Patients presenting with fecal incontinence require a respectful but thorough and methodological history and physical examination. The purpose of the interview is to translate the patient's genuine complaints into a detailed understanding of the type and extent of incontinence, awareness of incontinence episodes (urge vs passive incontinence), timing and frequency of symptoms, stool characteristics and habits, and other associated symptoms (e.g., prolapse, drainage, urinary or sexual dysfunction). A detailed obstetrical and surgical history is essential. Underlying disease processes such as diabetes, stroke, inflammatory bowel disease, malignancy, or specific medications may contribute to fecal incontinence and should be documented. The examination is not limited to defining the sphincter tone at rest and during squeezing and Valsalva maneuvers, but should evaluate for the presence of pelvic organ prolapse, masses, surrounding skin irritation, hemorrhoids, fissures, hemorrhoids, or perianal/rectovaginal fistulas. The perianal and rectal sensation are assessed, and the clinical integrity and function of the sphincter complex and accessory muscles determined on physical examination.

Various patient-reported scoring systems are used to quantify patients' degree of fecal incontinence in a standardized fashion. The Cleveland Clinic Fecal Incontinence Score (Wexner) is one of

the most commonly used system which scores the frequency of 5 different parameters from 0 to 4 and sums it to an aggregate score of 0 (perfect control) to 20 (complete incontinence). Other scoring instruments have a different emphasis and may be used in lieu of or complementary to the Wexner score. Examples include the Fecal Incontinence Severity Index, Fecal Incontinence Quality of Life Score, and the St. Marks Incontinence Score. All scoring systems are limited by the subjectivity of the reporting, failure to include coping mechanisms, a lack of objective physiologic test data, and most importantly the inability to accurately predict outcomes.

Objective workup primarily focuses on assessing (1) the sphincter integrity and (2) the anorectal function. Endoanal ultrasound is considered the most sensitive means to evaluate the integrity of the sphincter complex (Fig. 1). The anorectal function (muscle strength and the reservoir function) is assessed through a combination of anal manometry, anorectal sensation, volume tolerance, and determination of rectal compliance. Conventional water-based manometry has increasingly been replaced by high-resolution manometry using an integrated probe that allows for three-dimensional analysis and visualization of pressure profiles. Pudendal nerve terminal motor latency and electromyography may be useful in select circumstances, but they are of very limited prognostic value. It should be noted that amphetamine testing is not helpful because it is commonly distorted in patients with a severe anatomical pathology such as a full-thickness rectal prolapse. It is recommended that the anatomy first be corrected before subjecting the patient to predictably unreliable assessment of the anorectal function.

Additional workup steps are optional and depend on the individual setting. Occasionally, particularly with predominant pelvic organ instability (organ descent/prolapse), a dynamic magnetic resonance imaging scan, and/or defecating proctogram may be useful to visualize the positional instability and the involved pelvic compartments. If necessary, based on findings or clinical suspicion, consider early multidisciplinary involvement by gynecology, urology, and/or neurology.

Patients who meet national screening guidelines or have concerning symptoms should undergo a full colonoscopy, otherwise, flexible sigmoidoscopy is adequate to evaluate for associated masses or inflammation. If tests reveal a specific disease such as cancer or inflammatory bowel disease, the primary focus lies in appropriate management of these conditions according to respective guidelines.

TABLE 1 Causes of Fecal Incontinence

Category	Details
Acquired structural abnormalities	Obstetric injury (vaginal delivery) Anorectal surgery (e.g., hemorrhoid, fistula, fissure) Rectal intussusception/prolapse Sphincter sparing bowel resection Trauma (e.g., pelvic fracture, anal impalement, and laceration)
Functional disorders	Chronic diarrhea Irritable bowel disease Inflammatory bowel disease Radiation proctitis Hypersecretory tumors Fecal impaction (paradoxical diarrhea) Physical disabilities Psychiatric disorder
Neurologic disorders	Pudendal neuropathy (radiation, diabetes, chemotherapy) Spinal surgery Multiple sclerosis Dementia Central nervous system disorder: stroke, trauma, tumor, infection Spina bifida
Congenital disorders	Imperforate anus Cloacal defect Spina bifida (myelomeningocele, meningocele)

NONOPERATIVE MANAGEMENT

Patient Self-Directed Measures

The initial management of fecal incontinence, regardless of etiology, should be nonoperative and begin with the patient to control symptoms and attempt to correct any modifiable factors contributing to the patient's presentation. The most pressing goals are to (1) optimize stool consistency, (2) slow down bowel motility, and (3) minimize the average stool load in the rectum, particularly before going to bed or leaving the security of the private home. Supportive measures

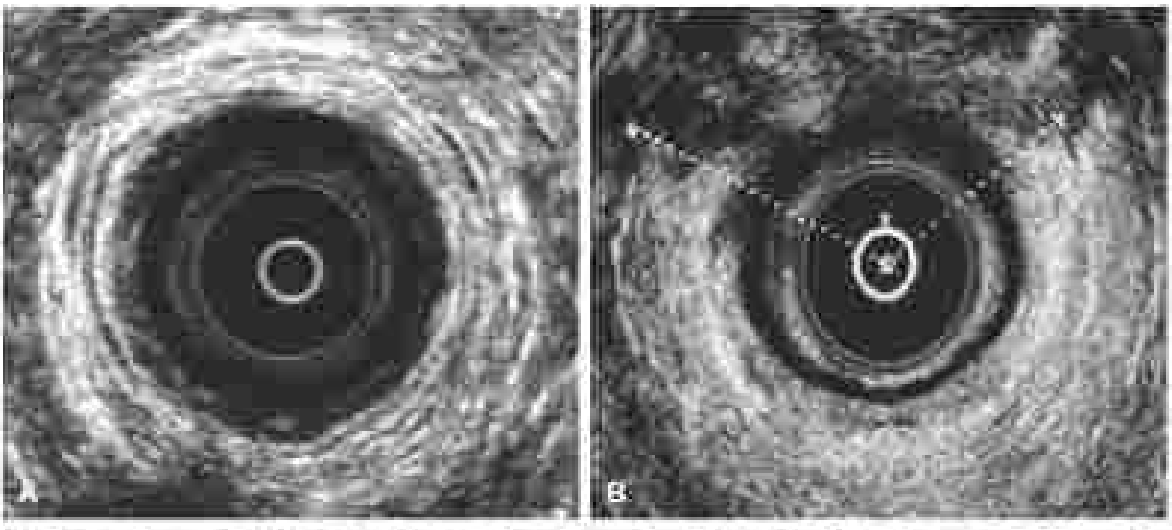

FIG. 1 Endoanal ultrasound imaging of the anal sphincter muscle. (A) Intact circumferential sphincter complex. (B) Approximately 110-degree anterior sphincter defect.

include perianal skin care to minimize irritation, which is a common complaint in incontinent patients and can progress to larger wounds and predispose patients to infection. Incontinence pads and barrier creams are useful adjuncts in this setting. A number of anal plugs have come to market over time, but most were either poorly tolerated or utterly ineffective in controlling fecal incontinence or skin complications.

The nonoperative therapy goal of optimizing stool consistency and decreasing the stool burden and the propulsive motility can be pursued by dietary and habit changes, as well as pharmacological and bowel management interventions. Dietary changes should focus on avoiding foods that promote urgency or diarrhea and on managing daily fluid intake. In individuals with a weak sphincter function, dietary fiber supplementation requires caution and may prove counterproductive because of increased stool volume or less desirable stool consistency. Pharmacologic interventions include antidiarrheal medications such as loperamide and diphenoxylate atropine. In patients with irritable bowel syndrome, tricyclic antidepressants such as amitriptyline or newer irritable bowel syndrome–specific drugs such as alosetron or ibrexadoline may be considered. A bowel management program starts with patient education about regularity and timing in relation to the gastrocolic reflex and further aims to eliminate misconceptions. In addition, scheduled tap water enemas may be a useful adjunct to reduce the stool load, particularly if antidiarrheal medications seem to aggravate constipation; enemas are a must in patients with fecal impaction and overflow incontinence.

Professional Nonoperative Intervention

Physical therapy and biofeedback training are common techniques that focus on strengthening and re-coordinating the pelvic floor and sphincter function in response to rectal distention. The approach is simple, noninvasive, and without any adverse side effects. A subjective benefit has been noted in 64% to 89% of the patients. However, an objective improvement compared with standard care is frequently impossible. The most significant effect from physical therapy and biofeedback training may be that the patients are tasked to take an active role in addressing their incontinence.

OPERATIVE MANAGEMENT

If conservative management in patients with fecal incontinence has been exhausted and failed to offer an acceptable quality of life, surgical options are explored. Depending on the nature and severity of the symptoms, the operative strategy has several levels of intervention (Table 2). Before focusing on incontinence-specific approaches, it is important to correct major anatomic abnormalities such as rectal or hemorrhoidal prolapse, rectovaginal/rectourinary and other fistulas, and chronic (or severe) keyhole deformities. Restoring a comparably normal anatomy itself has the potential to normalize much of the missing control function.

Regarding specific strategies, several options that involved different types of implants have unfortunately recently been taken off the market. Therefore, the remaining surgical strategies are limited to a sphincter repair, sacral nerve stimulation (SNS), or creation of a stoma. Fortunately, however, there are a few additional entries as well as new modalities that are in the research and development stage or early clinical implementation.

SPHINCTEROPLASTY

If there is a relevant defect in the sphincter complex from obstetric injury, anorectal surgeries, or trauma, a repair of the sphincter (sphincteroplasty) seems to be a rational and still probably the most frequently used approach. The goal is to reconstitute the circular configuration of the muscle around the anal canal. This will restore the high-pressure zone at rest and during squeezing (Fig. 2). Furthermore, the shortening of the muscle fibers during a contraction translates into a centripetal force that effectively narrows the anal canal.

Patient selection is important for the success of sphincteroplasty. Even in a defect size between 60 and 180 degrees, repair of smaller defects, isolated internal sphincter defects, or of multisegmental sphincter fragmentation is not typically beneficial. Furthermore, repeat sphincteroplasties or repair of very scarred muscles without identifiable contractility are not promising.

The data as for other anorectal procedures, the prone jackknife offers many advantages, but some surgeons prefer the lithotomy position. A transverse or curvilinear incision in the perineum midway between the anus and vagina (Fig. 3) provides access to the anterior defect to dissect down to the sphincter complex and associated scar tissue. Injuries to either the rectum or vaginal wall should be avoided under all circumstances because they may be complicated by formation of a fistula. The concept is to mobilize the scarred ends of the sphincter on either side as much as necessary to allow for an overlap but as little as possible to avoid denervation (pudendal nerves) or ischemia. If the sphincter muscle is absent in the middle and has been replaced by an unstructured scar, it is sometimes challenging to find the right level of dissection that continues into the true sphincter structures. Trimming the scar tissue is not desirable because it provides a much better anchor for the sutures than the native muscle tissue would. The scar tissue overlying the anterior defect is divided and subsequently overlapped (Fig. 3). A series of 2-0 absorbable mattress sutures are placed and subsequently tied. It is important to create an adequate length of a high-pressure zone. This may be supplemented by adding an anterior levatoroplasty. A sphincter repair without overlap but more end-to-end apposition may be considered in cases of acute sphincter disruptions if done at the time of the injury. A sphincter plication if there is no identifiable defect has proven ineffective.

Short-term results following anterior sphincteroplasty are generally favorable with rates of improved incontinence in the range of 75% to 80%. Because the effect of the original and reparative surgical trauma are undetermined, however, this response over time appears to deteriorate such that less than one half of patients remain fully continent at 5 to 10 years. Nonetheless, and not since the artificial

TABLE 2 Surgical Targets and Options

Goal	Options
Correction of complex pelvic deformities	Prolapse Repair, correction, or removal of: • Cloaca • Keyhole deformity • Rectovaginal fistula • Cloacogenic anomaly • Tumor
Sphincter repair	Overlapping sphincteroplasty
Enhancement of impaired sphincter function	Sacral nerve stimulation Radiofrequency energy administration (SECCA) Injection of bulking agents (e.g., NASHA/Dx, Solesta)
Sphincter replacement/support	Artificial bowel sphincter Implantation of magnetic anal sphincter (Torax) Levatoroplasty Implantation of cardiac (Dynamyo) Implantation of pelvic sling system
Diversion	Colostomy
Reduction of fecal load	Malone antegrade continence enema

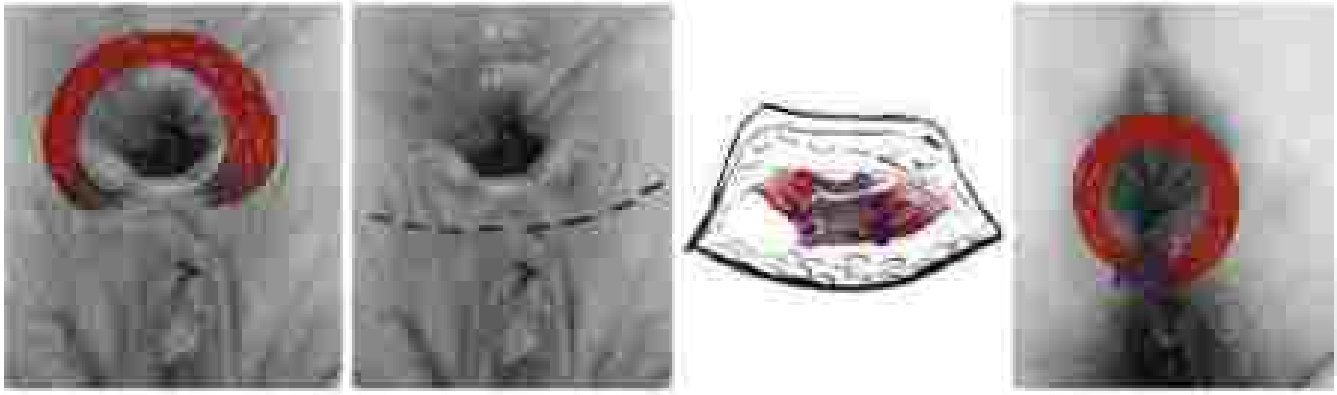

FIG. 3 Steps of overlapping sphincteroplasty.

sphincter implant options have been taken off the market, a substitute approach is not justified and should be avoided.

SNS

SNS has evolved into the treatment of choice for patients with fecal incontinence with very few exceptions. The treatment initially expanded after a benefit on bowel control was noted in patients treated with SNS for urinary incontinence. In 2011, it secured US Food and Drug Administration approval for use in patients with fecal incontinence. Although the exact mechanism of action remains unclear, SNS via direct, low voltage stimulation of the sacral nerve roots appears to simultaneously affect multiple levels of the complex neuromuscular pathway that controls fecal continence. The implantation is carried out in two stages, both in the outpatient setting. The first stage is considered a trial phase and involves the percutaneous placement of a wire with four leads into the S3 foramen (Fig. 4). Correct lead placement is confirmed by means of fluoroscopy (Fig. 5) and intraoperative test stimulation, which should result in a contraction of the pelvic floor musculature (Barlow's sign) and ipsilateral great toe flexion. These leads are then connected to an external stimulator. Symptoms are tracked over 2 weeks before and after the implantation. If the stimulation results in at least a 50% reduction in fecal incontinence episodes, it is considered a success, and the patient moves on to stage 2; otherwise, the temporary lead is removed. Stage 2 procedure involves the permanent implantation of the actual stimulator in the soft tissue of the buttocks just below the iliac crest (Fig. 6).

Studies have shown that definitive implantation was associated with a greater than 50% improvement in bowel incontinence episodes in 80% to 83% of patients and with nearly perfect control in 40% of the patients. Even in the long-term analysis, the success appeared to persist, but after 3 to 5 years, a battery change is needed. The method has a favorable safety profile, and complications (e.g., pain, infection, bleeding, paresthesia) are comparably rare.

The success of SNS has caused a major paradigm shift in the workup and treatment of patients with incontinence. It has become clear that no preoperative test, but only the trial lead placement, can predict treatment success. Therefore, the traditional recommendation to do anal physiology and pudendal nerve testing before any surgical intervention has lost regard. SNS is now indicated following failed nonoperative management of any incontinence regardless of whether there is a sphincter defect or pudendal neuropathy. Exceptions are limited to gross congenital or acquired anatomical alterations of the rectum and pelvic floor, local tissue infections, a predictable need for magnetic resonance imaging scans, or a failed test phase.

FECAL DIVERSION

Fecal diversion with the creation of a well-constructed diverting colostomy at a carefully selected site remains a more satisfying than acknowledged approach that gives the patient back predictability and health. Despite the negative stigma that many patients associate with stomas, most report minimal negative impact on quality of life, and approximately 80% would choose fecal diversion again. A thyroid colostomy, laparotomy loop or end stoma, is the preferred method. If

there is a history of previous pelvic reactive surgeries, caution should be used to ensure the exact blood supply of the existing anatomy is well studied.

UNAVAILABLE OR UNCOMMON SURGICAL OPTIONS

It is rational to consider methods to increase the anorectal outlet resistance if the sphincter complex is weak and dysfunctional. Different approaches have been explored and obtained US Food and Drug Administration approval. They included, from most to less effective, the implantation of the artificial bowel sphincter (Acticon Neosphincter), the magnetic ring (Fenix), radiofrequency administration (Secca), or injection of bulking agents (e.g., NASHA/Dx) into the anal canal. Risks and effectiveness seemed to have a direct correlation. Options with a low risk profile had (despite statistical significance) very low clinical success rates (radiofrequency, bulking agents); the magnetic ring was associated with an intermediate risk profile and offered moderate clinical success; and the artificial bowel sphincter had a significant complication rate (infection, erosion), but was highly effective in patients who did not experience complications. Mostly for economic reasons though, the manufacturers took these options off the market, and their future remains uncertain.

Other options, such as a gracilioplasty or the Malone antegrade continence enema are rare options in adult patient populations and should be reserved for centers with experience.

FUTURE OPTIONS

Research centers around other types and delivery mechanisms to enhance the outlet resistance (e.g., placement of perianal self-expandable implants that are placed by means of an applicator gun [LiaoKeeper]). Definitely a cause for excitement is the stem cell research that has the goal to regenerate muscular tissue around the anus. There have already been early-stage reports and most recently presentations about three-dimensional bioprinters that are able to generate contractile tissue rings.

CONCLUSIONS

Fecal incontinence is frequent but, because of the stigma, underreported. It results from an imbalance or decompensation of the continence factors (anal sphincter complex, stool consistency, rectal reservoir function, neurologic function). Symptom severity should be quantified using one of several validated scoring systems. Objective evaluation tools include anorectal ultrasound and anorectal physiology testing but may lead to further imaging or a referral to associated specialties (urology, gynecology). There is no single technique that would guarantee perfect outcomes without any morbidities, and successful management needs to combine different approaches. Operative strategies are explored for patients with obvious structural deformities or significant fecal incontinence that is refractory to conservative management. Current options include sphincter repair, SNS, or creation of a stoma. Other options such as implants have despite efficacy been taken off the market.

Rectovaginal Fistula

Mitchell A. Bornstein, MD, FACS, FASCRS, and Josef A. Shikhani, MD, FACS, FASCRS

Rectovaginal fistulas (RVFs) are abnormal communications between the anus or rectum and the vagina and can present a challenge for both the patient and the surgeon. Patients may present with stool per vagina resulting in frank incontinence, or gas or drainage per vagina. This condition can have extensive morbidity related to a negative impact on the patient's social, sexual, and overall quality of life and can be extremely disabling and associated with significant distress to affected women. Additionally, the morbidity and success of a repair is directly dependent on both the cause and the complexity of the fistula. Many surgical repair options exist for this disease; however, many patients fail multiple procedures before going to a tertiary care center. RVFs are uncommon in the general population but are seen frequently by colorectal surgeons.

The literature is made up of case series with small numbers of patients and the systematic reviews analyzing them. It is therefore difficult to advocate for one repair technique or directly compare the results between techniques.

With these limitations in mind, in this chapter we discuss the surgical management of RVF and propose a broad treatment algorithm based on current reported literature.

ETIOLOGY/CAUSES

RVFs are most commonly the result of obstetric injuries, cryptoglandular disease, or Crohn's disease. Other causes encountered are malignancy, radiation therapy, or complications following leaks from a colorectal, colonal, or ileal pouch anal anastomosis (Box 1).

Obstetric injury is the most common cause of RVF. Approximately 2% of all vaginal deliveries are associated with third- and fourth-degree perineal tears with 3% of these patients subsequently developing an RVF accounting for 0.1% to 0.3% of all vaginal deliveries. Fistulas arising from obstetric injury often are associated with anterior anal sphincter defects that lead to fecal incontinence in

RECTOVAGINAL FISTULA

Mitchell A. Bornstein, MD, FACS, FASCRS, and Josef A. Shabahang, MD, FACS, FASCRS

Rectovaginal fistulas (RVFs) are abnormal communications between the anus or rectum and the vagina and can present a challenge for both the patient and the surgeon. Patients may present with stool per vagina resulting in frank incontinence, or gas or drainage per vagina. This condition can have extensive morbidity related to a negative impact on the patient's social, sexual, and overall quality of life and can be extremely disabling and associated with significant distress to affected women. Additionally, the morbidity and success of a repair is directly dependent on both the cause and the complexity of the fistula. Many surgical repair options exist for this disease; however, many patients fail multiple procedures before going to a tertiary care center. RVFs are uncommon in the general population but are seen frequently by colorectal surgeons.

The literature is made up of case series with small numbers of patients and the systematic reviews analyzing them. It is therefore difficult to advocate for one repair technique or directly compare the results between techniques.

With these limitations in mind, in this chapter we discuss the surgical management of RVF and propose a broad treatment algorithm based on current reported literature.

ETIOLOGY/CAUSES

RVFs are most commonly the result of obstetric injuries, cryptoglandular disease, or Crohn's disease. Other causes encountered are malignancy, radiation therapy, or complications following leaks from a colorectal, colonal, or ileal pouch anal anastomosis (Box 1).

Obstetric injury is the most common cause of RVF. Approximately 2% of all vaginal deliveries are associated with third- and fourth-degree perineal tears with 3% of these patients subsequently developing an RVF accounting for 0.1% to 0.3% of all vaginal deliveries. Fistulas arising from obstetric injury often are associated with anterior anal sphincter defects that lead to fecal incontinence in

BOX 1 Cause of Rectovaginal Fistulas

Obstetric Injury

Episiotomy, third- and fourth-degree perineal lacerations

Inflammatory Bowel Disease

Crohn's disease

Iatrogenic

Vaginal surgery (hysterectomy, sectocele repair)
Abdominal surgery (hysterectomy, low anterior resection, J pouch, procedure for prolapse and hemorrhoids)

Infectious

Cryptoglandular abscess, diverticulitis, tuberculosis

Neoplastic

Anal cancer, rectal cancer, vaginal cancer, cervical cancer

Radiation Induced

External beam radiation, brachytherapy

FIG. 1 Small rectovaginal fistula with intact perineum and anal sphincters. (From Kumar RR, Rectovaginal fistula and perineal injuries. In Wexner SD, Abcarian H, eds. Surgery and Interventional Tools. Surgery 4th ed. Philadelphia: Elsevier; 2015.)

varying severity. They typically become apparent around 1 to 2 weeks after delivery following the breakdown of a fourth-degree repair. Prolonged labor resulting in compression of the rectovaginal septum by the infant's head can lead to necrosis of the rectovaginal septum and cause an RVF that presents in a more delayed fashion. These generally occur cephalad to the pelvic floor and sphincter complex where the rectovaginal septum is thinnest. Traumatic injury from an instrumented delivery can also result in fistula formation and generally occurs in the thin portion of the rectovaginal septum.

Crohn's disease is the second most common cause of RVFs. Approximately 10% of women with Crohn's disease will develop an RVF, and they are more common in those who suffer from colonic Crohn's disease. RVFs associated with Crohn's disease have a high recurrence rate and often require multiple procedures before healing repair. They are variable in their presentation and location, are the result of transmural inflammation from the anorectum, and frequently associated with perianal sepsis, branching fistula tracts, as well as scarring and stricturing of the anorectum.

Cryptoglandular disease, commonly the cause of simple anorectal fistulas, can also cause RVFs. If an anteriorly located anal gland or its associated duct becomes occluded it may result in abscess formation within the rectovaginal septum and decompression into the vagina. If the communication fails to heal, an RVF results. These are generally located at the level of the dentate line on the rectal side and course through the anal sphincters to the low vagina or introitus.

CLINICAL INDICATIONS AND APPROACH TO DIAGNOSIS

In the initial evaluation and treatment of RVFs, underlying pathology such as cryptoglandular abscess, inflammatory bowel disease, or malignancy must be addressed first because procedures performed to eliminate the fistula in the setting of active disease or infection will often fail.

Symptoms may vary depending on the etiology, although generally the most common presenting symptoms are passage of stool or gas via the vagina, which often can be misinterpreted as fecal incontinence. In addition, patients may offer a history of recurrent urinary tract infections, dyspareunia, or vaginal discharge. History and physical examination are of paramount importance because details may affect the approach and method of repair.

History taking may be directed toward the patient's previous obstetric history, history of abdominal and anorectal operations, history of radiation treatment, and signs and symptoms of Crohn's disease or diverticulitis (which may help to differentiate from a colovaginal fistula).

On physical examination, an indurated fistula tract can often be identified on digital examination. Anoscopy or vaginal speculum examination may be used to visualize granulation tissue at the level of the fistula tract. Additionally, the condition of the perineal body and rectovaginal septum should be noted. Care should be taken to assess the quality and strength of the anal sphincters because the status of the sphincter complex plays an integral role in the choice of repair. Although large RVFs may be readily apparent on rectal examination, bimanual examination may be required to detect smaller fistulas. The location of the fistula relative to the sphincter muscles and pelvic floor should be determined as this can affect the type of repair chosen. Nevertheless, not all RVFs are identified on an initial clinical examination in the office. In these cases, an office-based tampon test can be undertaken. A tampon is placed in the vagina, and an enema of diluted methylene blue dye is given as an enema. The patient is asked to ambulate and later (i.e., after 20–30 minutes), the tampon is removed and inspected for evidence of blue dye. If dye is identified on the tampon, a fistula is highly suspected. If still not clinically apparent, an examination under anesthesia (EUA) is the best modality to define the fistula tract and plan surgical treatment. If the primary opening is identified, but with difficulty identifying the secondary opening, hydrogen peroxide or methylene blue can be used. A fistula probe can be placed into the fistula tract (Fig. 1).

Physical examination should also reveal any signs of continuing perianal sepsis, such as undrained abscesses or purulent perineal drainage and in many instances patients with Crohn's disease should also undergo an EUA as an initial step after clinical examination to identify the fistulous anatomy and evaluate for the degree of inflammation of the anus and rectum which may affect timing of surgery.

The necessary steps in preoperative evaluation are to (1) identify the fistula, (2) determine the cause, (3) evaluate the extent of the disease, and (4) identify surrounding injuries. The evaluation and management of simple or low rectovaginal (anovaginal) fistulas may differ from the approach to complex and high RVFs. Endoanal ultrasound (EUS) and magnetic resonance imaging are the most useful imaging studies to identify a fistula, with magnetic resonance imaging also having the advantage of identifying other disease within the pelvis. Both modalities may be enhanced by injecting hydrogen peroxide into the fistula tract. EUS is also useful in that it enables assessment of the anal sphincters. It should be performed routinely in patients with an RVF secondary to obstetric trauma as they may have associated sphincter damage. Anorectal manometry and pudendal nerve

terminal motor latency testing may be necessary if there is a history of an anal sphincter injury or presence of fecal incontinence because anal sphincter injury or pudendal nerve injuries can cause recurrent symptoms of fecal incontinence even after a successful fistula repair.

In cases of malignancy and inflammatory bowel disease, a complete evaluation of the small bowel or colon and rectum may be necessary to determine the extent of luminal stigmata. This workup may include small bowel series, endoscopy, computed tomography/magnetic resonance enterography, computed tomographic/magnetic resonance colonography, endoscopy, or contrast enema.

If a fistula is still not identified, alternate etiologies to explain the patient's symptoms should be considered, such as a colovaginal fistula rather than an RVF. Colovaginal fistulas from diverticulitis are a more common condition, and a contrast computed tomography scan of the abdomen and pelvis may demonstrate inflammation of the sigmoid colon directly overlying the vagina if this is the case. This would be more prevalent in patients that are postHysterectomy. However, very small or high RVFs may not be palpable on examination.

Classification

RVFs are often classified according to their relationship to the anal sphincter complex and are broadly classified as low RVFs and high RVFs. (high fistulas are defined as those above the sphincter complex and low fistulas are those at or below the level of the sphincters. these also are referred to as anovaginal. Trauma after vaginal delivery is almost always the cause of low fistulas, which often are associated with an associated sphincter injury. Alternatively, RVFs may be classified as simple or complex. Simple fistulas are located in the middle or lower portion of the rectovaginal septum, are less than 2.5 cm in diameter, and are caused by local trauma or infection. Commonly, complex fistulas are usually greater than 2.5 cm, located in the upper portion of the rectovaginal septum, or are secondary to causes other than trauma and infection, such as neoplastic, diverticular, effects of pelvic radiation, or inflammatory bowel disease.

Preoperative management

The extent of preoperative preparation is largely subjective but usually varies with the extent of the procedure planned for the repair. For simple repairs and local vaginal-based repairs, a phosphate enema on the morning of the procedure is adequate. For more extensive repairs, such as an overlapping sphincteroplasty or an interposition flap, and especially when fecal diversion is anticipated, or a bowel resection with a coloproctostomy or colorectal anastomosis, a full mechanical and antibiotic bowel preparation should be performed. Perioperative antibiotics and deep venous thrombosis prophylaxis are administered as per Surgical Care Improvement Project and institutional guidelines.

Surgical Management

In the initial evaluation and treatment of RVFs, underlying pathology such as cryptoglandular abscess, inflammatory bowel disease, or malignancy must be addressed and controlled first as procedures performed to eliminate a fistula in the setting of active disease or infection will often fail. The presence of active sepsis is an absolute contraindication to any attempt at surgical repair. Surgical drainage of any abscesses and resolution of sepsis is the first and most important step and a draining seton may be required to facilitate resolution of acute inflammation, edema, or infection associated with RVF infection so that the success of subsequent repair is more likely. Setons may also provide long-term symptomatic relief for patients who are poor candidates for definitive repair and may benefit patients with an active inflammatory or neoplastic process that requires other treatments before or as part of definitive repair of the fistula. Although there is no defined period of drainage before definitive repair, a seton should be left in place until the acute inflammation and any infection have resolved. This may last 3 to 6 months in some cases. In certain instances, when a seton and wound care are inadequate to control RVF associated symptoms, a diverting ostomy may be necessary.

The goal of treatment is to preserve continence while achieving healing of the fistula. Because the status of the sphincter complex plays an integral role in the choice of repair, assessment of anal sphincter function is another key step in the initial evaluation.

