patient.

[illegible] Principles of Palliative Care [illegible]. [illegible]. 2004;[illegible]:[illegible]. Adapted with permission from [illegible] et al. [illegible] Surg. 2000;[illegible]:[illegible].

Assessment and Intervention

A conceptual model for pain and suffering is helpful for framing a workable strategy for palliative intervention. The primary target for palliative intervention is distress, not disease. Useful models of pain and suffering widely recognized in clinical palliative care are Cicely Saunders's model of "total pain" and Eric Cassell's concept of suffering. Saunders's model outlines four cardinal dimensions of pain (physical, socioeconomic, psychologic, and spiritual) that in aggregate are referred to as "total pain" and contribute to suffering. Cassell described suffering as the feeling that arises from a threat to integrity (wholeness) of the person. The elements of personhood include the individual's past, present, and future; his or her social role, private life, and a transcendent dimension. Suffering is not relieved until the threat to personhood has passed or is diminished.

Skillful and empathic communication is the core intervention of palliative care. It is analogous to the proper conduct of an operation—it requires creation of the right physical and social context, assessment of the individual's preparedness, permission to proceed, definitive action with economy of delivery, acknowledgment of the impact of the action upon the recipient, closure, and follow-up.

Palliative care assessment includes identification of decision-making capacity, previous illness and treatments, sources of pain in all its dimensions, sources of personal strength, vulnerabilities, and individual values and wishes. Surrogacy and advance medical directives may be addressed at this time. Relief of pressing symptoms should be done prior to or concurrently with assessment. Patient's goals of care that emerge from this discussion set the parameters for the surgeon's involvement. In cases where operative intervention is anticipated, preoperative anesthesiology consultation is helpful in planning intraoperative and perioperative analgesia (especially if use of regional anesthesia is anticipated), reviewing patient's goals of care in light of what anesthesia expertise can offer, and reconsideration of existing do not resuscitate (DNR) orders.

BOX 2 Center to Advance Palliative Care General Referral Criteria: Triggers for Specialist Palliative Care Referral

- Presence of a serious illness and one or more of the following:
  - New diagnosis of life-limiting illness for symptom control, patient/family support
  - Declining ability to complete activities of daily living
  - Weight loss
  - Progressive metastatic cancer
  - Admission from/to long-term care facility
  - Two or more hospitalizations for the same illness within 3 months
  - Difficult to control physical or emotional symptoms
  - Patient, family, or physician uncertainty regarding prognosis
  - Patient, family, or physician uncertainty regarding appropriateness of treatment options
  - Patient or family requests for futile care
  - DNR order uncertainty or conflicts
  - Uncertainty or conflicts regarding the use of artificial feeding/hydration in cognitively impaired, seriously ill or dying patients
  - Limited social support in setting of serious illness (e.g., no family support system, lives alone, homeless, chronic mental illness)
  - Patient, family or physician request for information regarding hospice appropriateness
  - Patient or family psychologic or spiritual distress

DNR, Do not resuscitate.

Physical symptom relief takes immediate priority of action over intervention for nonphysical distress, even if nonphysical issues are ultimately more important to the patient. Symptom management is the primary work of palliative care and requires an interdisciplinary approach. A strong liaison with clinical pharmacists is particularly helpful because of the effectiveness of pharmacotherapy for most symptoms and the frequency of adverse drug reactions, including costs, that add to total symptom burden. Because the elderly represent a substantial portion of patients receiving palliative care it is helpful to be mindful of the Beers Criteria for Potentially Inappropriate Medication Use in Older Adults, also known as the Beers List, which are guidelines for improving safety in prescribing medications for the elderly.

Tables 1 through 3 show medications and their conversions commonly used for control of major symptoms encountered during palliative care in the hospital setting. For nonphysical symptoms, the surgeon's role is to identify, triage, and refer appropriately and promptly. The importance of colleagueship with individuals entrusted with spiritual care of the individual cannot be overemphasized, particularly if spiritual anguish is the predominating form of the patient's distress. For specific ethical concerns frequently encountered in surgical palliative care, see Table 4.

The armamentarium of surgical palliative care includes palliative surgery, which is no longer defined as noncurative surgery but, instead, the more affirmative concept of deliberate symptom control and restoration of quality of life. This transition has been guided by increased emphasis on determining personal relevance for symptom relief, minimizing morbidity, improvement in nonphysical domains, and durability of symptom relief.

Considerations for palliative surgery include the expected course of the disease, the psychology of the patient, the effectiveness of the given operation, and the capacities of the surgeon/surgical team. Therapeutic benefit from palliative surgery must achieve symptom control, durability of symptom control, and symptom control with minimal morbidity (including social morbidity of hospitalization of an individual during the last weeks of life). After operative

TABLE 1 Overview of Pain Symptoms, Assessment, and Management

Symptom	Assessment	Treatment
Somatic pain	• Easily localized; includes acute postsurgical pain • Prescribe standing regimen with immediate release rescue doses available for breakthrough or uncontrolled pain • Unless contraindicated, a bowel regimen should be administered with opioids for prophylaxis against constipation • Symptomatic control should be assessed frequently to guide evaluation and refinement of the treatment regimen	• Mild pain: acetaminophen or NSAIDs • Moderate pain: titrate short acting opioids • Severe pain: titrate short acting opioids until adequately controlled, then transition to long acting opioids of equivalent potency and rescue doses
Bone pain	• Type of somatic pain from highly sensitive nociceptors of periosteum • Can be caused by fractures or irritation from underlying metastases found on radiographs and isotope bone scans • Bone metastases in the spine may lead to spinal cord compression and neurologic deficits • To decrease risk of NSAID induced gastropathy with chronic NSAID use, selective COX-2 inhibitors and coadministration with a gastroprotective agent (i.e., proton pump inhibitors) is advisable	A regimen combining NSAID s and opioids may alleviate generalized bone pain • Radiotherapy is effective for isolated metastases • Orthopedic interventions can be considered to stabilize pathologic fractures
Muscle spasm	• Prolonged, forceful, or sustained involuntary muscle contraction • Can be iatrogenic from medication side effects or because of electrolyte imbalances or dehydration	Pharmacologic therapeutics to include anticonvulsants (e.g., diazepam) and muscle relaxants (e.g., baclofen) • Manipulations to relax the muscle include stretching and massage • Physiotherapy treatments include electrical stimulation of the nerves or ultrasound thermotherapy
Neuropathic pain	• Common examples include post thoracotomy pain, phantom limb pain after amputation, ischemic limb pain, and pain from tumor invasion of nerves (i.e., pancreatic cancer pain) • May be accompanied by altered sensation	• Tricyclic antidepressants (e.g., amitriptyline) and anticonvulsant medications (e.g., gabapentin) may be helpful in combination with opioids • Pancreatic cancer pain may be alleviated temporarily by local neurodestructive (celiac axis blockade) or permanently by celiac axis neurolysis procedures • Anti-inflammatory properties of corticosteroids may reduce peritumoral edema
Visceral pain	• Often diffuse and poorly localized • Can be caused by distension, ischemia, and inflammation of the thoracic, pelvic, or abdominal organs • Solid organ tumor burden may cause stretch or irritation of peritoneal surfaces	• Treatment options are tailored to the site and etiology, and may include anti-inflammatory medications, corticosteroids, and opioids
Intestinal colic	Distension of the small intestine and colon cause visceral pain • Common examples include paralytic ileus, malignant obstruction, and intestinal pseudo-obstruction	• Treatment begins with addressing any reversible causes of distension • Nondestructive distension pain can be treated with antispasmodic agents (e.g., hyoscine butylbromide) and opioids

NSAIDs, nonsteroidal antiinflammatory drugs.

TABLE 2 Approximate Opioid Equivalences for Management of Moderate to Severe Pain

Analgesic	IM, SC, IV Route (mg)	Oral Route (mg)
Morphine	10	30
Hydromorphone	1.5	7.5
Oxycodone	NA	20
Hydrocodone	NA	30

...ose is a rough recommendation for opioid... patients. The ratios are... titration, and variability in opioid response between individuals among... Consult an expert before switching... IM, intramuscular; IV, intravenous; NA, not available; SC, subcutaneous.

TABLE 3 Overview of Nonpain Symptoms, Assessment, and Management

Symptom	Assessment	Treatment
Nausea/vomiting	• Rule out reversible causes such as hypercalcemia and infection. Treat underlying cause if nausea and vomiting results from intestinal obstruction or intracranial processes (i.e., increased intracranial pressure from space-occupying lesion or hemorrhage) • Toxins and medications can act centrally to stimulate the CTZ of the brain, inducing nausea and vomiting • Upper gut dysmotility from ineffective and delayed gastric emptying results in gastric distention, nausea, and vomiting	• Antiemetics target different receptors and may be combined • Dopamine antagonists (e.g., prochlorperazine, haloperidol) are effective for vomiting related to the CTZ • Antihistamines (e.g., meclizine) and anticholinergics (e.g., scopolamine) act centrally on receptors in the vomiting center of the vestibular system. They can be combined with dopamine antagonists • Serotonin antagonists (ondansetron) have diffuse inhibitory effects on serotonin receptors of the small bowel, vagus nerve, and chemoreceptor trigger zone. They are indicated for chemotherapy-induced nausea and vomiting • Nausea from dysmotility can be treated with prokinetics (e.g., metoclopramide)
Delirium/agitation	• May be caused by electrolyte imbalances and accumulation of toxic metabolites • Can be produced or worsened by certain medications (e.g., opioids, benzodiazepines)	• Identify underlying causes • Frequent reorientation • Antipsychotics are first-line pharmacotherapy (e.g., haloperidol, chlorpromazine) for moderate symptoms • For severe symptoms, benzodiazepines (e.g., lorazepam, midazolam) can be combined with antipsychotics to achieve sedation
Diarrhea	• First consider infection (e.g., *Clostridium difficile*) and iatrogenic (e.g., laxatives, medication side effect) causes • Diarrhea may be caused by chemotherapy or radiation enteritis • Patients may have altered anatomy (e.g., colectomy, bowel resection, high-output fistula, enteric intruder)	• Dietary modification, electrolyte repletion and adequate hydration • If infectious and reversible causes are ruled out, antidiarrheals can be used (e.g., loperamide, kaolin and pectin) • Patients with steatorrhea from pancreatic insufficiency should receive pancrelipase • Octreotide can be given to patients with secretory diarrhea, high-output stoma, or gastrointestinal fistula • Aspirin or NSAIDs, cholestyramine, and psyllium may be helpful for patients with radiation enteritis
Constipation	• Commonly associated with poor fluid intake, weak or debilitated patients, and those on opioid analgesics • Fecal impaction can cause partial or complete obstruction	• Stimulant laxatives (e.g., senna, bisacodyl) are indicated for patients without complete obstruction and should be given in combination with stool softeners (e.g., docusate sodium, polyethylene glycol, lactulose)
Dyspnea	• Several acute processes may cause dyspnea in surgical patients, including pneumothorax, atelectasis, and uncontrolled pain • The physiologic stressors of surgical treatment may exacerbate chronic conditions, including congestive heart failure and chronic obstructive pulmonary disease • When physical causes of dyspnea have been ruled out, emotional or situational challenges should be considered (i.e., anxiety)	• Reversible causes of dyspnea should be assessed quickly and treated appropriately, i.e., management of fluid overload for congestive heart failure and administration of bronchodilators or steroids for obstructive airway disease • Administration of supplemental oxygen using face masks should be avoided in the terminal setting • "Air hunger" is palliated with opioids and anxiolytics • Particularly when responding respiratory failure is a concern, an immediate conversation about preferences for invasive and noninvasive ventilation should occur with the patient or surrogate, with appropriate documentation in the medical record
Anorexia	Assess for reversible causes such as constipation, untreated pain, and endobronchial wounds	Megestrol acetate, steroids, nutraceutical

CTZ, Chemoreceptor trigger zone; NSAIDs, nonsteroidal antiinflammatory drugs.

TABLE 4 Common Ethical Issues in Surgical Palliative Care

Issue	Commentary
Disclosure of bad news	Broad legal and ethical consensus supporting disclosure of bad news when permitted by patient or surrogate. No evidence that disclosure of bad news "takes away hope" if conveyed gently and in the spirit of non-abandonment. Empathic truth telling fosters trust that is the basis of hope
Perioperative DNR orders	The American College of Surgeons, the Association of Operating Room Nurses, and the American Society of Anesthesiologists position papers condemn policies requiring automatic cancellation of existing DNR orders for patient undergoing anesthesia based on the principle of patient autonomy. All recommend preoperative discussion ("required reconsideration") during which patient or surrogate confirms patient's treatment goals and limits of care including revision or implementation of a DNR order, risks of patient's care plan; and recommendations by anesthesiologist and surgeon. During this discussion the anesthesiologist and patient can set the parameters for resuscitation for the procedure itself and in the recovery room
Withhold/withdraw of life support	The withholding and withdrawal of medical treatments are considered legally and ethically equivalent and are based on the right to bodily integrity. It is generally more difficult to withdraw a life supporting treatment once it has been started than to not initiate it at all. A surrogate's persistent reluctance to consider termination of life support is usually related to their fear that they will be "killing the patient" or their fear that withdrawing life support will cause suffering. Legally and ethically, termination of an unwanted medical treatment of the properly informed and uncoerced patient/surrogate is not considered homicide or suicide.
Aggressive symptom management	• Aggressive symptom management of unbearable symptoms is a moral imperative if effective treatment is available, even at the risk of hastening or causing death, as long as causing death is not the intention of treatment. The risk of hastening death is present with any surgical treatment for serious illness, including attempts to cure. • In situations where rapid escalation of dosing is necessary to relieve intractable severe symptoms (pain, dyspnea, agitated delirium) in the imminently dying patient, the DDE, broadly accepted by ethicists, is invoked. DDE is comprised of these elements: • The act must be good or morally neutral • Bad effects are foreseen but not intended • A good end cannot justify a bad means • The risk/benefit ratio must be reasonable
Terminal sedation	Rarely indicated in palliative care. Reserved for severe, intractable symptoms (pain, overwhelming existential distress) where death is imminent. The goal of palliative sedation is to use the minimum amount of sedation necessary to relieve severe physical symptoms to the point of unconsciousness, if necessary, and deliberate induction of coma or hastening of death. Consultation with ethics committee, neuropsychiatric consultant for determine competency), and palliative care specialist are recommended.

DNR, Do not resuscitate; DDE, rule of double effect.

complications dramatically worsen the prospects of achieving durable symptom relief up to the time of death.

Although life expectancy of less than 2 months has been suggested as a contraindication for palliative surgery, prognostication by physicians is notoriously inaccurate, especially if a symptom (e.g., pain) is the reason for loss of function rather than progression of disease. For many palliative intraabdominal procedures, such as malignant bowel obstruction, generally agreed upon relative contraindications include cachexia or hypoalbuminemia, poor performance status, significant comorbidities, diffuse intraperitoneal carcinomatosis, advanced disease refractory to chemotherapy, palpable multiple intraabdominal masses, multiple liver metastases, extraabdominal metastases, pleural effusions, multiple sites of partial obstruction or prolonged transit time of contrast on intestinal radiographic series, advanced age, recurrence following recent laparotomy for malignant obstruction, and previous abdominal radiation therapy.

The availability of stenting, minimally invasive procedures, laparoscopic approaches, and improved adjuvant chemo and radiation therapies have increased flexibility in relieving symptoms related to obstruction, pain, bleeding, fistula, and contaminated wounds. Many of the principles and interventions useful for the palliation of malignant disease can be applied to nonneoplastic disorders encountered in surgical practice such as chronic pancreatitis, congestive heart failure, and chronic liver failure.

Patient self report is the gold standard for outcomes measurement following palliative treatment. Numerous validated measuring instruments exist, some of which offer multiple languages and disease specific modules with ongoing updates. Some of the more commonly used questionnaires include the Functional Assessment of Cancer Control Version (FACT-G), the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 (EORTC QLQ C30), and the McGill Quality of Life Questionnaire (MQOL).

Surgeons should consider the option of hospice referral for patients with an estimated survival of 6 months or less if the illness pursues the expected course without further attempts to reverse it. The hospice option, which includes the patient's understanding of its prognostic criteria for enrollment, should be included for discussion during the informed consent process for palliative and nonpalliative surgery. See Boxes 2 and 4 for screening prognosis and referral criteria for hospice services.

BOX 3 Prognostic Indicators for Palliative Care Patients

General Indicators of Poor Prognosis

- Functional ability, single most important predictive factor
- Median survival of 3 months or less if ECOG ≥ 3 or KPS ≤ 50
- Additional evidence: unintentional progressive weight loss >10% over prior 6 months
- Serum albumin <2.5 g/dL (not to be used in isolation from other factors)

Cancer-Related Indicators of Poor Prognosis

- Patients with solid tumors typically lose 30% of functional skill in the last 3 months of life
- If >50% of time is spent sleeping or lying down and is increasing, median survival is 3 months, less with increasing symptoms, especially dyspnea
- Most solid tumors that progress through 2 rounds of chemotherapy: <6 months
- Hypercalcemia: 8 weeks (except newly diagnosed myeloma or breast cancer)
- Pericardial effusion: 8 weeks
- Carcinomatous meningitis: 8–12 weeks
- Multiple brain metastases: 1–2 months without radiation, 3–6 months with radiation
- Malignant ascites or pleural effusion: <6 months

Most metastatic solid cancers, acute leukemias, high-grade lymphomas not on chemotherapy: <6 mos

ECOG, Eastern Cooperative Oncology Group.

SYNDROME OF IMMINENT DEMISE AND COMFORT MEASURES ONLY

The syndrome of imminent demise or active dying can be easily overlooked in the differential diagnosis of clinical decline attributed to reversible causes such as drug-induced delirium or organ failure. The stages of syndrome of imminent demise can span from less than 24 hours to 2 weeks. The syndrome commences with a (usually) bed-bound patient with diminished oral intake and increased sleep and confusion. This progresses to further cognitive decline and increased somnolence punctuated with periods of lucidity. In the final stage coma, "death rattle" extremity mottling, and variable respiratory patterns including apneas are present. Progression tends to be more rapid for patients who are malnourished and/or infected. Its recognition is crucial because of the implications for its management. To meet the family's desire for privacy and avoidance of suffering of the patient, interventions and paraphernalia not relevant to comfort should be quietly discontinued. When a patient has an automated implantable cardioverter defibrillator, this should be addressed with the patient and/or family to provide the opportunity to program off the defibrillator portion of the device. There is no palliative indication for programming of pacer function.

Family members should be reassured of minimal discomfort of the patient by the medical team, especially because family may fear they have abandoned the patient themselves by discontinuing life-sustaining treatments. As death approaches, dyspnea (air hunger), upper airway secretions (death rattle), altered sensorium (delirium, loss of consciousness, agitation), incontinence, and pain are the likely symptoms that will require proactive management. An important part of preparing the family for what death will look like includes explaining the mechanisms of the death rattle before it occurs. This can be much to reassure family if it does because its occurrence is due to a small amount of pooled secretions around the vocal cords, not "drowning." In addition to preemptive medication with antisecretory drugs, positioning patients on their side or elevating the head of the bed may reduce noisy respirations.

In cases when ventilator withdrawal is necessary to initiate comfort care, paralytics should be discontinued, allowing time for neuromuscular function to return. The patient should be premedicated adequately for sedation with opioids and benzodiazepines to prevent dyspnea and anxiety. Additional medications should be available at bedside for immediate titration. FiO_2 is then lowered to room air and positive end expiratory pressure is discontinued. Further titration with opioids and anxiolytics is based on apparent respiratory distress, not oxygen saturation. If there is no apparent distress after tapering down to an inspiratory rate of 4/minute, extubation can be done with or without family presence. A substantial majority of patients will expire within an hour and most of the remainder within 24 hours. If the patient remains stable for several hours, transfer to a suitable nonmonitored bed can proceed as long as the family is notified before transfer. The possibility of unexpected prolonged survival and its implications for transfer should be addressed before initiation of comfort measures only. After death occurs, the family should be given adequate time and privacy to say goodbye and private at the bedside. Confidential and bereavement support should be offered at this time.

BOX 4 Medicare Hospice Benefit

Eligibility

- Enrolled in Medicare Part A
- Two physicians certify terminally ill status with life expectancy of less than 6 months if illness pursues its natural course
- Patient opts for symptom management care only and forgoes life-prolonging treatments for terminal illness of record and other comorbidities.

From Medicare Benefit Policy Manual, Chapter 9, Coverage of Hospice Services Under Hospital Insurance. www.cms.gov/Regulations-and-Guidance/Guidance/Manuals/Downloads/bp102c09.pdf

BEREAVEMENT

Access to bereavement services is a critical component of surgical palliative care, not only for patients and families but also to hospital caregivers. Hospital-based bereavement services including pastoral care departments and family support services have been shown to affect long-term psychosocial functioning of surviving family members and decisions about organ donation. Surgeons may also benefit from these services as they seek the balance between detachment and overwhelming emotions in response to serial losses. Writing a condolence letter to the deceased patient's family is a simple but significant gesture that supports the family and the surgeon's bereavement.

In summary, the surgical community has too many seriously ill people in its care and has too much unique experience to refer them to not assume an active role as a provider of palliative care to its patients and families regardless of prognosis.

CARDIOVASCULAR PHARMACOLOGY

Jay G. Shake, MD, MS, and J. Michael Brewer, DO, FS

The need to pharmacologically manipulate the cardiovascular system is relatively common for practicing surgeons and those caring for patients in the perioperative period. Most surgical residents often state to their trainers that we surgeons should strive to be the best doctors in the hospital. And, to be able to operate. This statement probably applies itself well in the familiarity and comfort we should have regarding the use of common cardiovascular medications because this occurs so frequently in our patient population. The most encountered scenarios often involve managing a patient with severe hypotension or shock, heart failure, hypertension, and an assortment of common cardiac arrhythmias. This chapter aims to give the reader an overview of these common conditions and how they can be managed with a few cardiovascular medications.

MANAGEMENT OF SHOCK/ HYPOTENSION

Assessment of Shock

Shock is a disturbance of the adequate forward flow of blood that is essential for the delivery of oxygen and nutrients and removal of carbon dioxide and waste from cells and tissues. Multiple factors contribute to normal blood flow, including heart rate (HR), myocardial contractility, preload, and systemic vascular resistance (SVR)/afterload; and, when perturbed, may result in inadequate blood flow and shock. The surgeon must quickly and accurately assess a patient to determine the etiology of shock (i.e., inadequate preload, cardiac failure, or low SVR [afterload]) to correctly manage the condition, including the correct choice of inotrope or reassessment of preload. Shock is not simply a state when the mean arterial pressure (MAP) is less than 65 mm Hg or the patient requires medications to maintain this parameter, though these factors may be markers of shock. Blood pressure is not a measure of the forward flow of blood in the cardiovascular system. Rather, it is simply a pressure measurement; therefore, we make every attempt to not interchange low blood pressure (or hypotension) and shock if possible. A patient can have a normal or elevated blood pressure and be in cardiogenic shock with a cardiac output (CO) that is not compatible with life. This can be understood by review of a simple physiology equation:

$$CO = HR \times (MAP - CVP)/SVR$$

in which CVP is central venous pressure.

Another simple equation that the reader needs to remember is as follows:

$$CO = HR \times SV$$

in which SV is stroke volume.

The human body can quickly and easily adjust its CO to meet bodily needs by increasing the HR. Similarly, cardiac surgeons often place temporary pacing leads on the surface of the heart to artificially increase the CO in patients with low flow states. Usually 80 to 90 beats/min has been the preferred HR range in these cases or even higher in orthotopic heart transplant patients. SV is particularly influenced by preload, contractility, and SVR (afterload). Although, just to be thorough, a number of other things can directly or indirectly affect SV, including heart rhythm, atrioventricular synchrony, and pulmonary vascular resistance.

To describe what we call the forward flow of blood in the cardiovascular system, some clinicians use CO, but certainly in the cardiovascular intensive care unit, we have become more comfortable using cardiac index (CI) because it adjusts for the size of the patient, more specifically body surface area (BSA). A single value can be the target of any size individual from the young thin teen or emaciated elderly individual to the massive obese adult males that we more commonly care for today.

$$CI = CO/BSA$$

A landmark paper in congenital cardiac surgery simply and eloquently demonstrated that an "inflection point" occurs at about a CI of 2 L/min per m² (Fig. 1). Values consistently below this value were directly proportional to the increased probability of acute cardiac death. It is not surprising that most cardiac centers have developed a practice of treating cardiac medications to target MAPs greater than 65 mm Hg and cardiac indexes greater than 2.0–2.2 L/min per m². In our experience, values below this routinely result in parameters of inadequate perfusion including metabolic acidosis and elevation in lactate levels. Again, remember that a low CI can coexist with a normal or even elevated blood pressure.

Shock patients can be placed in three categories:

1. *Hypovolemic shock.* This form of shock is related to low filling pressures or preload seen by the heart and cardiovascular system. Certainly, hemorrhagic shock is in this category. Resuscitation with crystalloid, colloid, or blood products would be the correct management depending on the etiology of volume loss. Resuscitation of the proper amount of fluid is also important (see the Perioperative Optimization section for more details.) It is important to remember that up to 40% of all causes of hypotension in the intensive care unit can at least initially respond to fluid resuscitation alone. Start with this approach while you are gathering more information to treat a patient in one of the other categories. Other diagnoses that need to be remembered, and clinically behave like hypovolemic shock because they are impeding the appropriate filling of the heart, are cardiac tamponade and pulmonary embolism. Each of these diagnoses has a unique decision tree with appropriate management.
2. *Cardiogenic shock.* This form of shock is related to inadequate CO (or CI), which is directly related to dysfunction of the heart and often some contribution of the systemic vascular system. This can be related to a problem directly related to myocardial contractility such as either acute left heart failure, acute right heart failure, or both. A simple example to demonstrate this would be following an acute myocardial infarction in the perioperative period. More commonly, this can be seen with an acute on chronic process such as chronic systolic heart failure or chronic diastolic heart failure. Unfortunately, the compensatory mechanism to elevate the blood pressure to an acceptable level in this type of patient is elevation of the SVR. This in turn makes the failing heart need to work even harder to eject the blood against the increased resistance. Sometimes these very sick hearts need inotropic supportive medications and also afterload reduction to adequately increase the cardiac indices to a level compatible with life. Our analogy to trainees is that you need to "step on the gas" and also "let off the brake" to a failing car engine. It is thus not surprising that home inotropic therapy in the heart failure patient population has traditionally been with milrinone and dobutamine, both inotropic agents with vasodilatory properties.
3. *Distributive shock.* This form of hypotension is related to vasoplegia or relative loss of arterial vascular tone. Often these patients have a high CO and yet remain hypotensive because of low SVR. Anaphylactic shock and spinal shock would both fall into this category. Septic shock would initially fall in this category too, but in advanced cases, there is also the component of septic cardiomyopathy. The use of vasoconstrictor medications is often necessary to support these patients.

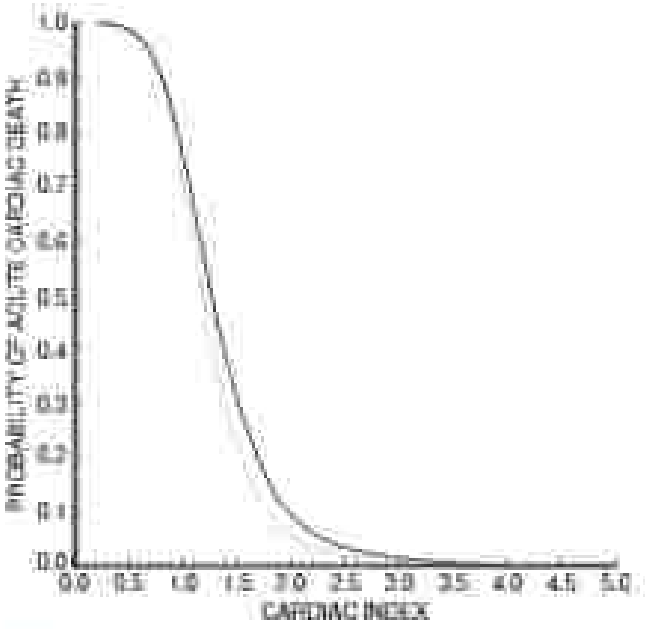

FIG. 1 Mortality and cardiac indexes. [illegible]

Preload Optimization

Although aggressive intravenous fluid resuscitation is often undertaken as an initial measure for a patient in shock, it cannot be stressed enough that there is mounting evidence that too much fluid is also harmful to our patients. Excessive intravenous fluid resuscitation can lead to severe hypoxia (pulmonary edema) or arrhythmias (atrial or ventricular overload) and may increase mortality in critically ill patients. The goal is therefore optimization of the preload, ideally without leaving the patient's intravascular space either underfilled or overfilled. Modern fluid management incorporates the use of dynamic tests to induce brief changes in cardiac preload while assessing for increase in SV and CO.

Historically, physicians have used static parameters such as CVP and pulmonary capillary wedge pressure as predictors of intravascular volume status or a response to fluid bolus challenges to their assessment of an appropriate preload; however, these have repeatedly been shown to be inaccurate and therefore can misguide management. Our line of reasoning is that the CVP is not a gas gauge in which a single predetermined number predicts the correct filling pressure for all patients. As a result of these collective findings, the use of Swan-Ganz catheters has dramatically declined. The use of dynamic parameters such as pulse pressure or SV variation, respiratory variation of the inferior vena cava, mini fluid challenge, and expiratory occlusion test (in mechanically ventilated patients), and passive leg raising test are likely better predictors of which patients will have an increase in SV following administration of intravenous fluids, which is the ultimate goal of fluid resuscitation in patients with shock. These tests can be performed easily at the bedside, though some require a method of measuring changes in SV or CO or special monitors. Surgeons caring for critically ill patients should be familiar with the limitations of any dynamic parameters they wish to incorporate into care of patients.

Left Heart Failure

Perhaps the most ill and difficult to manage patients in the intensive care unit (ICU) is the subset of patients who have left heart failure. This is particularly true when they have additional confounding problems such as sepsis or pulmonary hypertension. The vasoplegia and need for added CO to maintain adequate blood pressures and metabolic needs can amount to the need for a concoction of numerous cardiovascular medications to achieve our desired parameters at doses that are sure to result in end organ injury and likely death. Vasoactive agents (inotropes targeted at increasing the blood pressure often make matters worse by increasing the pulmonary hypertension with their α-adrenergic stimulation.

Also commonly seen in the ICU are patients with hypotension/shock from worsening of preoperative chronic systolic heart failure or new acute myocardial infarction. This is referred to as an acute on chronic disorder. The management is the same except the magnitude of support is often increased a logarithm, or more, and of course the outcomes can be extremely poor.

Although there is no proven outcome benefit for invasive hemodynamic monitoring in these patients, the authors routinely use these invasive devices to achieve reasonable hemodynamic goals, usually MAPs $\geq$ mm Hg or greater and cardiac indexes of 2.2 L/min per m^2 or greater when there is any indication that there is more than one etiology contributing to the hypotension. An example would be a patient with septic shock and significant left ventricular dysfunction. Fortunately, there have been an increasing number of new monitoring devices, some mentioned previously, offering less invasive techniques and with more real-time feedback to adjust management.

If adequate cardiovascular parameters cannot be achieved with multiple high-dosed intravenous medications one could obtain consultation for consideration of an intraaortic balloon pump or even extracorporeal mechanical circulatory support in a select patient population with acute heart failure.

Right Heart Failure

One must attempt to understand the etiology of right heart failure to be able to manage it correctly. Remember, right heart failure is most commonly a result of left heart failure. This needs to be assessed first; however, if elevated pulmonary pressures and right heart failure are found with satisfactory left heart function, then therapy needs to be targeted at decreasing the pulmonary vascular resistance. This would include avoiding α-1 agonists and correcting hypoxemia, hypercarbia, and severe acidosis. Elevated airway pressures from high ventilator settings or positive end-expiratory pressure should also be avoided. Inhaled vasodilator therapy should also be considered.

The guiding principles to improve left heart failure are otherwise nearly identical to right heart failure. An echocardiogram is often indicated to identify if there is a single- or two-ventricle issue and whether there is a cardiac valve problem contributing to the situation. Inotropic therapy would be the mainstay of therapy with the preferred agent to be milrinone or dobutamine due to their increase in inotropy without vasoconstriction.

Single-ventricle mechanical support is now possible with percutaneous right ventricular assist device or venoarterial extracorporeal mechanical circulatory support in extreme cases.

CARDIOVASCULAR MEDICATION CHOICE ALGORITHM

The goal(s) of the cardiovascular medication would be to improve myocardial contractility enough to improve the SV and subsequently the forward flow (CO), without worsening or provoking an acute myocardial infarction. At the same time, the agent might need to increase the afterload to restore the mean arterial blood pressure to an acceptable level. The indications of the commonly used inotropic and vasopressor medications are dependent on the receptors that they activate (Table 1) and the resulting physiologic response. The specific effects of the receptors (Table 2) are important to remember and in combination with the drug's mechanism of action one should be able to more accurately choose an agent to accomplish the desired effect.

A few specific effects of the cardiovascular medications deserve review. β_1 stimulation increases myocardial contractility (inotropy),

an increased HR (chronotropy), and increased conduction of impulses down the heart's conduction system (dromotropy). Additionally, stimulation of α-1 receptors angiotensin II receptors, and vasopressin 1 (V_1) receptors all result in vasoconstriction.

Our medication drip strategies are as follows (assuming preload is optimized):

1. If more forward flow (CO) is needed and the blood pressure is low, use an agent with both β-1 agonist with α-1 activity. We choose epinephrine first for very impaired contractility and norepinephrine first for moderately impaired contractility. Severely impaired hearts often need both. Otherwise, sometimes a second agent is needed such as vasopressin or even angiotensin II for refractory hypotension. Milrinone (phosphodiesterase inhibitor) can be added to the β agents to increase the contractility. Their actions are synergistic because of the separate mechanisms of action.
2. If more forward flow is needed and the blood pressure is elevated or normal use an agent to lower the afterload (vasodilator) and add a β-1 agonist or phosphodiesterase inhibitor if needed to increase the contractility. A single agent that does both, such as dobutamine or milrinone, can be useful.
3. If there is normal or elevated forward flow but hypotension remains, then there is an afterload problem. A vasoconstrictor is needed with α-1 angiotensin II, or vasopressin 1 stimulation with titration targeted to a desired endpoint. If one drug is started and the patient remains refractory, start a second agent that works by a different mechanism. Norepinephrine is currently the drug of choice in sepsis, so this would need to be started first in this patient population. If patients fail to respond adequately to norepinephrine, our practice is to add either vasopressin or epinephrine as a second agent. If further escalation of vasopressor support is needed, intravenous angiotensin II may be considered. Also consider endocrinopathy as a cause for distributive shock. There is some evidence that intravenous hydrocortisone may be helpful in the setting of refractory septic shock. Other medications such as intravenous methylene blue or high dose hydroxocobalamin may be considered for rescue therapy in the most refractory of cases.
4. In a patient with distributive shock and severe pulmonary hypertension, avoid use of any agent with α-1 adrenergic properties. Instead, initiate a trial with vasopressin.

MANAGEMENT OF SYSTEMIC HYPERTENSION

It is relatively common to encounter systemic hypertension in the perioperative period. Often, this is seen with pain as the inciting event, so this should always be addressed first. Then we must ensure that patients are not put at increased risk by the discontinuation of their chronic antihypertensive medication(s). This can be particularly difficult when the gastrointestinal tract is involved during surgery, with accompanying loss of bowel function or ileus. In particular, cessation of β-blockers has been shown to be harmful to patients at risk of ischemic heart disease. Fortunately, there are intravenous medication substitutions that can be ordered as a replacement with similar pharmacologic profile. Other classes of agents, in particular long-acting agents, have no other parental medications and other classes of medications need to be chosen. Sometimes shorter acting agents of the same drug classification can be used. Last, after surgery the need to restart home medications needs to be considered.

Direct vasodilators via the parenteral route are very useful as first line antihypertensive agents in the perioperative period for many patients. Intermittently dosed agents include hydralazine (10–20 mg intravenous [IV] every 2–4 hours as needed) and labetalol (20–80 mg IV every 10 minutes as needed with a maximum dose of 300 mg/d). Usually, the lower range of doses is attempted first and then escalating doses are added as needed. The next step would be a continuous infusion with clevidipine, labetalol, nicardipine, nitroglycerin, or sodium nitroprusside. Clevidipine (1–21 mg/hr IV) is a calcium channel blocker that has a lipid formation so should be discouraged if using other lipid accompanying agents such as propofol as a sedative. Labetalol is also a very effective continuous infusion (0.5–20 mg/min) particularly in β-blocker naïve patients. Nicardipine (1–15 mg/hr IV) is in the same drug class; however, it has a much longer half life (8.6–14.4 hours) so one must anticipate the change in blood pressure and adjust the dosing along with the clinical picture. Nitroglycerin and sodium nitroprusside are both venodilators so should be used to caution in patients with intracranial hypertension. Nitroglycerin (5–200 μg/min IV, start 5 μg/min and increase by 5 μg/min every 3 to 5 minutes until a response is seen) is a rather weak antihypertensive agent and is therefore used more for its antianginal properties in the perioperative period. Sodium nitroprusside (0.4 μg/kg per minute with starting doses 0.3–0.5 μg/kg per minutes IV) is a very effective direct vasodilator with a relatively short circulatory half life (2 minutes); however, cyanide toxicity can be seen with high doses, lengthy duration, or renal impairment due to secondary medicine clearances (thiocyanate half life 3 days). Also, both nitroglycerin and sodium nitroprusside can develop tachyphylaxis with continued use.

Direct vasodilators offered via the oral route include calcium channel blockers and hydralazine (10–50 mg PO four times daily). Several calcium channel blockers are offered as many hospital formularies including amlodipine (2.5–10 mg by mouth [PO] every day), diltiazem (immediate release 30–90 mg PO four times daily), verapamil, and more. Several of these are also offered in a formulation with long acting properties. Usually, we suggest starting the shorter half life agents first to demonstrate stability and then transition to the longer acting medication at a later time.

Parenteral β-blocking agent use has primarily centered on labetalol (mixed α- and β-antagonists), esmolol, and metoprolol. Labetalol, as noted previously, can be a very effective at lowering blood pressure because of its actions on the vascular tone in addition to the β-blocking properties. Intravenous metoprolol tartrate (2.5–10 mg IV every 6 hours) is still a mainstay of therapy to control HR, blood pressure, and even atrial fibrillation prophylaxis in many ICU patients. Esmolol (50–200 μg/kg per minute IV) is a β-blocker worth mention because of its ultra-short half life (9 minutes). Although this implies rapid onset and easy titration, we find a limited subset of patients to which this is really useful, in large part because of the large volume of infusion need to achieve the dosages that are need to get good HR or blood pressure control. Esmolol may be started in the acute setting in an unstable patient, and then we rapidly convert to intravenous infusion of metoprolol with similar effects as able.

There are numerous β-blockers offered in an enteral form; however, again we tend to mostly concentrate on oral labetalol and metoprolol, although other agents could certainly be used. Labetalol (100–800 mg PO bid) is commonly used at many centers for perioperative blood pressure control. We tend to gravitate to metoprolol, and there are two forms that providers must know and be comfortable using. Metoprolol tartrate (Lopressor, 12.5–100 mg PO twice daily) is the most common oral β-blocker formulation that we use in our cardiovascular ICU and has a shorter half life. We start at the lower end of the dosing range and then titrate to effect. Metoprolol succinate (Toprol XL, 25–200 mg/day PO) is a long acting agent that can be used after a period of stability with the shorter acting agent.

Several other antihypertensive classes exist, including angiotensin converting enzyme inhibitors, angiotensin receptor blockers (ARBs), clonidine, diuretics, and some combination medications that contain agents with more than a single drug category. Although angiotensin converting enzyme inhibitors are often held around the time of surgery, sometimes they need to be restarted in a patient that is unable to tolerate oral medications, in this case, enalaprilat is a reasonable choice with a starting dose of 0.625 mg IV every 6 hours and then increased every several doses to maximum of 2.5 mg IV every 6 hours. The most commonly used ARB in our unit

TABLE 1 Commonly Used Intravenous Inotropic and Vasopressor Agents

Medication	Dose range	Mechanism/receptor	Indication
Angiotensin II	1.25–40 ng/kg/min	Angiotensin	Vasoconstrictor
Dobutamine	1–20 μg/kg/min	β 1, β 2	Inotrope, vasodilator
Dopamine	1–20 μg/kg/min	α 1, α 2, β 1, β 2, dopamine	Inotrope, vasoconstrictor
Epinephrine	1–20 μg/min	α 1, α 2, β 1, β 2	Inotrope, vasoconstrictor
Isoproterenol	1–20 μg/min	β 1, β 2	Inotrope, chronotrope
Milrinone	0.125–0.75 μg/kg/min	Phosphodiesterase 3 inhibitor	Inotrope, vasodilator (including pulmonary)
Norepinephrine	1–30 μg/min	α 1, α 2, β 1	Inotrope, vasoconstrictor
Phenylephrine	20–200 μg/min	α 1	Vasoconstrictor
Vasopressin	0.01–0.06 U/min	V1, V2	Vasoconstrictor

TABLE 2 Effects of Adrenergic and Other Receptor Subtypes on the Cardiovascular System

Receptor	Location	Effect
α 1	Systemic arterioles (viscera, coronary, skeletal muscle), veins, pulmonary arterioles	Vasoconstriction
α 2	Presynaptic and postsynaptic sympathetic nerve terminal, central nervous system	Vasodilation
β 1	Heart	Inotropy, chronotropy, dromotropy
β 2	Systemic arterioles (viscera, coronary, skeletal muscle), veins, pulmonary arterioles	Vasodilation
Dopamine	Systemic arterioles (viscera, coronary, skeletal muscle), veins, pulmonary arterioles	Vasodilation
Vasopressin 1	Vascular smooth muscle	Vasoconstriction
Vasopressin 2	Renal distal convoluted tubule and collecting duct	Antidiuresis
Angiotensin II	Systemic arterioles, kidney, adrenal cortex	Vasoconstriction

to losartan (25–100 mg/day PO, divided every day or twice daily). Caution must be taken when using both the angiotensin converting enzyme inhibitors and ARBs in patients with renal artery stenosis, hepatic or renal impairment, and volume depletion. Clonidine (0.1–0.4 mg PO twice daily) can be quite helpful for those patients refractory to a cocktail of several high dose antihypertensives. Several of the combination drugs are helpful but not ideal in the acute settings, but need to be considered later in the hospitalization to simplify the antihypertensive regimen. An example would be isosorbide dinitrate/hydralazine (1 tablet PO three times daily, 20 mg/37.5 mg).

MANAGEMENT OF PULMONARY HYPERTENSION

A common incorrect diagnosis made in the ICU or laboring a patient with pulmonary hypertension just because the pulmonary artery pressures are elevated on the Swan Ganz catheter. If these are seen with concomitant elevated systemic blood pressures, they really mean little. We find the ones that need to be managed are when they approach two thirds of systemic pressures. Moreover, it is helpful to know if this is reversible or not. Attempting inhaled or IV vasodilatory medication is not helpful if there is no response to the medication; therefore, if true pulmonary hypertension is identified, then begin an investigation into the etiology, which might mean consultation with a cardiologist or pulmonologist. Primary pulmonary hypertension can be treated with inhaled medications. To the contrary, elevated pulmonary artery pressures as a result of a left heart valve insufficiency might be worsened by a pulmonary vasodilator and attention would need to be directed to the medical or surgical management of the underlying disease process.

Inhaled nitric oxide (1–80 parts per million) can be used as a potent pulmonary vasodilator through the existing ventilator tubing is helpful, but increasingly expensive. Rarely does one need to go above 20 parts per million. Many centers have moved to inhaled epoprostenol with similar efficacies and at a substantial decrease in cost of the medications. This can often amount to millions of dollars at a large academic facility.

BRADYARRHYTHMIAS

Bradyarrhythmias are probably the least encountered arrhythmia in the ICU setting, at least those requiring medical management. This is because, as a general rule, bradycardia is well tolerated as long as there is an adequate CO; however, bradyarrhythmias can be seen as a result of the administration of nearly any medical blocking agent, particularly when several are used for hypertension refractory to monotherapy or in the case of treatment for tachyarrhythmias (mentioned in subsequent sections). In these cases, removal of the inciting agent(s) is most often the first step, along with correction of any correctable electrolyte abnormality.

In an unstable patient, or one with symptomatic status bradycardia, then management is per advanced cardiac life support (ACLS) protocol. In brief, the first line agent would be atropine at a starting dose of 0.5 mg IV and redosed, as needed, every 3 to 5 minutes to a maximum dose of 3 mg. Additionally, ACLS would recommend the addition of a chronotropic intravenous agent, either epinephrine or dopamine, to achieve an adequate HR. Epinephrine at 2 to 20 μg/min or dopamine 2 to 10 μg/kg per minute IV are the recommended doses. Other less common IV agents to treat bradycardia include glycopyrrolate (0.2–0.6 mg IV) and isoproterenol (2–10 μg/min IV). More commonly, I have seen isoproterenol used on heart transplant

TABLE 3: Common Rate-Control Agents

Medication	Acute Rate Control: Initial Dose	Following Dose(s)	Oral Dosing: Acute or Chronic Rate Control
β-BLOCKERS			
Metoprolol	2.5–5 mg IV over 2 minutes	Repeat every 15–20 minutes up to 3 doses	25–100 mg PO twice daily
Esmolol	0.5 mg/kg IV bolus	0.05–0.25 mg/kg/min	NA
CALCIUM CHANNEL BLOCKER: NONDIHYDROPYRIDINE			
Diltiazem	0.25 mg/kg IV over 10 minutes	Repeat 0.35 mg/kg IV × 1 after 15 minutes, may follow with 5–15 mg/hr IV for <24 hr	30–, 0 mg PO 4 times per day, starting with 30 mg, maximum, 360 mg/d
CARDIAC GLYCOSIDES			
Digoxin	0.25–0.5 mg IV (renal adjust dose)	0.125–0.25 mg IV every 2–6 hr up to 1.5 mg total dose (renal adjust dose)	0.0625–0.25 mg PO every day
OTHER			
Amiodarone	150 mg IV over 10 min	1 mg/min for 6 hours, then 0.5 mg/min for 18 hr 150 mg IV over 10 minutes may be repeated during the infusion	400 mg PO twice daily or 800 mg PO three times daily loading dose, then 200 mg PO every day

IV, Intravenous; NA, not available; PO, by mouth.

response to loss of successful capture of temporary pacemaker leads, although ICE is certainly mentioned in the ACLS pathway.

Temporary pacing can be achieved with several approaches, although transcutaneous with the defibrillation pads is probably the most common in the ICU in emergent situation because it is fast, easy, and nursing staff is well versed in this technique with ACLS training. Of course, this is temporary and usually requires patients to be sedated, often challenging in an unstable patient. With specialized training, an intravenous pacing catheter (several models and types) can be floated to provide pacing, but this is difficult if central venous access is not already achieved. In fact, this is probably limited to a cardiovascular ICU.

TACHYARRHYTHMIAS

Narrow Complex Tachyarrhythmias

Sinus tachycardia is one of the most common perioperative tachyarrhythmias. Assure if the patient has an adequate circulating blood volume and adequate pain control. These should be addressed first and can often correct the abnormality. Once these are ruled out, or corrected, then an agent to control the accelerated rate could be considered if the patient would be thought to have an increased cardiac risk. Rate control for the sake of rate control in each and every patient is unnecessary and could actually confuse this compensatory mechanism from another unrecognized etiology.

There is an array of other narrow complex tachyarrhythmias including accelerated junctional rhythm, paroxysmal supraventricular tachycardia, and certainly the most common arrhythmia in this category and worth mention is atrial fibrillation. In general, atrial fibrillation is very well tolerated in most patients. The loss of atrial contraction and atrial ventricular dyssynchrony only results in hemodynamic instability when there is a setting of decreased ventricle filling capacity. Should the patient become unstable with hemodynamic compromise or develop severe cardiopulmonary symptoms (angina, dyspnea, etc.), then you are hard pressed to take action. Rarely, a patient with paroxysmal atrial fibrillation in the clinical scenario will need light sedation and electrical cardioversion per ACLS protocol. It should be mentioned that attempting cardioversion in a patient with long-standing persistent or permanent atrial fibrillation will be unsuccessful and, in our opinion, a waste of precious time. More commonly, these patients will require the administration of a vasopressor such as phenylephrine or norepinephrine to stabilize the blood pressure and then receive an intravenous agent such as amiodarone (Table 3) for rate control while attempts are made to correct other causes such as electrolyte abnormalities or addressing causes of myocardial ischemia. Amiodarone protocols usually include a 150 mg IV loading bolus over 10 minutes followed by an amiodarone drip at 1 mg/min for 6 hours and then 0.5 mg/min for another 18 hours. Additional amiodarone boluses of 150 mg IV can be given during the infusion period, each over 10 minutes. Digoxin can also be considered in these patients, particularly if the patient has severe pulmonary disease or has already demonstrated a hypersensitivity to amiodarone. We also often use another underappreciated and rather benign antiarrhythmic, intravenous magnesium sulfate (2 × g IV). This can be considered as long as the patient does not have corresponding severe acute or chronic renal dysfunction or elevation of other intracellular cations (potassium). We initially target rate control for less than 100 beats/min. If this is tolerated, we then lower our target to 80 beats/min, which in our experience seems helpful for chemical cardioversion.

Stable patients with new onset atrial fibrillation can often be managed in a stepwise manner. Again, the goal is rate control over rhythm control. The ventricular rate is usually controlled first with a parenteral dose of β blocker (usually metoprolol) or calcium channel blocker (diltiazem). β blockers are especially preferred if the patient has known ischemic heart disease. A single or series of IV doses can also be used to achieve more rapid HR control in acute settings. Once the maximum dose has been given, then a second agent will need to be added to either the diltiazem or metoprolol. If the patient is still hypertensive, then we often add the other agent (add diltiazem if metoprolol given first). Or rather, if the blood pressure is more marginal now, consider adding either digoxin or amiodarone. Either an IV or parental route can be used to load amiodarone. Ten grams is needed if using the oral dosing regimen and 5 g is needed for the IV route. Once the agent is loaded a standard maintenance dose can be given (usually 200 mg PO every day). Digoxin is usually avoided for patients with decreased creatinine clearances because of its renal clearance (or a dose adjustment to avoid digoxin toxicity). Amiodarone is usually avoided in patients with a prior sensitivity or severe lung disease. Last, one must use caution when adding a third high dose nodal blocking agent and using amiodarone in combination with digoxin.

Systemic anticoagulation is usually considered for patients who persist in atrial fibrillation beyond 48 hours. Most commonly, this is with intravenous heparin using a nurse-driven titration protocol. Of course, the benefit of such anticoagulation, to prevent thromboembolism, must be weighed against the individual's risks of bleeding. More long-term oral anticoagulation has been shown to decrease the risk of stroke in persistent atrial fibrillation by more than 60%; however, again, taking risk factors into account, whether or not to anticoagulate a patient long-term most clinicians would calculate a congestive heart failure, hypertension, age 75 years or older, diabetes mellitus, prior stroke, vascular disease, age 65 to 74 years, and sex score to help steer their management. Specifics of this decision-making regarding continued anticoagulation is not covered in this chapter.

Wide Complex Tachyarrhythmias

Wide complex arrhythmias are much less common in the perioperative surgical patient. Examples include monomorphic ventricular tachycardia, polymorphic ventricular tachycardias such as torsades de pointes, and a wide QRS complex in a patient with a preexisting bundle branch block. An unstable patient should be treated per ACLS protocol, usually with a synchronized cardioversion attempt. Stable patients are usually treated first with a β-blocker or amiodarone. The stable patient with torsades de pointes is managed differently. Precipitating medications that prolong the QTc periods are discontinued first and then parenteral magnesium is given (1–2 g IV over 30–60 seconds and may be repeated in 5–15 minutes) even with normal serum magnesium levels.

Glucose Control in the Postoperative Period

Tamara L. Seaver, MD, FACS, MCCM, Benjamin L. Moran, MD, and Ronald Tarpley, MD, FACS

In 2014, the US National Diabetes Statistic Report demonstrated that, in addition to 21 million individuals diagnosed with diabetes, there were approximately 8.1 million with undiagnosed diabetes. These numbers would indicate that roughly 9.3% of the American population may be suffering from diabetes. In addition, approximately 30% of intensive care unit (ICU) patients have preexisting diagnostic criteria for diabetes, and the rate of diabetes was highest among those 65 years of age and older.

Diabetic and nondiabetic surgical patients are at risk for acute hyperglycemia resulting from the body's response to the stress of surgery and acute illness. A causal relationship between hyperglycemia and morbidity and mortality has been demonstrated in the surgical population, and intensive glucose control in postoperative populations has been shown to increase survival and decrease surgical complications. Given the increasing prevalence of diabetes and aging of the population, these findings make postoperative glycemic control an integral part of providing safe quality surgical care. As paradigms in care shift and the surgical acuity and comorbid conditions in patients increase, glycemic control will continue to be of critical importance in the care of the surgical patient. Unfortunately, the appropriate range and variability of blood glucose has more significant debate in the literature and the lack of consensus is further evident by the widespread differences in published blood glucose guidelines. Although some studies have shown a reduction in morbidity and mortality when intensive insulin therapy is used to maintain blood glucose at or below 110 mg/dL in the surgical ICU, other studies have not only failed to reproduce this result, but also have demonstrated increased mortality with intensive insulin therapy. It is clear that a negative impact of hyperglycemia on wound infection and surgical complications exists, but the optimal level of glucose control while avoiding the potential complications of hypoglycemia and glucose variability remains unknown. This chapter will review the pathophysiology of stress-induced hyperglycemia, examine the three tenets of glycemic control (treating hyperglycemia, preventing hypoglycemia, and decreasing glycemic variability), and present targeted glucose guidelines for diabetic and nondiabetic patients in various surgical environments.

INDICATIONS

There is a well-established association between postoperative hyperglycemia and poor outcomes in surgical patients. Elevated postoperative glucose has been strongly associated with respiratory complications, venous thromboembolism, myocardial infarction, cardiac arrest, and need for reoperation. Additionally, hyperglycemia appears to be an independent predictor of surgical site infection, pneumonia, urinary tract infection, and sepsis within 30 days of surgery. Elective surgery patients who develop hyperglycemia have a twofold higher risk of infection, and patients who receive noncardiac general surgery procedures have a 30% increase in postoperative infectious complications for every 40 mg/dL increase in hyperglycemia. The association of hyperglycemia after cardiac surgery, hepatectomy, colectomy, and general and vascular surgeries correlating with worse outcomes in the postoperative period has been repeatedly demonstrated.

Unfortunately, even in the absence of preexisting diabetes, stress-induced hyperglycemia is a common finding in critically ill patients and in patients undergoing major surgical procedures. Stress-induced hyperglycemia in nondiabetic patients has been defined as a blood glucose level greater than 140 mg/dL, and in diabetic patients as a blood glucose greater than 180 to 220 mg/dL.

Hyperglycemia in critically ill patients and those undergoing major surgical procedures occurs as a result of a catecholamine-induced stress response. Catecholamine release is activated by the sympathetic nervous system during acute periods of stress and modulated by the suprarenal glands with additional positive and negative feedback regulated through the pituitary gland (Fig. 1). Glucose production may also be increased because of gluconeogenesis and glycogenolysis. Some degree of hyperglycemia in response to stress is normal and can be initially protective as part of the adaptive response for survival; however, in acute and severe illnesses, the resultant state of hyperglycemia may be too high for the bodies normal mechanisms and require glycemic therapy to manage.

Severe hyperglycemia is a well-documented marker of illness severity. It may be worsened by medical treatments, such as dextrose infusions, parenteral nutrition, and corticosteroids, often are necessary to treat the acutely ill. The patient's hyperglycemic condition

Systemic anticoagulation is usually considered for patients who persist in atrial fibrillation beyond 48 hours. Most commonly, this is with intravenous heparin using a nurse-driven titration protocol. Of course, the benefit of such anticoagulation, to prevent thromboembolism, must be weighed against the individual's risks of bleeding. More long-term oral anticoagulation has been shown to decrease the risk of stroke in persistent atrial fibrillation by more than 60%; however, again, taking risk factors into account, whether or not to anticoagulate a patient long-term most clinicians would calculate a congestive heart failure, hypertension, age 75 years or older, diabetes mellitus, prior stroke, vascular disease, age 65 to 74 years, and sex score to help steer their management. Specifics of this decision-making regarding continued anticoagulation is not covered in this chapter.

Wide Complex Tachyarrhythmias

Glucose Control in the Postoperative Period

Thomas M. Scalea, MD, FACS, FCCM, Benjamin Moran, MD, and Ronald Tanoriers, MD, FACS

In 2014, the US National Diabetes Statistic Report demonstrated that, in addition to 21 million individuals diagnosed with diabetes, there were approximately 8.1 million with undiagnosed diabetes. These numbers would indicate that roughly 9.3% of the American population may be suffering from diabetes. In addition, approximately 30% of intensive care unit (ICU) patients have preexisting diagnostic criteria for diabetes, and the rate of diabetes was highest among those 65 years of age and older.

Diabetic and nondiabetic surgical patients are at risk for acute hyperglycemia resulting from the body's response to the stress of surgery and acute illness. A causal relationship between hyperglycemia and morbidity and mortality has been demonstrated in the surgical population, and intensive glucose control in postoperative populations has been shown to increase survival and decrease surgical complications. Given the increasing prevalence of diabetes and aging of the population, these findings make postoperative glycemic control an integral part of providing safe quality surgical care. As paradigms in care shift and the surgical acuity and comorbid conditions in patients increase, glycemic control will continue to be of critical importance in the care of the surgical patient. This chapter will review the pathophysiology of stress-induced hyperglycemia, examine the three tenets of glycemic control (treating hyperglycemia, preventing hypoglycemia, and decreasing glycemic variability), and present targeted glucose guidelines for diabetic and nondiabetic patients in various surgical environments.

INDICATIONS

There is a well-established association between postoperative hyperglycemia and poor outcomes in surgical patients. Elevated postoperative glucose has been strongly associated with respiratory complications, venous thromboembolism, myocardial infarction, cardiac arrest, and need for reoperation. Additionally, hyperglycemia appears to be an independent predictor of surgical site infection, pneumonia, urinary tract infection, and sepsis within 30 days of surgery. Elective surgery patients who develop hyperglycemia have a twofold higher risk of infection, and patients who receive noncardiac general surgery procedures have a 30% increase in postoperative infectious complications for every 40 mg/dL increase in hyperglycemia. The association of hyperglycemia after cardiac surgery, hepatectomy, colectomy, and general and vascular surgeries correlating with worse outcomes in the postoperative period has been repeatedly demonstrated.

Unfortunately, even in the absence of preexisting diabetes, stress-induced hyperglycemia is a common finding in critically ill patients and in patients undergoing major surgical procedures. Stress-induced hyperglycemia in nondiabetic patients has been defined as a blood glucose level greater than 140 mg/dL, and in diabetic patients as a blood glucose greater than 180 to 220 mg/dL.

Hyperglycemia in critically ill patients and those undergoing major surgical procedures occurs as a result of a catecholamine-induced stress response. Catecholamine release is activated by the sympathetic nervous system during acute periods of stress and modulated by the suprarenal glands with additional positive and negative feedback regulated through the pituitary gland (Fig. 1). Glucose production may also be increased because of gluconeogenesis and glycogenolysis. Some degree of hyperglycemia in response to stress is normal and can be initially protective as part of the adaptive response for survival; however, in acute and severe disease, the resultant state of hyperglycemia may be too high for the bodies normal mechanisms and require glycemic therapy to manage.

Severe hyperglycemia is a well-documented marker of illness severity. It may be worsened by medical treatments, such as dextrose infusions, parenteral nutrition, and corticosteroids, often are necessary to treat the acutely ill. The patient's hyperglycemic condition

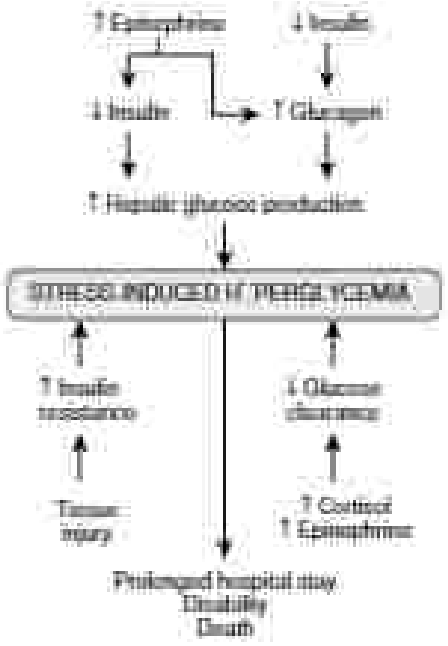

FIG. 1 Hormonal mechanisms of stress-induced hyperglycemia. [illegible]. A. Inzucchi et al., [illegible], *Diabetes Metabolism Research and Reviews* [illegible].

generally subsides after the afflicting illness and periods of stress have resolved. In the acute hyperglycemic patient, the resulting hyperglycemia is a direct correlation to the insufficient insulin secretion needed to overcome the hyperglycemic effects of catecholamines; however, in those with chronic disease, insulin resistance also contributes and patients with significant amounts of tissue injury or surgical stress may require augmented insulin levels.

Hyperglycemia leads to limited vascular reactivity by the angiotensin II and nitric oxide synthase pathways, inhibition of neutrophil chemotaxis and phagocytosis, and increased vascular permeability and leukocyte and platelet activation. Through these mechanisms, hyperglycemia plays a significant role in the development of stroke, myocardial infarction, surgical site infections, and impaired wound healing, increasing morbidity and mortality in surgical patients. In colorectal and nondiabetic patients, one single postoperative elevated glucose value has been associated with infectious and noninfectious complications, with the rates of complications increasing parallel to the degree of hyperglycemia. Given the association of hyperglycemia with increased morbidity and mortality, tight glucose control has become a target to improve outcomes in the postsurgical and critically ill patient.

TECHNIQUES

Management of glycemic control is directed toward treating hyperglycemia, preventing hypoglycemia, and limiting glycemic variability. Derangements in more than one of the domains of glycemic control are associated with a cumulative increase in mortality among patients without diabetes.

Hyperglycemia

The standard management of hyperglycemia was challenged in 2001 when Van den Berghe et al compared strict blood glucose control with the current management of glucose in 263 patients admitted to a surgical ICU. They demonstrated that tight blood glucose of 80 to 110 reduced hospital mortality by 5% to 8% compared with goals less than 180. Tight glucose control was also associated with reductions in bloodstream infections, acute kidney injury, critical illness polyneuropathy, hypercalcitraemia, anemia, and the duration of mechanical ventilation. These results were remarkable; however, they were unable to be reproduced. In 2009, the Normoglycemia in Intensive Care Evaluation Survival Using Glucose Algorithm Regulation trial randomized more than 6000 mixed medical and surgical ICU patients to tight glucose control (81–108 mg/dL) vs conventional (<180 mg/dL) but had markedly differing results. They demonstrated a higher 90-day mortality and had a 13-fold increased risk of hypoglycemia with tight glucose control. Other studies have suggested that there should be differences in glycemic targets between diabetics and nondiabetics.

With a rising population of diabetic and prediabetic individuals in the United States, the risk of severe hyperglycemia among critically ill patients is increasing, especially in those with undiagnosed diabetes mellitus. Patients with preexisting diabetes tend to have a persistent state of hyperglycemia resulting from insulin resistance and hyperglucagonemia that are consequences of the disease's natural progression. As a result, these patients are more likely to require control with hypoglycemic medications and strict glucose monitoring. Multiple studies have demonstrated a U-point association between glycemic levels in the ICU and the risk of death, with the lowest risk of death associated with normal glucose levels for age. There are many observations that this U-shaped relationship is flattened in diabetic patients with lower levels of mortality occurring at higher levels of glucose than in nondiabetics; however, Kosiborod and colleagues demonstrated that patients without diabetes had a lower mortality when mean blood glucose was maintained between 80 and 140 mg/dL, whereas a mean blood glucose of 80 to 110 mg/dL was associated with increased risk of mortality compared with ranges of 110 to 140, 140 to 180, and even greater than 180 mg/dL in diabetic patients. These findings suggest that, although nondiabetic patients benefit from glucose levels near normal, the diabetic patient may benefit from higher levels. This may be due to chronic hyperglycemia inducing adaptations, where acutely lowering blood glucose to normoglycemic ranges may activate hypoglycemia like responses. These findings suggest that diabetic ICU patients with chronic poor glycemic control evidenced by elevated hemoglobin A1c (HbA1c) levels may benefit from a more liberal blood glucose range.

Hypoglycemia

Hypoglycemia is a dangerous situation in both diabetic and nondiabetic patients. Hypoglycemia has been associated with increases in cardiovascular mortality thought to be related to QT prolongation and derangements in cardiac cell repolarization. Hypoglycemic episodes have been independently associated with increased risk of mortality among diabetic and nondiabetic patients. Diabetic patients hospitalized with acute myocardial infarction had a 93% increased mortality rate when hypoglycemia was present during their hospitalization. A group of 2601 patients hospitalized in the ICU were evaluated for ICU mortality when moderate or severe hypoglycemia was present and compared with a group with no episodes of hypoglycemia. Patients with severe and moderate hypoglycemia had 34% and 18% increase in 90-day mortality when compared with their normoglycemic counterparts. Patients with multiple hypoglycemic events had a 44% increase in mortality when compared with normoglycemic patients. Optimal therapy expresses need to treat hyperglycemia without inducing episodes of hypoglycemia.

Glycemic Variability

Glycemic variability has been defined as acute glycemic fluctuations. These upward and downward fluctuations are often a direct result of treatment for hyperglycemia. Glycemic variability leads to increased oxidative stress at a cellular level, which causes endothelial dysfunction and vascular damage, and may be associated with worse outcomes than persistent hyperglycemia in critically ill patients. Glycemic variability confers an increased risk of mortality by 25.7% in

critically ill nondiabetic patients. Nondiabetic patients appear to be more affected than diabetic patients; variability of greater than 20% increases the risk of mortality among nondiabetic patients but not in diabetics. There is no current consensus on the range of acceptable glycemic variability. Although a range of 80 mg/dL has been suggested because it corresponds to the normal physiologic variability in nondiabetic patients, this definition has not been validated.