There are four general categories of surgical approaches to an RVF: transanal, transvaginal, transperineal, and transabdominal.

Transanal

Fistulotomy

A fistulotomy, by definition, is the laying open of the fistula tract, which may also be curetted or excised (Fig. 2). This often is performed as a two-stage procedure: first, a draining seton is placed and then removed after fistula tract maturation and fibrosis. The second stage involves cutting of the remaining tissue to lay open the tract. Although fistulotomy is the most successful surgery for managing perianal fistulas, it is in some cases contraindicated because it inevitably results in some degree of incontinence, either from the paucity of sphincteric muscle to suture internally or a resulting keyhole defect. The incontinence is often permanent. Therefore, although lay-open fistulotomy theoretically is indicated for superficial fistulas, it very rarely is used today. Epiproctotomy, which involves fistulotomy followed by subsequent sphincter repair, is discussed later.

Endorectal Advancement Flap

Endorectal advancement flap (ERAF), with or without sphincteroplasty, is a mainstay of treatment for most simple and low RVFs (Fig. 3). The procedure uses a partial-thickness flap of rectal wall to cover the defect in the rectovaginal septum and is typically performed in the prone jack-knife position, which offers excellent exposure of the anterior rectal wall. Both the anus and vagina are prepared, and the fistula is identified with a fistula probe or a previously placed seton. A Pratt bivalve anoscope is used to expose the anterior rectal wall and a U-shaped flap then is outlined with the base cephalad and twice the width of the apex. The U shape and 2:1 dimension ensure that there are no flap corners to become ischemic and the flap pedicle is adequate to ensure blood supply to the advancement or suture line. The flap is created 1 cm distal to the fistula and consists of the rectal mucosa, submucosa, and a portion of the underlying internal sphincter, including the fistula opening at the apex; this is raised in cephalad manner with the use of needle tip electrocautery. A sufficient length of flap should be mobilized 3 to 4 cm proximal to the fistula opening to ensure a tension-free closure after excision of the fistula. Injection of a dilute epinephrine solution facilitates dissection and minimizes blood loss.

After the flap is elevated, the fistula tract is curetted to remove all granulation tissue, and the defect in the remaining internal sphincter is closed by approximating the fibers of the muscle with simple interrupted absorbable sutures. The apex of the flap then is excised to remove the fistula opening, and the flap is advanced cephalad and sutured in to tension-free. The flap is sutured in place with 2-0 running rapid absorbable sutures to close the wound by first placing sutures at either end of the wound and then continually bisecting the wound with sutures until closed. The vaginal opening is left open to facilitate drainage. Postoperative care includes a high-fiber diet, laxatives to avoid fecal impaction, and sitz baths.

The ERAF offers the advantages of performing the repair from the high-pressure side of the fistula as well as sphincter preservation. Short-term success rates for rectal advancement flaps alone vary from 43% to 88% in the small series in the current literature with varying and often short follow-up. The primary downside of the ERAF is the need for dissection of otherwise healthy rectal wall and sphincter. Flap failure and ischemia may result in flap loss and a subsequent rectal defect that is much larger than the original opening. Rates of early (within 1 week) flap loss have been reported as high as 6% with

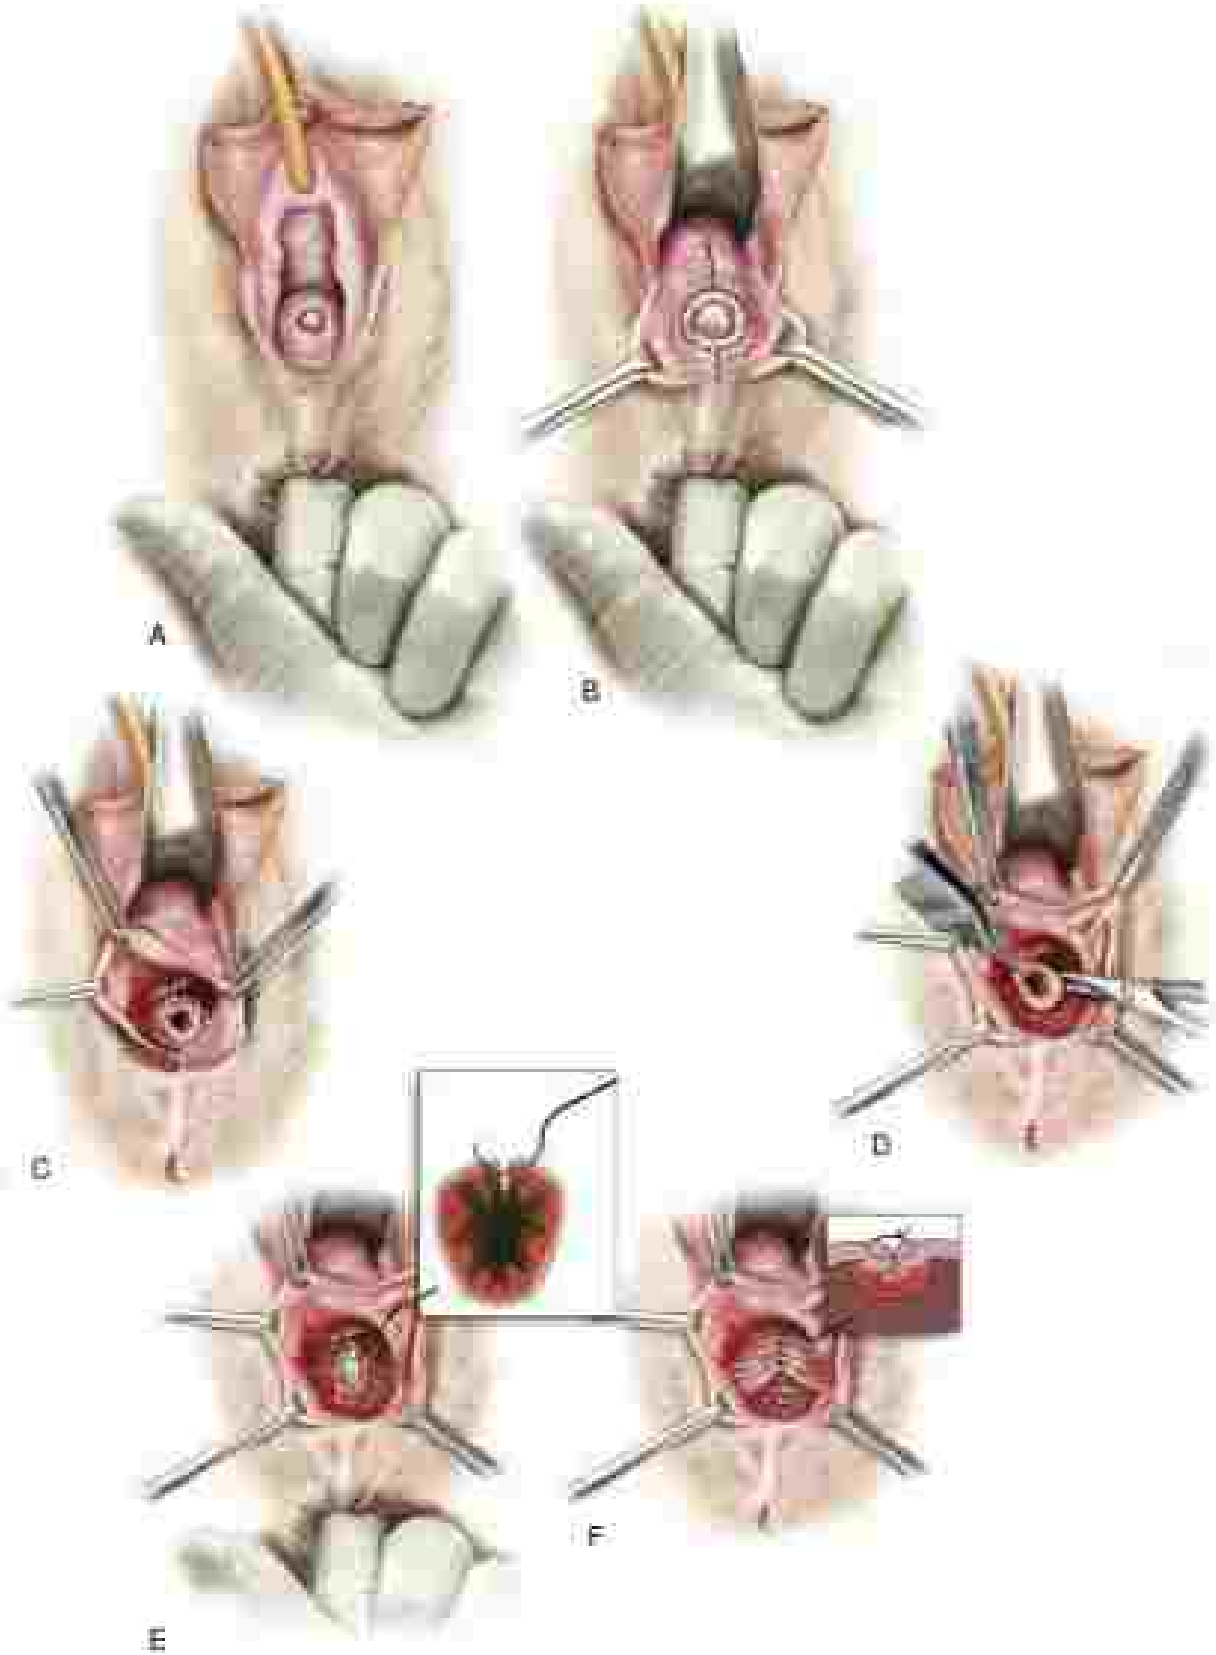

FIG. 3. Rectovaginal fistula repair in a patient with an intact perineum. (A) A rectovaginal fistula present in the midportion of the posterior vaginal wall. (B) The dashed line demonstrates the site of the posterior vaginal wall incision. (C) The vaginal wall is mobilized off the posterior rectal wall. (D) The fistulous tract is excised. The rectal wall is not back-cut from edges are reapproximated. (E) Perpendicular closure of the posterior rectal wall with decomposed, fine, indigent, absorbable sutures. (F) The second layer interposes the muscular portion of the wall of the rectum over the initial layer. The repair is completed by placing the rectovaginal tissue over the posterior vaginal wall. [Mark Klimek MM, Rectovaginal fistula and postanal pseudotract. In Walters and Klimek: Urogynecology and Reconstructive Pelvic Surgery. 4th ed. Philadelphia: Mosby; 2011.]

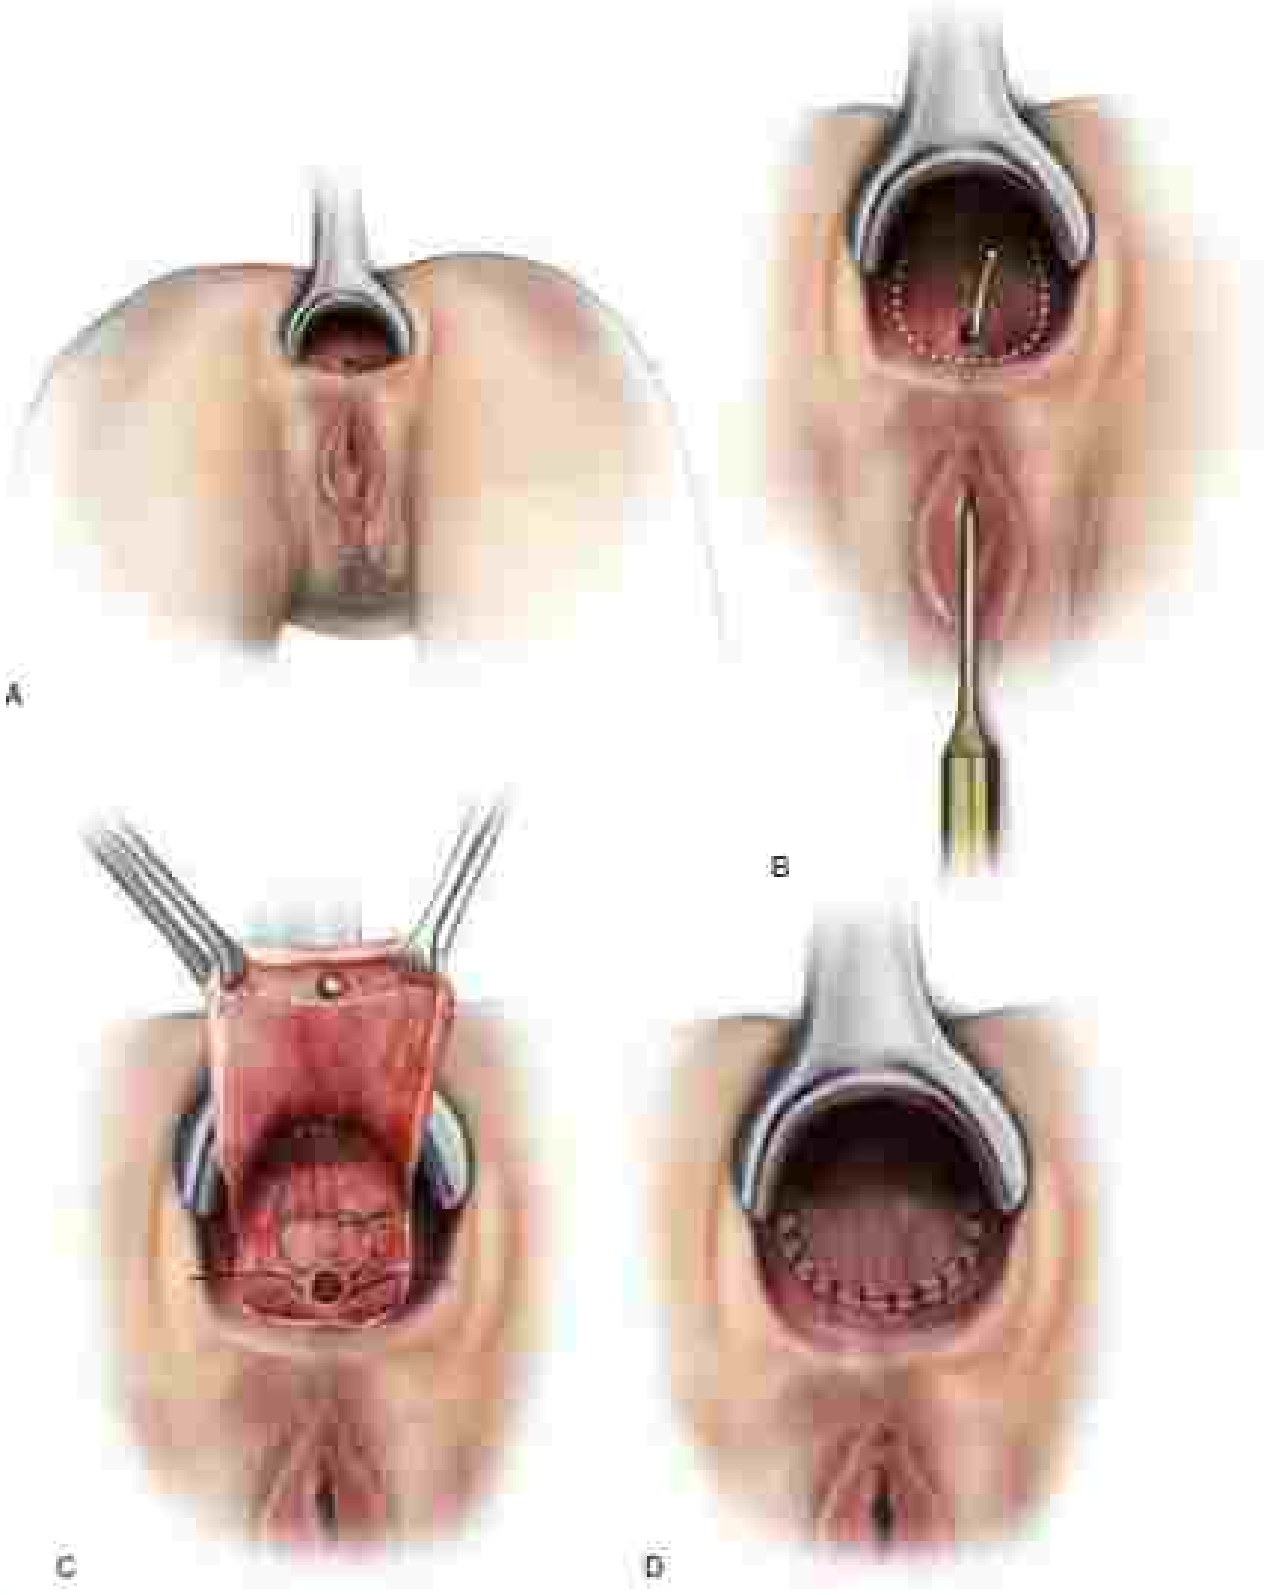

FIG. 3 Technique of endonasal advancement flap procedure. (A) The patient is placed in the prone position with the hips elevated in preparation for a low or mid-level rectovaginal fistula repair. (B) With the patient in the prone position, the anal speculum is placed posteriorly. The rectovaginal fistula is identified by placing a small probe from the anal into the vagina. The dissection line outlines the borders of the rectal mucosa used to develop the advancement flap. (C) The epithelium-lined fistula tract is excised, and the muscular wall of the rectum is reapproximated with absorbable sutures. The rectal advancement flap has been mobilized and is ready to be placed over the site of the fistula repair. (D) The flap is secured with interrupted absorbable sutures. (From Fleming MM, Birnbaugh K, Rodin DA, Gurland B. Endonasal flap and anterior sphincteroplasty for complex anterior fistula. Surgery. 2015;157(1).)

late flap breakdown rates ranging from 16% to 37%. Patients with fecal incontinence or a sphincter defect detected by EUS or an anal manometric defect who underwent sphincteroplasty had markedly higher (>80%) fistula healing rates than those who underwent flap alone (33%). The link between endorectal advancement flap failure and incontinence mandates a careful assessment of anal sphincter function and consideration of EUS before repair of RVFs. Additional factors that may be associated with failure of this technique may include Crohn's disease, complex fistula, and recurrent fistula. Although prior failed attempts at fistula repair are a risk factor for endorectal advancement flap failure, success with repeat flaps is possible, albeit lower, with success reported in 30% to 92% of patients. A diverting stoma has not been shown to improve the outcome of endorectal advancement flap for RVF but can be considered on an individual basis.

Some surgeons have described a technique of using a biologic graft as part of the procedure, whereby the endorectal flap was raised, and a 2 × 3 cm graft from porcine small intestine mucosa was placed in the rectovaginal space, and the flap sutured over the graft. They reported successful healing in 15 of 21 patients (71%).

Last, the use of an endorectal advancement flap for the treatment of low rectovaginal (anovaginal fistula) may potentially lead to bothersome anal mucus discharge. To prevent this, an alternative flap, created from the underarm and perineal skin (axillothoracic), instead of rectal mucosa, may be considered. This technique, combined with sphincteroplasty, was used by Chew and Rieger for seven patients with obstetrical low RVFs and resulted in healing in 100% of patients.

Fibrin Glue

At the time of EUS, the rectal and vaginal fistula tract openings are identified. The fistula tract then is curetted and fibrin adhesive is injected into the fistula tract until it exits the secondary opening. The goal of fibrin glue placement is to plug the fistula with material that allows fibrous tissue ingrowth and results in analogous fistula healing with no disruption of the surrounding structures or sphincters. However, experience with fibrin glue in RVFs has been very limited and plagued by disappointing results predominantly secondary to glue extrusion because of short fistula length.

Bioprosthesis

Two bioprosthetics have been used for RVFs: the bioprosthetic mesh (Surgisis mesh; Cook Surgical) and the RVF plug (Surgisis Doughnut Button; Cook Surgical). Both products are made from lyophilized porcine intestinal submucosa, which provides a matrix for ingrowth of connective tissue.

The bioprosthetic mesh is used as an interposition graft. The rectovaginal septum is dissected through a perineal incision, and the fistula is excised. After closure of the rectal and vaginal openings, the rehydrated mesh is placed between the rectum and vagina with an adequate overlap over the rectal and vaginal closures; it is sutured in position with interrupted absorbable sutures, with the mesh kept as taut as possible. The bioprosthetic mesh is useful when tissue grafts are not suitable options.

The bioprosthetic RVF plug is tapered at one end to facilitate insertion. A fistula probe is introduced from the vaginal to the rectal opening, and the tapered end of the plug is tied to the probe with a suture. The probe is then withdrawn, the plug is brought from the rectal to vaginal side, excess length on the plug is trimmed, and it is sutured in place with absorbable suture, which close the rectal mucosa over the plug. The vaginal side is left open. The short length of the fistula tract poses the same problem with the plug as with fibrin glue, which makes the plug suitable only for RVFs that are more than 1 cm in length. The experience with bioprosthetics in RVFs is very limited. Success rates of fistula closure by interposition techniques have been reported to be from 50% to 86% with short follow up. Complications are rare and generally benign and include primarily infection and plug extrusion.

Transvaginal Approach

Vaginal Advancement Flap

In a technique similar to the rectal advancement flap, a flap of vaginal mucosa is raised, and the fistula tract is excised. The rectal mucosa is closed separately, over which the defect in the rectovaginal septum is approximated with interrupted absorbable sutures. The apex of the flap then is trimmed to excise the fistula opening and is sutured into position to close the wound. The primary advantage of a vaginal flap is the use of healthy, pliable, and well-vascularized vaginal tissue, and proponents of a transvaginal repair emphasize the relative ease and better exposure gained through the vagina as compared to the anus. Nevertheless, the disadvantage remains that the repair is on the low-pressure side of the fistula. A vaginal flap is easier to mobilize than a rectal flap, therefore transvaginal repairs should involve closure of the rectum and not just of the vagina. A comparative analysis of 11 studies showed no statistically significant difference in the closure rates between a rectal and vaginal advancement flap closure in RVFs resulting from Crohn's disease. Therefore, especially when fibrotic rectitis disease is present in the anus or a transanal approach has failed, a transvaginal advancement flap is a viable option, although many of these patients may have fecal diversion as part of the treatment plan as well.

Transperineal Approach

Episiosphincteroplasty

Episiosphincteroplasty is a transperineal approach that may be used to repair obstetrical or cryptoglandular RVFs associated with extensive anal sphincter damage and associated fecal incontinence. This repair converts the fistula into a fourth degree perineal tear by dividing all the tissue between the rectum and vagina through the perineal body (Fig. 4). The rectum and vagina are separated from one another and the fistula tract divided. Ideally, some tissue, preferentially muscle, is interposed between the rectum and vagina. This may be done via levatoroplasty or sphincteroplasty. A layered closure then is performed to close the rectal mucosa, the rectal and vaginal muscular walls, and finally the vaginal mucosa. A rectal advancement flap can be added to the procedure. Success rates for this technique range from 70% to 80% in the literature with a reduction of preoperative fecal incontinence from 50% to 8% (Halverson, et al.).

Following repair, some authors advocate placement of a biologic graft to separate the vagina and rectum. Ellis described a transperineal repair with a graft made from porcine intestinal submucosa placed in the rectovaginal septum. He reported an 81% success rate (22 of 27).

The greatest disadvantage of this procedure is the creation of a full thickness defect in a previously uninjured part of the anal sphincter; therefore, a repair deficiency risks significant incontinence, which may not have been the case preoperatively. This procedure should be attempted only by experienced surgeons and in patients with documented existing sphincter defects with fecal incontinence. In experienced hands, healing rates superior to EAAF closure (97.7% vs 62.5%) have been reported with improved sexual function ($P = .04$) and decreased rates of fecal incontinence (improved in episiotomy group, unchanged in EAAF group, $P = .001$) when compared with EAAF.

Transperineal Ligation With a LIFT Procedure, Overlapping Sphincteroplasty

Simple transperineal ligation of the fistula tract can be undertaken with the ligation of the intersphincteric fistula tract procedure similar to a repair of a fistula in ano. A perineal incision is made over the intersphincteric groove and carried through the intersphincteric space, while a fistula probe is traversing the fistula tract. The fistula tract is ligated with absorbable sutures and divided. The rectovaginal septum of the rectum and vagina can also be imbricated. A rectal advancement flap can be added to the procedure. If there is no sphincter defect, the wound is irrigated and closed in layers.

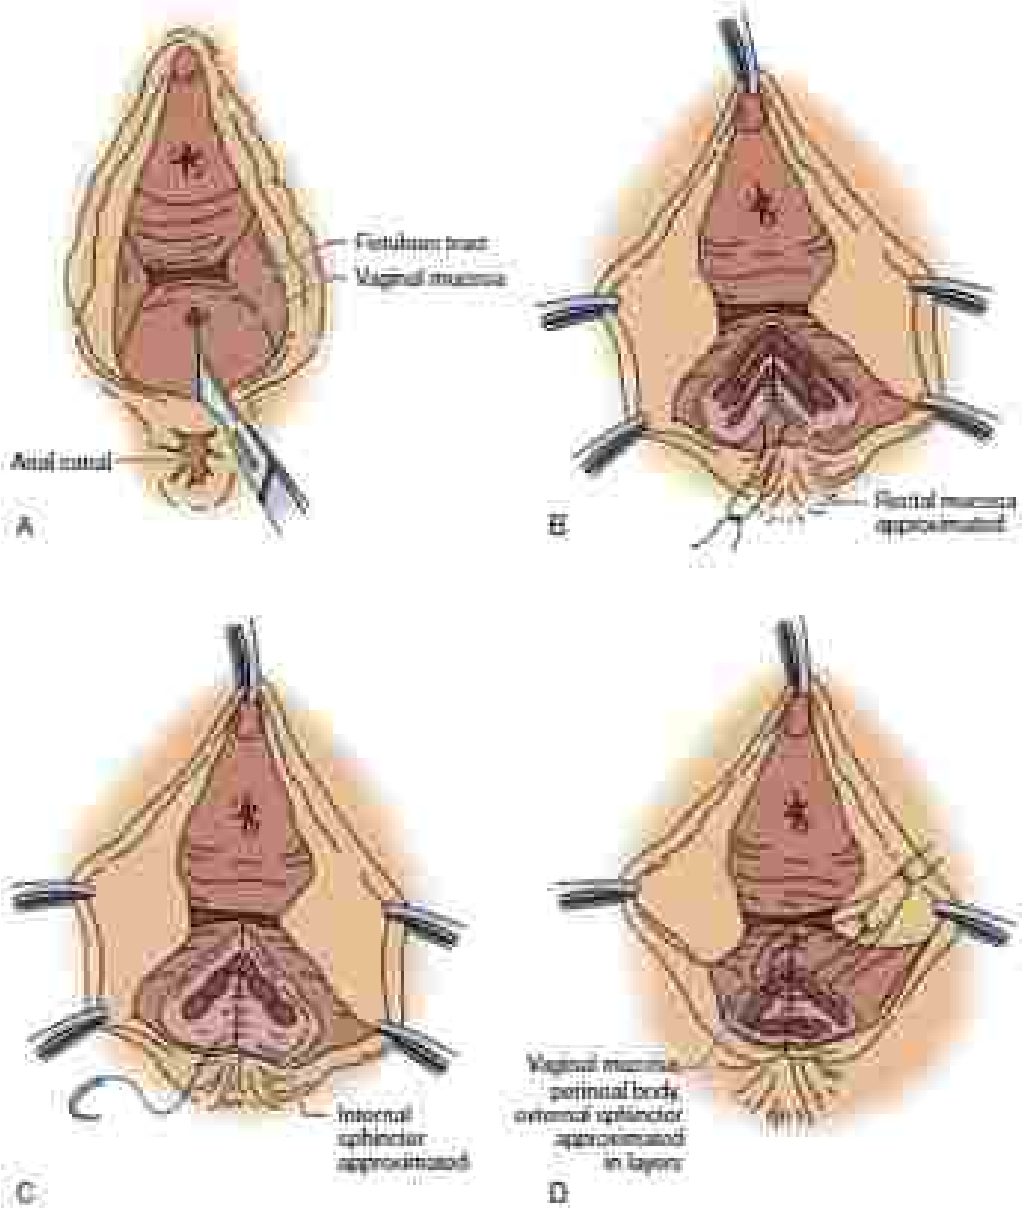

FIG. 4 Perineoproctotomy. (A) The patient is placed in the lithotomy position. The fistula is identified and excised from a full-thickness laceration. (B) The layers are dissected and repaired, first repairing the rectal mucosa. (C) The repair continues, approximating the internal sphincter. (D) The external sphincter is identified and repaired. Many patients will not have a discernible plane between the internal and external sphincters, in which case the internal and external sphincters may be repaired together. The vaginal mucosa is approximated. [From Beck DE, Roberts PL, Saclarides TJ, et al. Fistula-in-ano and anorectal fistulas. In: Cameron JL, Cameron AM, eds. Current Surgical Therapy. 12th ed. Philadelphia: Elsevier; 2017.]

In women who have a sphincter defect (most often from obstetric injury), a sphincteroplasty should be performed as well. Healthy ends of the external sphincter muscle are identified and skeletonized. The sphincter then is mobilized in the midline to ensure overlap without tension. Often the sphincter is so attenuated at the site of injury that the healthy ends of the sphincter can be overlapped and sutured into position without the need to divide or excise any tissue. The sphincter is overlapped and sutured in place with 2-0 absorbable interrupted mattress sutures. The wound is approximated loosely with the center of the skin incision left open for drainage. The technique should achieve similar results of sphincteroplasty and, if it should fail, will not result in worse than preoperative incontinence. In addition, when a sphincter injury is present, the addition of an overlapping sphincteroplasty to the approach has been reported to increase both the rate of fistula closure and restore continence.

Finally, similar to the techniques described for EIAF repair, some authors advocate placement of a biologic graft to separate the vagina and rectum. Ellis described a transperineal repair with a graft made from porcine intestinal submucosa placed in the rectovaginal septum. He reported an 81% success rate (22 of 27).

Interposition Flaps

Tissue transposition repairs offer the advantage of interposing healthy, well-perfused tissue between the rectum and vagina, and are potentially useful following previous failed local repair attempts. They add bulk to the rectovaginal septum and physically increase the distance between the rectum and vagina, and bringing their own blood supply may aid in healing. A disadvantage of the techniques is the potential for dyspareunia. The gracilis and bulbocavernosus (Martius) flaps are the two most described pedicled flaps for RVFs. Although not mandatory, fecal diversion typically is recommended and generally is undertaken before the flap procedure.

Gracilis Muscle Transposition

Repair using a gracilis muscle transposition offers the advantage of providing a large bulk of well-vascularized muscle to separate the vagina and rectum. Its origin is near the perineum, which makes it a convenient donor. It is, however, associated with higher morbidity due to the mobilization and transposition of this large muscle. A gracilis flap was most often used to repair recurrent RVFs of various etiologies or in patients with poor native tissue

and to some studies has typically been combined with concomitant fecal diversion.