Management of Hyperglycemia

Glycemic control is difficult in the surgical patient because of the multifactorial, complex, and dynamic nature of perioperative hyperglycemia. HbA_{1c} levels indicate average glucose levels over the preceding 4 months, and elevated levels have been associated with worse surgical outcomes. The American Diabetes Association defines prediabetes as HbA_{1c} 5.7 to 6.4%, diabetes as HbA_{1c} greater than 6.4%, and poorly controlled diabetes as HbA_{1c} greater than 7.0%. HbA_{1c} level should be obtained to elective preoperative patients over the age of 45, and in those who are overweight or obese and have an additional risk factor for diabetes. Levels greater than 7.0% have been associated with postsurgical infections, increased morbidity, and prolonged hospital length of stay. Although some have advocated for delays in elective surgery until reduction in levels of HbA_{1c}, whether lowering levels before surgery will lead to improved outcomes remains unknown. Measuring HbA_{1c} in acute hospitalized hyperglycemic patients may allow the differentiation between stress-induced hyperglycemia and undiagnosed diabetes for patients with levels greater or equal to 6.5%.

Intravenous insulin infusion is the most precise way to quickly adjust and control blood glucose levels because of its rapid onset of action, titratability, and potential to avoid glycemic variability. It is particularly useful in critically ill surgical patients whose nutritional intake may be variable and interrupted. There has been demonstrated substantial risk of hypoglycemia in patients who are being managed with tight glycemic control. One developing technology that may ease glycemic management is continuous inline glucose monitoring systems. These systems sample blood from a central venous line every 15 minutes and report glucose levels. Initial studies have shown improved glycemic variability and maintenance of therapeutic glucose ranges compared with 1- and 2-hour intermittent glucose measurements.

The intensive monitoring required for insulin infusion therapy is not possible for most patients outside of an ICU environment; thus, most postsurgical patients will require treatment with subcutaneously dosed insulin. Sliding scale insulin (SSI) regimens, in which patients are administered a set amount of regular insulin in response to degree of hyperglycemia, are increasingly discouraged in favor of basal, bolus, and correctional regimens. SSI regimens treat hyperglycemia after it occurs rather than preventing its development, are associated with increased hyperglycemia, hypoglycemia, and glycemic variability, do not deliver physiologic insulin levels, and may be dangerous in patients with type 1 diabetes. Additionally, they have been associated with adverse outcomes in general surgery patients with type 2 diabetes mellitus. There are several randomized trials in medical and surgical studies that have demonstrated improved glycemic control and decreased complications with basal and bolus insulin regimens compared with SSI. For patients who were managed with an insulin infusion, the 24 hour insulin requirements are calculated and 50% of this is administered as basal long-acting insulin once- or twice-daily divided doses. The other 50% is administered as rapid-acting insulin with meals in divided doses, or as part of a correctional dose based on preprandial glucose. For patients on continuous or parenteral nutrition, basal long-acting insulin plus rapid-acting insulin every 4 hours or short-acting insulin every 6 hours should be used. In noncritically ill patients, initial basal insulin dose range between 0.3 and 0.5 units/kg per day. Dosing should be adjusted daily based on blood glucose response and the amount of insulin administered on the prior day. Pragmatically, a period of correctional dose insulin without basal may be necessary to establish a baseline need in patients whose diabetic status and degree of stress hyperglycemia is unknown.

RESULTS

Although the association with hyperglycemia and postoperative outcomes is clear, the ideal degree of glucose control remains to be determined. Although a tight glucose target range of 80 to 110 mg/dL was found to be associated with a morbidity and mortality benefit by Van den Berghe, subsequent studies have shown worsened mortality with such a tight degree of glucose control due mainly to increased episodes of severe hypoglycemia. At this point, most advocate for a glycemic target slightly above a normal physiologic range to avoid the threat of hypoglycemia. As medicine advances new technology, such as inline glucose monitoring, it may allow for tighter glucose control without the threat of hypoglycemia and be able to produce results similar to those seen in the van den Berghe study.

Multiple medical societies have published recommendations for glycemic control in different patient populations. The Society of Thoracic Surgeons' guideline recommends that patients who have undergone routine cardiac surgery should maintain glycemic levels below 180 mg/dL. For postcardiac surgery patients anticipated to spend greater than 3 days in the ICU, however, and who require mechanical ventilation, myocardial or renal support, or need inotropic or antidysrhythmic medications, a level below 150 mg/dL is recommended. The Society of Critical Care Medicine task force recommends maintaining a blood glucose level below 150 mg/dL (alternately <180 mg/dL) and avoiding levels less than 100 mg/dL to prevent hypoglycemia for critically ill patients. Similar degrees of glycemic control are recommended in neurocritical care patients. Goal ranges of 110 to 140 mg/dL or 140 to 180 mg/dL if hypoglycemia cannot be prevented and an overall emphasis on prevention of hypoglycemia especially in patients with a traumatic brain injury. In patients with neurodistressing sepsis, the Surviving Sepsis Campaign guidelines set a goal blood glucose less than 180 mg/dL. The American Diabetes Association sets its target between 140 and 180 mg/dL in critically ill patients and the Endocrine Society recommends 110 to 140 mg/dL for postcardiac surgery populations. Table 1 summarizes the various societal recommendations for glycemic control.

SUMMARY

Hyperglycemia has been reproducibly associated with worsened outcomes in postsurgical and critically ill patients. Improved glycemic

TABLE 1 Societal Recommendations of Glycemic Control in Critically Ill Patients

Cohort	Glucose Control Goal
Nondiabetic ICU patient	140–180 mg/dL
Diabetic ICU patient	140–180 mg/dL[a]
Cardiac surgery ICU patients	<180 mg/dL (<150 mg/dL if anticipated ICU stay >3 days, ventilator dependent, or requiring renal support, mechanical cardiac support, or inotropic or antidysrhythmic infusions)
Surgical ICU patients	100–150 mg/dL (alternately <180 mg/dL)
Septic ICU patients	<180 mg/dL

[a]Poorly controlled diabetes (HbA_{1c} >7%), may benefit from blood glucose levels <200 mg/dL; however, more data needed.

ICU, intensive care unit.

control improves infectious and noninfectious morbidity as well as mortality in these patient populations; however, the ideal glycemic target remains unclear. Initial enthusiasm for tight glucose control (90–110 mg/dL) has waned in favor of a slightly supranormal glycemic range (100–180 mg/dL) in most patient populations because of worsened outcomes associated with hypoglycemia with lower target ranges. Whether poorly controlled diabetics should have a slightly higher target range, and what the appropriate degree of glycemic variability is, remains unknown. Although insulin infusions are likely the ideal strategy for controlling blood glucose, the need for close monitoring makes them unsuitable for the majority of postsurgical patients outside of the ICU. Most patients will continue to be managed with intermittent dosing of a combination of rapid-, short-, and long-acting subcutaneous insulin analogs ideally using a basal, bolus, and correctional regimen. Noncritically ill patients should have a target premeal blood glucose lower than 140 mg/dL, with random glucose levels lower than 180 mg/dL. Technologic advances in the ICU, such as inline glucose monitoring, allow a lower and tighter glycemic target while avoiding hypoglycemia and may adjust the ideal glycemic range in the future. For now, a target range between 140 and 180 mg/dL in most critically ill patients seems prudent.

Postoperative Respiratory Failure

Rachael A. Callcut, MD, MSPH, FACS

Respiratory dysfunction after operative intervention is the most common postoperative complication seen after both elective and emergency surgery. Postoperative pulmonary complications (PPCs) result in significant increases in morbidity and mortality rates and cost. In fact, it is the leading cause of postoperative death. The most serious of the PPCs is postoperative respiratory failure (PRF). Historically, most definitions of PRF have required the criteria of need for mechanical ventilation exceeding 48 hours after a procedure or need for reintubation in the 30 days after operative intervention. However, this definition excludes the mild forms of PRF, which are exceedingly common, and there has been a growing interest in treating PRF with noninvasive techniques including continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), and high flow nasal cannula (HFNC). Thus the newest definitions that are most often used to define postoperative respiratory failure include one or more of the following criteria:

- Failure to wean from mechanical ventilation within 48 hours of a procedure
- Need for reintubation in the first 30 days after a procedure
- Partial pressure of oxygen (PaO_2) less than 60 mm Hg
- Partial pressure of oxygen (PaO_2) to fraction of inspired oxygen (FiO_2) less than 40 kPa (PF ratio <300 mm Hg)
- Inability to maintain an oxygen saturation greater than 90% with supplemental oxygen
- New-onset hypoxemia requiring oxygen supplementation for more than 48 to 72 hours

This chapter focuses on the cause and management of PRF, including preoperative identification of high-risk patients, strategies to prevent PRF during and after operation(s), and treatment for the most severe form, acute respiratory distress syndrome (ARDS).

Types of Postoperative Respiratory Failure

PRF includes both hypoxemic and hypercarbic respiratory failure. Hypoxemic respiratory failure (PaO_2 <60 mm Hg on room air), known as type I, is the most common in the postoperative period and is primarily attributed to increased dead space ventilation and shunting. Dead space results from increased ventilation perfusion (V/Q) mismatch. Shunting occurs when the unventilated lung is well perfused. These are both increased in the postoperative period secondary to the effects of decreased functional residual capacity from atelectasis. Atelectasis occurs both related to intraoperative ventilator technique and poor postoperative pain control. Additional causes of postoperative hypoxemia are listed in Box 1.

control improves infectious and noninfectious morbidity as well as mortality in these patient populations; however, the ideal glycemic target remains unclear. Initial enthusiasm for tight glucose control (90–110 mg/dL) has waned in favor of a slightly supranormal glycemic range (100–180 mg/dL) in most patient populations because of worsened outcomes associated with hypoglycemia with lower target ranges. Whether poorly controlled diabetics should have a slightly higher target range, and what the appropriate degree of glycemic variability is, remains unknown. Although insulin infusions are likely the ideal strategy for controlling blood glucose, the need for close monitoring makes them unsuitable for the majority of postsurgical patients outside of the ICU. Most patients will continue to be managed with intermittent dosing of a combination of rapid-, short-, and long-acting subcutaneous insulin analogs ideally using a basal, bolus, and correctional regimen. Noncritically ill patients should have a target premeal blood glucose lower than 140 mg/dL, with random glucose levels lower than 180 mg/dL. Technologic advances in the ICU, such as inline glucose monitoring, allow a lower and tighter glycemic target while avoiding hypoglycemia and may adjust the ideal glycemic range in the future. For now, a target range between 140 and 180 mg/dL is most critically ill patients seems prudent.

Postoperative Respiratory Failure

Rachael A. Callcut, MD, MSPH, FACS

Respiratory dysfunction after operative intervention is the most common postoperative complication seen after both elective and emergency surgery. Postoperative pulmonary complications (PPCs) result in significant increases in morbidity and mortality rates and cost. In fact, it is the leading cause of postoperative death. The most serious of the PPCs is postoperative respiratory failure (PRF). Theoretically, most definitions of PRF have involved the criteria of need for mechanical ventilation exceeding 48 hours after a procedure or need for reintubation in the 30 days after operative intervention. However, this definition excludes the mild forms of PRF, which are exceedingly common, and there has been a growing interest in treating PRF with noninvasive techniques including continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), and high flow nasal cannula (HFNC). Thus the newest definitions that are most often used to define postoperative respiratory failure include one or more of the following criteria:

- Failure to wean from mechanical ventilation within 48 hours of a procedure
- Need for reintubation in the first 30 days after a procedure
- Partial pressure of oxygen (PaO_2) less than 60 mm Hg
- Partial pressure of oxygen (PaO_2) to fraction of inspired oxygen (FiO_2) less than 40 kPa (P/F ratio <300 mm Hg)
- Inability to maintain an oxygen saturation greater than 90% with supplemental oxygen
- New onset hypoxemia requiring oxygen supplementation for more than 48 to 72 hours

This chapter focuses on the cause and management of PRF, including preoperative identification of high risk patients, strategies to prevent PRF during and after operation(s), and treatment for the most severe form, acute respiratory distress syndrome (ARDS).

Types of Postoperative Respiratory Failure

PRF includes both hypoxemic and hypercarbic respiratory failure. Hypoxemic respiratory failure (PaO_2 <60 mm Hg on room air), known as type I, is the most common in the postoperative period and is primarily attributed to increased dead space ventilation and shunting. Dead space results from increased ventilation perfusion (V/Q) mismatch. Shunting occurs when the unventilated lung is well perfused. These are both increased in the postoperative period secondary to the effects of decreased functional residual capacity from atelectasis. Atelectasis occurs both related to intraoperative ventilator technique and poor postoperative pain control. Additional causes of postoperative hypoxemia are listed in Box 1.

BOX 1 Common Causes of Postoperative Hypoxemia

Atelectasis—most common
Aspiration
Cardiogenic pulmonary edema
Pulmonary embolism
Pneumothorax
Bronchospasm
Mucus plugging
Pulmonary contusion

BOX 2 Common Causes of Postoperative Hypercapnia

Residual inhaled anesthetic
Residual neuromuscular blockade
Opioid use
Sedatives
Neuromuscular disorders
Chronic obstructive pulmonary disease
Sepsis
Obesity

Hypercapnic respiratory failure, known as type II, results from a failure to clear carbon dioxide. This can occur when an increased work of breathing is required to maintain a partial pressure of carbon dioxide ($PaCO_2$) less than 50 mm Hg on room air. This can also result from apnea from failure to clear anesthetics or from the effects of opioids in the perioperative period. Additional causes are listed in Box 2. Those suffering from type II respiratory failure will still require oxygen supplementation.

RISK FACTORS AND PREVENTION STRATEGIES

Numerous authors in recent years have attempted to quantify, using risk prediction scores developed from retrospective cohorts, the modifiable and nonmodifiable risk factors associated with postoperative respiratory complications. Unfortunately, all these risk factor assessments have grouped any type of perioperative pulmonary complication (PPCs i.e., pneumonia, aspiration, pulmonary edema, respiratory failure, pulmonary embolism, bronchospasm, hypoxemia) together, making the scores less useful for determining the specific risk of PRF. At least one PPC occurs in up to 19% of all patients, with PRF occurring in 2% to 3.5%.

Despite the limitations in the studies available, common themes have emerged. The nonmodifiable risk factors most commonly associated include advanced age (>65 years old), functional dependence, emergency surgery, chronic obstructive pulmonary disease (COPD), preoperative low oxygen saturation on room air, major open abdominal or thoracic surgery, neurologic surgery, and vascular surgery (specifically aortic surgery). American Society of Anesthesiologists class greater than 2 is a particularly strong predictor of PPCs. Modifiable risk factors included preoperative rehabilitation, improving nutrition (risk highest with albumin <30 g/dL), smoking cessation, minimizing procedure length (increased risk with procedures >3 hours), intraoperative ventilator strategy, intraoperative volume management, minimization of transfusion, and postoperative multimodality care approaches (adequate pain control, minimization of atelectasis, early mobility).

Intraoperative Strategies

Intraoperative changes occur almost immediately that have deleterious effects on pulmonary function. Volatile anesthetics result in a decrease in mucociliary function, which efficiently creates a more desirable environment for bacteria. Alveolar capillary permeability also increases, as does a decrease in surfactant. This combined impairment has been implicated in the development of postoperative pneumonia, which is a major cause of PRF. There is also a rapid decrease in functional residual capacity that increases V/Q mismatch and leads to significant atelectasis.

Adopting a ventilator strategy that minimizes the effects of general anesthesia has been shown to decrease the risk of PRF. This includes a lung protective ventilation strategy of smaller tidal volumes of 6 to 8 mL/kg. The role of positive end expiratory pressure (PEEP) remains controversial, with some data supporting low PEEP and others higher PEEPs (5–10 cm H_2O). Despite conflicting results, most advocate for an intraoperative PEEP of 5 to 8 cm H_2O. Recruitment maneuvers have been shown to have a limited effect on combating the atelectasis that occurs in nearly 75% of all patients receiving paralytics for induction. Volume controlled ventilation is preferable, especially in thoracic and abdominal surgery where compliance can dramatically change during a procedure. It is particularly important to avoid volutrauma resulting in alveolar overdistention. Often overlooked is the role of hyperoxia (FIO_2 >80%) for prolonged periods intraoperatively. It is important to minimize the time at high FIO_2 concentrations to avoid the development of oxygen associated absorption atelectasis.

In addition to mechanical ventilation strategies, alterative volume management has been shown to be advantageous. Recent studies have also shown that those exposed to colloids (albumin) and greater transfusion exposures are at a higher risk of PRF. However, the key is judicious management of volume needs. It is not advantageous to avoid needed transfusion by increasing exposure to crystalloids. It is well known from the trauma literature that patients exposed to high volumes of crystalloid also have a detrimental effect on posttraumatic pulmonary outcomes. In general, more restrictive fluid resuscitation strategies are preferred over liberal approaches, especially in trauma patients and those undergoing thoracic surgery.

One of the easiest modifiable risk factors for PRF is adequately assessing residual neuromuscular blockade remaining at the end of a procedure. Prolonged neuromuscular blockade or residual effects can result in impaired diaphragmatic strength, poor cough, and a net reduction in the forced vital capacity. These are a setup for developing PRF. Also, extubating a patient who has severe pain that is inadequately controlled can also worsen atelectasis. For abdominal or thoracic procedures, strong consideration to epidural placement should be considered because this has been linked to lower postoperative pulmonary complications.

Postoperative Strategies

In addition to adequate pain control strategies (that achieve optimized comfort while minimizing respiratory depressant medications such as opioids), a multimodality approach to postoperative care has been demonstrated to minimize PRF. This includes nutritional support, selective nasogastric tube decompression after abdominal surgery, careful volume management avoiding fluid overload, and lung expansion maneuvers. Lung expansion maneuvers include incentive spirometry 10 times per hour while awake, deep breathing and coughing every 2 hours, and adjuvant physiotherapy (cough assist, flutter valve, chest physiotherapy, intermittent positive pressure ventilation) for high risk patients. The most important factor for all patients is early mobilization. Early mobilization improves V/Q mismatch. It also passively increases lung volumes because patients are more likely to take a larger breath when in the upright position. It also increases airway clearance and promotes coughing.

There has been growing interest and comfort with using noninvasive ventilation to decrease the need for intubation in patients suffering PRF. Noninvasive ventilation (NIV) includes CPAP (for hypoxemic patients) and BiPAP (for those with concomitant hypoxia and hypercapnia), both of which provide positive pressure

ventilation. It is especially useful in those having preexisting COPD. For these patients, it has been shown to lower mortality rates and decrease intensive care unit length of stay and the need for intubation. It is not useful for patients in whom secretions, aspiration, emesis, or inability to comply with wearing a face mask are issues. NIV can reduce work of breathing associated with pain from upper abdominal or thoracic procedures. It is useful in recruiting atelectatic lung and effectively increases forced vital capacity.

HFNC is a newer strategy to increase positive airway pressure via a noninvasive and well tolerated nasal prongs. Oxygen is delivered at 35 to 60 L/min, which produces 5 to 8 mm Hg of positive pressure. HFNC has been shown to decrease work of breathing and postoperative pulmonary complications. Humidified and heated air can be provided via this mechanism. For specific postoperative respiratory failure, there is no clear evidence that HFNC is superior to other forms of NIV, but a current ongoing clinical trial is investigating this.

Overall, NIV has been shown to be safe in postoperative patients. A recent study recommended 30 minutes of intermittent CPAP over the first 7 postoperative days was advantageous for high risk patients. A total of five CPAP treatments per patient were applied. Although compliance was variable, most patients were able to initiate this therapy within the first postoperative day.

For those unable to be extubated at the end of their procedure, similar approaches to intraoperative ventilator management are keys to avoiding pulmonary complications. This includes lung protective ventilation at 6 mL/kg tidal volume for high risk patients, maximum of 8 mL/kg for low risk patients, a PEEP of at least 5 cm H_2O, and limiting airway plateau pressure to 28 cm H_2O. Intermittent recruitment maneuvers should be used as necessary. Minimizing fraction of inspired oxygen to less than FiO_2 0.6 helps to minimize absorption atelectasis and oxygen radical secondary to lung injury.

Daily sedation interruption (spontaneous awakening) and spontaneous breathing trials (SBTs) are imperative to minimizing the time on the ventilator. A successful SBT includes a patient maintaining adequate work of breathing without tachypnea and oxygenation. SBTs are typically done at a low level of CPAP (5 cm H_2O) for 30 minutes. If the rapid shallow breathing index (breaths per minute divided by tidal volume in liters) remains below 105, there is an 80% chance of a successful extubation. Additional extubation criteria include minimal secretions, ability to protect the airway, minimal airway edema (presence of a cuff leak when tested), adequate pain control, and hemodynamic stability. If patients are not able to be extubated after SBT, they are returned to their prior mechanical ventilator settings.

ARDS

The most severe form of postoperative respiratory failure (PRF) is acute, diffuse, progressive, resulting in acute respiratory distress syndrome. Although ARDS is relatively uncommon after elective operations, it occurs with a higher frequency in those undergoing emergency operations. ARDS can be a lethal condition, with mortality rates exceeding 30% to 50% when it occurs in its most severe form during the postoperative period. Postoperative ARDS tends to occur early as a median of 2 days after surgery. Once a patient develops ARDS, therapeutic interventions are aimed at minimizing further barotrauma or volutrauma while addressing the underlying cause of the ARDS. For those requiring mechanical ventilation, a lung protective ventilation strategy (low tidal volume with 6 mL/kg of predicted body weight) has been shown to be the most effective therapy in the treatment of ARDS for reduction in mortality rates. The vast majority of the remaining treatments, known as rescue therapies, have only short term benefits in improving oxygenation but fail to provide any long term survival benefit. Rescue therapies are particularly important in postoperative ARDS where increased pulmonary shunting from severe atelectasis is one of the major contributing factors to the PRF. These therapies are aimed at reducing the increased pulmonary shunting. Despite having no survival benefit, rescue therapies are vital components in management of severe ARDS.

Definitions

The definition of ARDS has undergone multiple iterations since first described in 1967, and the most current version was adopted in 2011. A consensus panel representing the European Society of Intensive Care Medicine, American Thoracic Society, and the Society of Critical Care Medicine developed the Berlin criteria. The definition requires an interval of onset within 1 week of illness, injury, or surgery. Other criteria include a minimum of 5 cm H_2O for PEEP to required, bilateral opacities involving at least three quadrants by chest radiographs that are not fully explained by effusions, lobar/lung collapse, or nodules, and the degree of hypoxemia must not be fully explained by cardiac failure. The condition is classified as mild (PF 201–300 mm Hg), moderate (PF 101–200 mm Hg), and severe (PF <100 mm Hg).

Therapeutic Targets and Standard Therapies

The treatment of ARDS is largely supportive care focused on minimizing the underlying conditions contributing to the development of ARDS (like pneumonia or sepsis). The mainstay of therapy is to maintain oxygenation while minimizing risk of barotrauma and oxygen toxicity. There are no clear criteria for safe minimum oxygenation criteria; however, most clinicians try to reach an oxygen saturation of 88% or greater, with PaO_2 levels greater than 55 to 60 mm Hg. Oxygen toxicity and further lung injury can result if the PaO_2 is sustained less than 60% to 65% within 48 hours.

Lung protective ventilation has become the standard of care for those patients suffering from ARDS. The ARDS Network of investigation has repeatedly demonstrated a survival benefit when low tidal volume ventilation is used. Tidal volumes at 6 mL/kg or less of ideal body weight are desirable while limiting transpulmonary pressure (plateau pressure <30 mm Hg). This strategy is almost universally applied with high respiratory rates (>30 breaths/min) to maintain adequate minute ventilation and avoid severe acidosis secondary to hypercapnia. The approach of permissive hypercapnia (allowing pCO_2 levels to rise to minimize plateau pressures) is used in most patients. The most commonly recommended mode of ventilation for patients with ARDS is volume control to minimize the risk of ventilatorinduced that can occur with the variable tidal volumes seen in pressure control modes.

Bicarbonate infusions may be necessary if pH levels fall to 7.15 to 7.20 to minimize cardiac dysfunction occurring due to the acidosis from permissive hypercapnia. A conservative fluid volume management approach has also been shown to be advantageous, resulting in fewer ventilator days, lower plateau pressures, lower PEEP, and improved P/F ratio. Steroids remain controversial, with most clinicians recommending that they only be given before 14 days and reserved for patients who are failing to improve. Used in this manner, they have been associated with a favorable improvement in oxygenation and fewer ventilator days without any increase in infectious complications, but they did not result in a long term survival benefit.

Rescue Therapies

Rescue therapies include neuromuscular blockade, recruitment maneuvers, inhaled nitric oxide or inhaled prostacyclins, prone positioning, and extracorporeal membrane oxygenation (ECMO). High frequency ventilation (HFOV) is no longer routinely used for the management of adult ARDS after the findings of the OSCILLATE trial were published in 2013 in the *New England Journal of Medicine*, which showed increased mortality rates for those treated with HFOV compared with conventional ventilation.

Clinically, the question of when and how to use rescue therapies arises frequently when patients are perceived to have refractory hypoxemia. There is no standard definition of refractory hypoxemia. Most would consider it to include the following criteria: PaO_2 less than 60 mm Hg with plateau pressures greater than 30 cm H_2O with an FiO_2 of 0.8 or greater, a P/F ratio less than 100, or a saturation persistently less than 88%. Further complicating treatment is the lack of a clear therapeutic target for a minimum PaO_2 that is safe. Most ARDS protocols target a PaO_2 greater than 55 mm Hg. For those who have

significant neurologic impairment (stroke or traumatic brain injury), a higher PaO_2 goal is desired. Although for brain injured patients guidelines recommend a PaO_2 greater than 100 mm Hg, in those with concomitant ARDS it is usually difficult to achieve this without risk of further lung injury. For these patients, a common practical target is 70 to 80 mm Hg.

Fig. 1 demonstrates a stepwise approach for selecting from the rescue therapies described below. It is important to understand that the goal of rescue therapies is to improve oxygenation while the underlying pathophysiology contributing to ARDS can be addressed. Most rescue therapies provide only short-term benefit for those suffering life-threatening hypoxemia. Only low tidal volume ventilation, higher PEEP, and prone positioning have been shown to improve survival.

Neuromuscular Blockade

Although neuromuscular blockade (neuromuscular blocking agents) is considered standard therapy by some clinicians for those suffering moderate to severe ARDS, it is technically a rescue therapy. It should only be used if prolonged mechanical ventilation is expected and should be used early (<2 days) in the course of ARDS. They are most effective for improving oxygenation in those with significant ventilator asynchrony. There is limited evidence that there may be a small survival benefit at 90 days. Heavy sedation is required if neuromuscular blockade is used.

Recruitment Maneuvers and Higher PEEP

After neuromuscular blockade, recruitment maneuvers and high PEEP are used next to determine whether areas of lung can be "recruited." Significant atelectasis is one of the consequences of lung protective ventilation strategies. Portions of lung may not be well inflated due to the lower pressures and volumes targeted. Hypoxemia results from shunting when there are perfused alveoli that are not aerated.

Recruitment maneuvers are brief sustained inflations of the lungs to higher airway pressures and volumes than ordinarily used in mechanical ventilation. At our institution, we attempt bolusing the inspiratory pressure at 60 mm Hg for 40 seconds. We repeat the maneuver several times over a short 15- to 20-minute interval if the patient tolerates the initial attempt. For patients who are volume deplete, this can result in transient hypotension. Patients also occasionally have worsened hypoxemia initially as the recruited lung is opening up. Alternative strategies include holding the pressure for shorter time intervals (20–30 seconds) and the use of intermittent PEEP. Intermittent PEEP can be used with volume control modes of ventilation typically set for 4 above the baseline PEEP. The ventilator delivers this extra PEEP every few breaths. Additional maneuvers include periodic large tidal volume breaths (or sighs).

Inhaled Nitric Oxide

Inhaled nitric oxide (iNO) causes improved ventilation perfusion matching through vasodilation of the pulmonary circulation, occurring preferentially to the alveoli that are well ventilated. One of the major contributors to refractory hypoxia is a consequence of acute pulmonary hypertension secondary to regional hypoxia. iNO has a net effect of reducing the acute pulmonary hypertension. Clinical studies have generally failed to find a universal survival benefit of iNO for all patients with moderate to severe ARDS, but there are minimal improvements in hypoxemia. For those suffering life-threatening hypoxemia, it may provide enough time to allow other therapies to take effect or provide a bridge to more advanced interventions such as prone positioning or ECMO. The typical starting dose is 5 ppm, with titration to 40 ppm. Patients also must be monitored for methemoglobinemia, and improvement in oxygenation is greatest in the first 24 to 48 hours.

Inhaled Prostacyclin

Prostacyclin act as vascular smooth muscle dilators that can target the pulmonary vasculature when given in an inhaled formula. The net result is reduction in afterload for the right heart by reductions in mean pulmonary pressure and pulmonary vascular resistance.

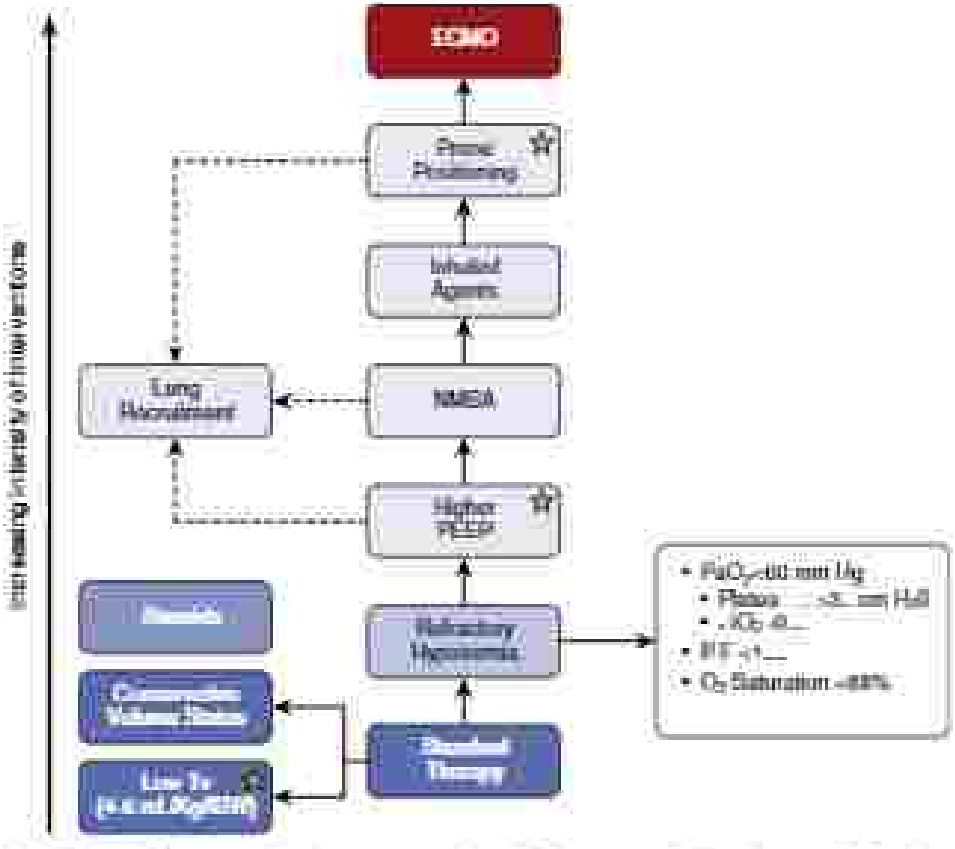

FIG. 1 Rescue therapy algorithm. ECMO, Extracorporeal membrane oxygenation; NMBA, neuromuscular blocking agent; PEEP, positive end-expiratory pressure.

while attenuating the peripheral effect of hypotension. They may also have a secondary benefit of reducing inflammation in the pulmonary tissue through antiinflammatory properties including inhibiting platelet aggregation and neutrophil adhesion.

The most widely available inhaled prostacyclin is epoprostenol (Flolan). The half-life of epoprostenol is very short, lasting only minutes, and typical dosing ranges from 1 ng/kg per minute to 60 ng/kg per minute. It is given as a continuous nebulized solution hooked in line with the ventilator. Inhaled prostacyclins are typically significantly less expensive than iNO. A recent Cochrane review failed to find any high-quality evidence assessing the survival benefit of inhaled prostacyclins; however, it has been shown to improve short-term oxygenation.

How to Use iNO and Inhaled Prostacyclins

An arterial blood gas (ABG) to assess preexposure PaO_2 should be obtained 5 to 15 minutes before administration of the inhaled agent and again 30 to 60 minutes after exposure. Those with an increase in PaO_2 or oxygen saturation are considered responders. Clinically, occasionally a patient will not respond at 30 to 60 minutes, but a subsequent response will be seen after a longer exposure interval up to 4 hours. If a patient is not a responder, the inhaled agent should be withdrawn. The caveat is that some patients who do not appear to benefit with regard to improved oxygenation will improve when the therapy is coupled with prone ventilation.

Prone Positioning

Prone positioning has been available as a rescue therapy for decades, but until the recently reported PROSEVA study, its survival benefits had been questioned. The results were quite remarkable with a reduction in 28-day mortality from 33% in the supine group to 16% in the prone group. The patients were left in the prone position for at least 16 consecutive hours per day. This study combined with multiple prior works supports that improvements in oxygenation are seen for those placed in the prone position. As with other rescue therapies, the greatest benefit is if it is used early. In the trial, prone positioning was continued until the P/F ratio improved to 150 mm Hg or greater with 10 cm or less of water of PEEP and 60% or less FiO_2 after being in the supine position for 4 consecutive hours.

When prone, the FiO_2 should be weaned to maintain the goal PaO_2 over the 16 hours. Before returning to a supine position the first time, they should be preoxygenated to 100% FiO_2. Once supine, ABGs and oxygen saturation levels should be monitored as FiO_2 is weaned. When weaning PEEP, it should be done slowly with a maximum change of 1 cm of H_2O per 12 hour period. When supine, patients should be returned to the prone position if the PaO_2 falls below the goal or if saturations reach less than 87% to 88%. Typically, the first time the patient is supine, we will limit the patient to 30 to 60 minutes in the supine position. In subsequent intervals of supine positioning, the time supine can be increased stepwise to 4 hours.

ECMO

Venovenous ECMO has been used with success over the last several decades in some centers with specialized expertise (Fig. 2). However, no well-done randomized trials have been completed demonstrating benefit over other rescue therapies. The major drawbacks to ECMO include it being highly invasive compared with other rescue techniques.

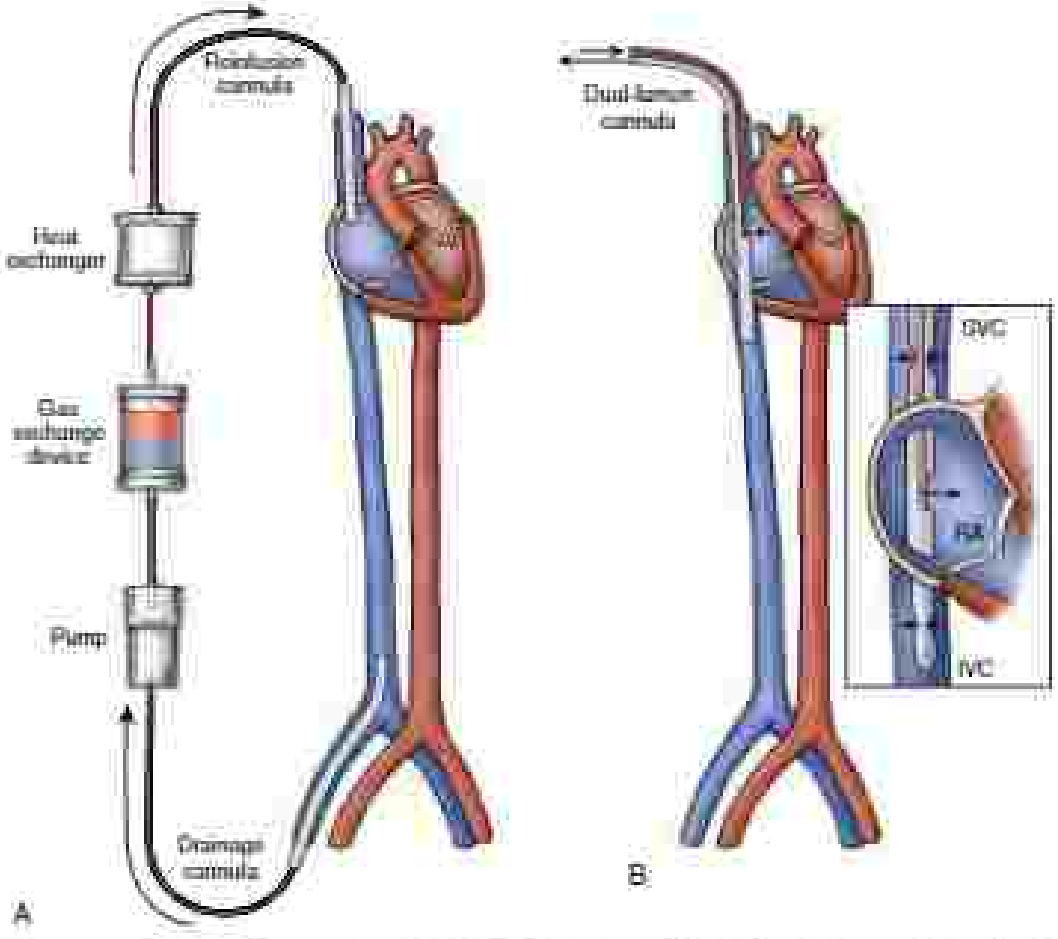

FIG. 2 Venovenous extracorporeal membrane oxygenation. (A) Jugular configuration. Blood is drained from the femoral vein and then passes through a pump, a gas exchange device, and a heat exchanger before returning into the internal jugular vein. expensive, and almost always requiring systemic anticoagulation. These limitations are balanced against the ability of ECMO to allow patients to be ventilated at smaller tidal volumes without the consequences of hypocapnia. This lower ventilation helps to avoid further secondary lung injury that occurs due to volutrauma and barotrauma. This strategy helps to allow the underlying lung to heal. Despite the lack of clinical trials, some centers have had case series with significant benefit, and ECMO is considered as a potentially life saving therapy for patients to consider who do not respond to other rescue therapies.

Ventilator-Associated Pneumonia

Navpreet K. Dhillon, MD, and Eric J. Lay, MD

Pneumonia remains a continually encountered medical condition that continues to carry significant morbidity and mortality despite advances in medical care. Community acquired pneumonia accounts for 8.4% of primary care physician visits annually with a mortality rate nearing 12% for those who ultimately require hospital admission. Likewise, the associated mortality resulting from hospital-acquired pneumonia is high, with 2016 National Healthcare Safety Network data indicating that 44% of patients die during admission and an additional 23% die within a year of admission, reflecting an overall mortality rate of 67% from the first year from diagnosis. Ventilator-associated pneumonia (VAP) is associated with prolonged mechanical ventilation time, longer hospital stays, and especially high mortality. VAP has classically been defined as pneumonia that developed after at least 48 to 72 hours of endotracheal intubation and leads to the most common intensive care unit (ICU)–acquired infection. Although the high mortality after pneumonia diagnosis is associated with the patient's underlying condition, every measure possible should be considered to reduce pneumonia related mortality.

Respiratory infections constitute one-half of all infections in ICUs. Further, multiple studies have shown that surgical and trauma patients develop VAP at higher rates compared with other patients, highlighting why surgeons should be aware of this condition. Although the incidence of VAP appears to be decreasing, it remains largely an iatrogenic disease. Clinicians continue to encounter several challenges with regards to the prevention, diagnosis, and treatment of VAP.

Risk Factors

Elderly patients, the immunocompromised, and those with lung disease or other comorbidities are at increased risk for VAP. In addition, prolonged supine positioning, use of paralytics, and aspiration are associated with VAP. Several studies have identified risk factors for VAP among trauma patients which include increased injury severity score, emergent intubation, transfusion requirements, spinal cord injury, thoracic injury, and need for operative intervention. Patients presenting with traumatic brain injury are at a particularly high risk and require a high index of suspicion for the diagnosis and treatment of VAP.

Prevention

Many cases of VAP result from iatrogenic causes. Clinicians must understand the methods and strategies that are used to prevent VAP, especially those that minimize or prevent intubation.

Early Extubation

There is a direct correlation between the duration of mechanical ventilation and the risk of VAP occurrence. The surgical intensivist should exhaust all measures to minimize ventilation duration. This includes using daily sedation holidays during which sedation is temporarily held to the point that a patient can follow commands. In addition, a daily spontaneous breathing trial is necessary to allow the patient to demonstrate respiratory ability with the assistance of minimal pressure alone. Daily sedation holidays when paired with spontaneous breathing trials help to facilitate regular assessment of the patient's respiratory status and to determine if the patient is a suitable candidate for extubation. Failure to do so leads to prolonged ventilation and unnecessary ventilator days. The decision to extubate should be made early in the day such that the proper personnel are readily available in case the patient requires reintubation. In addition, awake patients waiting for extubation have a high risk for endotracheal tube dislodgment and the need for urgent reintubation. Anecdotally, our "extubation rounds," in which we briefly walk through the unit before formal rounds to identify potential extubation candidates, leads to early extubations and limits refusal delays. Finally, a surgical ICU team should be available 24 hours a day to evaluate those patients who are young, healthy, and ready to be weaned from the ventilator.

expensive, and almost always requiring systemic anticoagulation. These limitations are balanced against the ability of ECMO to allow patients to be ventilated at smaller tidal volumes without the consequences of hypocapnia. This lower ventilation helps to avoid further secondary lung injury that occurs due to volutrauma and barotrauma. This strategy helps to allow the underlying lung to heal. Despite the lack of clinical trials, some centers have had case series with significant benefit, and ECMO is considered as a potentially life saving therapy for patients to consider who do not respond to other rescue therapies.

Ventilator-Associated Pneumonia

Navpreet K. Dhillon, MD, and Eric J. Lay, MD

Pneumonia remains a continually encountered medical condition that continues to carry significant morbidity and mortality despite advances in medical care. Community acquired pneumonia accounts for 8.4% of primary care physician visits annually with a mortality rate nearing 12% for those who ultimately require hospital admission. Likewise, the associated mortality resulting from hospital-acquired pneumonia is high, with 2011 National Healthcare Safety Network data indicating that 44% of patients die during admission and an additional 23% die within a year of admission, reflecting an overall mortality rate of 67% from the first year from diagnosis. Ventilator-associated pneumonia (VAP) is associated with prolonged mechanical ventilation time, longer hospital stays, and especially high mortality. VAP has classically been defined as pneumonia that developed after at least 48 to 72 hours of endotracheal intubation and leads to the most common intensive care unit (ICU)–acquired infection. Although the high mortality after pneumonia diagnosis is associated with the patient's underlying condition, every measure possible should be considered to reduce pneumonia related mortality.

Respiratory infections constitute one-half of all infections in ICUs. Further, multiple studies have shown that surgical and trauma patients develop VAP at higher rates compared with other patients, highlighting why surgeons should be aware of this condition. Although the incidence of VAP appears to be decreasing, it remains largely an iatrogenic disease. Clinicians continue to encounter several challenges with regards to the prevention, diagnosis, and treatment of VAP.

Risk Factors

Elderly patients, the immunocompromised, and those with lung disease or other comorbidities are at increased risk for VAP. In addition, prolonged supine positioning, use of paralytics, and aspiration are associated with VAP. Several studies have identified risk factors for VAP among trauma patients which include increased injury severity score, emergent intubation, transfusion requirements, spinal cord injury, thoracic injury, and need for operative intervention. Patients presenting with traumatic brain injury are at a particularly high risk and require a high index of suspicion for the diagnosis and treatment of VAP.

Prevention

Many cases of VAP result from iatrogenic causes. Clinicians must understand the methods and strategies that are used to prevent VAP, especially those that minimize or prevent intubation.

Early Extubation

There is a direct correlation between the duration of mechanical ventilation and the risk of VAP occurrence. The surgical intensivist should exhaust all measures to minimize ventilation duration. This includes using daily sedation holidays during which sedation is temporarily held to the point that a patient can follow commands. In addition, a daily spontaneous breathing trial is necessary to allow the patient to demonstrate respiratory ability with the assistance of minimal pressure alone. Daily sedation holidays when paired with spontaneous breathing trials help to facilitate regular assessment of the patient's respiratory status and to determine if the patient is a suitable candidate for extubation. Failure to do so leads to prolonged ventilation and unnecessary ventilator days. The decision to extubate should be made early in the day such that the proper personnel are readily available in case the patient requires reintubation. In addition, awake patients waiting for extubation have a high risk for endotracheal tube dislodgment and the need for urgent reintubation. Anecdotally, our "extubation rounds," in which we briefly walk through the unit before formal rounds to identify potential extubation candidates, leads to early extubations and limits refusal delays. Finally, a surgical ICU team should be available 24 hours a day to extubate those patients who are young, healthy, and ready to be weaned from the ventilator.

Preventing Reintubation

Another opportunity to reduce the rate of VAP is to reduce reintubation with select noninvasive measures. Noninvasive devices deliver ventilatory support without an endotracheal tube. Noninvasive ventilation (NIV) has been shown to reduce rates of intubation and mortality in select patients admitted with chronic obstructive pulmonary disease exacerbation or acute cardiogenic pulmonary edema. Extubating patients at risk for reintubation to NIV will reduce the rate of reintubation; however, if a patient develops delayed respiratory failure after extubation, there is little role for NIV to prevent reintubation. In fact, a multicenter randomized control trial demonstrated that patients who received traditional NIV therapy after developing respiratory failure within 48 hours from extubation had a higher mortality rate compared with those receiving standard therapy. Attempting to salvage respiratory failure with NIV after a failed extubation is highly dangerous and should be avoided to favor of reintubation.

The use of high flow nasal cannula (HFNC) has emerged recently as an alternative method to standard NIV therapy with potential results in preventing reintubation. HFNC is designed to deliver humidified air and oxygen at a rate that exceeds other traditional oxygen modalities. A large multicenter randomized control trial demonstrated that there was a reduction in mortality and lower intubation rates in patients with acute hypoxemic respiratory failure placed on HFNC. In a single-center retrospective study, HFNC was associated with lower adjusted reintubation rates in critically ill surgical patients specifically. The use of HFNC after extubation is not standard throughout ICUs, but should be considered to select patients who are high risk for reintubation.

Lung Protective Ventilation

Understanding the mechanics of ventilation and how this may facilitate lung injury in critically ill patients is imperative. It is well established that ventilating ventilation with lower tidal volumes carries a lower risk of mortality in patients with acute respiratory distress syndrome (ARDS). Likewise, this strategy during abdominal operations is also associated with lower rates of pneumonia and other complications, presumably resulting from an attenuated inflammatory response from the ventilator itself. In general, lower tidal volumes to reduce barotrauma should be favored to lower the incidence of VAP.

Bundles

VAP bundles have gained popularity over the past decade, and much focus has been given to the development and adherence to these bundles. The original bundle introduced by the Institute for Healthcare Improvement included several interventions with the intention of reducing VAP. Components of the VAP bundle often include head of bed elevation, daily sedation holidays, daily spontaneous breathing trials with routine extubation evaluations, stress gastric prophylaxis, and venous thromboembolism prophylaxis. Variants of the bundle emphasize oral hygiene with chlorhexidine.

Because much of the care required by VAP bundles has become standard, the efficacy of mandatory bundles is uncertain. Some studies suggest that VAP bundles effectively reduce the incidence of VAP and costs, whereas others question their ability to do so. A multiinstitutional study in trauma patients showed that not only was true VAP bundle compliance difficult to attain, VAP rates occurred independent of compliance. Despite questionable benefits, VAP bundles are not detrimental and therefore frequently adopted in ICU settings.

TERMINOLOGY AND DIAGNOSIS

The terminology associated with VAP and the related events can be perplexing, but important for healthcare providers to understand. In fact, a substantial reason why VAP rates have declined significantly nationwide is because of the evolving definition of what constitutes VAP. VAP historically referred to a pneumonia that develops 48 to 72 hours after endotracheal intubation; however, defining a pneumonia can be challenging because the clinical and bacteriologic criteria used are neither sensitive nor specific. The Centers for Disease Control and Prevention's National Healthcare Safety Network introduced new terminology in 2013 (Fig. 1) to better describe the associated conditions.

Ventilator associated events (VAEs) describe several entities including ventilator associated conditions (VACs), infection related VAC (IVAC), and possible VAP (PVAP). VAC occurs after a patient who has been on mechanical ventilation for at least 2 days develops a change in respiratory status manifested by either a need for increased fraction of inspired oxygen or higher positive end expiratory pressure. VAE can derive from both infectious etiologies such as pneumonia, and noninfectious etiologies such as pulmonary edema, atelectasis, ARDS, and pulmonary embolus. A VAE, complicated by either changes in temperature (either <36°C or >38°C) or white blood cell count (either <4000 cells/mm³ or >12,000 cells/mm³), which requires treatment with an antimicrobial agent for at least 4 days is further categorized as an IVAC. IVACs with purulent secretions and/or positive laboratory testing are classified as PVAPs. The specific criteria that results in a positive laboratory test can be found in Fig. 1. Although bronchoalveolar lavage (BAL) in some instances may be superior to endotracheal aspiration for diagnosing VAP, both are effective and diagnosis by either method is associated with similar ventilator days, ICU and hospital length of stay, and mortality.

Despite these definitions, the criteria for VAP remains subjective because there is no universally accepted definition. Some clinicians rely heavily on chest radiographic findings such as the development of consolidations, whereas others may use more objective criteria. Scoring systems, such as the Clinical Pulmonary Infection Score, can be used to determine if a PVAP is VAP (Table 1). Clinical Pulmonary Infection Score accounts for the nature of tracheal secretions, chest radiographic findings, temperature, laboratory values, and ventilator settings. A score of 6 or more correlated with a 100% sensitivity and 93% specificity in one study. Another study, however, revealed a 77% sensitivity and 62% specificity, questioning the utility of the scoring system. Defining VAP will continue to be a challenge as the terminology is expected to evolve with new scoring systems.

TREATMENT

Given the high mortality associated with untreated VAP, clinicians should start broad spectrum empiric antibiotics immediately after the suspicion for VAP arises. In fact, early antibiotic administration is linked with lower mortality rates. Some may be reluctant to start antibiotics without a definitive diagnosis because of concerns for the development of multidrug resistant (MDR) organisms, however, recent evidence suggests that resistance is not as prevalent as previously thought. Ultimately, the liberal or conservative use of antimicrobials is at the discretion of the attending physician. In either case, antibiotics should be deescalated and tailored once culture results and sensitivities become available.

Local antibiograms can guide initial therapy. Antibiograms provide an overview of common pathogen susceptibilities at a certain institution when laboratory results are pending. This report is synthesized by compiling institutional laboratory data periodically. Alternatively, the Infectious Diseases Society of America and the American Thoracic Society developed guidelines in 2016 that can be used when initiating treatment (Fig. 2). Empiric VAP treatment using this algorithm is highly dependent upon the risk for both MDR VAP and the prevalence of resistant gram negative bacilli and methicillin resistant *Staphylococcus aureus* (MRSA) within a given unit. Any patient who either received intravenous antibiotics within the past 90 days, developed septic shock at the time of the presumed VAP incident, had ARDS preceding VAP, was hospitalized for at least 5 days before VAP onset, or required acute renal replacement is deemed high risk and should receive two agents for gram negative and pseudomonal coverage (one β-lactam based and one non β-lactam based antimicrobial) and an additional agent that will specifically cover MRSA. Similarly, individuals who are not considered high risk for MDR VAP

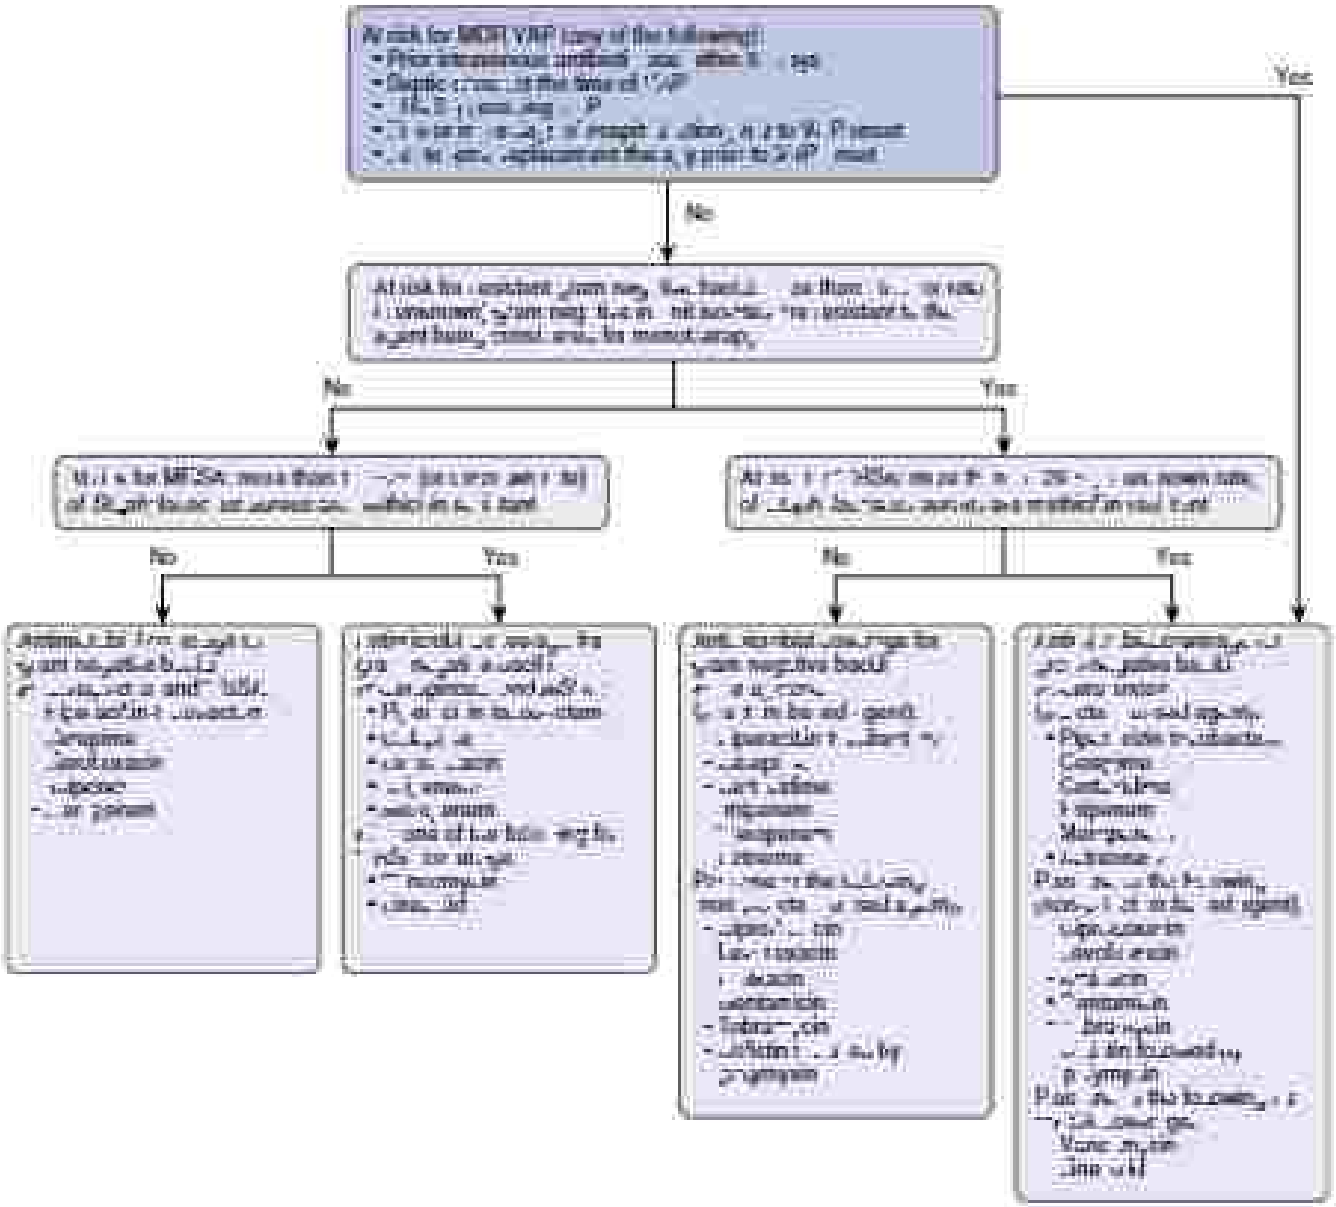

FIG. 2 Proposed algorithm for empiric antibiotic treatment for VAP. ARDS, acute respiratory distress syndrome; MDR, multidrug resistant; MRSA, methicillin-resistant *Staphylococcus aureus*; PSEA, methicillin-sensitive *S. aureus*; VAP, ventilator-associated pneumonia. (Modified from Kalil AC, Metersky ML, Klompas M, et al. Management of adult with hospital-acquired and ventilator-associated pneumonia: 2016 Clinical Practice Guidelines by the Infectious Diseases Society of America and the American Thoracic Society. *Clin Infect Dis.* 2016;63:e61.)

but are in units where more than 10% (or unknown rate) of the gram-negative bacilli isolates are resistant to monotherapy and more than 10% (or unknown rate) of *S. aureus* isolates are resistant to methicillin should receive the same regimen. MRSA coverage can be removed if there is a low rate of MRSA isolates within the unit. Monotherapy can be used to empirically cover gram-negative bacilli and *Pseudomonas* species if a unit has a low level of gram-negative bacilli resistance. Typical agents used for monotherapy include piperacillin-tazobactam, cefepime, and levofloxacin.

The duration of antimicrobial therapy is another factor that needs to be considered. There is significant variability with how long pathogens remain after the initiation of therapy, with some clearing within 72 hours of treatment and others remaining for nearly a week. At the same time, prolonged treatment may be associated with resistance. Magnotti et al describe a protocol wherein a BAL is obtained on day 4 of treatment; if the BAL demonstrates a growth of less than 10,000 CFU/mL, then antibiotics are continued for a total of 7 days. Antibiotics are otherwise continued for 10 to 14 days if there is more growth. Recent guidelines from the Infectious Disease Society of America and the American Thoracic Society, in contrast, recommend a 7 day course rather than an extended course, irrespective of BAL results. There were no differences in ventilator days, ICU length of stay, or mortality when comparing patients who had shorter antibiotic courses with those with longer courses in a recent meta-analysis. Of note, one third of VAP cases are due to non-glucose fermenting gram-negative bacilli including *Pseudomonas* and *Acinetobacter*, which benefit from prolonged courses to reduce recurrent infection.

CONCLUSIONS

VAP continues to be a condition that occurs in a sizable portion of critically ill surgical patients and carries substantial morbidity and mortality especially when left untreated. Defining VAP can be challenging, but it is important to start therapy with broad-spectrum coverage as soon as the clinical suspicion for VAP arises. Antibiotics should be deescalated and tailored according to study results. Emphasis should also be placed on VAP prevention through early extubation and reducing reintubation.

EXTRACORPOREAL MEMBRANE OXYGENATION FOR RESPIRATORY FAILURE IN ADULTS

Candice C. Low, MD, Robert J. Morana, MD, and George J. Magovern Jr, MD

Acute respiratory distress syndrome (ARDS), first described nearly 50 years ago, continues to be a major contributor to morbidity and mortality, as well as an important component of resource consumption in the intensive care unit. The syndrome is the most severe manifestation of acute lung injury, which can develop from a wide range of direct pulmonary (aspiration, toxic inhalation, infection, near drowning) or extrapulmonary sources (disseminated sepsis, thoracic trauma, circulatory shock). Ventilator management focuses on minimization of barotrauma and prevention of increasing levels of CO_2 retention. Standard ventilator strategies aimed toward limiting development of pulmonary distention and promoting recruitment of atelectatic alveoli include pressure-controlled ventilation, inverse-ratio ventilation, and low frequency ventilation. Current mortality rates remain high, however, ranging between 39% and 60% in published reports. Ventilator-induced lung injury secondary to barotrauma limits the efficacy of standard therapy, even when used under the direction of respiratory specialists. Theoretically, the technique of extracorporeal membrane oxygenation, or extracorporeal membrane oxygenation (ECMO) is a logical approach to broker the competing problems of lung protection and effective gas exchange in ventilator-dependent patients because it separates these processes and allows control over the degree of native lung function.

ECMO SYSTEM DESCRIPTION

A typical ECMO system is comprised of a membrane oxygenator, heat exchanger, roller or centrifugal pump, circuit tubing, and cannulae appropriate to the mode of access. A parallel circuit containing a second pump and oxygenator may be used to ensure efficient CO_2 removal at low flow rates or to increase oxygenation at higher flow rates. In some systems, a parallel circuit is included to minimize the effects of oxygenator complications and to facilitate oxygenator exchange. Heparin-bonded components are used when possible to decrease anticoagulation requirements. Most systems maintain the circulating blood at normothermic temperatures, but slight hypothermia has been suggested to reduce oxygen consumption requirements when metabolic demand is high.

Indications

Venovenous (VV) ECMO should be considered in any adult patient suffering from acute onset and potentially reversible severe respiratory failure with significant hypoxia or hypercarbia despite maximal ventilator management. Although there are many causes of respiratory failure in adults including pulmonary embolism, acute cardiogenic pulmonary edema, and hypercarbic respiratory failure, the most common etiology is ARDS. The Berlin Definition of ARDS, published in 2012, established the current widely accepted diagnostic criteria based on timing and etiology of respiratory symptoms, radiographic findings, and presence of hypoxemia (Box 1). Several methods for grading the severity of ARDS have been developed, but the most commonly used to predict clinical therapies in ARDS trials has been the Murray Lung Injury Score, which assesses four factors: (1) extent of infiltration on chest film; (2) degree of hypoxemia; (3) level of positive end expiratory pressure (PEEP) required to achieve oxygenation; and (4) respiratory system compliance (Table 1). A Murray score of more than 2.5 is generally accepted as an indication for consideration of VV ECMO in severe ARDS (Box 2).

but are in units where more than 10% (or unknown rate) of the gram-negative bacilli isolates are resistant to monotherapy and more than 10% (or unknown rate) of *S. aureus* isolates are resistant to methicillin should receive the same regimen. MRSA coverage can be removed if there is a low rate of MRSA isolates within the unit. Monotherapy can be used to empirically cover gram-negative bacilli and *Pseudomonas* species if a unit has a low level of gram-negative bacilli resistance. Typical agents used for monotherapy include piperacillin-tazobactam, cefepime, and levofloxacin.

The duration of antimicrobial therapy is another factor that needs to be considered. There is significant variability with how long pathogens remain after the initiation of therapy, with some clearing within 72 hours of treatment and others remaining for nearly a week. At the same time, prolonged treatment may be associated with resistance. Magnotti et al describe a protocol wherein a BAL is obtained on day 4 of treatment; if the BAL demonstrates a growth of less than 10,000 CFU/mL, then antibiotics are continued for a total of 7 days. Antibiotics are otherwise continued for 10 to 14 days if there is more growth. Recent guidelines from the Infectious Disease Society of America and the American Thoracic Society, in contrast, recommend a 7 day course rather than an extended course, irrespective of BAL results. There were no differences in ventilator days, ICU length of stay, or mortality when comparing patients who had shorter antibiotic courses with those with longer courses in a recent meta-analysis. Of note, one-third of VAP cases are due to non-glucose fermenting gram-negative bacilli including *Pseudomonas* and *Acinetobacter*, which benefit from prolonged courses to reduce recurrent infection.

CONCLUSIONS

VAP continues to be a condition that occurs in a sizable portion of critically ill surgical patients and carries substantial morbidity and mortality especially when left untreated. Defining VAP can be challenging, but it is important to start therapy with broad-spectrum coverage as soon as the clinical suspicion for VAP arises. Antibiotics should be deescalated and tailored according to study results. Emphasis should also be placed on VAP prevention through early extubation and reducing reintubation.

EXTRACORPOREAL MEMBRANE OXYGENATION FOR RESPIRATORY FAILURE IN ADULTS

Candice T. Lee, MD, Robert J. Maraca, MD, and George J. Magovern Jr, MD

Acute respiratory distress syndrome (ARDS), first described nearly 50 years ago, continues to be a major contributor to morbidity and mortality, as well as an important component of resource consumption in the intensive care unit. The syndrome is the most serious manifestation of acute lung injury, which can develop from a wide range of direct pulmonary (aspiration, toxic inhalation, infection, near drowning) or extrapulmonary sources (disseminated sepsis, thoracic trauma, circulatory shock). Ventilator management focuses on minimization of barotrauma and prevention of increasing levels of CO_2 retention. Standard ventilator strategies aimed toward limiting development of pulmonary distention and promoting recruitment of atelectatic alveoli include pressure-controlled ventilation, inverse-ratio ventilation, and low frequency ventilation. Current mortality rates remain high, however, ranging between 39% and 60% in published reports. Ventilator-induced lung injury secondary to barotrauma limits the efficacy of standard therapy, even when used under the direction of respiratory specialists. Theoretically, the technique of extracorporeal membrane oxygenation, or extracorporeal membrane oxygenation (ECMO) is a logical approach to bypass the competing problems of lung protection and effective gas exchange in ventilator-dependent patients because it separates these processes and allows control over the degree of native lung function.

ECMO SYSTEM DESCRIPTION

A typical ECMO system is comprised of a membrane oxygenator, heat exchanger, roller or centrifugal pump, circuit tubing, and cannulae appropriate to the mode of access. A parallel circuit containing a second pump and oxygenator may be used to ensure efficient CO_2 removal at low flow rates or to increase oxygenation at higher flow rates. In some systems, a parallel circuit is included to minimize the effects of oxygenator complications and to facilitate oxygenator exchange. Heparin-bonded components are used when possible to decrease anticoagulation requirements. Most systems maintain the circulating blood at normothermic temperatures, but slight hypothermia has been suggested to reduce oxygen consumption requirements when metabolic demand is high.

Indications

Venovenous (VV) ECMO should be considered in any adult patient suffering from acute onset and potentially reversible severe respiratory failure with significant hypoxia or hypercarbia despite maximal ventilator management. Although there are many causes of respiratory failure in adults including pulmonary embolism, acute cardiogenic pulmonary edema, and hypercarbic respiratory failure, the most common etiology is ARDS. The Berlin Definition of ARDS, published in 2012, established the current widely accepted diagnostic criteria based on timing and etiology of respiratory symptoms, radiographic findings, and presence of hypoxemia (Box 1). Several methods for grading the severity of ARDS have been developed, but the most commonly used to predict clinical therapies in ARDS trials has been the Murray Lung Injury Score, which assesses four factors: (1) extent of infiltration on chest film; (2) degree of hypoxemia; (3) level of positive end-expiratory pressure (PEEP) required to achieve oxygenation; and (4) respiratory system compliance (Table 1). A Murray score of more than 2.5 is generally accepted as an indication for consideration of VV ECMO in severe ARDS (Box 2).

BOX 1 Berlin Definition of ARDS (All Criteria Must be Present)

- *Timing of respiratory symptoms:* onset of symptoms within 1 week of known clinical insult, or new or worsening symptoms arising during the past week
- *Radiographic findings:* bilateral pulmonary infiltrates on chest radiograph or CT scan
- *Rule out other etiologies:* respiratory symptoms that cannot be fully explained by cardiac failure or fluid overload
- *Hypoxemia:* The severity of ARDS is defined by the degree of hypoxemia, as indicated by the ratio of PaO_2/FIO_2
  - *Mild:* PaO_2/FIO_2 >200 mm Hg but <300 mm Hg, on mechanical ventilator settings with PEEP or CPAP ≥5 cm H_2O
  - *Moderate:* PaO_2/FIO_2 >100 mm Hg but <200 mm Hg, on mechanical ventilator settings with PEEP ≥5 cm H_2O
  - *Severe:* PaO_2/FIO_2 ≤100 mm Hg on mechanical ventilator settings with PEEP ≥5 cm H_2O

The Berlin Criteria, established in 2012, replace previously accepted 1994 American-European Consensus definition of ARDS.
ARDS, Acute respiratory distress syndrome; *CPAP,* continuous positive airway pressure; FIO_2, fraction of inspired oxygen; PaO_2, partial pressure of oxygen in arterial blood; *PEEP,* positive end-expiratory pressure.

TABLE 1 Murray Lung Injury Score

Category	Score
1. Extent of infiltration on chest radiograph	
No alveolar consolidation	0
Confined to 1 quadrant	1
Confined to 2 quadrants	2
Confined to 3 quadrants	3
Involving all 4 quadrants	4
2. Degree of hypoxemia (partial pressure of oxygen in arterial blood/fraction of inspired oxygen)	
≥300	0
225–299	1
175–224	2
100–174	3
<100	4
3. Level of positive end-expiratory pressure (cm H_2O)	
≤5	0
6–8	1
9–11	2
12–14	3
≥15	4
4. Respiratory system compliance (mL/cm H_2O)	
≥80	0
60–79	1
40–59	2
20–39	3
≤19	4

Final Murray score is calculated by the addition of scores from each component. Score 0 = no lung injury, 1–2.5 = mild-moderate lung injury, >2.5 = severe lung injury.

BOX 2 Indications and Contraindications for VV ECMO

Indications

1. Hypoxic respiratory failure resulting from any cause where there is >80% risk of mortality. Consider VV ECMO when risk of mortality is >50%.
   - PaO_2/FIO_2 <150 on FIO_2 >90%, and a Murray score of 2–3 is associated with a 50% risk of mortality
   - PaO_2/FIO_2 <100 on FIO_2 >90% and a Murray score of 3–4 is associated with an 80% risk of mortality
2. Refractory CO_2 retention despite high pressure mechanical ventilation settings (peak plateau >30 cm H_2O)
3. Intubation in end stage lung disease patient awaiting lung transplant
4. Massive air leak
5. Acute cardiopulmonary collapse secondary to PE, airway obstruction, trauma, etc.

Contraindications

1. Mechanical ventilation with high settings (FIO_2 >90%, peak plateau >30 cm H_2O) for >7 days
2. Recent or expanding CNS hemorrhage
3. Immunosuppressed (ANC <400/mm^3)
4. Non-correctable comorbidity (i.e., terminal malignancy, major CNS damage, end stage lung disease without transplant option)

ANC, Absolute neutrophil count; *CNS,* central nervous system; FIO_2, fraction of inspired oxygen; PaO_2, partial pressure of oxygen in arterial blood; *PE,* pulmonary embolism; *PEEP,* positive end expiratory pressure; *VV, ECMO,* venovenous.

Contraindications

VV ECMO can be a lifesaving tool for severe refractory respiratory failure when appropriate patients are selected. There are no absolute contraindications for VV ECMO; however, factors associated with poor outcomes despite ECMO are considered relative contraindications. These include active intracranial hemorrhage, prolonged high pressure and fraction of inspired oxygen (FIO_2) ventilation beyond 7 days, metastatic malignancy with a short life expectancy, and severe baseline advanced respiratory failure without a treatment option beyond ECMO (e.g., lung transplant, lung volume reduction surgery) (Box 2). Potential conditions in patients considered for VV ECMO are very common; thus, each patient should be evaluated on a case-by-case basis. In particular, patients should be assessed as to their premorbid function, baseline comorbidities, duration of illness, current number of organ system failures, and overall prognosis. Younger patients with few to no medical problems and isolated ARDS will tend to have the best outcomes. Daily multidisciplinary assessment of futility should be evaluated by the progression of illness, subsequent organ failure, and complications.

Technique

Insertion of VV ECMO to establish rapid pulmonary support is of critical importance. There are two well accepted percutaneous configurations.

1. Right femoral vein to the inferior vena cava (IVC) and right internal jugular (IJ) vein to the right atrium, with two separate cannulae (Fig. 1).
2. Right internal jugular vein into right atrium and IVC with a single dual-lumen three-port cannula (Fig. 2).

The goals of both of these approaches are to take deoxygenated blood from the IVC (Fig. 1) or IVC and superior vena cava (SVC; Fig. 2), pass it through an oxygenator, and return oxygenated and decarboxylated blood to the right atrium. Before placing VV ECMO,

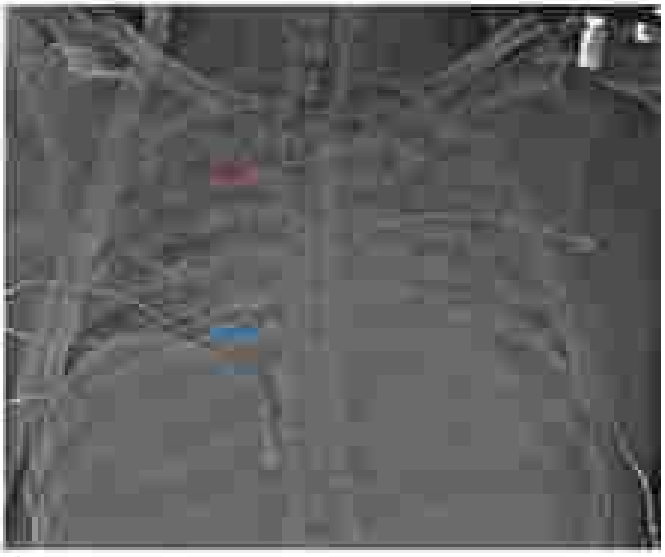

FIG. 1 Standard venovenous extracorporeal membrane oxygenation cannulation. Long venous cannula is inserted with its tip in the inferior vena cava (blue arrow) and inflow cannula in the right internal jugular (red arrow).

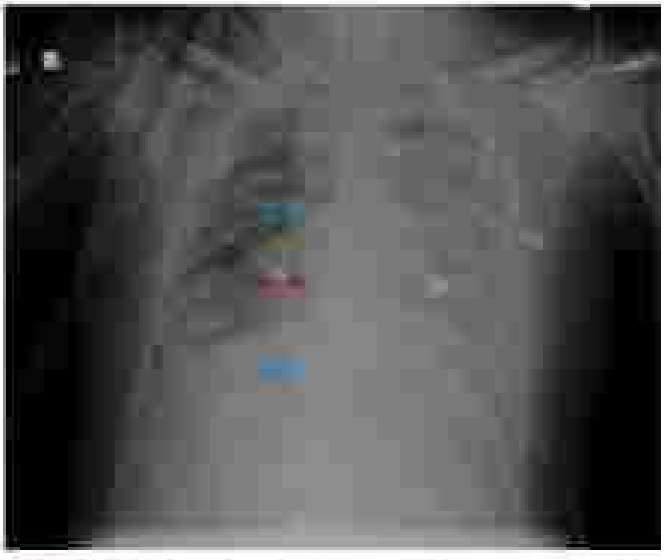

FIG. 2 Single dual-lumen three-port venovenous extracorporeal membrane oxygenation cannulation with two drainage ports (blue arrows) in the superior vena cava and inferior vena cava and one inflow port in the right atrium (red arrow).

patients should have a central line in the left internal jugular or left subclavian vein, as well as an arterial line. In addition, continuous telemetry monitoring during the procedure is crucial because malignant arrhythmias can often occur with wire manipulation within the right atrium of a hypoxic patient. Before insertion, we confirm the planned cannulation sites and supine position with head turned to opposite side of the neck being accessed. The patient is widely prepped with chlorhexidine antiseptic at the neck from the tragus to the sternal notch and bilateral groins to the knees. It is important to use sterile drapes that extend from the patient's head to the feet. It is our preference to access the right femoral vein because the left femoral vein crosses behind the left common iliac artery making the insertion more difficult. Using ultrasound guidance and the Seldinger technique, the right femoral vein and IJV are identified, accessed, and wires are placed. Once both wires have been placed, a bolus of heparin, 100 U/kg intravenous is administered. The IJV vein is serially dilated and an 18Fr cannula is inserted, the wire and dilator are removed, and the cannula is clamped. Either simultaneously or sequentially, the right femoral vein is serially dilated in preparation for cannulation. Before inserting the long 24Fr venous cannula, we estimate the appropriate insertion depth by measuring the distance between the patient's groin to the costal margin. The long venous cannula is inserted and clamped as well. The VV ECMO limbs are then brought onto the field and both cannulas are connected to the circuit. It is critical to ensure that no air bubbles are entrained in the tubing during connection. In addition, communication with the perfusionist should ensure that the inflow outflow from the patient to the pump to the femoral cannula and the outflow into the patient is through the IJV. Cannulas are secured in position with 0 silk sutures at the insertion point and Foley catheter holders along the leg and behind the ear onto the chest. Transient desaturation after the institution of VV ECMO commonly occurs because of the transfer of pump prime into the circulation and should resolve within 1 to 2 minutes.

ECMO flow and oxygenation should provide oxygen delivery and CO_2 removal capable of supporting normal patient metabolism. This usually equates to VV blood flows of about 60 to 80 mL/kg per minute. Typically most patients will flow between 3.5 and 5 L/min with 2000 to 2800 revolutions per minute. If a circuit is planned for CO_2 removal only, flows 50% to 25% of cardiac output should suffice. Maximum inflow suction pressure should not exceed −250 mm Hg and the maximum outflow pressure should not exceed 300 mm Hg. Initial ECMO settings should be set at full support with the oxygenator FiO_2 of 100% and the sweep of 4 to 6 L/min. ECMO settings are then adjusted based on the first arterial blood gas on ECMO. Chest and abdominal radiographs are obtained to confirm cannula position. The long venous cannula should be positioned such that the tip lies just below the right costal margin in the IVC. Systemic heparin infusion is initiated and titrated to maintain an activated partial thromboplastin time (aPTT) of 40 to 50 seconds.

The Avalon cannula (Maquet) is a multiport dual lumen cannula designed to be inserted into the IJV and provide full VV ECMO access. The cannula includes two outflow ports in the IVC and SVC and an additional inflow port in the right atrium (Fig. 2). This configuration affords the advantage of a single cannula and avoidance of groin access with the potential for patient ambulation on VV ECMO. One critical caveat to the Avalon must be inserted under echocardiographic or fluoroscopic guidance to ensure the introducer wire is positioned within the IVC and not in the right ventricle. There have been several case reports of improper wire position and subsequent cannula insertion through the free wall of the right ventricle with frequently fatal consequences.

MANAGEMENT

A critical care nurse and an ECMO specialist (typically a perfusionist, respiratory therapist, or physician) should be assigned to provide 24-hour monitoring and care for the ECMO patient and the patient on support. It is imperative that institutions develop its own protocols based on Extracorporeal Life Support Organization (ELSO) guidelines with the perfusion staff, nursing, critical care, and the surgeons for ECMO-circuit management and issues.

Ventilator Management

The goal of VV ECMO is to minimize both barotrauma from hyperinflation and high airway pressure and to limit pulmonary oxygen toxicity. Following stabilization on VV ECMO, we typically follow ARDSNet ventilator protocols to minimize further barotrauma, including pressure control or assist control mode ventilation, with the goal being low tidal volumes of 4 to 6 mL/kg, maximum peak airway pressures 30 cm H_2O or less, and minimizing FiO_2. From this point, we aggressively wean the ventilator FiO_2 to 40% to maintain a partial pressure of oxygen in arterial blood (PaO_2) greater than all but

and then subsequently wean VV ECMO FIO_2 and sweep. Patients with primary hypercarbic respiratory failure can be maintained on low-flow ECMO (15–30 mL/kg per minute) to effect carbon dioxide removal while providing maximum lung rest.

Baseline lung compliance is calculated and then measured daily to assess improvements in the respiratory system. Static lung compliance is calculated by dividing the tidal volume by the difference in plateau pressure and PEEP and has been shown to correspond with successful weaning from VV ECMO.

$$C_{stat} = \frac{\text{Tidal volume}}{[P_{plateau} - P_{EEP}]}$$

Normal lung compliance is approximately 100 mL/cm H_2O and 70 to 80 mL/cm H_2O for ventilated patients. Patient with acute lung injury and ARDS have decreased lung compliance, ranging from 30 to 50 mL/cm H_2O and less than 30 mL/cm H_2O, respectively. It is our belief that the ventilator should be weaned to compliance of more than 30 mL/cm H_2O and FIO_2 40% before weaning ECMO.

Systemic Anticoagulation

Systemic anticoagulation is maintained with continuous infusion of heparin to maintain an aPTT of 40 to 50. It is not uncommon for platelet counts to drop by more than 50%.

Aggressive correction of coagulopathy and prompt surgical response to bleeding sites can reduce bleeding complications to manageable levels in most patients. To optimize the oxygenation carrying capacity in patients, we maintain a hemoglobin greater than 10 to 12 g/dL. The membrane oxygenator is changed either on a fixed schedule based on experience or when signs of impending membrane failure develop. These signs include decreasing efficiency of gas exchange, fraying, and evidence of deposition on the membrane.

Sedatives and Analgesia

The use of sedation and paralysis is based on patient requirements. In situations where agitation significantly elevates oxygen demand, both may be needed. Airway management is facilitated by sedation, especially before tracheostomy; however, the use of increased levels of sedation hinders neurologic evaluation, which is critical for ongoing survivability assessment. In addition, the prolonged use of sedatives and especially paralytics in the intensive care unit can have deleterious consequences. Recently, studies have demonstrated decreased bioavailability of many sedatives and opioids related to circuit sequestration of these agents. Lipophilic drugs, such as midazolam, diazepam, lorazepam, fentanyl, and propofol, are particularly subjected to this phenomenon, resulting in larger dosages and decreased effectiveness of these drugs while on ECMO. Morphine tends to be less affected by circuit sequestration.

Renal

An attempt should be made to aggressively diurese the patient to dry weight or less to reduce and minimize interstitial pulmonary edema. In situations in which renal function is compromised, early use of continuous VV hemofiltration is used to remove volume. Continuous VV hemofiltration can be integrated into the ECMO circuit, thus eliminating the need for an additional venous catheter.

Infection

Prophylactic antibiotics are given before insertion and discontinued within 24 hours, with further antibiotic or antifungal therapy as directed by the presence of any underlying infectious illness. White blood cell count, C-reactive protein, and systemic vascular resistance are good indicators of ongoing infection. Temperature, on the other hand, may be unreliable while on ECMO because a significant amount of passive cooling occurs and can mask fevers. Therefore, cultures are routinely performed biweekly while on ECMO. Activated protein C has a demonstrated survival benefit in severe sepsis; however, its use with ECMO poses a serious bleeding risk.

TROUBLESHOOTING ECMO

Recirculation

Recirculation is a phenomenon that occurs when the inflow and outflow cannulas are too close together (Table 2). Although not inherently dangerous, it reduces the efficiency of the VV ECMO circuit and may be a cause of persistent hypoxia. This can be assessed by visually examining the cannulas for appropriate color differential (the outflow should be dark and the inflow bright), radiographic location of the cannulas (the tip of the femoral venous cannula should be below the diaphragm, there should be sufficient distance between the inflow and outflow cannulae tips). In addition, the PaO_2 of the outflow cannula should not be higher than the systemic PaO_2 or have a saturation greater than 75%. When this does occur, repositioning the outflow cannula will solve the problem.

SVC Syndrome

SVC syndrome can occur in patients on VV ECMO because of mechanical obstruction of the SVC typically with the ECMO cannula. SVC syndrome is typically seen in smaller patients with a body surface area less than 1.6 m^2 and in patients with significant hardware already lying within the SVC (e.g., pacemaker leads, indwelling dialysis catheters). It may occur rapidly after insertion or insidiously over the first several hours. Manipulation of the patient's position is reverse Trendelenburg is only a temporary measure. Once identified, it is best managed by downsizing and exchanging the SVC cannula. It is important to obtain an echocardiogram to ensure that cardiac misadventures with resulting cardiac tamponade is not the cause.

Persistent Hypoxia

Some patients with severe respiratory failure may require maximal ventilator support in addition to maximal VV ECMO support for several days to weeks before any sign of recovery is seen. If patients are persistently hypoxic, we confirm the oxygenator is functioning. Another cause of persistent hypoxia arises from an increase in deoxygenated blood returning from bronchial arteries. In this instance, conversion to veno-arterial venous (VAV) ECMO cannulation strategy is an option.

Hemolysis

Hemolysis with VV ECMO is a relatively rare event that occurs in 10% of patients, according to ELSO registry data. With the use of heparin bonded circuits and centrifugal pumps, hemolysis is not a common problem. It typically is manifested by refractory anemia and elevated bilirubin and should be considered in instances where there is not an overt source of bleeding. It is confirmed by elevated serum plasma free hemoglobin (>10 mg/dL), elevated lactate dehydrogenase, and decreased haptoglobin. Potential sources of hemolysis include clots in the pump chamber, elevated suction pressures (< −300 mm Hg), high resistance of the outflow cannula, or kinking in the circuit. It is important to identify the source of hemolysis and correct it.

Thrombocytopenia

Thrombocytopenia is a common problem with VV ECMO and is infrequently caused by heparin-induced thrombocytopenia (HIT). A drop in platelet count of greater than 50% from baseline prompts HIT screening with anti-heparin PF4 antibody and serotonin release assay testing. If testing is positive for HIT, we will switch to a direct thrombin inhibitor (e.g., argatroban, bivalirudin). There are many reports of patients being managed safely without systemic heparin; however, this will affect the longevity of the membrane oxygenator. Platelets are transfused as necessary to maintain the platelet count at greater than 25,000.

TABLE 2 Troubleshooting Venovenous ECMO

Problem	Signs	Treatment
Recirculation	Persistent hypoxia Outflow blood saturation >5% or partial pressure of oxygen (outflow) > partial pressure of oxygen (inflow) No color differential between outflow and inflow cannula blood Chest radiograph: cannular tips too close together	Reposition outflow cannula
SVC syndrome	Facial plethora Localized edema of face and upper extremities Rule out cardiac tamponade	Downsize and exchange IJ cannula
Oxygenator thrombosis/failure	Persistent hypoxia Decreased post-oxygenator partial pressure of oxygen in arterial blood Hemolysis Elevated outlet pressure	Exchange oxygenator
Hemolysis	Anemia and hyperbilirubinemia Plasma free hemoglobin >10 mg/dL Elevated lactate dehydrogenase Low haptoglobin	Identify source and treat
Thrombocytopenia	>50% drop in baseline hemoglobin platelet count Onset within 5–10 days of prior heparin exposure New thrombosis or skin necrosis Heparin-induced thrombocytopenia testing: anti-heparin PF4 antibody, serotonin release assay Rule out other causes (e.g., hemolysis, disseminated intravascular coagulation, sepsis, idiopathic thrombocytopenic purpura	Stop heparin Start direct thrombin inhibitor (i.e., argatroban, bivalirudin) Can consider no anticoagulation
Hypovolemia	Elevated inlet suction pressure (< −300 mm Hg) Fluctuating and low flows Hypotension Evaluate for bleeding Confirm correct cannula size, position; look for cannula kinking	Give volume; consider blood transfusion for hemoglobin <10 g/dL
Disseminated intravascular coagulation	Recent trauma, sepsis, malignancy Diffuse bleeding Thrombocytopenia Thrombosis Abnormal coagulation profile: ↑ prothrombin time and activated partial thromboplastin time, ↓ fibrinogen, ↑ D-dimer, ↑ fibrin degradation products	Identify underlying cause and treat Supportive care Transfuse to keep platelet count >50,000 and fibrinogen >100 mg/dL

WEANING AND LUNG RECOVERY

The return of lung function is signaled by improving PaO_2 with ability to wean the ventilator FIO_2, improving lung compliance (>30 mL/cm H_2O) and tidal volumes, and a reduction in the peak airway pressures. The ventilator is set to 7 to 8 mL/kg with peak airway pressure less than 35 mm Hg, and an FIO_2 less than 40%, then VV ECMO FIO_2 is weaned slowly over several days to maintain a systemic PaO_2 greater than 70. Once an ECMO FIO_2 of 21% (room air) is maintained for 24 to 48 hours with PaO_2 greater than 70 on ventilator FIO_2 <40% with a lung compliance of 30 mL/cm H_2O or greater, the heparin infusion is stopped and the ECMO cannulae are clamped and removed at the bedside. Hemostasis is achieved with direct pressure for at least 30 to 45 minutes. In our experience, open surgical repair of the venous access sites is rarely needed. The patient is maintained on the ventilator until a standard ventilator weaning process is instituted.

DISCUSSION

ECMO was first used successfully more than 30 years ago and has become the standard of care for refractory respiratory failure in neonates and older children. Adult ARDS carries a mortality rate that can approach 100% in patients who are failing conventional treatment, and the care of these patients is expensive and resource intensive. Theoretically ECMO support melds well with the needs of the ARDS patient; it provides excellent CO_2 removal while reducing barotrauma and oxygenation demands on the potentially recoverable native lung. ECMO support is associated with significant comorbidity, particularly related to anticoagulation and bleeding, but these complications are usually manageable and occur at a rate that can be reconciled with the high mortality seen in untreated patients.

Strategies for ARDS are quite diverse. ECMO is rarely evaluated in a cohort consistent for diagnosis because these niche populations are usually too small for timely recruitment. Nevertheless, over the past decade, survival to discharge following ECMO appears to be stabilizing at around 50% for patients with respiratory failure without concomitant cardiac failure (Fig. 3). This appears to be related to the development of improved oxygenators and cannulae and use of VV rather than venoarterial cannulation when cardiac support is not necessary. Use of heparin-bonded components in the ECMO circuit have not eliminated serious bleeding events but have reduced the level of heparin infusion required to maintain an acceptable anticoagulation status.

FIG 3. Extracorporeal life support committee, January 2018. (Courtesy Extracorporeal Life Support Organization.)

Recognition of the role of ventilator-induced barotrauma in limiting the efficacy of mechanical ventilation has led to the development of low-traumatic ventilator management approaches such as pressure-controlled and inverse ratio ventilation. When used as a component of a standardized protocol, these methods can increase the number of patients who recover without transition to ECMO support and may also increase the recovery potential of the native lung in patients who progress to ECMO.

In summary, although the results of a robust randomized clinical trial in a well-defined patient population are awaited, there is evidence that VV ECMO can increase survival in patients with ARDS refractory to conventional therapy. Use of this technique, however, is appropriate only in conjunction with a well-constructed respiratory management protocol that is initiated at the time of ARDS diagnosis.

Tracheostomy

Christopher R. Read, MD, Krista L. Haines, DO, MA, and Suresh K. Agarwal, MD

Tracheostomy is a common procedure performed in intensive care units (ICUs) and the operating room (OR) worldwide. Over 100,000 tracheostomies are performed annually in the United States, a number that appears to have grown steadily up until the 2000s, with a slow rate of decline since. This decline may be explained in part by results from more recent studies on the timing of tracheostomy. Nearly 3% of all hospital admissions in the United States require mechanical ventilation for acute or chronic respiratory failure, the major indications for tracheostomy. Among all patients requiring mechanical ventilation annually, more than 10% undergo tracheostomy as an inpatient, and more than 70% of patients with new tracheostomies are discharged to long-term assisted care facilities. The frequency with which the procedure is performed and its implications for ongoing care in the postacute setting mean that the timing and application of tracheostomy are of major economic importance as well. A recent cost estimate of long-term acute care for chronic critical illness in the United States placed the overall figure at $35 billion annually. Therefore, a general understanding of the indications, risks, benefits, and potential complications of the procedure should be of interest to any medical practitioner or policymaker.

The procedure is typically performed by general, thoracic, or otolaryngology head and neck surgeons, by surgical intensivists, or by medical intensivists with specialized procedural training in the percutaneous dilational technique. A small study found no significant difference in outcomes of percutaneous dilational tracheostomy performed by surgical or interventional pulmonology teams, as long as patients were appropriately selected for the procedure.

Indications and Contraindications

The indications for tracheostomy can be partitioned broadly into three categories, listed in descending order of prevalence: need for prolonged mechanical ventilation, airway protection (i.e., following cerebrovascular accident), and upper airway obstruction (Table 1). Finally, emergency tracheostomy is also a consideration in certain situations in which it is not possible to perform translaryngeal intubation.

The only absolute contraindications to the procedure are soft tissue infection overlying the intended surgical site and operative transport error. Relative contraindications include very high ventilator support settings, uncorrected coagulopathy, and laryngeal cancer prior to definitive treatment given the increased risk of local disease spread.

The contraindications specific to the percutaneous dilational technique are emergency airway, enlarged thyroid, inability to palpate landmarks, unstable cervical spine fracture (or a patient who is otherwise unable to extend their neck), and previous surgery at the site, including prior tracheostomy.

Respiratory Failure with Need for Prolonged Mechanical Support

The most common indication for tracheostomy is the anticipated need for prolonged mechanical ventilation in the context of respiratory failure. Respiratory failure results in over 2 million hospitalizations annually in the United States alone, a number that is steadily growing. Approximately 40% of patients admitted with respiratory failure will require endotracheal intubation with mechanical ventilation, and more than 10% will undergo tracheostomy placement. Two-thirds of all tracheostomy procedures in the United States are performed on mechanically ventilated patients in the ICU, and this is the largest and best-studied population of patients undergoing the procedure. The underlying etiology of respiratory failure is not necessarily an indication or contraindication to tracheostomy, although careful consideration must be given to the expected duration of ventilator support required to avoid unnecessary procedures. Unfortunately, despite considerable study, there is no broad consensus on appropriate timing of tracheostomy after endotracheal intubation.

Common causes of respiratory failure requiring prolonged mechanical ventilator support include sepsis, respiratory failure secondary to other medical problems (i.e., cardiogenic pulmonary edema), and perioperative or traumatic respiratory failure (i.e., after multiple rib fractures). Respiratory failure is often multifactorial and may also result from a combination of conditions; additional risk factors for respiratory failure requiring tracheostomy include increasing age and morbid obesity.

The primary benefit of tracheostomy over translaryngeal tracheal intubation is improved patient comfort and an attendant decrease in sedative and narcotic requirements, which facilitates weaning efforts. This patient-centered outcome has been reiterated in multiple randomized trials and is the only well-established improved outcome over conventional translaryngeal intubation. Tracheostomy also improves ease of pulmonary hygiene and expedites ICU discharge to a ventilator capable step-down unit or post-acute facility with a primary focus on rehabilitation. Most perceived benefits of tracheostomy over translaryngeal intubation have not been consistently demonstrated in prospective studies (ventilator-associated pneumonia, overall mortality).

Recognition of the role of ventilator-induced barotrauma in limiting the efficacy of mechanical ventilation has led to the development of low-traumatic ventilator management approaches such as pressure-controlled and inverse ratio ventilation. When used as a component of a standardized protocol, these methods can increase the number of patients who recover without transition to ECMO support and may also increase the recovery potential of the native lung in patients who progress to ECMO.

In summary, although the results of a robust randomized clinical trial in a well-defined patient population are awaited, there is evidence that VV ECMO can increase survival in patients with ARDS refractory to conventional therapy. Use of this technique, however, is appropriate only in conjunction with a well-constructed respiratory management protocol that is initiated at the time of ARDS diagnosis.

Tracheostomy

Christopher R. Read, MD, Krista L. Haines, DO, MA, and Suresh K. Agarwal, MD

Tracheostomy is a common procedure performed in intensive care units (ICUs) and the operating room (OR) worldwide. Over 100,000 tracheostomies are performed annually in the United States, a number that appears to have grown steadily up until the 2000s, with a slow rate of decline since. This decline may be explained in part by results from more recent studies on the timing of tracheostomy. Nearly 3% of all hospital admissions in the United States require mechanical ventilation for acute or chronic respiratory failure, the major indications for tracheostomy. Among all patients requiring mechanical ventilation annually, more than 10% undergo tracheostomy as an inpatient, and more than 70% of patients with new tracheostomies are discharged to long-term assisted care facilities. The frequency with which the procedure is performed and its implications for ongoing care in the postacute setting mean that the timing and application of tracheostomy are of major economic importance as well. A recent cost estimate of long-term acute care for chronic critical illness in the United States placed the overall figure at $35 billion annually. Therefore, a general understanding of the indications, risks, benefits, and potential complications of the procedure should be of interest to any medical practitioner or policymaker.

The procedure is typically performed by general, thoracic, or otolaryngology head and neck surgeons, by surgical intensivists, or by medical intensivists with specialized procedural training in the percutaneous dilational technique. A small study found no significant difference in outcomes of percutaneous dilational tracheostomy performed by surgical or interventional pulmonology teams, as long as patients were appropriately selected for the procedure.

Indications and Contraindications

The indications for tracheostomy can be partitioned broadly into three categories, listed in descending order of prevalence: need for prolonged mechanical ventilation, airway protection (i.e., following cerebrovascular accident), and upper airway obstruction (Table 1). Finally, emergency tracheostomy is also a consideration in certain situations in which it is not possible to perform transoral intubation.

The only absolute contraindications to the procedure are soft tissue infection overlying the intended surgical site and operative transperitoneal. Relative contraindications include very high ventilator support settings, uncorrected coagulopathy, and laryngeal cancer prior to definitive treatment given the increased risk of local disease spread.

The contraindications specific to the percutaneous dilational technique are emergency airway, enlarged thyroid, inability to palpate landmarks, unstable cervical spine fracture (or a patient who is otherwise unable to extend their neck), and previous surgery at the site, including prior tracheostomy.

Respiratory Failure with Need for Prolonged Mechanical Support

The most common indication for tracheostomy is the anticipated need for prolonged mechanical ventilation in the context of respiratory failure. Respiratory failure results in over 2 million hospitalizations annually in the United States alone, a number that is steadily growing. Approximately 40% of patients admitted with respiratory failure will require endotracheal intubation with mechanical ventilation, and more than 10% will undergo tracheostomy placement. Two-thirds of all tracheostomy procedures in the United States are performed on mechanically ventilated patients in the ICU, and this is the largest and best-studied population of patients undergoing the procedure. The underlying etiology of respiratory failure is not necessarily an indication or contraindication to tracheostomy, although careful consideration must be given to the expected duration of ventilator support required to avoid unnecessary procedures. Unfortunately, despite considerable study, there is no broad consensus on appropriate timing of tracheostomy after endotracheal intubation.

Common causes of respiratory failure requiring prolonged mechanical ventilator support include sepsis, respiratory failure secondary to other medical problems (i.e., cardiogenic pulmonary edema), and perioperative or traumatic respiratory failure (i.e., after multiple rib fractures). Respiratory failure is often multifactorial and may also result from a combination of conditions; additional risk factors for respiratory failure requiring tracheostomy include increasing age and morbid obesity.

The primary benefit of tracheostomy over transoral tracheal intubation is improved patient comfort and an attendant decrease in sedative and narcotic requirements, which facilitates weaning efforts. This patient-centered outcome has been reiterated in multiple randomized trials and is the only well-established improved outcome over conventional transoral intubation. Tracheostomy also improves ease of pulmonary hygiene and expedites ICU discharge to a ventilator capable step-down unit or post-acute facility with a primary focus on rehabilitation. Most perceived benefits of tracheostomy over transoral intubation have not been consistently demonstrated in prospective studies (ventilator-associated pneumonia, overall mortality).

Table: 1 Indications for Tracheostomy

Indication	Condition
Need for prolonged mechanical ventilation	Acute and chronic respiratory failure (i.e., sepsis or degenerative neuromuscular disease)
Airway protection	Neurologic catastrophe Cerebrovascular accidents
Upper airway obstruction	Congenital high airway obstruction Inability to transbronchially intubate trachea Neoplasms of the oropharynx, hypopharynx, or larynx Oral, neck, or maxillofacial trauma or burns Angioedema Laryngeal (i.e., vocal cord paralysis or radiation fibrosis) Infection (i.e., epiglottitis) Obesity hypoventilation syndrome Obstructive sleep apnea Thyroid goiter with compressive signs and symptoms

Importantly, tracheal stenosis and tracheoesophageal fistula, complications most exclusively attributed to prolonged endotracheal intubation, are now also being described following tracheostomy. Additionally, tracheoinominate arterial fistula, once thought to be exclusively a complication of tracheostomy, can also be seen with transtracheal intubation. The complications of tracheal stenosis, tracheoesophageal fistula, and tracheoinominate arterial fistula are more likely related to excessive cuff pressure and pressure necrosis than the means by which ventilation is delivered. Careful consideration of perceived and demonstrated benefits and risks of tracheostomy should be undertaken during discussions with patients or their medical decision makers when pursuing informed consent.

A lack of decisive guidance on timing and a broad range of clinical conditions indicating the procedure underscore the importance of the clinician's role in patient selection and timing of tracheostomy.

Airway Protection

Patients who have had significant head trauma, ischemic stroke, or intracranial hemorrhage may have protracted or permanent dysphagia and are at risk for aspiration. Although lesions affecting the posterior cerebral circulation are classically implicated in post-stroke dysphagia, inability to swallow to present in 30% to 40% of all stroke survivors. In broad terms, neurologic catastrophe resulting in dysphagia with inability to protect the airway is a common indication for tracheostomy. Some patients may respond to nutritional therapy through an enteric tube with oil per os until swallow function and airway protection improve, but many patients with deficits severe enough to require long-term enteral access will ultimately continue to aspirate their own secretions and require tracheostomy.

There have been considerable efforts to predict which patients will require tracheostomy in the neuro-ICU setting. Importantly, many patients in this population also require mechanical ventilation due to central hypoventilation or associated comorbidities. Among patients requiring ventilatory support after intracranial hemorrhage or ischemic stroke, several studies have identified decreased Glasgow Coma Scale scores (typically <8) and severity of radiographic lesions as correlates of need for tracheostomy. However, the heterogeneity of this population and comorbidity between respiratory failure and inability to protect one's airway again ultimately leave the final judgment regarding timing and patient selection to the clinician.

Upper Airway Obstruction

Tracheostomy effectively bypasses functional or mechanical causes of upper respiratory tract obstruction. Congenital causes of upper respiratory tract obstruction include laryngeal atresia (or severe stenosis), a rare condition that may be diagnosed prenatally and important with emergent tracheostomy at the time of birth. The Pierre Robin sequence with severe micrognathia and glossoptosis causing respiratory distress may also be an indication for pediatric tracheostomy.

Obstructing neoplasm affecting the aerodigestive tract is also an indication. Benign and malignant tumors affecting the head and neck can cause respiratory compromise, and tracheostomy may be performed as an adjunct at the time of surgical resection, or as a palliative intervention. Importantly, there is evidence that tracheostomy prior to definitive intervention for laryngeal carcinoma may be associated with increased local disease spread, and the decision to perform tracheostomy and timing relative to definitive treatment should be made with the patient's multidisciplinary oncology team in the context of their treatment plan.

Acquired causes of upper airway obstruction that may be an indication for tracheostomy include stricture from radiation fibrosis or bilateral vocal fold paralysis, for example after iatrogenic recurrent laryngeal nerve injuries or neck malignancy. Any condition causing a difficult or impossible translaryngeal intubation may require tracheostomy. For example, angioedema, burn injury, and trauma to the head and neck in a stable patient with threat to the airway constitute indications for urgent tracheostomy if emergent cricothyrotomy is to be avoided. In the era of vaccination, infectious epiglottitis (i.e., from *Haemophilus influenzae*) is exceedingly rare in the United States but was previously an indication for tracheostomy among children (and less commonly adults). Obesity hypoventilation syndrome and obstructive sleep apnea not responding to conventional management may also require tracheostomy.

Emergency Airway Considerations

In the event that emergent cervical access to the airway is required (i.e., for inability to perform translaryngeal intubation after traumatic injury or cardiopulmonary arrest), cricothyrotomy is the preferred method for expeditiously ventilating unless laryngeal injury is suspected. Surgical or percutaneous (i.e., via needle or hollow catheter) methods may be employed, with the latter preferable among children owing to the relatively small size of affected structures. The speed and reliability of cricothyrotomy makes it the procedure of choice in the majority of urgent surgical airway situations. Conversion of emergency cricothyrotomy to formal tracheostomy should be performed once the patient has stabilized and is able to safely undergo general anesthesia in a controlled environment.

In the event of suspected or confirmed laryngeal injury (i.e., after head and neck trauma), endotracheal intubation and cricothyrotomy should both be avoided. A formal emergent surgical tracheostomy should be performed to decrease risk of extending or otherwise exacerbating the injury. The procedure is performed emergently under local anesthesia when there is concern for impending airway obstruction with suspicion for laryngeal injury based on clinical impression after penetrating or blunt injury. In a stable patient in whom laryngeal injury is suspected without evidence of impending airway compromise, computed tomography and flexible fiberoptic laryngoscopy should be performed prior to any instrumentation of the airway (including endotracheal intubation).

ANATOMY

In the adult, the trachea is a 10 to 13-cm, centrally located, hollow organ with a cervical portion that begins approximately at the sixth cervical vertebral body (Fig. 11.1) traverses the neck and gives way to a thoracic portion that enters the mediastinum and terminates with the carina at the T4–T5 disk level. The hollow and flexible structure of the trachea is supported by the prominent thyroid cartilage, the circumferential

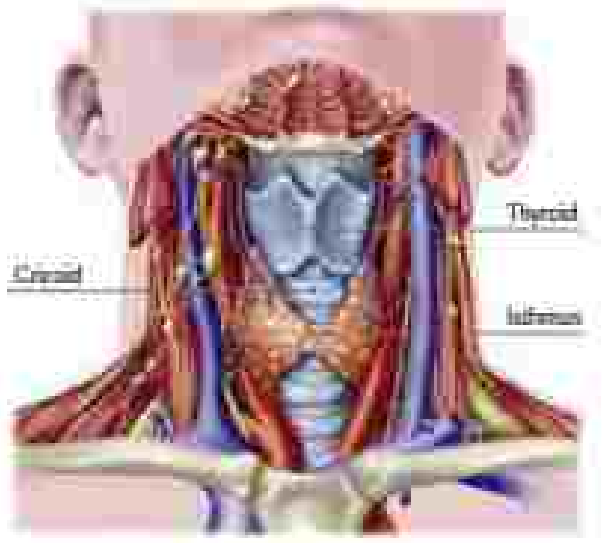

FIG. 1 Safe tracheostomy by any technique requires knowledge of neck anatomy.

cricoid cartilage, and 15 to 20 incomplete cartilaginous rings inferiorly. When viewed in cross section, such as with a bronchoscope, the normal human trachea appears to be nearly cylindrical with posterior flattening. This flattening is evident on histology as the membranous portion of the trachea at the opening of each C-shaped tracheal ring. The posterior wall may also be identified during bronchoscopy by the dense longitudinal folds of the trachealis smooth muscle.

The most superficial and therefore surgically accessible portion of the trachea lies between the thyroid cartilage and the sternal notch. At this point, only the skin, subcutaneous tissue, strap muscles, thyroid isthmus, and pretracheal fascia overlie the organ. The cervical esophagus lies immediately posteriorly, and the lobes of the thyroid and anterior jugular veins border the trachea laterally. The innominate (brachiocephalic) artery crosses over the right anterolateral trachea approximately at the sixth to tenth tracheal rings.

The vascular supply and drainage of the cervical trachea is predominately via the inferior thyroid artery and vein, respectively. Tracheoesophageal branches of the vessels enter the trachea through lateral tissue pedicles, highlighting the importance of midline anterior access during tracheostomy to avoid significant vascular injury. The paired supply and drainage provides some vascular redundancy in the event of significant injury or resection. The supply of the distal trachea may have contributions from subclavian, intercostal, internal thoracic, and bronchial arteries.

The location, length, and anatomic relations of the trachea are less predictable in childhood and normally vary in the adult somewhat with respiration.

OPERATIVE TECHNIQUES

Open Surgical Versus Percutaneous Dilational Tracheostomy

Modern tracheostomy procedures can be described as either open or percutaneous. Conventional "open" or surgical tracheostomy was first described in ancient Egypt over 3600 years ago and remains in use for select patients today. Percutaneous dilational tracheostomy was pioneered using the Seldinger technique to gain access to the trachea in the 1960s by Toye and Wilmoth. However, it was not until Ciaglia described a technique of serial radial dilations in 1985, that percutaneous dilational tracheostomy gained the widespread popularity that is seen today.

Today, percutaneous dilational tracheostomy is recommended over surgical tracheostomy for most adults without contraindications based on evidence for decreased stoma infection, bleeding, and improved scar cosmesis. Although several variations exist, the single-step dilator kits Ciaglia Blue Rhino (Cook Medical) and Portex Ultra-PERC (Smiths Medical) with bronchoscopic guidance are used most commonly. In a 2006 meta-analysis of 17 randomized controlled trials (RCTs) including 1232 patients undergoing tracheostomy, the authors found that percutaneous technique was generally equivalent to surgical tracheostomy with respect to bleeding, major early and long-term complications, and mortality. The only statistically significant benefit of percutaneous technique was a decreased stoma site infection. A more recent 2014 meta-analysis of 973 patients in 14 RCTs agreed with the prior findings of decreased stoma inflammation and infection but cautioned that technical difficulties were more common among percutaneous procedures, perhaps due in part to the increasing prevalence of the procedure and heterogeneity in training among proceduralists.

Preoperative Assessment

Preoperative assessment should include a thorough history and physical examination, and review of laboratory studies and any pertinent imaging or endoscopy. Besides determining if the patient is an appropriate and safe procedural candidate in general, attention should be given to details that may favor surgical (open) tracheostomy over percutaneous dilational tracheostomy.

Relevant historical data include history of malignancy of the head, neck, or upper aerodigestive tract; history of radiotherapy to the head or neck; and any pertinent surgical history. In particular, prior neck surgery (including tracheostomy placement) may lead to scarring that obscures or obliterates anatomic planes and relationships, and therefore increases the complexity of the procedure, and cervical spinal fusion may limit the extension of the neck required for safe percutaneous dilational approach. Although prior neck procedures, including prior tracheostomy, may make the procedure more difficult, they do not necessarily obviate the ability to perform a percutaneous dilational tracheostomy. Fractures of the cervical spine are a relative contraindication to percutaneous tracheostomy, particularly if there is any concern for instability.

For patients in an ICU setting who are intubated and mechanically ventilated, careful attention to hospital course and current and recent ventilator settings is important. The cause of respiratory failure and length of mechanical ventilation, and failed extubation attempts (spontaneous breathing trials or unplanned reintubations) should be considered. Finally, special attention to the fraction of inspired oxygen (FIO_2) and especially the positive end expiratory pressure (PEEP) is critical in planning for a safe tracheostomy. At our institution, patients must generally be able to tolerate FIO_2 less than 0.4 while lying flat at PEEP no greater than 20 mm Hg to be considered for surgical tracheostomy due to the risk and the consequences of potential rapid alveolar de-recruitment during the procedure.

On physical examination, careful attention to the limits of neck extension and palpation of bony and cartilaginous landmarks may ultimately direct the decision to perform surgical tracheostomy. Inability to palpate relevant landmarks or less than 1 cm between the cricoid cartilage and sternal notch are relative contraindications to percutaneous dilational tracheostomy. Generally, an ideal percutaneous dilational tracheostomy candidate will have 2 to 3 tracheal rings palpable below the cricoid cartilage.

It is our practice to check prothrombin time (PT/INR), partial thromboplastin time, and complete blood count within 48 hours of the procedure to ensure that there is no uncorrected severe coagulopathy (PT/INR > 1.5 or platelets < 100,000). The ideal candidate will have normal coagulation parameters. We typically do not interrupt deep venous thrombosis chemoprophylaxis (subcutaneous low molecular weight heparin or unfractionated heparin) or antiplatelet therapies (aspirin, clopidogrel) in preparation for tracheostomy.

For intubated patients, the most recent chest radiograph should be reviewed to ensure that there are no previously unrecognized findings (pneumonia, pneumothorax) preoperatively. If cross-sectional imaging of the neck is available, it should be reviewed to evaluate for aberrant vascular or other anatomy, although there is not a specific indication for preoperative imaging. Similarly, if bronchoscopy or laryngoscopy has been performed, any upper airway pathology should be reviewed prior to performance of the procedure.

Procedural Technique: Surgical Tracheostomy

Although typically performed in the OR with general anesthesia and neuromuscular blockade, surgical tracheostomy may also be performed in the ICU setting. Informed consent from the patient's medical decision maker is garnered preoperatively and a discussion of potential risks should address the most common complications of the procedure including bleeding, infection at the stoma site, accidental decannulation, and pneumothorax. The patient is placed in the supine position with the neck extended using a shoulder roll to improve anterior tracheal exposure if possible. Subtle reverse Trendelenburg position decompresses the veins of the neck, and facial hair is removed using mechanical clippers to the mandible. The patient's skin is prepped from the upper lip to mandible and draped with typical sterile technique. The patient is preoxygenated with 100% FiO$_2$ and ventilator settings that minimize acidosis. Finally, sedation, analgesia, and paralysis are administered by anesthesia staff to improve the safety and efficiency of the procedure.

After a time out for safety that includes discussion of airway and risk mitigation, the relevant landmarks are palpated in preparation for incision (Fig. 2). The preferred 3-cm skin incision may need to be longer for patients with difficult anatomy or obese habitus and is made over the second tracheal ring, or approximately 1 cm below the cricoid cartilage. Although a transverse skin incision (with careful attention to avoid anterior jugular venous injury) is preferred for cosmetic reasons, a vertical incision may be used. The subcutaneous tissues and platysma are divided using a combination of electrocautery and blunt dissection (Fig. 3). Strap muscles (sternohyoid and sternothyroid) are retracted laterally to expose the thyroid isthmus (Figs. 4 and 5). It is our practice to divide the isthmus using electrocautery, although it may be retracted superiorly or inferiorly if it is sufficiently mobile to allow exposure to the trachea. The pretracheal fascia can be divided and dissected bluntly laterally, exposing the trachea (Fig. 6). A cricoid hook is then used to elevate the trachea, which is sharply incised using a scalpel below the first or second tracheal rings. Alternatively, two tracheal "stay" sutures may be placed to facilitate elevation of the trachea; these sutures also may facilitate tracheostomy tube replacement by a trained provider in the event of early inadvertent decannulation (Fig. 7). There are several variations on the tracheal incision itself; some surgeons advocate for a longitudinal "fenestrated H" incision spanning the first through third rings, whereas an alternative approach involves three careful incisions to raise a flap. We make a longitudinal incision involving the second and third tracheal rings approximately 1 cm long, or just sufficient to admit the tracheostomy tube (Fig. 8). The transoral endotracheal tube may need to be retracted slightly to allow placement of a new tracheostomy tube, which is inserted into the new tracheal defect using sterile technique (Fig. 9). The inner cannula is placed, the

FIG. 2 Palpation of surface landmarks facilitates the procedure. The thyroid and cricoid cartilages are outlined with ease and the sternal notch is marked with a cheerful lobotomy. The planned 3-cm cricothyroid incision is marked approximately over the second or third tracheal rings.

FIG. 3 After skin incision, electrocautery and blunt dissection reveals the platysma.

FIG. 4 After incision of the platysma, a combination of electrocautery and blunt dissection reveals the sternohyoid and sternothyroid (strap) muscles, which are retracted or divided.

FIG. 5 (A) The thyroid isthmus is encountered, dissected off of the pretracheal fascia and (B) then divided and suture-ligated between clamps.

tracheostomy cuff is inflated, and the ventilator circuit is connected to the new tracheostomy tube. End tidal CO_2 and breath sounds are confirmed before removal of the translaryngeal tube, and 2–0 monofilament nonabsorbable monofilament sutures are used to secure the tracheostomy neck plate to the skin (Fig. 10).

Procedural Technique: Percutaneous Dilational Tracheostomy (Single-Step Dilation Technique)

Percutaneous dilational tracheostomy may be performed in either the OR or ICU settings. There are significant cost and time savings associated with performing the procedure in the ICU given that it obviates the need for OR staff and related resources. In the ICU, the optimal staff complement will include an anesthesiologist or intensivist with advanced airway and procedural sedation training to manage the existing translaryngeal tube and reintubate if necessary, and to provide bronchoscopic guidance during the initial portion of the procedure and administer anesthetics and neuromuscular blockade. An ICU or OR nurse familiar with the procedure and principles of sterile technique should also be available to assist throughout.

Informed consent is similar to that for surgical tracheostomy. The patient is positioned supine with neck extension and slight reverse Trendelenburg position. The patient's neck is shaved, and skin is prepped from nipple line to mandible and a sterile field established with towels and drapes, and a time out for safety is called that includes verification of functional flexible bronchoscopy.

The patient is preoxygenated with 100% FiO_2 and landmarks are palpated. The ideal location for percutaneous dilational tracheostomy is between the first and second or second and third tracheal rings; any higher risks injury to the cricothyroid membrane that may increase long-term incidence of stenosis, whereas lower penetration may increase risk of tracheoinnominate arterial fistula. The site is chosen primarily based on palpation of relevant landmarks including the tracheal rings themselves; bronchoscopy may provide an adjunct as well. The skin and subcutaneous tissues are infiltrated with lidocaine with epinephrine. A 1.5 cm transverse or vertical incision is made sharply in the midline of the neck over the intended site of entry, and underlying subcutaneous tissues are bluntly dissected using Kelly forceps (Fig. 11). The bronchoscope is withdrawn to the level at which it transilluminates the skin at the intended site of entry. The cuff on the endotracheal tube is deflated sufficient to allow retraction of the tube to the site. Finally, a 14 gauge introducer needle is used to puncture the trachea in the midline under bronchoscopic guidance with 10 to 15 degrees of angulation inferiorly (Fig. 12). Careful attention is paid to avoid posterior tracheal wall injury during this

FIG. 6 The pretracheal fascia is divided to reveal the tracheal rings.

FIG. 13 The introducer needle is used with bronchoscopic guidance to puncture the trachea in the midline.

step, which can result in pneumomediastinum or tracheoesophageal fistula. Aspiration of air in conjunction with bronchoscopic guidance confirms access to the trachea, and a flexible J-tipped guidewire is threaded through the needle toward the carina (Figs. 13 and 14). The needle is removed, and an initial dilation is performed with a 14Fr introducer dilator followed by single-step dilation using the dilator provided (Figs. 15 and 16). A mark on the dilator indicates the depth of dilation required relative to the skin surface. Finally, the leading dilator surface is lubricated, a new tracheostomy tube is loaded onto the appropriately sized leading dilator, and the tracheostomy tube is

FIG. 11. The J-tipped guidewire is inserted into the trachea under bronchoscopic guidance to ensure distal direction of the wire.

FIG. 12. The cannula is removed, leaving the guidewire in place.

introduced (Figs. 12 and 13). The leading dilator is removed, the tracheostomy cuff is inflated, and the ventilator circuit is transitioned to the new tracheostomy. Ventilation is assured via end tidal CO_2 and breath sounds before removal of the translaryngeal endotracheal tube. The neck plate of the tracheostomy is secured in place using 2-0 nonabsorbable monofilament sutures.

Of note, new tracheostomy tubes that are provided in modern percutaneous kits have a longer tapered tip and low profile cuff to avoid the gap between tube and leading dilator that previously complicated insertion. Angular tracheostomy tubes do not taper or conform to the leading dilator tip well and frequently require significant force to pass through the tracheal wall, potentially contributing to tracheal ring fracture and posterior tracheal wall injury. Therefore, tracheostomy tubes designed for percutaneous insertion should be used during this procedure.

FIG. 13. The 14-gauge dilator is advanced into the trachea.

Other and Emerging Procedural Techniques

Griggs' Forceps, PercuTwist, and Ciaglia Blue Rhino

There other major techniques for percutaneous dilational tracheostomy have been described and remain in use. The Griggs forceps technique, formally described in 1991, relies on forceps that are designed to accommodate the J-tipped guidewire to guide their entry into the trachea. The forceps are then used to dilate the tracheal defect, analogous to the single-step dilator used in the Ciaglia technique, before insertion of the new tracheostomy tube. The PercuTwist technique provides dilation in a single step but is advanced by a cork screw motion into the trachea. A 2008 single-center prospective observational study suggested that the procedure may be more likely to result in posterior tracheal wall injury and longer procedural times compared with the Ciaglia Blue Rhino single-dilator technique; however, RCTs have demonstrated only equivocal differences. Finally the Ciaglia Blue Dolphin system decreases the number of steps to complete the procedure and provides theoretical benefits of purely radial tracheal dilation by combining a dilating balloon on the same cannula that loads the new tracheostomy tube. The tracheostomy introducer is threaded over a J-tipped wire as in other percutaneous tracheostomy procedures, but a balloon on the introducer is delivered into the tracheal defect and then inflated to 11 atm to provide sufficient dilation for entry of the tracheostomy tube, which is preloaded onto the introducer and advanced into intratracheal position after dilating balloon deflation. The procedure potentially improves economy of motion and reduces tracheal trauma during dilation. The technique was shown to be equivalent in outcomes to the Ciaglia Blue Rhino single-step dilation technique in a single-center RCT.

Although the different percutaneous dilational techniques have been compared in small randomized trials, it should be reiterated that differences in outcomes are equivocal, and operator experience is more important than the technique chosen.

Ultrasonography for Percutaneous Dilational Tracheostomy

Point-of-care ultrasonography (US) has become ubiquitous in ICUs over the last decade, with clearly defined roles in many bedside procedures and evaluations. However, the role of US in percutaneous dilational tracheostomy has been slower to evolve. This is likely because of the excellent safety profile of the procedure with bronchoscopy, and conservative patient selection in which inability to clearly palpate landmarks have traditionally been a contraindication to the procedure.

FIG. 16 The single-step dilator is advanced into the trachea to the limit indicated on the dilator.

FIG. 17 The tracheostomy tube is loaded onto the appropriately sized dilator and advanced into position. End-tidal CO_2 is confirmed and fiberoptic bronchoscopy confirms tip position.

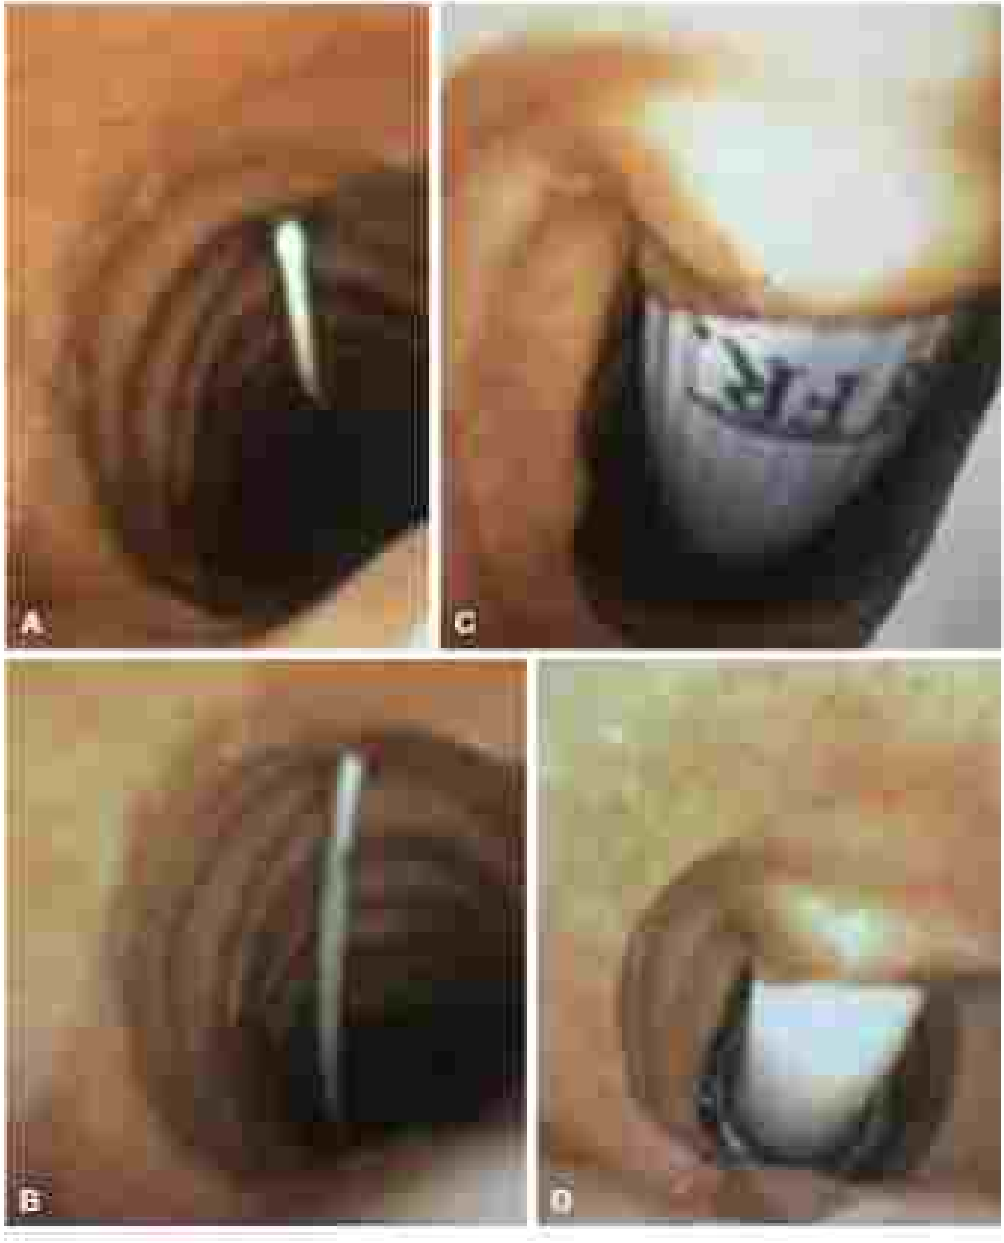

FIG. 18 Bronchoscopic view during tracheostomy. (A) Introducer needle in the midline. (B) ... are visualized in distal direction. (C) Single-step dilator. (D) Tracheostomy tube in appropriate position.

As percutaneous dilational tracheostomy becomes the procedure of choice for most patients, new adjuncts to improve the safety of the procedure among patients with suboptimal surface anatomy may be useful. One major benefit of US during percutaneous dilational tracheostomy is the ability to visualize the relative locations of the hyoid bone, tracheal cartilage, cricoid cartilage, and even the superior tracheal rings in real time. This allows selection of an appropriate skin puncture site and facilitates tracheal puncture under direct guidance. Furthermore, US may guide selection of tracheostomy tube size and identify anomalous vascular or thyroid anatomy associated with bleeding complications prior to injury.

Aided by easy access to high resolution bedside units in ICUs, the role of US in safe tracheostomy continues to evolve. In absence of RCTs demonstrating efficacy and safety of the sole guidance technique, US guidance should be considered an adjunct to bronchoscopy as it undergoes further study.

COMPLICATIONS

Complications can be divided into early and late events (Box 1). Minor early adverse events, including stoma infection and self-limited bleeding, are common. Serious complications and mortality are rare but reported. The frequency with which the procedure is performed means that clinicians should be prepared to deal with a serious complication during their career, and any physician who performs the procedure should be familiar with recognition and management of early and late complications. Pneumothorax and pneumomediastinum are rare (<1%) but important early complications. Subcutaneous emphysema (<2%) during the procedure raises concern for extratracheal cannulation. Late complications include bleeding from granulation tissue, tracheoesophageal and tracheoinnominate arterial fistulae, or accidental decannulation.

Decannulation

Accidental decannulation during or after the placement of a tracheostomy is an important cause of morbidity and mortality. Early decannulation (prior to maturation of the stoma tract, usually 5 to 7 days) should be distinguished from late decannulation, as the former is an indication for emergent translaryngeal endotracheal intubation to reassure the patient's airway. Endotracheal reintubation avoids the potential complication of malpositioning the replaced tracheostomy which can lead to bleeding or creation of a false tract with ventilation of the mediastinum or paratracheal tissues. Replacement of the tracheostomy tube through the stoma should be reserved only for those patients with a mature fistula.

BOX 1 Complications of Tracheostomy

Early Complications

- Minor or major hemorrhage
- Soft tissue ulceration or infection
- Tracheal ring fracture
- Failure to complete the procedure
- Aspiration
- Loss of airway and hypoxemia, hypercarbia
- Pneumothorax, pneumomediastinum
- Subcutaneous emphysema

Late Complications

- Tracheal stenosis
- Granuloma tissue, obstruction, hemorrhage
- Tracheomalacia
- Pneumonia
- Tracheoinnominate arterial fistula
- Tracheoesophageal fistula
- Accidental decannulation or obstruction with hypoxemia, hypercarbia
- Dysphagia
- Dysphonia

Tracheoinnominate Arterial Fistula

Fistulization between the innominate (brachiocephalic) artery and the trachea is an uncommon but feared complication of tracheostomy. Most commonly manifesting after postoperative day 7, the complication has been described as early as 48 hours after surgery. The classic presentation is a small but now perfusional bleed in the weeks after the procedure, which heralds impending massive hemorrhage. In reality, approximately 50% of cases will present with this self-limited sentinel bleed. Mortality is typically owing to hypoxemia and airway occlusion by blood long before hemorrhagic shock, and airway protection is the immediate concern in suspected cases. Tracheoinnominate fistula should be considered the most likely culprit for any perfusional hemorrhage 1 week or more postoperatively from tracheostomy, and immediate management consists of the following:

- Maximize oxygenation
- Consider urgent bronchoscopy in a stable patient to confirm the source of bleeding
- Overinflate tracheostomy cuff (may temporarily occlude source of hemorrhage) and avoid further cuff manipulation
- If unable to control hemorrhage with cuff inflation, emergent translaryngeal intubation and digital compression through stoma site
- Proceed with urgent surgical exploration.

The usual surgical management is isolation and ligation of the innominate artery in an unstable patient. Vascular interposition graft or bypass may be a consideration in a stable patient, but the priority remains avoiding further airway hemorrhage that may compromise oxygenation. Extracorporeal membrane oxygenation has also been described in the interposition of tracheoinnominate arterial fistula, but the mainstay of treatment remains rapid control of the hemorrhage and surgical intervention.

TIMING OF TRACHEOSTOMY

Historically, tracheostomy was performed after approximately 3 weeks of mechanical ventilatory support via translaryngeal endotracheal tube. The 1989 consensus statement from the American College of Chest Physicians reflects this arbitrary threshold for tracheostomy. The 1990s saw increased interest in identification of patients who would benefit from earlier tracheostomy, with the perceived benefits of tracheostomy probably inflated due to prior reliance on high-pressure, low-volume cuffed endotracheal tubes. Subsequent enthusiasm for early tracheostomy among critically ill patients may be attributed in part to a well-designed study involving three hospitals and 120 patients by Rumbak and colleagues in 2004, which demonstrated impressive reductions in mortality and ventilator-associated pneumonia. From 2004 through 2014, multiple attempts were made to address whether early (variably defined as 4 to 7 days of intubation) or delayed (typically >7 days of intubation) tracheostomy would improve a variety of outcomes for patients in the mechanically ventilated ICU population.

Italian 2010 Multicenter Study and 2013 United Kingdom TracMan Trial

The largest two randomized trials studying the timing of tracheostomy are the 2010 Italian multicenter study described by Terragni and colleagues (n = 419), and the 2013 United Kingdom TracMan trial (n = 909). In the Italian study, a mixed medical and surgical population from 12 Italian ICUs were used to comparison of early (≤ 10 days after intubation) versus late (≥ 11 to 15 days of intubation) tracheostomy.

Outcomes were ventilator-associated pneumonia, early and delayed mortality, ventilator- and ICU-free days, procedural adverse events, hospital length of stay, and successful weaning. Although ventilator- and ICU-free days were improved in the early tracheostomy group, none of the other outcomes were significantly improved, including pneumonia, overall hospital length of stay, and mortality. Similarly, the TracMan trial included a varied ICU population in the United Kingdom and compared early tracheostomy (within 4 days of intubation) versus delayed (after 10 days of intubation and mechanical ventilation). Outcomes included early and delayed mortality, antibiotic use, and sedative use per day. The trial reiterated the findings from the Italian study with no significant difference in all-cause mortality at multiple timepoints; additionally, there was no difference in antibiotic use between groups, which may be a reasonable surrogate for pneumonia. Unsurprisingly, there was a significant decrease in the amount of sedation required in the early tracheostomy group. One additional important finding from the TracMan trial was that nearly 25% of patients who were randomized to receive late tracheostomy never required the intervention, primarily due to respiratory recovery (Fig. 1F).

2013 Cochrane Library Systematic Review

A 2013 Cochrane review on the subject of early versus delayed tracheostomy among mechanically ventilated, critically ill patients included patients from eight randomized trials, including those summarized earlier (Box 1). Among the remaining six studies, only one small trial (Rumbak et al, 2012; n = 40) demonstrated any improvement in mortality in the early tracheostomy group. Interestingly however, the group's meta-analysis concluded that there was a very small but statistically significant improvement in late mortality in the early versus late tracheostomy groups (42.1% and 53.2%, respectively; $P = .02$). Earlier mortality measures were generally equivalent, and statistical heterogeneity precluded a meta-analysis of pneumonia. The authors cautioned that data were insufficient to identify any specific subgroup or patient characteristics that would make them better candidates for early tracheostomy.