The operation involves a transperineal incision, in which the rectum and vagina are separated. The fistula is divided and both the rectum and vagina are closed primarily. Dissection should continue cephalad to the fistula until healthy tissue is reached. An interposition advancement flap can be added to the procedure as well. The perineal incision created does not differ from that in other transperineal approaches. The muscle of either leg can be used and is harvested through an incision in the medial aspect of the thigh. This can be performed with a long incision along the length of the gracilis, or with separate smaller incisions near the muscle's origin and insertion. The muscle is mobilized with division of the perforating vessels. It is divided just above its insertion. The harvested muscle then is tunneled through the subcutaneous tissue to the groin and maneuvered into the perineal incision. Care must be taken that the flap is not rotated excessively and its blood supply not kinked. The muscle is secured to the apex of the rectovaginal dissection and the transperineal incision closed with interrupted absorbable sutures. The success rate of the gracilis muscle flap has been reported to range between 47% and 92% with the largest series published by Pinto et al, reporting a 79% success in 24 patients.

Bulbocavernosus (Martius) Flap

The Martius flap, which involves harvesting of the bulbocavernosus muscle with the overlying fat in the labia majora, is based on the perineal branch of the pudendal artery and is placed in the rectovaginal septum in similar fashion (Fig. 5). As with all interposition flaps, this repair has the potential risk for increased postoperative dyspareunia, but labial function and cosmesis do not appear to be compromised. As described previously, the operation involves a transperineal incision, in which the rectum and vagina are separated and the fistula is divided and both the rectum and vagina are closed primarily. To harvest the donor tissue, a vertical incision is made in the labia majora. The labial fat pad and underlying bulbocavernosus muscle are dissected out from the surrounding tissues. The amount of muscular tissue varies from patient to patient and may not be visible in some. Dissection occurs in a lateral to medial direction, taking care not to injure the blood supply. The flap is transected superiorly and tunneled to the rectovaginal septum. The success rate with this procedure has been reported to vary from 50% to 93.8% with the largest case series by Patel et al. in 2011 using the Martius flap reported a 65% success rate in 23 patients, with 78% of the patients having been diverted.

Transabdominal Approach

Transabdominal repairs and rectal resections are generally reserved for patients with circumferential or stitching disease as in the case with Crohn's disease and for fistulas classified as high and complex (including recurrent fistulas following failed local repair). Additionally, this is the treatment of choice for radiation induced fistulas that have failed local flap repair. These tend to be fistulae that are located in the mid rectum with an internal opening at the fornix of the vagina, which can often be difficult to access from a perineal or endoluminal approach. This generally involves a low anterior resection, where the segment of rectum containing the fistula is resected and a colorectal or coloanal anastomosis is performed. Depending on the height of the fistula, this may be done transabdominally only, or with a transabdominal transanal approach and colonic pull through. The vaginal side of the defect can be closed primarily.

Primary Repair With Omental Interposition

Primary repair with omental interposition is a transabdominal approach is a repair best suited for high RVFs. These fistulas are usually a complication of surgical injuries or diverticulitis. The approach entails dissecting the rectum down to the level of the fistula, which is then divided to expose both the rectal and vaginal openings. If the rectal wall is healthy, the fistula tract can be debrided and closed primarily. The vaginal opening is also closed primarily, and a pedicled omental flap is placed between the two closures and held in position with interrupted sutures. Some described approaches advocate for additional transperineal dissection of the rectovaginal septum with inserting of the omental flap to the subcutaneous tissue of the perineum or even to the levator ani along the lateral pelvic walls for tension free interposition. If the surrounding rectum is indurated or diseased a sleeve advancement can be undertaken.

Rectal Resection/Advancement and Sleeve Advancement

Rectal resection/advancement and sleeve advancement is indicated in circumferential or stitching disease as in the case with Crohn's disease, radiation induced fistulas, and for fistulas classified as high and complex.

The sleeve advancement technique includes resection of the rectum proximal to the fistula, circumferential mucosectomy of the fistulized and distal rectum, pull through of healthy colon into the remaining muscular tube of rectum, and a coloanal anastomosis (Fig. 6). Several studies report a fistula healing rate of 75% to 79%, with 72% of patients reporting normal continence. Nonetheless, more recent studies demonstrate early and late postoperative complications rates to be 41% and 33%, respectively.

Other Surgical Considerations

Fecal Diversion

Preoperative fecal diversion has not been shown consistently to lead to better outcomes, but this again may represent selection bias in those patients chosen for diversion.

There is no consensus on the indication of proximal fecal diversion in RVFs, and fecal diversion has not been shown to decrease the rate of fistula recurrence, although this may well be because the patients that undergo fecal diversion have more complicated disease. When low rates of success are anticipated (e.g., multiple failed attempts at repair, poor tissue compliance), preoperative fecal diversion should be considered. Additionally, most surgeons are more likely to perform fecal diversion with complex repairs such as an omental pedicle flap and those approaches that require a low colorectal or a coloanal anastomosis.

"Choice of Repair"

Considering the diverse causes, the large number of surgical options, and the lack of good quality comparative studies, there is no clear guideline on the choice of procedures to undertake first for RVF repair. The choice of procedure is determined largely by the type of fistula (low or high, simple or complex), the cause, whether a sphincter defect exists, the number of prior failed attempts, and the functional status of the patient. In addition, in deciding on a surgical approach, the surgeon should evaluate the patient for continuing inflammation or ongoing pelvic sepsis. The anatomic location of the fistula will also dictate the approach to repair (local repair vs transabdominal approach). Fistulas located in the mid rectum and upper vagina will not be accessible via a local approach and should therefore be managed with a transabdominal approach. A proposed algorithm for first line treatment and subsequent repairs is explained later and listed in Fig. 7.

Reported success rates vary greatly for each procedure. Experience likely plays a large role in this; however, even in experienced hands a certain failure rate is expected; therefore, all attempts should be made to avoid sphincter division and anal canal scarring in early repairs.

The first decision point in a proposed algorithm is whether a sphincter defect and associated incontinence are present. Overlapping sphincteroplasty will address the fistula and incontinence and is first line treatment in this patient population, typically those with obstetric trauma. An EAUS can be added to increase the fistula healing rate.

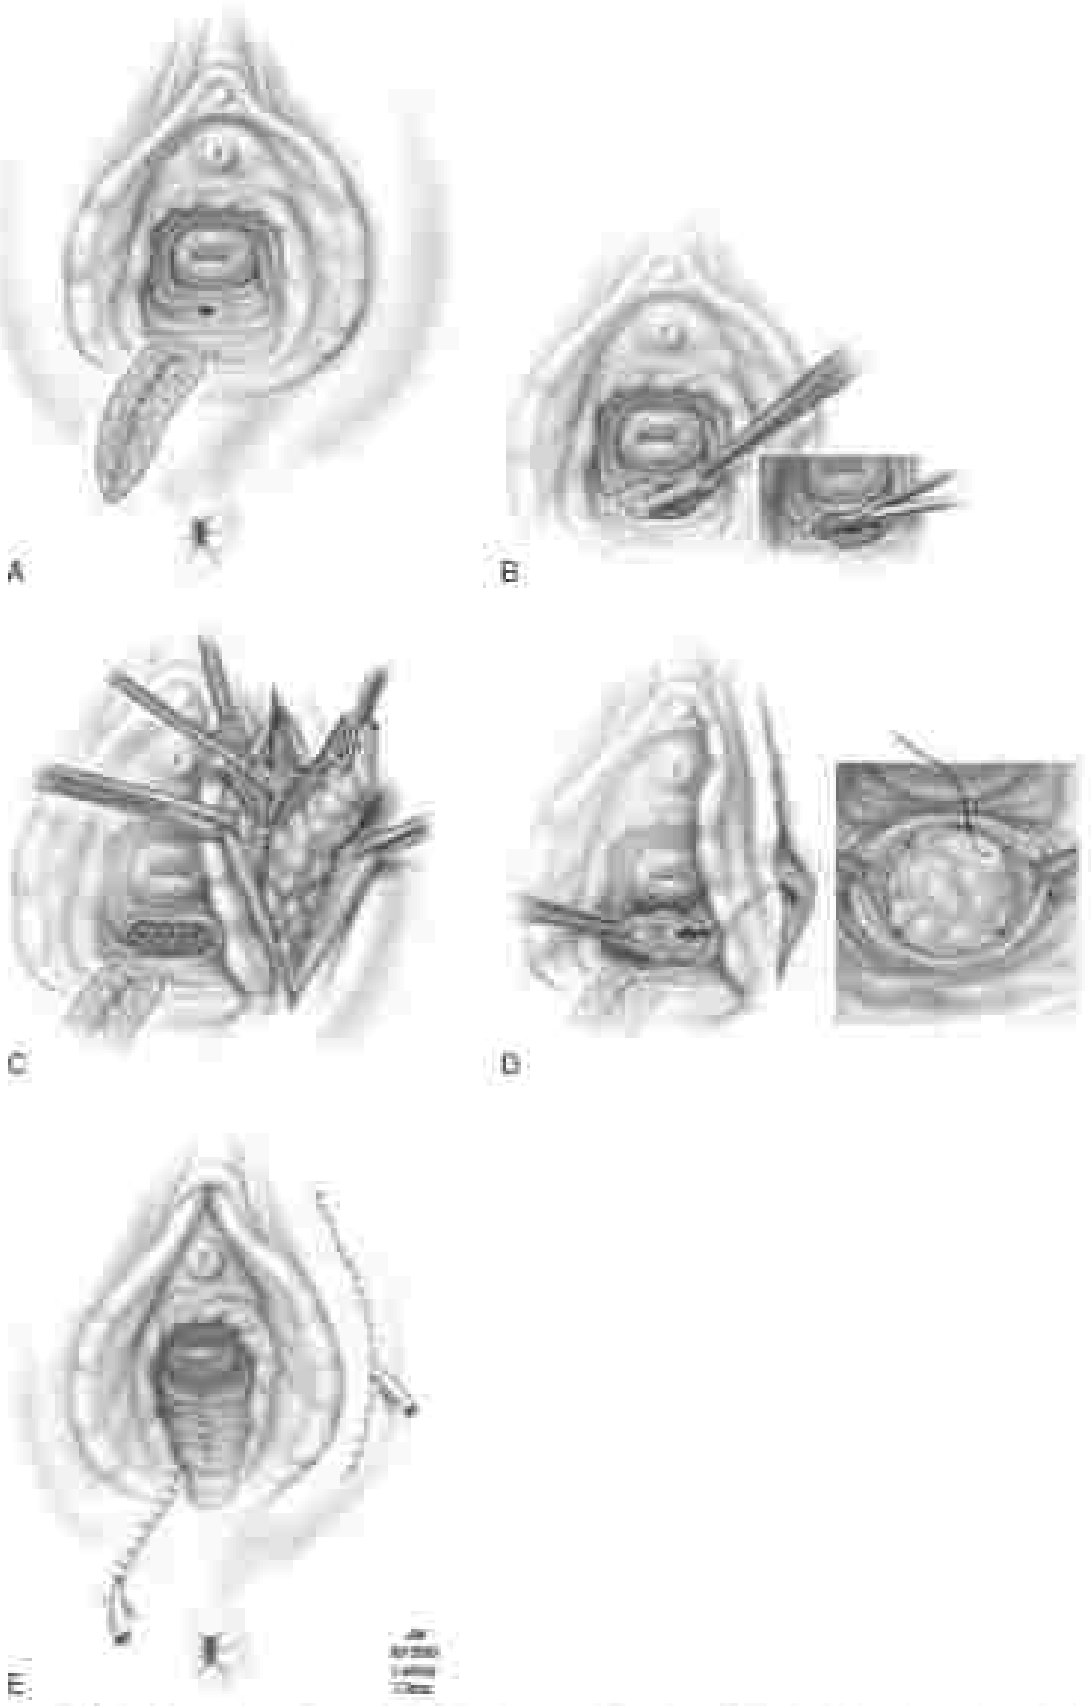

FIG. 5 Bulbocavernosus (Martius) flap. (A) The patient is placed in the lithotomy position, and a mediolateral episiotomy incision is made. (B) The vaginal side of the fistula is mobilized and excised. The rectal side of the fistula is closed. (C) Along the opposite labia majora, an incision is made and the bulbocavernosus muscle and tissue for graft are mobilized. (D) The bulbocavernosus muscle and tissue for graft are brought through a subcutaneous tunnel and secured to the previously closed rectal side of the fistula (here,). (E) The vaginal defect is closed, and the episiotomy incisions are closed. Drainage is accomplished with a Penrose or closed-suction drain. (Copyright 1999 Lahey Clinic, Burlington, MA. From Rosin JD, Kaufman HS: Anatomical and Acquired Issues of the Genitalia. In Wexner SD, Jorge JMN, Lowry AC, editors: Colorectal Surgery, 4th ed. Philadelphia: Elsevier; 2011.)

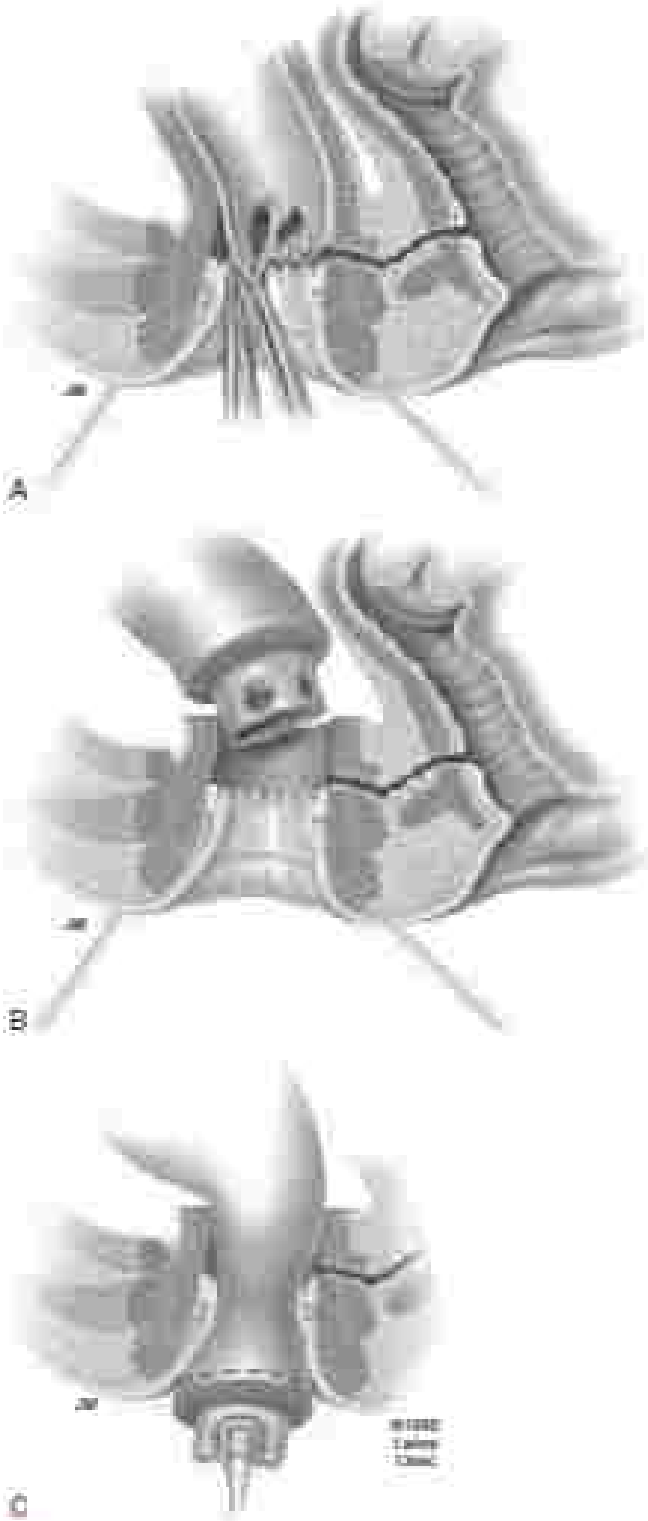

FIG. 6 Advancement flaps. (A) Connecting at the level of the dentate line, a circumferential dissection of mucosa and submucosa is performed, that leaving the stomach areas of the anal canal. (B) The dissection is continued cephalad and into the supralevator space, completing rectal mobilization. (C) The fistula can then be cored out and closed, and the distal cuff (rectal flap or the mucosa is preserved and sutured to the sphincter. (Copyright 1999, Lippincott Williams & Wilkins, from Wexner SD, Marchesa P, Jagelman DG. Anorectal and Colovaginal Fistula. In: Corman ML, ed. Colon and Rectal Surgery. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2000.)

In those patients without sphincter defect, either a rectal or vaginal advancement flap can be undertaken as first line options. Although the results for both procedures are thought to be similar, a rectal advancement flap puts the repair on the high-pressure side of the fistula but requires healthy rectal mucosa, whereas the vaginal flap saves the rectal mucosa from scarring and internal sphincter from disruption but places the repair on the low-pressure side of the fistula.

If either the rectal or vaginal flap fails, the subsequent step can be performing the opposite procedure versus proceeding with a more advanced repair such as a transperineal approach (sphincteroplasty or transperineal LIFT procedure) or a local interposition pedicled flap (either gracilis or Martius), with or without the addition of fecal diversion. If the local tissues are still healthy with minimal scarring, a repeat flap can be attempted. However, with every subsequent failed procedure, increased tissue ischemia is produced, and the chances of failure increase further. At this point, either a proctectomy or sleeve advancement may be necessary for definitive repair because this will resect the diseased rectum and bring healthy proximal rectum to the anal canal.

Because experience with biosynthetics is limited, there is no formal recommendation for their use currently. However, because biosynthetics rely on tissue ingrowth from surrounding tissue, a biosynthetic enhanced repair is not likely to succeed in an ischemic rectovaginal septum.

Radiation-Induced Fistulas

With the widespread use of radiation for locally advanced pelvic malignancies, the number of radiation-induced complications will continue to increase. The first step in management of radiation-induced RVFs is to rule out the presence of malignancy, either primary or recurrent. This requires detailed imaging and an examination with the patient under anesthesia with multiple biopsies of areas of irregularity or random biopsies if no irregularity exists. Once the presence of malignancy has been ruled out, the condition of the rectum, vagina, and surrounding perineal tissues must be evaluated.

It is recommended that no definitive repair be undertaken for at least 6 months after the completion of radiation treatment to allow for the resolution of the acute inflammatory effects of radiation and for the recovery of the surrounding tissue. If the local tissues are viable, a rectal or vaginal advancement flap can be attempted. The repair is less likely to succeed because it is performed in radiated tissue; therefore only one attempt at primary tissue repair should be undertaken. In the setting of primary repair failure, fistula repair may be attempted with muscle flap interposition, rectal sleeve excision with coloanal anastomosis, or proctectomy with coloanal anastomosis with or without fecal diversion.

Crohn's Disease

Most patients with Crohn's proctitis and an RVF will require an EUA and seton before definitive repair. Optimization of medical management is mandatory before surgical repair. Multidisciplinary management is critical; any repair is doomed to fail if all disease is not rendered quiescent. The Crohn's Disease Clinical Trial Evaluating Infliximab in a New Long-term Treatment Regimen in Patients With Fistulizing Crohn's Disease II study showed that patients who initially responded to infliximab (at least 50% reduction in fistula) had a 50% rate of full closure of the fistula. If medical management fails or is not an option, surgical treatment is undertaken, though successful surgical treatment of Crohn's-related RVF varies in the literature, with success rates ranging from 30% to 70%. Patients most likely to have a successful repair are those with an isolated RVF without other perianal disease and in whom their Crohn's disease is quiescent. If the rectum is healthy, either rectal or vaginal advancement flaps can be undertaken first. However, if the rectum is inflamed or scarred, vaginal advancement flap is the preferred first choice. There should be a low threshold for diversion in these cases. Crohn's disease–associated RVFs have an overall poor prognosis, with a recurrence rate

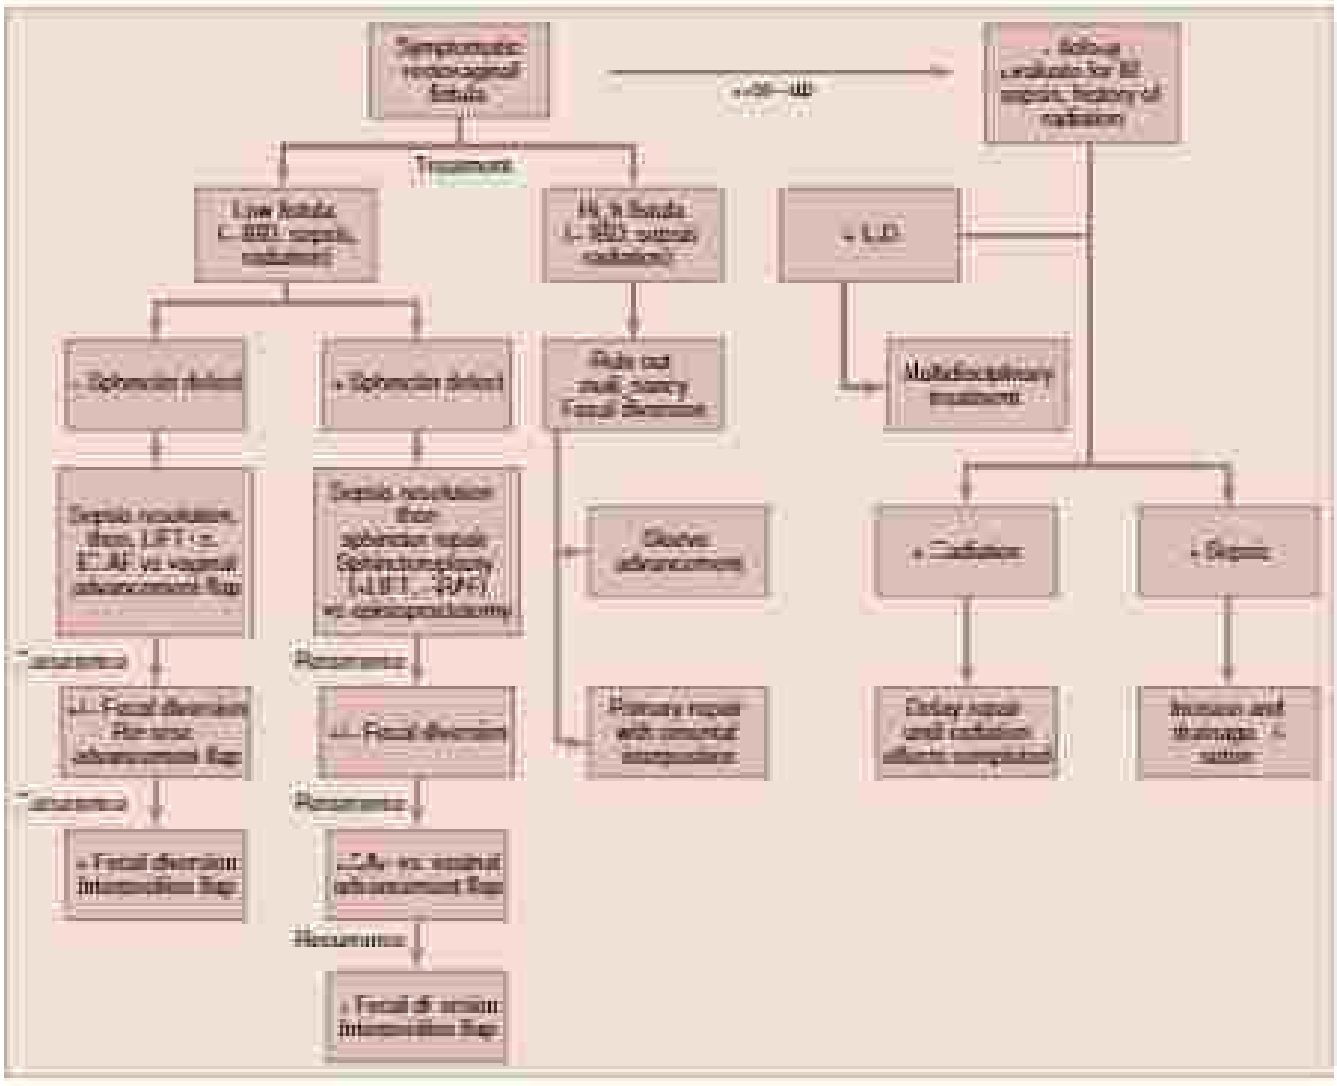

FIG. 7 Proposed algorithm for the management of rectovaginal fistulae. (ASIS, endoanal advancement flap; IBD, inflammatory bowel disease; LIFT, ligation of the intersphincteric fistula tract. *From Stone JF, Roehl KC. Rectovaginal and Complicated Fistulas. In the I.J. Stoker editorial: Surgery of the Alimentary Tract, 6th ed. Philadelphia: Elsevier; 2013.*)

that varies from 25% to 50%. It is therefore very important to appropriately counsel patients and set realistic treatment goals. In patients with poorly controlled proctitis, surgical options are very limited. Often, patients are symptomatic from the abscesses associated with the rectoanal fistulae and require optimization of medical management and prolonged setton drainage. With multiple failed procedures and recurrent fistulae, proctectomy with end colostomy is the definitive treatment of last resort.

Malignancy

The definitive treatment of malignant RVFs is an en bloc surgical resection of the malignancy, contiguous organs involved, and the fistula tract. This often requires a pelvic exenteration. A diverting stoma often is placed to control symptoms and decrease pelvic and perineal sepsis while the patient receives neoadjuvant therapy. The patient is reevaluated after neoadjuvant treatment to determine the extent of treatment response and to suitability to undergo a major operation. In patients with good performance status and a satisfactory response to neoadjuvant therapy, a pelvic exenteration can be considered. However, in most patients who are not suitable candidates for exenteration, the treatment focus is palliative.

CONDYLOMA ACUMINATA

Raymond Yap, MBBS, BMedSci, MSurgSc, FRACS and John R.T. Monson, MD, FRCS, FACS, FASCRS

Condyloma acuminata (Fig. 1), commonly known as genital warts, is an extremely common sexually transmitted disease, with a prevalence of approximately 1%. The causative factor is human papilloma virus (HPV), a double stranded DNA virus with more than 120 genotypes identified. The most important clinical variants of HPV are split into two categories: those with minimal malignant potential (types 6, 11, 42, 43, 44) associated with genital warts, and high risk variants (types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, etc, etc), which are associated with precancerous lesions and squamous cell carcinoma (SCC). Coinfection with multiple strains is common.

HPV typically arises through contact with virus laden secretions through breaks in the anogenital epithelium. The most common method of transmission is sexual intercourse, with a higher risk confirmed in those in the men who have sex with men and HIV populations. Condom use reduces the risk of transmission; however, transmission can still occur in areas of skin beyond the condom. Other forms of transmission such as through virus secretions in bathrooms, swimming pools, and autoinoculation are also possible, although less common. There is usually a long latent period before symptoms arise.

The clinical presentation is of warty outgrowths that do not cause much discomfort. Their appearance can be quite varied, with the cauliflower type most common. Other types include flat, dome shaped, or keratotic. They may present with itchiness or bleeding where the warts have been irritated. More significant is the psychological distress that accompany them. A rarer form of presentation is with giant condylomata also known as Buschke-Lowenstein disease (see the following section and Fig. 5).

Careful examination of the anogenital region with inspection, digital rectal examination, and anoscopy will reveal most lesions. Good lighting is essential. Inspection of the pubic area and oral cavity should also be performed. The differential diagnosis includes melanoma, SCC, SCC in situ, basal cell carcinoma, molluscum contagiosum, and seborrheic keratosis.

MANAGEMENT

Deciding on a management modality is dependent on factors such as the size and distribution of the condylomata as well as a patient's underlying physical state. Although spontaneous resolution of warts has been reported, complete response is uncommon, and most patients will need some form of intervention, whether in the form of topical therapy or operative management. There is little evidence to advocate one treatment over another in terms of success or recurrence rates. Table 1 outlines the various treatment modalities. Indeed, if the virus lies dormant within the basal squamous cells, recurrence is highly likely at some point in the patient's lifetime. Therefore, treatment goals are to treat all visible warts, preserve as much normal tissue, and to keep close surveillance for malignant change.

We have favored an operative approach to the management, with the patient either under conscious sedation or general anesthesia. Although we prefer a lithotomy position, a prone jack-knife position is also acceptable. This allows for meticulous inspection and examination for lesions. The entire genital region should be examined if possible, including the penis and scrotum in men and the labia majora and minor in women. Examination with an anal retractor such as a Pratt or Hills-Ferguson retractor should be performed for any anal canal lesions, which can be easily missed in the office. Representative biopsies are then taken for histopathologic examination to both confirm the diagnosis and detect if there is any premalignant (low or high grade dysplasia) or malignant change.

If there is a single large wart or the warts are confined to a small local area (approximately 1 inch in diameter), excision and closure with an absorbable suture such as 4-0 undyed Vicryl is appropriate in an interrupted fashion. We prefer the use of diathermy to excise the lesions to maintain a bloodless field (Fig. 2). Where the lesions are scattered, or widespread, monopolar diathermy is used to fulgurate the lesions. Once an eschar has been formed, the wart is then curetted, which may cause profuse superficial bleeding easily controlled with diathermy. As long the base of the wart is narrow and there is intervening healthy skin, the risk of anal stenosis is minimal. For perianal lesions, the use of a Lone Star retractor can be useful to enable better access to the lesion (Fig. 3).

Although the risk of transmission to the healthcare provider is minimal with the use of fulguration, we still recommend the use of an N95 respirator or similar grade face mask to further reduce this risk.

There are cases where staged operative management is indicated. If the affected skin is carpeted with lesions and affects more than 50% of the anal circumference, it is highly recommended to perform up to multiple visits to the operating room (OR) to clear the affected warts by excising or fulgurating a portion (no more than one third to one half of the anal circumference) and closing the wound if appropriate at each visit, the risk of anal stenosis is greatly reduced. The OR visits should be spaced out by 4 to 6 weeks.

Close surveillance is then required. Where no dysplasia or malignant change has been detected, after the initial postoperative visit, using the patient at the 3- and 6-month marks is appropriate. The recurrences that happen are usually few in number and easily treated with office based ablative procedures or topical therapy. Choice of therapy depends on both patient and physician choice.

SPECIAL CASES

Dysplastic Condyloma

Unfortunately, there is a rising incidence of anal cancer and dysplasia in the United States. Risk factors include men who have sex with men, HIV, transplantation, or other immunosuppression, cervical or vulvar neoplasia, smoking, and intercourse. The lesions are typically classified as low grade anal intraepithelial lesions (corresponding to anal intraepithelial neoplasia grade 1), high grade anal intraepithelial lesions (anal intraepithelial neoplasia grades 2/3), or as malignant (SCC).

Traditionally, anal cytology and high resolution anoscopy have been used for screening and surveillance of disease. Anal cytology is similar to cervical cytology in which a moist swab is inserted into the anal canal and smeared onto a slide. The pathologist may report one of five results: normal, insufficient, abnormal cells of undetermined significance, low grade, and high grade squamous intraepithelial neoplasia. The other modality is high resolution anoscopy. The area is swabbed with acetic acid and then examined with a high resolution microscope looking for changes associated with dysplasia. Unfortunately, the equipment is expensive and the learning curve is steep.