With a lack of consensus and no clearly demonstrated benefit to early tracheostomy demonstrated across multiple large randomized studies, research efforts have shifted from increasing the number and power of studies to focusing on specific patient populations that may stand to benefit from earlier intervention. Bösel and colleagues' 2013 Stroke-related Early Tracheostomy versus Prolonged Orotracheal Intubation in Neurocritical Care Trial (SETPOINT) represents such an effort and was included in the Cochrane review described earlier. The patient population was restricted to those with severe stroke in the acute ICU. This small but well-controlled pilot study is an important marker in the field in that it demonstrated considerable mortality benefits in the early tracheostomy group. Based on these results, the larger, multiinstitutional SETPOINT-2 is underway to further assess the question in the neurocritical care population.

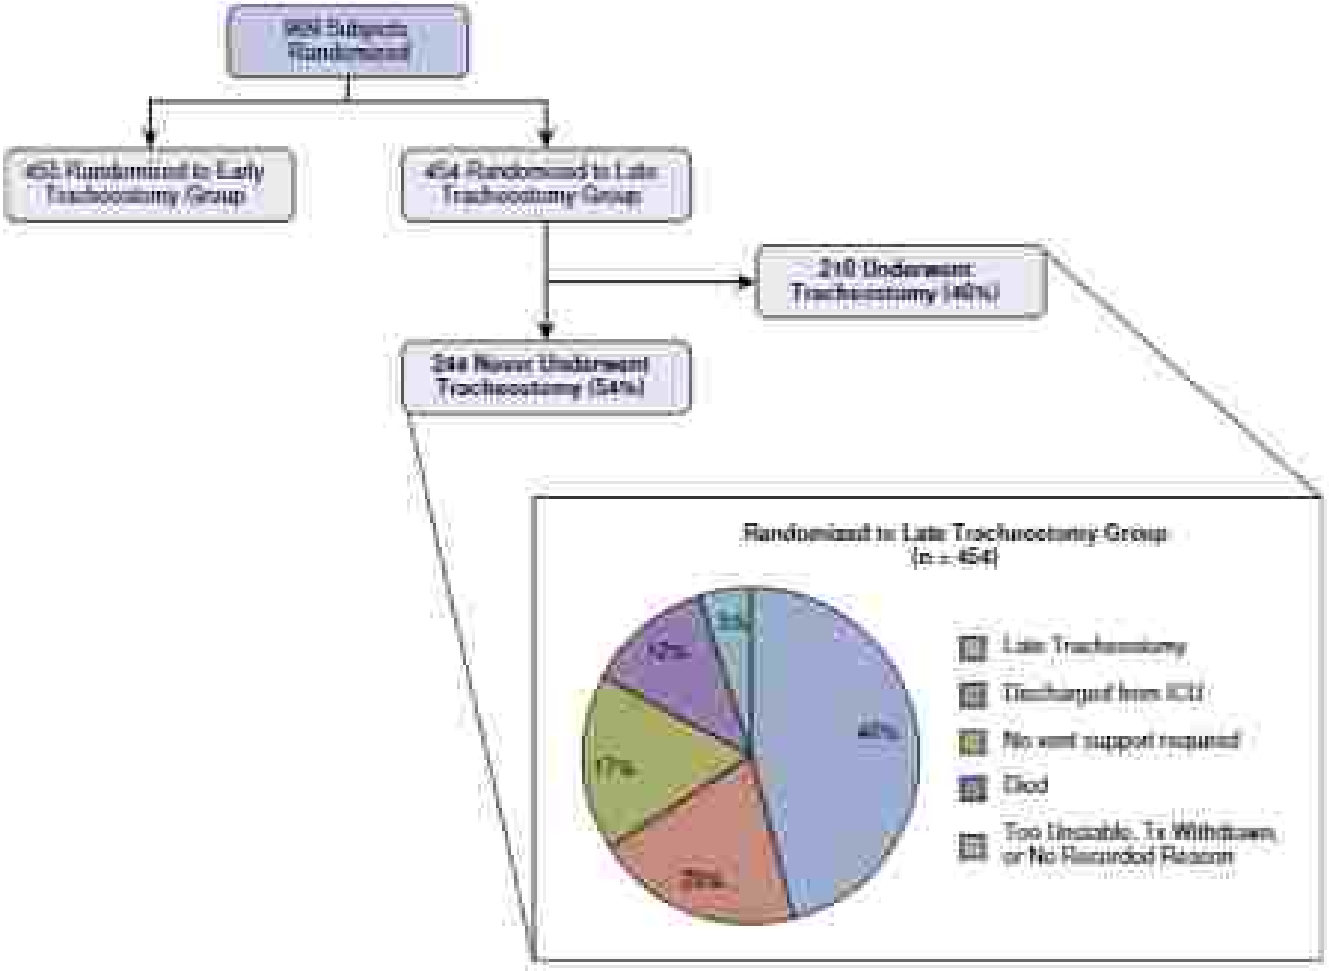

FIG. 1F Summary of late tracheostomy group in 2013 TracMan trial. More than half of the patients randomized to late tracheostomy (>10 days) never underwent the procedure, as it was no longer clinically indicated at that time. ICU, intensive care unit; Tx, treatment. (Data from Young D, Harrison DA, Cuthbertson BH, et al. For the TracMan Collaborators. Effect of early vs late tracheostomy placement on survival in patients receiving mechanical ventilation: the TracMan randomized trial. JAMA. 2013;309(20):2121–2129.)

Griffiths RD, Griffiths RR, Saunders H, et al. Early versus late tracheostomy for critically ill patients. Cochrane Database Syst Rev 2010;1:CD007271.

Synopsis and Recommendations

Given the fairly common nature of adverse events with tracheostomy, the poor ability of clinicians to determine need for prolonged mechanical ventilation potentially leading to unnecessary procedures, and the lack of durable improvements in outcome demonstrated by the largest and best-powered trials, it is prudent to wait 10 to 14 days after intubation to ensure that a patient has ongoing requirements for mechanical ventilation and will benefit from tracheostomy. However, the data are numerous and occasionally conflicting on the subject, once again highlighting the importance of clinical judgment in each patient's case.

OUTCOMES

In-hospital mortality among patients undergoing tracheostomy is approximately 2% overall. Mortality is typically associated with the patient's underlying disease process rather than with the procedure itself. In a nationally representative sample from the United States including over 100,000 tracheostomized adults, the overall perioperative complication rate was approximately 3%, including minor and relatively common complications such as stoma infection and minor hemorrhage. However, the in-hospital mortality was nearly 20%. Patients with cardiac comorbidities were at the highest risk of in-hospital death after tracheostomy, and only 0.6% of patients experienced both a complication of tracheostomy and in-hospital mortality, reflecting mortality dependence on underlying medical problems rather than the procedure itself.

Depending on the indication, tracheostomy can be a palliating or otherwise permanent procedure. However, decannulation (removal of tracheostomy tube with subsequent closure of the stoma) after resolution of precipitating respiratory failure is usually the desired outcome. Among patients with respiratory failure ultimately liberated from mechanical ventilation during ICU stay, the median time to decannulation after tracheostomy is approximately 3 weeks. Unfortunately, only approximately 30% of patients with respiratory failure requiring tracheostomy are decannulated by the time they are discharged from the hospital.

SUMMARY

Tracheostomy is a common procedure performed in the OR or the ICU that allows durable protection of the airway and a means to provide mechanical ventilation. Benefits of tracheostomy over prolonged translaryngeal endotracheal intubation include decreased use of sedatives and paralytics, which facilitates weaning and ICU discharge. However, other perceived benefits (prevention of pneumonia and cuff-related complications) have not been borne out in recent studies. For patients with normal neck anatomy and acceptable habitus, the percutaneous dilational technique is preferred for improved efficiency and a small but significant decrease in risk of minor complications. Surgical tracheostomy has nearly equivalent outcomes but is typically reserved for patients with difficult anatomy owing to its requiring surgical personnel to perform. Serious early and late complications including mortality are rare but reported, and any physician that performs the procedure should be familiar with diagnosis and treatment of its complications. Finally, the timing of tracheostomy for patients requiring mechanical ventilatory support has undergone extensive study without clear evidence of benefit for early tracheostomy. The decision on when and in whom to perform tracheostomy should be individualized to the patient, but generally should not be considered early in ventilator course without surrounding circumstances (i.e., quadriplegia) pending further research in specific patient populations.

Acute Kidney Injury in the Injured and Critically Ill

Maria E. Tecca, MD, and Rasly L. Fanning, MD, FACS

Injury and critical illness can create an environment that put the kidneys and other organs at risk for hypoperfusion. This can be a result of shock itself, or the physical and medical events by which the body and physicians respond to it, such as vasoconstriction and vasopressors. In addition to being susceptible to ischemic physiologic states, the kidneys can also fall victim to injury mediated by toxins including drugs, myoglobin, medications, infectious pathogens, and oxygen free radicals.

When caring for patients in the context of renal injury, we must consider the magnitude by which function deviates from baseline. The classification of kidney injury is variable and lacking in specific, protocol-driven treatment algorithms. To help delineate the disparate elements of renal impairment and construct a framework for treatment, acute kidney injury (AKI) and acute renal failure were defined by the Acute Dialysis Qualitative Initiative (ADQI), Acute Kidney Injury Network (AKIN), and Kidney Disease: Improving Global Outcomes (KDIGO).

EPIDEMIOLOGY

As many as 30% of patients that undergo surgery will develop AKI; of these, approximately 50% to 80% are preventable. It occurs often

Acute Kidney Injury in the Injured and Critically Ill

Maria E. Tecce, MD, and Keely L. Buesing, MD, FACS

Injury and critical illness can create an environment that puts the kidneys and other organs at risk for hypoperfusion. This can be a result of shock itself, or the physical and medical events by which the body and physicians respond to it, such as vasoconstriction and vasopressors. In addition to being susceptible to ischemic physiologic states, the kidneys can also fall victim to injury mediated by toxins including drugs, myoglobin, medications, infectious pathogens, and oxygen free radicals.

When caring for patients in the context of renal injury, we must consider the magnitude by which function deviates from baseline. The classification of kidney injury is variable and lacking in specific, protocol-driven treatment algorithms. To help delineate the disparate elements of renal impairment and construct a framework for treatment, acute kidney injury (AKI) and acute renal failure were defined by the Acute Dialysis Qualitative Initiative (*ADQI*), Acute Kidney Injury Network (AKIN), and Kidney Disease: Improving Global Outcomes (KDIGO).

EPIDEMIOLOGY

As many as 30% of patients that undergo surgery will develop AKI; of these, approximately 50% to 80% are preventable. It occurs often

to patients with multiple comorbidities and is associated with an increase in mortality up to 50%. Even when patients recover from AKI, their risk for eventual chronic kidney disease increases and they have significantly increased length of stay and hospital costs. Furthermore, mortality related to AKI can reach levels of 30% to 60% in developed nations and up to 90% in developing countries. When acute renal failure is considered, estimates ranging from 5% to 25% of intensive care unit (ICU) patients are afflicted, resulting in a mortality that can reach 60%. With the prevalence of AKI in our surgical patients, a thorough understanding of preventable contributing factors and a defined algorithm for diagnosis and treatment is worth consideration.

The US Renal Data System compiles an annual report that emphasizes outcomes of patients with a diagnosis of AKI during hospital admission. According to that 2013 report, up to 8.2% of patients aged ≥65 with a first hospitalization for AKI will die during their stay. Of those who survive, only 48.2% will return home on discharge, with the others being discharged to another institution (30.6%), other (7.5%), or hospice (5.8%). This dismal disposition profile of patients with a diagnosis of AKI during their first hospitalization underscores the importance of preventative measures for avoiding renal dysfunction.

CLASSIFICATION OF AKI

Glomerular filtration rate (GFR) is the gold standard marker for chronic kidney disease, but the current equations for calculating GFR (Cockcroft-Gault, Modification of Diet in Renal Disease Study, and Chronic Kidney Disease Epidemiology Collaboration) rely on serum creatinine (SCr) to be in steady state, which is often not the case in AKI. Moreover, SCr may be erroneously elevated in patients with a high percentage of lean body mass (i.e., athletes). Other parameters, such as oliguria, also have fault as measures specifically, oliguria can be a representation of normal renal tubule response to exogenous, thereby hyperconcentrating urine. Conversely, malfunctioning renal tubules can also yield adequate urine output (UO), by way of inability to properly concentrate urine. The latter scenario is of particular concern when evaluating AKI in ICU and septic patients. When taken singularly or in broad context, these parameters are demonstratively fallible. Equations for kinetic GFR calculation when SCr is fluctuating have been proposed but not validated. The lag time of SCr changes behind current kidney function makes it an imperfect surrogate marker for AKI stage. Other factors can also contribute to changes in SCr, such as reduction in creatinine production during acute illness and volume overload leading to creatinine dilution.

In 2012, the KDIGO workgroup aimed to decrease the heterogeneity of classification systems found in published work by combining elements from prior definitions of AKI (Table 1 lists the elements of the KDIGO classification system). While considering this guideline for classification of AKI (which is currently the most widely accepted iteration of a standardized definition), it should be steadfastly kept in mind that the intention of the KDIGO authors was not to "…replace or to exclude clinical judgment…" but rather "…provide a framework for the clinical diagnosis of AKI…." The diagnosis of AKI remains a complex issue, requiring astute clinical judgment.

Acute Dialysis Quality Initiative and RIFLE

The ADQI developed a method for assessing AKI via analysis of severity classes (risk, injury, and failure), and outcome states (loss and end-stage disease), a model otherwise known as RIFLE. Under this context the worst parameter: SCr or UO, is used to define the severity class, whereas time is used to distinguish the outcome state. The minimum ICU admission RIFLE status has been shown to strongly correlate with mortality, with AKI yielding an attributable mortality of 8.8%, 11.4%, and 26.3% for classes R, I, and F respectively. Conversely, those without AKI were reported to have a mortality of 5.2%.

AKIN and KDIGO

AKIN further modified RIFLE with respect to both diagnostic criteria and injury state. The AKIN AKI diagnostic criteria evaluate changes in SCr or UO over a 48-hour timeframe. An increase in SCr ≥0.3 mg/dL, increase in SCr ≥50% (baseline SCr ≥ 1.5 or more), or decrease UO (<0.5 mL/kg per hour for ≥6 hours) mark the first stage of AKI according to AKIN criteria. By using absolute and percent increase over baseline values for any given patient, AKIN aims to account for interpatient variation such as gender, amount of lean body mass, and age. To assess AKI according to the AKIN parameters using the UO guided approach, all elements that could impair UO must be excluded. Patients must only fulfill one criterion to be assigned a stage; any patient on renal replacement therapy is considered to be in stage 3.

Last, the KDIGO guidelines define patients as being in AKI if they exhibit an increase in SCr ≥0.3 mg/dL in 48 hours, increase in SCr ≥1.5 times baseline within 1 week, or UO less than 0.5 mL/kg per hour for 6 hours. Notably, KDIGO also considers a GFR <35 mL/min per 1.73 m^2 body surface area for patients under the age of 18 to be stage 3 as well.

Regardless of classification system used to define the extent of AKI, the main tenets of treatment include identifying the underlying cause and working toward resolution, mitigating risk factors, and investing in follow-up testing to ensure resolution of AKI. AKIN and KDIGO criteria are summarized in Table 2 for reference.

Biomarkers

Investigations into biomarkers that reflect tubular injury and renal stress are ongoing. Tubular injury biomarkers include neutrophil gelatinase–associated lipocalin, interleukin 18, liver-type fatty acid binding protein, and kidney injury molecule 1. Renal stress

TABLE 1 RIFLE Criteria for AKI

RIFLE Severity Class	SCr/GFR Criteria	UO Criteria	ICU AKI-Attributable Mortality
Risk	SCr × 1.5 or GFR ↓ >25%	UO <0.5 mL/kg/hr × 6 hr	8.8%
Injury	SCr × 2 or GFR ↓ >50%	UO <0.5 mL/kg/hr × 12 hr	11.4%
Failure	SCr × 3 or GFR ↓ >75% or SCr >4 mg/dL (acute ↑ ≥0.5 mg/dL)	UO <0.3 mL/kg/hr × 24 hours or anuria × 12 hours	26.3%

	AKIN Criteria		KDIGO Criteria	
Stage	SCr Criteria	UO Criteria	SCr Criteria	UO Criteria
1	>0.3 mg/dL or 150%–200% of baseline	<0.5 mL/kg/hr; >6 hours	1.5–1.9 × baseline or ↑SCr ≥0.3 mg/dL	<0.5 mL/kg/hr; 6–12 hr
2	>200%–300% of baseline	<0.5 mL/kg/hr; >12 hours	2–2.9 × baseline	<0.5 mL/kg/hr; ≥12 hr
3	>300% of baseline or SCr >4 mg/dL + acute ↑ ≥0.5 mg/dL	<0.3 mL/kg/hr; ≥24 hr or anuria ≥12 hr	3 × baseline or SCr >4 mg/dL or renal replacement therapy	<0.3 mL/kg/hr; ≥24 hr or anuria ≥12 hr

AKI, acute kidney injury; AKIN, Acute Kidney Injury Network; SCr, serum creatinine; UO, urine output.

biomarkers include tissue injury metalloproteinase 2 and insulin-like growth factor binding protein 7, which are currently marketed as the Nephrocheck Test (Astute Medical) and identify patients at high risk of developing KDIGO stage 2 to 3 AKI. Neutrophil gelatinase-associated lipocalin, cystatin C, and kidney injury molecule 1 can be useful in identifying patients who may develop AKI when the disease process is still in the subclinical phase; that is, before a detectable change in UO or SCr. It is hoped that these biomarkers will eventually aid the classification of AKI into precise phenotypes that can be targeted with specific therapeutics.

PREVENTION OF AKI

The mainstay of AKI prevention is centered on fluid status maintenance. Patients who are at risk for developing AKI should be adequately fluid resuscitated in an effort to treat any component of dehydration, nephrotoxicity, or low flow state that could contribute to renal dysfunction. Plasma volume should be expanded in patients who need contrast imaging studies as their disease physiology permits. If unable to give the patient fluids, there may be some utility in administering N-acetyl cysteine; however, there is not an additive effect observed from N-acetyl cysteine when the patient can receive intravenous fluids. Other medications (such as dopamine, fenoldopam, loop diuretics, and calcium channel blockers) have not been shown to be consistently protective of renal function in ICU patients. Conversely, loop diuretics may actually hinder AKI recovery, as evidenced by a study in which significant increase in mortality and persistent renal dysfunction were found in patients who received loop diuretics (odds ratio, 1.77; 95% confidence interval, 1.14–2.76).

The AIKIII recommends avoiding hyperchloremia that can lead to metabolic acidosis in patients at risk for AKI. A study of ICU patients who were assigned to either chloride liberal or chloride restrictive groups revealed that the chloride restrictive group exhibited a decreased SCr change ($P = .02$), decreased requirement for renal replacement therapy (RRT) ($P = .06$), and decreased number of patients classified as RIFLE I and F ($P < .06$)[1]. Chloride levels should be monitored and controlled as a prophylactic measure when the potential for AKI is considered.

Much debate remains regarding the types of fluids and medications that are helpful or harmful when resuscitating and treating patients at risk for AKI while receiving ICU care. The European Society of Intensive Care Medicine released a document of conglomerate expert recommendations for renal preservation, which are summarized in Table 3. Notably, the recommendations at the 1A level exist promoting the use of specific fluids or medications.

AKI WITH SPECIAL CONSIDERATIONS

The ICU setting can present unique situations that can lead to or further complicate the development of AKI. Comorbid conditions can increase the likelihood of developing a renal complication, or underlying renal dysfunction can be exacerbated in these circumstances.

Abdominal Compartment Syndrome

Abdominal compartment syndrome (ACS) is clinically defined by an intraabdominal pressure exceeding 20 mm Hg accompanied by clinically relevant organ dysfunction such as decreased UO, reduced cardiac output as a result of impaired venous return to the right atrium leading to decreased preload, and so on. One of the clinical manifestations of elevated intraabdominal pressure is oliguria, when the kidneys succumb to the reduced vascular flow to the nephron. The amelioration of ACS is dependent upon its cause. Paracentesis may be adequate to relieve ACS caused by massive ascites, whereas more invasive surgical intervention may be necessary to treat ACS related to hemoperitoneum or abscess with accompanying intestinal ileus. Although these procedures can dispel acute decompensation and improve the overall condition of the patient, kidney dysfunction is not likely to be alleviated regardless of subsequent improvement in renal venous hypertension or arterial hypotension. This is sometimes because of persistent renal hypertension, which can be caused by edema of the kidney or a subcapsular hematoma requiring incision and drainage. When considering the care of a patient with ACS, fluid management should be strictly monitored. A "crystal fluid cap" that limited to 0 L total before ICU admission has been shown to decrease pre-ICU fluid volume by 0.8 L, intraabdominal hypertension, necessity of open abdominal intervention, and ICU length of stay. Aggressive fluid resuscitation can be harmful in the setting of ACS.

Rhabdomyolysis

Rhabdomyolysis is characterized by the systemic release of intracellular components, including heme pigment from myoglobin, after muscle necrosis. Other features include high creatine kinase (CK) levels, myoglobinuria, and myalgias. This process has nephrotoxic potential because tubules can become damaged or obstructed, and blood supply to the outer medulla can be compromised via vasoconstriction. Although a healthier patient may be able to self-regulate these disturbances, the multifactorial disease processes present in critically ill or decompensated ICU patients can be compounded, thereby precipitating AKI. Identifying patients with rhabdomyolysis who are at risk for the development of AKI is critical to treating the disease state; those with CK >15,000 to 20,000 U/L have higher risk, as do those who are hyperuricemic or acidotic.

In an effort to identify the risk of requiring RRT or death secondary to AKI in patients with rhabdomyolysis, a risk prediction score was developed. Patients scoring less than 5 had a low risk (<2.3%–3%) for death or severe complications from AKI, whereas those scoring more than 10 were found to have a high risk (>39%–41%) for complications up to and including death. The cutoff value of 6 had a negative predictive value of 87%–88%. Although promising, this study was limited by the fact that it was performed in two urban hospitals, and requires validation in more diverse settings. Results are summarized in Table 4.

Prompt recognition of hypovolemia and electrolyte abnormalities is key in treating rhabdomyolysis and preventing AKI. Appropriate fluid resuscitation should be initiated, the underlying cause should be

TABLE 3 ESICM Recommendations and Suggestions for AKI Prevention and Treatment

PVE	Recommendations	Suggestions
Fluid resuscitation for volume depletion	1C	
Prophylactic PVE with isotonic fluids in those at risk of RCN	1B	
Avoid 10% HES ≥500/0.5	1B	
Avoid gelatins and dextrans in sepsis		2C
Prophylactic PVE with crystalloids to prevent AKI by certain medications		2C
DIURETICS		
Avoid loop diuretics to prevent or ameliorate AKI	1B	
Vasopressors and Inotropes		
MAP should be maintained >60–≤65 mm Hg	1C	
Norepinephrine or dopamine (plus PVE) are first-line agents for vasodilatory shock	1C	
Avoid low-dose dopamine to protect against AKI	1A	
VASODILATORS		
Vasodilators may be useful for renal protection after resuscitation and with hemodynamic monitoring		2C
Fenoldopam may be useful in cardiovascular surgery patients at risk of AKI		2B
Avoid fenoldopam for RCN prophylaxis		1A
Theophylline to mitigate RCN risk in those who cannot undergo PVE		2C
Avoid natriuretic peptides as the protective agents against AKI in general intensive care unit patients but may be considered in cardiovascular surgery patients		2B
METABOLIC INTERVENTIONS		
Avoid routine selenium supplementation as an AKI preventive	2C	
Enteral nutrition is preferred for patients at risk of AKI		2C
Avoid N-acetyl cysteine as prophylaxis against RCN or other forms of AKI		2B

identified and mitigated as best able, and sequelae such as metabolic acidosis should be anticipated and promptly corrected. Although appropriately aggressive fluid resuscitation is a key component of therapy for rhabdomyolysis, care should be taken to avoid the pitfalls of ACS development.

Septic AKI

A patient with septic shock may face a myriad of complications, the most likely of which is AKI. Fluid resuscitation in the face of sepsis may induce hypernatremia in the renal vasculature; this process is unique when compared to other modalities of AKI that are influenced heavily by the patient's hemodynamic state. In contrast, sepsis-induced AKI may be mediated by toxins, inflammation, or immune responses. Renal blood flow should be carefully monitored. A multicenter randomized controlled trial found no significant difference in overall 90-day mortality between RIFLE failure class patients with early septic shock who began RRT within 12 hours of failure class AKI identification vs those who began 48 hours after identification (58% vs 54%, $P = .38$).

Impact of AKI on Outcomes

AKI has a profound impact on a patient's healing process and can lengthen ICU stay by up to 1.5 weeks. Although renal support therapies (RST) continue to improve, patients whose renal dysfunction necessitates RRT can have mortality rates as high as 60% when multisystem organ dysfunction is cautionary. Approximately 12% to 15% of patients who undergo RRT for AKI during their admission will remain on chronic RRT; this figure increases to 35% when acute on chronic kidney injury is considered.

MANAGEMENT AND RECOVERY OF AKI

Poorly controlled hypertension and diabetes mellitus are the most common etiologies of slowly developing renal failure outside of the hospital. Inpatient AKI is often precipitated by acute episodes of hypoperfusion or drug toxicity, which often occur now on a background of mild chronic renal dysfunction from the prehospital period in many of our patients.

Up to 50% of AKI may be prevented by early recognition and mitigation of risk factors; however, the basics of care for patients at risk are often neglected. Fluid balance assessment, fluid therapy to maintain renal perfusion, and regular laboratory monitoring comprise the foundation of care for patients at risk for AKI. Underlying risk factors include advanced age (defined for this purpose as >55 years), preexisting chronic renal dysfunction, prior episodes of acute kidney injury, existing comorbidities such as diabetes mellitus, congestive heart failure and sepsis, among others. Nephrotoxic medications such as aminoglycosides, nonsteroidal antiinflammatory drugs,

TABLE 4 Risk Prediction for Rhabdomyolysis-Associated Acute Kidney Injury or Mortality

Parameter	Score
Age >60–<70 years	1.5
Age >70–<80 years	2.5
Age >80 years	3
Female	1
Initial SCr 1.4–2.2 mg/dl	1.5
Initial SCr >2.2 mg/dl	3
Initial calcium <7.5 mg/dl	2
Initial CK >40,000 U/L	2
Underlying cause other than seizure, syncope, exercise, statins, or opioids	3
Initial serum phosphate 4.0–5.4 mg/dl	1.5
Initial serum phosphate >5.4 mg/dl	2
Initial serum phosphate <1.9 mg/dl	2

and iodinated contrast should be avoided in at-risk patients. Because there are no specific therapies for ischemic or nephrotoxic AKI, attention to intravascular volume in high-risk patients is perhaps one of the most easily accessible interventions. Judicious restoration of intravascular volume has been shown to reduce the incidence of such cases AKI dramatically.

Several trials have attempted to uncover the effect of modalities of dialysis. The Acute Renal Failure Trial Network revealed a 45.2% day 28 dialysis dependence after 5000 intermittent dialysis events. Conversely, the randomized evaluation of normal vs augmented level renal replacement therapy trial found a lower level at day 28 dialysis dependence (13.9%) after 344 instances of intermittent dialysis. Additionally, the Sepsis Occurrence in Acutely Ill Patients Trial showed that lower fluid status per day was associated with survival.

RENAL SUPPORT THERAPY

Two broad categories of RST exist: intermittent and continuous. The term RRT has been used to describe these modalities but may obscure the context of the therapies. Rather than replacing all functionality of the kidney, these treatments make alterations to water and solute; any vascular tonic or parenchymal dysfunction is not corrected. With this understanding, it may be more suitable to consider the therapies as RST rather than RRT.

Solute clearance during RRT is achieved through diffusion, convection, or a combination of both. Small molecule removal (size <1 kDa) is best achieved through diffusion, which is based on a concentration gradient across the membrane. Convection, which is based on

TABLE 5 Modalities of RRT

Comparison of Intermittent and CRRT

Parameter	IHD	CCRT
Time per day	3 to 4 hours	24 hours
Flow rate	High	Low
Specialty nurse requirement	Yes	No
Cost	Lower	Higher
GFR	Variable	Constant
Real-time volume management	While running	Continuously
Recirculation	Higher	Lower
Use with pressors	No	Yes
Membrane clotting	Uncommon	Occasional
Intraoperative use	No	Yes
Reduced renal blood flow	Yes	No
Nutritional support volume management	More difficult	Easier

Comparison of Different RRT Modalities

Intermittent	Mechanism	Use	Continuous
Hemodialysis	Diffusion	Small particle clearance (size <1 kDa)	Continuous venovenous hemofiltration dialysis
Hemofiltration	Convection	Water and medium particle clearance (size <50 kDa)	Continuous venovenous hemofiltration
Hemodiafiltration	Both	Both	Continuous venovenous hemodiafiltration

CCRT, Continuous renal replacement therapy; IHD, intermittent hemodialysis; RRT, renal replacement therapy.

ultrafiltration, is ideal for water and molecule removal with size up to 50 kDa. The high flow process of ultrafiltration is not only useful in the setting of fluid overload, but also for drug overdose or electrolyte disturbances.

Hemodialysis uses diffusive clearance on an intermittent schedule, typically for 4 to 6 hours per session, with three to four sessions per week. Blood and solutes flow in opposite directions, creating a concentration gradient that facilitates diffusion across the semipermeable dialysis membrane. Hemofiltration is a related concept that uses hydrostatic pressure gradients to create solvent drag via convection, which in turn promotes convective clearance. During hemofiltration, no dialysis solution is used; instead, replacement fluid is used to replete the solutes that are cleared. Electrolytes and urea are filtered in the same concentration as plasma, which also limits solution to preserve the concentration gradient. Hemodiafiltration, as the name implies, uses both diffusive and convective clearance. During hemodialysis, solute clearance is increased by increasing either the blood or dialysate flow rate. In hemofiltration, increasing the ultrafiltration (or effluent) flow rate will increase solute clearance.

A middle ground exists between intermittent and continuous RRT techniques, termed prolonged intermittent RRT, of which slow low efficiency dialysis is a subtype. As the name would suggest, this type of dialysis uses a slower rate (and in turn, longer treatment time) that typically occurs over a span of 8 to 15 hours (every other day or daily). This is a gentler approach to fluid and electrolyte shifts that is tolerated better, with less side effects, by those who are more critically ill and susceptible to large swings in their hemodynamics.

The continuous RRT (CRRT) modalities are performed 24 hours per day. The continuous modalities are also better tolerated in hemodynamically unstable patients. Methods for CRRT include both venous and arterial cannulation; however, continuous arterio-venous hemofiltration is not commonly used in current practice because of the bleeding complications with arterial cannulation. The veno-venous approach accounts for the bulk of continuous RRT modalities, including continuous veno-venous hemofiltration dialysis, continuous veno-venous hemofiltration, and continuous veno-venous hemodiafiltration. These CRRT modalities apply the same concepts as described for their respective intermittent hemodialysis (IHD) counterparts in a treatment setting that can be run 24 hours per day at the bedside. This style of treatment allows for those who are hemodynamically (including those requiring pressor support) to tolerate RRT without experiencing large swings in fluid dynamics that could otherwise compromise their care. The selection of modality is influenced by the target molecule identified for clearance, similar to IHD. Notably, continuous veno-venous hemofiltration may be preferable for clearance of immunomodulators in the setting of inflammation. Additionally, a constant CFR is achieved with CRRT, allowing for specific medication dosing, as well as nutritional adjustments.

Indications

The indications for RRT for patients with AKI include severe metabolic acidosis (or other acid-base imbalances refractory to medical therapy), hyperkalemia refractory to medical therapy, drug intoxication (lithium, ethylene glycol, methanol, salicylates, theophylline, phenobarbital), volume overload, and uremia and its associated complications (pericarditis, encephalopathy, bleeding). Debate continues regarding the precise timing of initiation of RRT. Evidence shows no significant difference in overall 90 day mortality in early vs late initiation in the setting of sepsis. Other studies have shown greater impact when starting treatment at lower blood urea nitrogen and with earlier initiation in specific patient populations, including those who have undergone cardiac procedures, trauma patients, and mixed surgical/medical patients. Moreover, no significant benefit to CRRT over IHD when adjusted for illness severity (considering the limitation of CRRT as the only RRT option for pressor-dependent patients), and IHD does provide better eventual recovery of kidney function. Further analysis is necessary for develop algorithms for initiation of RRT in the critically ill, and attention should be given to ability to use IHD vs CRRT.

CONCLUSIONS

The care of a critically ill patient should go beyond treating the acute disease process at hand and encompass care that consider prevention of possible further decompensation. Kidney protective measures should be initiated, and the patient's renal status should be evaluated with RIFLE, AKIN, or KDIGO guidelines. The patient should also be monitored for the development of disease states that could hasten clinical decline, such as sepsis, rhabdomyolysis, and ACS. RRT is a useful adjunct to the care of a critically ill patient with AKI. Goals should be defined to guide the decision making process regarding which modality of RRT should be used, and consideration should be given to the possibility of maintaining the patient on RRT, so long as clinical status requiring more resource intensive CRRT are not factors (hemodynamic instability, pressor support, or limitations of fluid shifts).

Fluids and Electrolytes

Umar Khan, MBBS, MD

Claude Bernard is quoted as saying, "The living organism does not really exist in the inflow exterior (the atmosphere if it breathes, salt or fresh water if that is its element) but in the liquid inflow interieur formed by circulating organic liquid, which surrounds and bathes all tissue elements." This concept of a condensed ecology within ourselves at the cellular level is crucial to understanding the changes pathology imparts on the critically ill. This understanding allows us to picture the disorders of water balance and salt balance that plague many surgical patients, both acutely and chronically.

TOTAL BODY WATER AND FLUID COMPARTMENTS

The "water" component of the body makes up approximately 60% of an individual's lean body weight. The body divides its water content into two major compartments (Fig. 1): the extracellular fluid compartment (ECF) and intracellular fluid compartment (ICF). These compartments are divided by a highly selective lipid bilayer, known as the cell membrane, which allows water to pass freely but not electrolytes. Specifically, the extracellular compartment maintains a relatively higher concentration of sodium, chloride, and bicarbonate, whereas the intracellular compartment stores higher concentrations of potassium and phosphate. Further, as the lean proportion of the body decreases (as in obesity), the total body water percentage also decreases.

The fluid in the various compartments and the electrolytes that reside within them are all inextricably linked and interdependent. This is defined by the concept of osmolarity (mOsm/L). Solutes dissolved in water (fluid) do not freely traverse a semipermeable membrane; they are known as osmoles. Hence, osmolarity is a measure of the concentration of osmoles in a solution. Modern laboratories are able to measure osmoles directly per weight of solution; this is known as osmolality (mOsm/kg). As can be deduced from the equation, sodium is by far the most important osmole in plasma with glucose and urea exerting their effects mainly during disease states such as diabetes and renal failure respectively:

$$P_{osm}(mOsm/kg) = 2 \times [Na^+] + [glucose]/18 + BUN/2.8$$

in which BUN indicates blood urea nitrogen. The normal osmolality of plasma ranges from 275 to 290 mOsm/kg.

Finally, plasma tonicity (also known as effective osmolality) is the parameter that determines the transcellular distribution of water. Water moves from an area of lower tonicity to an area of higher tonicity (i.e., from an area of higher water content to an area of lower content). Tonicity only takes into account the distribution of solutes that do not freely permeate the cell membrane; this lack of free distribution is what causes water to shift across cell membranes. Tonicity is differentiated from osmolality in that certain solutes are ineffective osmoles and are distributed equally across cellular membranes (such as urea). Effective osmoles, on the other hand, do not easily cross a membrane and therefore exert an osmotic pressure favoring the retention of water.

This concept is exemplified by the following physiologic scenario: Renal failure results in the retention of abnormally large concentrations of urea. This can result in an increase in osmolality (see the formula presented previously), but the tonicity is unchanged because urea is an ineffective osmole and redistributes freely across cell membranes (i.e., there are equal concentrations in both the ICF and ECF compartments). If hemodialysis is instituted, urea is rapidly removed from the ECF. This removal may be faster than urea can equilibrate across the blood brain barrier. Hence, in this scenario, urea temporarily acts as an effective osmole and imparts both increased osmolality and increased tonicity to the cerebral cells. This can result in water influx and cerebral edema, which can lead to dialysis disequilibrium syndrome.

Fluid Compartments and Regulation of Volume

Sodium homeostasis, through the regulation of urinary sodium excretion, is the primary determinant of the ECF volume. This is accomplished through several mechanisms.

In hypovolemia, the renin angiotensin aldosterone and sympathetic nervous systems (which promote renin secretion) are activated resulting in sodium retention. Conversely, atrial distention from hypervolemia results in the release of natriuretic peptides promoting sodium excretion. Severe hypovolemia that is significant enough to result in hypotension can trigger the release of antidiuretic hormone (ADH) as well. In this scenario ADH activates both V2 receptors, which increase water retention at the level of the distal tubules and collecting ducts, and V1 receptors, which result in peripheral vasoconstriction (hence the synonym vasopressin). The primary role of ADH, however, is in the regulation of plasma osmolality via osmoreceptors (rather than volume sensitive receptors that activate in severe hypovolemia). The volume of the extracellular fluid compartment is thereby regulated.

In a slightly less direct way, the extracellular sodium concentration also regulates the intracellular fluid volume. Modulation of extracellular sodium results in the alteration of plasma tonicity as described earlier, which results in the movement of water into or out of the ICF.

This interrelationship is demonstrated in the management of the acutely brain injured patient, a scenario commonly seen in many intensive care units. The administration of hypotonic intravenous fluids results in hyponatremia, with decreased plasma osmolality and tonicity (as sodium is an effective osmole). Because water moves from an area of low tonicity to an area of high tonicity, water would enter the brain causing cerebral edema and result in worsening of the traumatic insult. The administration of hypotonic fluid in the brain injured patient is, therefore, contraindicated. Conversely, the administration of hypertonic fluid (such as 3% sodium chloride) results in hypernatremia with increased plasma osmolality and tonicity. This would result in flow of water out of the brain and decrease cerebral edema; therefore, the therapeutic increase in plasma sodium levels through the administration of hypertonic saline is a common therapy for neurologic injury.

The reverse process occurs in dehydration. Instead of altered regulation of solute, dehydration results from excessive loss of water resulting in a significant total body water deficit. This will often result in a hypernatremia.

Regulation of Osmolality

As mentioned previously, the primary hormonal mechanism of regulating plasma osmolality is antidiuretic hormone. It is secreted by the posterior pituitary gland in response to very small changes in plasma osmolality as detected by the body's osmoreceptors. Hence, suppression of ADH is the primary mechanism of protection against water retention in the setting of low plasma osmolality, whereas the stimulation of thirst is the primary protective mechanism against excessive water loss (by increasing intake) in the setting of elevated plasma osmolality. ADH may also be secreted in response to large levels of volume depletion via volume sensitive receptors.

The preceding discussion engenders an understanding of normal physiology and homeostasis. The surgical intensivist will, however, care for patients suffering derangements of any number of these of regulatory mechanisms.

Syndrome of Inappropriate ADH

Syndrome of inappropriate ADH (SIADH) is a condition in which the secretion of ADH is autonomously elevated and unrelated to plasma

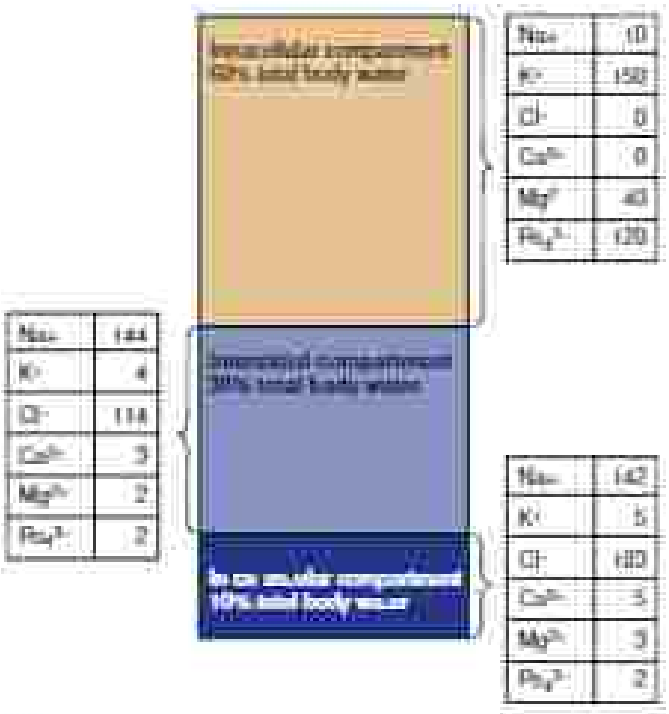

FIG. 1 Distribution and composition (mEq/L) of total body water. Ca^{2+}, calcium; Cl^-, chloride; K^+, potassium; Mg^{2+}, magnesium; Na^+, sodium; PO_4^{3-}, phosphate.

osmolality. This results in an abnormally high amount of free water retention and subsequent hyponatremia. The syndrome is frequently seen in perioperative patients and is thought to be related to pain receptor activation. It can, however, occur in a variety of other conditions including various neurologic disorders (including stroke, trauma, and hemorrhage), transsphenoidal pituitary surgery, malignancies (particularly small cell cancer of the lung), and drugs (such as carbamazepine, selective serotonin reuptake inhibitors, haloperidol, opiates, nonsteroidal antiinflammatory drugs [NSAIDs], ephedrine, amitriptyline, and cyclophosphamide). The diagnosis should be entertained in patients with hyponatremia and an appropriate antecedent history. Laboratory evaluation (Fig. 2) would demonstrate low plasma osmolality (<270 mOsm/kg) with a high urine osmolality (>100 mOsm/kg) and high urine sodium concentration (>40 mEq/L). These findings in a clinically euvolemic patient with no recent diuretic use, and no evidence of thyroid, adrenal, or pituitary insufficiency can lead to the diagnosis.

The treatment of SIADH is fluid restriction (<1 L/d) and in usually all that is needed to mediate a gradual increase in plasma sodium levels. However, the hyponatremia is severe and/or symptomatic, hypertonic saline may be required. This is particularly pertinent in patients with subarachnoid hemorrhage who develop SIADH, fluid restriction may precipitate vasospasm and ischemic insults. In this scenario, therefore, low volume 3% hypertonic saline may need to be administered to gradually raise the sodium level without predisposing to hypervolemia. Additional therapies include the use of oral salt tablets (9 g/d) and loop diuretics (to increase free water excretion).

The temptation to use isotonic saline should be avoided in all cases of SIADH because urine osmolality is usually far higher than the concentration of sodium in isotonic saline. Because sodium handling is intact, all administered sodium will be excreted; however, all the water will not be excreted since the urine is highly concentrated in the setting of high plasma ADH levels. Hence, water will be retained preferentially to sodium and will worsen the hyponatremia.

Finally, the diagnosis of SIADH should not be confused with cerebral salt wasting (CSW) syndrome. This is a similar, but much rarer disorder with similar laboratory findings but which is characterized by clinical evidence of hypovolemia.

Diabetes Insipidus

On the other end of the spectrum of osmolar dysregulation syndromes is diabetes insipidus (DI). In this disease state there is either a deficiency in the body's ability to secrete ADH (central DI) or in the ability of the distal tubules and collecting ducts to respond to the circulating ADH (nephrogenic DI). Because of the absence or inefficiency of ADH, the kidneys excrete high volumes of dilute urine; hence, DI is diagnosed (Fig. 2) in the presence of a high normal serum sodium concentration (>142 mEq/L resulting from free water loss) associated with polyuria (up to 10 L/day of dilute urine [osmolality: <200 mOsm/kg]) and an elevated plasma osmolality (>296 mOsm/kg).

Central DI can be seen after pituitary surgery or trauma, whereas the most common cause of nephrogenic DI is lithium toxicity. DDAVP (desmopressin) can help differentiate the two diseases; administration results in improvement of urine osmolality in the former, but not in the latter. The treatment of DI includes a low salt, low protein diet, diuretics, and NSAIDs supplemented by DDAVP in central DI.

SPECIFIC ELECTROLYTE DISORDERS

Sodium

Plasma sodium levels are directly affected by fluid balance. Hyponatremia results from excess water intake that is not excreted, whereas hypernatremia results from an excessive loss of free water.

Hyponatremia is defined as a sodium level less than 135 mEq/L (mild: 130–134 mEq/L; moderate: 120–129 mEq/L; severe: <120 mEq/L). True hyponatremia that is secondary to excess plasma free water retention will result in decreased plasma osmolality, due to the most common kind of hyponatremia in surgical patients and to consider hypotonic hyponatremia. There are certain conditions, however, that can result in hyponatremia without a decrease in plasma osmolality; therefore, a serum osmolality is generally the first step in the workup of hyponatremia. If the plasma is isotonic, the "hyponatremia" occurs in the context of abnormally elevated lipid or plasma protein levels. This is known as a pseudohyponatremia because the decreased sodium level is an artifact of older laboratory measurement techniques that uses the total plasma volume rather than the aqueous portion when measuring the sodium levels. If the plasma is hypertonic, this indicates the presence of a significant number of minor osmolar constituting to hyperosmolality in lieu of sodium; this can occur with, for example, severe hyperglycemia or in the presence of high levels of mannitol. These osmolar cause free water to move from the ICF to the ECF and result in a decreased plasma sodium level. In hyperglycemia, this level of sodium can be predicted for every 100 mg/dL increase in glucose levels, the plasma sodium will decrease by 2.4 mEq/L on average. This association is nonlinear and, in fact, a correction factor of 1.6 may be needed for glucose levels above 400 mg/dL. Similarly, the use of surgical irrigants such as during a transurethral resection of the prostate or bladder or hysteroscopy can lead to hyponatremia through the absorption of hypotonic water and the expansion of the ECF. In all these scenarios, treating the underlying source of the normal plasma tonicity will address the hyponatremia.

Once a true hypotonic hyponatremia is diagnosed, the volume status needs to be assessed. Patients who are overtly hypervolemic likely have an underlying disorder that results in total body water retention, but with diminished effective intravascular circulation. This can result from disease processes such as cirrhosis, congestive heart failure, nephrotic syndrome, and hypoalbuminemia. The diminished intravascular circulating volume results in the nonosmotic stimulation of ADH release leading to free water retention despite the underlying hypervolemic status. The hyponatremia is generally asymptomatic and chronic in nature precluding the need for rapid reversal in situations of mild or moderate hyponatremia. In general, the mainstay of treatment is fluid restriction.

Euvolemic hyponatremia is the most common cause of hyponatremia in the hospitalized patient. After confirmation of a true hyponatremia, the workup entails checking the urine osmolality. A

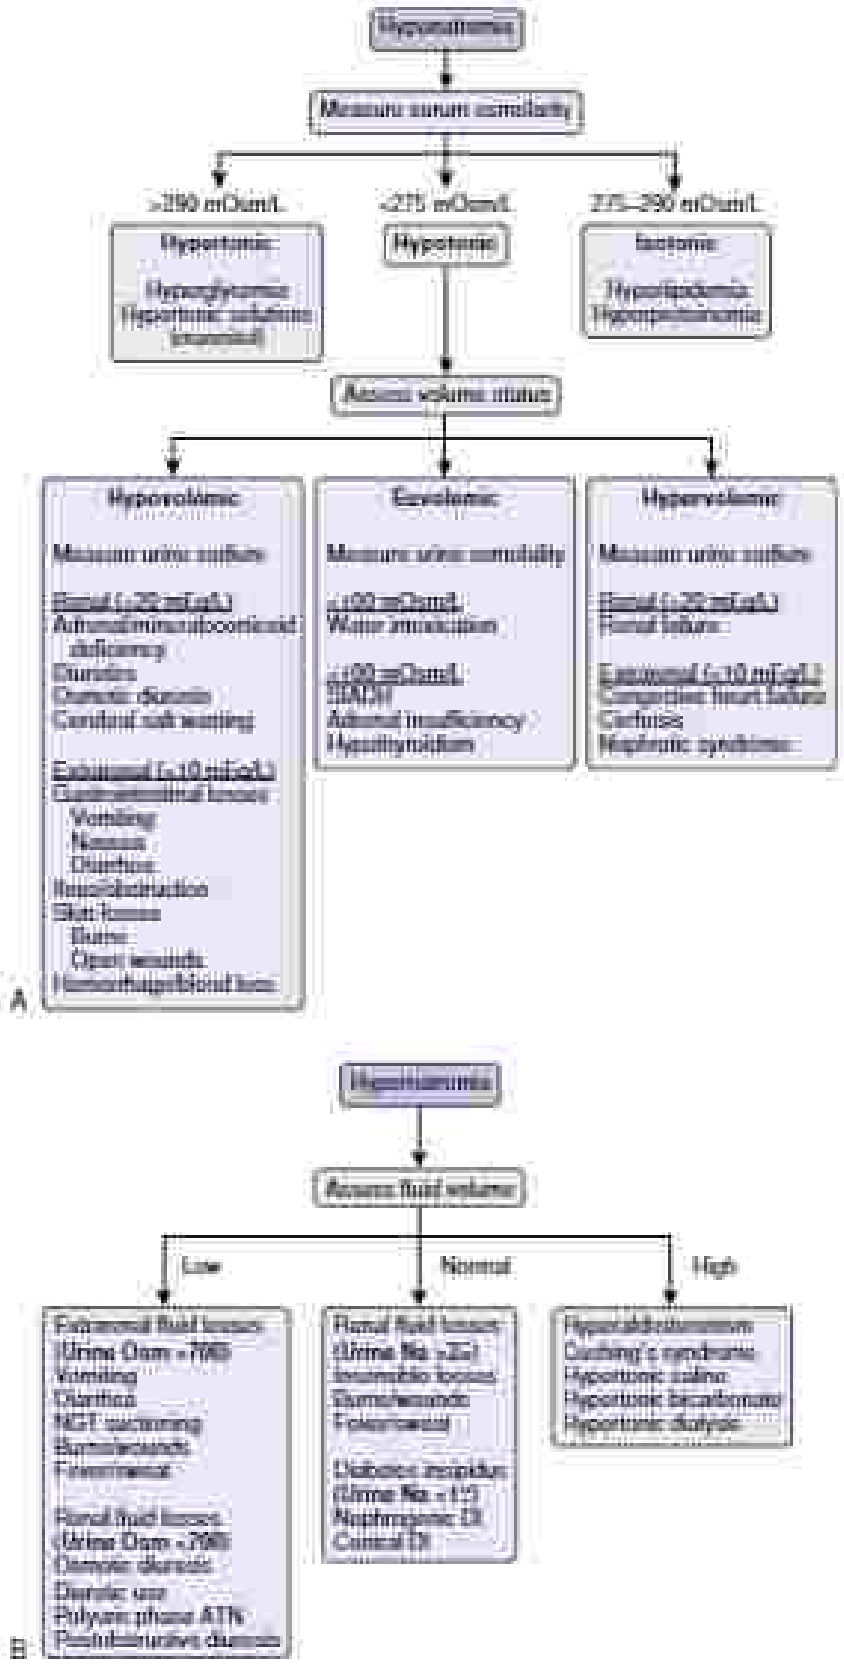

FIG. 1 (A) ... glucosemia. (B) Hyponatremia. ATN, acute tubular necrosis; DI, diabetes insipidus; Na, sodium; NCT, nasogastric tube; Or ..., osmolality; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

high urine osmolality implies the presence of SIADH and an internal homeostasis disorder (see the previous section), whereas a low urine osmolality suggests excessive exogenous intake (water intoxication).

Hypovolemic hyponatremia is the most common cause of hyponatremia in the postoperative state and can be seen in conditions of high fluid loss such as through the gastrointestinal (GI) tract, fluid sequestration (third spacing), or from hemorrhage. Again, the volume loss results in a nonosmotic stimulation of ADH release and the retention of free water resulting in hyponatremia and concentrated urine with a low sodium concentration (<10 mEq/L). Primary renal losses can lead to a similar clinical condition except with a more elevated urine sodium level (>20 mEq/L). Finally, large volume sodium depletion can occur in the CSW. This syndrome can occur in the setting of brain injury and results in the active excretion of sodium with high levels in the urine (>40 mEq/L). In contrast to SIADH, fluid restriction will compound the hyponatremia because there is an underlying hypovolemia in CSW. Volume and salt replacement, such as with isotonic intravenous fluids, is therefore the mainstay of treatment.

An important consideration in the management of hyponatremia is the rate of correction. Patients with chronic hyponatremia are at much higher risk for central pontine myelinolysis than those who develop hyponatremia acutely (within 48 hours). In the former situations, a slow correction of the hyponatremia should be considered (0.25–0.5 mEq/L per hour). Correction that is too rapid can predispose to the development of central pontine myelinolysis, which generally occurs 2 to 6 days after the sodium correction. Symptoms include dysarthria, paresis, seizure, lethargy, and coma among others. Symptoms tend to be irreversible. Severely ill critical patients may experience locked-in syndrome, in which patients are awake but unable to communicate except through eye movements. In acute hyponatremia, a faster correction (1–2 mEq/L per hour) is safe and can be accomplished through the infusion of 3% hypertonic saline.

Hypernatremia is defined as a sodium level greater than 145 mEq/L (moderate, 146–159 mEq/L; severe, ≥160 mEq/L). Clinical signs include restlessness and insomnia but can progress to lethargy and coma at extremely high sodium levels. Similar to hyponatremia, hypernatremia can occur in all variations of intravascular volume.

In the surgical patient, hypovolemic hypernatremia is the most common scenario and is secondary to unreplaced water loss. This can be secondary to GI losses such as nasogastric suctioning, vomiting and diarrhea; renal losses such as with diuretic use or with multiple, large open wounds (e.g., burns) resulting in evaporative losses. A key differentiating factor is that renal losses will have elevated urine sodium loss (>20 mEq/L) compared with decreased urine excretion in other etiologies.

Euvolemic hypernatremia most commonly develops in the context of DI (see the previous section). Hypervolemic hypernatremia is usually iatrogenic and related to large volume administration of isotonic or hypertonic saline. Mineralocorticoid or glucocorticoid excess may also cause similar findings (Conn's and Cushing's syndrome, respectively).

Irrespective of the volume status of the patient, however, all patients of hypernatremia have a free water deficit; therefore, the treatment of hypernatremia revolves around the administration of hypotonic fluid and may be supplemented with diuretics in hypervolemic states. To accomplish this, the free water deficit should be calculated and can be done with the following formula:

$$\text{Free water deficit} = \frac{[\text{Na}^+]_{\text{measured}} - 140}{140} \times \text{total body water}$$

In general, half the calculated water deficit is replaced in the first 24 hours and the remaining half over the next 24 hours. The choice of fluid used to correct the hypernatremia depends on any other ongoing electrolyte abnormalities and the underlying etiology. In general, hypernatremia is treated with the administration of hypotonic fluid (oral or intravenous) such as 0.45% saline or 5% water; however, if the hypernatremia is associated with hypovolemia (i.e., both fluid and salt lost) additional solute may be required such as with the administration of more isotonic solutions such as 0.9% normal saline or balanced crystalloids. A further consideration is the rate of correction: acute hypernatremia (within 48 hours) is generally safe to correct rapidly (1–2 mEq/L per hour for example), but rapidly correcting hypernatremia that is more chronic can lead to cerebral edema. Hence, chronic hypernatremia should not be corrected at a rate faster than 0.5 mEq/L per hour.

Chloride

Chloride is the second most abundant electrolyte in the ECF. Its primary roles are in its contribution to osmolality as well as muscular function, GI and pulmonary function, as well as urine concentration by the kidney.

The primary method of chloride homeostasis is via excretion through the kidney and its range is maintained between 95 and 105 mEq/L. Hyperchloremia is generally seen in situations of dehydration where it is paired with a hypernatremia such as with large volume diarrhea. These situations entail the development of a normal anion gap metabolic acidosis (i.e., high loss of bicarbonate and retention of chloride). Biliary and pancreatic fistulas are other important causes. Iatrogenic hyperchloremia is common secondary to the large volume administration of acidic isotonic fluid such as 0.9% normal saline, which has a much higher concentration of chloride (154 mEq/L) compared with plasma (~110 mEq/L). Consequently, a rise in chloride leads to a drop in serum bicarbonate and a hyperchloremic metabolic acidosis.

Conversely, hypochloremia is generally associated with a metabolic alkalosis and may be physiologic as in physiologic chloriduria where renal excretion of chloride is increased in exchange of bicarbonate reabsorption as a compensatory response in the setting respiratory acidosis. Primary hypochloremia is usually secondary to GI losses such as congenital chloride diarrhea, nasogastric suctioning, and high ileostomy output, which preferentially lose high volumes of chloride. In these scenarios, the fluid lost may also have a relatively low bicarbonate content relative to the ECF. The water loss leads to contraction of the ECF with a relatively stable bicarbonate concentration and a contraction alkalosis. Uncontrolled renal losses, such as with diuretic therapy or renal failure, can also contribute to a hypochloremic metabolic alkalosis.

Potassium

Unlike sodium and chloride, potassium is primarily an intracellular cation. Potassium is the primary determinant of the resting membrane potential across the cell membranes of most cells and that is why alterations can lead to dysrhythmias and cardiac abnormalities. Its homeostasis is maintained primarily through renal excretion.

Hypokalemia is a common condition particularly in the postoperative state. It is defined as a serum potassium value of less than 3.5 mEq/L. Hypokalemia can occur through GI losses, renal losses, alkalosis, the administration of insulin, as well as others (Table 1). Patients complain of nonspecific symptoms such as fatigue and weakness, and hypokalemia can predispose to intestinal ileus. Severe hypokalemia can lead to electrocardiogram changes such as T wave flattening.

In addition, most of the causes of hypokalemia also predispose to hypomagnesemia. These patients are likely to be refractory to replacement of potassium alone without treating the hypomagnesemia as well; hence, magnesium levels should be checked and replaced in all hypokalemic patients. Potassium can be replaced orally or intravenously. The latter is generally considered in patients with more severe hypokalemia and should be administered in a monitored setting due to the risk of arrhythmias.

Oral repletion of potassium is a frequent necessity for surgical services. The healthcare provider should be cognizant of not administering a high potassium load through the GI tract all at once because it can lead to nausea and vomiting. Potassium is, therefore, generally repleted over 4 to 6 divided doses (Table 2); in all confirmed or

TABLE 1 Causes of Abnormal Potassium Levels

Hypokalemia	Hyperkalemia
EXTRARENAL LOSSES	**EXTRARENAL CAUSES**
• Diarrhea • Malabsorption • VIPoma • ZE syndrome • Villous adenoma	• Pseudohyperkalemia • Metabolic acidosis • Succinylcholine • Beta 2 adrenergic antagonists • Digoxin • Rhabdomyolysis • Tumor lysis syndrome • Ethanol or methanol • Salt shock • Insulin deficiency
INTRACELLULAR POTASSIUM SHIFT	**RENAL ETIOLOGIES**
• Metabolic alkalosis • Beta 2 adrenergic agonists • Theophylline • Caffeine • Hypothyroidism	• Renal failure • Mineralocorticoid deficiency (low-degree hyporeninemia, Addison's disease, ACE inhibitors, ARBs, NSAIDs)
RENAL LOSSES	• Mineralocorticoid resistance (spironolactone, amiloride/trimterene, cyclosporine, tacrolimus)
• Diuretics (loop, thiazide, and osmotic agents) • Other medications (amphotericin B, cisplatin, foscarnet, aminoglycosides) • Hypercalcemia/renal (Conn's syndrome, Cushing's syndrome, dehydration) • Magnesium deficiency • Defective tubules	

ACE, Angiotensin converting enzyme; ARBs, angiotensin receptor blockers; NSAIDs, nonsteroidal antiinflammatory drugs; ZE, Zollinger Ellison.

TABLE 2 Example of Electrolyte Replacement Protocol[a]

Serum Level (mg/dL)	Replacement Dose
POTASSIUM[b]	
3.5–3.9	40 mEq KCl PO/IV
3.0–3.2	60 mEq KCl PO/IV
2.6–2.8	80 mEq KCl IV
<2.6	100 mEq IV
MAGNESIUM[c]	
1.6–1.9	4 g $MgSO_4$ IV or 250 mg MgO PO × 2 doses[d]
1.0–1.5	6 g $MgSO_4$ IV
<1.0	8 g $MgSO_4$ IV
PHOSPHORUS[e]	
2–2.5	20 mmol Na Phos or K Phos (provides ~20 mEq K^+)
1.6–1.9	30 mmol Na Phos or K Phos (provides ~44 mEq K^+)
<1.6	40 mmol Na Phos or K Phos (provides ~60 mEq K^+)
CALCIUM[f,g]	
3.5–3.9	2 g IV Ca gluconate
3.0–3.4	4 g IV Ca gluconate
<2.9	6 g IV Ca gluconate

[a]Excludes patients on dialysis or with creatinine clearance <20 mL/min.
[b]IV KCl infusion rate should not exceed 10 mEq/hr through peripheral line or 40 mEq/hr using central line and continuous cardiac monitoring.
[c]IV $MgSO_4$ infusion rate should not exceed 2 g/hr.
[d]Oral magnesium replacement should be avoided in patients with poor oral tolerance or GI disturbance.
[e]For simultaneous K+ replacement, subtract the amount given with K Phos and give remainder as KCl.
[f]Normal calcium, 3 mg/dL = 0.25 mmol/L.
[g]IV Ca gluconate infusion rate should not exceed 2 g/hr; for CaCl, give one-third dose using central line and continuous cardiac monitoring.
CaCl, Calcium chloride; Ca gluconate, calcium gluconate; GI, gastrointestinal; IV, intravenous; K^+, potassium; KCl, potassium chloride; K Phos, potassium phosphate; Mg+, magnesium oxide; $MgSO_4$, magnesium sulfate; Na Phos, sodium phosphate; PO, per oral(ly).

hypokalemia, the renal function must be evaluated. Aggressive replacement may be inappropriate in patients with renal insufficiency as they have a reduced capacity for potassium excretion.

Hyperkalemia is defined as a potassium level exceeding 5.5 mEq/L. A frequent cause of an elevated laboratory value of serum potassium is due to hemolysis of the specimens. The serum potassium should be repeated in these cases. The etiology of hyperkalemia can be from a variety of sources and includes mineralocorticoid deficiency, renal failure, ischemia reperfusion injury, and the use of succinylcholine in certain clinical conditions such as burns or major trauma.

True hyperkalemia will result in muscle weakness and cardiac conduction abnormalities. This usually occurs with severe hyperkalemia (>7.8 mEq/L) or lesser elevations that occur acutely. Cardiac abnormalities include peaked T waves and shortened QT intervals. Symptomatic hyperkalemia, hyperkalemia of more than 6.5 mEq/L, and/or hyperkalemia in the presence of renal impairment or other sources of ongoing potassium absorption are considered hyperkalemic emergencies. In these scenarios the management of hyperkalemia should be implemented in two paradigms:

1. Rapidly acting therapies that mobilize potassium back into the cells.
2. Therapies that remove potassium from the body.

In hyperkalemic emergencies rapidly acting therapies should be implemented. This includes the administration of IV calcium (e.g., 1000 mg of intravenous calcium gluconate over 30 to 60 minutes) to antagonize the effects of potassium on the cell membranes and to provide a membrane stabilizing effect. In addition, 10 U of intravenous insulin should be administered be administered to mobilize potassium into the cells. To prevent hypoglycemia, dextrose may be administered in addition to the insulin (e.g., 50 mL of 50% dextrose solution).

It should be emphasized that the aforementioned therapies are temporizing measures and do nothing to alter the total body potassium content. To truly decrease the body's potassium levels other therapies will need to be instituted. These therapies include the administration of diuretics, gastrointestinal cation exchangers, and the use of hemodialysis.

The administration of loop diuretics can lead to a kaliuresis and decrease the body's potassium levels. This is particularly helpful in cases of preserved renal function; however, most patients with refractory hyperkalemia will have some element of renal dysfunction. In these patients, loop diuretics should not be used in isolation.

The use of sodium polystyrene sulfonate has historically been frequently cited as a therapy to remove potassium through the GI tract, but studies have shown that complications are frequent and include intestinal necrosis. Sodium polystyrene sulfonate should therefore only be used as a last resort. Other cation exchangers, such as patiromer, may be used instead.

The mainstay of therapy for hyperkalemia is hemodialysis and should be instituted as soon as possible. Other therapies may not be necessary if dialysis and vascular access are immediately available.

The administration of beta 2 adrenergic agonists and sodium bicarbonate may be considered as supplements to the therapies discussed previously.

Magnesium

Magnesium is also an electrolyte the majority of which resides in the ICF. Hypomagnesemia is defined as a serum level of <1.8 mg/dL and is common in surgical patients with GI losses, diuretic, or those with poor oral intake. Symptoms include seizure, seizures, and dysrhythmias. Repletion can be done orally or parenterally, however, oral repletion should be used with caution as diarrhea can sometimes be precipitated. Furthermore, rapid repletion of serum levels may inhibit renal reabsorption of magnesium; therefore, severe hypomagnesemia should be managed with more prolonged infusion (e.g. 12 hours). Conversely, magnesium administered to short ureate dysrhythmias (e.g., torsades de pointes) should be infused rapidly.

Hypermagnesemia occurs with serum levels greater than 2.8 mg/dL. Symptoms include decreased deep tendon reflexes, lethargy, and cardiac conduction abnormalities. Because of the efficiency with which the kidneys clear magnesium, hypermagnesemia is an uncommon entity. It generally occurs in renal insufficiency or in the context of a large magnesium load. In the setting of normal renal function, loop diuretics may be used to help clear the hypermagnesemia. In addition, patients with renal insufficiency may need hemodialysis. Symptomatic hypermagnesemia should be interpreted with the administration of intravenous calcium to counteract magnesium's effects in precipitating abnormal cardiac conduction and its effects on the neurologic system.

Calcium

Calcium is the most abundant electrolyte in the body but mostly exists in a mineralized state in the skeletal system. The normal range of total serum calcium is 8.5 to 10.5 mg/dL, and the normal range of the active, ionized form of calcium is 4.65 to 5.25 mg/dL. This ionized portion constitutes approximately 45% of the plasma calcium. The rest is bound to albumin (40%) or complexed to anions such as phosphate and citrate (15%). The consequence of this is that serum albumin concentration has a direct correlation to the measured total calcium concentration, a decrease in albumin of 1 g/dL leads to a measured decrease of 0.8 mEq/L of serum calcium (therefore requiring correction of any laboratory measurements of total calcium). Calcium homeostasis is accomplished via the hormones parathyroid hormone (PTH), vitamin D (calcitriol), and calcitonin (Fig. 1).

1. PTH is secreted by the parathyroid glands in response to hypocalcemia. This leads to an increase in calcium levels (via stimulation of osteoclasts and kidney reabsorption) and a decrease in phosphate levels (via excretion by the kidneys). The increased phosphate excretion allows the liberated calcium to remain in the plasma as the active, ionized form.
2. PTH also stimulates the production of vitamin D in the kidneys, which further stimulates the reabsorption of calcium from the gastrointestinal tract and kidney. Vitamin D also stimulates bone resorption and remodeling.
3. Calcitonin is produced by the parafollicular cells of the thyroid gland and serves to decrease calcium levels by inhibiting bone resorption.

Hypocalcemia occurs if the plasma calcium level falls below 8.4 mEq/L (or an ionized calcium of <4.5 mEq/L). Classic symptoms of hypocalcemia include perioral numbness and tingling, twitching of the facial muscles on tapping the facial nerve in the region of the parotid gland (Chvostek's sign), and carpopedal spasm at the level of the hand and forearm precipitated by ischemia, such as by the application of a blood pressure cuff on the ipsilateral arm (Trousseau's sign). Electrocardiogram findings include a prolonged QT interval and arrhythmias. Hypocalcemia is often seen after thyroid and parathyroid surgery, severe acute pancreatitis, vitamin D deficiency, hyperphosphatemia, hypomagnesemia, and malnutrition. In the critically ill population, hypocalcemia develops frequently and is likely a consequence of suppressed PTH and vitamin D production, as well as end organ resistance to the actions of PTH likely secondary to decreased magnesium levels and the effects of inflammatory cytokines. Large volume blood transfusion can also predispose to hypocalcemia because the citrate used as an anticoagulant acts as a calcium chelator (the total calcium is therefore detected as normal but in effect the level of ionized calcium is low). Hypocalcemia should be treated if the levels fall below a total calcium of 7 mEq/L (ionized calcium <3 mEq/L), or if symptoms develop. This repletion is frequently through the intravenous route in the form of calcium gluconate or calcium chloride. The latter formulation has three times the elemental calcium of the former; it can rapidly reverse dysfunction but infusions

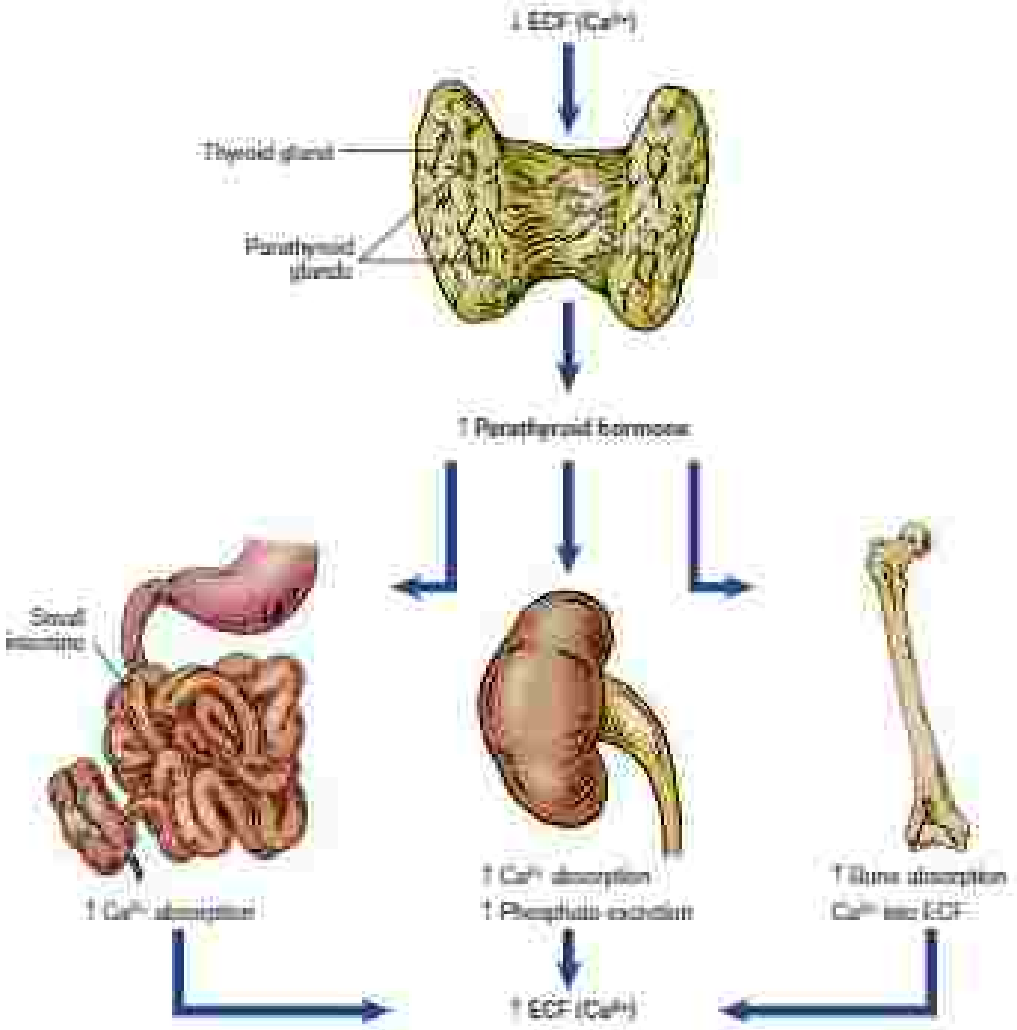

FIG. 3. Calcium homeostasis. Ca^{2+}, Calcium; ECF, extracellular fluid.

need to be through central venous catheters and in a monitored setting. Oral calcium carbonate or calcium gluconate can be used in chronic or milder forms of hypocalcemia.

Hypercalcemia is defined as a total calcium level above 10.6 mEq/L (>5.6 mEq/L ionized calcium) and is represented by a classic constellation of symptoms (and an oft repeated mnemonic): myalgias and arthralgias ("painful bones"), the development of "kidney stones," nausea, vomiting ("abdominal groans"), lethargy, and altered mental status ("psychic moans"). Hypercalcemic crisis can occur with levels over 14 mEq/L. The most common cause of hypercalcemia in nonhospitalized patients is hyperparathyroidism, whereas it is malignancies (such as breast, lung, and multiple myeloma) that cause hypercalcemia most frequently in hospitalized patients. Other causes include immobilization, familial hypocalciuric hypercalcemia, thiazide diuretics, and medications such as vitamin A and lithium. Treatment should be instituted for severe elevations (>14 mEq/L) or if symptoms are present, including the following.

1. Isotonic saline to correct any fluid losses related to hypercalcemia-induced urinary salt wasting and vomiting. An initial rate may need to be as high as 300 to 500 mL/hr until adjustments can take place to maintain a urine output of 100 to 150 mL/hr.
2. Intramuscular or subcutaneous calcitonin should be administered concurrently at a starting dose of 4 IU/kg every 6 to 12 hours. This allows for increased urinary excretion and decreased bone breakdown.
3. Finally, bisphosphonates, such as pamidronate, should also be administered. Bisphosphonates interfere with osteoclast-mediated bone resorption. Although the administration of bisphosphonates is the most potent treatment, their peak effect does not occur until 2 to 4 days after administration; therefore, combination therapy with saline and calcitonin (which reduces calcium levels more rapidly) is the mainstay of treatment.

Phosphorus

Similar to calcium, the majority of phosphorus is also contained in the bone and is also regulated by PTH and vitamin D. Hypophosphatemia occurs if the phosphorus level falls below 2.5 mg/dL and is seen frequently in the postoperative setting especially after hepatic resections. If severe, deficiencies can lead to heart and respiratory failure. Refeeding syndrome is also an important and common cause of hypophosphatemia in the critically ill and malnourished. Other causes include the administration of diuretic medications, intestinal malabsorption, vitamin D deficiency, and hyperparathyroidism. Repletion can occur via the oral or parenteral route. Hyperphosphatemia can occur after parathyroid or thyroid surgery, the symptoms are usually related to the concomitant hypocalcemia. In the acute setting this is treated with volume expansion. Chronic hyperphosphatemia, however, is seen commonly in renal failure and can be treated with phosphate binders.

SUMMARY

The preceding discussion should impart to the reader the importance of the fluid milieu of the human body, whether the intracellular or the extracellular components, and the salts that are dissolved within it. Successful recognition and management of these complex problems requires a patient and systematic evaluation while recognizing the pitfalls of performing electrolyte abnormalities that may be appropriate physiologic responses or chronic derangements.

ACID-BASE PROBLEMS

Ana M. Velez-Rawsthorne, MD, and Marko Baker, MD, FACS

The human body's tightly regulated pH of 7.35 to 7.45 is vital to maintaining homeostasis for a variety of physiologic functions including oxygen transport, cardiac electrophysiology, neurotransmission, enzymatic activity, and drug metabolism, among others. Different stressors, including trauma, surgical intervention, and critical illness, can precipitate acid-base disturbances that may result as a direct consequence of these inciting events or as a result of preexisting comorbid conditions.

Different theories exist to explain acid-base physiology, the most prominent of which is the traditional model. Alternative methods of acid-base analysis such as Stewart's physicochemical model exist and are beyond the scope of this summary. In clinical practice, one theory has not been shown to be superior to the other and both are limited as they describe the state of a biologic solution at the moment of analysis. The traditional model is based on the initial Lowry's theory, which characterizes acids as hydrogen ion (H^+) donors and bases as H^+ acceptors. This is based on the notion that any change to concentration of H^+ in the body results in a compensatory response to restore the pH into normal range. As determined by the Henderson-Hasselbalch equation, the traditional model uses measured concentrations of plasma carbon dioxide (CO_2) and bicarbonate (HCO_3^-) to determine the pH of blood. This equation is shown below where pK is the acid dissociation constant, 0.03 is the solubility constant of CO_2 in the blood, and $PaCO_2$ is the partial pressure of carbon dioxide in the arterial blood.

$$pH = pK + \log_{10}[HCO_3^-/0.03\,(PaCO_2)]$$

ACID-BASE HOMEOSTASIS

The narrow pH range of body fluids is maintained despite the normal acid loads produced as a byproduct of metabolism. To maintain this stable plasma acid-base balance, endogenous acid load is efficiently neutralized by a combination of mechanisms that vary temporally and can be used to help determine the acuity of the disorder present. These include extracellular and intracellular buffer systems (which act in minutes), changes in alveolar ventilation (which occurs in hours), and renal excretion (which takes days). When acid-base disturbances are present, existing physiologic adaptations are better at combating acidosis than alkalosis.

Buffer Systems

Proteins and phosphates are the main intracellular buffers, whereas hemoglobin is the main buffer within red blood cells, with histidine moieties acting as H^+ binding sites. The bicarbonate-carbonic acid system is the most prominent extracellular buffer, whereas plasma proteins such as albumin and inorganic phosphates contribute to a lesser extent. Bone, although not an acute buffer, can absorb H^+ in exchange for sodium (Na^+) and potassium (K^+), and releases calcium, HCO_3^-, carbonate, and phosphates.

Respiratory System

In patients with normal gas exchange, CO_2 diffuses quickly and is cleared via compensatory changes to alveolar ventilation in response to pH changes sensed in the carotid body and by medullary chemoreceptors. This leads to rapid changes in $PaCO_2$.

Renal System

The proximal tubule modulates both H^+ excretion and reabsorbs 85% of the filtered HCO_3^-. Additionally, the distal tubule functions to excrete H^+, either in exchange for Na^+, or in combination with ammonia as ammonium chloride (NH_4Cl).

DISORDERS OF ACID-BASE METABOLISM

Acid-base disorders occur when there is a lack of balance between the production of acids and bases and the body's ability to compensate. This may be due either to a rapid rate of production or a defect in the physiologic compensatory mechanisms. These disturbances are markers of an underlying disease process. Correction of abnormalities should occur while simultaneously searching for inciting causes.

Acidemia is defined as a plasma pH less than 7.35, and alkalemia is defined as a plasma pH greater than 7.45. These definitions are a reflection of the serum pH, not necessarily a reflection of the acid-base disorders that collectively may or may not lead to pH alterations. Acidosis is defined as any process that lowers the pH (increases H^+) and alkalosis any process that increases the pH (decreases H^+). Acid-base disorders can develop as a result of metabolic or respiratory alterations. Additionally, multiple acid-base disorders can exist at one time and can be uncovered by examining the expected and observed compensatory changes in $PaCO_2$ and HCO_3^- responses. It is important to note that "compensatory" responses to the primary acid-base disturbance occur in the same direction and are only partially corrective. For example, in metabolic acidosis the serum HCO_3^- level decreases with a physiologic decrease in the $PaCO_2$ through increased minute ventilation. Estimates of physiologic responses are depicted in Table 1. If compensation is greater or less than predicted, that is, the $PaCO_2$ or HCO_3^- is not within the range predicted by the formula, it is important to evaluate for a mixed acid-base disorder.

Physiologic Effects of Acidosis and Alkalosis

Acidosis, acidosis has physiologic benefits, such as enhanced peripheral oxygen delivery by decreased binding of oxygen to hemoglobin and catecholamine and aldosterone stimulation augmenting cardiac

ACID-BASE PROBLEMS

Ana M. Velez-Rawlinson, MD, and Marko Baker, MD, FACS

The human body's tightly regulated pH of 7.35 to 7.45 is vital to maintaining homeostasis for a variety of physiologic functions including oxygen transport, cardiac electrophysiology, neurotransmission, enzymatic activity, and drug metabolism, among others. Different stressors, including trauma, surgical intervention, and critical illness, can precipitate acid-base disturbances that may result as a direct consequence of these inciting events or as a result of preexisting comorbid conditions.

Different theories exist to explain acid-base physiology, the most prominent of which is the traditional model. Alternative methods of acid-base analysis such as Stewart's physicochemical model exist and are beyond the scope of this summary. In clinical practice, one theory has not been shown to be superior to the other and both are limited as they describe the state of a biologic solution at the moment of analysis. The traditional model is based on Brønsted and Lowry's theory, which characterizes acids as hydrogen ion (H^+) donors and bases as H^+ acceptors. This is based on the notion that any change to concentration of H^+ in the body results in a compensatory response to restore the pH into normal range. As determined by the Henderson-Hasselbalch equation, the traditional model uses measured concentrations of plasma carbon dioxide (CO_2) and bicarbonate (HCO_3^-) to determine the pH of blood. This equation is shown below where pK is the acid dissociation constant, 0.03 is the solubility constant of CO_2 in the blood, and $PaCO_2$ is the partial pressure of carbon dioxide in the arterial blood.

$$pH = pK + \log_{10}[HCO_3^-/0.03\,(PaCO_2)]$$

ACID-BASE HOMEOSTASIS

The narrow pH range of body fluids is maintained despite the normal acid loads produced as a byproduct of metabolism. To maintain this stable plasma acid-base balance, endogenous acid load is efficiently neutralized by a combination of mechanisms that vary temporally and can be used to help determine the acuity of the disorder present. These include extracellular and intracellular buffer systems (which act in minutes), changes in alveolar ventilation (which occurs in hours), and renal excretion (which takes days). When acid-base disturbances are present, existing physiologic adaptations are better at combating acidosis than alkalosis.

Buffer Systems

Proteins and phosphates are the main intracellular buffers, whereas hemoglobin is the main buffer within red blood cells, with histidine moieties acting as H^+ binding sites. The bicarbonate-carbonic acid system is the most prominent extracellular buffer, whereas plasma proteins such as albumin and inorganic phosphates contribute to a lesser extent. Bone, although not an acute buffer, can absorb H^+ in exchange for sodium (Na^+) and potassium (K^+), and releases calcium, HCO_3^-, carbonate, and phosphates.

Respiratory System

In patients with normal gas exchange, CO_2 diffuses quickly and is cleared via compensatory changes to alveolar ventilation in response to pH changes sensed in the carotid body and by medullary chemoreceptors. This leads to rapid changes in $PaCO_2$.

Renal System

The proximal tubule modulates both H^+ secretion and reuptake 85% of the filtered HCO_3^-. Additionally, the distal tubule functions to excrete H^+, either in exchange for Na^+, or in combination with ammonia as ammonium chloride (NH_4Cl).

DISORDERS OF ACID-BASE METABOLISM

Acid-base disorders occur when there is a lack of balance between the production of acids and bases and the body's ability to compensate. This may be due either to a rapid rate of production or a defect in the physiologic compensatory mechanisms. These disturbances are markers of an underlying disease process. Correction of abnormalities should occur while simultaneously searching for inciting causes.

Acidemia is defined as a plasma pH less than 7.35, and alkalemia is defined as a plasma pH greater than 7.45. These definitions are a reflection of the serum pH, not necessarily a reflection of the acid-base disorders that collectively may or may not lead to pH alterations. Acidosis is defined as any process that lowers the pH (increases H^+) and alkalosis any process that increases the pH (decreases H^+). Acid-base disorders can develop as a result of metabolic or respiratory alterations. Additionally, multiple acid-base disorders can exist at one time and can be uncovered by examining the expected and observed compensatory changes in $PaCO_2$ and HCO_3^- responses. It is important to note that "compensatory" responses to the primary acid-base disturbance occur in the same direction and are only partially corrective. For example, in metabolic acidosis the serum HCO_3^- level decreases with a physiologic decrease in the $PaCO_2$ through increased minute ventilation. Formulas of physiologic responses are depicted in Table 1. If compensation is greater or less than predicted, that is, the $PaCO_2$ or HCO_3^- is not within the range predicted by the formula, it is important to evaluate for a mixed acid-base disorder.

Physiologic Effects of Acidosis and Alkalosis

Acutely, acidosis has physiologic benefits, such as enhanced peripheral oxygen delivery by decreased binding of oxygen to hemoglobin and catecholamine and aldosterone stimulation augmenting cardiac

TABLE 1 Expected Compensation for Primary Acid-Base Disturbance

Metabolic acidosis	$PaCO_2 = (1.5 \times [HCO_3^-]) + 8 \pm 2$
Metabolic alkalosis	$PaCO_2 = (0.7 \times [HCO_3^-]) + 40 \pm 2$
Acute respiratory acidosis	$\uparrow HCO_3^- = \Delta PaCO_2/10$
Acute respiratory alkalosis	$\downarrow HCO_3^- = 2\ (\Delta PaCO_2/10)$
Chronic respiratory acidosis	$\uparrow HCO_3^- = 4\ (\Delta PaCO_2/10)$
Chronic respiratory alkalosis	$\downarrow HCO_3^- = 5\ (\Delta PaCO_2/10)$

$\Delta PaCO_2$ is calculated from the normal value of 40.
HCO_3^-, Bicarbonate; $PaCO_2$, partial pressure of carbon dioxide.

output. At the pH decreases below 7.2, however, deleterious effects such as decreased cardiac inotropy, hyperkalemia-induced cardiac conduction deficits, and central venous vasoconstriction may occur. Neurologic effects are manifested by decreased sensorium, which may progress to coma, and cerebral vasodilation that in turn results in increased intracranial pressure.

Clinical manifestations of alkalosis are subtle. Acute metabolic consequences are most commonly related to associated electrolyte derangements and neurologic effects. Increased pH results in hypokalemia, hypophosphatemia, and hypocalcemia resulting from increased uptake of K^+ and phosphate into cells, and increased binding of calcium to albumin. This can lead to cardiac and neuromuscular effects such as altered coronary blood flow and arrhythmias, increased neuromuscular excitability, presenting as paresthesias and muscle cramps, can progress to encephalopathy and seizures. Additionally, oxygen delivery is diminished as a result of increased binding of oxygen to hemoglobin.

APPROACH TO ACID-BASE DISTURBANCES: BLOOD GAS INTERPRETATION

When these disorders occur in the perioperative period, it is imperative to have a rapid and accurate clinical approach to developing a diagnostic and therapeutic plan that optimizes the patient's outcome. The blood gas sample is the test most commonly used to evaluate acid-base physiology at the bedside. The pH, arterial partial pressure of oxygen, and $PaCO_2$ are measured directly. The derived components include arterial oxygen saturation, HCO_3^- (using the Henderson-Hasselbalch equation), and the base excess (BE). Normal values in both arterial and venous samples can be seen in Table 2.

Systematic blood gas interpretation typically proceeds in the following order (Fig. 1):

1. The pH value provides the first and most representative estimate of the severity of the acid-base disorder, with acidosis at a pH less than 7.35 and alkalosis at a pH greater than 7.45.
2. In primary metabolic disorders, the pH and pCO_2 values are displaced in the same direction, with change in opposite directions indicating a primary respiratory disorder. If there is compensation, the change in pH may still occur though in a less pronounced form.
3. HCO_3^- is reduced in metabolic acidosis and as a compensatory mechanism in chronic respiratory alkalosis. It is increased in metabolic alkalosis and in chronic respiratory acidosis.
4. BE is the amount of acid measured in mmol/L required to titrate 1 L of blood to a pH of 7.4 at 37°C; normal values are between −3 and 3. A positive BE indicates lack of acid and thus a component of metabolic alkalosis. A negative BE indicates excess acid with a contributing metabolic acidosis; therefore, BE reflects the pure metabolic component of the acid-base disorder.

TABLE 2 Normal Blood Gas Values

	Arterial	Venous
pH	7.40 ± 0.04	7.38 ± 0.04
$PaCO_2$ (mHg/L)	40 ± 4	46 ± 4
HCO_3^- (mEq/L)	24 ± 2	26 ± 2

HCO_3^-, Bicarbonate; $PaCO_2$, partial pressure of carbon dioxide.

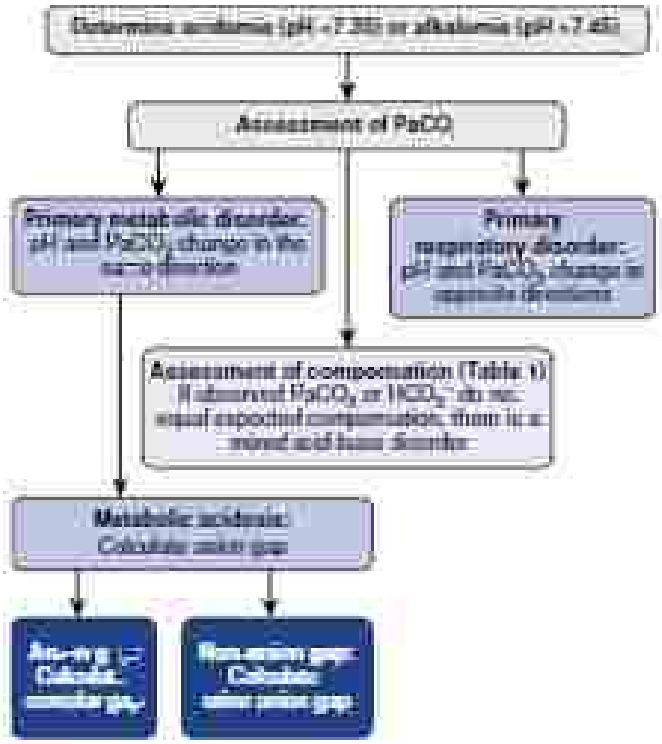

FIG. 1 Systemic approach to interpreting arterial blood gas. HCO_3^-, Serum bicarbonate; $PaCO_2$, partial pressure of carbon dioxide.

5. PO_2 levels provide an evaluation of pulmonary function and in cases of respiratory alkalosis, changes in PO_2 indicate whether the primary stimulus is hypoxemia or another cause.
6. Compensatory changes in mixed disorders can be diagnosed based on differences between expected and observed levels of pCO_2 and HCO_3^- (Table 1). The pH can change in the same direction (mixed disorders in the same direction) or remain neutral (mixed acidosis and alkalosis).

Although arterial blood gas analysis is the gold standard for determining the metabolic milieu in a critically ill patient, arterial samples may be difficult to obtain and may not provide significant additional information compared to venous blood gas (VBG) samples that would lead to diagnostic or therapeutic changes. Studies have shown acceptable correlation of VBG and arterial blood gas samples in noncritically ill patients. Arterial partial pressure of oxygen has significant variability and is typically 35 mm Hg lower than arterial in central venous samples. Central VBG samples offer the additional benefit of providing an assessment of global oxygen consumption by measuring central venous oxygen saturation.

ANION GAP METABOLIC ACIDOSIS

In the perioperative period, the most frequently encountered acid-base disturbance is metabolic acidosis, which occurs when the

plasma HCO_3^- to less than 22 mEq/L. The differential diagnosis depends on the presence or absence of an anion gap (AG). The AG represents unmeasured serum anions such as albumin, phosphates, sulfates, and lactate that are not typically quantified in routine laboratory measurements. The AG is calculated by subtracting the measured serum anions (chloride [Cl$^-$] and [HCO_3^-]) from the cations (Na^+ and K^+), though K^+ has such a low concentration in the serum that is generally omitted from the equation. The normal range for AG is 8 to 16, though this may vary as each institution reports its own expected normal.

$$AG = Na^+ - (Cl^- + HCO_3^-)$$

The utility of the anion gap depends on normal circulating levels of albumin, which is also a weak acid. As most critically ill patients are hypoalbuminemic, the AG is lower than expected. To correct for this discrepancy the following equation can be used:

Corrected AG = AG + 2.5 × (4.5 − Serum albumin concentration [g/dL])

The AG may be used to determine the etiology of the metabolic disturbance, with an increased AG indicating accumulation of acids. The *MUDPILES* mnemonic is commonly used to define the differential diagnosis of AG metabolic acidosis, with the most common causes being lactic acidosis, ketoacidosis, and renal insufficiency (Box 1). In patients with an AG metabolic acidosis not explained by common causes and when toxic ingestion is suspected, the osmolar gap (OG) should also be calculated. The OG is the difference between the measured and calculated plasma osmolarity. An elevated OG indicates the presence of osmotically active substances in the plasma, such as ingested agents like methanol or ethylene glycol. The normal OG is less than 10 mOsm/kg and can be determined with the equation, where BUN is blood urea nitrogen.

OG = Measured plasma osmolarity − Calculated plasma osmolarity

$$\text{Calculated plasma osmolarity} = 2[Na^+] + \left(\frac{\text{glucose (mg/dL)}}{18}\right) + \left(\frac{\text{BUN (mg/dL)}}{2.8}\right)$$

Lactic Acidosis

Lactic acidosis occurs when lactate levels exceed 5 mmol/L, with a pH less than 7.35 and an increased AG. It accounts for approximately one-half of all AG metabolic acidoses in the critically ill surgical patient. Lactate has important therapeutic and prognostic implications and has been shown to correlate with outcome in patients in hemorrhagic and septic shock. Lactic acidosis results from tissue hypoxia and anaerobic metabolism resulting in lactate production at a rate that exceeds its clearance. This may be due to sepsis, shock (hypovolemic and cardiogenic), trauma, or severe heart failure; however, not all causes of lactic acidosis are associated with tissue hypoxia, such as seizures, underlying liver disease and poisoning with salicylates, cyanide, and toxic alcohols. Certain medications such as epinephrine, metformin, and linezolid may also cause lactic acidosis.

BOX 1 Anion Gap Metabolic Acidosis: MUDPILES

- Methanol, metformin, muscle injury (rhabdomyolysis)
- Uremia (renal failure), unoccupied (oxidative phosphorylation (cyanide)
- Diabetic ketoacidosis
- Propofol infusion syndrome, paraldehyde, propylene glycol (gastrointestinal, lorazepam)
- Isoniazid
- Lactic acidosis
- Ethanol, ethylene glycol (antifreeze)
- Salicylates, short gut (D lactate with bacterial overgrowth)

Although the majority of lactate is cleared by the liver, up to 20% is eliminated renally. Persistent lactate elevation may result from deficiency of pyruvate dehydrogenase or thiamine, a cofactor of pyruvate dehydrogenase, the enzyme responsible for lactate breakdown. Treatment of lactic acidosis is directed at identifying and treating the cause of this derangement and restoring tissue perfusion. Additionally, appropriate fluid resuscitation and optimization of oxygen delivery are vital. Sequential monitoring of serum lactate levels with arterial or venous samples is a useful therapeutic marker of appropriate resuscitation. Lactate levels should be correlated with the BE and failure to correct these values should prompt the consideration of an ongoing source of shock, including an unidentified injury or source of sepsis. Attempts to counteract the acidosis with exogenous administration of HCO_3^- without addressing the cause of tissue hypoxia will be unsuccessful and may in fact result in a superimposed respiratory acidosis due to the additional CO_2 load that is generated from HCO_3^- metabolism. In patients with maximal respiratory compensation and ventilatory hyperventilation this imbalance can result in worsening acidosis. Other buffers that have a lower CO_2 load such as Carbicarb and sodium acetate may be used when available. Generally speaking, administration of buffers has a limited role in the management of metabolic acidosis. In cases when the pH falls below 7.2 with associated instability, the HCO_3^- deficit may be calculated using the following equation:

HCO_3^- Deficit (mEq/L) = 0.6 × weight (kg) × (15 − plasma HCO_3^- [mEq/L])

This equation partially corrects the HCO_3^- deficit to a concentration of 15 mEq/L, with further correction being unnecessary.

NORMAL ANION GAP METABOLIC ACIDOSIS

A metabolic acidosis with a normal AG results from the loss of plasma HCO_3^- with a compensatory increase in Cl$^-$ reabsorption by the kidneys or from a net gain of Cl$^-$. The differential diagnosis can therefore be divided based on history, with the most common surgical causes being iatrogenic dilutional acidosis from intravenous saline infusion, gastrointestinal losses resulting in decreased body HCO_3^-, or renal failure with diminished H^+ excretion (Box 2).

Rapid administration of normal saline is the most common iatrogenic cause of a normal AG metabolic acidosis. Normal saline has a 1:1 Na^+ to Cl$^-$ ratio, whereas plasma has a ratio of 140:100, which decreases with rapid saline infusions, resulting in a relative increase in Cl$^-$ concentration with new body HCO_3^- losses to maintain electroneutrality. Insufficient urinary excretion of excess Cl$^-$ as ammonium chloride and decreased renal HCO_3^- reabsorption induced by hyperchloremia results in a metabolic acidosis. Evidence suggests that iatrogenic hyperchloremic acidosis results in important adverse clinical effects, with increased rates of renal dysfunction and use of dialysis noted in critically ill patients treated with normal saline compared with balanced crystalloid solutions.

BOX 2 Normal Anion Gap Metabolic Acidosis

Iatrogenic
- Rapid administration of normal saline
- Total parenteral nutrition with insufficient acetate

Kidneys
- Renal tubular acidosis
- Carbonic anhydrase inhibitors
- Spironolactone
- Ureteral diversion

Gastrointestinal tract
- Diarrhea
- Duodenal, biliary, or pancreatic diversion

Normal AG metabolic acidosis as a consequence of renal dysfunction or gastrointestinal (GI) losses can be clinically distinguished using urine pH and urine anion gap calculation using the following formula:

$$\text{Urine anion gap} = \text{urine } (Na^+ + K^+) - Cl^-$$

Renal causes of normal AG metabolic acidosis, such as renal tubular acidosis, result in a net increase in acid resulting from either impaired HCO_3^- absorption in the proximal kidney or inability to secrete H^+ as ammonium in the distal kidney. The urinary pH will be alkaline, usually greater than 5.5, and the urine AG will be positive as a result of increased urinary ammonium.

GI loss of HCO_3^-–rich fluid, commonly resulting from diarrhea, fistulas, and GI diversions, can result in a normal AG metabolic acidosis as a result of disproportionate loss of Na^+ compared to Cl^-. Normal kidneys compensate by increasing H^+ excretion and HCO_3^- regeneration; therefore, the urinary pH is low, usually less than 5, and the urine AG is negative.

METABOLIC ALKALOSIS

Metabolic alkalosis occurs when the plasma $[HCO_3^-]$ exceeds 26 mEq/L and is the most common acid-base disturbance encountered in hospitalized patients. Because normal kidneys are very efficient at excreting HCO_3^-, this typically occurs when there is both an increase in alkali and impaired excretion of HCO_3^-. The differential diagnosis in a patient with this disturbance can be broadly distinguished by whether there is ongoing H^+ loss, either from the GI tract or the kidneys, or exogenous administration of HCO_3^- or bicarbonate precursor, as can occur from citrate in stored blood, acetate in parenteral nutrition, or sodium lactate in Ringer's solution.

In surgical patients, metabolic alkalosis frequently develops as a result of H^+ loss, as can occur with vomiting or nasogastric drainage, or from excess HCO_3^- regeneration as a result of diuretic therapy. In these situations, hypovolemia stimulates aldosterone secretion that in turn stimulates renal excretion of both H^+ and K^+ in exchange for Na^+. This results in reabsorption of Na^+, Cl^-, and HCO_3^-, and K^+ loss. Additionally, hypochloremia, which develops from gastric losses, prevents HCO_3^- excretion by inhibiting renal Cl^-/HCO_3^- exchange. The overall effect leads to the classic hypochloremic, hypokalemic metabolic alkalosis with paradoxical aciduria.

Metabolic alkalosis can occur less commonly as a result of hormonal mechanisms, such as mineralocorticoid excess, which results in a chronic state of Cl^- loss. To distinguish the cause of the disorder, urine Cl^- measurement can be used. A urine Cl^- concentration less than 25 mmol/L is suggestive of acute Cl^- loss, which can be effectively replaced, and thus is chloride responsive. Chloride-responsive metabolic alkalosis is commonly seen in surgical patients and can be treated with intravenous normal saline and potassium supplementation. Formulas for calculating estimated Cl^- deficit and replacement volume of saline needed are available. A urine Cl^- concentration greater than 40 mmol/L is indicative of a hormonal mechanism causing ongoing Cl^- loss, which would be resistant to chloride administration. In this case the supportive treatment includes administration of carbonic anhydrase inhibitors (i.e., acetazolamide) or hydrochloric acid infusion in severe cases while the underlying cause is treated.

RESPIRATORY ACIDOSIS

Respiratory acidosis develops when the $PaCO_2$ exceeds 40 mm Hg, and can be a result of pulmonary or extrapulmonary pathologies that cause inadequate CO_2 elimination by the lungs relative to the rate of CO_2 produced by cellular metabolism. Acute respiratory acidosis can result from depression of the central respiratory center, which may be due to cerebral disease (stroke, trauma) or drugs (narcotics, sedatives). It may also develop from neuromuscular impairment, as can be seen with residual paralysis after general anesthesia, as well as with hypophosphatemia or hypokalemia, or from airway obstruction related to acute exacerbation of obstructive lung disease. Chronic respiratory acidosis is caused by existing neuromuscular disease, chest wall disease such as kyphoscoliosis, or chronic obstructive pulmonary disease. If mechanical ventilation is being used, the minute ventilation rate should be adjusted to reach the desired $PaCO_2$ levels. In patients with chronic respiratory acidosis, caution should be used to not overcorrect CO_2 levels to normal values as this can result in difficulty weaning from the ventilator as well as cerebral ischemia from vasoconstriction. Associated hypoxemia is common in patients with acute respiratory acidosis. In a patient breathing room air, $PaCO_2$ cannot exceed 80 mm Hg before severe, life-threatening hypoxemia develops. Prompt assisted ventilation is vital and treatment should be directed toward the underlying cause.

Central respiratory depression resulting from medications may be addressed with administration of reversal agents such as naloxone or flumazenil, whereas bronchodilators are used in the treatment of airway obstruction. In patients with unaltered sensorium and ability to protect the airway, noninvasive ventilatory support may be a useful adjunct. Mechanical support should be considered in unstable patients, those with deterioration in central nervous system function, recent upper GI surgery, and patients exhibiting signs of respiratory muscle fatigue.

RESPIRATORY ALKALOSIS

Respiratory alkalosis develops when $PaCO_2$ is less than 40 mm Hg, occurring when alveolar ventilation exceeds the rate necessary to eliminate CO_2 produced by cellular metabolism. Acute respiratory alkalosis can result from stimulation of the central respiratory center from pain, fever, central nervous system lesions, and salicylate toxicity. Hyperventilation can also be stimulated by pulmonary receptors in patients with primary pulmonary disorders such as pneumonia, pulmonary edema, or pulmonary embolism. Chronic respiratory alkalosis may be seen in pregnancy, hyperthyroidism, and liver failure.

Severe alkalemia is uncommon in patients with respiratory alkalosis; however, this acid-base derangement should alert the clinician to search for an underlying disorder. In patients who are mechanically ventilated, changes in respiratory rate, tidal volume, or pain/sedation regimen can correct alkalosis that develops from hyperventilation.

Catheter Sepsis in the Intensive Care Unit

Alfred Crotinus, MD, Kenji Kamp, MD, and
Jill R. Cherry-Bukowiec, MD, MS

Central venous catheters (CVCs) have become one of the most essential tools for caring for critically ill patients. Despite their utility, use of CVCs is not without risk. One of the most common, and expensive, complications of CVC use is development of central line–associated bloodstream infection (CLABSI). According to estimates by the Centers for Disease Control and Prevention (CDC) in 2009, there were 18,000 CLABSIs in hospitals across the United States. These infections are considered the costliest healthcare acquired infection (HAI) with an estimated per infection cost of $45,000 due to increased length of stay, additional critical care needs, and prolonged expensive antibiotic treatment. CLABSIs can also be deadly and are associated with a mortality of up to 15%. Because of the significant impact on patients, and the reasoning that most CLABSIs can be prevented, the CDC deemed CLABSI a "never event" in 2008 eliminating reimbursement. This incentivized the healthcare industry to aggressively develop and institute preventative measures, which resulted in significant reductions in the incidence of CLABSI across the United States, effectively saving thousands of lives.

As part of these efforts, the CDC has outlined standardized definitions for infections involving CVCs. A CLABSI is most often used for surveillance. It is a clinical diagnosis requiring laboratory confirmation of a bloodstream infection arising in a patient with a CVC in place for at least 48 hours before the onset of infection and is not caused by an infection at another site. Catheter related bloodstream infection (CRBSI), however, requires a culture positive catheter tip or a differential time to positivity of blood cultures that identify the catheter as the source of the infection, ruling out other sources of the bacteremia/fungemia (Table 1). Evidence based clinical practice guidelines, published in 2009 and 2011 by the Infectious Disease Society of America (IDSA), concisely outline the prevention, diagnosis, and management of catheter related infections and provide the framework for this discussion.

DIAGNOSIS

Index of Suspicion

The presence of CLABSI should be considered in patients with CVCs in place who exhibit derangements in temperature, either fever or hypothermia, without other apparent cause. Manifestations of systemic signs of infection such as hypotension, tachycardia, tachypnea, evidence of decreased perfusion, or altered mental status should raise the index of suspicion for sepsis or septic shock and prompt treatment should follow standard guidelines.

Investigation

When a patient is suspected of having a bloodstream infection, the catheter site should be examined for erythema, discharge, pain, and catheter integrity. Blood cultures should be collected followed by prompt administration of empiric antibiotic treatment. Two blood samples are drawn from a peripheral vein, preferably by a phlebotomy team, as this has been shown to reduce contamination of the culture and reduce the rate of obtaining false positive results. If peripheral samples cannot be obtained, samples may be obtained from the catheter, preferably one set from each lumen. However, it should be noted that contamination of blood cultures taken from catheters are common. Ideally, cultures are sent prior to infusion of antimicrobial therapy, but should not delay antibiotic administration, particularly in the setting of sepsis and septic shock as delay significantly increases morbidity and mortality. If the suspicion for CRBSI is high, removal of the CVC is advised as soon as safe to do so and the tip should be sent for culture. It should also be noted that random culturing and/or surveillance of patients not suspected of having a bloodstream infection is not recommended. Contamination of the blood culture by normal skin flora can lead to excessive false positive results and inappropriate treatment, placing the patient at risk for complications and adding undue cost and length of stay (Fig. 1).

Diagnosis

Definitive diagnosis of CRBSI can be determined in two ways. The first requires that the same organism grow from at least one peripheral blood culture and from the tip of the CVC. Alternatively, one sample from a peripheral vein and one obtained from a catheter hub can meet CRBSI criteria by quantitative blood cultures or differential time to positivity (DTP) blood sample analysis. Quantitative blood cultures are considered the most accurate method. If the colony counts sampled from the catheter are three orders of magnitude greater than those sampled from the periphery with the same organism, the findings are considered diagnostic for CRBSI. DTP blood sample analysis is performed by continuously monitoring blood culture samples for microbial growth. A greater inoculum of bacteria will require a shorter incubation period. When microbial growth in a catheter sample is identified greater than 2 hours before growth is identified in the peripheral samples the source of the infection is considered the catheter and is consistent with diagnosis of a CRBSI. The DTP method has shown similar accuracy when compared to quantitative blood cultures in the critical care population. An approach to diagnosing CVC infections is located in (Fig. 1).

INFECTION PREVENTION

Insertion and Maintenance Bundles

There are four mechanisms by which CVC can become infected and cause a CLABSI: skin colonization, intraluminal or hub contamination, secondary hematogenous seeding from a bloodstream infection, and contamination of infusate (Fig. 2). Over the last 15 years, utilization of evidence based catheter care bundles has reduced rates of CLABSI by more than 70%. The bases of these bundles are rooted in the recommendations from the Joint Commission and IDSA clinical practice guidelines and includes healthcare personnel education and knowledge assessments regarding the proper procedures for insertion and maintenance of CVCs. These bundles can be broken into two major categories, those interventions associated with the insertion of new catheters and those associated with the maintenance of existing lines. Recent recommendations in the literature advocate for inclusion of additional practices or materials, use of commercially prepared insertion kits, and limiting the number of overall attempts at a particular access site to be added to the bundles (Tables 2 and 3).

Patient Preparation

As with every patient encounter, proper hand hygiene practices should be employed immediately before and after patient contact. Use of full barrier precautions, including sterile gowns, gloves, and full patient sterile draping. Always wear eye protection, hat, and mask to protect from splashes. The Joint Commission also recommends using a 2% chlorhexidine gluconate in 70% isopropyl alcohol solution to prep the skin, allowing it to dry for at least 30 seconds. If the patient is sensitive and/or allergic to chlorhexidine, povidone iodine prep is the alternate prep of choice. Maintain aseptic sterile technique throughout the procedure. Using checklists and performing a

TABLE 3 Central Venous Catheter (CVC) Maintenance Bundle

Maintenance Bundle Elements	Recommendations
Daily review of line necessity	Remove unnecessary CVCs promptly
Require accurate documentation	Document CVC location, date of insertion, indwelling duration, date of removal, and any associated complications
Hand hygiene	Perform proper hand hygiene immediately before and after manipulation of the IV system
Catheter injection ports	Cover open lumens (such as catheter hubs, stopcocks, or injection ports) with sterile end caps or needleless connectors Caps should not be changed more frequently than every 72 hours
Maintain catheter site dressing	Change gauze dressing every 2 days, clear dressings every 7 days (and more frequently if soiled, damp, or loose)
Catheter access manipulation	Use aseptic technique for all line access episodes
IV infusion set maintenance	Adhere to institutional evidence-based best practice guidelines
Infusate preparation	Use aseptic technique in preparation and transportation of infusate according to institutional standards
Infusate administration	Prioritize infusions requiring central venous access Minimize use of CVC for infusions not requiring central venous access when possible
Educate personnel	Standardize and mandate routine hands-on and competency-based education for all practitioners involved with CVC placement and maintenance

CVC, central venous catheter; IV, intravenous.

tions set can help to reduce errors and ensure adherence to your local hospital CVC placement guidelines.

Catheter Selection

The more lumens a catheter has and the longer it is in place, the more likely it is going to get infected. Selecting a catheter with the minimum number of lumens required to fulfill its purpose can reduce the infectious risk. If a catheter is not needed, removal is the best way to prevent infection. In situations where a line is expected to be needed for a prolonged duration, use of antimicrobial impregnated catheters can reduce the risk of infection. Antimicrobial impregnated catheters have been extensively studied, and results of these studies to administrators, but do indicate benefits for patients whose catheter is expected to remain in place for more than 7 days. A meta-analysis of chlorhexidine silver sulfadiazine or minocycline rifampin impregnated catheters demonstrated a reduction in the absolute risk of CLABSI and CVC infections, but failed to demonstrate improvement in clinically diagnosed sepsis or mortality.

Peripherally Inserted Central Catheters

Placement of peripherally inserted central catheter (PICC) lines in the neonatal care unit (NICU) has been an ongoing topic of debate. Currently, PICC lines are widely used for patients requiring intermediate and long-term access in outpatient and inpatient settings. Use of these lines in outpatient and not critically ill patients has shown exceptionally low infection rate profile approximately 0.4 infections per 1000 catheter days. Prospective studies have shown, however, that PICC lines used in high-risk hospitalized patients have a comparable rate of CLABSI similar when compared to conventional CVCs (approximately 2 to 5 infections per 1000 catheter days). There have been few [illegible] reporting PICC lines to CVCs associated complications with PICC lines compared to CVCs include high rates of line thrombosis, more challenging blood draws, and increased rate of deep venous thrombosis. It is imperative to utilize PICC lines with caution in patients with renal failure. Preservation of upper extremity veins is required for potential future arteriovenous fistula or arteriovenous graft creation. Salt-laden steroids is also concerning long-term complication in renal failure patients as it can interfere with the creation, function, and durability of arteriovenous fistula.

Indwelling Port and Tunneled Lines

Insertion of indwelling subcutaneous infusion ports and tunneled hemodialysis lines in acutely ill patients is generally avoided, as is accessing ports and tunneled lines already in place at the time of admission. There is an increased risk of CLABSI with repeated use and often patient's acuity is prohibitive for placement, or replacement, of these more invasive lines. If no other suitable intravenous (IV) access is available in an emergent setting, use of indwelling ports and tunneled lines may be required and can be lifesaving. Securing another venous access site should be prioritized according to the patient's condition. The indwelling port/tunneled line should only be used until another infusion access site is secured.

Insertion Site Selection

Several considerations should be kept in mind when selecting a CVC insertion site. Patient condition, practitioner experience, equipment availability, insertion technique, plan for catheter use, intended duration, and infection risk should be weighed. Additional patient factors such as bleeding risk and ability to tolerate complications of line placement must also be considered. Recent studies have demonstrated that the subclavian vein catheterization is associated with the lowest risk of CLABSI (0.9%) compared with femoral (4.7%) or internal jugular (1.9%) catheterization. The authors postulated potential explanations for this observation include a longer subcutaneous course before vein entry, the area with lowest bacterial line burden, and the location with the least dressing disruptions. Conversely, immediate mechanical complication of a pneumothorax is greatest with subclavian vein catheterization, as is the risk of subclavian vein stenosis. The subclavian vein should be avoided if possible in patients with advanced kidney disease and/or who will require long-term hemodialysis as subclavian vein stenosis can interfere with function, ing and durability of upper extremity arteriovenous dialysis fistula.

Dressings

Scheduled maintenance of catheter dressings has reduced the rate of CLABSIs. Several commercially available dressings impregnated with chlorhexidine gluconate are available, and meta-analysis have shown moderate evidence of reduction in both frequency of CRBSI and reduce catheter tip colonization compared with standard dressings. Additionally, the frequency of dressing changes has been shown to affect the rate of infection. The data now supports changing unruffled adherent dressings every 7 days with immediate change of any soiled or leaking dressings.

Catheter Access/Manipulation

Use of CVCs for intermittent intravenous medication administration creates the opportunity for translocation of bacteria. The data are clear that when lines are accessed, proper hand hygiene should be performed before manipulation of the IV system. The connectors should also be scrubbed with disinfecting solutions. Less clear is the precise technique, local duration of scrubbing, and optimal type of disinfectant solutions employed to minimize infection rates.

Intravenous Infusion Tubing Sets

Special consideration should be given to replacing sets immediately after administration of blood products and within 4 hours following administration of infusates that enhance microbial growth, such as fat emulsions and parenteral nutrition.

Connector caps

Open lumens (catheter hubs or stopcocks) should be kept covered when not in use by injection ports, sterile end caps, or needleless connectors. Recently engineered caps impregnated with disinfectant solutions designed to remain on the IV connector in between episodic and require scrubbing before initiation of infusion, administration of medications, or blood draws. This new technology has been studied in a variety of settings from the ICU to oncology units.

Retrospective data indicated that disinfection caps significantly reduce the CLABSI rates from 1.6 infections per 1000 catheter days to 0.6 per 1000 catheter days. Large investigation and prospective studies need to be done in order to ascertain clearer guidelines.

Antimicrobial Locks

The practice of instilling antimicrobial solution in catheters between line uses, to be removed just before the next time the line is used, is commonly termed an antimicrobial "lock." This strategy is often recommended in the outpatient and oncology settings to reduce the incidence of line infections, but this strategy has not been well studied in the acute inpatient setting. Close adherence to line manufacturer inserts is imperative as not all catheters are compatible with the commonly used antimicrobial solutions. Some catheters may degrade with the use of certain types of agents causing erosion, brittleness, and breakage. Additionally, not all catheters have been tested for compatibility with available antimicrobial solutions.

Routine Replacement

Catheter infection risk is directly related to the indwelling duration, and the daily infection rate is considered a constant. Studies have examined the historical practice of routine replacement of central lines. Although the practice was able to decrease the number of infections per any individual catheter, routine CVC changes did not reduce number of infections per catheter day or reduce patient risk. Therefore, routine replacement of CVCs to prevent CLABSI is not supported in the literature and is not recommended.

Process Standardization

Reducing variability in practice can help reduce human error. The Joint Commission recommends insertion bundles include ongoing education about CLABSI prevention, creation of CVC carts that contain all necessary supplies, with checklists to improve adherence to evidence-based practices. Hands-on training of personnel is usually considered most effective. Retention is enhanced when follow-up education is provided at regular intervals. Bedside personnel should be empowered to stop nonemergent procedures when the bundles are not being followed. Proper documentation, including date and name provider performing the procedure, and catheter tip number is recommended. Providing feedback on CLABSI and CRBSI rates can be useful in investigating the cause of negative trends, which can help educate personnel how to and improve adherence to evidence-based guidelines to create and maintain a culture of infection prevention. (An example of an insertion checklist is provided in Fig. 3.)

Preventative Removal

The best way to prevent CLABSIs/CRBSIs is to not have a CVC in place. Daily review for the ability to remove the CVC should be performed and prompt removal of CVC should be done when appropriate. Safe removal practices must be followed to prevent introduction of air emboli and excessive bleeding. Details of removal should be

documented in the medical record including the date, location of the CVC, and identification of the provider.

MANAGEMENT

Antimicrobial Selection

Several professional organizations and institutions have published on management strategies of CRBSI. The most common CRBSIs are caused by *Staphylococcus aureus*, coagulase negative staphylococci, Enterococcus, gram negative bacilli, and *Candida*. Empiric antibiotic treatment regimens should be prescribed based on local antibiograms, with consideration of specific patient factors, such as immunosuppression and ability to remove and/or replace the line. Antimicrobial therapy should be tailored to the organism once culture results are obtained. For complicated or unique situations, such as multidrug resistant organisms or inability to remove CVC access, providers may require alterations to selection and duration of antimicrobials.

Central venous Catheter removal versus Line Salvage

Ideally, all short-term catheters should be removed from patients with CRBSI, if possible. The IDSA guidelines also recommend removal of long-term indwelling catheters and ports from patients with severe sepsis, suppurative thrombophlebitis, or endocarditis secondary to CRBSI. CRBSIs with *S. aureus*, *Candida* sp, pregnant, lung, or myelodysplastic are particularly challenging to treat and usually necessitate the removal of indwelling catheters. There are some cases, however, where line salvage may be attempted. In these cases, antibiotic lock therapy should be used for catheter salvage. If this is not an available modality of treatment, then the systemic antibiotics should be administered through the colonized catheter. If catheter salvage is attempted, surveillance cultures should be taken every 24 hours until negative. If the bloodstream infection persists despite 72 hours of antimicrobial therapy to which the infecting microbes are susceptible, then the CVC should be removed.

SUMMARY

Bloodstream infections from CVCs remain a costly problem with significant morbidity and mortality. Aggressive preventative measures have greatly reduced the incidence of CLABSIs/CRBSIs, yet they persist to be a common clinical problem in the ICU environment. Prevention remains the most critical intervention. Early diagnosis, catheter removal, and timely initiation of appropriate antimicrobial agent tailored to culture results and local antibiograms are the foundation for management.

SEPTIC RESPONSE AND MANAGEMENT

Charles A. Adams ..., M... ...an... ...ole, ... C... ...S, FCCM

Sepsis, a serious, life-threatening condition affecting nearly every organ system in the body, is due to dysregulation of the host's immune inflammatory response to infection. Each year 1.7 million Americans develop sepsis, resulting in nearly 270,000 deaths, one-third of all hospital deaths are due to sepsis. Clearly, sepsis is a public health problem that consumes significant healthcare expenditures in addition to lives. The Surviving Sepsis Campaign, an international effort to raise awareness of the problem and promote evidence-based therapies in a "sepsis bundle" has done a great deal to focus attention and resources on the condition. It is somewhat ironic that the larger medical community has finally embraced many of the basic tenets of managing this condition that surgeons have been practicing for nearly a century.

ABCDE PRINCIPLES

The basic principles of treating sepsis center on its early recognition, eradication of the origin of sepsis, restoration of an effective circulating volume and timely administration of appropriate antibiotics. One of the greatest challenges of treating sepsis is identifying the septic patient, thus it is imperative that clinicians maintain a high index of suspicion that a deteriorating patient may be exhibiting early signs of sepsis. A detailed and thorough history and physical examination should be undertaken to identify a point of infection. Laboratory assessments and radiologic imaging studies can narrow the differential and home in on the correct diagnosis. If an infected focus is identified, concerted efforts to contain or eradicate it should ensue. The act of eliminating the cause of sepsis is termed "source control" and surgeons have been performing this activity for centuries. The inability to obtain source control prolongs the course of sepsis and generally portends a worse outcome than those patients in whom prompt source control is achieved. Studies looking at the effect of source control on sepsis related mortality have found that it is more important than compliance with all other components of the sepsis bundle establishing its prime importance in the management of sepsis.

SOURCE CONTROL

Source control has many components and may include the excision or removal of infected tissue, organs, or foreign bodies. The simplest examples of source control include removal of infected intravenous or urinary catheters. Other implanted devices such as orthopedic hardware or prosthetic meshes are not as easily removed but extensive surgery to remove these devices is often required in cases of severe or life-threatening sepsis. Infected organs that are amenable to surgical extirpation such as the gallbladder, appendix, or sigmoid colon should be removed if they are the *de* cause sepsis. Abscesses should be drained, whereas those in the pleural or peritoneal spaces are

documented in the medical record including the date, location of the CVC, and identification of the provider.

MANAGEMENT

Antimicrobial Selection

Several professional organizations and institutions have published on management strategies of CRBSI. The most common CRBSIs are caused by *Staphylococcus aureus*, coagulase negative staphylococci, Enterococcus, gram negative bacilli, and *Candida*. Empiric antibiotic treatment regimens should be prescribed based on local antibiograms, with consideration of specific patient factors, such as immunosuppression and ability to remove and/or replace the line. Antimicrobial therapy should be tailored to the organisms once culture results are obtained. For complicated or unique situations, such as multidrug resistant organisms or inability to remove CVC access, providers may require alterations to selection and duration of antimicrobials.

Central Venous Catheter Removal versus Line Salvage

Ideally, all short-term catheters should be removed from patients with CRBSI, if possible. The IDSA guidelines also recommend removal of long-term indwelling catheters and ports from patients with severe sepsis, suppurative thrombophlebitis, or endocarditis secondary to CRBSI. CRBSIs with *S. aureus*, *Pseudomonas aeruginosa*, fungi, or mycobacteria are particularly challenging to treat and usually necessitate the removal of indwelling catheters. There are some cases, however, where line salvage may be attempted. In these cases, antibiotic lock therapy should be used for catheter salvage. If this is not an available modality of treatment, then the systemic antibiotics should be administered through the colonized catheter. If catheter salvage is attempted, surveillance cultures should be taken every 24 hours until negative. If the bloodstream infection persists despite 72 hours of antimicrobial therapy to which the infecting microbes are susceptible, then the CVC should be removed.

SUMMARY

Bloodstream infections from CVCs remain a costly problem with significant morbidity and mortality. Aggressive preventative measures have greatly reduced the incidence of CLABSIs/CRBSIs, yet they persist to be a common clinical problem in the ICU environment. Prevention remains the most critical intervention. SEPTIC RESPONSE AND MANAGEMENT

Charles A. Adams Jr, MD, and William G. Cioffi, MD

Sepsis, a serious, life-threatening condition affecting nearly every organ system in the body, is due to dysregulation of the host's immune inflammatory response to infection. Each year, 1.7 million Americans develop sepsis, resulting in nearly 270,000 deaths; one-third of all hospital deaths are due to sepsis. Clearly, sepsis is a public health problem that consumes significant healthcare expenditures in addition to lives. The Surviving Sepsis Campaign, an international effort to raise awareness of the problem and promote evidence-based therapies in a "sepsis bundle" has done a great deal to focus attention and resources on this condition. It is somewhat ironic that the larger medical community has finally embraced many of the basic tenets of managing this condition that surgeons have been practicing for nearly a century.

BASIC PRINCIPLES

The basic principles of treating sepsis center on its early recognition, eradication of the origin of sepsis, restoration of an effective circulating volume and timely administration of appropriate antibiotics. One of the greatest challenges of treating sepsis is identifying the septic patient, thus it is imperative that clinicians maintain a high index of suspicion that a deteriorating patient may be exhibiting early signs of sepsis. A detailed and thorough history and physical examination should be undertaken to identify a point of infection. Laboratory assessments and radiologic imaging studies can narrow the differential and home in on the correct diagnosis. If an infected focus is identified, concerted efforts to contain or eradicate it should ensue. The act of eliminating the cause of sepsis is termed "source control" and surgeons have been performing this activity for centuries. The inability to obtain source control prolongs the course of sepsis and generally portends a worse outcome than those patients in whom prompt source control is achieved. Studies looking at the effect of source control on sepsis-related mortality have found that it is more important than compliance with all other components of the sepsis bundle, establishing its prime importance in the management of sepsis.

SOURCE CONTROL

Source control has many components and may include the excision or removal of infected tissue, organs, or foreign bodies. The simplest examples of source control include removal of infected intravenous or urinary catheters. Other implanted devices such as orthopedic hardware or prosthetic meshes are not so easily removed but extensive surgery to remove these devices is often required in cases of severe or life-threatening sepsis. Infected organs that are amenable to surgical extirpation such as the gallbladder, appendix, or sigmoid colon should be removed if they are the *de* cause sepsis. Abscesses should be drained, whereas those in the pleural or peritoneal spaces are

BOX 1 Red Flag Signs and Symptoms of Necrotizing Soft Tissue Infections

- Hypotension
- Altered mental status
- Pain out of proportion to physical examination
- Rapidly progressing erythema
- Dusky skin color
- Hyperthermia or hypothermia
- Bullae
- Skin necrosis
- Cutaneous anesthesia
- Tachycardia

[illegible] Clin Infect Dis. 2007;45:63–68.

often drained percutaneously. Organ space infections, such as liver abscesses, can be percutaneously drained but it may not be desirable to approach all abscesses in this fashion. Lung abscess are best drained through internal bronchoscopic efforts rather than percutaneous methods to avoid bronchopleural fistulae.

When achieving source control, it is paradoxical that the sicker the patient is, the more aggressive and definitive the attempts at source control must be. Soft tissue infections such as necrotizing fasciitis or necrotizing cellulitis need to be debrided such that all infected and compromised tissue is removed (Box 1). This often requires removal of some healthy uninfected tissue just beyond the area of obvious infection to completely contain the infection, akin to how firefighters contain brush fires. Tentative or limited resection typically allow these infections to continue to spread through adjacent tissue and ultimately results in greater tissue loss than would have occurred had the initial operation been definitive. Inadequate debridement that fails to achieve source control is associated with worse outcomes. In extreme cases in which the soft tissue infection extends into the muscle compartment causing myonecrosis, amputation of infected limbs may be necessary. Similarly, patients in septic shock resulting from *Clostridium difficile* infections require a total abdominal colectomy because limited resections, which fail to achieve source control, frequently result in the patient's demise. A long rectal stump following colectomy may perpetuate sepsis and should be avoided. Vancomycin enemas are a helpful adjunct in very severe cases of *C. difficile* even after surgery. Interestingly, infections where definitive source control cannot be achieved, such as ventilator associated pneumonia or meningitis, usually exhibit a more protracted and prolonged course of sepsis and are often associated with further complications. The benefit of prompt source control cannot be overstated, a recent study revealed that in patients with peritonitis and septic shock, time to operation was an independent predictor of mortality.

DIAGNOSIS

The diagnosis of sepsis can be exceedingly difficult if the source of sepsis is not readily apparent. Various scoring system and clinical decision tools have been proposed to aid in the diagnosis of sepsis however no gold standard exists. The systemic inflammatory response syndrome (SIRS) was initially proposed as an early marker of a patient manifesting septic physiology (Table 1). The concept was that there was an orderly progression from SIRS to severe sepsis to septic shock; however, this continuum has been disproven. In fact, most intensive care unit (ICU) patients meet SIRS criteria on unit admission and many ward patients exhibit two or three criteria at some point during their hospital stay as well, indicating that SIRS criteria are overly sensitive but not very specific for diagnosing sepsis. Although SIRS has fallen out of favor as an indicator of sepsis because most believe it is overly sensitive, a very large retrospective study showed that up to 12% of septic patients had less than two SIRS criteria. This study illustrates the limited ability of SIRS criteria to diagnose sepsis as well as the tremendous genetic variability of response to systemic infections.

TABLE 1 Systemic Inflammatory Response Syndrome Criteria

Temperature	<36°C or >38°C
Heart rate	>90 beats/min
Respiratory rate	>20 breaths/min or partial pressure of carbon dioxide <32 mm Hg
White blood cell	>12,000 cells/mm^3 <4000 cells/mm^3, >10% bands

Two or more need to be present for diagnosis; presence of SIRS in infection may require sepsis.

BOX 2 Six Parameters Composing the National Early Warning System for Sepsis

- Respiratory rate
- Oxygen saturation
- Temperature
- Systolic blood pressure
- Pulse rate
- Level of consciousness/confusion

From Kyriacos RM, Mitchell R, et al. Clinical early warning scores in emergency department triage may allow earlier identification of patients with severe sepsis and septic shock: a retrospective observational study. Emerg Med J. 2014; 31:55–61.

The Third International Consensus Definitions for Sepsis and Septic Shock (aka Sepsis 3) proposed the quick Sequential Sepsis related Organ Failure Assessment (qSOFA) as a rapid and simple bedside tool to help diagnose sepsis. The components of this score comprise hypotension, tachypnea, and altered mental status; derangements in any two of the three should prompt consideration of sepsis. Criticisms of the qSOFA stem from the fact that the patient must manifest end organ damage before the tool suggests the diagnosis of sepsis, thus, the sensitivity of qSOFA may be too low and overreliance on this instrument may expose patients to increased mortality due to delays in diagnosis and treatment. Novel early warning scores for sepsis such as the National Early Warning Score or Modified Early Warning Score consider six clinical parameters that aim to identify patients at risk for deterioration; however, these scores have not yet been validated (Box 2). It is likely that no scoring system, combination of biomarkers, or other clinical decision tool will emerge as the benchmark for diagnosing sepsis because of genetic heterogeneity and the variability of individual manifestations of whole body immune inflammatory activation.

The importance of a detailed and thorough history and physical when encountering a patient who may be septic cannot be overstated, but this process may be adversely affected by sepsis itself. Of all the organ systems impacted by sepsis none is more important than the central nervous system (CNS). The sensitivity of the CNS to dysfunction in sepsis is why nearly every sepsis diagnostic tool or scoring system considers alterations in sensorium or level of consciousness as one of the indicators of sepsis. Septic encephalopathy, a global CNS dysfunction in response to systemic infection, is a common manifestation with an incidence between 30% and 70%. The etiology of this

dysfunction is not well elucidated, but it is thought to be due to the body's inflammatory response to systemic infection. ...ghere there are localizing signs, imaging studies are exceedingly low yield and are not routinely indicated in workup septic encephalopathy. Previously, septic encephalopathy was thought to be transient and reversible; however, emerging data suggest that there may be lifelong neurocognitive deficits in survivors of sepsis. This long-term prolonged CNS dysfunction is one of the central features of postintensive care syndrome (PICS). It appears that PICS may be more common following ICU discharge for sepsis compared with poly trauma or other causes of critical illness. There are no therapies or interventions to treat septic encephalopathy other than supportive care, so its prevention through the timely diagnosis and treatment of sepsis is the best option. Similarly, efforts to avoid ICU delirium appear to be the best intervention to prevent PICS. The interplay between delirium and encephalopathy is complex and not well understood but both likely contribute to PICS. A bundle of ICU based efforts known as the ABCDEF (Assess and treat pain, awakening and spontaneous breathing trials, Choice of drugs, Delirium assessment, Early mobility, and Family engagement) bundle appears to be a very effective strategy to prevent delirium and PICS and decrease overall ICU mortality (Table 2).

As with the CNS, the heart is also sensitive to dysfunction in sepsis, particularly in cases of septic shock. The initial response of the cardiovascular system to systemic infection is to increase cardiac output through tachycardia. This typically results in a hyperdynamic state but as the sepsis progresses, 20% to 50% of patients will manifest sepsis related myocardial dysfunction. Circulating cytokines and other inflammatory mediators promote capillary leak and loss of intravascular fluid into the interstitium, sometimes referred to as the third space. Myocardial dysfunction is compounded by the loss of preload and cardiac output falls due to decreased stroke volume. One of the mainstays of therapy for septic patients is the administration of intravenous crystalloid to restore an effective circulating volume. Nearly two decades ago, a landmark trial showed that aggressive fluid administration to achieve predetermined endpoints of resuscitation within 6 hours in patients with severe sepsis or septic shock yielded lower mortality than standard therapy.