The utility of either of these methods in the prevention of SCC is unknown. Recent data from overseas suggest that without a visible lesion, progression to malignancy is extremely rare. In light of this, we recommend routine careful visual inspection and digital rectal examination, with OR examination and biopsies of any lesions are found. In the same vein, routine anal mapping with punch biopsies is also unlikely to be of benefit.

The initial management of dysplastic condylomata is similar to nondysplastic condylomata. Again, operative ablation with electrocautery is usually sufficient. A clear microscopic margin is not needed, macroscopic clearance is sufficient. Previously, wide local excision of the area was recommended, but because of high recurrence rates and its uncertain role in the prevention of malignancy, this has been

FIG. 1 Condyloma acuminata types. (A) Cauliflower, (B) flat, (C) dome, and (D) keratotic.

TABLE 1 Treatment Modalities

Treatment	Technique	Side Effects	Clearance Rate (%)	Recurrence Rate (%)
PATIENT APPLIED				
5-Fluorouracil (Efudex), 1% or 5% cream	1% cream twice daily for 4–6 weeks or 5% cream applied daily for 8–10 weeks	Pain, induration, erythema, ulceration	40–75	25–50
Imiquimod (Aldara), 5% cream	Applied overnight and washed off in morning 3 times per week for 12–16 weeks	Pain, induration, erythema, ulceration	50–80	10–20
Podofilox (Condylox), 0.5% gel	Twice daily for 3 consecutive days each week for 2–4 weeks	Pain, induration, erythema, ulceration	30–70	10–30
Sinecatechins (Veregen), 15% ointment	Applied 3 times per day for 12–16 weeks	Pain, induration, erythema, ulceration		
OFFICE MANAGEMENT				
Trichloroacetic acid (Tca Chloe), 80%–90% solution*	Apply directly to lesions, avoid surrounding skin; repeat monthly as required	Pain, irritation	70	20–40
Liquid nitrogen*	Apply with applicator until area white; repeat monthly as required	Pain, edema, eschesis, ulceration	70	2–40
Podophyllin (Podocon), 25% extract	Applied once per week, needs to be washed off 4 hours later, up to 6 treatments; do not exceed 0.5 mL per treatment	Pain, induration, erythema, ulceration. Can cause cancrin and CNS depression if systemically absorbed	50–70	30–50
OPERATIVE MANAGEMENT				
Electrocautery*	Fulgurate lesions, avoid normal skin	Pain, scarring	70–90	30
Laser*	Vaporize lesions, avoid normal skin	Pain, scarring	70–90	30
Surgical excision*	Excise lesions while preserving normal skin	Pain, bleeding, scarring, infection	70–90	40

*Safe to use in pregnancy.
CNS, central nervous system.

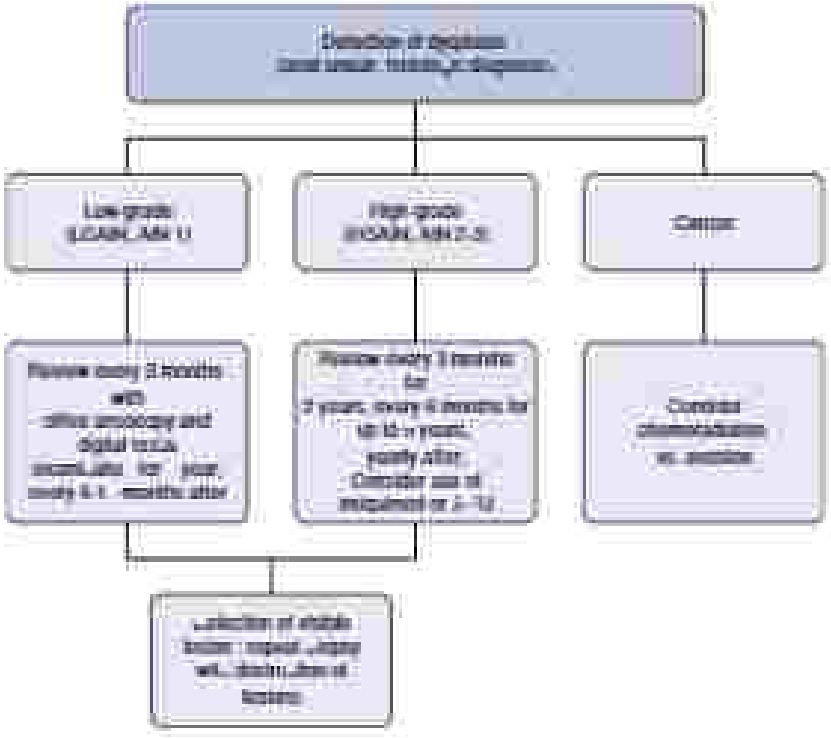

FIG. 3 Treatment algorithm for dysplastic lesions.

largely abandoned. Postoperatively, although the evidence base is only moderate, the use of fluorouracil 5% cream and imiquimod has been shown to reduce recurrence rates. Imiquimod is the most tested and has shown to be effective if used regularly, although cessation often results in recurrence. There is mixed evidence for either of these as a first-line treatment to better either downgrading of lesions or preventing malignancy and therefore the authors use it in the postoperative setting.

We would recommend close office surveillance of any patient with dysplasia. A suggested algorithm is outlined in Fig. 4.

Giant Condylomas

First described by Buschke and Lowenstein almost a century ago, this rare variant has local malignant potential with invasion into deeper structures. It is a slow growing, ulcerative, and large lesion that has up to a 50% risk of SCC. Wide local excision is the mainstay of treatment. The use of imiquimod is usually as an adjunctive therapy after excision is complete. Lesions may require the use of abdominoperineal resection. There are a few reports of the use of chemoradiation similar to those for SCC, although recurrence rates are high. An example is shown in Fig. 5.

FIG. 4 Electrocautery in excision of an irritated lesion.

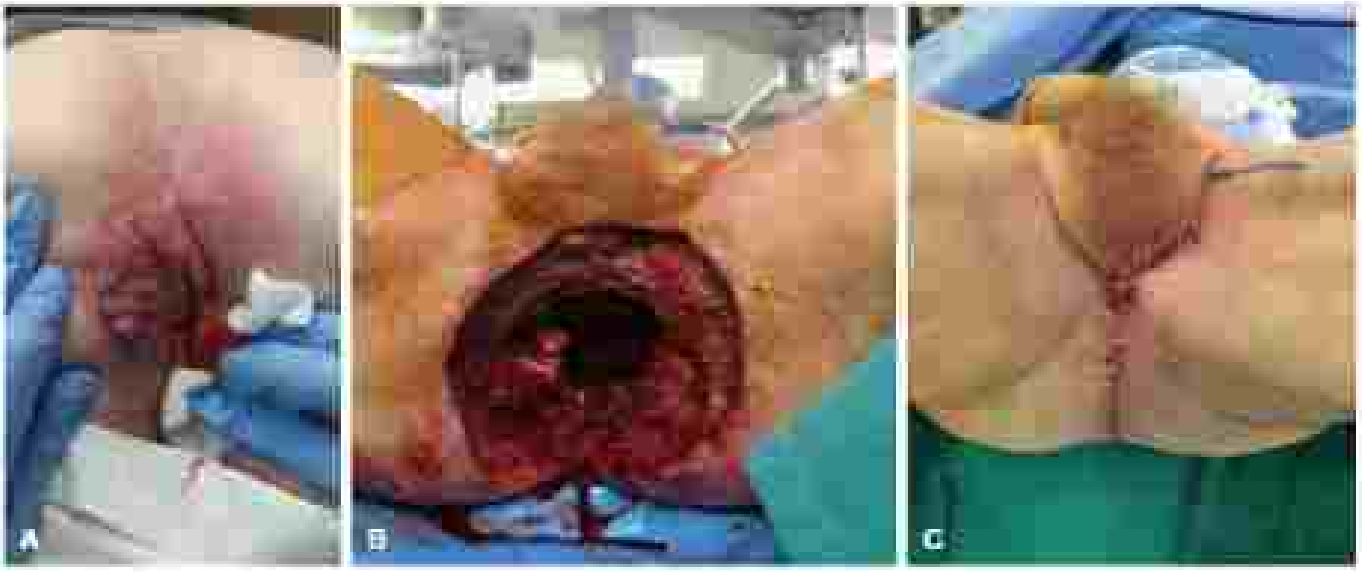

FIG. 5 (A) Giant condyloma with squamous cell carcinoma. (B) Defect left after abdominoperineal resection. (C) Use of bilateral gracilis flaps was required to provide a satisfactory result.

HPV Vaccine

Vaccination has very limited side effects and should be considered as a component of the management of HPV. Three vaccines are available in the United States: a quadrivalent vaccine (HPV4 Gardasil) targeting strains 6, 11,16, 18; a 9 valent vaccine (HPV9 Gardasil 9) targeting HPV 6, 11, 16, 18, 31, 33, 45,52, 58, and a bivalent vaccine (HPV2 Cervarix) targeting HPV 16 or 18. There are current recommendations to inoculate all young women and men. In women, the routine age is 11 to 12 years, or up to 26 years if not started previously. For males, routine administration should be at ages 11 to 12, or until age 21 if not started previously. In addition, if there are risk factors such as HIV, routine administration should be considered until age 26. There is some emerging evidence that the rates of dysplasia are reduced with the use of the vaccine, even in strains that are not actively protected against. Whether HPV vaccination arrests or downgrades the development of dysplasia is uncertain and therefore the efficacy of the vaccine in a therapeutic setting is unknown. A consultation with an infectious disease physician is recommended for these matters.

SUMMARY

Condyloma acuminata is a sexually transmitted disease, typically caused by HPV. Careful anoscopic inspection, digital rectal examination, and anoscopy are usually sufficient for diagnosis. Management aims are to eliminate all visible disease, exclude dysplasia and preserve normal skin, usually in the OR setting initially. Practitioners should be aware of the risk of dysplasia and the need for close surveillance if detected.

Management of Pilonidal Disease

Naomi M. Sell, MD, MHS, and Todd D. Francone, MD, FACS, FASCRS

Pilonidal disease is a common, acquired inflammatory condition of the skin and subcutaneous tissue of the sacrococcygeal region. This disease most commonly affects young adults in their late teens and 20s, rarely presenting past the age of 40. Men are afflicted at three to four times the frequency than women. It has an incidence of 25 per 100,000, and most recent numbers describe 70,000 Americans seeking treatment annually. Its predilection for young adults harbors a unique socioeconomic burden because patients often require significant time away from work or school. Attention to the prevalence and social impact of this disease was brought to the public during World War II when 70,000 young American soldiers were admitted to US military hospitals for care typically requiring greater than 2 months of medical leave.

The disease can present acutely, often in the form of active infection or abscess, or individuals can live with smoldering, intermittent symptoms for many years. These various presentations have led to controversy among surgeons on the best treatment method, whether operative or nonoperative. Despite every surgeon's hope to eventually name one operation superior to others, it cannot be understated that each treatment decision for this disease should be patient specific because there are varying benefits to many of the options that will be described in this chapter.

ETIOLOGY

Acquired Condition

Pilonidal disease was first described by Herbert Mayo in 1833. His initial theory was that this disease was congenital in origin. However, after decades of controversy, research has now firmly established that pilonidal disease is not a congenital, but rather an acquired condition. There is no epithelial lining within the abscess cavity found in pilonidal disease, therefore, the cavity is not a cyst and the term "pilonidal cyst" is a misnomer. An abscess may or may not be present at certain points of the disease. When present, the abscess is simply a subcutaneous collection of debris and pus.

Name

The name pilonidal originates from two Latin terms: pilus, meaning hair, and nidus, meaning nest. Hair is a key component in the development of pilonidal disease. The other requirement being a deep natal cleft. Hair is often found within pilonidal abscesses. These hairs are not ingrown; rather, they are hairs that have been shed, either from the scalp or back, and have become lodged within this deep natal cleft.

Causes

Pilonidal disease is caused by the unfortunate alignment of all components of the disease being present at the same time. The three main components that lead to the development of this disease are: a deep gluteal cleft, loose hairs, and friction. The deep cleft facilitates entrapment of shed hairs, often from hirsute individuals, within that space. These loose hairs penetrate the skin and cause a foreign body reaction at that site. This reaction facilitates the dilation of midline pores and follicles through which additional debris accumulates, such as hair and shed skin. Friction, often in the form of sitting, aids this reaction by mechanically rubbing the hair into these openings. The entrapment of hair and debris leads to the development of midline pits and an eventual abscess. The moist environment of the deep cleft makes healing difficult and is welcoming of anaerobic bacteria.

A sinus tract develops when the body attempts to clear the infection. In an effort to remove the abscess contents, the body tries to expel the contents through a second external opening, often located at the cephalad aspect of the cleft. These sinuses are not the cause, but rather the byproduct of the disease.

Risk Factors

Although a few risk factors have been determined through small non-randomized studies, none constitute a direct cause and effect relationship. The risk factors associated with pilonidal disease include obesity, a sedentary lifestyle, and a hirsute body. Through appropriate questioning and by identifying these traits, lifestyle modifications may be used to deter the development of this disease.

MAKING THE DIAGNOSIS

The initial diagnosis of pilonidal disease is a clinical one based on a patient's history and physical examination findings in the gluteal cleft. Often, the disease either presents as an acute abscess or a chronic draining sinus. Pilonidal disease can be present for months to years before the development of symptoms.

Physical Examination

Characteristic physical examination findings reveal the sinus and fine pits found in the natal cleft (Fig. 1). The recognition of these pits, with or without a draining sinus, establishes the diagnosis of pilonidal disease. It is often difficult to see the midline opening; placing upward traction on the natal cleft can improve visualization. Shed hairs can often be seen protruding from these midline pits. In the setting of acute disease, examination may be painful and may be associated with cellulitis or an abscess. If an abscess is present, the swelling can make it difficult to visualize the midline pit. The pit can only sometimes be seen once the abscess has been drained and the edema resolves.

The presence of a draining sinus is indicative of chronic disease. Sinus tracts develop as the body's attempt to resolve and externalize the infection itself. Typically, the sinus opening lies outside the natal cleft, laterally either to the left or right; however, there are instances in which the opening is contained within the natal cleft (Fig. 2).

Differential Diagnosis

In making the diagnosis, it is important to distinguish pilonidal disease from alternative disease processes such as perianal abscess, perianal fistula, Crohn's disease, hidradenitis suppurativa, or unusual skin infections including tuberculosis, syphilis, or actinomycosis. Draining openings at the inferior aspect of the gluteal cleft can be either the result of a draining pilonidal sinus or a perianal fistula. Should an abscess be present and low lying near the anus, it can be difficult to distinguish acute pilonidal disease from a perianal abscess. It is important to perform a thorough anorectal exam to evaluate for concomitant fistulous disease or other anorectal pathology.

Imaging Studies

Imaging is often not beneficial, nor required, to confirm the diagnosis of pilonidal disease. There are cases of low lying sinus tracts that need to exclude the possibility of an anal fistula, in which magnetic resonance imaging may be useful. Probing easy to interrogate these openings are of little benefit. Magnetic resonance imaging is also helpful

FIG. 1 Multiple pits are present in the midline near cleft with evidence of hair shafts. (Courtesy Eric Johnson, MD, FACS, Cleveland Clinic, Cleveland, OH.)

in rare circumstances of suspected actinomycetes of the sacrum in the setting of deep chronic infections.

ACUTE PILONIDAL DISEASE

Acute pilonidal disease typically presents as an abscess with or without cellulitis. Standard care is the same as for any other type of abscess, with treatment by adequate incision and drainage (Fig. 3). To allow for improved healing, the incision should be made off the midline over the area of fluctuance and should be either in an ellipse or crucial form. It is often difficult to visualize the midline pits in the setting of edema associated with the abscess. This procedure can be done in an office examination room under local anesthesia rather than an operating room. Packing of the wound is dependent on the depth of the abscess and risk of reepithelialization before complete wound healing. If it is difficult to reach area, to should packing be required, make sure to develop a plan for wound care with the patient's family member or visiting nurse service before being sent home.

If adequate drainage is achieved, then antibiotics are not necessary. Should the patient be diabetic, immunocompromised, or have other concerns for infection, then the use of antibiotics to cover gram positive skin flora and anaerobic bacteria is appropriate.

Wound care and close follow up are key points in the care of acute pilonidal disease. Sitz baths should be used by the patient at home several times a day for the week after drainage. Daily showers with soap and adequate drying are also beneficial. These steps help keep the wound clean and prevent recurrence. The patient should follow up within 2 weeks from incision and drainage to assess healing. Recurrence rates of this method are 15% to 40% because of the failure of simple incision and drainage to remove the debris from within the abscess cavity.

CHRONIC PILONIDAL DISEASE

Longstanding pilonidal disease can lead to the development of a sinus tract that drains contents from the midline pit to the outside world. These sinuses typically develop after a patient has suffered multiple prior acute abscesses, but, on occasion, draining sinuses have been the initial presentation in patients with mild disease. This tract most commonly opens cephalad to the natal cleft usually off to one side rather than directly in the midline.

Sinus tracts are often associated with chronic drainage and local irritation for which patients desire treatment. What differs from acute disease is that, in addition to the midline pit and abscess, the sinus tract must be addressed as well. Directing treatment only at the secondary opening will be inadequate and fails to address the underlying midline pits that are the true cause of this disease. Depending on symptom severity, there are both nonoperative and operative interventions available to treat this condition.

NONOPERATIVE MANAGEMENT

Asymptomatic patients and those with very minor symptoms should attempt to be managed nonoperatively. Conservative measures that include observation or simple hygiene optimization should be first line in those without significant pain or evidence of infection. The use of different hair removal techniques are a popular nonoperative land despite minimal clinical evidence. The goal of these interventions is to remove the hair seen as the stalks for the development of this disease process.

Hair Removal

Although not the distinct cause of disease, hair has a key role in the pathogenesis of pilonidals, which has led to the increased role of hair removal. It is used both as a sole nonoperative strategy and as adjunct to operative treatment. The most common technique of hair removal is by local hair shaving. Studies of this modality are limited. Although there is little proven benefit, hair shaving has been shown to be safe with minimal additional morbidity. Hair removal may actually be of most benefit before the development of pilonidal disease because the midline pits have not yet formed, however, there is no way of predicting who will or will not develop disease. There is no consensus on the frequency of hair shaving though the American Society of Colon & Rectal Surgeons recommends at least weekly.

Another method of hair removal is laser ablation. When used as an adjunct to surgical treatment of pilonidal disease, studies have shown decreased disease recurrence (<13%) compared with those

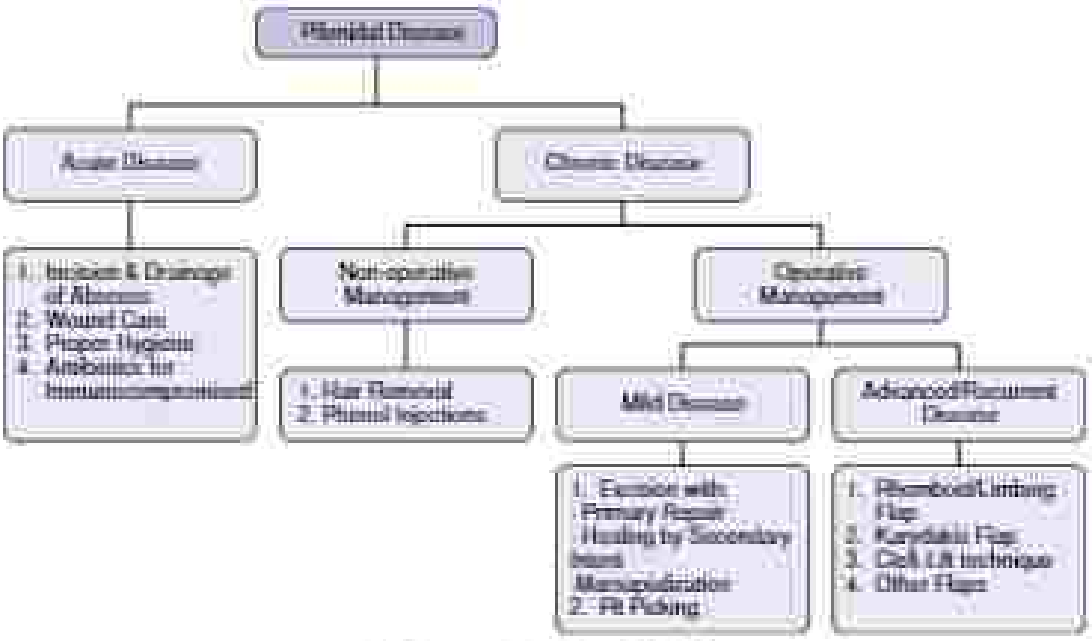

FIG. 3 Treatment algorithm for pilonidal disease.

without laser hair removal. Limitations to this method are that it often requires multiple treatments and may require local anesthetic. There are insufficient data to make recommendations for or against its utilization.

Phenol Injections

The use of phenol injections into the pilonidal tract can also be used rather than an operation. Phenol is a caustic substance that destroys the local tissue of the sinus tract. This procedure is performed by injecting 1 to 3 mL of 80% phenol into the pilonidal sinus. The solution is left there for 1 minute before being expressed out. The tract is then curetted to remove the broken down tissue, including the hair and debris that had been present. This can be repeated up to three times in a single setting, for up to 3 minutes of phenol exposure. A range of one to four separate procedures have been described as being necessary to achieve success. The procedure can be repeated as frequently as every 4 to 6 weeks.

The principle side effect reported is pain from the chemical. Local anesthetic must be used when performed in the outpatient setting. Other complications include burning of the surrounding skin and local wound infection. Compared with surgical tract excision, this procedure results in more rapid healing and return to normal activities. Disease recurrence rates are approximately 20% and more conclusive studies are needed before this becomes a standard treatment.

OPERATIVE MANAGEMENT

The indications for operative intervention include recurrent acute abscesses, symptomatic chronic pilonidal sinuses, and patient's preference. Many patients prefer surgical intervention even in the early stages of disease, given the uncertainty of disease recurrence and desire to prevent multiple life interruptions by recurrent episodes.

Early Disease

Early pilonidal disease can be treated with simple surgical excision rather than an extensive flap procedure. Some of these small procedures can be performed in the office under local anesthesia, whereas others require use of an operating room; however, all of these patients can return home the same day.

FIG. 4 A probe can be used to define the sinus tract to allow for unroofing. (Courtesy Eric Johnson, MD, FACS, Cleveland Clinic, Cleveland, OH.)

Excision With Primary Repair

Chronic pilonidal disease necessitates excision of the pit and associated sinus. Some advocate that for those undergoing their first surgical procedure for pilonidal disease, simple excision rather than a flap procedure should be used. Excision with primary repair is just as the name suggests. A simple midline excision of the dermis and associated subcutaneous tissue, typically to an ellipsoid fashion, that includes the midline pit and sinus, is removed. To remove the entire extent of the sinus tract, use of a lacrimal probe is beneficial. The probe is inserted through the lowest pit and is passed through the sinus until it exits at its most cephalad opening (Fig. 4). Either a knife or electrocautery can then be used to make a narrow elliptical incision over the probe, connecting the two openings. To prevent

FIG. 3 Sinus tract has been unroofed with subsequent marsupialization. (Courtesy Erik Johnson, MD, ACS Cleveland Clinic, Akron General, Akron, OH.)

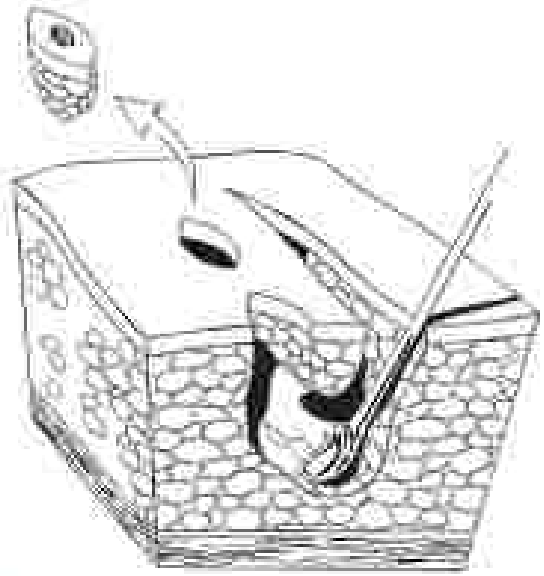

FIG. 4 Pit picking technique involves making an incision based on the pilonidal sinus cavity. This sinus cavity is usually connected with the pit being excised either en bloc or separately. (Modified from Hellinger J, Herold DeMeo S, Cornish J (Hellinger), editors. Principles and Practice of Surgery for the Colon, Rectum, and Anus. St Louis, 1992, Quality Medical.)

recurrence, a curette is used to remove associated debris and lining of the tract. The skin is then brought together primarily to close the defect in the midline. Small unroofings can be performed easily in the office under local anesthesia but, if there is any concern that the sinus tract may be too long to be well tolerated, then regional or general anesthesia in the operating room may be required. The benefit of closing the wound is that there is less need for continued wound care and therefore less pain. Small studies have also demonstrated faster healing rates compared with letting a wound close by secondary intention. Unfortunately, primary closure in the midline has a significantly higher recurrence rate than those who are packed and heal by secondary intention. A 2010 Cochrane review found that healing by secondary intention decreased disease recurrence rates by 50% when compared with primary repair. Both have similar surgical wound infection rates.

Excision With Healing by Secondary Intention

When chronic pilonidal disease has concomitant cellulitis, it is best to excise the wound, lay the tract open, and let it heal by secondary intention. This is a slower healing process compared with primary repair and can lead to much frustration with patients. This open wound requires daily wound care, which is cumbersome. The average healing time for these wounds is 2 months but can take up to 4 to 6 months. Given the burden on patient quality of life, the use of this style of intervention should be used selectively.

Excision With Marsupialization

The third variation of this simple technique is excision followed by marsupialization. After excision of the diseased tissue, the cavity is debrided to remove all residual hair and debris. The skin margins are then sutured to the primeval fascia at the edge of the wound bed (Fig. 5). This is meant to decrease the surface area that is left open to heal by secondary intention, which decreases healing time. It also prevents abscess formation and minimizes the chronic recurrence risk seen with primary closure.

Pit Picking

An alternative office based procedure is "pit picking." Pit picking is an option for patients with an acute abscess, several midline pits, or even those with a short sinus tract. This technique uses two incisions to address all components of the disease (Fig. 6). First, a small elliptical incision is made around the midline pit. This can be done with a fine 11-mm blade or even through use of a 2-mm punch biopsy. Care is taken not to go too wide around the pit. The small ellipse is then closed with a simple 3-0 monofilament suture. Next, a deeper lateral incision is made that is 1 to 2 cm off the midline location of the pit being addressed. This lateral incision allows access to the underlying abscess cavity and/or sinus tract. The incision is taken down to the abscess and then a curette is used to debride the underlying cavity and remove all debris and abscess/sinus contents. This incision is left open to drain. Packing is typically not required. Patients should follow up in 1 week for a wound check and removal of the suture. The wound typically heals in 3 to 4 weeks.

Advanced Disease

For patients with recurrent or refractory disease, more advanced surgical intervention is the most treatment option. The goal of surgery is to thoroughly remove all components of the disease to prevent recurrence, but to do so in the least disfiguring way. Historically, surgeons used to perform wide excisions of the natal cleft encompassing the midline pits and sinus tracts and excising as deep as the sacrococcygeal fascia. Although thorough, this would leave large open wounds that took months to properly heal. The extensive daily wound care required after this type of excision has significant limitations on patient quality of life, particularly given the young median age of this disease. Fortunately, there have been many advances in the use of rotational flap techniques that are able to excise disease, reduce the depth of the cleft, and provide less disfiguring, quicker wound healing. As a result, these techniques have become the recommended treatment option for complex pilonidal disease but require practiced hands to perform them successfully.

Rhomboid/Limberg Flap

The rhomboid, or Limberg, flap is the first rotational skin flap used to treat chronic pilonidal disease. Alexander Limberg first introduced this flap in 1946 to close midline wounds. This incision is in a diamond shape with 60 degree angles and traditionally lies over

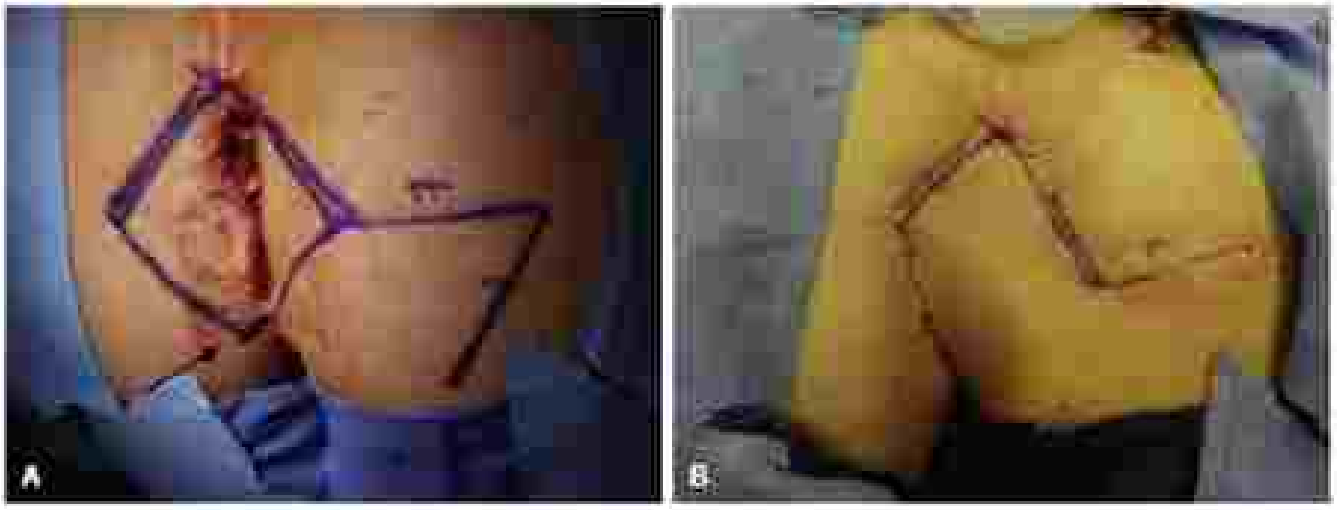

FIG. 7 (A) A rhomboid or diamond pattern delineates the area of excision in preparation for performing a Limberg flap. (B) Completion of the Limberg flap allows for flattening of the previously deep natal cleft. *Courtesy of Dr. Steven Bell, FACS, Jackson Clinic, Cincinnati, OH.*

the midline natal cleft (Fig. 7A). The excision is taken down to the presacral fascia to include all associated pits, abscesses, and sinus tracts. To cover this defect, a full thickness flap in a rhomboid shape is created to retain and cover the excisional defect (Fig. 7B). This pattern allows for flattening of the natal cleft. One recommendation is to use the modified, or oblique, variations in which the orientation of the diamond is rotated off midline in a diagonal manner. With this amount of tissue mobilization, the primary complication is wound dehiscence. The majority of these complications heal without recurrence; however, they do require prolonged wound care.