The results of this breakthrough study have had far reaching effects on the management of septic patients and have rendered the resuscitation of septic patients more uniform. Subsequent prospective trials have failed to show a benefit of additional intravenous fluid resuscitation following an effective resuscitation. The interpretation of this finding should not be that fluid administration is not beneficial in sepsis, as previously shown, but rather that the standard of care in managing septic shock now universally includes early and aggressive fluid resuscitation and that supra physiologic resuscitation is not helpful. Three decades ago, a similar finding was observed when surgical patients who were resuscitated and exhibited supra normal parameters had better outcomes compared with those with standard parameters. The survival benefit of supra normal resuscitation was lost when compared with surgical patients who were adequately resuscitated before randomization to an indicated supra physiologic group. Considering these two seminal papers, the goals of resuscitation in septic patients ought to be to administer enough fluid to restore tissue and organ perfusion, while avoiding overresuscitation.

FLUID RESUSCITATION

The definition of adequate fluid resuscitation has always been controversial and despite a myriad of surrogate endpoints, there is no ideal marker or endpoint of resuscitation in sepsis. It is important that clinicians remember this because overreliance on any one single sign is likely to lead to more adverse outcomes than good. Central venous pressure (CVP) has had varying degrees of popularity over the years as a marker of resuscitation. Early sepsis guidelines suggested that patients be resuscitated to a CVP of 8 to 12 mm Hg; however, CVP does not correlate with responsiveness to fluid administration. CVP has limited ability to estimate cardiac preload or left ventricular end diastolic pressure but may help in differentiating certain types of shock states; a high CVP is observed in cardiogenic shock, whereas a low CVP is observed in hypovolemic shock. It must be remembered that CVP is not precise enough to fine tune the amount of fluid to administer to a septic patient. Similarly, elevated lactic acid is found as both an indicator of sepsis and lactate clearance is proposed to be a marker of adequate fluid administration. The kinetics of lactic acid metabolism are variable based on patient genetics, muscle mass, and microcirculation and may be dramatically affected by certain medications. Overreliance on lactic acid determination is likely to result in excess fluid administration, particularly if the lactic acid is due to other causes besides anaerobic tissue metabolism as is seen in so called type B lactic acidosis. Lactate clearance has been extensively studied in sepsis and the preponderance of data suggests that those patients who clear their lactic acidosis will have lower mortality than those who do not clear there is some utility in trending this parameter.

Although sepsis guidelines do not include any recommendations for pulmonary artery catheter (PAC) use in the management of septic patients, it still has an important role in care of the septic patient. The PAC measures cardiac output, systemic and pulmonary vascular resistance, and mixed venous oxygen saturation and facilitates calculation of oxygen delivery and consumption. Of all the measurements and parameters that can be determined from PAC, none is more useful that the mixed venous saturation (S_vO_2). $S-O_2$, the oxygen saturation of the sum of all the venous return to the body, is a global indicator of oxygen delivery and consumption. If the S_vO_2 is above 60%, it can be assumed that all vascular beds are receiving adequate oxygen (and blood flow) but, as with all measurements, there are pitfalls to relying on a single number. S_vO_2 is susceptible to sampling errors and may be falsely elevated in some medical conditions where an arteriovenous shunt exists, such as portal hypertension or in those patients with a hemodialysis fistula. In addition to the morbidity of central access and the catheter itself, PAC use is associated with higher complications, thus its routine use in sepsis is not recommended. Rather

iterations of the sepsis guidelines recommended monitoring of the mixed venous saturation of blood obtained from the superior vena cava ($ScvO_2$) to guide resuscitation of the septic patient. Although some of the morbidity of having a catheter residing inside the patient's heart was avoided, $ScvO_2$ monitoring is associated with many of the same pitfalls that were seen with SvO_2 monitoring. SvO_2 or $ScvO_2$, if available, can aid in the decision to transfuse a septic patient, especially in cases where cardiac output is fixed however restrictive transfusion practices are generally safe in septic patients. A transfusion "trigger" of 7 mg/dL is reasonable.

Systolic cardiac failure is less common in sepsis than diastolic dysfunction but to extreme cases, the heart will manifest both forms of cardiac failure. This biventricular type of infection induced cardiac failure is termed septic cardiomyopathy. Patients with septic cardiomyopathy typically exhibit severely diminished cardiac contractility and a low cardiac output. This type of cardiac failure does not respond to additional fluid administration; these patients require inotropic support to boost their cardiac output. This population typically requires a PAC to guide management. Dobutamine is the most commonly used agent to increase cardiac contractility but it can worsen hypotension via its vasodilatory effect on certain vascular beds. Epinephrine, a second line agent, can augment both cardiac output and blood pressure, but it is arrhythmogenic and can wreak havoc on glucose metabolism. The preferred vasoactive agent in septic shock is norepinephrine because it greatly increases vascular tone and blood pressure as well as increases cardiac output through its inotropic effects. Dopamine should not be used and is associated with higher mortality than norepinephrine in the treatment of septic cardiomyopathy. Patients with hypotension refractory to norepinephrine benefit from treatment with the nonadrenergic agent vasopressin, which increases vascular tone and blood pressure but has no effect on cardiac output or contractility. Interestingly, during a recent shortage of norepinephrine, sepsis mortality was noted to rise in large national databases when phenylephrine was substituted, thus this agent should not be used in the management of septic shock.

CURRENT RECOMMENDATIONS

Current recommendations are to administer 20 mL/kg of balanced crystalloid (e.g., lactated Ringer's) to septic patients exhibiting hypotension and/or increased serum lactate, over 3 hours, which is about 2 L of fluid for an average 70 kg patient. Classic biomarkers such as urinary output, heart rate, blood pressure, and skin perfusion should be continually assessed and monitored for responsiveness to fluid administration and can roughly guide resuscitation. There are conflicting data about the risks and benefits of colloids in the resuscitation of septic patients. Albumin is costly and does not have a mortality benefit or improved organ function when compared to crystalloid resuscitation. Allogenic hydroxyethyl starches, a relatively small molecule, and passes freely from the vasculature into the interstitium in septic patients. This fact is in direct opposition to the often cited dictum that albumin is a large molecule that tends to stay in blood vessels and as such is falsely believed to be a superior resuscitation fluid. The use of hydroxyethyl starches in septic patients is associate with the need for renal replacement therapy and should not be used in the resuscitation of septic patients.

Current sepsis guidelines have moved away from static measurements of serum lactate or global markers of perfusion and now consider fluid responsiveness in identifying those patients requiring further resuscitation. Passively raising a patient's legs 45 degrees by raising the lower half of the hospital bed such that the legs are above the heart is a simple bedside test that can guide fluid resuscitation. Patients who exhibit an increase in systolic blood pressure within 60 seconds of the maneuver are very likely to benefit from additional fluid administration; however, this test can be invalid if the patient has elevated intraabdominal pressures, ascites, etc. Mechanically ventilated patients exhibiting a varying baseline on their arterial tracing are likely intravascularly depleted. As the ventilator cycles, intrathoracic pressure rises, and cardiac preload falls with a resultant narrowing of the pulse pressure. Many bedside monitors are now able to detect and calculate this pulse pressure variation (PPV). Patients with a PPV of 12% or more will benefit from additional intravenous fluid while those with a PPV less than 8% are likely euvolemic. A PPV between 8% and 12% is indeterminate and cannot accurately guide fluid administration.

Bedside echocardiography performed by intensivists is rapidly becoming the modality of choice to help guide fluid resuscitation in septic and critically ill patients. As with PPV, variation in the diameter of the inferior or superior vena cavae during the respiratory cycle can identify those patients who are likely hypovolemic. Patients with small contracted cardiac ventricles require further fluid resuscitation and papillary appearance or "kissing ventricles" strongly indicates that the patient will be fluid responsive. Like PPV, stroke volume variation is another indicator that can guide resuscitation and patients with a stroke volume variation of 12% or more are very likely to be fluid responsive. Narrowing of the outflow tract during systole implies left ventricular underfilling and can also guide fluid management. It is best if several echocardiographic findings are considered and a global picture is constructed indicating the patient's volume status and likelihood of responding to additional fluid rather than fixating on any one single echocardiographic parameter. Although echocardiography is an excellent bedside tool to help guide the resuscitation of septic patients, it has not yet been validated as the gold standard to govern volume resuscitation to sepsis.

Cardiac System

The cardiac system is affected several ways to sepsis and it is not uncommon for a septic patient to manifest elevations to troponin in the bloodstream. Elaboration of troponin from the myocardium is a sign of inflammation rather than a marker of coronary atherosclerosis disease and the treatment of this damage should be to obtain timely source control, begin fluid resuscitation and antibiotic therapy. It is inappropriate to delay either the source control to focus on the troponin elevation and cardiology consultations introduce delays in definitive therapy. Even significant sepsis related cardiac failure will resolve in a few days if the basic directives of sepsis management are observed and long term cardiac dysfunction is not common. Troponin elevation during sepsis is a true biomarker of sepsis related injury and the degree of elevation appears to directly correlate with mortality in sepsis.

As with troponin elevations, atrial fibrillation (AF) is another common finding in sepsis. The most likely explanation for AF in septic patients is that it is due to the presence of multiple inflammatory mediators that makeup septic response. The incidence of AF rises as patients are treated with fluid and vasoactive substances to achieve higher mean arterial pressures (MAPs) rather than lower MAPs. Nearly one in five patients with sepsis will manifest AF and its incidence appears to be higher in those patients with preexisting cardiac comorbidities. Analogous to troponin leaks, the development of AF in sepsis portends a higher mortality. β blocker therapy in the treatment of sepsis related AF confers a survival benefit, but this does not appear to be the case with other rate or rhythm controlling agents such as calcium channel blockers or antidysrhythmics. Amiodarone is preferred over β blockers for AF in patients with a compromised or failing left ventricle. It is likely that some of β blocker's survival benefit is derived from widespread antiinflammatory protective effects and that the survival benefit is not solely derived from its effects on the cardiovascular system. Unlike nonsepsis related AF, anticoagulation to prevent stroke is associated with increased bleeding events. Although evidence to guide clinicians is limited, it appears that the increased bleeding complications of anticoagulation in sepsis outweighs it benefits, particularly in those patients with incisions, drainages, and other surgical interventions.

Lungs

Unlike the heart, the lungs are both a frequent home of sepsis, but as well as a target of the inflammatory products of sepsis. The initial

response of the pulmonary system to sepsis is to increase respiratory rate promoting a respiratory alkalosis to compensate for worsening metabolic acidosis. Ironically this increase in work of breathing contributes to metabolic acidosis as well because ischemic respiratory muscles elaborate lactic acid. Capillary leak and fluid resuscitation increase lung water and alveolar congestion, which hinders oxygen diffusion far more than that of carbon dioxide, resulting in hypoxemia. Respiratory collapse is common in sepsis so early intubation and mechanical ventilation should be done electively rather than in response to respiratory arrest. Bicarbonate causes adrenal vasoconstriction through a direct inhibition of one of the hydroxylases necessary for the creation of cortisol thus other induction agents such as midazolam or ketamine are preferred. Ventilator management should follow the lung protective strategy initially outlined by the Acute Respiratory Distress Syndrome (ARDS) Network consortium. Tidal volumes should be targeted at 6 mL/kg of ideal body weight and respiratory acidosis is tolerated if the patient's pH is 7.2 or greater. This ventilator strategy is termed lung protective or open lung ventilation and aims to minimize volutrauma in patients with ARDS and sepsis related respiratory failure. Similarly, positive end expiratory pressure (PEEP) should be increased to raise mean airway pressure and further limit stretching of the alveoli. The increase in mean airway pressure also improves oxygenation through opening of partially filled alveoli in a process termed recruitment. Inspired fractions of oxygen above 60% are associated with oxygen toxicity and further lung damage, so increased PEEP may also improve oxygenation while limiting toxicity. Lung recruitment improves as PEEP is increased but so do adverse hemodynamic effects, so ventilator management must be tailored to balance the optimization of these two criteria in septic patients. Hypovolemic patients are particularly sensitive to the negative hemodynamic effects of increased PEEP, so it is advisable to allow fluid resuscitation to occur before making significant increases in PEEP.

Patients with severe ARDS may benefit from several additional measures such as prone positioning, advanced ventilator modes, neuromuscular blockade and in severe cases, extra corporeal membrane oxygenation (ECMO). Prone positioning is labor intensive and exposes the patient to complications such as pressure ulcers, dislodgement of medical devices, and limits physical examination, but it can dramatically improve oxygenation in patients with refractory hypoxemia. Several studies have shown that prone positioning confers a mortality benefit when compared to supine ventilation in patients with life threatening ARDS. In extreme cases, patients may be placed into prone position even if they have an open abdomen, but it is prudent to reinforce the temporary abdominal dressing in these patients. Patients failing conventional ventilator management may benefit from advanced modes such as airway pressure release ventilation, jet ventilation, and inverse pressure control ventilation. Patients with profound ventilator dyssynchrony or poor pulmonary compliance with hypoxemia should be paralyzed with neuromuscular blockers (NMBs). NMBs have conferred a mortality benefit in patients with ARDS, but only if the degree of hypoxemia is severe and life threatening. NMB has an added benefit of maximizing oxygen delivery to the brain and vital organs, whereas oxygen consumption by skeletal muscle is minimized; however, NMB use is associated with ICU myopathies and muscle atrophy. ECMO is emerging as an effective rescue strategy for life threatening ARDS and many patient conditions that were formerly believed to be a contraindication to this modality have been disproven. ECMO can accomplish the gas exchange that failing lungs cannot as well as provide cardiovascular support while allowing the lungs to rest and recover from the toxic effects of high pressures, volumes, and required oxygenation.

Kidneys

Perhaps no organ system is more adversely affected in sepsis than are the kidneys since nearly half of septic patients will exhibit acute kidney injury (AKI). AKI increases septic mortality by six to eight times and leads to chronic kidney disease in survivors. Even minor AKI negatively affects survival in sepsis and can have lifelong adverse effects. Sepsis impairs renal perfusion at both the macroscopic and microscopic levels, and septic patients who are normotensive may still develop AKI. As with other organ systems, circulating toxins, oxidative products, cytokines, and other inflammatory mediators that are part of the septic milieu adversely affecting the renal system. The action of these circulating factors can be compounded by hypoperfusion of the kidney; thus, effective fluid resuscitation and management is critical to reducing sepsis-related AKI. The ideal MAP to reduce the occurrence of AKI has not been determined. As previously noted, lactated Ringer's is the preferred fluid because normal saline resuscitation yields higher rates of AKI. Again, the goal should be to restore an effective circulating volume without overresuscitating. - some fluid has detrimental effects on many organ systems, especially the lungs, and in the late stage of sepsis, positive fluid balance contributes to excess mortality. For patients who require renal replacement therapy, there is no clear cut directive governing the type or timing of this therapy despite a multitude of clinical trials. Continuous renal replacement therapy is the practical choice for patients unable to tolerate the negative hemodynamic effects of standard hemodialysis but there appears to be no benefit to early, preemptive continuous renal replacement therapy.

Liver, Pancreas

Unlike the kidneys, sepsis induced liver failure is a rare complication, and its appearance is typically a preterminal event. The liver is intimately involved in the body's response to sepsis and performs a whole host of critically important activities ranging from phagocytosis and clearance of bacteria from the bloodstream, production of countless crucial proteins, regulation of iron metabolism to modulation of the host's inflammatory response. Patients with preexisting liver dysfunction are particularly vulnerable to sepsis that is borne out by the fact that nearly one third of cirrhotic patients will require hospitalization for bacterial infections. Like the liver, outright pancreatic failure is a very uncommon finding in septic patients, however most septic patients will manifest some degree of pancreatic dysfunction. Elevations in serum amylase and lipase are common as are some disturbances in the exocrine function of the pancreas. Digestive insufficiency can adversely affect patient's nutritional status and can lead to malabsorption of fat soluble vitamins resulting in clinical deficiency syndromes, especially in long term ICU patients. Stools should be examined for signs of fat malabsorption and if suspected, replacement therapy with enteral pancreatic enzymes is an effective treatment. While pancreatic endocrine function is minimally affected by sepsis, dysregulation of glucose metabolism is exceedingly common.

The gut has been described as the "motor" of multiple system organ failure, highlighting its importance as both a cause of sepsis as well as a target for sepsis-induced failure. The bowel lymphoid tissue is the largest aggregate of immune cells in the human body and is necessary since the gut is home to more than 100 trillion bacteria known as the microbiome. Although previously thought to be innocuous, the microbiome is being implicated in a wide range of pathologic conditions and is a very active area of investigation. As with the lung, the gut may be the site of a septic focus as well as negatively affected by sepsis from a remote location resulting in an ileus. In the absence of an ileus, the gut ought to be used, several benefits of enteral over parenteral nutrition have been described. Critically ill patients can be tube fed into the stomach and the utility of checking gastric residuals has been disproven, but clinicians must remain vigilant for feeding intolerance. It remains controversial whether transpyloric feedings are safer than gastric feeding, but massive aspiration is far likely and postpyloric feeding is avoided with the transpyloric route. Vasopressors are a relative contraindication to enteral nutrition, however, the threshold for withholding feedings has not been established. In practical terms, patients with escalating requirements for vasopressor support or those requiring a second vasopressor or

lactate should not be enterally fed. Patients who are intolerant of enteral nutrition or in those that cannot have their needs met enterally ought to receive parenteral nutrition and prolonged periods of starvation must be avoided in critically ill patients.

Glucose Control

Like many other forms of organ dysregulation, sepsis induced hyperglycemia is both a marker of disease severity as well as a mediator of further injury. Cytokines, cortisol, catecholamines, and other inflammatory agents cause alterations in the hormonal control of insulin as well as engender a state of peripheral insulin resistance. Although there have been few studies specifically looking at glucose targets in sepsis, there have been several major clinical trials aiming to identify the optimal blood glucose level in critically ill patients. After many iterations, it appears that the ideal glucose value in ICU patients lies between 140 and 180 mg/dL, and the trigger for glucose management should commence at 180 mg/dL. Hyperglycemia is to be avoided because this has been shown several times to be an independent risk factor for death in critically ill patients. Patients with preexisting diabetes are at several fold increased risk of sepsis but surprisingly are not at increased risk for death when admitted to the ICU with sepsis, and those with poor premorbid glucose control have even lower death rates, yielding a "diabetes paradox." This contradiction only applies to ICU patients because diabetic patients admitted to other levels of care in the hospital have worse outcomes than those without diabetes.

One of the greatest controversies in the management of critically ill patients centers around the role of the adrenal glands and corticosteroids in patients with shock. After several conflicting large clinical trials, the current recommendation is that patients requiring vasopressors for blood pressure support ought to be given 200 mg of hydrocortisone in divided doses. There is no need for adrenal stimulation studies or for coadministration of pure mineralocorticoid agent such as fludrocortisone. Interestingly, pure glucocorticoid agents such as dexamethasone appear to treat relative adrenal insufficiency despite a lack of any mineralocorticoid activity; however, this drug is not used to treat adrenal insufficiency. "Stress dose" steroids do not need to be weaned and should be discontinued once the patient is adequately resuscitated and vasopressors are no longer required to maintain MAP. Steroids shorten the time that patients require vasopressors, which has practical benefits, but they do not confer a mortality benefit. Steroid therapy can worsen sepsis induced hyperglycemia and many patients will require exogenous insulin to keep their blood glucose in the desired range. Conversely, despite their well established immunosuppressive actions, stress dose steroids are not associated with increases in infectious complications.

Immune System

The complexity of the immune system and its alterations and dysregulation in response to sepsis is profoundly intricate and is why there is not a single approved medication to reduce mortality in sepsis despite the performance of well over 100 large clinical sepsis trials. Every single component of the humoral and tissue immune systems is altered in response to sepsis and these changes generally follow a similar pattern. Initial immune activation is typically followed by a period of hyperinflammation, resolution to homeostasis, or immune suppression but any one of the conditions may predominate at any given time. In some ways, obtaining source control diminishes the trigger that sets off the immune inflammatory cascade. Complementary to this is the timely administration of appropriate antibiotics directed against the most likely pathogens. Clinical studies have repeatedly shown that the longer the interval is between the onset of sepsis to dosing of appropriate antibiotics, the worse the outcomes. A retrospective review of the Surviving Sepsis database found that in-hospital septic mortality increased for every hour that antibiotic therapy was delayed beginning 2 hours after patients were diagnosed with sepsis. This rise in mortality increased up to a 1.5 times the odds ratio of death when antibiotic therapy was delayed by 6 hours. Much like failure to obtain prompt source control, delays to administering antibiotics to a septic patient contributes to excess mortality.

Antibiotic Selection

Similarly, choosing the wrong empiric antibiotic usually increases the mortality of sepsis by a factor of two to five times. It is imperative that clinicians select antibiotics based on the most likely bacteria for each given septic focus and consider local resistance patterns and patient comorbidities. Blood and other cultures should be obtained at the start of therapy, but antibiotics should never be withheld in that cultures can be drawn. It may be necessary to use more than one agent if the most likely microbes causing sepsis cannot be treated with monotherapy. The possibility that the septic response is due to infections caused by yeast or viruses should not be overlooked, particularly in patients taking immune modulating agents for inflammatory conditions or immunosuppression following transplantation.

Considering the mortality of delayed or inappropriate antibiotic selection in the treatment of sepsis, clinicians must resist the urge to use overly broad antibiotics or powerful last line agents. Doing so will lead to opportunistic infections, antibiotic resistant infections, and further complications. Accordingly, antibiotic therapy ought to tailor based on culture results as these become available, typically in 2 or 3 days, and the broad spectrum empiric antibiotics switched to the narrowest possible agent. This process is known as antibiotic deescalation and it minimizes antibiotic resistance, opportunistic infections, and waste of resources. The duration of antibiotic therapy ought to be limited based on available evidence in the literature and there is no role for long courses of broad spectrum "empiric" antibiotics even for the sickest patients. Patients with pertonsitis who achieve source control can be treated with a 4 day duration of antibiotics based on clinical data. Similarly, ventilator associated pneumonia can be treated with 8 days of therapy for all bacterial infections except those caused by the Enterobacteriaceae family.

Occasionally a patient will manifest ongoing sepsis for several days despite negative culture data and no obvious source. This conundrum is particularly vexing if the patient is elderly or has serious medical comorbidities. In this situation, all antibiotics should be stopped, and new cultures obtained from blood and other likely sites of infection. An exhaustive physical examination should be performed, and computed tomography scanning is usually required to assess for occult infections in the peritoneal and/or thoracic cavities. Surgeons must be humble and should consider that the source of sepsis may be a complication of their surgical intervention. If a septic source is identified, vigorous efforts to achieve source control should be undertaken and reoperative surgery is often necessary. Although stopping antibiotics in someone with ongoing sepsis seems risky, another way of looking at this is that the patient is not responding to the antibiotics that he or she is receiving so stopping them can do no further harm.

SUMMARY

Sepsis remains a challenging and costly problem for society, and surgeons continue to play a central role in its therapy. The diagnosis of sepsis remains difficult because of its variable presentation, so it is mandatory that clinicians have a high index of suspicion that a deteriorating patient could be septic. Overreliance on septic clinical parameters, biomarkers, or laboratory value is likely to lead to complications and higher mortality. Therapeutic interventions and management strategies need to be continually reevaluated because what seems like an effective or beneficial therapy is often found to be untrue when rigorously studied. Sepsis mortality has fallen as the principles of source control, fluid resuscitation, and timely antibiotics have become widely embraced and surgeons need to stay involved in this process if the best outcomes are to be achieved.

Multiple Organ Dysfunction and Failure

Mitchell Ryan Levitt, MD, PhD and Arthur Vanessa Vaughn, MD

Critically ill patients are complex and require a systematic approach to ensure excellent care. They are often managed by thinking about each system in turn so that all of their maladies are considered and appropriately treated. Unfortunately, despite a physician's best efforts, patients may deteriorate to the point that multiple organs are dysfunctional and heading toward failure. When this occurs, the acuity and complexity of these patients escalate and considerable attention to the details of each system is paramount.

After a short history of the term multiple organ failure (MOF), this chapter will briefly discuss the end-organ dysfunction and failure often encountered in each organ system in critically ill surgical patients. Appropriate grading systems for the organ systems and patients as a whole will be discussed, as well as a few special populations that deserve mention. Finally, the importance of when to consider end of life and palliative care is included.

History

The term *multiple organ failure* was first coined by Arthur Baue in 1975. In the years following, numerous attempts have been made to ascribe an etiology and pathophysiology to this entity while recognizing that each organ system may suffer some dysfunction without being in frank failure. Organ dysfunction that occurs short of failure has now been termed multiorgan dysfunction syndrome (MODS). Decades of research have ensued in an effort to effectively treat and reverse MODS before it becomes MOF, and many advances have been made. Aside from correcting the underlying etiology, however, there has been no single treatment strategy that can be used to cure all patients. Moreover, salvage therapies are lacking for severe MODS that progresses to MOF.

Dysfunction and Failure by Organ System

Neurologic

The neurologic function of critically ill patients is often abnormal and can be affected by numerous factors. Mental status change is a common early sign of MODS and shock; however, delirium, stroke, traumatic brain injury, and exposure to sedative medications also cause altered mental status and should remain on the differential.

When a patient's mental status deteriorates, a prompt workup should occur to determine the underlying cause and the change should not be attributed to medications alone. Effects of medications on mental status, while important to consider, should essentially be a diagnosis of exclusion. The earliest and most often used assessment of global neurologic function in the initial evaluation is the Glasgow Coma Score (GCS; Table 1). Patients with a GCS of 8 or less have a mental status change significant to prevent them from protecting their airway and intubation should be considered. Further, GCS is included as part of the Sequential Organ Failure Assessment (SOFA) score (Table 2) and the Marshall MOD Score (Table 3), since on the SOFA and quick SOFA scores appear in the section on scoring systems) and thus is essential in evaluating a newly critically ill patient.

Pain control is also a parameter used to assess neurologic dysfunction. Patients with seemingly increased or out of proportion pain should be assessed for an underlying etiology. The addition of the pain could be one of the many causes of MODS or MOF (i.e., abscess, sepsis, bowel perforation, and bleeding). If these underlying etiologies have been ruled out, a multimodal pain regimen should be implemented that adequately controls pain while limiting the risk of delirium. More recently, intensive care units (ICUs) have adopted pain, agitation, and delirium protocols to help better treat these conditions in a more real time way using bedside nursing assessment to drive management. Pain services should be used for patients requiring increasing pain medications, and neuraxial blockade should be considered if appropriate.

There is evidence that ICU patients may have brain dysfunction and depression that lingers beyond their recovery. It is well recognized that to prevent changes in consciousness and reduce delirium in the ICU, we should strive to maintain sleep-wake cycles, reduce sedation as much as is possible in mechanically ventilated patients (by providing sedation vacations), avoid benzodiazepines, and be aggressive with physical therapy and daily mobilization.

The ultimate central nervous system dysfunction or failure is brain death. Brain death can be thought as from any of the causes mentioned previously if they ultimately result in global ischemia of the brain and subsequently the absence of blood flow to the brain. This typically occurs as a result of increased intracranial pressure such that it decreases cerebral perfusion pressure to the point that the brain completely dies. Once this happens, the damage is irreversible. The legal declaration of brain death varies from state to state, but typically requires at least two examinations by two providers with an interval observation period. In addition, to be declared brain dead, metabolic causes of brain dysfunction must be excluded. These include being normothermic, having a negative toxicology screen, normal electrolytes, and normal acid base status.

Cardiovascular

Dysfunction of the cardiovascular system, in the form of hypotension and shock, is perhaps the most frequent cause of ICU admission. Cardiovascular abnormalities can have numerous causes and in the noncardiac surgical patient, is often a secondary result from a different primary disease, for example sepsis. Cardiac complications from surgery do occur and cardiovascular collapse can be due to postoperative myocardial infarction, submassive or massive pulmonary

embolism, or atrial fibrillation. Distinguishing the cause of cardiovascular collapse is important because the physiology surrounding cardiovascular dysfunction will dictate its treatment. Bedside and formal echocardiography may be helpful in determining the cause of cardiovascular dysfunction if the diagnosis is unclear. Echocardiography may also be helpful in tracking the adequacy of resuscitation both by evaluating the ventricular function, assessing valvular abnormalities, atrial filling, and fullness of the inferior vena cava.

In the setting of distributive shock (e.g., sepsis, anaphylaxis) there is vasodilation, capillary leak, and resulting hypotension. In hypovolemic/hemorrhagic shock, there is vasoconstriction in an attempt to preserve blood pressure, however, because of the low blood volume, hypotension persists. Cardiogenic shock is due to injury to the heart itself and results in pump dysfunction or failure, that then leads to poor blood distribution to end organs resulting in vasoconstriction, cold extremities, and ultimately hypotension resulting from inadequate pumping. Obstructive shock causes a central cardiac outflow obstruction that results in hypotension. Neurogenic shock results in vasodilation, reduced preload, and frequently bradycardia all of which work together to cause hypotension. Different types of shock are treated with different algorithms, it is important to recognize the type of shock a patient has and treat accordingly.

Cardiovascular dysfunction sets off a cascade of injury to other organ systems because of inadequate perfusion. It is therefore imperative to support the cardiovascular system, regardless of the cause of dysfunction, to prevent further injury to end organs. This is often done with a combination of fluid resuscitation and vasopressors depending on the type of shock present. In general, these interventions are targeted to maintain a mean arterial pressure (MAP) of 65 and lactate less than 2 mmol/L to ensure adequate end organ perfusion. Details of management for each of type of shock can be

found elsewhere in this text but will be reviewed briefly here. Distributive shock, which is most commonly associated with sepsis, is treated using Surviving Sepsis principles with aggressive fluid resuscitation (typically 30 mL/kg in bolus form over the first 3 hours), antibiotics (which should be given within an hour of the first episode of hypotension), and source control. If MAPs are still not adequate, norepinephrine should be used as the vasopressor of choice. On occasion, vasopressin can be added for extra support, but this does not change overall mortality. In the case of anaphylactic shock, epinephrine should be administered. The treatment of hypovolemic/hemorrhagic shock should consist of fluid/blood resuscitation combined with controlling the source of blood or fluid loss. In addition, vasopressors can be added if necessary and typically norepinephrine or phenylephrine are used. Cardiogenic shock requires inotropic support and epinephrine is usually the best first line agent for this; however, dobutamine is also used frequently and can be added as a second line agent (note that supporting heart failure is in fact more nuanced than this depending on whether failure is systolic, diastolic, left or right sided, but this is discussed elsewhere in this text). Intra-aortic balloon pumps and transvenous pacing may also be necessary with extracorporeal membrane oxygenation as another potential salvage option. Obstructive shock is most commonly from a large pulmonary embolus and this should be treated with tissue plasminogen activator, anticoagulation, or pulmonary thromboembolectomy depending on the severity of the situation and presence or absence of contraindications to tissue plasminogen activator or anticoagulation. Neurogenic shock is treated with large volumes of intravenous fluids to fill the venous system and augmented with phenylephrine to help maintain MAP. If neurogenic shock is associated with severe bradycardia, dopamine may be preferred over phenylephrine to improve chronotropy while simultaneously providing alpha 1 stimulation. If untreated, the final common pathway for cardiovascular dysfunction and collapse is cardiac arrest.

Pulmonary

Inadequate gas exchange and pulmonary failure are a mainstay of critical illness. MODS, and MOF. In general, the pulmonary failure of MODS in the ICU manifests as the acute respiratory distress syndrome (ARDS). ARDS can result from direct or indirect lung injury. Direct lung injury is as it sounds with an insult to the lungs such as pneumonia, aspiration, smoke inhalation injury, or traumatic lung injury. Indirect lung injury is when inflammation or a nonpulmonary insult results in ARDS such as sepsis, hemorrhage/hypovolemia (often from a combination of inflammation and aggressive fluid resuscitation), transfusion related lung injury, or severe pancreatitis. Both categories of lung injury are common in the surgical ICU.

The pathophysiology of ARDS involves poor oxygen exchange across the alveolar membrane. The initial effect of ARDS is atelectasis and ventilation perfusion mismatch. This is quickly followed by neutrophil activation and sequestration in the lungs where they degranulate, releasing inflammatory molecules. This results in a capillary leak and increased fluid and edema of the alveoli preventing oxygen diffusion. As the process continues, inflammation leads to fibrosis further worsening oxygen exchange and so called hyaline membrane disease can develop. If severe enough, patients with ARDS will die of failure to oxygenate. Due to the initial exudative stage of diffuse alveolar damage and lasts 7 to 10 days. If patients survive this stage, they may progress through the fibroproliferative stage and ultimately the fibrotic stage.

The Berlin criteria have been developed to aid in the diagnosis of ARDS. For the diagnosis, all of the following criteria must be present: respiratory symptoms started within 1 week of inciting insult, bilateral opacities must be present on radiograph or computed tomography, the respiratory failure must not be fully explained by cardiac disease or fluid overload, and a moderate impairment of oxygenation must be present (i.e., at least a minimum partial pressure of oxygen/fraction of inspired oxygen ratio of less than or equal to 300 mm Hg when on positive end expiratory pressure or continuous positive airway pressure of 5 cm H_2O).

Patients with ARDS require respiratory support that minimizes volutrauma/barotrauma to the lungs and worsening of the lung disease using the guidelines well published by the ARDSNet group. The principles of ARDSNet ventilation include low tidal volumes (6 mL/kg of predicted body weight), permissive hypercapnia, and maintaining a plateau pressure of 30 cm H_2O or less with the oxygenation goal of partial pressure of oxygen 55 to 80 or blood oxygen saturation 88% to 95% and pH goal of ~ 30 to 7.45. Overresuscitation should be avoided to prevent further worsening of oxygenation. If ARDSNet strategy of ventilation does not provide enough oxygenation, appropriate patients may be placed in prone position and/or given a paralytic to improve survival. If done, these maneuvers should not be delayed because benefit is improved with earlier initiation. Other modes of ventilation may be attempted such as airway pressure release ventilation, bilevel, or in some settings, high frequency oscillatory ventilation as salvage therapies. Inhaled nitric oxide is also used on occasion to improve oxygenation, but with no proven survival benefit. Finally, patients that continue to have respiratory failure, extracorporeal membrane oxygenation may be necessary to provide adequate oxygen, prevent further barotrauma, and to allow the lungs to heal.

Renal

Acute kidney injury (AKI) is common to the surgical patient and the ICU. It is estimated that AKI affects 2% to 18% of all hospital inpatients and 20% to 57% of ICU admissions. Of the cases of AKI, 30% to 40% occur in the perioperative setting. There are numerous causes of AKI such as prolonged hypotension (from hypovolemia, heart failure, etc.), sepsis/inflammation (one of the most common causes in the ICU setting), exposure to nephrotoxic drugs/toxins (including iodinated contrast), microangiopathic hemolytic anemias, or vasculitis. AKI carries with it a significant increase in perioperative mortality, with some studies suggesting 30 day mortality as high as 34% compared with 1.0% in those without AKI.

The definition of AKI has been murky, but consensus definitions have been in place now since 2004; however, there are currently three different criteria for defining AKI: the risk, injury, failure, and stage renal disease (or RIFLE criteria), the criteria put forth by the Acute Kidney Injury Network (or AKIN criteria), and the Kidney Disease: Improving Global Outcomes Foundation (or KDIGO) criteria. They have similarities and overlap in their definitions (Table *). The RIFLE criteria evaluate urine output and relative changes in serum creatinine, the AKIN criteria are similar but allow for absolute changes in serum creatinine to define injury, and the KDIGO criteria combine the RIFLE and AKIN criteria but add an allowance for short term changes in 48 hours and for those that occur over a longer time course (i.e., 7 days). Numerous biomarkers have been investigated to help identify AKI early, but to date none of them have the sensitivity nor specificity to be useful clinically.

AKI has traditionally been categorized as having one of three broad causes: pre renal, intrinsic kidney injury, and postrenal. In reality, AKI is often multifactorial and a patient can be suffering from more than one of the basic pathophysiologic mechanisms (i.e., prolonged pre- or postrenal injury can result in intrinsic injury). In addition, one should think about intrinsic renal injury by the region of the kidney affected: damage to the renal vasculature from emboli or vasculitides, damage to the renal interstitium from allergic reactions or infection, or damage to the renal tubules resulting from inflammation from toxins such as contrast, antibiotics, myoglobin, or hemoglobin.

The perioperative patient has many factors that put them at risk for AKI. First, there are numerous comorbidities that have been recognized as increasing the risk of AKI: obesity, chronic kidney disease, diabetes, cardiovascular disease, liver disease, chronic obstructive pulmonary disease, smoking, chronic steroid use, and cancer. In addition, the type (e.g., cardiac, transplant) and urgency of surgery being performed can increase the risk. Intraoperative factors also play

TABLE 4 RIFLE, AKIN, and KDIGO Classifications of Renal Failure

Stage	↑Serum Creatinine	Urine Output
RIFLE CLASSIFICATION OF RENAL FAILURE		
R: Risk for renal injury	Baseline Cr × 1.5 Decrease GFR >25%	<0.5 mL/kg/hr × 6 hr
I: Injury to kidney	Baseline Cr × 2 Decrease GFR >50%	<0.5 mL/kg/hr × 12 hr
F: Renal failure	Baseline Cr × 3 Cr >4 mg/dL with increase ≥0.0 mg/dL Decrease GFR >75%	<0.3 mL/kg/hr × 24 hr Anuria × 12 hr
L: Loss of renal function	Persistent renal failure Loss of renal function >4 weeks	
E: ESRD	Renal failure >3 months	
ACUTE KIDNEY INJURY NETWORK (AKIN) CLASSIFICATION OF AKI		
1	Baseline Cr × 1.5–2 Increase >0.3 mg/dL in 48 hr	<0.5 mL/kg/hr × 6 hr
2	Baseline Cr × 2–3	<0.5 mL/kg/hr × 12 hr
3	Baseline Cr × 3 Cr >4 mg/dL with acute increase 0.5 mg/dL Renal replacement therapy	<0.3 mL/kg/hr × 24 hr Anuria × 12 hr
KIDNEY DISEASE IMPROVING GLOBAL OUTCOMES (KDIGO) STAGING OF AKI		
1	Baseline × 1.5–1.9 Increase >0.3 mg/dL	<0.5 mL/kg/hr for 6–12 hr
2	Baseline × 2–2.9	<0.5 mL/kg/hr for >12 hr
3	Baseline × 3 Increase >4 mg/dL Initiation of renal replacement therapy <18 years old, decreased GFR <35 mL/min per 1.73 m²	<0.3 mL/kg/hr for 24 hr Anuria >12 hr

AKI, Acute kidney injury; Cr, creatinine; ESRD, end-stage renal disease; GFR, glomerular filtration rate.

a role. In particular, hypovolemia, hypotension (from hypovolemia or decreased systemic vascular resistance from anesthetic), increased intraabdominal pressure, or direct injury to the kidneys themselves. The use of nonbalanced fluids (normal saline) can result in hyperchloremia, which is associated with perioperative AKI. Interestingly, intraoperative urine output does not correlate well to risk for AKI at least for elective surgeries. This is likely because the fluid administered during anesthesia has reduced distribution and clearance from the vascular space and thus intraoperative oliguria may not accurately reflect the actual fluid status of the patient. To reduce a patient's risk of postoperative AKI, one must consider all possible risk factors, modify those that can be changed preoperatively, minimize the intraoperative risk of developing AKI by maintaining an intraoperative MAP of ≥65 mm Hg or greater with the use of fluids and vasopressors when necessary, and avoiding nephrotoxic drugs when able.

The primary treatment for AKI, once it has started, is to fix its underlying cause (fluid resuscitate the patient, treat sepsis, improve cardiac output, and avoid nephrotoxic drugs as examples) along with supportive care, assuming the patient has not progressed to kidney failure requiring renal replacement therapy. If kidney failure does occur, then renal replacement therapy should be initiated if indicated (i.e., volume overload, acidosis, electrolyte disturbances, hyperkalemia, hyperuremia in particular). In the ICU setting, this is commonly done via hemofiltration using continuous venovenous hemodialysis because it results in fewer swings in blood pressure. However, once a patient is stabilized, intermittent hemodialysis can also be performed.

Gastrointestinal

Gastrointestinal (GI) dysfunction and failure occur in ICU patients as a result of either direct injury or indirect injury secondary to hypoperfusion. Once injury occurs, there can be loss in the normal gut flora and barrier, causing translocation of gut bacteria and bacterial products into the lymphatics and bloodstream causing severe inflammation. GI dysfunction can be difficult to diagnose and there are a wide variety of definitions of it in the literature. More recently a consensus definition of four grades of acute gastrointestinal injury (AGI) has been developed by the Working Group on Abdominal Problems of the European Society of Intensive Care Medicine. These definitions were developed for research purposes and have not yet been well validated in the clinical setting.

In general, the new consensus definitions of AGI involve diagnosis by clinical symptoms with the assistance of radiologic studies (i.e., abdominal radiographs and computed tomography scans). There are no good nor validated biomarkers or blood tests (such as creatinine for kidney function) that can define, quantify, or help follow AGI. AGI grade I represents being at risk for injury and involves still limiting symptoms such as postoperative nausea/vomiting, mild diarrhea, and abdominal distention. AGI grade II is GI dysfunction that requires interventions, consists of severe or several less severe symptoms, and which does not cause deterioration of the patient's general medical condition. Examples of dysfunction in this category include gastroparesis, having large gastric residual volumes (typically considered to be more than 250 mL), thus, severe diarrhea requiring electrolyte correction,

grade I: intraabdominal hypertension (intraabdominal pressure of 12–15), or visible blood in gastric contents or stool. ACS grade III represents GI failure, defined as symptoms that persist or progress despite interventions or that is part of worsening MODS. Symptoms in ACS grade III include all those of grade II, which worsen despite intervention and also include persistent abdominal signs. Finally, ACS grade IV is GI failure that is life threatening. Examples of grade IV would include necrotic bowel, GI bleeding causing hemorrhagic shock, Ogilvie's syndrome, and abdominal compartment syndrome.

Management of ACS depends on the symptoms and should be approached systematically. In general, enteral nutrition should be used to feed the gut and at least trophic feeds (typically agreed on to be 20 mL/hr of feeds) should be attempted in patients as long as they do not have ACS grade IV and they are able to tolerate it. Trophic feeds help maintain gut barrier function and prevent the abnormal translocation of enteric bacteria into the lymphatics and bloodstream and thus systemic infection. When possible, prevention of ACS should be the goal, accomplished by minimizing narcotics and sedatives, early mobilization, early enteral nutrition, and early institution of a bowel regimen; however, many of these interventions may be difficult to achieve in an ICU patient.

Hepatic

Although the liver can initiate MODS, especially in the setting of acute liver failure or acute on chronic liver failure, it is frequently secondarily involved. Hepatic dysfunction as a part of MODS has two phenotypes: acute sudden failure, termed shock liver, or a more insidious dysfunction that presents as mild hyperbilirubinemia with or without cholestasis and normal liver function. In shock liver, the first abnormality observed is a marked elevation in transaminases, followed by hyperbilirubinemia, and, last, a loss of synthetic function represented by an increase in international normalized ratio, hypoglycemia, and hyperammonemia. The second form of hepatic dysfunction typically resolves if MODS resolves. Treatment of hepatic dysfunction, in addition to treating the underlying cause of MODS, is supportive care of the liver while avoiding hepatotoxins that might worsen the injury. In addition, patients should receive adequate nutrition and have their encephalopathy (if present) closely managed.

When shock liver is severe, the inflammatory mediators from the Kupffer cells of the liver spill over into the systemic circulation and can greatly affect and damage other organ systems. In addition to synthetic dysfunction in their failure causing a coagulopathy, patients may also have trouble clearing lactate and an already nutritional hypoglycemia and hyperammonemia. Inflammation from the liver can affect the brain causing encephalopathy from hyperammonemia and cerebral edema from inflammation in microglial cells and glutamine accumulation in astrocytes. Not surprisingly, if hepatic failure or dysfunction is the initial insult, it can also cause ARDS, AKI, shock, and, as previously mentioned, MODS with MOF.

Endocrine/Metabolic

Critical illness, surgical, and traumatic insults all result in a wide variety of endocrine and subsequently metabolic disturbances. Both the central nervous system and the innate immune system are involved in recognizing and responding to threats of homeostasis (i.e., injury/infection), with the central nervous system being responsible for perceiving and responding to macroscopic threats and the innate immune system responsible for recognizing microscopic threats (e.g., pathogens). The responses to injury that ensue affect the hypothalamic–pituitary–adrenal axis, glucose metabolism, and the hypothalamic–pituitary–thyroid axis. Each of these will be discussed briefly in turn.

Adrenal insufficiency is a common problem in the ICU. The initial response of the hypothalamic–pituitary–adrenal axis to critical illness is to increase cortisol secretion usually in proportion to the injury sustained. As inflammation continues, this system is exhausted and relative adrenal insufficiency may develop. Cortisol is important because it maintains the vascular reactivity to catecholamines. Historically, adrenocorticotropic hormone stimulation tests were performed to assess for adrenal insufficiency and to determine who should be treated with exogenous steroids. This has fallen out of favor, and now steroids are recommended only for those patients that do not respond appropriately to adequate resuscitation with fluids and the appropriate vasopressors. In these cases, hydrocortisone is administered at no more than 300 mg/d in divided doses. The adrenal gland is also responsible for the secretion of vasopressin (also known as ADH). Vasopressin acts on numerous receptors to increase vascular vasoconstriction, to increase water reabsorption, and it even acts centrally in the anterior pituitary to stimulate the release of adrenocorticotropic hormone; thus, vasopressin has effects on cortisol secretion. After initial injury, vasopressin levels rise rapidly, but then also fall rapidly. Vasopressin levels are not routinely measured because a majority of it is bound to platelets and it has a short half-life. Although vasopressin is not recommended as a first-line vasopressor agent, it can be added (as described previously) in low doses if normal MAPs are not achievable after adequate fluid resuscitation and other vasopressors maximized. When vasopressin is added, it is typically only in a dose of 0.02 to 0.04 U/min.

Critical illness causes a hypermetabolic state because of a surge of catecholamines, cortisol, glucagon, and growth hormone. The release of these substances results in insulin resistance, hepatic gluconeogenesis, muscle catabolism, and hyperglycemia. Uncontrolled hyperglycemia is known to cause numerous increased risks and complications in the critically ill such as increased risk of infection, neurologic outcomes, and increase in mortality. Potential mechanisms for worsening outcomes in hyperglycemic patients include effects on the host response such as reduced chemotaxis, phagocytosis, increased inflammatory cytokines, increased oxygen free radicals, prothrombotic effects, and dysregulation in the production of endothelial nitric oxide production. Thus, glucose should be monitored and controlled within a reasonable range. Current recommendations suggest a permissive hyperglycemia with a glucose target range of 140 mg/dL to 180 mg/dL to prevent excessive hyperglycemia while avoiding life-threatening hypoglycemia.

Thyroid abnormalities are common in critical illness and are often referred to as sick euthyroid syndrome or nonthyroidal illness syndrome. The decrease in thyroid hormone is mediated primarily by inflammatory cytokines and is thought to be a protective mechanism to increase resistance to stressors by reducing cellular metabolism. Sick euthyroid syndrome begins with a decrease in T_3 as a result of decreased conversion of T_4 to T_3. This is followed by a subsequent decrease in T_4 and thyroid binding globulin. These abnormalities typically correct once the critical illness is resolved and no specific treatment is needed and should not be implemented. If a patient is found to have sick euthyroid syndrome, they may benefit from repeat thyroid testing once they are well to ensure they do not have baseline thyroid dysfunction.

Immunohematologic/Disseminated Intravascular Coagulation

Anemia is common in the ICU, with estimates that 30% to 50% of ICU patients receive red blood cell transfusions. Anemia in the ICU occurs via mechanisms associated with anemia of inflammation or chronic disease. There are three main abnormalities associated with the host response that result in anemia: dysregulation of iron homeostasis, impaired proliferation of erythroid progenitor cells, and decreased erythropoietin response. Numerous clinical trials have evaluated whether a liberal or restrictive transfusion strategy should be used in the ICU with the overwhelming evidence supporting a restrictive transfusion strategy (i.e., only transfusing patients with blood if their hemoglobin is less than 7 g/dL, or less than 8 g/dL if the patient has an acute coronary syndrome). The exception to these transfusion thresholds is the bleeding patient who should receive blood as necessary; however, once bleeding is controlled, a restrictive transfusion strategy should be maintained. In addition, these transfusion triggers should not be used blindly, but should be considered in concert with the clinical parameters of the patient and with

regard to their overall tissue oxygenation. Anemia in the ICU can be exacerbated by phlebotomy and so all strategies to reduce anemia in the ICU should also be used. These include decreasing phlebotomy, using low volume blood sample tubes, using as few blood conservation devices that reinfuse waste blood, and using cell salvage during surgical procedures when possible.

Thrombocytopenia is generally defined as a platelet count less than 150,000/μL, although more recently it has been graded into mild, moderate, and severe thrombocytopenia corresponding to platelet counts of 100,000 to 149,000/μL; 50,000 to 99,000/μL, and less than 50,000/μL. Thrombocytopenia can have numerous etiologies such as heparin induced, drug induced, autoimmune disease, sepsis, disseminated intravascular coagulation (DIC), consumption (from trauma or cardiopulmonary bypass), or mechanical circulatory devices such as intraaortic balloon pump. The most common causes in the ICU are sepsis, DIC, consumption, and mechanical circulatory support devices. Exact transfusion thresholds for platelets have not been as well studied as for red blood cells, but general guidelines exist and depend on the risk of bleeding. In patients with ongoing bleeding, platelet counts should be kept above 50,000/μL. If the bleeding is intracranial or a neurosurgical intervention is being planned, the goal should be 100,000/μL. Otherwise, without bleeding or planned intervention, a platelet transfusion threshold of 10,000/μL is recommended. Other recommendations include the following thresholds: greater than 10,000 to 20,000/μL for central venous catheter placement, greater than 50,000/μL for laparotomy or chest tube placement, and greater than 20,000/μL for lumbar puncture.

Coagulopathy is also common in the critically ill and like anemia and thrombocytopenia has the same numerous potential causes. In addition, liver failure can result in decreased synthesis of coagulation factors and administration of anticoagulant medications can alter the clotting cascade. Despite this, there are specific indications for transfusion of plasma and almost all relate to active bleeding. Thus, in those patients that have massive hemorrhage, fresh frozen plasma (FFP) should be given. In addition, those that have warfarin induced coagulopathy and active bleeding or are in need of a surgical procedure, FFP should be administered. Other indications for FFP administration include liver disease with active bleeding, DIC with active bleeding, thrombotic thrombocytopenic purpura, or hemolytic uremic syndrome during the initial treatment phase and with plasmapheresis, and in cases of acquired deficiencies of a single coagulation factor for which the appropriate factor replacements are not available or are ineffective. In general, in a bleeding patient or a patient needing a procedure, the international normalized ratio goal of FFP transfusion should be less than 1.5. Patients may require other blood products (such as individual factors or cryoprecipitate) depending on the coagulation abnormality present. Recently, the thromboelastogram has emerged as an excellent tool to monitor and guide treatment of coagulation abnormalities. However, these considerations are discussed in detail elsewhere in this text and are outside the scope of this chapter.

Sepsis and MODS are known after the innate and adaptive immune responses and their changes can persist after the acute phase of MODS has resolved. These long-term changes cause ongoing chronic inflammation and immune suppression that put patients at risk for recurrent, secondary, and nosocomial infections resulting in risk of death even months after patients have recovered from their initial illness. Much work on understanding these cellular mechanisms and how to treat them is still required.

GRADING SYSTEMS OF ORGAN DYSFUNCTION

Organ dysfunction in the ICU patient can be categorized by the deranged physiologic system that requires intervention or by the degree and extent of intervention necessary (i.e. mechanical ventilation, renal replacement therapy, cardiovascular support). Numerous grading systems and scales exist to characterize and grade the severity of MODS based on the following systems: respiratory, cardiovascular, renal, hepatic, neurologic, and hematologic. The most recent and most commonly used assessment is called the Sequential Organ Failure Assessment (SOFA) score, which was described by J.L. Vincent and colleagues in 1996 (Table 2). The SOFA score assigns a value of 0 to 4 in six system categories with the higher score indicating a worse derangement. A shorter form of the SOFA score, called the quick SOFA or qSOFA for simpler bedside evaluation of potentially septic patients, has been developed. In this score, only three criteria are evaluated as being present or absent with a point assigned for each one that is present. The criteria are GCS less than 15, respiratory rate greater than or equal to 22, and systolic blood pressure less than or equal to 100 mm Hg. If two of these criteria are met, patients are thought to be at high risk for organ dysfunction and they should be thoroughly worked up, closely monitored, and a full SOFA score should be performed. The Marshall MODS score was developed in 1995 and assigns a score of 0 to 4 in six organ systems as well (Table 3). With both of these scoring systems, the risk of ICU death increases as the severity of organ dysfunction and number of failing organs increases.

The Acute Physiology and Chronic Health Evaluation II score was developed in 1985 by Knaus et al. to evaluate severity of illness by assigning scores to 12 physiologic parameters and including age and previous health status. The parameters include: temperature, MAP, heart rate, respiratory rate, oxygenation, arterial pH, serum sodium, serum potassium, serum creatinine, hematocrit, white blood cell count, GCS, age, and chronic health status. The score ranges from 0 to 71, with higher scores predicting a higher mortality rate.

MODS generally develops within 48 hours of an inciting event. Subtle neurologic disturbances are noted first, followed by acute dysmutic respiratory and cardiac dysfunction. Generally, hepatic, gastrointestinal, and renal dysfunction develop at a slightly later time during the disease course.

SPECIAL POPULATIONS

Pregnant Patients

With the rise in maternal mortality, it is only natural that pregnant women are frequenting ICUs. It is estimated that 1 in 329 deliveries will be admitted to the ICU in the United States. Changes in maternal physiology, fetal considerations, and medical emergencies related to pregnancy pose complications to critical care practitioners. With the increase in maternal mortality, ICUs must become adept to critical care obstetric issues.

The most common reason for ICU admissions in the United States includes hypertensive disorders of pregnancy (preeclampsia, eclampsia, and hemolysis, elevated liver enzyme, low platelet [HELLP] syndrome), followed by obstetric hemorrhage, and sepsis. During pregnancy, the maternal physiology can change significantly. By the mid second trimester, there is an increase of 50% in intravascular volume leading to an increase in cardiac output facilitated by a decrease in systemic vascular resistance. These changes are thought to aid the perfusion of the growing placenta and fetus. The increase in volume results in an increase in glomerular filtration and physiologic anemia with a standard hemoglobin of 10 to 11 g/dL.

Pulmonary physiology also significantly changes. Although there is a marginal increase in inspiratory capacity, the growing uterus causes marked decrease in the expiratory reserve volume and functional reserve capacity. These changes can place pregnant women at risk for progression of severe disease in pulmonary infections (i.e., pneumonia and influenza).

Hypertensive Diseases of Pregnancy and the ICU

Preeclampsia affects 2% to 5% of all pregnancies in the United States and is described as new onset hypertension and proteinuria usually occurring in the third trimester of pregnancy (Table 4). In general, many women with a hypertensive disorder of pregnancy are not admitted to the ICU because obstetric providers feel comfortable

TABLE 5 Diagnostic Criteria for Preeclampsia, HELLP Syndrome, and Eclampsia

Preeclampsia	Blood pressure Nonsevere: SBP >140 mmHg or DBP >90 mmHg after 20 weeks Severe: SBP >160 mmHg or DBP >90 mmHg after 20 weeks	Proteinuria Protein >300 mg/24 hr urine collection Protein/creatinine ratio >0.3 Dipstick reading of 1+ (only if other methods not available)
	In the absence of proteinuria, new-onset hypertension with new onset of any of the following: Platelet count <100,000/μL Serum creatinine >1.1 mg/dL or doubling of serum creatinine concentrations Elevated blood concentration of liver transaminases twice normal Pulmonary edema Cerebral or visual symptoms	
Eclampsia	Presence of new-onset grand mal seizure in a woman with preeclampsia	
HELLP syndrome	Platelets <100,000/μL, elevated liver transaminases twice normal, and signs of hemolysis (elevated lactate dehydrogenase or indirect bilirubin)	

caring for women in labor and delivery wards. However, ICU practitioners should become familiar with the most severe forms of hypertensive diseases of pregnancy (i.e., HELLP syndrome and eclampsia). The organ damage specific to these diseases can involve severe liver injury from subcapsular hematoma, intracranial hemorrhage from severe ranges of blood pressures, kidney failure, and hematologic abnormalities including DIC.

HELLP syndrome affects 0.1% to 0.2% of all pregnancies in the United States and is on the spectrum of hypertensive disorders of pregnancy. Women with HELLP syndrome are generally diagnosed based on laboratory parameters (Table 6). Women with HELLP syndrome have a higher maternal mortality and mortality secondary to DIC and hepatic rupture. Therefore, women with rising aspartate aminotransferase and alanine aminotransferase with dropping hemoglobin should be evaluated for a subcapsular hematoma by either sonography or computed tomography. Because of the high morbidity of disease, women are usually urgently delivered, and magnesium sulfate is given to women with both preeclampsia and HELLP syndrome for eclampsia prophylaxis. The regimen for eclampsia is 4 g intravenously over 20 minutes, then 2 g intravenously hourly while intrapartum and 24 hours after delivery.

Monitoring for magnesium toxicity is usually done by physical examination, which includes deep tendon reflexes, mental status, and urine output to ensure adequate clearance. Magnesium levels can be monitored as well, and the goal level is 4 to 7 g/dL. If eclamptic seizure occurs, a redose of magnesium sulfate of 4 to 6 grams intravenously can be given on top of the continuous infusion. In the setting of eclamptic seizures, magnesium sulfate is superior to other forms of seizure prophylaxis (i.e., benzodiazepines and phenytoin). In the setting of magnesium toxicity, which can result in lethargy (levels >8 g/dL) and cardiac arrest (levels >10 g/dL), calcium chloride 1 g intravenously or calcium gluconate 3 g intravenously should be administered. Although HELLP syndrome is highly morbid, it is by definition limited to pregnancy and should resolve within 72 hours after delivery.

In the event maternal improvement does not occur, ICU staff should consider alternative diseases. Differential diagnosis should include atypical hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, and other autoimmune disease such as systemic lupus erythematosus. These diseases may be quiescent throughout life and may be newly triggered by pregnancy.

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy (AFLP) is an incredibly rare, morbid disorder characterized by quickly progressive liver failure. Although AFLP affects 1 to 10,000 pregnancies, maternal mortality from this process can be as high as 5% to 9%, so a tertiary care center. Women with AFLP have liver abnormalities but usually to the most severe form. In AFLP, both aspartate aminotransferase and alanine aminotransferase usually are above 500 IU/L and can often be above 1000 IU/L. There are also other signs of liver failure including unexplained hypoglycemia, acidosis, an elevated direct bilirubin and altered mental status from hyperammonemia. Upon imaging, the liver shows steatosis.

Commonly, women with AFLP have coagulopathy and DIC and pose a high transfusion risk. Women with AFLP should be at centers with an efficient blood bank at time for delivery for risk of massive transfusion. Although patients with AFLP can progress to complete liver failure with renal injury, the disease is usually limited to pregnancy and after delivery patients tend to have full liver recovery within 1 week. Supportive measures such as transfusion for bleeding and DIC, mechanical ventilation for respiratory failure, extensive glucose supplementation, and ammonia-clearing agents are warranted during the recovery. For patients who have liver recovery, neither transplant nor biopsy is warranted; however, if recovery is not seen, these options should be considered to rule out other forms of failure. Because of the rarity of the disease, other forms of liver failure should be considered in reproductive age women as well. Aminoglycoside toxicity, drug induced from other medications, infections, newly diagnosed HIV, and hepatitis to name a few.

Obese Patients in the Critical Care Unit

Obesity continues to be a huge medical problem in the United States. Obesity is associated with cardiovascular disease, coronary artery disease, and diabetes as well as increased health care cost. Although obesity can cause increased complications, superobese patients (body mass index >50) may pose different challenges to critical care practitioners. Patients with superobesity and obesity are more likely to have longer length of stays in the ICU when compared with nonobese patients. They are also more likely to need noninvasive ventilation and succumb to pulmonary disease.

Postoperatively, superobesity carries risk of higher perioperative morbidity including infections, which include sepsis, septic shock, and urinary tract infections. Patients with superobesity are also more likely to have prolonged ventilatory days, unplanned or emergent intubations, renal insufficiency, and pulmonary embolism. Dosing of weight-based medications such as antibiotics and anticoagulation also pose a problem and put these patients at risk for critical illness secondary to subtherapeutic levels.

PALLIATIVE CARE AND ETHICS

In a culture of medicine that focuses on curing disease, palliative care remains an underused service in many institutions. Patients with terminable or incurable preexisting conditions are at most risk of disease-causing MODS like sepsis. The most common preexisting condition associated with palliative care is metastatic cancer; however, critical care providers should be aware the scope of palliative care can

be used in severe heart failure, pulmonary hypertension, as well as end-stage pulmonary disease.

Palliative care consultation is also not just for presenting conditions. In cases with intractable septic shock, irreparable bleeding, or organ failure without the ability to transplant, palliative care should be considered. A multidisciplinary team of the primary surgeon, intensivist, the patient or family, as well as a provider well versed in palliative medicine should discuss and determine what is "success" for these patients. Palliative care should be considered and integrated early in a diagnosis of serious illness to help facilitate treatment and patient goals.

Despite being advocated by the World Health Organization, many patients do not have palliative care initiated until the final days of life. This is likely secondary to the negative stigma that palliative care focuses on death, dying, and hopelessness. Palliative medicine is rooted in symptom control, pain management, and improved quality of life.

In patients undergoing end-of-life care, it is important for clinicians to discern what is futile in their treatment. Futile interventions are those that simply cannot accomplish the intended physiologic goal, and clinicians should not provide futile interventions. In clinical settings where there is concern for futile treatment, ethics committees should be consulted if available.

SUMMARY

This chapter attempted to provide an overview of multiple organ dysfunction that is often seen in the ICU and to describe each organ in turn. MOF is the final common pathway for many ICU patients and especially those that develop severe MODS that is not expeditiously corrected. We have described commonly used grading systems to help discern the severity of the organ dysfunction. These grading systems can be helpful in gauging the severity of and in some cases the predicted mortality for patients with MOD. We have also described select special patient populations that are increasingly encountered in the ICU. Finally, we have emphasized the importance of involving palliative care early in the course of patients that experience MODS and MOF and in necessary cases, ethics consultants when the ICU practitioner has reached the point that they deem further curative intent care to be futile.

Antibiotics for Critically Ill Patients

Kelly A. Ervin, MSc and David J. Milia, MD

Infection remains a significant source of morbidity and mortality in the intensive care unit (ICU). As in polytrauma, acute myocardial infarction, and stroke, early identification and appropriate management of sepsis reduces mortality and improves outcomes. Although initiatives such as the Surviving Sepsis Campaign have been shown to improve outcomes, the most fundamental tenet in the management of the septic patient is source control. In surgical patients, procedural interventions are the mainstay for achieving source control in the appropriate clinical setting. To accompany this, proper antibiotic choice and duration can augment surgical control through local and systemic effects (Tables 1 and 2).

APPROACH TO ANTIBIOTIC USE IN THE CRITICALLY ILL

Sepsis in the surgical patient continues to be a challenge for surgical intensivists. Early identification of septic patients, timely implementation of therapies, and identifying the source of infection are

be used in severe heart failure, pulmonary hypertension, as well as end-stage pulmonary disease.

Palliative care consultation is also not just for processing conditions. In cases with intractable septic shock, unstoppable bleeding, or organ failure without the ability to transplant, palliative care should be considered. A multidisciplinary team of the primary surgeon, intensivist, the patient or family as well as a provider well versed in palliative medicine should discuss and determine what to "maximize" for these patients. Palliative care should be considered and integrated early to a diagnosis of serious illness to help facilitate treatment and patient goals.

Despite being advocated by the World Health Organization, many patients do not have palliative care initiated until the final days of life. This is likely secondary to the negative stigma that palliative care focuses on death, dying, and hopelessness. Palliative medicine is rooted in symptom control, pain management, and improved quality of life.

In patients undergoing end-of-life care, it is important for clinicians to discern what is futile to their treatment. Futile interventions are those that simply cannot accomplish the intended physiologic goal, and clinicians should not provide futile interventions. In clinical settings where there is concern for futile treatment, ethics committees should be consulted if available.

SUMMARY

This chapter attempted to provide an overview of multiple organ dysfunction that is often seen in the ICU and to describe each organ in turn. MOF is the final common pathway for many ICU patients and especially those that develop severe MODS that is not expeditiously corrected. We have described commonly used grading systems to help discern the severity of the organ dysfunction. These grading systems can be helpful in gauging the severity of and in some cases the predicted mortality for patients with MOD. We have also described select special patient populations that are increasingly encountered in the ICU. Finally, we have emphasized the importance of involving palliative care early in the course of patients that experience MODS and MOF and in necessary cases, ethics consultants when the ICU practitioner has reached the point that they deem further curative interventions cant to be futile.

ANTIBIOTICS FOR CRITICALLY ILL PATIENTS

Kelly A. Boyle, MD, and David J. Milia, MD

Infection remains a significant source of morbidity and mortality in the intensive care unit (ICU). As in polytrauma, acute myocardial infarction, and stroke, early identification and appropriate management of sepsis reduces mortality and improves outcomes. Although initiatives such as the Surviving Sepsis Campaign have been shown to improve outcomes, the most fundamental tenet in the management of the septic patient is source control. In surgical patients, procedural interventions are the mainstay for achieving source control in the appropriate clinical setting. To accompany this, proper antibiotic choice and duration can augment surgical control through local and systemic effects (Tables 1 and 2).