Karydakis Flap

The next flap procedure introduced for pilonidal disease was by George Karydakis in 1973. His technique uses a lateral, off midline, incision that serves as an advancement flap. The center (or apex) of the ellipse should be approximately 2 cm off midline to allow for completeness of excision and adequate closure. The excised piece of skin contains the midline pits and associated chronic abscesses and/or sinus tracts. The skin and subcutaneous fat from across the cleft is mobilized as an advancement flap to close the wound. This flap is fixed to the underlying sacrococcygeal fascia as well as the opposing skin. These fascia sutures help close the space and prevent recurrence in the midline. To minimize the dead space, a closed suction drain is left under the flap and exits at the superior lateral portion of the wound. The success of this operation has been shown with recurrence rates of less than 1%. This technique does result in 7% to 8% risk of wound complications, most commonly being surgical site infection or seroma formations that require drainage. Predictors of wound complications include obesity and smoking. Unfortunately, this procedure does result in postoperative pain that can necessitate hospital admission. Multiple studies have demonstrated the Karydakis flap to be superior to open excision and healing by secondary intent.

Cleft Lift Technique

Developed by Dr. John Bascom in 2002, the cleft lift technique was the next advancement of rotational flap technique. While utilizing the lateral incision of the Karydakis procedure, this reduces the depth of the midline natal cleft. Compared with the deep excision of the prior flaps shown to fascia, the only tissue excised here is an ellipse of the skin. This minimizes the removal of healthy tissue which allows a "fill" of the once deep natal cleft. This has become the surgical procedure of choice for advanced pilonidal disease and therefore will be explained in further detail.

Before bringing the patient to the operating room, the patient should be marked to allow for proper flap approximation. The patient should stand to allow assessment and marking of the true gluteal cleft. The cleft is defined by where the skin from each buttock makes contact. Next, the patient should be asked to sit upright and a horizontal line should be marked where the patient's buttock meets the chair (Fig. 8A, B).

This procedure is best performed in the operating room under general anesthesia in the prone position. The buttocks should be spread apart with each cheek taped with gentle lateral tension (Fig. 8C, D). Because these patients are most often hirsute, the surrounding hair of the lower back, buttock, and natal cleft should be trimmed with hair clippers. An additional field block of local anesthesia with epinephrine helps postoperative pain control and limits bleeding in the surgical field.

Before making an incision, the surgical excision site should be marked. An asymmetric ellipse should be marked on one side of the natal cleft that includes all midline pits and the sinus opening. The proximal end of the ellipse should be 2 cm superior to the natal cleft, whereas the distal aspect will end in a curve toward the posterolateral anus. The medial edge of the ellipse should be just barely across midline to make sure to involve all midline pits but leave as much skin as possible for reconstruction. The lateral edge should closely approximate the skin marking that was drawn preoperatively (Fig. 8E). If a patient has undergone prior pilonidal surgery, excision is improved if the more scarred side is removed, as long as this does not compromise wound closure.

The incision should start at the superior apex and not extend deeper than the dermis. It should be carried along the midline to the lowest pit. Once the last midline pit is reached, the incision should extend caudally in a crescent shape that points toward the posterolateral aspect of the anus.

Next, a skin flap is elevated on the opposite side of the natal cleft. This should be taken as far lateral as the preoperative skin contact marking. The superior aspect of the flap should be kept thin, approximately 3 to 5 mm, but gradually thicken as it approaches the distal aspect. At the distal end, just superior to the anus, the sacrococcygeal fascia overlying the coccyx should be exposed and the anococcygeal ligament divided. Special care must be taken to avoid injury of the rectum. The division of this ligament allows the flap to rotate and provide adequate coverage.

Once the flap is fully mobilized, attention should shift to the piece of skin chosen to be excised. Begin at the medial aspect within the natal cleft and dissect the skin off the underlying subcutaneous tissue extending toward the lateral marking. Do not yet make the lateral incision and remove the skin. In contrast to the Karydakis procedure, the excised tissue should be only as thick as the dermis, leaving the subcutaneous fat in place to avoid the creation of dead space. Before

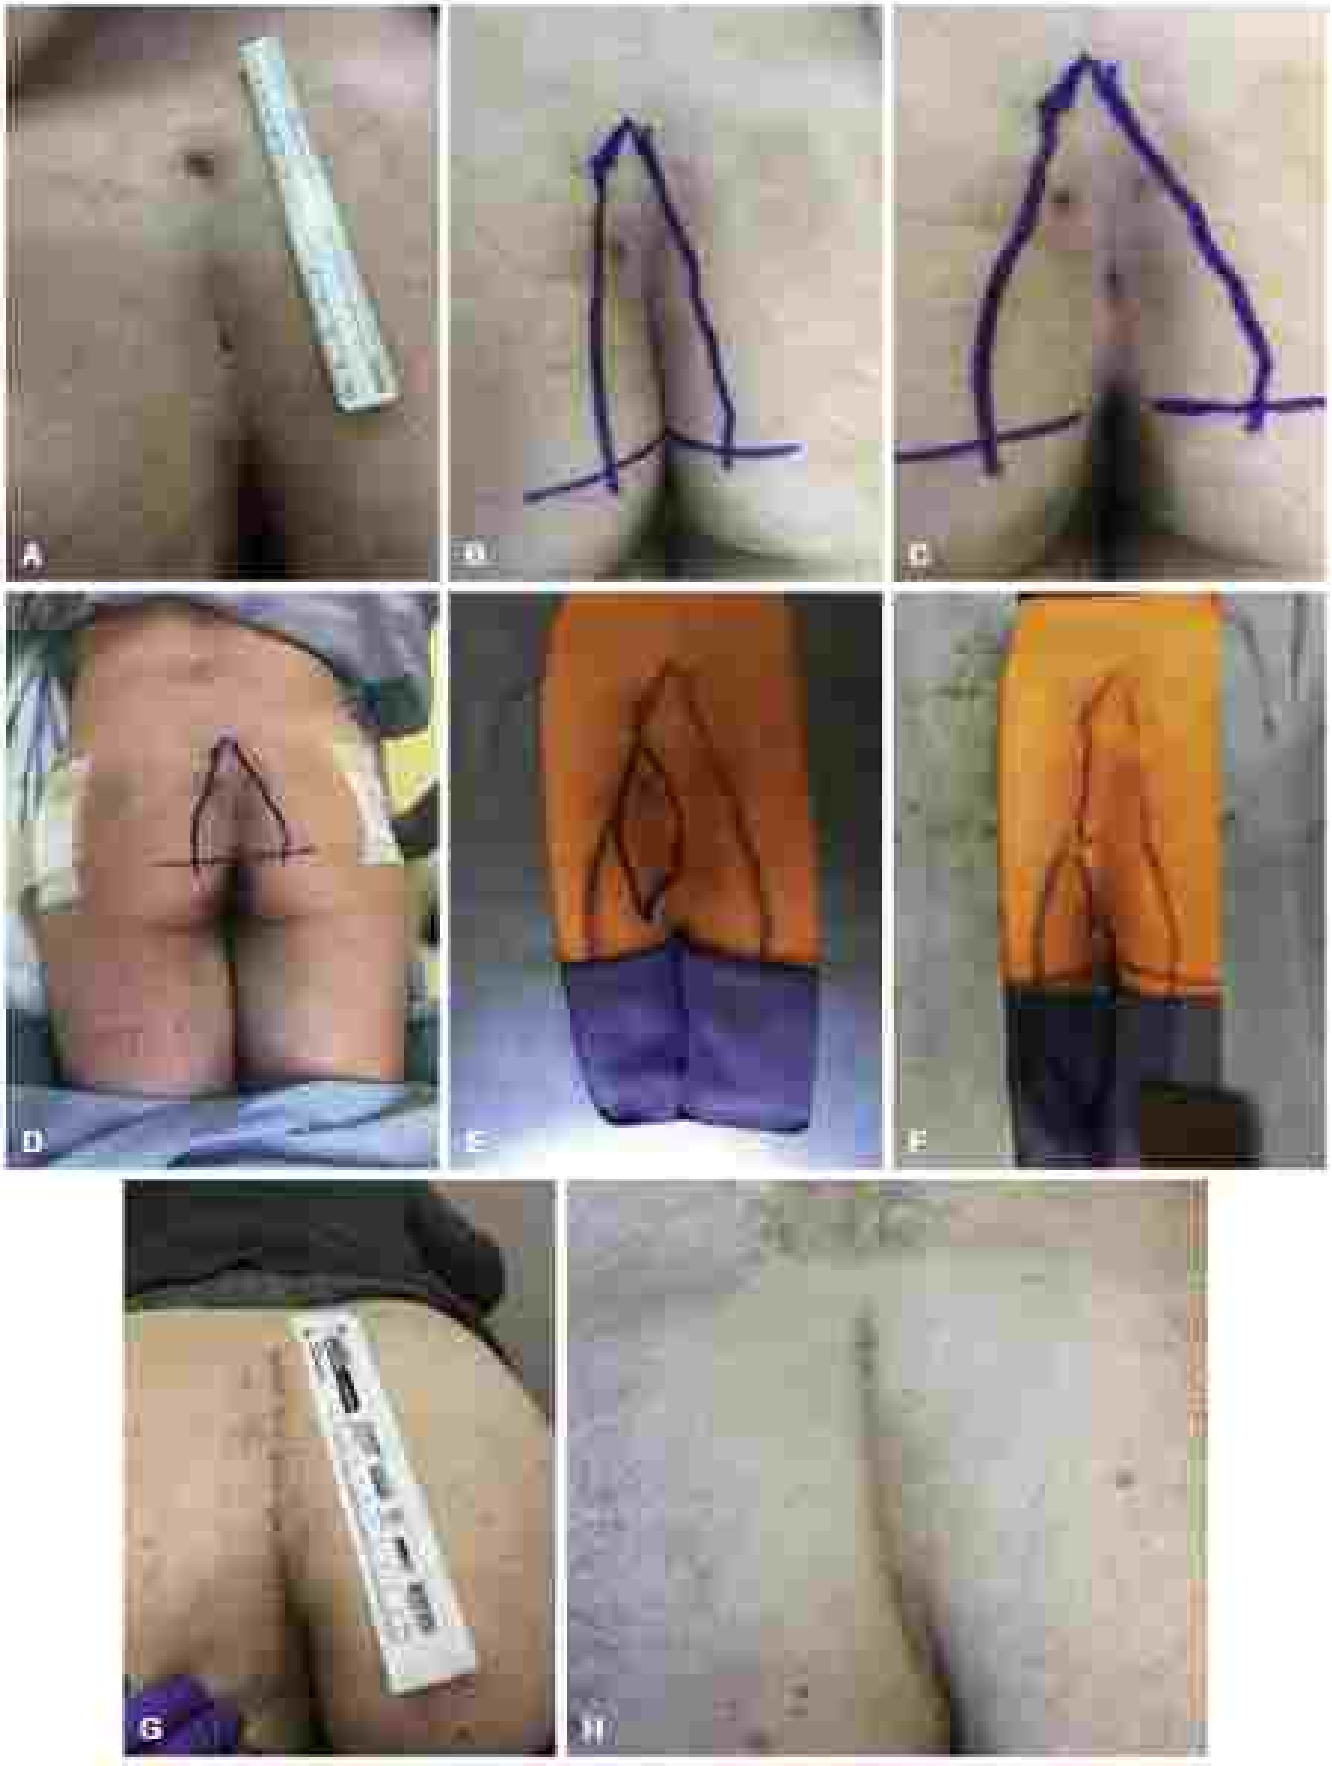

FIG. 8 Cleft-slit technique. (A) Preoperative photo demonstrates multiple midline pits in the natal cleft and a draining sinus located superior. (B) Operative planning markings demonstrate where the testicles meet the chair (horizontal line) and where the buttocks closely touch (vertical line). (C) The same markings are demonstrated with the buttock muscle spread to reveal the midline pits and sinus. (D) Patient positioning on the operative table. (E) Asymmetric ellipse is outlined on one side of the natal cleft that includes all midline pits and the sinus opening. (F) Postoperative appearance of the natal cleft following excision. (G) Four weeks after surgery. The natal cleft is much more shallow in comparison to before the operation. (H) Nine months after surgery. The incision is now well healed without recurrence. completing the excision, remove the tape from the buttocks. Have an assistant push the two buttock cheeks together and ensure that the advancement flap will cover the span of the wound. Once wound closure is ensured, the lateral aspect of the excised portion of skin can then be completely detached.

After removal of the skin, the underlying abscess cavity and sinus track can be viewed. These should each be unroofed and a curette used to clean out all debris without removing the abscess cavity itself. The cavity is left in place to prevent dead space and the collection of infected fluid within that space, which would compromise the flap. Instead, the cavity wall is divided into pieces through utilization of cross hatch incisions but remains attached to the underlying tissue. Thorough irrigation of the wound is critical at this step of the procedure.

Now the wound is ready for closure. Absorbable monofilament suture is used to sew the fibrofatty tissue of the buttock cheeks together. Multiple layers of closure are required to prevent dead space and decrease tension on the flap. A small vessel loop should be left under the flap to allow drainage of fluid. The vessel loop should be passed through a small stab incision at the superior lateral aspect of the flap and brought under the flap until it exits through the inferior incision near the anus. The superficial dermal layers should be closed with interrupted 3-0 absorbable suture and the final skin closure can be performed with running either a 3-0 or 4-0 monofilament suture (Fig. 8F). The two ends of the vessel loop should be tied to itself, similar to one in anal fistula procedures. Steri-strips and gauze can be used to cover the incision.

Patients can be sent home the same day but with clear wound care instructions. To prevent the accumulation of fluid, a family member or caregiver is instructed on how to apply a pressure dressing over the wound. It is also recommended to have this caregiver roll gauze slowly and gently over the flap three times a day to express fluid through the drainage openings. Given that these wounds are chronically infected before surgery and the abscess cavity is left in place, a 7- to 10-day course of broad-spectrum antibiotics is prescribed. Patients follow up should be within 1–2 weeks to assess healing and allow for removal of the vessel loop around day 10.

Bascom reported a 96% healing rate of his patients with refractory pilonidal disease (Fig. 8C, H). Complications include stitch abscess or wound dehiscence. Recurrence rates are similar to the Karydakis flap, but less wound complications arise. Improved short-term quality of life has been reported after a cleft lift procedure when compared with the Limberg flap.

Other Techniques

Additional closure techniques have been used for the treatment of chronic pilonidal disease. Common plastic surgery flaps, including the Z-plasty and V-Y advancement have shown promise when used at the hands of those trained in these procedures. The Z-plasty technique has been shown to have lower recurrence rates and lower morbidity when compared with excision with healing by secondary intent. However, when compared with the previously mentioned flap techniques, the Z-plasty has higher rates of wound infections and disease recurrence.

SUMMARY

Pilonidal disease is an acquired condition that most commonly affects young adults. The entrapment of hair and debris within a deep gluteal cleft often leads to the formation of an acute abscess at the site of a midline pit. Over time, these pits can develop a chronic pilonidal sinus that prevents simple healing of the wound. Early or first-time disease can attempt to be treated by nonoperative measures or simple surgical excision. For patients with advanced chronic or recurrent disease, a flap procedure may offer more benefit. Flap procedures allow for off-midline closure that reduces the depth of the gluteal cleft and decreases the risk of recurrence. Given the impact on the quality of life and frequent risk of recurrence, these advanced technical procedures should be performed by those with prior training.

MANAGEMENT OF LOWER GASTROINTESTINAL BLEEDING

Peter Marcolesky, MD, and Alexandra Fisher, MD, FACS, FASCRS

Lower gastrointestinal bleeding (LGIB) is a complex problem that exists on a spectrum of severity with multiple etiologies. Defined as bleeding in the gastrointestinal tract originating from distal to the ligament of Treitz, possible sources include small bowel, large bowel, and the anus. Some newer resources define LGIB as specifically occurring distal to the ileocecal valve, with middle GI bleeding defined as a separate entity. However, this chapter defines bleeding distal to the ligament of Treitz as LGIB. It is estimated that 30% to 40% of all GI bleeding originates distal to the ligament of Treitz, with approximately 85% of LGIB originating in the colon. LGIB can be a difficult problem from both a diagnostic standpoint and an eventual management standpoint because of its many etiologies, evolving nature, and wide range of severity. Consequently, a systematic and multidisciplinary approach toward diagnosis and management is recommended (Table 1, Fig. 1).

EVALUATION AND DIAGNOSIS

History and Physical Examination

Evaluation should begin with a thorough history and physical examination. Important parts of the patient's history include the frequency, volume, and description of the patient's blood per rectum, as well as other associated symptoms such as presence of abdominal pain, dizziness, weakness, nausea, vomiting, symptomatic arrhythmias, or changes in diet and bowel habits. The patient should also be asked about any recent surgeries, prior gastrointestinal bleeds and, if so, what was the etiology; details about any previous colonoscopies and endoscopies; whether he or she is taking anticoagulants or antiplatelet medications; history of recent trauma; and if there is a personal history of colon cancer, inflammatory bowel disease, arteriovenous malformations, immunosuppression (either organic or iatrogenic), or hemorrhoids.

The physical examination should consist of a thorough abdominal examination, including digital rectal examination. It is important to look for the presence of abdominal masses or hernias and abdominal tenderness, specifically rebound tenderness, guarding, or other signs

completing the excision, remove the tape from the buttocks. Have an assistant push the two buttock cheeks together and ensure that the advancement flap will cover the span of the wound. Once wound closure is ensured, the lateral aspect of the excised portion of skin can then be completely detached.

After removal of the skin, the underlying abscess cavity and sinus track can be viewed. These should each be unroofed and a curette used to clean out all debris without removing the abscess cavity itself. The cavity is left in place to prevent dead space and the collection of infected fluid within that space, which would compromise the flap. Management of Lower Gastrointestinal Bleeding

Peter Marcolesky, MD, and Alessandro Fichera, MD, FACS, FASCRS

Lower gastrointestinal bleeding (LGIB) is a complex problem that exists on a spectrum of severity with multiple etiologies. Defined as bleeding in the gastrointestinal tract originating from distal to the ligament of Treitz, possible sources include small bowel, large bowel, and the anus. Some newer resources define LGIB as specifically occurring distal to the ileocecal valve, with middle GI bleeding defined as a separate entity. However, this chapter defines bleeding distal to the ligament of Treitz as LGIB. It is estimated that 30% to 40% of all GI bleeding originates distal to the ligament of Treitz, with approximately 85% of LGIB originating in the colon. LGIB can be a difficult problem from both a diagnostic standpoint and an eventual management standpoint because of its many etiologies, evolving nature, and wide range of severity. Consequently, a systematic and multidisciplinary approach toward diagnosis and management is recommended (Table 1, Fig. 1).

EVALUATION AND DIAGNOSIS

History and Physical Examination

Evaluation should begin with a thorough history and physical examination. Important parts of the patient's history include the frequency, volume, and description of the patient's blood per rectum, as well as other associated symptoms such as presence of abdominal pain, dizziness, weakness, nausea, vomiting, symptomatic arrhythmias, or changes in diet and bowel habits. The patient should also be asked about any recent surgeries, prior gastrointestinal bleeds and, if so, what was the etiology; details about any previous colonoscopies and endoscopies, whether he or she is taking anticoagulants or antiplatelet medications, history of recent trauma; and if there is a personal history of colon cancer, inflammatory bowel disease, arteriovenous malformations, immunosuppression (either organic or iatrogenic), or hemorrhoids.

The physical examination should consist of a thorough abdominal examination, including digital rectal examination. It is important to look for the presence of abdominal masses or hernias and abdominal tenderness, specifically rebound tenderness, guarding, or other signs

of peritonitis. On digital rectal examination, the clinician should inspect for sources of blood, including hemorrhoids, fissures, or masses that may be palpable on examination. In addition, the quality of the stool in the rectal vault, whether it is impacted, melanotic, maroon colored, or frank blood, should be noted. Finally, the clinician should pay specific attention to the patient's vital signs because tachycardia or hypotension are signs of larger volume loss.

Further Studies

After initial examination of the patient, additional studies should be obtained for both diagnostic clarity and further management pearls found in the history.

Anoscopy

If the patient is complaining of blood covered stool, perianal pain, pain with defecation, or sensation of incomplete defecation, then anoscopy can be a quickly performed initial examination to search for hemorrhoids, anal fissures, fecal impaction, or local trauma to the anus. Anoscopy consists of inserting a tubular instrument into the patient's anus, this provides visualization of the anal canal and distal rectum. It is a quick method of visualizing the very distal most aspect of the lower GI tract for hemorrhoids, anal fissures, fecal impaction, or local trauma to the anus, and it can be done at bedside. If the patient has bleeding from internal hemorrhoids, then anoscopy can be used to assist with banding or other treatment of the hemorrhoids. Unfortunately, it is often uncomfortable for the patient, and it only provides limited visualization because it can only display a small segment of tract.

Rigid Sigmoidoscopy

In patients with a strong suspicion for distal LGIB, including the anus, rectum, and distal sigmoid, rigid sigmoidoscopy is also an initial option. The procedure is similar to anoscopy, except the instrument is longer and often has the ability to pump a small amount of air into the rectum to insufflate the bowel to provide better visualization of the mucosa. It is like anoscopy in that it is technically simple and can quickly assess the rectum and anus for bleeding sources, however, it is also uncomfortable for the patient and provides inferior visualization to a flexible sigmoidoscopy or full colonoscopy.

Colonoscopy

If there is a strong suspicion for a colorectal source of the LGIB, colonoscopy is usually a reasonable place to begin. Indicators that the bleeding may be from a colorectal source include anemia, hematochezia or maroon colored stools, tenesmus, chronic changes to bowel habits, palpable mass on digital rectal examination, older age, and history of diverticulosis or colorectal angiodysplasia. Ideally, the patient would undergo bowel prep before colonoscopy so the colon and rectum could be adequately visualized. If the bleeding is chronic in nature, then bowel prep is absolutely indicated because the differential diagnosis includes neoplasia and adequate visualization is necessary. If the bleeding is more acute and the patient is stable, then colonoscopy should occur within 24 hours of clinical presentation, and bowel prep should be attempted. The study consists of pushing a flexible scope through the entirety of the anus, rectum, colon, and usually past proximal to the ileocecal valve. Colonoscopy can detect an endoluminal source of bleeding such as neoplasia, bleeding diverticulosis, hemorrhoids, or angiodysplasia, in addition to diffuse sources of bleeding including inflammatory bowel disease, ischemic colitis, radiation proctitis, or infectious colitis. Furthermore, colonoscopy can be therapeutic as well as diagnostic because bleeding lesions can be either cauterized, clipped, coagulated with argon plasma, or injected with epinephrine to obtain hemostasis. Colonoscopy should be deferred if there is suspicion for active diverticulitis because this increases the risk of bowel perforation. In addition, if the patient has a heavy stool burden or is unable to tolerate bowel prep, then it may be difficult to sufficiently visualize the colon and rectum. Risks include bowel perforation, damage to mucosa, and the general risks of sedation.

Computed Tomography Angiography

Patients with active bleeding at a rate greater than approximately 0.5 mL/min can be visualized with a computed tomographic angiography (CTA). The study consists of injection of intravenous contrast while the patient is scanned by a multidetector helical CT scanner. The timing of the contrast is such that active arterial extravasation from a vessel into the lumen of the small bowel can be visualized on the study. A CTA can be rapidly obtained, is minimally invasive, and does not require any bowel preparation like a colonoscopy. Consequently it is very useful in hemodynamically unstable patients who are either only minimally or transiently responding to resuscitation and do not have time to undergo bowel preparation prior to intervention. CTA can also assist with the diagnosis of other causes of LGIB, such as mesenteric ischemia or ischemic colitis. To confirm and localize the

TABLE 1 Differential Diagnosis of Gastrointestinal Bleeding: Origin Site

Origin of Bleeding	Expected Symptoms/History/Findings
Small intestine	Melena/maroon colored stool Anemia
Colon/rectum	Melena/maroon colored stool/hematochezia History of diverticulosis Anemia Changes to bowel habits
Anus	Hematochezia/blood coated stool Palpable or visible hemorrhoids Anal fissure Pain with defecation Sensation of incomplete voiding of stool

FIG. 1 Evaluation based on severity of gastrointestinal bleeding.

bleeding, the patient must be actively bleeding at the time of the study, otherwise no extravasation will be visualized. Other disadvantages of CTA include possible allergic reaction to intravenous contrast, nephrotoxicity of intravenous contrast, exposure to radiation, that no therapeutic intervention is performed simultaneously with the study, and the difficulty with precisely localizing a small bowel source.

Nuclear Scintigraphy With Technetium 99m

Similar to the CTA, nuclear scintigraphy allows for radiographic visualization of the location of bleeding. In the study, the patient's red blood cells are tagged with technetium 99m, a radiotracer, and then injected back into the patient. The patient is then imaged to see where extravasation of the tagged red blood cells is occurring. Nuclear scintigraphy is a more sensitive test than CTA because it can detect bleeding down to a rate as low as 0.1 mL/min. It is also advantageous in that the radiolabeled red blood cells remain detectable in the patient for approximately 24 hours after initial labeling, so if the patient has a site of bleeding that is only intermittently active, then the patient can be rescanned over the course of the day which increases the sensitivity of the test. However, it is even less accurate at localizing the source of the bleeding than CTA. Pooled studies estimate a 25% false localization rate; therefore, it is more frequently used to screen for bleeding than to target a localized intervention.

Angiography

Should CTA or nuclear scintigraphy demonstrate active extravasation in the patient, an angiogram is a possible intervention to both further localize and potentially stop the bleeding. The patient is lightly sedated, and then intraarterial access is gained, usually through the femoral artery or other major artery. A catheter is inserted into the lumen of the artery and then guided through the aorta to the suspected bleeding artery. Contrast is injected through the catheter and then fluoroscopy is used to search for active extravasation. If the extravasation is localized, then that vessel can be embolized. If venous bleeding is suspected, the same process of embolization can be used in the venous system. Angiography can detect bleeding down to a rate of 0.5 mL/min or greater. Angiography is usually reserved for hemodynamically unstable patients or patients with a continued transfusion requirement only. The risks of angiography include the risks of undergoing sedation in an actively bleeding patient, vascular perforation, contrast allergy, contrast nephropathy, and pseudoaneurysm or bleeding at the access point. Provocative angiography is similar to angiography; however, during the procedure, the patient is given some form of anticoagulation with the goal of provoking an intermittently bleeding lesion into actively bleeding so that it can be captured on angiography. The lesion is then embolized, or at least identified for surgical resection, such as in the case of a hypervascular tumor. One single-center study demonstrated a 31% success rate with identifying a bleeding lesion with provocative angiography, without bleeding complications. Furthermore, the bleeding lesion was able to be successfully embolized or resected in all cases. Provocative angiography can be beneficial when searching for an intermittently bleeding lesion, but it does come with the standard risks of angiography, as well as the additional risk of hemorrhagic complications from giving a patient at high risk of bleeding a therapeutic dose of anticoagulant.

Capsule Endoscopy

Capsule endoscopy is a useful study for a hemodynamically stable patient who has chronic or episodic GI bleeding often associated with chronic anemia despite a negative workup of both upper and lower GI source because it can visualize the entirety of the small bowel. The patient swallows a pill-sized capsule that contains a camera, the camera then takes intermittent photographs as it moves through the patient's digestive tract. The images are reviewed to determine the source of bleeding. The test is relatively sensitive for detecting a source of bleeding, with some studies demonstrating a sensitivity of up to 90%. Capsule endoscopy does not have any therapeutic abilities because it is only a diagnostic test. However, it can help obtain a diagnosis, and determine appropriate future studies or management with its findings.

Balloon Enteroscopy

Similar to capsule endoscopy, double balloon enteroscopy allows for visualization of the small intestine. First, the patient is placed under anesthesia. The device used is an endoscope, but with an overtube that the endoscope can telescope in and out of. There are balloons on the distal aspect of the overtube and endoscope. The scope is advanced into the small intestine and then the overtube balloon is inflated and the overtube retracted, thus pulling the small bowel proximal to the endoscope and then allowing the endoscope to advance further into the small bowel. The endoscope's balloon is then inflated, and then overtube's balloon deflated, and the overtube advanced forward to meet the endoscope. The overtube's balloon is then inflated, allowing further retraction of the small bowel proximally. This process allows the overtube to retract small bowel, so the endoscope can be further advanced. The process is time consuming, but it does have the advantage over capsule endoscopy because the scope can be used to carry out therapeutic intervention, similar to a standard colonoscopy or endoscopy. Furthermore, the provider can begin the procedure from either the upper or lower ends of the GI tract. The study does come with the standard risks of endoscopy, including the risks of anesthesia and bowel perforation. Because it is so labor intensive, it is often unsuitable as are results of CTA, nuclear scintigraphy, or capsule endoscopy to plan a double balloon enteroscopy.

Nasogastric Lavage

Brisk bleeding from the upper GI tract, such as a bleeding peptic ulcer, angiodysplasia, or esophageal varices, can often manifest as visible blood in the stool, either hematochezia or maroon colored stool. Nasogastric lavage requires insertion of a nasogastric tube, and then the contents of the stomach are either suctioned, or saline is instilled into the nasogastric tube and then suctioned back to an effort to look for either blood or coffee grounds in the stomach. In a hemodynamically unstable patient, nasogastric lavage is a quick method of investigating the upper GI tract as a source of bleeding. Unfortunately, it is uncomfortable for the patient and it does not specifically localize the source of bleeding beyond identifying it as emanating from the upper GI tract. Furthermore, it does not have any therapeutic benefit.

Esophagogastroduodenoscopy

Endoscopic evaluation of the upper GI tract, including the esophagus, stomach, and duodenum, may be necessary if the patient's investigation of the lower GI tract is inconclusive. Esophagogastroduodenoscopy (EGD) is useful for diagnosing bleeding lesions, including peptic or duodenal ulcers, angiodysplasias, neoplasia, or inflammatory conditions that could be causing upper GI bleeding. Similar to a colonoscopy, the EGD has both diagnostic and therapeutic value. Additionally, ulcers can be inspected and biopsied to guide future medical management of peptic ulcer disease including PPI therapy and antibiotics for possible *Helicobacter pylori*. Its risks are similar to other endoscopic studies and includes perforation and any risks of sedation (Table 2).

MANAGEMENT

Initial management depends on the severity of the bleed. First, the quantity of blood in the patient's stool should be assessed, as should the patient's vital signs and associated symptoms. Because the acuity of management depends on the severity of the patient's bleeding and associated hemodynamics, we divide management into two separate categories for this chapter (Table 3).