APPROACH TO ANTIBIOTIC USE IN THE CRITICALLY ILL

Sepsis in the surgical patient continues to be a challenge for surgical intensivists. Early identification of septic patients, timely implementation of therapies, and identifying the source of infection are

TABLE 1 Antibiotic Classes and Agents Clinically Important in the Critically Ill: β-Lactam Antibiotics

β-Lactam antibiotics	Attach to penicillin-binding proteins in the cell membrane, interfering with peptide chain cross-linkages in the bacterial cell wall peptidoglycan, leading to cell lysis	
Groups	**Examples**	**Comments**
PENICILLINS		
Natural penicillins	Penicillin G	Very effective against *Streptococcus* spp., nonresistant *Enterococcus faecalis*, and *Clostridium perfringens*
Penicillinase-resistant penicillins	Oxacillin Nafcillin	Very effective against MSSA and *Streptococcus* spp.
Aminopenicillins	Ampicillin Ampicillin-sulbactam	Active against *Streptococcus* spp., MSSA, *E. faecalis*; variable activity against VRE Adding BLI extends activity against gram-negative bacilli and *Bacteroides fragilis* *Pseudomonas* is resistant …sobacterial cell resistance is rising; coverage is variable and unreliable
Ureidopenicillins	Piperacillin-tazobactam	Broad-spectrum activity including against *Pseudomonas* and anaerobes
CEPHALOSPORINS		
First generation	Cefazolin	• Active against MSSA, *Streptococcus* spp., *E. coli*, *Klebsiella*, *Proteus mirabilis*
Second generation	Cefuroxime	• Increased aerobic gram-negative activity, including against *Haemophilus* or *Moraxella*
Second generation (cephamycins)	Cefoxitin Cefotetan	• Extended activity against *B. fragilis*; resistance increasing • Methylthiotetrazole side chain inhibits vitamin K activation, resulting in rise in international normalized ratio
Third generation	Ceftriaxone Ceftazidime Cefotaxime	• Increased spectrum of activity against aerobic gram-negative bacilli • Vulnerable to inactivation by extended-spectrum β-lactamases and AmpC cephalosporinases
Third generation, antipseudomonal	Ceftazidime Cefoperazone-sulbactam Cefepime-tazobactam	• Active against *Pseudomonas*, less active against *Staphylococcus* • Adding BLI extends activity against resistant aerobic gram-negative bacilli
Fourth generation	Cefepime	• Very effective against aerobic gram-negative bacilli, including *Pseudomonas* • Able to avoid destruction by β-lactamases by rapid penetration through the cell wall • Maintains activity against *Staphylococcus* and *Streptococcus*
Fifth generation	Ceftaroline	• Broad-spectrum activity, including against MRSA and aerobic gram-negative bacilli • Inactive against *Pseudomonas*
OTHER β-LACTAMS		
Carbapenems	Ertapenem	• Broad-spectrum activity against gram-positive cocci, gram-negative bacilli, and anaerobes; readily penetrate cell membranes of gram-negative bacilli, have high affinity for penicillin-binding proteins, and are resistant to hydrolysis by β-lactamases • Ertapenem is not active against *Pseudomonas* or *Enterococcus*
AP carbapenems	Imipenem-cilastatin Doripenem Meropenem	• Seizure risk is greater than with other β-lactam antibiotics • Active against *Pseudomonas* • Doripenem is indicated for complicated intra-abdominal infections and urinary tract infections but not for pneumonia
Monobactam	Aztreonam	• Active against aerobic gram-negative bacilli, including *Pseudomonas*

BLI, β-lactamase inhibitor; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-susceptible *Staphylococcus aureus*; VRE, vancomycin-resistant *Enterococcus*.

essential to sepsis management. The practice of indiscriminate procalcitonin and initiation of broad-spectrum empiric antibiotics on all patients is falling out of favor. Instead, surgical intensivists should be taking a good history and performing a thorough physical examination to guide necessary laboratory tests, imaging studies, or interventions. Once potential sources are identified, directed culturing allows for tailored therapy. Depending on the site of infection and the clinical status of the patient, empiric antibiotics may be beneficial while cultures are pending or other interventions are being arranged. In addition to treating the infections that prompted admission to the ICU, the surgical intensivist will have to juggle the many complications that can arise in critically ill patients. Many of these complications are healthcare-associated infections related to indwelling devices, including ventilator-associated pneumonia, central line–associated bloodstream infection, catheter-associated urinary tract infection, and surgical site infection. It is imperative that every practitioner faced with the decision to start antibiotics appreciate this responsibility with good clinical stewardship. This means starting

TABLE 2 Antibiotic Classes and Agents Clinically Important in the Critically Ill: Non–β-Lactam Antibiotics

Group	Examples	Comments
Glycolipopeptides	Vancomycin Telavancin Oritavancin Dalbavancin	• Disrupts bacterial cell wall synthesis by impairing peptidoglycan synthesis • Active against gram positive cocci, including MRSA • Daptomycin and oritavancin active against VRE • Oral vancomycin effective against *Clostridium difficile* • Oritavancin and dalbavancin have very long half lives, allowing single dosing (oritavancin) or weekly × 2 dosing (dalbavancin) • Daptomycin is inactivated by surfactant, not used for pneumonia; also associated with myopathy; statins should be stopped; check CPK weekly
Polymyxins	Polymyxin B Colistin (polymyxin E)	• Cationic polypeptides that act as detergents to disrupt the bacterial cell membrane • Active against Enterobacteriaceae, *Acinetobacter*, *Pseudomonas*, and *Stenotrophomonas* • Cause significant renal toxicity
Aminoglycosides	Gentamicin Tobramycin Amikacin	• Inhibit bacterial protein synthesis by binding irreversibly to the 30S ribosomal subunit • Active against gram negative bacilli, including *Pseudomonas* (gentamicin less so than tobramycin or amikacin) • Synergistic activity with penicillins and vancomycin against *Enterococcus* and *Staphylococcus* • Exhibit concentration dependent activity and a significant postantibiotic effect • Significant incidence of renal toxicity and ototoxicity (auditory and vestibular) • Once daily dosing improves effectiveness and reduces toxicity • Limiting usage to 5 days reduces toxicity
Tetracyclines	Doxycycline Minocycline	• Inhibit bacterial protein synthesis by binding to the 30S ribosomal subunit • Active against *Staphylococcus*, including MRSA; variable activity against VRE and *Streptococcus*
Glycylcyclines	Tigecycline	• Broad spectrum agent active against gram positive cocci (MRSA and VRE), gram negative bacilli, and anaerobes • Inactive against *Pseudomonas* • US Food and Drug Administration black box warning; should not be used as first-line therapy
Macrolides, ketolides, azalides, chloramphenicol	Erythromycin Clarithromycin Azithromycin Telithromycin Clindamycin Chloramphenicol	• Inhibit bacterial protein synthesis by reversibly binding to 50S ribosomal subunit at overlapping sites; use of 2 or more of these classes results in antagonism • Variable activity against MSSA and *Streptococcus* spp.; active against atypical bacterial • Telithromycin only active against *C. difficile* • Azithromycin and clarithromycin active against *Haemophilus influenzae* • Active against *Staphylococcus* and *Streptococcus*; 90% to 95% of *Bacteroides fragilis* • Potentially additive to clostridial and streptococcal gangrene for its ability to inhibit toxin production • Active against *Staphylococcus* (MRSA), *Streptococcus*, *E. coli*, *Klebsiella*, *H. influenzae*, anaerobes • Variable activity against VRE • Limited use because of bone marrow suppression and rare aplastic anemia
Streptogramins	Quinupristin–dalfopristin	• Inhibits bacterial protein synthesis by binding to 50S ribosomal subunit • Active against gram positive cocci, including MRSA and VRE • Inactive against *Enterococcus faecalis* • Causes severe arthralgia, myalgia, and phlebitis; infuse through central line
Oxazolidinones	Linezolid Tedizolid	• Inhibit bacterial protein synthesis by binding to the 23S ribosomal RNA of the 50S subunit • Active against gram positive cocci including MRSA and VRE; resistance to linezolid can develop • High bioavailability; oral is as effective as intravenous • Bone marrow suppression with thrombocytopenia may occur after 10 days of treatment with linezolid; reversible after cessation • Tedizolid indicated for acute bacterial skin and skin structure infections for 6 days • Weak monoamine oxidase inhibitors; 1%–3% incidence of serotonin syndrome when given with monoamine oxidase inhibitors or selective serotonin reuptake inhibitors • Long term use associated with reversible optic neuropathy and irreversible peripheral neuropathy

Continued

TABLE 2 Antibiotic Classes and Agents Clinically Important in the Critically Ill: Non–β-Lactam Antibiotics—cont'd

Groups	Examples	Comments
Fluoroquinolones	Ciprofloxacin Levofloxacin Moxifloxacin	• Inhibit DNA gyrase and topoisomerase IV • Active against broad spectrum of nonresistant gram-positive cocci and gram-negative bacilli, including *Pseudomonas* (not moxifloxacin) • Moxifloxacin active against 85% of *B. fragilis*, but does not cover urine and cannot treat UTIs • Concentration dependent antibacterial effect • High bioavailability, oral to an effective IV • Not approved for children <16 years, associated with joint and tendon injuries
Nitroimidazoles	Metronidazole	• Chemically reduced in the bacterial cell and disrupts the DNA helix, causing strand breakage • Active against *Bacteroides* and *Clostridium*, *Peptostreptococcus* • Often combined with cephalosporins and fluoroquinolones for intraabdominal infections • One of the main therapies for *C. difficile* colitis • Disulfiram-like reaction occurs with alcohol consumption • Not tolerated long term, associated with bone marrow suppression
Rifamycins	Rifampin	• Inhibits DNA dependent RNA polymerase • Active against MRSA and VRE • Always used in combination with other agents, may reduce development of resistance • Has many drug interactions and may be hepatotoxic
Sulfonamides	TMP/SMX	• SMX inhibits dihydropteroate synthase, TMP inhibits dihydrofolate reductase: 2 steps in bacterial folate pathway • Active against MSSA, MRSA, coagulase negative *Staphylococcus*, *Stenotrophomonas*, *Burkholderia*, *Serratia* • Inactive against *Enterococcus* (despite in vitro sensitivity)
Other	Nitrofurantoin	• Inhibits bacterial enzymes, leading to cell death • Active against VRE, *E. coli*, *Klebsiella* • Oral antibiotic, used in urinary tract infection • Macrocrystal form causes less nausea • Do not use if creatinine clearance <60 mL/min

CPK, Creatine phosphokinase; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-susceptible *Staphylococcus aureus*; TMP/SMX, trimethoprim-sulfamethoxazole; VRE, vancomycin-resistant *Enterococcus*.

appropriate broad spectrum antibiotics with the discipline to narrow the spectrum when culture data results and the clinical situation allows. Evolving evidence from contemporary clinical trials should guide duration of use. Used in conjunction with adequate source control and management of alterations in physiology, this approach will yield optimal outcomes for both the patient and the healthcare system as a whole.

PATHOGENS ENCOUNTERED IN CRITICALLY ILL PATIENTS

Historically, patients admitted to the ICU from the community or early in a hospital stay were more likely to have the wild type spectrum of pathogens, including gram positive cocci and gram negative bacilli. Nosocomial infections were associated with higher rates of multidrug resistance; however, healthcare- and community acquired infections are no longer entirely distinct. The basis for this is multifactorial and includes enhanced virulence, increased antibiotic resistance, and increased transmissibility as healthcare associated infections spread to community contacts.

Community-Acquired Pathogens

Among gram positive cocci, *Staphylococcus* and *Streptococcus* are common causes of skin and skin structure infections. Methicillin susceptible *Staphylococcus aureus* (MSSA) is very sensitive to the penicillinase-resistant penicillins, oxacillin and nafcillin, and to cefazolin, a first-generation cephalosporin. Methicillin resistant *S. aureus* (MRSA) has traditionally been classified into healthcare associated (HA MRSA) and community associated; however, this distinction is becoming less clear as patients who develop MRSA colonization in one realm can develop manifestations of infection in another.

Community acquired methicillin resistant *S. aureus* (CA MRSA) is genetically distinct from HA MRSA. CA MRSA strains are classified by USA300 and USA400 clonal groups, and this smaller genetic package is thought to explain why CA MRSA is less resistant than HA MRSA. Patients with CA MRSA tend to be younger and healthier, may live in crowded conditions, or may be athletes. CA MRSA is more prevalent in intravenous drug abusers and in children younger than 2 years of age, usually presenting as cutaneous abscesses or boils. Most strains of CA MRSA are susceptible to clindamycin, trimethoprim-sulfamethoxazole (TMP/SMX), or a tetracycline and are usually resistant to macrolides and fluoroquinolones.

β Hemolytic *Streptococci*, groups A, B, C, and G, are responsible for many cases of cellulitis. Group A *Streptococcus pyogenes* can be the causative agent of streptococcal necrotizing skin and soft tissue infections. These organisms may be virulent but are susceptible to penicillin G, cefazolin, or ceftriaxone. Gram negative bacilli and anaerobes causing intraabdominal infections in the community are usually susceptible to cephalosporins with metronidazole and

to extended-spectrum penicillins with a β-lactamase inhibitor. A notable exception is *Escherichia coli*, which is commonly resistant to ampicillin/sulbactam. For this reason, ampicillin/sulbactam no longer is recommended as initial empiric therapy for intra-abdominal infections.

NOSOCOMIAL PATHOGENS

Gram-positive cocci in the hospitalized or other healthcare-associated patient include HA-MRSA, methicillin-resistant *Staphylococcus epidermidis*, and vancomycin-resistant *Enterococcus* (VRE). HA-MRSA is endemic in hospitals and healthcare facilities worldwide. Methicillin-resistant *S. epidermidis* and other coagulase-negative *Staphylococci* are common skin flora and frequently infect implanted devices such as central venous catheters. VRE overgrowth results from the selective pressure from broad-spectrum antibiotic therapy. VRE contains plasmids that confer resistance, and the VanA plasmid has been transferred to MRSA, conferring vancomycin resistance.

Clinically important members of the Enterobacteriaceae family include *E. coli*, *Klebsiella pneumoniae*, *Proteus* species, *Enterobacter* species, *Serratia* species, and *Citrobacter* species. Other important gram-negative rods are *Pseudomonas* species, *Acinetobacter* species, and *Stenotrophomonas* species. Many of these organisms have developed resistance by producing extended-spectrum β-lactamases, which hydrolyze penicillins and cephalosporins. AmpC β-lactamase hydrolyzes first-, second-, and third-generation cephalosporins. Carbapenemases that hydrolyze penicillins, cephalosporins, and carbapenems, but not aztreonam (a monobactam), are also now being observed. Some of these organisms contain plasmids that confer aminoglycoside resistance. *Clostridium difficile* can be infected not by broad-spectrum antibiotic therapy, especially by fluoroquinolones.

Multidrug resistance is a worrying problem, especially among these pathogens: *Enterococcus faecium*, *S. aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterobacter* species. The Infectious Diseases Society of America launched the 10 × '20 Initiative in 2010 to encourage greater research and development of antibiotic therapies to combat these organisms, with the goal of developing 10 new antibiotics by 2020. Since 2010, the US Food and Drug Administration has approved eight new antibiotics: ceftaroline, fidaxomicin, bedaquiline, dalbavancin, telavancin, oritavancin, ceftolozane–tazobactam, and ceftazidime–avibactam.

COMMON CONDITIONS

The following is a review of common conditions encountered in surgical ICUs, and treatment descriptions are based on general recommendations. Antimicrobial flora and resistance patterns can vary considerably between regions, and antimicrobial selection should be tailored based on institutional pathogram resistance patterns.

Pneumonia

Background

Postoperative pulmonary complications are a major cause of morbidity and mortality. Pneumonia is the third most common postoperative infection and may account for 15% to 20% of all nosocomial infections. Several factors increase the risk of developing postoperative pulmonary complications, including emergency surgery, age older than 65 years, surgery lasting longer than 3 hours, heart failure, and chronic obstructive lung disease. Many of these risk factors are unmodifiable. Although the pathogenesis of postoperative pneumonia is multifactorial, endotracheal intubation is a primary risk factor. The intubated population is at high risk for colonization of the airway and aspiration of contaminated gastrointestinal tract secretions. Hosts face an opportunity to modify risk factors, and considerable effort has been invested in ICU prevention bundles as a means of mitigating ventilator-associated pneumonia (VAP). Specific strategies include head-of-bed elevation, proper circuit maintenance, reduced sedation levels, and comprehensive oral care. Like most devices, removal of endotracheal tubes as early as clinically possible allows patients to cough and expel secretions aiding in reducing the development of pneumonia. For nonintubated patients, similar techniques can be applied, but also include early mobility and incentive spirometry. New concepts suggest focusing on perioperative interventions as well, including decreasing oral bacterial load with oral cleansing and nutritional systems paired with an oral antiseptic pre- and postoperatively.

Treatment

Empiric therapy for hospital-acquired pneumonia (HAP) and VAP should include agents with activity against *S. aureus* (20%–30% of VAP isolates), *P. aeruginosa* (10%–20% of VAP isolates), and enteric gram-negative bacilli (20%–40% of VAP isolates). The choice of a specific regimen for empiric therapy should be based on knowledge of the individual patient's risk factors for multidrug resistance and prior microbiology data. Early-onset pneumonia, in which there is low risk for multidrug-resistant organisms, can be treated with ceftriaxone, a fluoroquinolone, ampicillin/sulbactam, or ertapenem. Late-onset pneumonia, in which multidrug-resistant organisms are likely, need to be treated more aggressively with empiric combination therapy to minimize the chance of coverage gaps and to decrease mortality. Cefepime, piperacillin–tazobactam, or meropenem should be combined with either a fluoroquinolone or an aminoglycoside. If MRSA is also a risk, vancomycin or linezolid should be added. Many hospitals perform surveillance screening for MRSA, especially in ICU settings, to determine necessity of MRSA coverage. Negative MRSA surveillance studies need to be interpreted within the context of local prevalence of MRSA. Once culture and sensitivity results are available, the antibiotic regimen should be refined further. *Acinetobacter* species is found in approximately 5% to 10% of VAP isolates; ampicillin/sulbactam, a carbapenem, or a polymyxin may be necessary for treatment. Inhaled aminoglycosides or colistin may play a role in difficult-to-treat pneumonias, but the results of trials are not conclusive.

Catheter-Associated Urinary Tract Infections

Background

Catheter-associated urinary tract infection (CAUTI) is among the most common nosocomial infections worldwide. Urinary catheterization is a common practice in critically ill patients (>90% of ICU patients in some series) for the purposes of bladder drainage and accurate urinary output monitoring. Age, female sex, length of ICU stay, duration of catheterization, and obesity have all been shown to be independently associated with an increased risk of CAUTI. Preventive measures focus on sterile insertion technique, the use of unobstructed closed drainage systems, early removal, and the avoidance of catheter manipulation. There are novel devices on the market with antimicrobial-impregnated materials for urinary catheters; however, infections still occur with these devices and ultimate reductions in CAUTI remain unclear.

Treatment

Uncomplicated urinary tract infections are usually susceptible to TMP/SMX. Nitrofurantoin is effective against VRE and *E. coli* but should not be used in end-stage renal failure. Ciprofloxacin and levofloxacin are also effective agents and concentrate well in the urine. CAUTIs, however, are complicated and are often polymicrobial. If CAUTI is suspected, the indwelling catheter should be removed if possible. If an indwelling catheter has been in place for more than 2 weeks at the onset of CAUTI and is still indicated, the catheter should be replaced. Ideally, antimicrobial selection should be based on the culture results when available. Empiric therapy is warranted, however, for patients with signs of systemic toxicity. Common organisms include *Enterobacteriaceae*, *Pseudomonas* species, and *Enterococcus* species. As such, ampicillin and gentamicin, piperacillin–tazobactam, a carbapenem, or a fluoroquinolone may be used. If the risk of

Enterococcus is low, cefazolin, ceftriaxone, cefuroxime, cefotaxime, ceftazidime, cefepime are appropriate choices. Deescalation or change of antibiotic should be based on culture and sensitivity results.

Surgical Site Infections

Background

Surgical site infections (SSIs) are one of the most common complications affecting surgical patients. The frequency of SSI is closely related to the category of the operation (clean, clean-contaminated, contaminated, and dirty), with clean and low risk operations having the lowest incidence, and contaminated cases having higher infection rates. Should an infection arise at the surgical site, the classification is differentiated by the depth of the process:

- *Superficial:* Skin and subcutaneous tissue
- *Deep:* Deep soft tissues of the incision (fascia and muscle layer)
- *Organ/space:* Any part of the body deeper than the fascia or muscle layer that was opened or manipulated during the operative procedure

SSIs rarely occur during the first 48 hours after surgery. SSIs occurring during this time frame are almost always the result of *S. pyogenes* or *Clostridium* species. In general, SSIs usually require an additional procedure to ensure proper source control, and antibiotic therapy should only be used as an adjunct.

Treatment

Clinical practice guidelines exist to aid selection of appropriate antimicrobial prophylaxis for most surgical cases. The standardized approach offers the most effective use of antimicrobial agents for the prevention of SSIs based on current clinical evidence. In general, the prophylactic antibiotic targets the flora that may be present in the anatomy that is to be exposed. In the perioperative setting, antibiotic choice for SSI follows a similar mindset. An SSI from a clean case would likely target skin flora. Mild infections that require only oral therapy can be treated with cephalexin or dicloxacillin. If there is concern for MRSA, TMP/SMX, clindamycin, minocycline, or doxycycline can be used. More severe skin infections can be treated with cefazolin or vancomycin for MRSA. Daptomycin, telavancin, ceftaroline, linezolid, or tedizolid also may be used.

SSIs after clean-contaminated, contaminated, or dirty cases involving the gastrointestinal or genitourinary tract may be caused by skin flora and/or gram negatives and anaerobes. Antimicrobial options with action against aerobic gram negative bacilli and *Bacteroides fragilis* include ceftazidime, ceftazidime avibactam, ceftolozane tazobactam, cefepime, or a fluoroquinolone with metronidazole. Piperacillin tazobactam and antipseudomonal carbapenems can be used as single agents. Vancomycin or linezolid should be used if MRSA is likely. If cultures can be obtained, antibiotics should be deescalated or changed based on the results of culture and sensitivity.

Vascular Access Device–Related Infections

Background

Vascular access for the purposes of monitoring, fluid resuscitation, nutrition, and medication administration is often necessary in critically ill patients; however, up to 80,000 central venous catheter–related bloodstream infections occur in ICUs every year. Risk of bloodstream infection varies according to the intravascular device, the insertion site, experience of individual placing the catheter, frequency the catheter is accessed, and duration the catheter remains in place. Regardless of the device, standardized insertion and device maintenance bundles aimed at infection prevention should be used. These strategies generally involve proper hand hygiene, skin antisepsis, full barrier precautions at insertion, proper catheter site maintenance, and removal of the device as early as the clinical situation allows.

Treatment

Most catheter-associated infections are caused by skin flora, namely, *S. aureus* and *S. epidermidis*. Once a local infection or bacteremia is diagnosed, the catheter should be removed if possible. Vancomycin is recommended for empiric therapy in settings with a high prevalence of MRSA. If there is concern for aerobic gram negative bacilli, as in immunocompromised or burn patients, then cefepime, piperacillin tazobactam, or an antipseudomonal carbapenem should be added. Femoral catheters, catheters used for total parenteral nutrition, and catheters in immunocompromised patients may be infected with *Candida*, in which case an echinocandin should be added. Fluconazole could be considered in select patients without recent azole exposure or with low risk of *Candida krusei* or *Candida glabrata* infection. As always, deescalation is appropriate once culture and sensitivity results are available.

Abdominal Sepsis

Gastrointestinal Tract

Complicated intraabdominal infections remain a common problem, with a wide range of severity and resulting morbidity and mortality. After initial intravenous fluid resuscitation and stabilization, source control and antimicrobial therapy remain the mainstays of treatment.

Treatment

Antimicrobial regimens for intraabdominal infections should have activity against typical gram negative Enterobacteriaceae, gram positive cocci, and anaerobes. Infections of mild to moderate severity, including perforated appendicitis and diverticulitis in which there is no physiologic impairment, can be treated with first-, second-, or third-generation cephalosporins or fluoroquinolones with metronidazole. Appropriate single agents include cefoxitin, moxifloxacin, ertapenem, and tigecycline. Ampicillin/sulbactam should not be used as empiric therapy because of the high rate of resistance of *E. coli*. In patients who have undergone adequate source control, outcomes after shorter duration antibiotic therapy (4 days) are equivalent to those after a longer course of antibiotics (8 days). Severe infections with physiologic compromise should be treated with cefotaxime, ceftazidime avibactam, ceftolozane tazobactam, cefepime, or a fluoroquinolone with metronidazole. Piperacillin tazobactam and antipseudomonal carbapenems are appropriate single agents. Consider adding an aminoglycoside when there is a high rate of resistant *Pseudomonas* and extended-spectrum β-lactamase–producing Enterobacteriaceae in hospitalized patients. If MRSA is considered, add vancomycin or linezolid to the regimen. Deescalation or change in antibiotic therapy is warranted based on culture and sensitivity reports. Of note, *B. fragilis* may not grow but should be expected and treated.

Infections of the Biliary Tree

Biliary tree infections can arise primarily from ductal structures (cholangitis) or secondarily from stasis with or without obstructive causes (acute cholecystitis, acalculous cholecystitis, cholelithiasis). The mainstay of treatment is still adequate source control or appropriate drainage and effective antibiotic therapy.

Treatment

Cholecystitis is inflammatory in etiology and not always infectious; however, in patients undergoing cholecystectomy for acute cholecystitis, antimicrobial therapy may be added in the perioperative setting. Cholecystitis of mild to moderate severity can be treated with a first-, second-, or third-generation cephalosporin. Antibiotics should be discontinued within 24 hours if operation unless there is evidence of infection outside the wall of the gallbladder. More severe infections, including those in patients with biliary obstruction, biliary stent, malignancy, recent hospitalization, or in immunocompromised hosts are more likely to be drug-resistant or anaerobic. Piperacillin tazobactam and carbapenems are effective against gram negative aerobes and

ll, fogle. Fluoroquinolones, cefepime, cefotaxime (cefotaxime, and ceftriaxone with or without metronidazole.

C. Difficile Colitis

C. difficile is the most common cause of healthcare-associated infection in adults in the United States. Importantly, community-acquired C. difficile infection (CDI) is on the rise. There is a wide spectrum of disease, ranging from mild diarrhea to fulminant colitis, multiple organ failure, and death. Best methods for diagnosis remain controversial, but new guidelines suggest that physicians should only test patients with new onset and unexplained diarrhea involving three or more unformed stools in 24 hours. Given the significant burden on morbidity and mortality in surgical patients, a multidisciplinary approach is paramount, including early recognition, strict hand hygiene, contact precautions, evidence-based treatment strategies, and antibiotic stewardship to combat this potentially fatal pathogen.

Treatment

Resistance to current treatments and increase in treatment failure have presented clinical challenges and compelled changes to practice. Oral metronidazole used to be the mainstay of treatment of C. difficile colitis; however, new guidelines recommend oral vancomycin or fidaxomicin for an initial episode of CDI, which demonstrate higher cure rates than metronidazole. If impairment of the gastrointestinal tract is present, such as ileus or bowel discontinuity, and oral vancomycin would not reach the colon effectively, vancomycin enemas should be considered. Intravenous metronidazole should be administered with oral or rectal vancomycin if ileus is present. Recurrence is often treated with vancomycin as a tapered and pulsed regimen. Fecal microbiota transplantation should be used to treat patients with two or more recurrences of CDI, along with individuals who did not respond to traditional antibiotic treatment. Evidence for probiotics is mixed, and overall there are insufficient data to recommend probiotics for prevention of CDI. If surgical management is necessary for severely ill patients with fulminant CDI or megacolon, perform a subtotal colectomy with preservation of the rectum. An alternative approach is to create a diverting loop ileostomy, perform intraoperative colonic lavage, followed by antegrade vancomycin instillations postoperatively.

Necrotizing Soft Tissue Infections

Necrotizing skin and soft tissue infections (SSTIs) differ from milder, superficial infections by clinical presentation, operative management, and treatment strategies. Aggressive infections often mainly lead to necrosis of one or more layers of the skin, subcutaneous tissues, fascia, or muscle. These infections are potentially devastating because of the risk of major tissue destruction and death. The initial skin lesion may be innocuous, but as it progresses, there is local cellulitis, edema, pain, and possible gangrene that may be accompanied by systemic toxicity and septic shock. When suspected, early antibiotic therapy resuscitation, and surgical debridement should be sought immediately.

Treatment

Surgical intervention is the primary therapy for necrotizing SSTIs, but antimicrobial therapy should be administered until further debridement is no longer necessary, the patient has improved clinically, and fever has been absent for 48 to 72 hours. Because necrotizing SSTIs may be monomicrobial or polymicrobial, empiric antibiotic therapy should be broad spectrum initially, including MRSA coverage. Vancomycin, linezolid, or daptomycin may be continued with (1) piperacillin-tazobactam, (2) a carbapenem (imipenem-cilastatin, meropenem, and ertapenem), (3) fourth-generation (cefepime) or fifth-generation (ceftaroline) cephalosporins plus metronidazole, or (4) a fluoroquinolone plus metronidazole. Clindamycin or linezolid are often added because they suppress the streptococcal toxin and cytokine production responsible for toxic shock syndrome.

As culture results become available, deescalation of antibiotics is appropriate. If clostridial or group A streptococcal gangrene is identified, high-dose penicillin G with clindamycin is effective. Staphylococcal infections may be treated with vancomycin or daptomycin with clindamycin (for toxin inhibition). Alternatively, linezolid can be used as a single agent as it offers MRSA coverage and inhibits toxin production. Known MSSA infections can be treated with oxacillin or nafcillin with clindamycin.

Fungal Infections

Infection due to Candida species is largely a condition associated with medical progress and ranges from superficial mucosal infections to invasive disease associated with candidemia and metastatic organ involvement. Candidemia is associated with up to 47% attributable mortality. There are at least 15 distinct Candida species that cause human disease, but more than 90% of invasive disease is caused by the 5 most common pathogens: C. albicans, C. glabrata, C. tropicalis, C. parapsilosis, and C. krusei. Candida species may be causative agents in catheter infections, especially if the catheter is used for total parenteral nutrition. Early removal of the contaminated central venous catheter is associated with better outcomes. Candida peritonitis may complicate a perforated viscus. Candida rarely causes pneumonia or empyema unless the patient is immunocompromised. Aspergillus may infect burn wounds and can be found as pulmonary "fungus balls." Empiric antifungal therapy should be considered in critically ill patients with risk factors for invasive candidiasis and no other known cause of fever. Preferred empiric therapy for suspected candidiasis in immunogenic patients in the ICU is an echinocandin. Fluconazole is acceptable for patients with documented C. albicans and no recent azole exposure. C. krusei and C. glabrata are resistant to fluconazole and should be treated with an echinocandin or voriconazole. Voriconazole is also effective for Aspergillus. Recommended duration of empiric therapy for suspected invasive candidiasis in these patients who improve is 2 weeks, the same as for documented candidemia. For patients with no clinical response to empiric antifungal therapy at 4 to 5 days and no evidence of invasive candidiasis based on laboratory results, strongly consider stopping antifungal therapy.

Endocrine Changes in Critical Illness

Spyridoula Kontsiotis, MD, Gabrielle E. Hatton, MD, and Lillian S. [redacted]an, MD, FACP

Critical illness results in changes in whole body homeostasis, largely affecting the release of mediators affecting serum cortisol levels as part of the stress response. Alterations in acute critical illness include increased serum catecholamine levels, cortisol levels, insulin insensitivity, and changes in thyroid hormone levels. Both the hypothalamic pituitary adrenal (HPA) and the hypothalamic pituitary thyroid (HPT) axes are affected resulting in multiple endocrine changes. Given that these endocrine changes have been postulated to be adaptive responses to stress, it is controversial whether interventions to restore these axes to their normal state are necessary or beneficial. This chapter reviews the changes in endocrine function resulting from critical illness and the evidence for interventions to address these changes.

ADRENAL INSUFFICIENCY

Acute stress and critical illness activate the HPA axis, resulting in release of corticotropin releasing hormone and arginine vasopressin from the hypothalamus that stimulate the anterior pituitary gland to secrete adrenocorticotropic hormone (ACTH). In turn, ACTH activates the adrenal cortex to synthesize and release glucocorticoids, mainly cortisol, into the circulation. Regulation of the HPA axis occurs through a feedback loop. Elevated circulating cortisol levels provide negative feedback to suppress corticotropic releasing hormone and ACTH production (Fig. 1). Cortisol acts on the adrenal medulla to stimulate secretion of epinephrine and norepinephrine, resulting in the fight or flight response to stress and acute illness. Increased cortisol levels result in metabolic, cardiovascular, and immune effects. Cortisol mobilizes glucose for utilization by the brain and heart by increasing liver gluconeogenesis and decreasing glucose uptake by muscle and other tissues; improves hemodynamics by maintaining the responsiveness of vascular smooth muscle to catecholamines; inhibits the inflammatory response to injury; and suppresses the immune response.

It was previously thought that elevated cortisol levels seen during acute illness were due to stress induced activation of the HPA axis. On further investigation, ACTH was found to be unexpectedly low in critically ill patients. This relationship was deemed the ACTH-cortisol dissociation. There is now good evidence that elevated cortisol found in cases of severe and chronic critical illness is mediated outside of the HPA axis. There are several mechanisms that may explain this finding. Systemic inflammatory cytokines tumor necrosis factor α and interleukin-6 may independently stimulate cortisol production and are found to correlate positively with cortisol levels in critically ill patients. Increased sensitivity of the adrenals is unlikely, given that critically ill patients show a decreased response to corticotropin stimulation tests. Additionally, suppressed levels of cortisol metabolizing enzymes could explain reduced cortisol clearance. During critical illness, cortisol metabolizing enzymes such as A-ring reductases in the liver and 11β HSD2 in the kidneys are suppressed. Bile acids are known competitive inhibitors of both 11β-HSD2 and A-ring reductase, and cholestasis is often seen in critically ill surgical patients.

The concept of an inadequate response of the HPA axis and systemic cortisol resistance seen during stress has been termed *relative adrenal insufficiency* or *critical illness related corticosteroid insufficiency*. Symptoms and signs of adrenal insufficiency are often vague and nonspecific, such as weakness and fatigue, anorexia, nausea, and vomiting, abdominal pain, fever, and tachycardia. In critically ill patients, consideration for adrenal insufficiency should be triggered by the presence of hemodynamic instability refractory to adequate fluid resuscitation and vasopressor administration. Unfortunately, there are neither accurate diagnostic criteria nor strong evidence to guide indications for treatment of relative adrenal insufficiency. Measurement of total cortisol is problematic in that there is lack of uniformity in the accuracy of the tests; measurement of total serum cortisol levels does not reflect free, biologically active cortisol levels; and there is variability in the hourly secretion of cortisol. In addition, the synthetic ACTH stimulation test is unhelpful in making the diagnosis. In a large, multicenter randomized trial of glucocorticoids in septic shock, the results of this test did not predict responsiveness to glucocorticoid treatment. Other tests that have been considered include stimulation with low dose synthetic ACTH, at 1 μg, and measurement of salivary cortisol; however, neither of these tests has been extensively studied in critically ill patients.

The utility of treating septic shock with corticosteroids (either glucocorticoids or mineralocorticoids) remains controversial. Historically, two randomized, controlled trials, Corticosteroid Therapy of Septic Shock, reported contradictory mortality benefit with supplemental corticosteroids in septic shock. Similarly, two subsequent, large scale, multicenter trials—Activated Protein C and Corticosteroids for Human Septic Shock and Adjunctive Corticosteroid Treatment in Critically Ill Patients With Septic Shock—reported conflicting mortality benefit under similar clinical scenarios. Each of these studies reported accelerated shock reversal in the treatment groups, however (Table 1). Meta analyses from 2018 report an mortality benefit at 28 or 90 days with corticosteroid treatment in septic shock. There is low-quality evidence that there is faster shock reversal, faster wean from the ventilator, and shorter intensive care unit (ICU) length of stay. Tapering corticosteroids after resuscitation of hemodynamic status was previously recommended. New data suggest tapering after treatment for septic shock is not necessary and may be harmful.

Adjuncts to hydrocortisone may be beneficial in patients with septic shock. Vitamin C, which is acutely depleted in sepsis, reduces organ injury and improves survival in experimental models. The combination of vitamin C, corticosteroids, and thiamine may act synergistically in and in sepsis survival. In 2017, Marik et al. published a small, retrospective before-and-after study evaluating the addition of intravenous vitamin C and thiamine to hydrocortisone in patients with septic shock. Although there were numerous limitations to this study, the authors found the treatment group to have rapid reversal of shock physiology, no patient progressed to multi organ damage resulting from sepsis, and there was a significant decrease in hospital mortality from 40.4% in the control group to 8.5% within the treatment group. There are multiple randomized trials under way aiming to validate these results.

HYPERGLYCEMIA

Impaired glycemic regulation and insulin resistance are often seen in critical illness. Under normal physiologic conditions, blood glucose is maintained by a balance of pancreatic secretion of insulin and glucagon, hepatic gluconeogenesis, and peripheral glucose uptake. Glucose is transported across cellular membranes by carrier mediated facilitated transport by five glucose transporter isoforms (GLUT 1–5). Three of the isoforms, GLUT 1, GLUT 2, and GLUT 4, are important regulators of glucose uptake. GLUT 1 is found in many tissues and is responsible for basal glucose uptake. GLUT 2 mediates uptake and release of glucose by hepatocytes and regulation of glucose stimulated insulin secretion in the pancreas. GLUT 2 allows the liver to be permeable to glucose, ensuring that glucose transport is not rate limiting for hepatic glucose uptake.

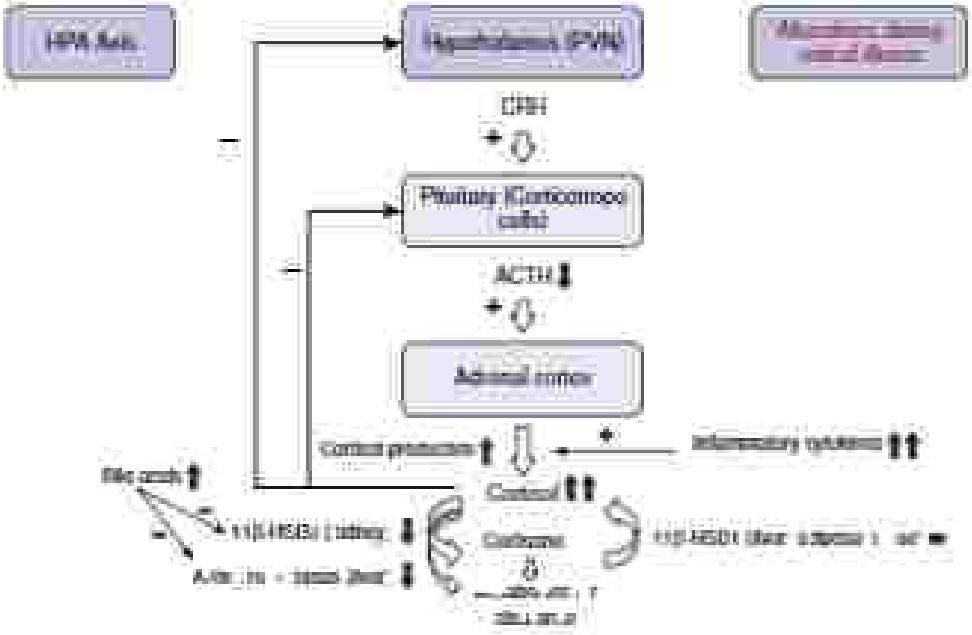

FIG. 1. Simplified overview of the regulation of the hypothalamic-pituitary-adrenal axis and cortisol production during critical illness. ↑, increase; plasma concentrations; ↓, decrease; plasma concentrations; +, stimulation; −, inhibition; ACTH, adrenocorticotropic hormone; PVN, paraventricular nucleus. (Modified from Pickkers P, Jansen J, Lorente JA, et al. Stress hormones and the immune response in acute renal failure. Kidney Int. 2004;66(2):770–776.)

Glucose stimulates insulin release by facilitated transport via GLUT 2, expressed on the surface of pancreatic beta cells. Insulin has potent antiinflammatory effects, although the exact mechanism of this in critical illness is not clear. One potential mechanism is insulin-mediated release of nitric oxide from the endothelium. Nitric oxide downregulates the expression of endothelial cell adhesion molecules and pro-inflammatory cytokines.

Marked insulin resistance and glucose dysregulation are frequently features of sepsis and critical illness. During sepsis, insulin-induced tyrosine phosphorylation of insulin receptor substrate 1 and subsequent activation of phosphoinositide 3 kinase is impaired, resulting in defective GLUT 4 receptor translocation, diminished glucose uptake, insulin resistance in skeletal muscle, and hepatic insulin resistance (Fig. 2). This dysfunctional glycemic regulation in critical illness, termed stress hyperglycemia, results in increased energy expenditure, changes in substrate utilization, and negative nitrogen balance (Fig. 3). Stress hyperglycemia improves with resolution of the underlying insult.

Multiple studies published over the past two decades have reported an association between uncontrolled stress hyperglycemia in hospitalized patients and poor clinical outcomes such as increased surgical site and healthcare acquired infections. Hyperglycemia contributes to a decrease in postoperative neutrophil phagocytic activity and decreases the oxidative burst of leukocytes, which may contribute to post operative infection susceptibility. Critically ill medical and surgical patients who are hyperglycemic have a higher mortality rate than patients who are normoglycemic. In 2001, a landmark single-center randomized trial, the Leuven trial, reported that tight glycemic control with an insulin infusion to target glucose levels of 80 to 110 mg/dL resulted in improved outcomes as compared to conventional control to target levels of 180 to 200 mg/dL. The most significant benefit of tight glycemic control was a reduction in mortality resulting from multiple organ failure in septic patients. Other benefits included decreases in bloodstream infections, acute renal failure requiring dialysis or hemofiltration, median number of red blood cell transfusions, and critical illness polyneuropathy. Although tight glycemic control with intensive insulin therapy was widely adopted, its benefit has not been substantiated in subsequent trials. Furthermore, in 2009, a multicenter randomized trial, the Normoglycemia in Intensive Care Evaluation and Surviving Using Glucose Algorithm Regulation trial, demonstrated increased mortality in patients receiving tight glycemic control. Severe hypoglycemia (blood glucose <40 mg/dL) was reported in 6.8% of patients receiving intensive glycemic control vs 0.5% in patients receiving conventional glycemic control. No significant difference between the two groups was noted in terms of median number of days in the ICU, number of days on mechanical ventilation, need for renal replacement therapy, or number of days in the hospital. Multiple explanations have been offered for the differences between these studies, both with regards to biological mechanisms and clinical trial methodology. In particular, the Normoglycemia in Intensive Care Evaluation and Surviving Using Glucose Algorithm Regulation trial had less risk of bias and more generalizability given its heterogeneous patient population and pragmatic trial design.

Although current glycemic targets are debated, several societies have advanced recommendations based on best available evidence. Across societies, the recommended glucose target range for critically ill patients is less than 180 to 200 mg/dL. In addition, the Society of Critical Care Medicine convened a task force regarding recommendations for insulin infusion therapy for management of hyperglycemia in critically ill patients. Despite the very low quality of evidence, they recommend initiation of insulin therapy at a blood glucose of 150 mg/dL and maintenance of glucose levels below 180 mg/dL. Optimally, glycemic targets must be achievable with low rates of hypoglycemia (<70 mg/dL) given the association between hypoglycemia and increased mortality. Therefore, individual intensive care units need to carefully evaluate their insulin protocols and monitoring processes to ensure reasonable rates of hyper- and hypoglycemia. Furthermore, patients on insulin infusions should be transitioned off using basal and bolus insulin rather than sliding scale insulin regimens. Basal-bolus insulin regimens based on long acting insulin (i.e., glargine) have been associated with improved glycemic control and reduced surgical site infections in noncritically ill surgery patients.

Additional strategies are under investigation in terms of their impact on glycemic control and clinical outcomes. Glucose-insulin therapy, whereby high glucose and high insulin infusions are simultaneously administered, has metabolic and immune effects that theoretically could improve outcomes. It has been evaluated in multiple randomized trials in cardiac surgery, but the results are mixed, and it is not currently recommended for routine use. Nutritional strategies for improving glycemic control such as diabetic formulas (i.e., low in carbohydrates and high in monounsaturated fatty acids), hypocaloric feeds, and glutamine supplementation have been studied as well. Although diabetic formulas and glutamine show promise in terms of intermediate outcomes such as rates of hyperglycemia and

TABLE 1 Select Randomized, Controlled Trials Investigating Mortality Benefit With Corticosteroid Treatment for Septic Shock

Trial	N	Inclusion Criteria	Treatment[a]	Shock Resolution	28-Day Mortality			Other Results	Conclusion
					Control (%)	Treatment (%)	OR or RR		
Cor Ins (CRIT, Annane et al)	299	Septic shock with hypotension resistant to >1 hr vasopressors and fluid resuscitation	Hydrocortisone + fludrocortisone, 7 days, no taper	Vasopressor withdrawal, median 7 days vs 9 days	61	55	Adjusted OR: 0.65 (95% CI: 0.32–1.07)	Effects enhanced in nonresponders to corticotropin stimulation test	↓ 28-day mortality ↓ Duration of vasopressor administration

hyperglycemia, some of these therapies have been demonstrated to improve clinical outcomes. Improved strategies for delivering insulin therapy such as use of short acting insulin infusions, continuous glucose monitoring in the inpatient and intensive care setting, and development of closed loop control systems are also promising, although further study is needed.

THYROIDAL DYSFUNCTION

The HPT axis modulates the neuroendocrine response in both healthy and critically ill patients. Abnormalities in thyroid hormone concentrations without evidence of coexisting thyroid or pituitary gland disease are commonly seen in a wide variety of illnesses including septic shock, myocardial infarction, burn injury, acute trauma, and major surgery. In healthy patients, serum levels of thyroid hormones are regulated through a feedback loop. Neurons in the paraventricular nucleus of the hypothalamus synthesize thyrotropin-releasing hormone, which in turn stimulates the anterior pituitary gland to synthesize and release thyroid-stimulating hormone (TSH) or thyrotropin in a diurnal and pulsatile manner. Binding of TSH to receptors on thyroid follicular cells results in the release of thyroid hormones into the circulation: 90% as tetraiodothyronine (thyroxine [T_4]) and 10% as triiodothyronine (T_3). Free thyroid hormone composes less than 1% of total circulating T_4 and T_3; the rest are bound to thyroxine-binding globulin, transthyretin, and albumin in that order. Once taken up by the target tissues, T_4, which acts as the prohormone, is acted upon by deiodinases 1, 2, and 3 (D1, D2, and D3). Depending upon the location of the iodine that is removed, T_4 can either be converted to its active form, T_3, or to an inactive form, reverse T_3 (rT_3). Serum thyroid hormone provide negative feedback to the hypothalamus and pituitary gland, which regulate TSH secretion (Fig. 4).

Critical illness is associated with profound changes of the neuroendocrine axis including abnormalities in thyroid hormone concentrations. Changes in thyroid hormone levels differ from those seen in primary and secondary thyroid disorders and are referred to by several interchangeable names: euthyroid sick syndrome, low T_3 syndrome, and nonthyroidal illness syndrome (NTIS). These changes include low plasma concentrations of T_3, low or normal plasma concentrations of T_4, or elevated plasma rT_3 in the presence of normal TSH. NTIS has specific measurable changes in thyroid hormone parameters in addition to having alterations in both the central regulation of the thyroid axis and in the peripheral conversion of thyroid hormone at the tissue level.

In acute critical illness, total and free T_3 levels decrease rapidly, whereas plasma concentrations of rT_3 rise within a few hours of

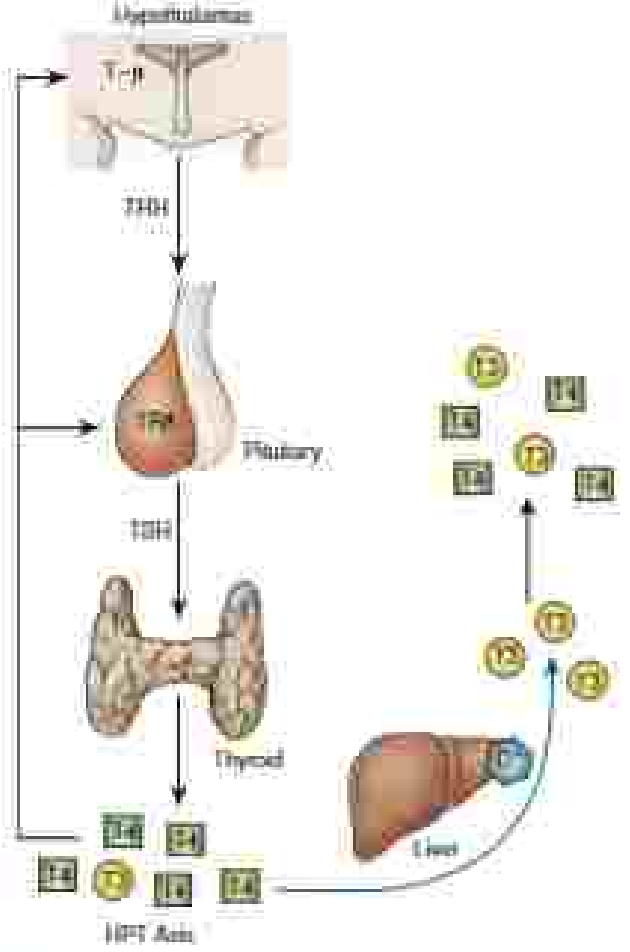

FIG. 1 posthumous pituitary-thyroid axis. D1, Deiodinase 1; T_3, thyroid hormone receptor β; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone; T_4, thyroxine. *From Araujo JA, Fonseca JJ, Moreira CA. Thyroid hormone metabolism in skeletal muscle-brain and adult brain neurotransmission. Endocr Rev. 2021;42(1):1–15.*

the fasting event. An acute alteration in the peripheral conversion of T_4 occurs because of decreased D1 activity and an increased D3 activity, thereby contributing to decreased conversion to T_3. Meyer et al. found no statistical difference between T_3 and free T_4 levels on admission compared to values obtained at 2 days and at discharge from ICU in critically ill patients. Notably, free T_4 levels significantly decreased in nonsurvivors and increased in survivors. Meyer et al. further showed that median T_3 levels on ICU admission were lower in septic patients as compared to those with a systemic inflammatory response syndrome. The lowest T_3 levels were found in patients with septic shock. The mechanism of the acute decrease in T_3 has not been completely elucidated; however, decreases in plasma concentrations of thyroid hormone binding proteins and albumin, in addition to inhibition of hormone binding, transport, and metabolism by elevated levels of free fatty acids and bilirubin, are important mediators of T_4 to T_3 conversion in acute illness.

In prolonged critical illness, T_3 levels remain low and rT_3 levels remain elevated. Total and free T_4 levels decline. TSH secretion dampens and loses its diurnal rhythm. Factors responsible for hypothalamic suppression during prolonged critical illness are not clear. A local increase in D2 activity in the hypothalamus may elevate local thyroid hormone levels, altering the set point for feedback inhibition. Additionally, unlike to acute injury, peripheral tissues in the prolonged phase of critical illness adapt by increasing thyroid hormone transporters, activating local thyroid hormone, and increasing gene expression of active receptors. For example, the majority of T_3 is produced by peripheral 5′-deiodination of T_4 to T_3 in organs such as muscle, liver, and kidney. This conversion is done by the enzyme 5′-monodeiodinase, which has decreased enzymatic activity when calorie intake is low and in fatal illness. T_3 is also inhibited by high concentrations of serum cortisol, free fatty acids, cytokines (such as interferon α, nuclear factor κB, and interleukin 6), and medications including amiodarone and propranolol. Furthermore, patients with critical illness often have circulating substances such as inflammatory mediators that inhibit T_4 binding to proteins, which results in a reduction in total serum T_4 concentrations and low serum free T_4 levels. The reduced circulating T_3 levels in sick patients may be due in part to a decreased peripheral T_4 deiodination by D1 or D2, or both.

Because of the changes that occur in the HPT axis, newly diagnosing primary thyroid disorders in acute illness is controversial. Both primary hypothyroidism and NTIS can result in elevated TSH levels. Although a normal TSH rules out primary hypothyroidism in healthy patients, TSH may be low in patients with primary hypothyroidism and NTIS. Furthermore, drugs may contribute to a paradoxically low TSH level. Primary hypothyroidism is usually accompanied by decreased T_3 and T_4 levels, which can also be seen in patients with prolonged critical illness or during recovery from NTIS. A high serum T_3 to T_4 ratio, a low serum rT_3, and a low thyroid hormone binding ratio may be more supportive of primary hypothyroidism; but the diagnostic accuracy of these tests is limited. Longitudinal follow-up with repeated testing after recovery from critical illness is necessary to confirm the diagnosis. Primary hyperthyroidism should be considered in patients with elevated serum T_3 and T_4 levels, given the rarity of this finding due to critical illness.

The management of thyroid dysfunction in the setting of known or suspected underlying disease is different from that for NTIS. If a patient is known to have preexisting primary hypothyroidism, the previous dose of thyroid replacement medication is continued. If a patient has myxedema coma, treatment is comprised of thyroid hormone replacement, treatment of the underlying condition, and supportive care such as passive rewarming, vasopressor therapy, and antibiotics as indicated. Intravenous glucocorticoids are recommended because of the possibility of concomitant adrenal insufficiency. If a patient has thyroid storm, treatment includes thionamides such as either propylthiouracil or methimazole followed by iodine administration. Hyperadrenergic symptoms can be treated with β-blockers, and glucocorticoids should be administered if adrenal insufficiency is suspected.

The question of whether NTIS warrants treatment is controversial. To date, there is no convincing evidence that treatment of NTIS is either needed or beneficial. Thyroid hormones have been evaluated in several small, underpowered trials in heterogeneous patient populations. For example, in a study of severely burned patients given daily T_3, no beneficial or detrimental effect was noted; however, improved myocardial function and the need for reduced amounts of vasopressor have been observed with T_3 infusion in adults undergoing coronary artery bypass surgery. Although there may be subgroups of patients for whom short-term benefits may exist such as heart failure patients, there are no outcome data demonstrating clear benefit in terms of long-term morbidity and mortality. Initial studies by Van den Berghe et al. in patients with severe NTIS showed that combination of TSH, growth hormone releasing hormone, and growth hormone releasing peptide 2 reduces protein catabolism by restoring physiologic hormone levels. However, the lack of association of low T_3/free T_4 in this study fails to lend evidence to the potential usefulness of thyroid hormone treatment in critically ill patients. Surrogate outcomes such as circulating thyroid hormone levels and markers of metabolism were improved, but there was no impact on morbidity or mortality.

Treatment of NTIS with thyroid hormones is fraught with challenges. First, thyroid hormone doses that are required for normalization of serum levels may result in high tissue levels. Second, pharmacologic doses of thyroid hormones can suppress the HPT

axis, resulting in utilization and depletion of thyroid reserves. Last, thyroid hormone treatment must be monitored closely as simultaneous recovery from NTIS may result in overtreatment and acute hyperthyroidism.

Nutrition Therapy in the Critically Ill Surgical Patient

Kimberly Joseph, MD, and Krishnan Sriram, MD, FCCM, FACS(C), FACS

Nutrition therapy, the preferred term, is not adequately emphasized in medical school curricula or even in residency and fellowship programs. With the abundance of information physicians are forced to absorb, nutrition therapy is often given low priority; however, in critically ill patients, nutrition therapy becomes all the more important because of significant changes in physiology and metabolism that accompany such illness. Concepts regarding critical care nutrition have evolved during the past few decades, with new information and controversies emerging with each passing year. There continue to be fundamental differences between guidelines published by various societies from different parts of the world. There is also significant evidence that nutrition therapy for surgical patients must be approached differently than therapy for medical patients. This chapter attempts to provide the reader with a practical approach to the nutritional care of the critically ill surgical patient.

Defining Malnutrition/ Nutrition Risk

Defining malnutrition has been a dilemma for several decades. No definitions or characterizations have been durable in terms of

axis, resulting in utilization and depletion of thyroid reserves. Last, thyroid hormone treatment must be monitored closely as simultaneous recovery from NTIS may result in overtreatment and acute hyperthyroidism.

Nutrition Therapy in the Critically Ill Surgical Patient

Kimberly Joseph, MD, and Krishnan Sriram, MD, FCCM, FRCS(C), FACS

Nutrition therapy, the preferred term, is not adequately emphasized in medical school curricula or even in residency and fellowship programs. With the abundance of information physicians are forced to absorb, nutrition therapy is often given low priority; however, in critically ill patients, nutrition therapy becomes all the more important because of significant changes in physiology and metabolism that accompany such illness. Concepts regarding critical care nutrition have evolved during the past few decades, with new information and controversies emerging with each passing year. There continue to be fundamental differences between guidelines published by various societies from different parts of the world. There is also significant evidence that nutrition therapy for surgical patients must be approached differently than therapy for medical patients. This chapter attempts to provide the reader with a practical approach to the nutritional care of the critically ill surgical patient.

Defining Malnutrition/ Nutrition Risk

Defining malnutrition has been a dilemma for several decades. No definitions or characterizations have been durable in terms of

universal and cost-effective applicability. Earlier definitions have been based on the World Health Organization's recommendations, which were in turn based on epidemiologic data and heavily relied on a patient's weight and anthropometric measurements. What used to be called nutritional laboratory markers, such as serum protein levels (transferrin, prealbumin) have been shown to be of limited value in hospitalized patients, hence are no longer widely recommended. As they reflect inflammation (and are inversely proportional to the level of serum pro-inflammatory markers such as C-reactive protein), they must be considered in the overall context of a patient's status with regards to inflammation rather than as nutrition markers per se. Similarly, although inflammation-based definitions for malnutrition have been explored, assaying highly specific biomarkers is expensive and not cost-effective.

To this end, several major societies joined forces to simplify the definitions, based more on subjective clinical assessment by a trained clinician. A diagnosis of malnutrition may be made if the patient has two or more of the following criteria:

- Insufficient energy intake
- Weight loss
- Loss of muscle mass
- Loss of subcutaneous fat
- Localized or generalized fluid accumulation
- Decreased functional status

It is highly likely that most critically ill perioperative surgical patients will fulfill two or more of these criteria; however, even this definition may not always capture acute onset disease-related malnutrition. Also, the presence of these criteria may not be immediately evident on presentation. Certain subsets of surgical patients may be considered to have some degree of disease-related malnutrition and should thus be considered candidates for early nutrition therapy, regardless of whether they satisfy the criteria listed at the time of presentation. Such patient populations include but are not limited to severely injured polytrauma patients, burn patients meeting criteria for resuscitation, patients with traumatic brain injury, and patients with major soft tissue and other infections.

It is worth specific mention of overweight and obese patients as a subpopulation; nutrition therapy for overweight/obese surgical patients is often delayed owing to a misperception on the part of clinicians regarding such patients' nutritional status. There is a persistent myth that overweight/obese patients cannot be malnourished; however, clinicians must remember that protein catabolism occurs at alarming rates in critically ill patients, with daily losses of up to 700 g of lean body mass, leading to sarcopenia. Overweight/obese patients experience the same losses; using the definitions and criteria mentioned previously, most overweight/obese critically ill patients will experience loss of muscle mass and localized/generalized fluid accumulation, as well as possible disease-related acute inflammation. Losses of this latter cannot be specifically measured. In light of this, it is vitally important that critically ill overweight/obese patients receive aggressive nutrition therapy.

Aside from definitions of and criteria for malnutrition, there are templates for assessing "nutrition risk" that clinicians may also find useful. One such template is the Nutrition Risk in the Critically Ill score, developed by Heyland et al., which incorporates illness severity parameters (Acute Physiologic Assessment and Chronic Health Evaluation score, Sequential Organ Failure Assessment) as well as an assessment of comorbidities, age, time to intensive care unit (ICU) admission, and interleukin-6 measurements. Scoring modifications were made for circumstances in which interleukin-6 measurements were not available. The complementary use of nutrition risk scoring tools along with the definitions/criteria for malnutrition mentioned previously may be useful for practitioners in making decisions regarding the initiation of nutrition therapy.

Finally, not all ICU patients are candidates for specialized nutrition therapy. Patients who are in the ICU for short periods and/or who can tolerate unrestricted oral intake early in their stay will likely be at low risk from a nutritional standpoint.

EVALUATION OF NUTRITION REQUIREMENTS IN THE CRITICALLY ILL SURGICAL PATIENT

Currently, the only recommended method to objectively evaluate the nutrition/energy requirements for critically ill patients is the use of indirect calorimetry. Aside from the expense involved, this methodology may be difficult to use in surgical patients, who often require frequent interventions that might preclude obtaining steady-state measurements. Predictive equations have fallen out of favor because of questions regarding their accuracy and reliability. There has been much interest recently in the use of imaging techniques to assess sarcopenia. These include bedside ultrasound of thigh musculature as well as computed tomography imaging of the lumbar/psoas musculature. At present, though, there are no universally accepted standards. For these and other reasons, a simple weight-based equation recommending 25 to 30 kcal/kg per day energy provision is considered applicable for most critically ill patients as a starting point.

The preponderance of current literature emphasizes the importance of adequate protein intake to attenuate muscle breakdown, hence the recent interest in optimizing perioperative protein intake and the availability of such enteral products. Protein intake has traditionally been recommended in ranges of 1.2 to 2 g/kg per day for these patients; however, more recent data suggest that provision of up to 2.5 g/kg per day is safe and may be more effective. For obese patients, guidelines suggest using a weight-based energy provision of 11 to 14 kcal/kg of *actual* body weight per day for patients with body mass index (BMI) of 30 to 50, and 22 to 25 kcal/kg *ideal* body weight per day for patients with BMI greater than 50. Protein intake for obese patients should consist of 2 g/kg ideal body weight per day for patients with BMI of 30 to 40, and up to 2.5 g/kg ideal body weight per day for patients with a BMI 40 or greater. These measures are important to minimize muscle wasting.

Micronutrients (vitamins and trace elements) have ubiquitous functions in the body and are critical for all enzyme functions. Wound healing is affected by deficiencies of several micronutrients, notably zinc, copper, vitamin A, vitamin C, among others. The micronutrients known to affect cardiac function include vitamin D, vitamin B$_1$ (thiamine), selenium, and copper. Preoperative measurement and correction are indicated only when a deficiency is suspected on clinical grounds. Polypharmacy, history of excessive alcohol intake, being elderly, and obesity are conditions where micronutrient deficiencies may go unsuspected. Thiamine deficiency, common in patients with history of excessive alcohol intake, may result in unexplained lactic acidosis and mental changes.

Refeeding syndrome occurs if nutrition therapy, parenteral or enteral, is administered to severely malnourished patients and advanced too rapidly, sometimes leading to death. Clinical features include fluid balance abnormalities, disturbances in glucose metabolism, hypophosphatemia, hypomagnesemia, hypokalemia, and thiamine deficiency. In addition, selenium deficiency may occur with its known effects on the myocardium, causing cardiomyopathy. Hypophosphatemia may contribute to failed weaning attempts, in addition to its effect on the oxygen dissociation curve. Surgeons should maintain a high index of suspicion to detect and intervene in patients suspected to have refeeding syndrome. In patients at risk, nutrition therapy is initiated at very slow rates of 10 kcal/kg per day and advanced while electrolyte levels are being normalized.

IMPORTANCE OF PROTEIN

As noted, the provision of adequate protein to critically ill patients is considered vitally important to attenuate muscle breakdown and wasting. Critically ill patients have a hypo-aminoacidemia that is characterized by a state of increased amino acid uptake in tissues experiencing rapid protein turnover (e.g., liver, bone marrow, splanchnic organs, immunologically active tissues); this is limited by the maximum rate of amino acid release from muscle and results in a

enteral protein deficiency. The provision of normal dietary amounts of protein is inadequate to meet these requirements, hence the recommendations for higher levels of protein provision in critical illness. The recommended amounts of protein to be administered have varied for different disease states and by different guideline-producing entities, however. In a 2012 systematic review, Heyland and Stapleton noted a number of difficulties with the then current recommendations, which included the simple issue of what type of weight was being used in different studies to make weight-based recommendations. They also noted that, even with the then current recommendations, many of the studies only achieved protein delivery in the range of 0.8 to 0.9 g/kg per day irrespective of the weight type used. Although these primary recommendations are for additional research, they felt comfortable concluding that protein substrate provision in the range of 1 to 2.5 g/kg/d normal body weight was safe and probably more effective relative to lower ranges. A more recent analysis by Kochanda et al. looked at the history of protein provision to hospitalized patients as well as newer methods to evaluate protein requirements. Some of these techniques may not be easily available to the majority of clinicians as yet.

Clinicians should therefore concentrate on practical methods to try to ensure adequate protein delivery. These may include the following:

- Rather than aiming for the minimum in the general recommended ranges, aim for a goal of 2.0 g/kg per day protein substrate provision in most patients. In severely obese patients (even when being provided with fewer overall calories), the goal may be as high as 2.5 g/kg per day; in burn patients, it may be higher.
- Consider the addition of modular protein supplements to meet the goals.
- Consider a volume-based approach (discussed later in the chapter) in cases in which it is anticipated that there will be frequent interruption of nutrition therapy.

The importance of protein provision cannot be overstated, even in situations in which overall calorie delivery must be altered, practitioners should maintain their focus on adequate protein delivery.

BENEFITS OF EARLY ENTERAL NUTRITION

For at least three decades, it has been accepted that enteral nutrition (EN) provides benefits to critically ill and injured patients. Surgical stress and the stress of major trauma/burns results in local release of inflammatory cytokines as well as counter-regulatory hormones (e.g., adrenocorticotropic hormone and cortisol). If that inflammation overwhelms the local or systemic environment, it can result in hypercatabolism, characterized by accelerated protein breakdown in skeletal muscle and clinical wasting. Alterations in gut lymphatic tissue in such circumstances also predispose to reduced immune competence. Multiple investigators have demonstrated that even small amounts of EN ("trophic feeding") results in preservation of tight junctions, microvilli height, and epithelial/mucosal surface area, thereby decreasing bacterial translocation. Conversely, delays in providing EN have been associated with gut mucosal atrophy as well as with impaired carbohydrate absorption, higher rates of pneumonia and other nosocomial complications, increased ventilator days, and longer lengths of stay. In a 2018 meta-analysis designed specifically to determine if EN provided within 24 hours was superior to other forms of nutrition, the authors concluded that there was no benefit to early EN. Even in this study, a priori subgroup analyses of trials in trauma and burn patients and of patients with secondary pancreatitis demonstrated a mortality benefit with early EN. This again emphasizes that surgical patients may have different requirements for and responses to EN than their medical counterparts.

Controversy persists regarding how trophic feeding/permissive underfeeding compares with full caloric EN therapy in terms of outcomes. Several recent studies suggest that there is no difference in patient outcomes between the two strategies. The NeMIT trial, for example, examined provision of 60% to 65% of nonprotein calories versus more than 70% calories with full protein provision and found no differences in near-term outcomes. It remains to be seen if these results can be widely replicated. Additionally, other studies have provided evidence that patients who accumulate significant caloric deficits over the course of their hospital stay have worse outcomes. It remains unclear how long it is safe to underfeed a patient. Underfeeding may also reduce the insulin response, limiting the ability of insulin to exert its beneficial anabolic effects. Additional research is needed to better clarify the role of permissive underfeeding.

As a general rule, critically ill surgical patients should receive early EN that is increased to estimated goal rates when feasible. If permissive underfeeding is used, practitioners should still focus on adequate protein delivery from the time of initiation of nutrition therapy. Frequent evaluations should be undertaken to determine when it might be safe to increase EN to appropriate estimated goal rates. This is necessary to avoid cumulative caloric deficits.

PREOPERATIVE NUTRITION THERAPY AND PREHABILITATION

Although the bulk of this chapter focuses on the critically ill surgical patient, it is worth understanding the needs of patients requiring elective major surgery as these patients may end up in the ICU. All patients scheduled for elective major surgical procedures, involving the gastrointestinal (GI) tract or otherwise, should be evaluated by a nutritionist at least 7 to 10 days before the planned procedure. Systems must be developed in hospitals requiring this crucial step in identifying patients who are risk for malnutrition or are actually malnourished. This is as important as clearance by a cardiologist or preoperative evaluation by an anesthesiologist. Preoperative nutritional evaluation and intervention forms an integral part of the Enhanced Recovery after Surgery protocols and pathways.

As part of these protocols, patients identified as being malnourished or at high nutritional risk are provided oral nutritional supplements using any standard complete balanced EN product. Literature supports providing approximately 500 mL of the liquid or reconstituted formula consumed over the course of 24 hours in divided doses per the patient's tolerance. Meta-analyses of such studies have shown that any standard enteral formulation can be used (vs specifically immune-enhancing products). Benefits of such interventions include shorter length of hospital stay and decreased infectious complications.

Preoperative nutritional evaluation is also an excellent opportunity to detect and correct drug-nutrient interactions, especially in elderly patients and obese individuals. Micronutrient deficiencies resulting from pharmaceuticals may go undetected if not suspected and treated appropriately prior to elective procedures. Various commonly used medications (e.g., diuretics, proton pump inhibitors, metformin) variably produce deficiencies of zinc, vitamin C, vitamin B_{12}, folate, and electrolytes, including magnesium.

INTRAOPERATIVE CONSIDERATIONS

Attention to maintain optimal and electrolyte levels continues during the operative procedure. The liberal use of epidural anesthesia is encouraged for its known benefits during the actual surgical procedure and for pain management during the postoperative period. Dependence on systemic narcotics is minimized, thereby decreasing postoperative nausea and vomiting and increasing tolerance to early resumption of oral or enteral feeding. It is prudent to consider GI access to facilitate early initiation or resumption of enteral feeding. Depending on the clinical situation, preemptive access may include a soft bore nasoenteral tube with the tip positioned in the stomach or jejunum or a formal gastrostomy or jejunostomy. The majority of patients can be successfully managed with intraoperative feeding, with prophylactic postfeeding only for patients deemed to be at high risk for aspiration. By obtaining GI feeding access during the operative

procedure itself, parenteral nutrition (PN) at a later time may be avoided. It is tempting for clinicians to trust their ability to predict when their patient will be able to resume oral nutrition and forego the placement of feeding access in the operating room. However, it should be remembered that it is usually far easier to remove temporary feeding access on discovery that it is not needed than it is to place it postoperatively if it turns out it is needed.

POSTOPERATIVE AND ICU CONSIDERATIONS

One of the challenges facing clinicians in the ICU and the postoperative period is determining how to monitor the success of nutrition therapy. Unlike other pharmacotherapies, nutrition therapy usually does not result in an obvious short-term effect. Other than indirect calorimetry, there are no reliable objective methods to assess energy needs. Measurements of acute phase proteins, while they may be useful to help evaluate changes in a patient's inflammatory state, do not specifically address nutritional status. Clinicians are largely reliant on their initial assessment of the patient's admission nutrition status and nutrition risk to determine parameters for provision of therapy.

A barrier that clinicians often encounter in the ICU when trying to deliver nutrition therapy is the frequent, temporary cessation of EN therapy as the patient leaves the unit for tests, procedures, and/or operations. One option that may lessen the consequences of these interruptions is to provide volume-based rather than rate-based therapy. As proposed by McClave and colleagues, the total volume goal of enteral nutrition for a 24-hour period is calculated; if the infusion is interrupted, it is increased above the baseline rate once resumed in such a way as to make up for the lost period. For example, if it is known that a patient is returning to the operating room at a specific time, the EN infusion rate may be increased to account for the estimated lost time. By doing so, the patient's cumulative caloric deficit is reduced. Multiple studies have demonstrated an association between reduction of caloric deficit and improved outcomes in critically ill patients. To accomplish this, however, a truly multidisciplinary approach must be employed; all the members of the team must be educated as to the importance of EN therapy and specifically of the potential consequences of interruption. Protocols must be developed that are easy for team members to follow (e.g., the Enhanced Protein Therapy Promotes via the Enteral Route in Critically Ill Patients protocol or the CAN WE FEED researchers). Collaboration with anesthesiologists can be explored to reduce EN cessation before planned operations.

Another reason that EN is interrupted is because clinicians may believe that the patient is not tolerating the EN because there are no bowel sounds, no stool production, and/or no flatus. Enteral formulations are specifically designed for easy absorption in the small intestine. The presence of bowel sounds or passage of flatus is not necessary to either initiate or continue EN. Clinicians should monitor for signs of ileus; however, postoperative ileus is more likely to be a function of immobility and/or opioid and sedative medications rather than appropriate administration of EN. If anything, EN is associated with an improvement in GI motility and mucosal integrity; this is true even in the presence of an anastomosis. GI and colonic anastomoses actually heal better when enteral feeding is sustained, even if the site of feeding is proximal to the anastomosis. The common reluctance of surgeons to use this as an excuse to delay initiation of EN is not supported by the literature. An exception is procedures involving the esophagus where it is customary to obtain contrast studies before initiating oral or tube feeding; however, even in such cases, placement of a more distal jejunal feeding access may obviate the need for delay.

There is persistent controversy regarding whether EN should be initiated in patients who are hemodynamically abnormal or are on vasopressor support. Patients who are on stable, "low" levels of vasopressor support may safely receive EN. This must be evaluated by the clinician with awareness that if such issues have led to a significant delay in EN initiation or resumption the patient may have accumulated a significant caloric deficit.

There are patients who demonstrate true EN intolerance. Should this persist for more than 5 to 7 days, consideration must be given to initiating PN; however, there are strategies that may be used in advance of this. If a gastric ileus is present, prokinetics such as metoclopramide or erythromycin may be useful; however, gastric residual volumes have not been shown to correlate with EN tolerance, and their routine measurement is no longer recommended. Placement of a postpyloric feeding access may be considered in patients who are considered at high risk for gastric feeding intolerance, since this may be difficult to predict a priori, consideration should be given to placement of a nasojejunal duodenal or jejunal tube intraoperatively in patients who are undergoing open abdominal surgery (as mentioned previously). Alternatively, there are many described methods for bedside postpyloric tube placement; endoscopic or radiologic placement may also be considered.

CONCEPTS AND CONTROVERSIES REGARDING IMMUNONUTRITION

The terminology in the area of immune-modulating nutrition can be confusing. Immune-modulating, immune-enhancing, and/or immunonutrition are terms used synonymously. Moreover, although there have been numerous studies done in this area, the results have often been contradictory, partly from differences in formulations used and populations studied. When discussing immunonutrition, clinicians are generally concerned with the following nutrients: arginine, omega-3 polyunsaturated fatty acids, nucleotides, glutamine, and antioxidants.

Arginine

There has been some concern that administering arginine-containing nutrition therapy may be harmful in septic patients. The Surviving Sepsis guidelines as well as the most recent American Society for Parenteral and Enteral Nutrition (ASPEN)/Society of Critical Care Medicine (SCCM) guidelines for nutrition in adult critically ill patients, published in 2016, recommend specifically against arginine-containing immunomodulating formulas in sepsis. These recommendations are based on a potential concern that inducible nitric oxide synthase, a metabolite of arginine, would cause harmful vasodilatation in this patient population, particularly medical patients who are septic. However, there is literature support for arginine supplementation for surgical ICU patients (pre- and postoperatively) as well as patients with severe trauma and traumatic brain injury. The suggested dose is 15 to 30 g/day. The literature also suggests that using arginine in combination with fish oil in surgical patients may deliver the best outcomes in terms of reducing nosocomial infections and decreasing length of stay.

Omega-3 Polyunsaturated Fatty Acids/Fish Oil

These nutrients are believed to exert their positive effect by competing with arachidonic acid for cyclooxygenase and 5-lipooxygenase binding sites, resulting in a reduction of the 2-series of prostaglandins and the 4-series of leukotrienes and thereby a reduction in the inflammatory response. Initial studies in the late 1990s suggested a beneficial role for the use of docosahexaenoic acid and eicosapentaenoic acid in patients with acute respiratory distress syndrome (ARDS); subsequent investigations have not been able to demonstrate this effect, and the ASPEN/SCCM guidelines recommend against their routine use in medical ICU patients and patients with ARDS. However, there is enough literature supporting their use in surgical ICU patients, usually in combination with other immune-modulating nutrients, to allow for a positive recommendation in this population. There is also evidence that these products may be beneficial in traumatic brain injury.

Nucleotides

The use of nucleotides in combination with arginine and/or fish oil is recommended for critically ill surgical ICU and trauma patients.

There is some suggestion in recent investigations that nucleotides may have a beneficial impact on the gut microbiome.

Antioxidants

The literature regarding the use of antioxidants, such as ascorbic acid, zinc, and selenium (along with other micronutrients) has been inconsistent. Although most enteral and parenteral formulations include these elements in recommended daily doses, there is not sufficient evidence to suggest that enhanced dosing is beneficial.

Glutamine

Studies in the late 1980s/early 1990s suggested that enteral glutamine was an essential component of immune enhancing regimens administered to trauma and burn patients, as well as patients undergoing major upper GI surgery. Subsequent studies failed to demonstrate a clear benefit of enteral glutamine, and some studies implied that it was possibly harmful. Investigations into the use of parenteral glutamine have also not demonstrated clear benefit despite the consistency of delivery (relative to the enteral route). Current recommendations are for the use of glutamine supplemented immunonutrition only in patients with traumatic brain injury and perioperative surgical trauma patients in the ICU, however, it should be noted that some researchers feel that the glutamine question remains unanswered. A recent meta-analysis by Chen and colleagues noted that patients in surgical ICUs did appear to benefit from glutamine supplementation.

Clinicians must consider the available literature, existing recommendations, as well as their own clinical judgment when deciding to use immunonutrition in their patients; however, there is sufficient evidence to suggest that critically ill surgical patient populations, more so than their medical ICU counterparts, are likely to derive benefit from such regimens.

PARENTERAL NUTRITION

PN has a limited role in the preoperative preparation of malnourished surgical patients; however, when initiated, it facilitates correction of electrolyte, vitamin, and trace element deficiencies. The duration of PN is generally not extended for more than 10 to 15 days. There are no reliable laboratory tests to identify an endpoint. Weight gain from PN is mostly gain of fat, not only in the usual sites of fat stores, but also in the muscle itself.

It is prudent to minimize the use of PN during the intraoperative period especially for complex and extended procedures. This avoids the need for close monitoring and management of glucose levels during the procedure. In order to avoid wastage of PN infusates, close coordination between the pharmacy, ICU, and operating room staff is needed.

During the postoperative period, all attempts are made to optimize timely initiation of EN and advancement to goal as early as the patient's condition permits. A time limit of 3 to 5 days to achieve this goal is reasonable. When it is obvious that EN cannot be depended on as the sole route of nutrition therapy, PN should be initiated either to supplement or replace EN. Cumulative protein and calorie deficits appear to correlate with postoperative and ICU mortality and morbidity. PN may be administered as a central venous formula or mixed with higher fat content (to decrease osmolality) for peripheral vein use.

Earlier initiation of PN can be justified in conditions such as high output fistulas or ongoing bowel obstruction where resumption of EN is clearly not possible. Ileus, the definition of which is vague, is not an absolute contraindication to initiate trophic EN. Guidelines also support early initiation of PN, either total or supplemental, in patients who are severely malnourished or are at risk of malnutrition. The difficulty is defining such patients clinically because laboratory tests do not have either a positive or negative predictive value. It is suggested that surgeons should have a low threshold to initiate PN based on sound clinical judgment to minimize the adverse effects of protein and calorie insufficiency. The use of newer fat emulsions, not based on soy, derived omega 6 fatty acids, is encouraged if available.

DISEASE/CONDITION-SPECIFIC NUTRITION THERAPY

Trauma

Severely injured trauma patients benefit from early EN with an emphasis on protein delivery; traditional recommendations have been 1.2 to 2 g/kg per day, but more recent recommendations suggest up to 2.5 g/kg per day are likely safe. This is also one of the patient populations for which immunonutrition formulas (with arginine and fish oil) are recommended. Severely injured trauma patients often require frequent visits to the operating room, making achieving goal EN challenging; volume based feeding should be strongly considered in such cases. EN should begin as soon as the patient is hemodynamically normal. Nutrition therapy should not be delayed out of concern for anastomoses or an open abdomen. Even in patients undergoing damage control procedures, the literature suggests that early EN does not result in delays in abdominal closure rates.

Burns

ASPEN/SCCM guidelines recommend that burned patients requiring resuscitation receive early EN with protein goals of 1.5 to 2 g/kg per day. American Burn Association recommendations have been higher, up to 3 g/kg per day. Some studies have recommended that nasoduodenal/jejunal nutrition be implemented as early as 4 to 6 hours post burn. Pharmacologic therapy with recombinant human growth hormone, insulin like growth factor, propranolol, and oxandrolone have also been suggested by some authors to mitigate the profound catabolic insult sustained by severely burned patients.

Traumatic Brain Injury

Patients with traumatic brain injury (TBI) suffer from significant catabolic stress following their injuries. Both the Brain Trauma Foundation Guidelines and the ASPEN/SCCM guidelines recommend early EN in TBI. Although there is some evidence that transpyloric feeding is associated with fewer incidences of late pneumonia, the majority of TBI patients can tolerate continuous gastric feeding when appropriate ventilator bundle protocols are adhered to. Recently there has been interest in the effect of omega 3 fatty acids in TBI; there is some evidence that they may be immunomodulator as well as neuroprotective. The ASPEN/SCCM guidelines recommend an arginine enhanced, immune modulating formula or supplementation of a standard formula with eicosapentaenoic acid/docosahexaenoic acid for TBI patients.

Pancreatitis

Current practice guidelines encourage enteral or oral feeding for acute pancreatitis include those classified as "severe" and with complications such as pancreatic ascites or abscess. A patient centric approach is appropriate. The concept of resting the gut or pancreas in acute pancreatitis is no longer valid. In patients who are mechanically ventilated, nasogastric feeding may be initiated, with transition to intrajejunal feeding only for specific situations of intolerance. A regular polymeric formula is used with peptide based formulas as a backup.

Open Abdomen

An open abdomen is not a contraindication for EN, either gastric or jejunal. Attention should be paid to fluid balance and loss of protein through the abdominal wall defect. An additional 30 to 40 g/day of protein is generally needed. Enterocutaneous fistulas do not

TABLE 1 New ICD-10 Codes for Malnutrition and Related Clinical Conditions

ICD-10 Code	Diagnosis
E43	Unspecified PCM
E44.0	Moderate PCM
E44.1	Mild PCM
E46	Unspecified PCM
E64	Sequelae of PCM
M62.84	Sarcopenia
M62.5	Muscle wasting and atrophy

preclude the use of EN unless the fistula is high output or electrolyte abnormalities are exacerbated by the additional volume supplied with EN. Supplemental PN may be used as needed.

Postoperative Patients on Ventilator Support Longer Than 48 Hours

The SCCM guidelines, based on high-quality evidence, recommend that either trophic or full EN support should be administered for patients with ARDS expected to have a duration of mechanical ventilation of 72 hours or longer. This should be initiated as soon as possible, but no later than 48 hours after ICU admission. PN should be considered only after 7 to 10 days of serious attempts to optimize EN.

Postoperative Patients Who Can Tolerate Oral Nutrition

Postoperative patients who are breathing spontaneously and have adequate mental status may be offered a regular or modified solid food diet, with appropriate consistency, depending on ability to swallow. Recent guidelines based on expert consensus indicate that, postoperatively, clear liquids are not required as the first meal. Should a clinician feel he or she must use clear liquids, there are commercial options that contain appropriate protein, but emphasis should be placed on resuming solid food as soon as feasible. In ICU patients, there is no consistent evidence that sodium intake is correlated with blood pressure or need for inotropes.

TEAM APPROACH

As has been observed in several areas in medicine, a team approach is crucial for successful implementation of guidelines and acceptance of newer practice patterns. This applies as well to the delivery of appropriate nutrition therapy. Surgical intensivists, surgeons, anesthesiologists, nurses, dietitians/clinical nutritionists, and all members of the patient's care team must buy in to the importance of nutrition therapy, and protocols must be put in place to make the process easy to understand and implement. The patient's family (and the patient, if possible) should also be involved in the decision-making process to optimize understanding and achievement of goals of care. Additionally, institution administration may require education on the importance regulatory bodies place on the assessment of malnutrition and appropriate coding (Table 1). Implementation of nutrition therapy protocols, particularly if they are new to the clinical setting or institution, may be slow. They may have to be done in stages to accomplish the culture change that might be needed to make aggressive and appropriate nutrition therapy the norm. Some suggestions include the following:

- Offer ongoing educational opportunities to all staff about nutrition therapy in critical illness using a multimedia approach: social media, in-person journal clubs, and so forth. If credit can be obtained for these offerings, some staff may take advantage of them.
- Begin early education of the nursing staff and actively seek their input when considering new protocols. Make sure that any protocols that require nursing involvement are truly nurse driven. This may require alteration of published protocols to meet local ICU or institution needs.
- Involve dietitians in the planning and implementation of new protocols as well as in the education of other staff, including medical staff. Advocate with administration for adequate dietitian staff in critical care areas to ensure patients are assessed and monitored appropriately (coding and reimbursement standards may be useful in justifying this).
- Include the patient and/or family early in discussions about the nutrition therapy plan.

When implementing a new protocol, it may help to be willing to start with a portion(s) of the protocol that all can agree on to get started, with the plan for additional implementation over time.

CONCLUSIONS AND FUTURE TRENDS

As nutrition therapy continues to evolve, it will be all the more important for practitioners to keep up to date on new developments in assessment and therapy. Exciting ideas have already been put forth regarding the importance of the gut microbiome and the potential use of probiotics in its manipulation to achieve benefit. Newer assessment techniques may become widely accessible, allowing for a more accurate nutrition therapy plan based on patient-specific information. A relatively newly described phenomenon, the persistent inflammation, immunosuppression, and catabolism syndrome (or PICS, not to be confused with post-intensive care syndrome using the same acronym), has brought attention to the subgroup of patients who have indolent, chronic inflammation. Being able to predict the development of this syndrome and apply nutrition therapy early may prevent functional losses after a long ICU and even late mortality. Some principles, however, such as the importance of adequate protein delivery, the benefits of early EN, and a comprehensive multidisciplinary approach to nutrition therapy have stood the test of time and should comprise the mainstay of all practitioners' approach to the nutrition care of critically ill surgical patients.

Coagulopathy in the Critically Ill Patient

Terence O'Keeffe, MD, FACS, FCCM

Coagulopathy is common not only in trauma but also among critically ill patients in the intensive care unit (ICU), with approximately one third of patients in either category demonstrating some degree of coagulation defect on standard blood testing. The ability of a patient's blood to clot is dependent on complex interactions between multiple proteins, enzymes, and platelets, with the potential for problems to any part of the clotting cascade to have life-threatening consequences.

This chapter is not designed to deal exhaustively with the science behind the interplay of the complex pathways of coagulation, but instead provide practical tools for the clinician to both recognize and treat these conditions.

INCIDENCE

Although the exact incidence of coagulopathy depends on the specific coagulation parameter being measured and the patient population, it is widely recognized that about 30% of ICU or trauma patients will have abnormalities in their prothrombin time (PT), partial thromboplastin time, or platelet count. This early coagulopathy in trauma patients is also associated with an increase in both multiorgan failure and mortality. Coagulation defects in ICU patients including thrombocytopenia are also independently associated with increased mortality. The incidence of thrombocytopenia in ICU patients also increases using different platelet count cutoff points with approximately 30% to 40% of patients having a platelet count below 150 during their ICU stay, 20% to 25% with a count below 100, and only 12% to 15% with a platelet count below 50.

CAUSES OF COAGULOPATHY

This chapter discusses only coagulation defects associated with acute changes in the clotting process in the critically ill. The multiple congenital causes of coagulopathy are not addressed because they are rare and usually do not present a problem for the practicing surgeon. Expert hematologic consultation is recommended in these complex patients, particularly before any invasive procedures.

Table 1 details the most widespread causes of coagulopathy, with the most frequently encountered coagulation defects being caused by severe sepsis, trauma, hemorrhage, platelet disorders, liver or renal failure, and medications.

Dilutional Coagulopathy

There has been a significant swing in resuscitation practices over the past decade away from the use of crystalloids in critically ill patients in favor of blood and blood products. This has been especially true for patients suffering traumatic injuries. The net effect has been a decrease in the incidence of dilutional coagulopathy, which has historically been one of more common causes of coagulopathy. In one study of more than 8000 patients in the German Trauma Registry from 2017, coagulopathy was present in up to 50% of patients who received 3 L of fluid or more. There is also increasing evidence that perioperative resuscitation with excess crystalloid solutions is detrimental to postoperative recovery in terms of morbidity, but given

Coagulopathy in the Critically Ill Patient

Terence O'Keeffe, MB ChB, FACS, FCCM

Coagulopathy is common not only in trauma but also among critically ill patients in the intensive care unit (ICU), with approximately one third of patients in either category demonstrating some degree of coagulation defect on standard blood testing. The ability of a patient's blood to clot is dependent on complex interactions between multiple proteins, enzymes, and platelets, with the potential for problems to any part of the clotting cascade to have life-threatening consequences.

This chapter is not designed to deal exhaustively with the science behind the interplay of the complex pathways of coagulation, but instead provide practical tools for the clinician to both recognize and treat these conditions.

INCIDENCE

Although the exact incidence of coagulopathy depends on the specific coagulation parameter being measured and the patient population, it is widely recognized that about 30% of ICU or trauma patients will have abnormalities in their prothrombin time (PT), partial thromboplastin time, or platelet count. This early coagulopathy in trauma patients is also associated with an increase in both multiorgan failure and mortality. Coagulation defects in ICU patients including thrombocytopenia are also independently associated with increased mortality. The incidence of thrombocytopenia in ICU patients decreases using different platelet count cutoff points with approximately 30% to 40% of patients having a platelet count below 150 during their ICU stay, 20% to 25% with a count below 100, and only 12% to 15% with a platelet count below 50.

CAUSES OF COAGULOPATHY

This chapter discusses only coagulation defects associated with acute changes in the clotting process in the critically ill. The multiple congenital causes of coagulopathy are not addressed because they are rare and usually do not present a problem for the practicing surgeon. Expert hematologic consultation is recommended in these complex patients, particularly before any invasive procedures.

Table 1 details the most widespread causes of coagulopathy, with the most frequently encountered coagulation defects being caused by severe sepsis, trauma, hemorrhage, platelet disorders, liver or renal failure, and medications.

Dilutional Coagulopathy

There has been a significant swing in resuscitation practices over the past decade away from the use of crystalloids in critically ill patients in favor of blood and blood products. This has been especially true for patients suffering traumatic injuries. The net effect has been a decrease in the incidence of dilutional coagulopathy, which has historically been one of more common causes of coagulopathy. In one study of more than 8000 patients in the German Trauma Registry from 2017, coagulopathy was present in up to 50% of patients who received 3 L of fluid or more. There is also increasing evidence that perioperative resuscitation with excess crystalloid solutions is detrimental to postoperative recovery in terms of morbidity, but given

TABLE 1 Congenital and Acquired Causes of Coagulopathy

Type of Coagulation Disorder	Effect on Clotting	Notes
CONGENITAL		
Hemophilia A	Increased bleeding	1 in 10,000; mostly males
Hemophilia B	Increased bleeding	1 in 34,000; mostly males
Antithrombin II deficiency	Hypercoagulability	1 in 2000; increased VTE risk
Antiphospholipid syndrome/lupus anticoagulants	Hypercoagulability	2–8 in 100; increased VTE risk in some patients
Von Willebrand factor disease	Increased bleeding	Usually mild; no spontaneous bleeding
Protein C deficiency	Hypercoagulability	2–5 in 1000; increased VTE risk
Protein S deficiency	Hypercoagulability	1 in 700; increased VTE risk; often asymptomatic
Factor V Leiden	Increased bleeding	Rare; affects 5 per million
Congenital fibrinogen deficiency	Increased bleeding	Rare; affects 1–2 per million
Congenital prothrombin deficiency (factor II)	Increased bleeding	Rare; symptoms include easy bruising, epistaxis
Congenital factor deficiencies—VII, X, XIII	Increased bleeding	Rare; symptoms include easy bruising, epistaxis, joint bleeding
ACQUIRED		
Medication induced	Increased bleeding and/or prothrombotic	See Table 6 for specific drugs
Traumatic brain injury	Increased bleeding	Possibly because of release of brain thromboplastin
Obstetric emergencies	Increased bleeding	Dilutional coagulopathy from blood loss or DIC
Sepsis/bacteremia	Increased bleeding and/or prothrombotic	Proinflammatory cytokines cause activation of clotting cascade; DIC also present
Pancreatitis	Increased bleeding and/or prothrombotic	Proinflammatory cytokines activate clotting cascade and platelets; also DIC
Burns	Increased bleeding	Dilutional coagulopathy from resuscitation; DIC
Disseminated intravascular coagulation	Increased bleeding	Multiple precipitating conditions
Hepatic disease	Increased bleeding	Prolonged PT
Renal disease	Increased bleeding	Platelet dysfunction from chronic uremia
Vitamin K deficiency	Increased bleeding	Most common in infants; in adults related to chronic conditions or medications

DIC, Disseminated intravascular coagulation; PT, prothrombin time; VTE, venous thromboembolism.

the lack of a more suitable substitute fluid for patients who suffer significant fluid shifts (e.g., burns, major abdominal surgery), these solutions are still the mainstay of therapy. It is therefore important to follow the volumes of fluid given and monitor coagulation parameters to detect impending changes early, and correct these where necessary.

Along with this move away from crystalloid resuscitation has been the explosion in massive transfusion protocols that were initially developed for trauma patients but have also been used in the bleeding nontrauma patient (e.g., obstetric hemorrhage, massive gastrointestinal bleeding). Close attention to red blood cell to fresh frozen plasma ratios and early transfusion of platelets attempts to mimic whole blood transfusions (also becoming used much more frequently) in critically ill trauma patients. When effectively performed, these massive transfusions will effectively negate any dilutional effects of multiple blood product transfusions and can reduce any catch up or need for top up transfusions after bleeding control has been achieved. Massive transfusion protocols will be dealt with in more detail in the chapter on coagulation in the trauma patient.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a syndrome that is a manifestation of an underlying systemic disorder affecting the coagulation system, simultaneously resulting in procoagulant activation, fibrinolytic activation, and consumptive coagulopathy that results in microvascular thrombi deposition in various organs thereby leading to organ dysfunction and possibly death. Patients with this condition will present with low and/or decreasing platelet counts, prolonged tests of coagulation, low levels of coagulation factors and inhibitors in the plasma, and increased d-dimer and/or fibrin degradation products. Clinically it presents with hemorrhage (although 5%–10% of cases may demonstrate only microthrombi) and in the overt form it is highly lethal, with mortality rates as high as 40%, depending on the underlying condition.

There are a multitude of disease processes that can trigger this condition, but it is most commonly the result of sepsis, although it can be caused by trauma, pancreatitis, transfusion reactions, malignancy, obstetric complications, and severe toxic reactions. Diagnosis is confirmed using either the Japanese Association for Acute

TABLE 2 Blood Tests of Clotting

Name of Blood Test	Measures	Comments
PT	Extrinsic pathway of coagulation	Useful in liver disease, warfarin effect, vitamin K deficiency
PTT	Intrinsic pathway of coagulation	Mostly used to measure efficacy of heparin infusions
INR	Standardized test of PT for patients on warfarin	Often used incorrectly as a measure of coagulopathy
Platelet count	Absolute platelet count	Does not measure platelet activity (e.g., if on medications)
Fibrinogen level	Levels of plasma fibrinogen	Can be useful if other tests are normal in the face of continued bleeding
D-dimer	Degradation product of fibrin	Used in diagnosing PE and also DIC
Fibrin split products	Degradation products of fibrin	Used in diagnosing DIC
Thrombin time	Bleeding disorders, in evaluating levels and function of fibrinogen	Superseded by functional fibrinogen assay
ACT	High doses of heparin therapy	Mostly used during cardiopulmonary bypass or cardiac device anticoagulation
Bleeding time	Mostly platelet function	Rarely used
TEG	All facets of coagulation	See discussion in chapter
Platelet function tests	Platelet function (after aspirin or postmedication)	Not often used routinely, controversial
Factor assay	Specific factors associated with a condition	Often used to investigate clotting protein deficiencies
Reptilase test	Conversion of fibrinogen to fibrin	Used when heparin is present, as reptilase is insensitive to it

ACT, Activated whole blood clotting time; DIC, disseminated intravascular coagulation; INR, international normalized ratio; PE, pulmonary embolism; PT, prothrombin time; PTT, partial thromboplastin time; TEG, thromboelastography.

Modified DIC criteria or the International Society on Hemostasis and Thrombosis overt DIC scoring criteria (Table 2). These score on the platelet count, prothrombin time, and presence of fibrin degradation products to make the diagnosis, the only major difference between the two being that the heparin score uses the presence of systemic inflammatory response syndrome criteria as opposed to absolute fibrin levels. They have been validated prospectively as both an aid to the diagnosis of DIC, as well as being useful in predicting multiple organ dysfunction syndrome and 28-day mortality. These scores can be used to differentiate DIC from other conditions that exhibit thrombocytopenia and prolonged prothrombin times, such as chronic liver disease.

Treatment of DIC is focused on the underlying clinical disorder while supporting the patient's coagulopathy. Platelet transfusion may be necessary if the platelet count falls significantly, although this may be allowed to drop as low as 20,000 × 10^9/L if the patient is not bleeding. Platelet transfusions to keep the count above 50,000 × 10^9/L will be necessary in cases of active hemorrhage. Other blood products may be required, but these should be directed by blood testing (e.g., giving cryoprecipitate to correct fibrinogen levels). Fresh frozen plasma (FFP) may be necessary in patients with excessively prolonged clotting tests. Heparin appears to be of benefit in patients with DIC resulting from certain specific conditions such as metastasized malignancies, purpura fulminans, and major vascular abnormalities. It also appears effective in the treatment of thromboembolic complications in patients with low grade sustained DIC; however, in patients with hemorrhagic complications resulting from DIC, the use of heparin can have deleterious effects. Other treatments for DIC such as antithrombin, thrombomodulin or activated protein C (no longer commercially available) remain controversial, with no clear indications for their use, although the latter two are used to treat DIC in Japan. In severe cases of DIC, early consultation with a hematologist is prudent to help manage specific factor deficiencies.

Hepatic Dysfunction

The majority of the proteins involved in the coagulation cascade are synthesized in the liver; therefore, it should not be surprising that liver disease can have a drastic effect on the body's clotting. This occurs by a number of mechanisms: decreased synthesis of these proteins leading to an increase in prothrombin time; thrombocytopenia; dysfibrinogenemia from failure to remove sialic acid from fibrinogen; reduction in absorption of lipid soluble vitamins to cholestasis; liver disease leading to low production of factors II, VII, IX, and X; and reduced metabolization of these pharmagens activator. In patients with chronic liver disease, however, the increase in PT is tempered by a reduction in the body's anticoagulants, leading to a relative balance between the anticoagulant and coagulant pathways. In the absence of any signs of hemorrhage, prolongation of the PT do not require specific treatment, although vitamin K supplementation should be considered early in these patients.

Homeostasis Disruption

Other features of homeostasis disruption can also contribute to coagulation issues as platelets start to become increasingly less effective once the temperature drops below 35°C. Below 33°C, synthesis of clotting enzymes and plasminogen activator inhibitors is impaired, thus ensuring a normal core body temperature is a critical aspect of treating coagulopathy. Enzymatic function of the clotting cascade is impaired in cases of significant acidosis (pH <7.25) and calcium is an essential cofactor for many of these enzymes, and attention also needs to be paid to hypocalcemia, especially in patients receiving large volumes of blood products (e.g., massive transfusions).

B PLATELET DISORDERS

Thrombocytopenia

This is one of the commonest coagulation problems in critically ill patients with an incidence of around 35% to 41% in patients admitted

to an intensive care unit, when defined as a platelet count of less than $150{,}000 \times 10^3/mm^3$. Severe thrombocytopenia with a platelet count less than $50{,}000 \times 10^3/mm^3$, occurs approximately 5% to 20% of the time. This thrombocytopenia is usually multifactorial and can likely be considered as a marker of severity, with a decreased platelet count responsible for an approximate twofold increase in mortality.

The most common causes of thrombocytopenia in the critically ill patients are presented in Table 3. These include hemodilution, pseudo-thrombocytopenia, increased consumption, increased destruction, decreased production, and increased sequestration. The effective function of platelets is critical to the body's response to bleeding as they form the initial plug at the site of injury even before the deposition of fibrin and thrombin cross linking (Fig. 1). Defects in either platelet function or platelet numbers can have devastating effects on the ability of the body to properly form clots and effectively stop hemorrhage from vessels.

There is often a natural drop in a patient's platelet count following major surgery. There is typically a nadir in the count approximately 2 to 3 days after surgery, with a recovery at days 3 to 4 depending on the exact surgery performed (abdominal surgery has less of a drop and recovers sooner than cardiac surgery, for example). This correlates with the increased production of platelets to compensate for those lost during the surgical procedure by the body's megakaryocytes, and thus early thrombocytopenia can be more reflective of the magnitude of trauma or blood loss initially. As a corollary to this, an absent rise or blunted response after the first four days is strongly associated with prolonged ICU stay and mortality, with thrombocytopenia present at day 14 or an absent increase over baseline predictive of at least a doubling in mortality.

The recognition of the critical function of platelets in the clotting process leads many clinicians to be wary of performing surgery or procedures in the thrombocytopenic patient; therefore in Table 4, I have outlined the generally accepted triggers for platelet transfusion under various circumstances. Platelets also form an important part of massive transfusion protocols, which has been covered separately in a different section on trauma patients.

TABLE 3 Thromboelastography-Directed Resuscitation Guidelines

TEG Parameters	Blood Product Transfusion
ACT >120	PRBCs and plasma
Reaction time >10 min	PRBCs and plasma
K >2.5 min	Cryoprecipitate/fibrinogen/plasma
Alpha angle <55	Cryoprecipitate/fibrinogen/plasma
MA <55	Platelets/cryoprecipitate/fibrinogen
LY30 >3%	Tranexamic acid

Data from Arnaud of surgery 2010 based on experience with 1074 consecutive trauma patients using TEG as point of care test.
ACT, Activated clotting time; K, interval between reaction time and fixed value of clot firmness; MA, maximum amplitude; LY30, degree of clot lysis at 30 min; PRBC, packed red blood cells; TEG, thromboelastography.

Heparin-Induced Thrombocytopenia

One of the more feared causes of thrombocytopenia is related to heparin use, and as its consequences can be very severe it warrants a more detailed and separate review here. Heparin induced thrombocytopenia (HIT) is a specific complication of heparin therapy that can appear in either one of two distinct forms; type 1 HIT is a non-immune disorder that results from the direct effect of heparin on platelet activation and develops within the first 48 hours from heparin exposure. The thrombocytopenia from type 1 HIT is thought to be due to platelet aggregation but will resolve with continued heparin therapy.

In general, the term HIT refers to type 2 HIT, which is an immune mediated prothrombotic disorder caused by antibodies to complexes of platelet factor 4 and heparin that subsequently cause platelet activation. This occurs 4 to 10 days after exposure to heparin and can lead to venous or arterial thrombotic complications that have been associated with amputations and death. The overall risk of HIT is thought to be approximately 0.2% in all heparin exposed patients, although the incidence may be as high as 5% to patients undergoing cardiac or orthopedic procedures or with prolonged heparin exposure. Interestingly, white race and male sex seem to confer less risk, with concomitant less risk for thrombosis. Unfractionated heparin confers a higher risk than low molecular weight heparin in surgical patients, and it can occur after systemic heparin flushes or even related to heparin coated catheters.

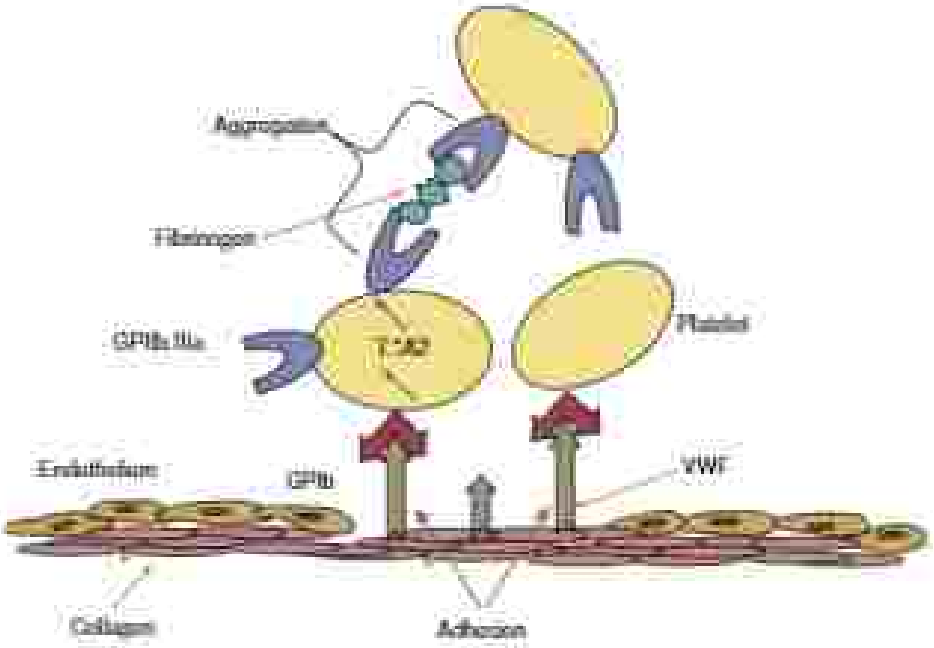

FIG. 1 Platelet functions. vWF, von Willebrand factor.

HIT should be suspected in any patient exposed to heparin who suffers a drop in platelet count below 50% of baseline. Clinical findings in true type 2 HIT may include skin lesions at heparin injection sites or acute systemic reactions including fever or chills after administration of an intravenous bolus of heparin. Venous thrombosis is the most common thrombotic complication of HIT although arterial thrombosis may also occur. Patients with HIT have a 40 fold higher risk of thrombosis than in subjects without HIT, with an absolute risk of thrombosis of 25% to 50% (and fatal thrombosis of as high as 9%–30%).

Diagnosis of HIT is based on a combination of clinical findings, thrombocytopenia characteristics, timing of the platelet drop, and laboratory studies of HIT antibodies. The Warkentin score or 4T score is used as a clinical pretest screening tool to guide in the diagnosis of HIT, and can help guide the clinician to evaluate whether further testing is required (Table 5). For patients with an intermediate or high probability score, a heparin/platelet factor 4 enzyme linked immunosorbent assay test is recommended. This widely available immunoassay has high sensitivity but low specificity in the diagnosis of HIT and depending on local laboratory facilities may take 1 to 3 days to be reported. In cases of patients with conflicting test results and Warkentin scores, a serotonin release assay may be used to confirm the diagnosis, this being a functional study often considered to be the gold standard for identification, but not widely used because of cost and being technically demanding to perform. Definitive diagnosis can be challenging in some patients, particularly in the absence of clinical thrombosis, and there are continued data to suggest that over treatment for this condition is common in the surgical population.

Treatment of HIT obviously starts with the elimination of exposure to all heparin products, including heparin flushes of any indwelling catheters. Heparin-bonded catheters need to be removed. These are prudent measures to adopt even while waiting for confirmatory laboratory testing in patients with a high pretest probability of HIT. In patients still requiring anticoagulation (the vast majority of patients), alternative agents include fondaparinux, which can be given subcutaneously, and parenteral direct thrombin inhibitors such as argatroban, bivalirudin, or oral agents such as dabigatran, apixaban or rivaroxaban. In practice, the exact agent used will depend on whether the patient has normal renal and hepatic function, as well as what is available on the hospital formulary. Anticoagulation should be continued for at least 4 weeks, and up to 3 months if thrombosis has occurred, with the patient transitioned to warfarin or a direct oral anticoagulant once stable and with a normal platelet count (>150,000 × 10^9/mm^3).

TABLE 4 Transfusion Triggers for Platelets

Condition	Desired Platelet Count
Stable hematology/oncology patient	>10,000
Complicated hematology/oncology patient	>20,000
Minor surgery/procedure	25,000–50,000
Major surgery/procedure	>50,000
Neurosurgery	>100,000
Acquired platelet dysfunction (e.g., medications, uremia)	Unknown if transfusion is effective
Congenital platelet dysfunction (e.g., von Willebrand factor, Glanzmann's thrombasthenia)	Unknown

Renal Dysfunction

Kidney disease leading to elevated urea can affect platelet function significantly by decreased production of thromboxane, alterations in platelet granules, as well as associated anemia and dysfunction of von Willebrand factor. The net effect is weaker formation of the initial platelet plug, and increases in bleeding, sometimes even spontaneously. Dialysis can be effective in restoring some of the function to platelets, as can desmopressin. The difficulty is in diagnosing platelet dysfunction in the face of a normal platelet count because many of the platelet function tests are not routinely available.

CLINICAL RELEVANCE OF COAGULOPATHY

The focus on coagulopathy has direct clinical relevance; abnormalities in platelet counts, coagulation defects or the presence of products of fibrin degradation are all independently associated with increased mortality and in hospital complications rates. In trauma patients, for example, coagulopathy is associated with approximately a threefold increased risk of death. Although it is clear that much of this coagulopathy is caused by the underlying disease processes, it is harder to ascertain whether treatment can actually impact morbidity or

TABLE 5 Estimating the Pretest Probability of HIT: The 4Ts

Category	2	1	0
Thrombocytopenia	>50% platelet fall and platelet nadir ≥20	Platelet count fall by 30%–50% or nadir 10–19	Platelet count fall by <30% or nadir <10
Timing of onset of platelet fall (or other sequelae of HIT)	Clear onset days 5–10 or platelet fall <day 1 with recent heparin in past 30 days	Consistent with days 5–10 fall, but not clear, onset after day 10, or fall <day 1 with recent heparin (past 31–100 days)	Platelet count fall <day 4 without recent exposure
Thrombosis or other sequelae	Confirmed new thrombosis, skin necrosis, or acute systemic reaction after intravenous unfractionated heparin bolus	Progressive or recurrent thrombosis, erythematous skin lesions, suspected thrombosis (not proved)	None
Other cause(s) of platelet fall	None evident	Possible	Definite
Points (0, 1, or 2 for each of 4 categories; maximum possible score = 8)			

Pretest probability score: 6–8 indicates high; 4–5, intermediate; and 0–3, low.
HIT, heparin-induced thrombocytopenia.

TABLE 6 Anticoagulants and Reversal Agents

Therapeutic Agent	Target	Comments
FFP	Warfarin Hepatic coagulopathy Traumatic coagulopathy	Rapid reversal for warfarin INR of FFP unit is 1.3–1.4 Risk of TRALI
Cryoprecipitate	Low fibrinogen levels	Stored frozen, requires preparation time
Platelets	Clopidogrel, prasugrel, aspirin	Risk of new platelets being inhibited by drug still present
Prothrombin complex concentrates Kcentra, Beriplex	Warfarin + Rivaroxaban/apixaban/edoxaban	Rapid reversal, needs vitamin K in addition for warfarin
Factor VIIa	Warfarin Dabigatran Rivaroxaban	Rapid reversal, needs vitamin K in addition for warfarin Acute trauma coagulopathy
FEIBA (anti-inhibitor coagulant complex)	Direct thrombin inhibitors Anti-factor Xa inhibitors Dabigatran	Activated PCC Factors II, VIIa, IX, X
Protamine	Heparin, dalteparin, enoxaparin	Risk for hypotension, anaphylaxis
Desmopressin (DDAVP)	Uremic platelet dysfunction + Clopidogrel, prasugrel	Rapid onset Lasts 6–8 hours Unclear if effective for drugs
Vitamin K	Warfarin Vitamin K deficiency	Relatively slow onset IV or PO equivalent at 24 hours
Aminocaproic acid	Hyperfibrinolysis	Often used post-cardiac bypass, decreases blood loss
Tranexamic acid	Hyperfibrinolysis	Used in trauma patients (CRASH-2 study) and post-cardiac bypass
Pradaxa (idarucizumab)	Dabigatran (Pradaxa)	Direct thrombin inhibitor antidote, antibody fragment
Andexanet	Rivaroxaban Apixaban Edoxaban	Factor Xa inhibitor antidote, awaiting final FDA clearance in 2018

FDA, US Food and Drug Administration; *FFP*, fresh frozen plasma; *INR*, international normalized ratio; *IV*, intravenous; *PCC*, prothrombin complex concentrate; *PO*, by mouth; *TRALI*, transfusion related acute lung injury.

mortality. In patients with critical illness, it is therefore important to test for and track any coagulopathy, at least initially, because of both its prognostic significance and to treat any specific problems that could arise as a result (e.g., thrombocytopenia) in a patient with an intracranial hemorrhage.

TESTS OF COAGULOPATHY

The vast majority of the blood tests currently available in the clinic can do not tell the complete picture when it comes to coagulopathy, especially because by the time that they are available the actual clotting milieu in the patient at the bedside may have already changed, particularly if the patient is undergoing significant resuscitative efforts with intravenous fluids or blood products. The most commonly used test to evaluate for possible coagulopathy, international normalized ratio (INR), was primarily developed to evaluate the effect of warfarin on the coagulation cascade; however, it has become the de facto surrogate of coagulopathy in critically ill patients, including trauma. The turnaround time in most laboratories for this test is 30 to 40 minutes, which places some serious limitations on its utility in many clinical scenarios. Although some point-of-care tests have been introduced (e.g., the i-STAT handheld device), their reliability for coagulation testing remains in doubt. Table 6 lists the most commonly ordered coagulation blood tests, and what they measure, whereas Table 7 shows how they are disordered in common disease processes.

Thromboelastography (TEG) testing has become increasingly used over the past decade in critically ill patients in assess multiple different aspects of coagulation including platelet function and fibrinolysis and may hold promise in developing better ways to evaluate and treat coagulopathy, particularly in the acute setting. I will deal with this test separately because each requires more detailed discussion due to the complexity of interpreting its results.

TEG or Viscoelastic Testing

Conventional tests of coagulopathy have significant limitations in accurately assessing the hemostatic profile and truly predicting bleeding risk in critically ill patients, especially considering that coagulation changes are often a dynamic phenomenon rather than a static one, with stages of hypercoagulability, hypocoagulability, and fibrinolysis. Viscoelastic testing has the ability to evaluate thrombosis and lysis simultaneously, and thus give a more complete picture of the coagulation profile of the patient. Although the PT is limited to the extrinsic clotting system (factors VIIa, Xa, and IIa) and partial thromboplastin time is limited to intrinsic clotting reactions (factors XIIa, XIa, IXa, and IIa), TEG allows assessment of the whole process from initiation of coagulation to fibrinolysis and clot degradation. Additionally, conventional assays (PT, INR) are performed in the laboratory under optimal temperature and pH so they fail to take into account the in vivo effects of hypothermia and acidosis on coagulation cascade. In contrast, viscoelastic tests are performed on whole blood samples that take into account the complex interactions between different blood cells and their biochemical characteristics, assessing blood hemostatic profile in real time at the bedside.

TABLE 7 Common Laboratory Findings for Disease Processes

Condition	Platelet Count	PT	PTT	Fibrinogen Level	D-Dimer	TEG Findings
DIC	Decreased	Prolonged	Prolonged	Decreased	Increased	Hypercoagulable then hypocoagulable
Dilution	Decreased	Prolonged	Prolonged	Decreased	Decreased	R prolonged
Vitamin K deficiency	Unaffected	Prolonged	Normal or prolonged	Unaffected	Unaffected	R, K prolonged MA decreased
Warfarin use	Unaffected	Prolonged	Normal or prolonged	Unaffected	Unaffected	R, K prolonged MA decreased
Aspirin use	Unaffected	Unaffected	Unaffected	Unaffected	Unaffected	K prolonged MA decreased
Apixaban use	Unaffected	Prolonged	Prolonged	Unaffected	Unaffected	R, K prolonged
Rivaroxaban use	Unaffected	Prolonged	Prolonged	Unaffected	Unaffected	R, K prolonged with higher doses
Dabigatran use	Unaffected	Prolonged	Prolonged	Decreased	Unaffected	R, K prolonged
Hyperfibrinolysis	Unaffected	Prolonged	Prolonged	Decreased	Very high	MA decreased LY30 increased
Uremia	Unaffected	Unaffected	Unaffected	Unaffected	Unaffected	R prolonged
Liver failure Early End-stage	Unaffected Decreased	Prolonged Prolonged	Unaffected Prolonged	Unaffected Decreased	Unaffected Increased	R, K prolonged MA decreased

Note: in the case of the direct oral anticoagulants, these laboratory findings do not correlate well to the degree of anticoagulation, but may be present in patients exposed to these agents.
K, interval between reaction time and fixed value of clot firmness; MA, maximum amplitude; R, reaction time.

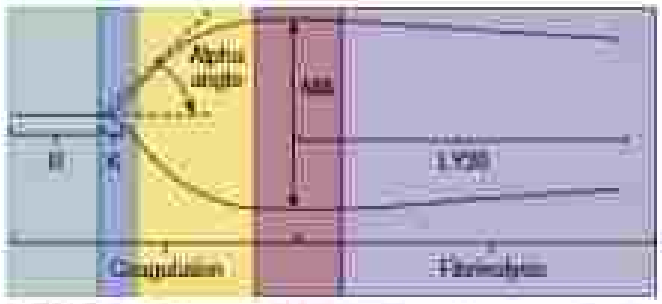

FIG. 2 Tracing of the resting blood clot. *K*, interval between reaction time and fixed value of clot firmness; MA, maximum amplitude; R, reaction time.

TEG results are presented as a combination of a graphic representation (Fig. 2) of complete timeline of the evolving blood clot generated via a transducer, which detects resistance to motion of interposition placed in rotating blood sample, as well as certain specific values related to this graph. The reaction time or *r* value (TEG activated clotting time in rTEG) represents the time taken for first measurable clot formation and is a reflection of enzymatic clotting activation. *k* value is the interval measured from the *r* to fixed value of clot firmness or the point that the amplitude of tracing reaches 20 mm; this reflects thrombin's ability to cleave soluble fibrinogen into insoluble fibrin strands. The *α* angle is the angle between the tangent line drawn from the base horizontal line to beginning of the cross-linking process, measured in degrees and primarily reflects speed at which fibrin builds up and crosslinking takes place. The maximum amplitude measures the end result of maximal platelet and fibrin interaction, reflecting the ultimate clot strength. The final reading of the tracing is LY30, the degree of clot lysis at 30 minutes of the tracing. Above normal value is indicative of hyperfibrinolysis. In addition, the TEG can measure (G), a log derivation of the maximum amplitude, representing the clot strength using dynes/cm, suggested to be the best measure of clot strength because it reflects both the enzymatic and the platelet components of hemostasis. The computer generated tracing reflects component deficits if any to coagulation proteins, platelets, fibrinogen, or fibrinolysis.

The unique ability of TEG to assess the component specific functionality of clotting blood provides the clinician with specific advantages to guiding goal directed therapy with increased accuracy compared with conventional tests of coagulation. In addition, with improvements in medical information, the TEG tracing can be observed in real time at the bedside, decreasing the time taken for potentially serious coagulation defects to be treated.

TEG and Platelet Mapping

One of the advantages to using TEG to assess platelet function is that the cells will be activated and demonstrate all of their functions to hemostasis (thrombin generation, clot formation, clot retraction, and lysis). The whole TEG assay measures the ultimate clot strength as maximum amplitude, which is 80% dependent on platelet function and 20% on fibrin activity. Whole blood TEG platelet mapping, in contrast, is a modification of the original TEG system using a focused technique to assess the independent contribution of platelets in clot formation by measuring the reactivity of the platelet activators arachidonic acid (AA) and adenosine diphosphate (ADP).

Whole blood TEG was developed to assess antiplatelet therapy most commonly in patients undergoing cardiac surgery with preoperative initiation of ADP to predict the development of microvascular bleeding in patients on aspirin or clopidogrel. The assay measures maximum hemostatic activity and the effect of therapy with aspirin (AA addition) or thienopyridines (ADP additive) is evaluated by comparing the TEG kaolin activated test curves with the AA or ADP stimulated TEG curves (Fig. 3). Although it may have a role in cardiac surgery, clinical applications so far seem limited by its inability to predict platelet or other blood component transfusions.

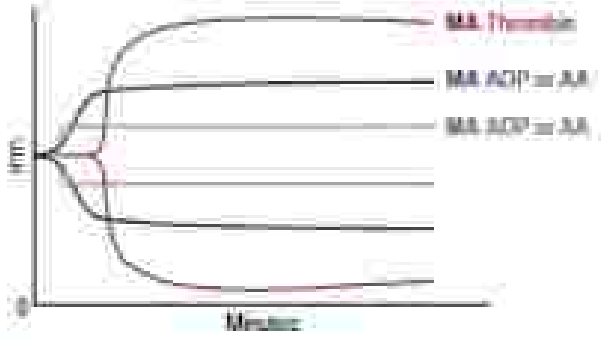

FIG. 3 Comparison of thromboelastography (kaolin activated) trace curves with arachidonic acid or ADP stimulated TEG curves. AA, Arachidonic acid; ADP, adenosine diphosphate; MA, maximum amplitude activity.

Platelet Function Tests

The absolute platelet count remains a poor marker for platelet effectiveness, and there has been an explosion of different platelet assays over recent years, from the various types of thromboelastography, aggregometry, and tests of function under shear stress.

Traditionally, the bleeding time was the first test used to measure true platelet effectiveness, and it assesses the platelet ability to develop a hemostatic plug by recording the time that the platelets take to occlude an in vivo skin wound for stopping the hemorrhage. Given how the test is performed, it is impractical to perform in all but the most stable of settings and has been generally abandoned clinically resulting from a lack of accuracy and difficulties with standardization.

Point of care testing devices have now become available that can measure platelet function by a number of different techniques. Whole blood aggregometry assesses the increase in impedance generated by aggregation of platelets to those already fixed on electrodes in the machine. This has been most useful in assessing the degree of platelet inhibition caused by medications (e.g., aspirin, clopidogrel), although it has been reported to help identify patients at risk of post-operative bleeding after cardiac surgery.

Other systems use a combination of aggregometry and optical detection, either detecting hemoconcentration caused by ADP to achieve clot/thrombus contraction, or simply assessing turbidity as fibrinogen attaches to activated platelets in the reaction chamber. These tests have been used to evaluate platelet granule dysfunction and verification of the platelet inhibitory effects of platelet antagonists. To date, despite multiple different systems having been developed (which are not discussed in detail here), little has been shown to have significant advantage in the clinical arena and to be robust as to accurately assess platelet function.

Platelet dysfunction should be considered in patients with normal blood test but continued evidence of bleeding, especially if there is a history of prior bleeding episodes without a clear precipitant, or in patients on antiplatelet medications.

Bleeding Disorders in Which Blood Tests Are Negative

The most common cause for unexplained bleeding when conventional blood tests are normal is platelet dysfunction, and frequently the reason for this is medication induced with antiplatelet drugs such as aspirin, clopidogrel, and prasugrel. Given the increased use of antiplatelet agents in general and the aging of the population, this should be strongly considered in all patients, especially if no medication history is available. Additionally, in patients with renal disease, uremia is a known factor affecting platelet function (which can be reversed to a certain extent by dialysis or administering desmopressin), whereas in patients with liver disease, the thrombocytopenia associated with cirrhosis seems to also come with a degree of platelet dysfunction.

Hypofibrinolysis is a rare but serious cause of bleeding and will usually only be demonstrated on TEG testing. Apart from its relationship with the acute coagulopathy of trauma (dealt with elsewhere in this book), it can also be associated with liver diseases and some advanced malignancies such as prostate cancer. Antifibrinolytic lysine derivatives such as tranexamic acid and aminocaproic acid are considered the medications of choice for hyperfibrinolytic bleeding.

Late diagnosis of inherited bleeding disorders, although very uncommon, may be a reason for unexplained bleeding and conditions such as hemophilias, von Willebrand's disease, and other platelet function disorders. Even more rarely some of the inherited disorders can actually develop in adult life, related to disorders of the immune system, such as autoantibodies or myelodysplastic syndromes.

PROCEDURES IN COAGULOPATHIC PATIENTS

Despite concerns regarding performing invasive procedures on patients with coagulopathy or low platelet counts, there is very little consensus on which procedures are safe to perform or what levels of clotting function are necessary to mitigate risk. There are even fewer data on whether transfusion of factors or platelets can mitigate the risk of complications. Based on a number of retrospective studies, it appears that in critically ill patients undergoing an invasive procedure, PT or INR values do not appear to be predictive of the risk of bleeding, likely because these tests only measure part of the clotting cascade. Unfortunately, despite this, in clinical scenarios, it seems that INR is the most universally used coagulation test used to decision making. A level somewhere between 1.4 and 1.6 seems to be acceptable for most neurosurgeons placing an intracranial pressure monitoring device for example or for anesthesiologists for epidural placement (although the most current American Society for Regional Anesthesia recommendations do not state a specific target number). Less invasive procedures such as central line or arterial line placement may be performed with higher INRs, particularly if they are placed in locations where pressure can be applied in the case of an unsuccessful attempt. There is little to no evidence of effectiveness for the prophylactic use of FFP before procedures, and this practice is not currently recommended.

Similarly, when looking at prophylactic platelet transfusion, there are few data to guide the physician, although clinical practice guidelines from the American Association of Blood Banks have suggested a platelet transfusion trigger of $20,000 \times 10^9$/L for central venous catheter placement, $50,000 \times 10^9$/L for lumbar puncture, and the same trigger for patients having major elective surgery (Table 4); however, these were all weak recommendations based on low-quality evidence. There are retrospective studies in trauma patients that suggest that patients with severe traumatic brain injury should have their platelet count maintained above $100,000 \times 10^9$/L, but this remains controversial, without good data to suggest that correcting this thrombocytopenia by platelet transfusion will improve outcomes.

ANTICOAGULANT MEDICATIONS

The most common reason for a coagulopathy in the twenty-first century is medication induced, that is, anticoagulant medications used to treat a chronic medical condition such as coronary artery disease, valvular heart disease, or atrial fibrillation (AF). Between 2.7 and 6.1 million Americans currently suffer from AF, and it is anticipated that 1 in every 4 people will develop AF in his or her lifetime. This incidence is expected to increase as the population increases. There has been a concomitant increase in the use of anticoagulant medications over the last decade including an explosion in the use of novel anticoagulants, as well as increased use of antiplatelet agents, leading to ever increasing numbers of patients having some form of acquired coagulation defect.

Table 5 lists the currently available anticoagulant agents, where they exert their effects, half-life, and clearance as well as any currently

TABLE 8 Clearance of Anticoagulants

Anticoagulant	Target	Half-life	Clearance	Comments
Unfractionated heparin	Xa and thrombin inhibition	≈1–90 min	Cellular and kidney	Can be used IV or SQ Reversed by protamine
Low-molecular-weight heparin	As above, but mainly Xa inhibition	3–7 hr	Kidney	Only given SQ Only ≈8% reversed by protamine
Fondaparinux	Indirect Xa inhibition	15–17 hr	Kidney	No specific antidote Consider PCC, aPCC, or Andexxa
Aspirin	Platelet cyclooxygenase inhibition	20–40 min Antiplatelet effects last 5–10 days	Liver	Risk of exogenous platelets being inhibited if drug still present
Antiplatelet agents, clopidogrel, prasugrel, ticagrelor	Platelet $P2Y_{12}$ antagonists	6–15 hr	Liver	Risk of exogenous platelets being inhibited after transfusion if drug still present
Warfarin	Vitamin K–dependent clotting factors (II, VII, IX, X, protein C and S)	20–60 hr	Liver	Reversal with vitamin K, prothrombin complex concentrates, or FFP depending on urgency
Dabigatran	Direct thrombin inhibition (IIa)	11–22 hr	80% via kidney	Antidote is idarucizumab (Praxbind), PCC or aPCC if not available
Rivaroxaban Apixaban Edoxaban	Direct Xa inhibition	4–12 hr 9–14 hr 10–14 hr	Liver and kidney	Antidote is andexanet alpha (Andexxa), PCC or aPCC if not available
Bivalirudin	Direct thrombin inhibition	20–40 min	80% plasma 20% kidney	No specific antidote
Argatroban	Direct thrombin inhibition	30–40 min	Liver	No specific antidote

aPCC, Activated prothrombin complex concentrate; FFP, fresh frozen plasma; IV, intravenous; PCC, prothrombin complex concentrate; PO, by mouth; SQ, subcutaneous.

recommended reversal agents or therapy, when available. The newer agents known as the novel or direct anticoagulants have been extremely challenging because specific reversal agents did not exist when they were first introduced. Nonspecific reversal agents, such as prothrombin complex concentrate, were the only available options for a number of years; however, idarucizumab, an antidote for dabigatran, became available in 2015. Idarucizumab is a recombinant immunoprotein that has high affinity for the dabigatran molecule and can effectively neutralize the anticoagulant effect of this drug. Although idarucizumab is effective at mitigating the underlying coagulopathy induced by dabigatran, it does not promote clot formation. Direct comparisons between the two strategies are currently lacking, but in theory, idarucizumab may have fewer thromboembolic complications than prothrombin complex concentrate; however, concerns remain about delays in the achievement of hemostasis seen in clinical trials evaluating idarucizumab. Unfortunately, the cost of reversal is more than 10 times the cost of a month's supply of the medication. In 2018, a recombinant, modified human factor Xa decoy molecule called andexanet alpha (Andexxa) was approved by the US Food and Drug Administration as a reversal agent for the anticoagulant effect of factor Xa inhibitors such as rivaroxaban and apixaban. Andexanet alpha binds to factor Xa inhibition, effectively reversing their anticoagulant effects; however, its half-life of 2 hours is much shorter than the anticoagulants being reversed, particularly in the setting of acute kidney injury. In addition, it suffers the same problem of expense, with a single dose for reversal estimated to be approximately $55,000.

Careful attention should be paid to use of anticoagulant medications in the face of hepatic or renal impairment. As Table 8 demonstrates, the vast majority of these drugs are cleared by one of these two routes; therefore, in the patient who has labile creatinine clearance or is going into hepatic failure, significant forethought should be given to the exact choice of drug. Additionally, there are many drug-drug interactions that can play havoc with the metabolism of warfarin, which is a difficult enough drug to dose correctly at the best of times. Other medications can have similar problems, and it has been estimated that around 20% of patients ingest herbal medications at the same time as anticoagulants, and up to 10% of these are at risk for herb-drug interactions. Clinicians need to be cognizant of these interactions, especially where new medications have been started in the hospital and the patient is then readmitted back to home anticoagulation.

Therapeutic Agents to Treat Coagulopathy

Table 9 lists the commonly used therapeutic agents for treatment of coagulopathy; however, in many patients the coagulation defect is not limited to just one part of the pathway and may treatment with more than one product (e.g., dilutional coagulopathy may require plasma, platelets, AND cryoprecipitate infusions), and warfarin reversal will require both prothrombin complex concentrates and/or FFP, in addition to vitamin K to prevent rebound INR increases. Administration of coagulation tests again may not correspond to clinically relevant bleeding risk, and the agents listed should be used in conjunction with clinical judgment rather than being based purely on a specific number, with treatment individualized to the specific coagulation defect and risk of hemorrhage.

TABLE 9 Commonly Used Therapeutic Agents for Treatment of Coagulopathy

Therapeutic Agent	Uses	Notes
FFP	General coagulopathy Warfarin effect reversal	Rapid reversal for warfarin INR of FFP itself is 1.3–1.4 Risk of TRALI
Platelets	Thrombocytopenia Reversal of drug effects	Vital part of an MTP Function difficult to measure
Cryoprecipitate	Low fibrinogen levels	Stored frozen, requires preparation time
Fibrinogen concentrate	Low fibrinogen levels	Data for efficacy in postsurgical patients
Prothrombin complex concentrates (e.g., Kcentra, Profilnine)	General coagulopathy Warfarin effect reversal Novel anticoagulant reversal	Increasingly used in trauma Rapid reversal, needs vitamin K in addition for warfarin
Factor VIIa	Traumatic coagulopathy Anticoagulant reversal	Less often used in trauma Possible use in reversal of novel anticoagulant agents
Tranexamic acid	Hyperfibrinolysis	Trauma patients Cardiac surgical patients
Desmopressin (DDAVP)	Uremic platelet dysfunction ↑ Clopidogrel, Prasugrel	Rapid onset, lasts 6–8 hr Questionable efficacy for medications
Vitamin K	Warfarin effect reversal Vitamin K deficiency	Relatively slow onset IV vs PO equivalent at 24 hr
Aminocaproic acid	Hyperfibrinolysis	Often used in cardiac surgery to decrease blood loss
Platelets	Thrombocytopenia Reverse antiplatelet effects	Risk of new platelets being inhibited by drug still present

FFP, fresh frozen plasma; *INR*, international normalized ratio; *IV*, intravenous; *MTP*, massive transfusion protocol; *PCC*, prothrombin complex concentrate; *PO*, oral; *TRALI*, transfusion-related acute lung injury.