Hemodynamically Stable Patient

A hemodynamically stable patient can present with a wide range of severity to his or her symptoms, including intermittent blood in the stool to someone with chronic anemia resulting from continued low rate of blood loss. Similar to a hemodynamically unstable patient, the clinician should begin with a history and physical examination. It is important to characterize the time course, amount of bleeding, appearance

TABLE 2 Evaluation of GI Bleeding by Site of Origin

CMV, cytomegalovirus; EHEC, enterohemorrhagic Escherichia coli; GI, gastrointestinal.

of the stool and associated symptoms, such as presence of abdominal pain, rectal pain, fever, weight loss, or changes in bowel habits. The physical examination should include a thorough abdominal examination searching for palpable masses, tenderness, or lymphadenopathy. A digital rectal examination should also be performed, taking care to note the presence of anal fissures, internal or external hemorrhoids, or any masses that are palpable in the anal canal. Anoscopy or rigid sigmoidoscopy can also be performed at this time if the patient tolerates it to gain better visualization of the anal canal, especially if there is suspicion for anal or rectal pathology or history and physical examination. If these examinations are not confirmatory of a diagnosis, then colonoscopy or flexible sigmoidoscopy should be considered as a next step.

In younger patients, blood on the stool is usually caused by internal or external hemorrhoids or anal fissure. Meckel's diverticulum is another possibility and is a frequent cause of painless bleeding in younger age groups. In older patients, malignancy is of greater concern, and therefore even if benign rectal pathology is uncovered on physical examination, the patient should be considered for colonoscopy. In older patients found to be anemic without a history of rectal blood loss in the stool, occult GI blood loss to stool, a possible etiologic, and EGD and colonoscopy should be considered for workup. Similar to a hemodynamically unstable patient, colonoscopy can be both diagnostic and therapeutic. If a bleeding polyp is noted, it can be removed either by forceps or resecting with a snare at the base of the polyp. Additionally, if the patient has a slow bleed from an angiodysplasia, argon plasma coagulation can be used during colonoscopy.

In a patient with intermittent bleeding, it can be useful to perform a tagged red blood cell scan because they can detect slower sources of bleeding. The radioactive tracer can remain in the patient's body for up to 24 hours, so he or she can be managed quickly should there be signs of further bleeding. Another option in an intermittently bleeding patient is provocative angiography to localize the lesion.

In a hemodynamically stable patient, surgical intervention can be warranted for several etiologies, including malignancy, inflammatory bowel disease refractory to medical management, bleeding hemorrhoids, or recurrent bleeding from a Meckel's diverticulum. If a bleeding Meckel's diverticulum is discovered, it is important to not only resect the diverticulum, but the adjacent bowel as well. The Meckel's diverticulum usually results in ulceration of the mucosa of the adjacent bowel resulting from the production of ectopic gastric contents from ectopic gastric tissue found in the diverticulum. Simple resection of the diverticulum without resection of the adjacent bowel will not control the source of bleeding.

Hemodynamically Unstable Patient

If the patient is found to be dizzy, tachycardic, hypotensive, or have other signs of hemodynamic instability or pending instability, then initial management should include obtaining vascular access with two large-bore intravenous needles, volume resuscitation, and baseline laboratory values, including hemoglobin, white blood cell count, platelets, liver function, renal function, and coagulation. The patient should be typed and crossed for blood products as well. An endoscopist should be consulted for possible colonoscopy, as well as EGD should there be suspicion for upper GI bleeding. Additionally, the clinician should consider placement of a nasogastric tube to perform nasogastric lavage if there is a concern that the bleeding could be coming from the stomach. If there is any coagulopathy or thrombocytopenia, then that should be corrected with vitamin K supplementation, fresh frozen plasma, and platelet transfusion. If the patient is taking any antiplatelet or anticoagulant drugs, they should be discontinued temporarily. Consultation with a cardiologist is recommended if the patient has had recent cardiac stent placement because discontinuation of dual antiplatelet therapy could result in thrombosis of the stent. Some sources recommend holding nonaspirin antiplatelet agents for 1 to 7 days while continuing aspirin in the setting of secondary prevention of cardiac ischemia. Goals of transfusion should be for a hemoglobin greater than 7.0 g/dL for patients without evidence of an active cardiac event, and more than 9.0 g/dL in patients with significant comorbidity including coronary artery disease. International normalized ratio should be corrected to a goal of less than 1.5. Platelets should be transfused for a goal of greater than 50,000/μL. If the patient requires a massive transfusion protocol, it is important to be mindful of maintaining a 1:1:1 ratio of units of packed red blood cells to platelets to fresh frozen plasma to ensure clotting factors and platelets are replaced in the setting of severe bleeding.

If the patient is responsive to initial resuscitation, then he or she should undergo EGD for evaluation of upper GI source because the upper GI tract is a more likely etiology for brisk bleeding than the lower GI tract. If the EGD is negative for a source of bleeding, then the patient should begin bowel prep to prepare for colonoscopy within the next 24 hours. At the time of colonoscopy, the entirety of the rectum, colon, and terminal ileum should be inspected by the performing physician for signs of active bleeding, as well as signs of recent bleeding, such as adherent clots or exposed blood vessels. If the source of bleeding is identified, then the bleeding vessel can either be cauterized, clipped, rubber band ligated, or injected with epinephrine to achieve hemostasis. Injection with dilute epinephrine, usually 1:10,000 or 1:20,000 dilution, is usually coupled with a second means of hemostasis, such as clipping of the vessel. In addition, the source of bleeding should be noted as a diverticular bleed versus angiodysplasia because angiodysplasia is amenable to argon plasma coagulation for hemostasis.

GI bleeding may be only part of the patient's hemodynamic instability; therefore, it is important to pay close attention to the patient's associated symptoms. For example, in acute mesenteric ischemia, the patient may be passing blood through the stool, but there are other factors present that are driving the patient's tachycardia and hypotension.

TABLE 3 Management of Gastrointestinal Bleeding

	Presentation	Diagnosis	Treatment
Diverticulosis	Maroon-colored stool or hematochezia Either painless or crampy pain Can be significant volume of blood in episodic bouts, usually occurs in older patients	Colonoscopy to identify bleeding diverticula	Most cases resolve without intervention Bleeding vessel can be clipped, cauterized, or injected during colonoscopy
Angiodysplasia	Low volume bleeding but can be more severe Hematochezia or maroon colored stool, either painless or crampy pain, usually occurs in older patients	Colonoscopy to identify bleeding vascular malformation	Argon plasma coagulation during colonoscopy Surgical resection is usually reserved for the case of continuous bleeding despite attempts at endoscopic management
Internal hemorrhoids	Painless bleeding with bowel movements Blood visible on stool, usually associated with frequent straining, constipation, pregnancy, or prolonged sitting	Digital rectal examination or anoscopy can visualize internal hemorrhoids	Conservative management includes stool softeners, high fiber diet, and limiting time spent on toilet If refractory to conservative measures, then they can either be rubber band ligated using anoscopy or excised surgically
External hemorrhoids	Pain with bowel movements Thrombosis of hemorrhoid usually results in continuous anal pain Blood present on stool or on toilet tissue, associated with frequent straining, constipation, pregnancy, or prolonged sitting	Visible on external aspect of anal canal and can be palpated on digital rectal examination	Conservative management includes stool softeners, high fiber diet, and limiting time spent on toilet Thrombosed hemorrhoids can be excised
Anal fissure	Pain with bowel movements, blood present on stool or on toilet tissue, usually associated with passing large/firm stools	Visible on external aspect of anal canal, usually tender on digital rectal examination	Conservative management with stool softeners, topical calcium channel blockers, topical numbing agents, topical nitroglycerine If refractory to medical treatment, lateral internal sphincterotomy can relieve sphincter spasm that can worsen fissure
Inflammatory bowel disease	Frequent, bloody bowel movements Crampy abdominal pain, anorexia, changes in bowel habits, diarrhea, weight loss, fevers, extraintestinal manifestations such as pyoderma, uveitis, erythema nodosum, primary sclerosing cholangitis, arthralgias	Colonoscopy can visualize the gross appearance of the intestine looking for cobblestoning, skip lesions, exhibition sag, or evidence of structuring or fistulizing disease; biopsies taken during colonoscopy often demonstrate inflammatory changes, noncaseating granulomas, or crypt abscesses	Inflammatory bowel disease can be medically managed with a combination of corticosteroids and other immunomodulating agents Regular endoscopic monitoring is needed because patients are at higher risk of neoplasia Surgery can be indicated for strictures, fistulas, or medically refractory disease Total abdominal colectomy is a definitive treatment in ulcerative colitis
Neoplasia	Occult bleeding, hematochezia/maroon colored stools, changes in bowel habits, weight loss, family history of neoplasia, personal history of inflammatory bowel disease, older patients	Colonoscopy can visualize the gross pathology and biopsy taken during colonoscopy confirms the diagnosis	Surgical resection can be curative, such as in the case of early stage anal benign disease, or it can be palliative, such as in the case of more advanced disease where complete resection is not possible
Ischemic colitis	Crampy abdominal pain associated with hematochezia or maroon-colored stools, older patients with coexisting coronary or peripheral arterial disease, usually precipitated by physiologic stress, such as surgery or illness	Flexible sigmoidoscopy or colonoscopy can diagnose ischemic changes or ischemic ulcerations to watershed regions of the large intestine, such as the sigmoid colon or splenic flexure	Supportive care with volume resuscitation and treatment of underlying insult Serial abdominal examinations are performed to monitor for worsening of intestinal ischemia, if the patient develops peritonitis, then surgical resection of the necrotic bowel should be performed

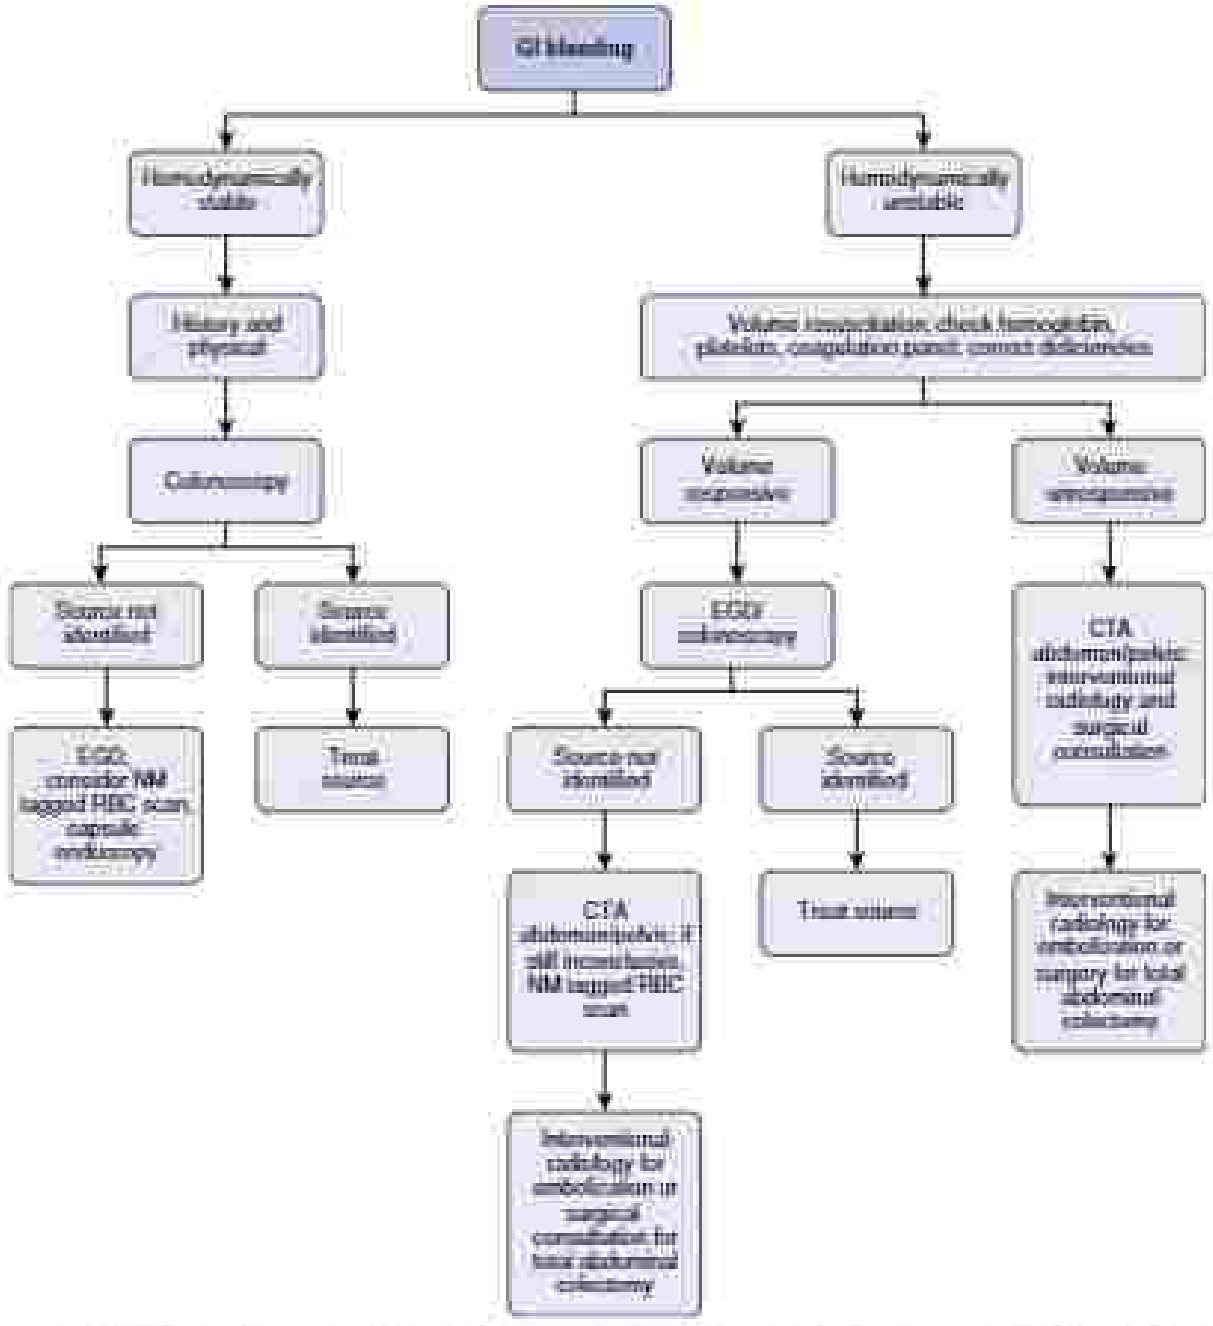

FIG. 2 Algorithm for treatment of gastrointestinal bleeding. CTA, computed tomography angiography; EGD, esophagogastroduodenoscopy; GI, gastrointestinal; NM, nuclear medicine; RBC, red blood cell.

If the patient is transiently responsive to resuscitation, then the patient should undergo stat CTA, as well as consultation to interventional radiology for angiography and possible embolization pending the results of the CTA. If the patient is only minimally responsive to resuscitation, then direct consultation of interventional radiology for angiography and embolization would be more appropriate. Emergent EGD should also be performed at this time as well. In a hemodynamically unstable patient with negative CTA and negative EGD/colonoscopy, the next step would be surgery as a salvage procedure. Additionally, if a patient undergoes EGD/colonoscopy that identifies the bleeding, but the bleeding is unable to be controlled endoscopically, then surgical intervention is also warranted. Surgical options include either a segmental bowel resection if the bleeding is identified preoperatively or intraoperatively, or a subtotal colectomy. The surgeon should have a low threshold to perform a damage control operation because the primary objectives would be to control the bleeding as quickly as possible, and then continue resuscitation of the patient in an intensive care setting. Surgical intervention for GI bleeding should be regarded as a salvage procedure and not first line because it carries a 40% mortality rate and is often difficult to localize the bleeding intraoperatively. If a patient were to have bleeding that could not be controlled endoscopically, one option would be to tattoo the segment of bleeding bowel endoscopically, so it could be identified intraoperatively. Finally, in the case of mesenteric ischemia, surgery would be indicated to remove any necrotic segments of bowel, as well as vascular surgical intervention to attempt to restore blood flow to the bowel (Fig. 2).

CONCLUSION

LGIB is a complex problem arising from a variety of etiologies with a range of severity. Consequently, it is important for the clinician to be thorough in his or her assessment, and to be mindful of concurrent resuscitation of the patient. Because approximately 80% of patients presenting with LGIB will spontaneously resolve, most patients may only require some degree of resuscitation and not require procedural intervention to achieve hemostasis. Endoscopic and interventional procedures should be first line for most episodes of GI bleeding that require intervention, with surgery usually reserved only for refractory cases of brisk bleeding. Furthermore, in a hemodynamically stable patient, endoscopic assessment is usually a reasonable method of obtaining a diagnosis. Surgical intervention can also be warranted in the setting of neoplasia, refractory inflammatory bowel disease, Meckel's diverticulum, necrotic intestine secondary to ischemia, or hemorrhoids.

Enhanced Recovery After Surgery

Alexis Gabre-Kidan, MD, and Jonathan Efron, MD

The key tenet of an Enhanced Recovery After Surgery, or ERAS, program is minimizing stress along the entire surgical care continuum from preoperative evaluation through postoperative follow-up. This requires several shifts to the standard approach to any given surgical patient. First, it must be accepted that outcomes depend on more than traditional preoperative cardiopulmonary optimization and surgical technique. Although we have made great advances in surgical technique, patients still suffer complications. This suggests that even as we continue to innovate and push the limits of our technical capabilities, we must also look beyond what happens in the operating room to make an impact on patient outcomes. Second, as we learned from multidisciplinary tumor boards in cancer care, a multidisciplinary approach with engagement of all stakeholders involved in the care of surgical patients is key. This starts, most importantly, with the patients themselves and includes outpatient surgical team members (i.e., nurses, support staff), surgeons, anesthesiologists, and inpatient care team members such as nurses, nutritionists, and physical therapy. Last, but perhaps most important, the adoption of an ERAS program requires a willingness to adopt evidence-based care that may be a departure from typical patterns of care. This is perhaps the most difficult and slowest step. However, as the emphasis on delivering high-quality, lower-cost care continues to grow, we must constantly evaluate and evolve beyond what dogma or preference dictates to ensure that we are delivering the best patient care possible.

This chapter reviews the standard elements of an ERAS program designed to minimize stress and, as a result, optimize patient outcomes. Past reviews have detailed each individual component of an ERAS program. Instead, we will outline the cornerstones of patient care in ERAS programs: minimizing fasting, judicious fluid administration, and optimizing analgesia. We will also demonstrate where each of these factors come in to play along the care continuum. Each element of ERAS affects one of these key tenets to ultimately minimize stress and decrease adverse outcomes.

EDUCATION

We propose that there is one additional key feature without which an ERAS program cannot succeed: education. This includes patient education as well as active engagement of all of the stakeholders that will participate in the patient's care along the care continuum.

An ERAS program may be a departure from what patients have experienced if they have had prior surgeries or even from their general expectations if they have not. Just as the adoption of ERAS by healthcare professionals requires a shift in the belief that patients who undergo major surgery need to be hospitalized longer, the common perception on the part of patients that surgery involves several days in the hospital for convalescence must also be adjusted. This begins with understanding patients' goals for surgery and educating them on the goals of an enhanced recovery pathway. It is important to explain the benefits of the ERAS pathway beyond simply reducing length of stay and avoiding terms such as *fast track* or *expedited recovery* because these do not convey the true goals of ERAS programs. Emphasis should be placed on decreasing complications, minimizing stress and anxiety, and guiding patients through their recovery as smoothly as possible. To this end, educational materials on preoperative instructions, what to expect during their hospitalization, and criteria for discharge are important to provide. Some programs use printed materials and give each patient an ERAS pamphlet to study before surgery, whereas others rely on Web-based materials. The most effective educational tools are written at an appropriate health literacy level and outline both daily milestones and overall goals for recovery (Fig. 1). These tools not only allow patients to take an active role in their care, but also expectation lower stress/anxiety and shorter hospital stays.

The creation and maintenance of a successful ERAS program revolves around a multidisciplinary, multimodal approach to care. This involves several team members, from anesthesiologists, surgeons, to nurses, and spans several settings from outpatient clinics to the operating room and inpatient wards. For many of these team members, the strategies used in caring for ERAS patients will signal a departure from their usual patterns of care. Similar to patient education, each team member must be educated on the overarching goals of the ERAS program and how his or her individual roles contribute to these goals. We will not review detailed steps on how to implement ERAS programs, because each implementation must be adapted to the culture and protocols of each institution. The first step, however, is education on the evidence that drives the various components of the pathway. Later in the chapter, we will discuss audit and compliance processes to ensure that ongoing education is taking place and any barriers are being addressed.

MINIMIZING FASTING

Perhaps the largest shift to caring for ERAS patients is the management of their nutritional status preoperatively and postoperatively. In

CONCLUSION

LGIB is a complex problem arising from a variety of etiologies with a range of severity. Consequently, it is important for the clinician to be thorough in his or her assessment, and to be mindful of concurrent resuscitation of the patient. Enhanced Recovery After Surgery

Alexis Gabre-Kidan, MD, and Jonathan Efron, MD

The key tenet of an Enhanced Recovery After Surgery, or ERAS, program is minimizing stress along the entire surgical care continuum from preoperative evaluation through postoperative follow-up. This requires several shifts to the standard approach to any given surgical patient. First, it must be accepted that outcomes depend on more than traditional preoperative cardiopulmonary optimization and surgical technique. Although we have made great advances in surgical technique, patients still suffer complications. This suggests that even as we continue to innovate and push the limits of our technical capabilities, we must also look beyond what happens in the operating room to make an impact on patient outcomes. Second, as we learned from multidisciplinary tumor boards in cancer care, a multidisciplinary approach with engagement of all stakeholders involved in the care of surgical patients is key. This starts, most importantly, with the patients themselves and includes outpatient surgical team members (i.e., nurses, support staff), surgeons, anesthesiologists, and inpatient care team members such as nurses, nutritionists, and physical therapy. Last, but perhaps most important, the adoption of an ERAS program requires a willingness to adopt evidence-based care that may be a departure from typical patterns of care. This is perhaps the most difficult and slowest step. However, as the emphasis on delivering high-quality, lower-cost care continues to grow, we must constantly evaluate and evolve beyond what dogma or preference dictates to ensure that we are delivering the best patient care possible.

This chapter reviews the standard elements of an ERAS program designed to minimize stress and, as a result, optimize patient outcomes. Past reviews have detailed each individual component of an ERAS program. Instead, we will outline the cornerstones of patient care in ERAS programs: minimizing fasting, judicious fluid administration, and optimizing analgesia. We will also demonstrate where each of these factors come in to play along the care continuum. Each element of ERAS affects one of these key tenets to ultimately minimize stress and decrease adverse outcomes.

EDUCATION

We propose that there is one additional key feature without which an ERAS program cannot succeed: education. This includes patient education as well as active engagement of all of the stakeholders that will participate in the patient's care along the care continuum.

An ERAS program may be a departure from what patients have experienced if they have had prior surgeries or even from their general expectations if they have not. Just as the adoption of ERAS by healthcare professionals requires a shift in the belief that patients who undergo major surgery need to be hospitalized longer, the common perception on the part of patients that surgery involves several days in the hospital for convalescence must also be adjusted. This begins with understanding patients' goals for surgery and educating them on the goals of an enhanced recovery pathway. It is important to explain the benefits of the ERAS pathway beyond simply reducing length of stay and avoiding terms such as *fast track* or *expedited recovery* because these do not convey the true goals of ERAS programs. Emphasis should be placed on decreasing complications, minimizing stress and anxiety, and guiding patients through their recovery as smoothly as possible. To this end, educational materials on preoperative instructions, what to expect during their hospitalization, and criteria for discharge are important to provide. Some programs use printed materials and give each patient an ERAS pamphlet to study before surgery, whereas others rely on Web-based materials. The most effective educational tools are written at an appropriate health literacy level and outline both daily milestones and overall goals for recovery (Fig. 1). These tools not only allow patients to take an active role in their care, but also expectation lower stress/anxiety and shorter hospital stays.

The creation and maintenance of a successful ERAS program revolves around a multidisciplinary, multimodal approach to care. This involves several team members, from anesthesiologists, surgeons, to nurses, and spans several settings from outpatient clinics to the operating room and inpatient wards. For many of these team members, the strategies used in caring for ERAS patients will signal a departure from their usual patterns of care. Similar to patient education, each team member must be educated on the overarching goals of the ERAS program and how his or her individual roles contribute to these goals. We will not review detailed steps on how to implement ERAS programs, because each implementation must be adapted to the culture and protocols of each institution. The first step, however, is education on the evidence that drives the various components of the pathway. Later in the chapter, we will discuss audit and compliance processes to ensure that ongoing education is taking place and any barriers are being addressed.

MINIMIZING FASTING

Perhaps the largest shift to caring for ERAS patients is the management of their nutritional status preoperatively and postoperatively. In

keeping with the principle of decreasing the stress response to surgery, several components of the pathway are aimed at maintaining a metabolically fed state to decrease stress, which in turn decreases insulin resistance and catabolism.

The first intervention in an ERAS pathway aimed at decreasing the stress response to surgery is to avoid keeping patients without food or drink from midnight the night before surgery. Although the traditional rationale has been to decrease the risk of aspiration during induction of anesthesia, newer evidence from the anesthesiology community has shown that it is safe for patients to have solids up to 6 hours before surgery and clear liquids up to 2 hours before surgery. This allows the opportunity for patients to enter surgery in a metabolically fed state. Current ERAS guidelines recommend consumption of complex carbohydrate drinks up to 2 hours before the time of surgery. The advantage to this was first shown in animal studies that demonstrated that animals sustaining surgical trauma had better responses to stress than those that entered in the metabolically starved state. These findings were then confirmed when it was shown that patients taking preoperative oral carbohydrate solutions had 50% less insulin resistance and decreased loss of muscle mass, suggesting that the effects were not only limited to glucose metabolism but protein and fat metabolism as well. Subsequent studies and meta-analyses have suggested that preoperative carbohydrate loading is an independent predictor of length of stay. From a psychological standpoint, remaining without food or water for several hours is also uncomfortable, with many patients complaining of thirst and hunger. This creates additional unnecessary stress and anxiety preoperatively. Patients that are malnourished need additional nutritional optimization before surgery and would benefit from a structured plan to boost their nutrition in the days and weeks leading up to surgery.

The goal of minimizing stress and catabolism by encouraging oral intake continues through to the postoperative period. Patients are encouraged to take liquids the evening of surgery. In several studies even beyond the ERAS populations, early enteral feeds have shown to have beneficial effects and decrease overall postoperative complications. Again, in addition to decreasing patient discomfort and anxiety associated with remaining without food or water, this serves to decrease catabolism. Although some programs will advance patients to a solid or semisolid diet on the first postoperative day, others focus on nutritional supplements. The exact diet progression is likely not as important as having a structured plan for patients within a given program that minimizes fasting. To this end, routine use of nasogastric tubes is discouraged. Not only do nasogastric tubes cause patient discomfort and impede mobilization, but they have been shown to delay return of bowel function and are associated with increased pulmonary complications such as atelectasis and pneumonia. Last, for patients to continue oral intake, postoperative nausea and vomiting (PONV) must be well controlled. This starts preoperatively with risk stratification using scoring systems such as the Apfel score (Fig. 2) and appropriate preoperative prophylaxis. All patients should receive

Risk factors	Points
Female gender	1
Nonsmoker	1
History of PONV	1
Postoperative opioids	1
Risk score =	0...4

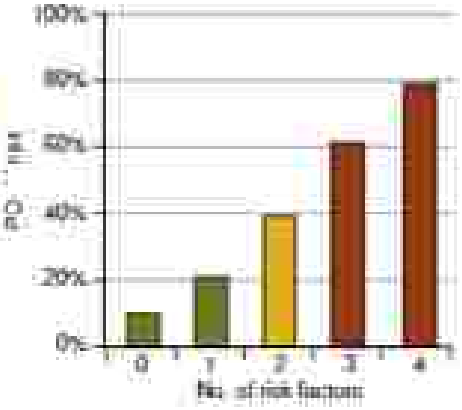

FIG. 1 Apfel score. PONV, postoperative nausea and vomiting.

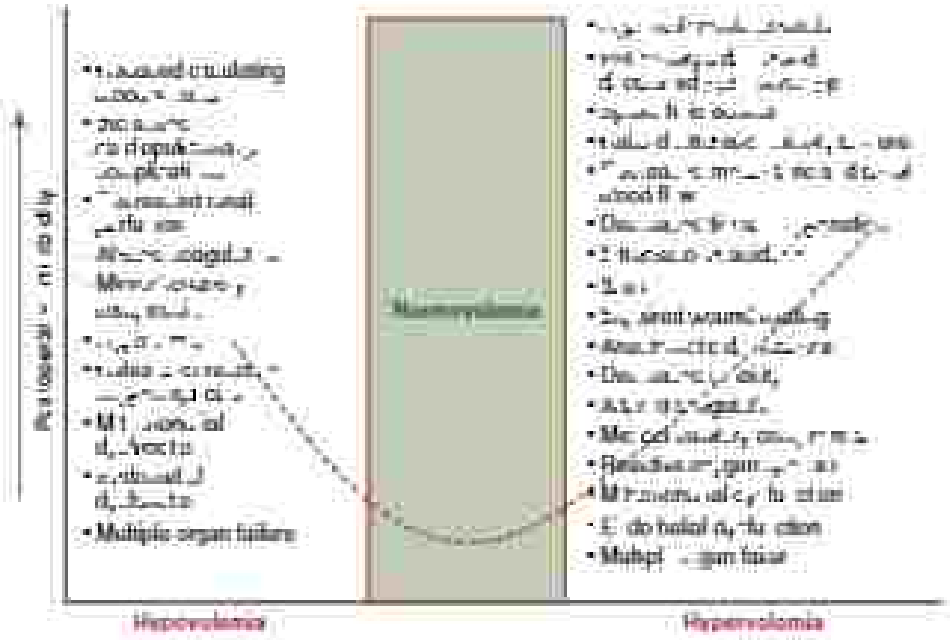

FIG. 2 Fluid balance.

dexamethasone before induction, ondansetron at the completion of surgery, and further interventions such as scopolamine patches based on their risk stratification. Several other intraoperative anesthetic factors affect rates of PONV and will be discussed in subsequent sections.

Despite measures to encourage early enteral feeding and decrease PONV, ileus remains a significant problem, and the most common reasons for increased length of stay in postoperative patients of all types. Prompt recognition of ileus and appropriate management is important to avoid delays in discharge and patient discomfort.

FLUID MANAGEMENT

Another large shift in the perioperative care of patients in the transition that fluid balance plays a large role in postoperative recovery. There are ample data to support the detrimental effects of both fluid overload and inadequate fluid resuscitation. The goal is to maintain patients in a euvolemic state by thoughtful and judicious use of intravenous fluids across the entire care continuum.

As discussed previously, patients are encouraged to take complex carbohydrate drinks up to 2 hours before surgery. This serves not only to minimize the stress response, but also to allow the patient to maintain fluid balance preoperatively. Another important consideration in preoperative fluid management is bowel preparation for colorectal surgery. The use of mechanical bowel preparation is meant to cleanse the colon to reduce fecal spillage and subsequently decrease infectious complications such as wound infections and anastomotic leakage. The literature regarding bowel preparation is mixed and controversial, with some studies demonstrating no benefit and others suggesting a benefit to mechanical bowel prep combined with oral antibiotic preparation. Strictly from a fluid management standpoint, mechanical bowel preparation leads to large preoperative fluid losses and patients potentially enter surgery in a hypovolemic state. This can lead to reflexive administration of additional intravenous fluids to compensate for preoperative losses. Several strategies have been advocated to minimize the routine use of mechanical bowel preparation for all patients undergoing colon and rectal resections, including the use of enemas for rectal resection and omitting preparation for right-sided resections entirely. However, multiple other studies have shown significant reduction in surgical site infections when mechanical preparations are used in conjunction with oral antibiotics. This requires further investigation and is an area where variability still remains, even within ERAS programs.

Intraoperative fluid balance is critical both within and outside of ERAS programs. Patients that leave the operating room in either extreme of fluid balance are at risk for postoperative complications. Recent emphasis has been on avoiding fluid overload because it has been shown to increase adverse outcomes such as pulmonary edema and ileus. Although the benefit of goal directed therapy has been demonstrated outside of ERAS programs, studies to date have been unable to show a benefit in ERAS programs. It is unclear if this is due to the increased use of laparoscopy or because ERAS programs already emphasize judicious use of intravenous fluids. Regardless, strategies to avoid fluid overload include tight titration with intravenous pumps, administration of a combination of balanced crystalloids and colloids, and use of pressors rather than fluids in hypotensive patients that appear euvolemic for other clinical indications. Several factors affect intraoperative fluid balance including the use of laparoscopy, thoracic epidural anesthesia, blood loss, and insensible losses. It is important that interventions that is administered thoughtfully in the intraoperative period because patients that enter the postanesthesia care unit and surgical wards in a state of fluid imbalance are at risk of deviating from the ERAS pathway.

Meta analyses have shown that fluid management is an independent predictor of outcome in ERAS programs, and the postoperative period is as important to overall fluid management as the intraoperative fluid balance. Fluid balance postoperatively should be oriented toward encouragement of oral intake of fluids and decreasing the use of intravenous fluids with a goal of between 1.75 and 2.5 L/day. Counter to traditional postoperative care, if oral intake is tolerated, intravenous fluids should be decreased or entirely discontinued on postoperative day 1.

The importance of effective management of fluids cannot be understated because it crosses all phases of care and involves all members of the team from patient to nurse. Improper use of fluids can lead to decreased end organ perfusion or pulmonary/bowel edema, both of which translate to slower recovery, increased morbidity, and increased length of stay.

ANALGESIA

Improving analgesia is an intuitive way to decrease the stress response to surgery and is a cornerstone of successful ERAS programs. As opposed to a more traditional approach to pain control, ERAS programs emphasize preemptive analgesia along with a multimodal approach to optimize response and minimize opioid use.

The method of preemptive analgesia most consistently demonstrated to decrease opioid use and alter the stress response to surgery is thoracic epidural analgesia. An epidural catheter is placed in the thoracic region preoperatively and maintained through the postoperative period, usually for up to 48 to 72 hours. Early ERAS data in open colonic surgery showed a strong benefit to epidural analgesia, but more recent studies with a higher percentage of ERAS patients undergoing laparoscopy have failed to show a benefit. Epidural analgesia is also not without its complications and contraindications and requires a pain management team to follow patients postoperatively, potentially posing a barrier to implementation. This has led to increased interest in other strategies for regional blocks such as transversus abdominis plane blocks administered by either the surgical or anesthesia team before surgery. Transversus abdominis plane blocks are generally performed with long-acting anesthetic agents. There has been increased interest in liposomal bupivacaine because it has been reported to provide analgesia for up to 72 hours after infiltration. It is unclear whether this provides additional narcotic sparing benefits beyond what is traditionally used in an ERAS program. However, this warrants further investigation because it may potentially be an avenue to limit opioid use which is highest in the early postoperative period.

In the absence of epidural analgesia, infusion of intravenous lidocaine intraoperatively has been shown to improve postoperative pain control, reduce opioid consumption, and is associated with quicker return of bowel function. Evidence for preemptive analgesia with acetaminophen and nonsteroidal antiinflammatory drugs remains unclear but there is more evidence to support the use of gabapentanoids preoperatively to decrease postoperative opioid use. Many centers also use alvimopan, a peripheral mu opioid antagonist, to decrease rates of ileus. There have been several studies across many surgical specialties showing that use of alvimopan can decrease rates of ileus and length of stay. Although the studies specifically investigating the benefit of alvimopan to an ERAS pathway are limited, they are promising and suggest that it can provide additional benefit in limiting ileus.

Multimodal analgesia is started preoperatively. Use of nonsteroidal antiinflammatory drugs and acetaminophen postoperatively has an opioid sparing effect. These medications should be used on a scheduled basis and do not have the same effects when used as needed. Use of these opioid sparing medications also secondarily decrease rates of PONV and ileus. Decreasing PONV and ileus in turn leads to earlier oral feeding and earlier mobilization.

There are two other ERAS recommendations that affect postoperative pain/discomfort and should be mentioned: urinary catheters and use of drains. Early removal of catheters, in some instances at the end of surgery, is encouraged. Not only does prolonged use of urinary catheters increase the risk of urinary tract infection, it also causes patient discomfort and impairs mobility. In the absence of significant pelvic dissection, it is recommended to remove catheters on the first postoperative day even in the presence of epidural catheters. Routine intraabdominal drainage is similarly discouraged and has never been

supported in the colorectal literature as a method of preventing or detecting potential complications. As ERAS guidelines continue to be developed for other surgical subspecialties, the literature specific to that field pertaining to the use of drains will need to be reviewed. If drains are used, early removal is advocated.

OUTCOMES/AUDIT

The success of any individual ERAS program relies not just on the initial implementation of the program, but also constant assessment of patient outcomes and program adherence. There is a clear stepwise association between adherence to the ERAS protocol and postoperative outcomes. When more than 70% of the ERAS elements are followed, symptom defying discharge, 30 day morbidity, and readmissions are significantly decreased. It is important to have an ongoing audit process to ensure that goals for the program are being met. Similarly, regular meetings with members of the ERAS team are important to discuss areas that may need improvement.

FUTURE DIRECTIONS

Although the most robust literature regarding ERAS pertains to colonic surgery, there has been an adoption of ERAS across several subspecialties (Table 1). There are 12 surgical subspecialties with separate ERAS guidelines from the ERAS Society and several more underway. Future study should be directed at the potential benefit of ERAS when applied to traditionally high risk surgical candidates such as the frail elderly population. For example, there is emerging interest in prehabilitation programs designed to optimize preoperative functional capacity to better prepare vulnerable patients to withstand the stress of surgery. The early data on these programs are mixed, and it is unclear whether they will offer additional benefits beyond ERAS or could be incorporated into ERAS programs. Last, the long-term benefits of participation in an ERAS program remain to be seen. Studies focusing on cancer specific outcomes suggest that adherence to ERAS protocols may be associated with increased 5 year cancer specific survival, but more studies of this nature are needed.

There is no doubt that implementation and maintenance of an ERAS program requires a large investment in resources, personnel, and time. However, with continued adherence, the benefits are clear and provide an opportunity to further improve the care of our surgical patients.

TABLE 1 Current ERAS Guidelines

Procedure and Topic	Year of Publication
Colonic resection	2012

PNEUMATOSIS INTESTINALIS AND THE IMPORTANCE FOR THE SURGEON

Paula Ferrada, MD, FACS, and Jason H. Delgado, MD, FACS

Pneumatosis intestinalis (PI) is defined as gas or air filled cysts on or in the bowel wall. This is a radiologic sign, not a disease, and it can be associated with multiple factors ranging from bowel ischemia to a more incidental finding. For the past decade, much research has been done to determine the significance of this sign, how to distinguish clinically when PI is pathologic or benign, and when it is the optimal time to perform surgery when patients have PI secondary to ischemia.

There is a likely a difference between PI identified on plain radiographs and the occurrence of this finding via more advanced radiologic methods such as computed tomography (CT). The latter imaging modality is more detailed and therefore can more sensitively identify pathologic PI in the early stages of ischemia, when it may still not be related to transmural necrosis. For this reason, it is important to note that PI should be evaluated in a clinical context that includes associated examination and laboratory data so that negative exploration on nontherapeutic laparotomy be avoided when possible.

This chapter presents an algorithm on how to identify patients who require an operation in the context of PI.

BENIGN PI

Benign PI presents as an incidental imaging finding without associated clinical signs/or indicative of ischemia. For example, some connective tissue disorders such as scleroderma have been associated with formation of cysts within the bowel wall not associated with ischemia. In the case of rupture of one of these cysts, the patient can even complain of abdominal pain that is self-limited, localized, and without any other clinical findings.

CLINICAL PRESENTATION OF PATHOLOGIC PI

Pathologic PI is present when there is associated ischemia. This can be associated with transmural necrosis. In pathologic PI, the patient usually presents with abdominal pain. If the abdominal pain

supported in the colorectal literature as a method of preventing or detecting potential complications. As ERAS guidelines continue to be developed for other surgical subspecialties, the literature specific to that field pertaining to the use of drains will need to be reviewed. If drains are used, early removal is advocated.

OUTCOMES/AUDIT

The success of any individual ERAS program relies not just on the initial implementation of the program, but also constant assessment of patient outcomes and program adherence. There is a clear stepwise association between adherence to the ERAS protocol and postoperative outcomes. When more than 70% of the ERAS elements are followed, symptom-defying discharge, 30-day morbidity, and readmissions are significantly decreased. It is important to have an ongoing audit process to ensure that goals for the program are being met. Similarly, regular meetings with members of the ERAS team are important to discuss areas that may need improvement.

FUTURE DIRECTIONS

Although the most robust literature regarding ERAS pertains to colonic surgery, there has been an adoption of ERAS across several subspecialties (Table 1). There are 12 surgical subspecialties with separate ERAS guidelines from the ERAS Society and several more underway. Future study should be directed at the potential benefit of ERAS when applied to traditionally high-risk surgical candidates such as the frail elderly population. For example, there is emerging interest in prehabilitation programs designed to optimize preoperative functional capacity to better prepare vulnerable patients to withstand the stress of surgery. The early data on these programs are mixed, and it is unclear whether they will offer additional benefits beyond ERAS or could be incorporated into ERAS programs. Last, the long-term benefits of participation in an ERAS program remain to be seen. Studies focusing on cancer-specific outcomes suggest that adherence to ERAS protocols may be associated with increased 5-year cancer-specific survival, but more studies of this nature are needed.

There is no doubt that implementation and maintenance of an ERAS program requires a large investment in resources, personnel, and time. However, with continued adherence, the benefits are clear and provide an opportunity to further improve the care of our surgical patients.

TABLE 1 Current ERAS Guidelines

Procedure and Topic	Year of Publication
Colonic resection	2012
Rectal resection	2012
Pancreaticoduodenectomy	2012
Cystectomy	2013
Gastric resection	2014
Anesthesia protocols	2015
Anesthesia pathophysiology	2015
Major gynecologic (parts 1–2)	2015
Bariatric surgery	2016
Liver resection	2016
Head and neck cancer surgery	2016
Breast reconstruction	2017
Hip and knee replacement	Under production
Thoracic antecolic surgery	Under production
Esophageal resection	Under production

PNEUMATOSIS INTESTINALIS AND THE IMPORTANCE FOR THE SURGEON

Paula Ferrada, MD, FACS, and Joseph Dutton, MD, FACS

Pneumatosis intestinalis (PI) is defined as gas or an air-filled cyst on or in the bowel wall. This is a radiologic sign, not a disease, and it can be associated with multiple factors ranging from bowel ischemia to a more incidental finding. For the past decade, much research has been done to determine the significance of this sign, how to distinguish clinically when PI is pathologic or benign, and when it is the optimal time to perform surgery when patients have PI secondary to ischemia.

There is a likely a difference between PI identified on plain radiographs and the occurrence of this finding via more advanced radiologic methods such as computed tomography (CT). The latter imaging modality is more detailed and therefore can more sensitively identify pathologic PI in the early stages of ischemia, when it may still not be related to transmural necrosis. For this reason, it is important to note that PI should be evaluated in a clinical context that includes associated examination and laboratory data so that negative exploration or subsequent laparotomy be avoided when possible.

This chapter presents an algorithm on how to identify patients who require an operation in the context of PI.

BENIGN PI

Benign PI presents as an incidental imaging finding without associated clinical signs/or indicative of ischemia. For example, some connective tissue disorders such as scleroderma have been associated with formation of cysts within the bowel wall not associated with ischemia. In the case of rupture of one of these cysts, the patient can even complain of abdominal pain that is self-limited, localized, and without any other clinical findings.

CLINICAL PRESENTATION OF PATHOLOGIC PI

Pathologic PI is present when there is associated ischemia. This can be associated with transmural necrosis. In pathologic PI, the patient usually presents with abdominal pain. If the abdominal pain

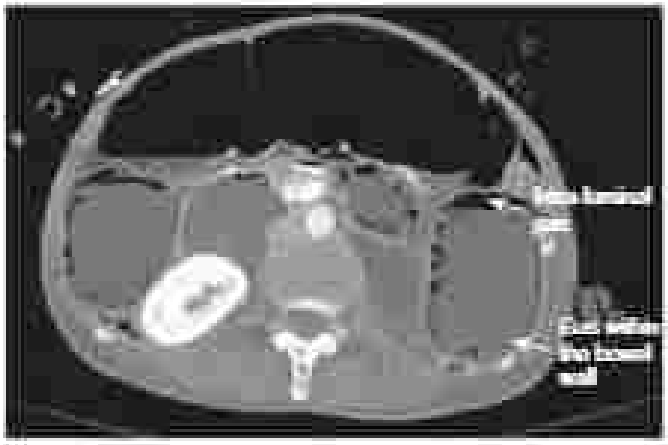

FIG. 1 Gravity assist the intraluminal gas asymmetry and the gas in the bowel wall can be distinguished because it is surrounded the entire loop of bowel.

is generalized, the parietal peritoneum is not yet inflamed. This is a reassuring sign that can signify lack of transmural involvement.

Patients with bowel ischemia have an identifiable cause in the majority of cases. These etiologies can include low-flow states in patients requiring hemodynamic support with multiple pressors, hypovolemia combined with proximal atherosclerosis, hypercoagulopathy, or other causes of shock states that compromise perfusion of the intestines in a more global fashion. Other pathologies, particularly acute thrombotic or embolic mesenteric arterial events, may result in more focal regions of ischemia. Mechanical compromise of perfusion, including strangulated small bowel obstruction, are other common etiologies. Severe compromise of venous mesenteric outflow, as can occur with significant portal venous or mesenteric venous thrombosis, can also prove a devastating cause of mesenteric ischemia.

LABORATORY FINDINGS

Patients with leukocytosis, increased lactate, and/or shock on vasopressors should be strongly considered for a surgical exploration because all of these have been shown to predict pathologic PI with transmural necrosis. Dubose et al. identified a lactate of 2.0 mmol/L or greater as the strongest independent predictor of pathologic PI on a retrospective multicenter trial. Ferraris et al. performed a prospective multicenter trial validated lactate higher than 2.0 mmol/L as a strong predictor of necrosis.

On the prospective multicenter trial, other laboratory findings such as elevated international normalized ratio and decreased hemoglobin where found to be predictive of ischemia. These are typical findings of patients that have bleeding in cases of pathologic PI secondary to necrosis of the bowel mucosa.

Other studies have examined dynamic renal function tests also to be predictive clinically, this correlates with patients that are septic and underresuscitated.

READING A CT SCAN WITH PATHOLOGIC PI

Gravity forces intraluminal air superiorly, however, gas within the bowel wall (PI) will completely surround the loop of bowel (Fig. 1). This can make it easier for the surgeon to identify PI on a CT scan.

After making the clinical diagnosis of pathologic PI, looking at the CT scan can help weigh the relative benefit of emergent surgical exploration versus initial resuscitation and physiologic optimization.

Ascites is an ominous sign if combined with pathologic PI because this is likely to be associated with third spacing and bowel inflammation secondary to transmural necrosis.

FIG. 2 Pneumatosis and portal venous air.

Small bowel pathologic PI is more likely to be associated with transmural necrosis than large bowel. The bowel, large or small, dies from the inside out. First, the mucosa becomes ischemic and necrotic. It sloughs off and, in some cases, passes as currant jelly stool. Patients then can lose blood and become anemic, with an increased international normalized ratio. Because the small bowel is thinner, it is more susceptible to these layers reaching the outer wall and perforating. The colon is thicker; therefore, the mucosa can be ischemic without showing signs of transmural necrosis on surgical exploration.

Portal venous gas is an ominous sign when associated with pathologic PI (Fig. 2). The physiopathology of portal venous gas is not well understood, although some of the theories proposed include the role of gas-forming bacteria in the portal venous circulation following necrosis and transmural dislocation of organisms from the enteric tract.

TECHNICAL RECOMMENDATIONS

Once the decision has been taken for surgical exploration, the surgeon has to keep in mind the principles of damage control resuscitation and understand the physiology of the patient.

Several key considerations are paramount to optimal outcome:

Constant communication with the anesthesiologist. If the patient is in shock, anesthetic can result in a further insult. Ensuring that further sedimentation is kept at a minimum can help the patient's perfusion.

Resuscitation as euvolemic. Hypovolemia will increase the chances of further necrosis and renal failure. Hypervolemia will result in further bowel swelling; goal directed resuscitation using methods such as arterial line waveform analysis or echocardiogram are advisable to maintain strict euvolemia.

How much to resect. These patients are usually in a state of shock. Minimizing blood loss and operative time is imperative. Consider resecting just the areas of necrosis and leaving the patient in discontinuity if necessary to allow for better resuscitation. These patients are often sick. Consider also minimizing dissection and blood loss and staying in the operating suite for the shortest necessary time.

Consideration for avoiding or delaying an anastomosis: Unless the cause of ischemia is mechanical, and it is diagnosed and treated in the operating room, consider that the bowel might still be in the process of continued ischemia. This can be disastrous for an anastomosis that can fail and place the patient at risk for a second source for intraabdominal sepsis.

Liver

Cystic Disease of the Liver

Victor M. Zaydfudim, MD, MPH, and Reid B. [illegible], M[illegible]

L[illegible] [illegible] and [illegible] The [illegible] majority [illegible] [illegible] in the general [illegible] [illegible] [illegible] [illegible] [illegible] and [illegible] in patients with autosomal dominant polycystic kidney disease. Asymptomatic, simple, or polycystic liver cysts do not require intervention, while management in symptomatic cysts depends on patient presentation, extent of cystic disease, and available center-specific treatment options. Patients with polycystic liver disease should be evaluated and treated at experienced referral centers using a multidisciplinary approach. Neoplastic liver disease, including cystadenoma, cystadenocarcinoma, and intraductal papillary mucinous neoplasm of the bile duct [illegible], is also rare. The carcinogenesis pathway between cystadenoma and cystadenocarcinoma is poorly understood. The decision to proceed with resection or surveillance in cystadenoma is multifactorial and depends on patient and imaging specific factors. [illegible] has a high risk of malignant transformation or malignancy on presentation and resection is recommended. Other etiologies of cystic disease are rare and are frequently cystic primary or secondary malignancies, such as cystic-appearing hepatocellular carcinoma, cystic-appearing primary liver sarcoma, cystic colorectal, neuroendocrine or other metastases with features masquerading as simple cysts. [illegible] essential considerations and diagnoses for radiographic findings of liver cysts [illegible] are summarized in [illegible]. Appropriate treatment depends on the following: [illegible] making deliberate and correct diagnosis, [illegible] if symptomatic, determining whether symptoms are related to the cyst, [illegible] and [illegible] selecting the best individualized treatment option for each patient.

[illegible]

[illegible] genetic [illegible]

A simple liver cyst is the most common liver parenchymal imaging abnormality present in up to [illegible] of the population. The vast majority [illegible] of patients with simple cysts are asymptomatic and do not require treatment. The cysts are spherical or ovoid with a smooth cyst wall without radiographic features such as thickening, nodularity, or asymmetry. Cysts can range in size from a few millimeters to greater than [illegible] centimeters. The cyst wall is lined by a smooth single layer cuboidal or columnar epithelium and most of the cysts do not communicate directly with the biliary system. Cyst fluid is often simple serous, and straw colored but can be brown in patients with prior intracystic hemorrhage or bilious in patients with intracystic biliary communication. While rare, simple cysts can become infected particularly in patients with prior biliary tract or cyst instrumentation and/or significant comorbid conditions (e.g., poorly controlled diabetes, congestive heart failure, and others).

Ultrasonography (US) is diagnostic in most patients with simple cysts. Typical sonographic characteristics include a sharply demarcated well circumscribed lesion with a thin, almost imperceptible wall, a homogeneous anechoic pattern typical for simple fluid, and posterior acoustic enhancement (Fig. 1A). Atypical cyst wall characteristics (wall asymmetry or thickening, mural nodules) are concerning for a neoplastic diagnosis. Echoic material within the cyst fluid may suggest intracystic hemorrhage but this ultrasonographic finding should be corroborated by clinical presentation or with cross-sectional imaging.

Liver cysts are also frequent incidental findings during computed tomography (CT) and magnetic resonance imaging (MRI). The typical features on contrast-enhanced CT are similar to those found on ultrasound. Simple cysts have a well-defined, thin, almost imperceptible cyst wall. The cyst is filled with a homogeneous, hypoattenuated fluid with low Hounsfield units similar to water (Fig. 1B). There is no wall enhancement on either pre- or post-contrast images. Small lesions (<[illegible] cm) are not well characterized with CT and are better evaluated with US or MRI. The accuracy of MRI for diagnosing cystic lesions is very high. In addition to the well-defined thin cyst wall without worrisome features, simple cysts demonstrate intracystic fluid signal intensity that is very low on T1-weighted sequences and very high on T2-weighted sequences. When MRI features confirm the diagnosis of a simple cyst, additional studies and follow-up are not required in the asymptomatic patient.

An advantage of MRI over US and CT, when prototypical features of a simple cyst are not present, is the ability to characterize the fluid. Fluid signal characteristics different than water suggest hemorrhagic products, proteinaceous/mucinous fluid, or the presence of subtle mural nodules/projections. Similar to US or CT, an enhancing cyst wall or solid element on MRI is concerning for a neoplasm.

Despite adequate imaging, diagnostic challenges can arise. By definition, simple cysts are just that, simple. When a cyst is other than simple, by definition complex, this raises the concern for a neoplastic process. However, diagnostic dilemmas can be seen when a simple cyst has lobulated borders, for instance when the cyst expands around a hard intrahepatic structure such as a portal pedicle. Similarly, two simple cysts that are adjacent can share a cyst wall giving the appearance of a complex cyst with an internal septum. These radiographic findings can be challenging to distinguish from a true complex cyst. Finally, any findings of ductal involvement, such as intrahepatic ductal dilatation or mass effect on the intrahepatic or extrahepatic biliary system, also raise concern for neoplasia.

Management

Patients with incidental findings diagnostic for a simple liver cyst do not require intervention or surveillance. Symptomatic cysts are rare and more typical in patients with large cysts (≥ 10 cm or larger) particularly if there is stretching of Glisson's capsule. Cyst growth is typically gradual and vague symptoms such as abdominal fullness, early satiety, dull pain, and discomfort are more common than acute pain syndromes. In patients with small cysts and in those in whom imaging findings are discordant with subjective symptoms, other potential etiologies for pain including biliary, pancreatic, gastrointestinal, renal, musculoskeletal, and pulmonary sources should be considered. Rarely, patients will have hemorrhage into a simple cyst. This can cause acute pain and rapid enlargement of the cyst. If a preexisting simple cyst has been seen on prior imaging, the diagnosis of hemorrhage into a simple cyst typically can be made on follow-up imaging. However, if this is the initial presentation, distinguishing a hemorrhagic simple cyst from a complex one is difficult.

Simple cyst aspiration is rarely useful. The diagnosis of a simple cyst is established without fluid analysis, as patients with worrisome radiographic features fall into the complex category and should be treated with a presumptive diagnosis of a neoplasm. Diagnostic aspiration can be considered in patients with discordant imaging findings and symptoms; however, it is unclear how often subjective improvement in symptoms after cyst aspiration is related to a placebo effect. Despite this uncertainty, we have found this useful for decision making in some patients. Therapeutic aspiration without sclerosis does not provide adequate, durable treatment.

TABLE 1 Differential Diagnosis of Liver Cysts

Benign liver cysts:	Simple cyst Polycystic liver disease
Infectious/inflammatory	Pyogenic abscess Amebic abscess Echinococcal disease
Neoplastic liver cysts	Cystadenoma Cystadenocarcinoma Intraductal papillary mucinous neoplasm of the bile duct Primary liver cancer (e.g., cystic hepatocellular carcinoma, cystic primary liver sarcoma) Cystic metastases to the liver (e.g., primary colorectal, neuroendocrine, gastrointestinal stromal tumor, squamous cell, and others) Dilated hepatic foregut cyst
Miscellaneous	Hepatic pseudocyst Traumatic cysts

Sclerotherapy

Image-guided cyst aspiration and sclerosis can provide durable cyst drainage and resolution. US-guided sclerotherapy is a multistep process involving cyst access, insertion of a drainage catheter with partial cyst decompression, contrast cystography, and instillation of sclerosant (such as 95% ethanol, minocycline, tetracycline, hypertonic saline, or others). Sclerosing agents destroy the lining epithelium, preventing further fluid secretion, and therefore recirculation, into the cyst. For large cysts multiple sequential sclerosing treatments might be required. Current success for sclerosis of solitary liver cyst exceeds 85%. Aspiration and sclerosis, however, diminishes for very large cysts; the exact cut off for "very large cyst" (0.1, vol.2 [...n>3) is debatable. Aspiration of bilious cyst fluid and/or communication with the biliary system identified during contrast cystography precludes safe cyst sclerotherapy.

Conclusion

Laparoscopic cyst fenestration provides durable treatment for patients with symptomatic simple liver cysts. Large liver cysts compress and displace adjacent hepatic parenchyma with distortion of major vascular and biliary structures. Polycystic hepatic parenchyma is frequently

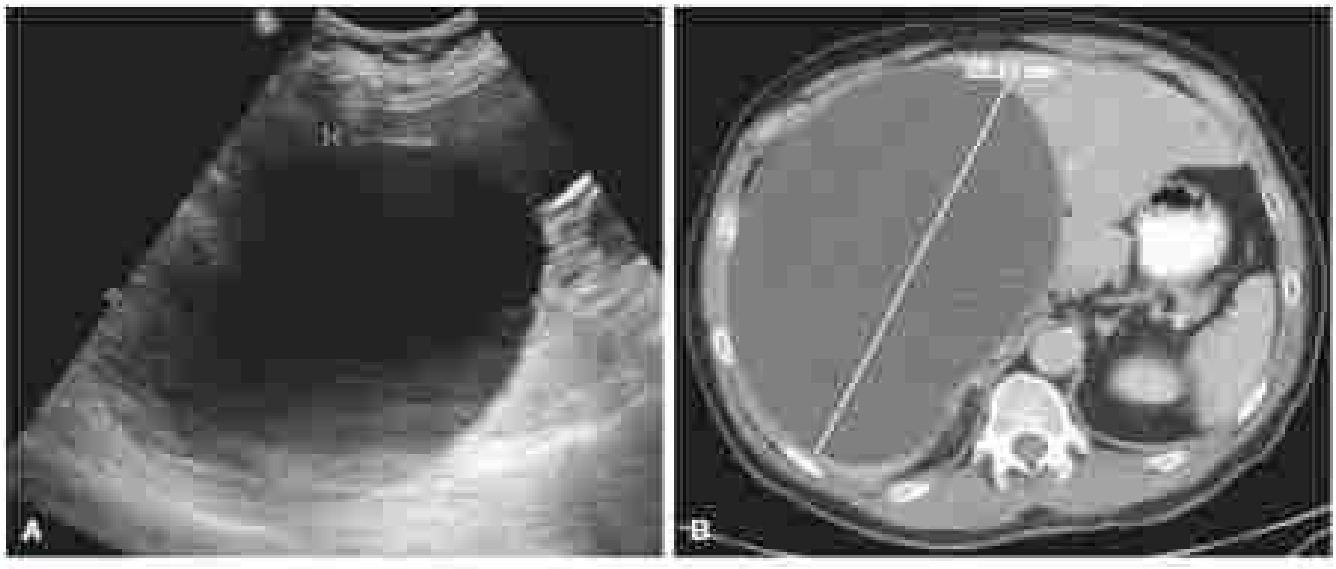

FIG. 1 (A) Ultrasound image findings consistent simple [illegible] (B) [illegible]

asymptomatic and both pericholangitis as well as major hepatic veins can be adjacent to the intrahepatic portion of cyst wall. As such, the goal of fenestration is to remove the portion of the cyst wall that is largely extrahepatic without injury to the intrahepatic portion of cyst wall, which may abut major vessels and bile ducts. First, the cyst is entered and aspirated to facilitate dissection and exposure. Next, the extrahepatic portion of the cyst wall is excised with an endovascular stapler or energy device (Fig. 2). Bile duct radicles can be present along the transection line, thus inspection following cyst wall resection for a bile leak is important. If present, this should be oversewn to avoid a postoperative bile leak. Following completion of cyst wall resection, the intrahepatic portion of the cyst wall is ablated to reduce secretions by the remaining epithelium. Ablation is safely and effectively performed with the argon beam coagulator, which coagulates the remaining cyst epithelium without penetration through the cyst wall into underlying structures. If bile is encountered during initial cyst entry and aspiration, communication with a biliary radicle along the intrahepatic portion of cyst wall is likely. The bile duct orifice should be identified and suture ligated to prevent a postoperative bile leak. At the completion of fenestration and ablation, an omental pedicle can be used to fill the space, although its benefit is not supported by data. Intraperitoneal drainage is not necessary. The resected cyst wall should be submitted for frozen and permanent pathologic examination to rule out a neoplastic cyst. If pathologic evaluation demonstrates features of a neoplastic cyst, complete resection of the cyst is appropriate and recommended.

FIG. 2. Laparoscopic cyst fenestration. The cyst is entered and aspirated to facilitate dissection and exposure. The extrahepatic portion of the cyst wall is excised with an endovascular stapler (shown), or energy device. The intrahepatic portion of the cyst wall is ablated with the argon beam coagulator to reduce secretions by the remaining epithelium.

Similar to current results with sclerotherapy, long-term success for fenestration of simple liver cysts exceeds 90%. Choice of initial approach (fenestration vs. sclerotherapy) depends on center experience and patient preference. Sclerotherapy is particularly useful for patients with significant comorbidity and high operative risk as well as for patients with large volume cysts located deep within the hepatic parenchyma. Fenestration is the preferred approach with very large cysts that can be accessed peripherally as well as in patients with biliary communication. In general, simple cysts do not require consideration of formal hepatic resection.

Polycystic Liver Disease

Phenotypic Features and Diagnostic Evaluation

Autosomal dominant polycystic liver disease (PLD) most frequently occurs in patients with autosomal dominant polycystic kidney disease (ADPKD) but also can develop in patients without ADPKD as a separate genotypic entity. While PLD is the most frequent extrarenal manifestation of cystic disease in patients with ADPKD, cystic disease of the kidneys is the most frequent extrahepatic manifestation of patients with PLD not associated with ADPKD. Histologic features of liver cysts associated with PLD are similar to simple cysts. Phenotypic and radiographic findings are individual, all and can vary from numerous cysts to innumerable cysts. Phenotypic manifestations of individual patients with PLD are dependent on second hit somatic mutations (in addition to the inherited autosomal dominant predisposition), which results in significant heterogeneity of these cystic diseases.

Most patients with PLD are asymptomatic and do not require treatment. When symptoms develop, they usually result from the mass effect of the accompanying hepatomegaly. Typical symptoms include abdominal fullness, early satiety, and pain, leading to long-term effects on the patient's quality of life. The other common complications are infection, frequently a result of cyst or biliary instrumentation or immunosuppression in kidney transplant recipients, and hemorrhage into a cyst(s). Complications of rupture or symptomatic vascular compression are very rare. Intrinsic hepatic function is preserved regardless of cystic extent or hepatomegaly.

Adequate PLD cyst characterization often requires contrast-enhanced CT or MRI. Imaging evaluation includes not only size and location of the cysts but, importantly, the extent of hepatic parenchymal preservation and vascular involvement. A number of classification systems have been proposed to assist in management of patients with PLD. The 2009 Mayo Clinic classification is particularly useful as it categorizes patients based on presence of symptoms, cyst or extent of normal liver parenchymal preservation, and the patency of hepatic venous outflow and hepatic venous outflow (Table 2 and Fig. 3). This classification system allows for individual all treatment decision making based on patient- and disease-specific factors. Patients with PLD should be managed with a multidisciplinary approach to determine the most appropriate operative or nonoperative treatment strategy. Other extrahepatic manifestations of ADPKD, in particular

TABLE 2 2009 Mayo Clinic Classification of Polycystic Liver Disease

Type	Symptoms	Cyst Characteristics	Sectors With Relatively Normal Liver Parenchyma	Hepatic Venous Outflow Obstruction or Portal Hypertension
A	Absent or mild	Any	Any	Any
B	Moderate/severe	Limited # of large cysts	≥2 sectors	Absent
C	Severe or moderate	Any	≤1 sector	Absent
D	Severe or moderate	Any	Any	Present

Modified with permission from Gigot JF, Jadoul P, Que F, et al. Adult polycystic disease with massive hepatomegaly: preoperative embolization of liver cysts. Ann Surg. 1997;225(3):286–294.

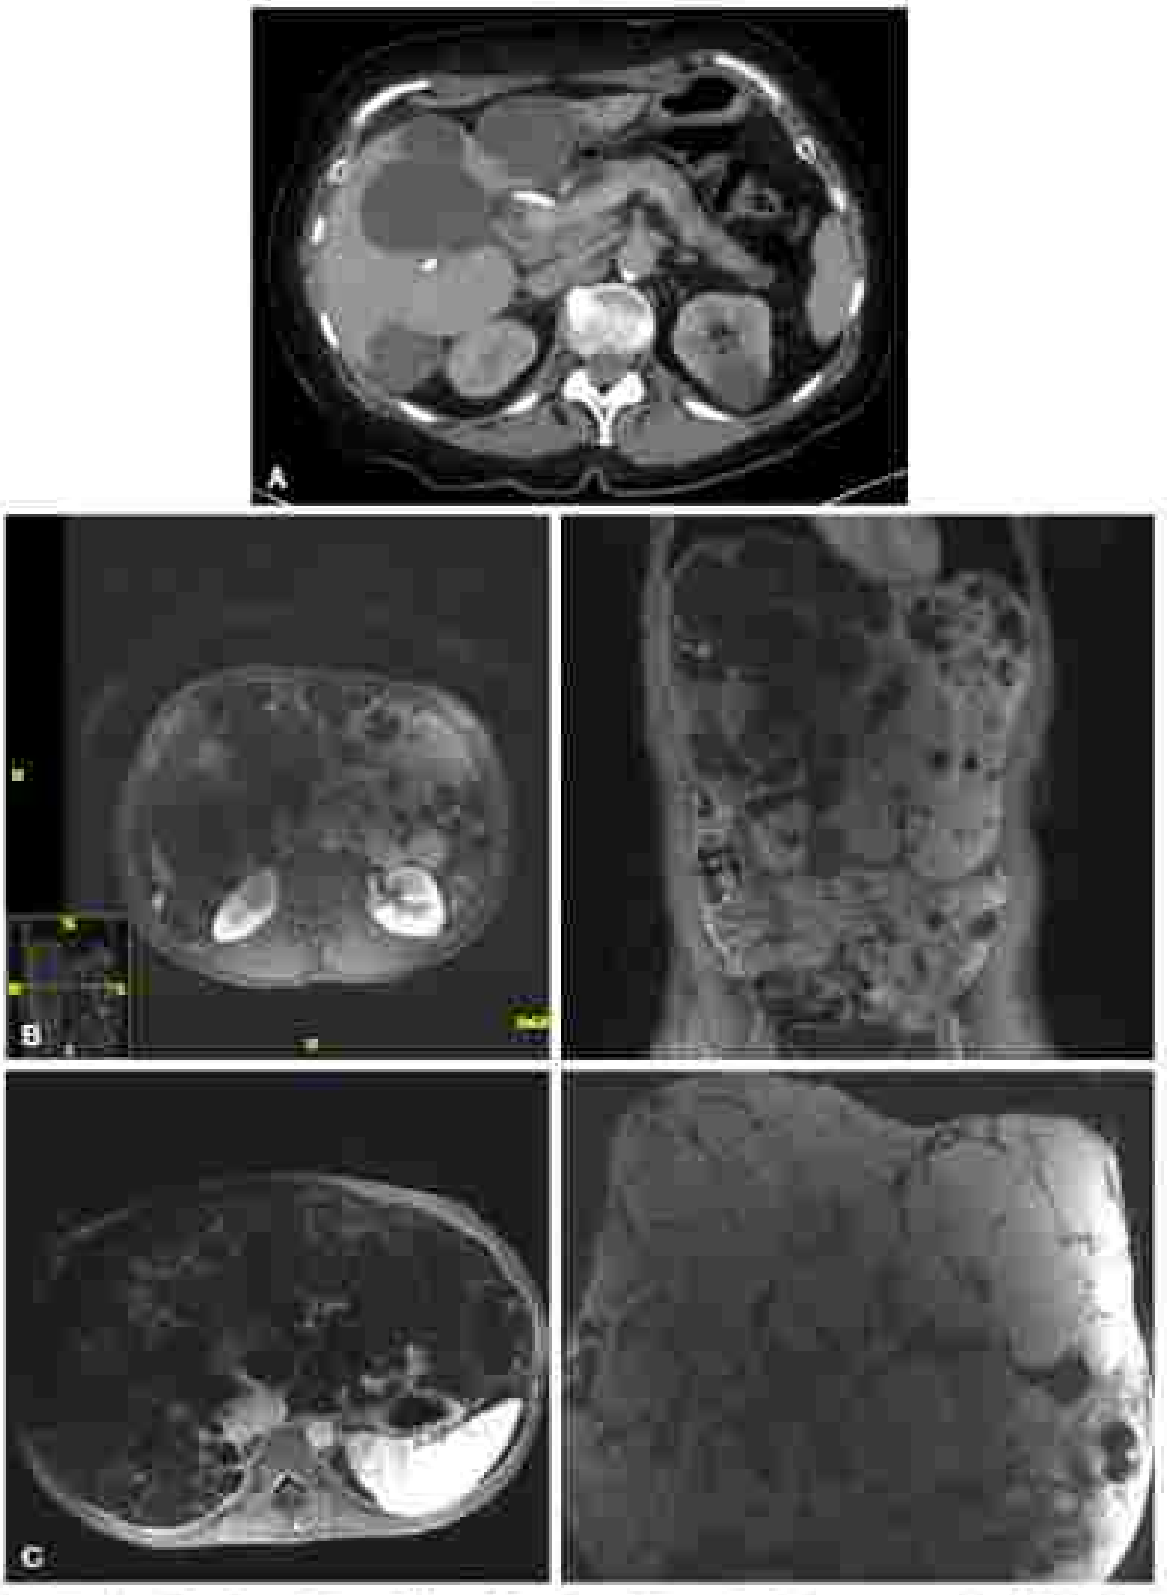

FIG. 3. Patients with polycystic liver disease (PLD) type A (A), type C (B), and type D (C) cyst distribution. Note preservation of left hepatic vein and relative sparing of left lobe hepatic parenchyma in a patient with type C PLD (B). Presence of symptoms consist of hepatic parenchymal and vascular problems (as summarized in Table 2) almost uncommon combination. Patients with PLD should be managed with a multidisciplinary approach to maximize the most appropriate treatment strategy. (*Left to right*) Courtesy Dr Vasiliki Rahaniotis.

evaluation and treatment of cerebral aneurysms, should be performed prior to considering liver directed therapy.

Management

Patients with type A cysts typically require no treatment or are considered for medical management. Use of long acting release octreotide decreases the total liver volume in patients with PLD and improves health related quality of life. Use of mTOR inhibitors, as monotherapy or combined with somatostatin analogues, have not been shown to improve outcomes when compared to long acting octreotide. To date, long acting release octreotide is the preferred medical management supported by published data. Select patients with PLD develop symptoms either from a dominant, infected, or hemorrhagic cyst. If such a cyst is identified, percutaneous cyst aspiration with subsequent sclerosis should be considered.

Patients with type B cysts should be considered for fenestration. In general, these patients have a limited number of large cysts with preservation of over half of the normal hepatic parenchyma. Fenestration without major parenchymal resection allows cyst unroofing and epithelial ablation. Fenestration of peripheral cysts usually can be achieved safely with a laparoscopic approach. However, despite large cyst volume and a relatively small number of cysts, an open rather than laparoscopic approach is favored if deep intraparenchymal cysts are selected for fenestration. Major vascular and biliary structures such as segmental portal pedicles or large hepatic vein branches can occupy the septa between neighboring cyst walls and be prone to injury. This requires meticulous division of septa between adjacent intrahepatic cysts to maintain hemostasis and bile stasis, avoiding significant bleeding, bile leak, or inadequate drainage of symptomatic disease.

Patients with type C cysts can be considered for anatomic hemihepatectomy of the dominantly affected liver lobe and concomitant fenestration of cysts in the remaining parenchyma. A clear understanding of the vascular anatomy, particularly hepatic inflow and outflow must be established by preoperative imaging to allow preservation of the liver remnant vasculature during the course of the operation (Fig. 2e). Due to the extent of cystic disease, parenchymal transection largely is performed through cysts and intracystic septa. Similar technical caveats discussed for type B cyst fenestration apply. Technical challenges in these patients result from the grossly distorted anatomy making identification and verification of vascular and biliary structures difficult. Postoperative complications such as ascites with or without venous outflow obstruction, bile leaks, and bleeding are more common than after fenestration alone. Hence, liver resection for type C cysts should be undertaken at centers with technical and multidisciplinary expertise.

Patients with type D cysts can be considered for liver transplantation. It is rare for a patient with PLD to have biochemical liver disease, thus even with massive cysts and hepatomegaly the vast majority of patients do not qualify for a deceased donor liver allocation under the current Model for End Stage Liver Disease (MELD) system. Recertification for select patients is possible with MELD exception point allocation, which is at the discretion of regional Organ Procurement and Transplantation Network review boards. Combined liver and kidney transplantation has been used in patients with ADPKD with both end stage renal disease and severe symptomatic PLD. Previous operative management of cystic liver disease increases morbidity of liver transplantation emphasizing the importance of a multidisciplinary approach and centralization of care for patients with PLD.

Cystic Hepatobiliary Neoplasms: Cystadenoma, Cystadenocarcinoma, Intraductal Papillary Mucinous Neoplasm of the Bile Duct

Phenotypic Features and Diagnostic Evaluation

Hepatobiliary cystadenoma is the most common cystic neoplasm of the liver with phenotypic similarity to pancreatic mucinous cystic neoplasms (MCN). Approximately 80% to 95% of all resected cystadenomas contain ovarian type stroma similar to MCN; patients with cystadenoma with ovarian type stroma are women. Cystadenoma without ovarian type stroma can occur in both men and women. Unlike simple cysts, the epithelium of cystadenoma consists of either columnar or cuboidal glandular lining with papillary projections and crypt like invaginations. Cystadenoma, with and without ovarian type stroma, can contain epithelial dysplasia, atypia, or metaplasia and both are considered to have neoplastic potential. The neoplastic cyst is surrounded by a dense pseudocapsule that pushes and displaces adjacent hepatic parenchyma allowing for enucleation. Typically, cystadenomas are at least partly intrahepatic and solitary but can be multilobulated. Usually, no communication exists between the cyst cavity and biliary system; however, bile ducts can be directly abutting the cyst pseudocapsule resulting in the possibility of fistulization. The true incidence of cystadenoma is unknown. Diagnosis cannot be confirmed without resection and there is likely an imaging overlap between a large proportion of patients with simple cysts and those with small cystadenomas without worrisome features. It is not uncommon to resect or biopsy a small incidental cyst during an unrelated liver directed operation and establish an incidental diagnosis of cystadenoma.

Cystadenocarcinoma is very rare and comprises less than 1% of primary hepatic malignancies. In a recent multiinstitutional study spanning 30 years, approximately 10% of patients with worrisome hepatobiliary cystic neoplasms who were selected for resection had cystadenocarcinoma and not cystadenoma. Factors associated with neoplastic progression to cystadenocarcinoma are poorly understood. Two possible pathways to malignancy are a time dependent malignant transformation from cystadenoma to cystadenocarcinoma and/or a different initial mutational composition that predisposes some cystic neoplasms to progress to carcinoma while others do not grow or transform. While there are case reports of cyst growth, progression of worrisome imaging findings including cyst complexity, mural nodule development, and/or wall thickening and enhancement, longitudinal studies evaluating a cohort of patients with biliary cystadenoma that allow an estimate of growth rate and the risk of malignant degeneration are not available.

Intraductal papillary mucinous neoplasm of the bile duct (IPMN-B) is a solid mucin producing neoplasm that originates within the biliary tract of the hepatic hilus or intrahepatic bile ducts. Past descriptions included papillary cholangiocarcinoma and intraductal peripheral cholangiocarcinoma. IPMN-Bs are histologically and phenotypically similar to pancreatic IPMN. Papillary growth and mucin formation results in upstream biliary dilatation of the affected lobar or sectoral biliary system and can cause cystic dilatation of the peripheral bile duct to resemble a large neoplastic cyst. Unlike cystadenoma, IPMN-Bs demonstrate direct communication with the biliary system since it is involved by the neoplasm. Multiinstitutional resection series demonstrate a significant proportion (up to 90%) of high-grade dysplasia and invasive carcinoma in patients with IPMN-B and resection should be considered for all patients with this neoplasm.

Diagnosis of cystadenoma rather than simple cyst is suspected based on imaging. Both ultrasonography and contrasted cross-sectional imaging (CT and/or MRI) demonstrate findings typical for a complex cyst (Fig. 4). US findings concerning for a neoplastic cyst include internal septations, mural nodules or projections, intracystic debris, and/or a thick cyst wall. CT findings are similar with additional findings including Hounsfield units denser than water, fluid fluid levels, enhancing mural nodules or septations within the cyst, and/or an enhancing cyst wall. Advantages of MRI over US and CT is the ability to definitively characterize small cysts and intracystic fluid features. Fluid signal characteristics different than water suggest hemorrhagic products, proteinaceous/mucinous fluid, or the presence of subtle mural nodules/projections. Similar to CT, an enhancing cyst wall or solid element is concerning for a cystic neoplasm. The most common imaging findings in patients with cystadenoma include multilocular architecture and/or internal septations; these imaging findings are present in the vast majority of patients. Complex cyst wall features including nodularity and intracystic solid projections are less common and are concerning for malignant transformation.

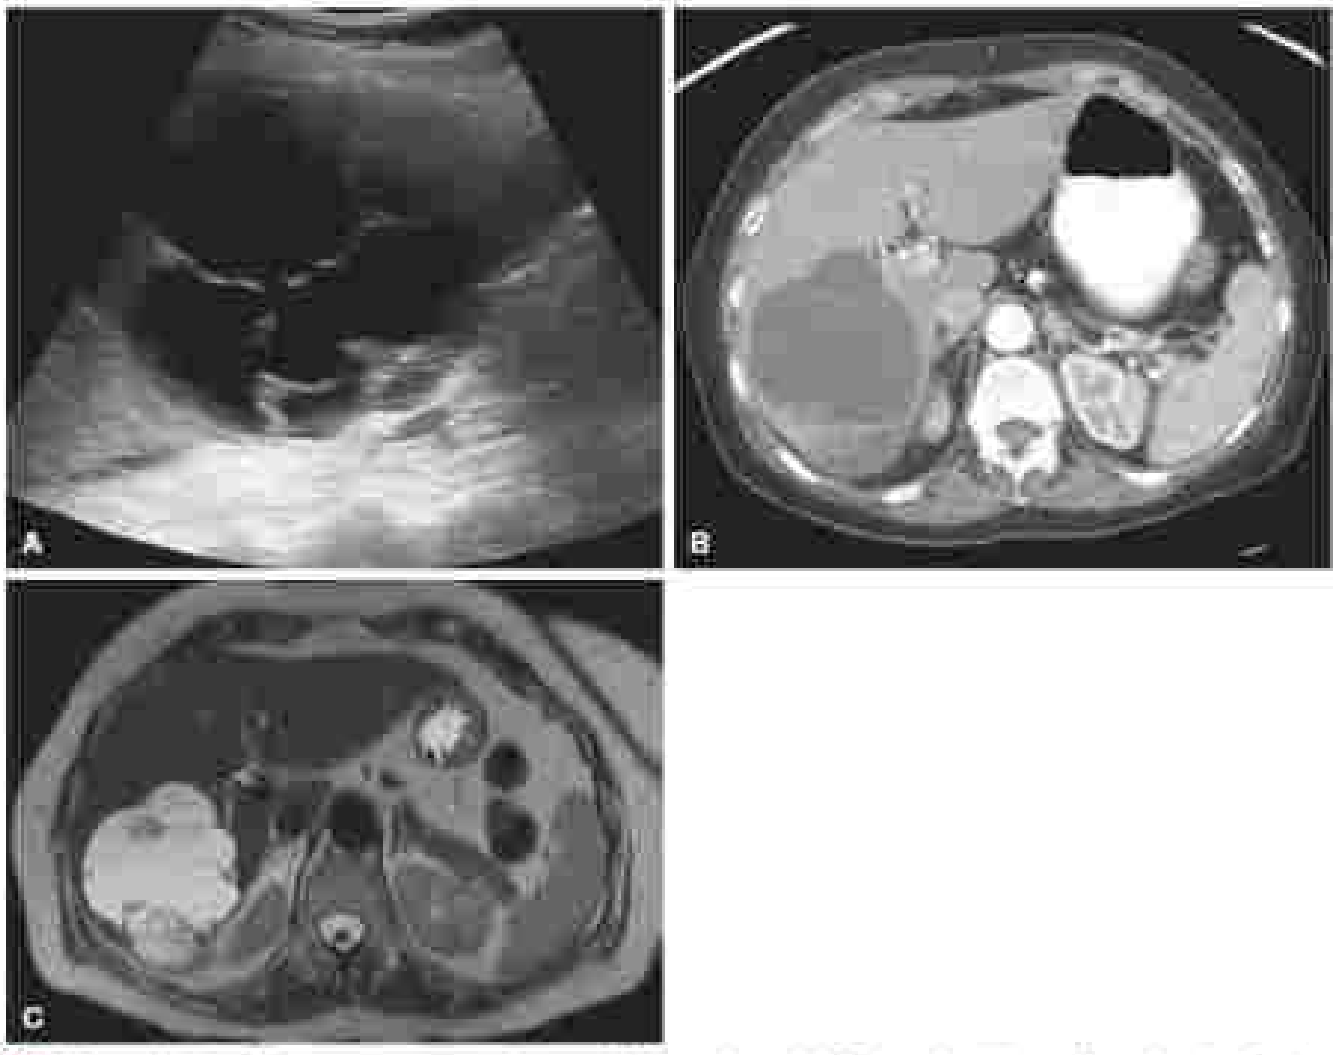

FIG. 4. Ultrasound (A) image findings consistent with complex cyst typical for cystadenoma including internal septations and hyperechoic projections and debris. Corresponding computed tomography (B) and magnetic resonance (C) images demonstrating multicystic intraductal complexity.

While no specific imaging findings are diagnostic for cystadenocarcinoma, increasing complexity of the cyst with soft tissue components including asymmetrical wall thickening with a solid component, a mural nodule, and/or papillary projections are concerning for malignant degeneration particularly if comparisons to previous imaging are available and these findings are new.

IPMN-B by definition involves the biliary system and communication with the bile ducts is frequently evident on imaging. Patients with intraductal papillary neoplasm only within the main biliary system have imaging findings consistent with pure biliary cholangiocarcinoma (Fig. 5). Patients with a cystic component from upstream biliary obstruction develop cystic dilatation with radiographic communication to the central bile ducts (Fig. 6). Endoscopic retrograde cholangiography can be useful in evaluation of IPMN-B. Papillary neoplasms can be directly visualized with cholangioscopy and the macroscopic neoplastic extent can be defined with cholangiography.

Cyst fluid analysis similar to fine needle aspiration of neoplastic cysts rarely assist with diagnosis or impact management. Carcinogenic antigen 19-9 (CA19-9) is expressed by normal biliary epithelium and is frequently elevated in patients with both simple cysts and neoplastic cysts. No specific value has been shown to discriminate between simple cysts and cystadenoma or between cystadenoma and cystadenocarcinoma. Other tumor markers are similarly neither sensitive nor specific. Biopsy of high risk features such as complex cyst wall components could be considered but is unlikely to change management in a patient considered for resection.

Management

The majority of patients with cystadenoma have imaging demonstrating a multilocular cyst wall or thin intracystic septations without worrisome cyst wall complexity. Management of these patients is controversial. The chance of malignancy in patients with these imaging findings is low; cross-sectional studies report the proportion of carcinoma in patients with cystic neoplasms selected for resection ranges between 2% and 10%. Long-term surveillance studies are lacking, but many patients with cystadenoma without worrisome features can be observed. Surveillance can be particularly prudent if the patient's age or comorbidity increases the risk of resection. If surveillance is selected for patients who would be candidates for resection, pragmatic adherence to a surveillance program is important. A number of case reports highlight the possibility of cyst growth and malignant degeneration over long (>10 years) surveillance intervals. Consequently, a recommended surveillance duration is undefined.

Among patients with cystadenoma selected for resection, enucleation is an appropriate and the most commonly used operative strategy. The plane between the cyst pseudocapsule and

FIG. 5 Magnetic resonance cholangiography demonstrating a soft tissue filling defect at the bile bifurcation (A, arrow) typical for patients with intraductal only IPMN-B and corresponding neoplasm after resection (B).

FIG. 6 Magnetic resonance imaging demonstrating IPMN-B with both cystic component and involvement of left hepatic duct. Left hepatectomy is indicated for resection of both left ductal and cystic components.

adjacent hepatic parenchyma is entered and pericystic dissection can be completed in a fairly avascular plane. Vascular and biliary structures frequently abut the intrahepatic portion of the pseudocapsule and, similar to the mass effect seen with simple cysts, both portobiliary pedicles as well as major hepatic veins can be distorted by cystadenoma. Pericystic dissection should aim at removing the cyst with preservation of major surrounding structures. Structures entering the pseudocapsule or densely adherent to it can be ligated. If a fistula with the biliary system is encountered, the intrahepatic radicles should be repaired or ligated to avoid a bile leak. Formal hepatic resection is rarely required for peripheral cystadenoma, but may be necessary for deeper intrahepatic cystadenomas. Since, by definition, the aim of cystadenoma resection is to eliminate the risk of malignancy or malignant transformation, cyst fenestration is contraindicated.

Patients with complex cyst wall features concerning for malignancy are considered for formal resection. If there is concern for malignancy, liver resection of both the cystic neoplasm and surrounding parenchyma to ensure a margin negative resection is performed. Similarly, patients with IPMN-B are treated by resection. Resection for IPMN-B depends on the location and extent of papillary portion of the neoplasm and the duct involved; resection should not be limited to the cystic component alone. Resections for main duct IPMN-B can include pancreaticoduodenectomy, common bile duct complex resection, or a combined hepatectomy and bile duct complex resection with reconstruction (just like cholangiocarcinoma type operations). Resection of intrahepatic IPMN-B typically requires anatomic hepatectomy to include both the biliary ductal and cystic components of the neoplasm. Resection of the cystic component without the intraductal component can result in tumor recurrence.

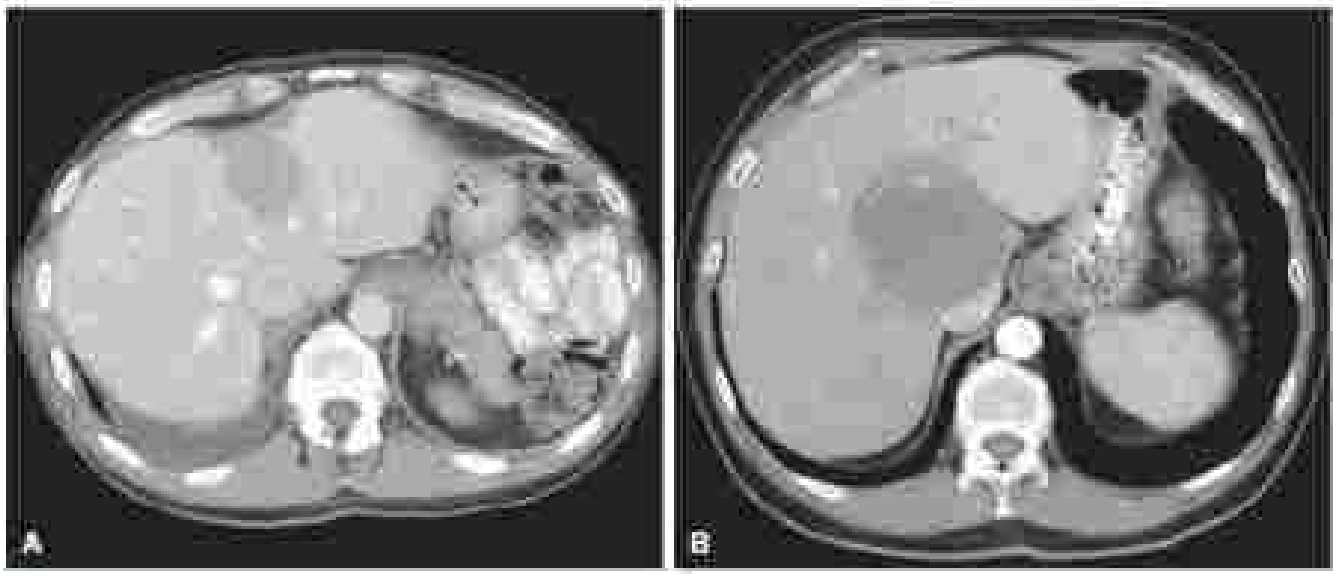

FIG. 3. Patients with malignancy can present with imaging characteristics that can be misinterpreted as cystic disease; both clinical history and imaging characteristics such as capsular retraction (A, patient with metastatic squamous cell cancer) or hepatic wall enhancement (B, patient with metastatic gastrointestinal stromal tumor) should raise suspicion of malignancy.

Cystic Malignancies

Both primary liver cancer (such as hepatocellular carcinoma and primary liver sarcoma) as well as metastases to the liver from primary colorectal, neuroendocrine, squamous cell, gastrointestinal stromal tumor, and others can demonstrate cystic features. The cystic wall of these lesions is complex, and they are distinguishable in most cases by any imaging modality from a simple cyst (Fig. 3). The combination of clinical history and imaging findings should raise suspicion for a cystic malignancy in patients with a personal history of cancer. Benign cysts typically do not grow (or do so slowly) and do not contain evolving and/or worrisome intracystic components during cancer surveillance. Persistent diagnostic equipoise between cystic malignancy and a simple liver cyst after review of cross sectional imaging is rare but can be resolved by biopsy. If the diagnosis remains elusive and the patient is a candidate for resection of a hepatic primary malignancy or metastatic disease, treatment planning should proceed as if these were malignant and not simple cysts, in other words, by a formal hepatic resection.

Miscellaneous Cysts

Biliary Hepatic Foregut Cysts

Ciliated hepatic foregut cysts (CHFCs) are very rare. CHFCs are typically located in segment four and abut the gallbladder. Histologic diagnosis is confirmed by presence of ciliated, pseudostratified, columnar epithelium covered by three layers of connective tissue, smooth muscle, and a fibrous capsule. The majority of patients with resected CHFCs present incidentally; symptoms, if present, are similar to patients with other cystic diseases of the liver. Patients with imaging findings atypical for a simple cyst or symptoms have been selected for resection. If resection is pursued, enucleation rather than fenestration should be performed. To date, five cases of squamous cell carcinoma presumably as a result of malignant transformation from squamous metaplasia within CHFCs have been reported.

Traumatic Cysts

Traumatic cysts are a rare complication of prior hepatic trauma or invasive procedures. They may result from resolving hematoma or a contained bile leak (biloma). Consequently, these are pseudocysts and lack an epithelial lining. The imaging appearance is similar to simple cysts, except a fluid–fluid level may be present if blood products are present in the cyst. The majority are incidental and do not require treatment. Rare patients with a symptomatic cyst (usually from mass effect) are treated similar to simple hepatic cysts. Percutaneous drainage can be attempted. If a biloma is identified, percutaneous drainage and endobiliary decompression will frequently lead to resolution. If cyst resolution cannot be achieved with percutaneous techniques, either laparoscopic or open cyst fenestration is reasonable. Similar to the operative management of simple cysts, if a biloma is present, identification, and suture ligation, of the biliary radicle should be performed to prevent bile leak or recurrence.

Hepatic Pseudocysts

Also rare, hepatic pseudocysts can develop during an episode of acute pancreatitis. These cysts have no epithelial lining. They are thought to occur as a result of fluid dissection into the hepatoduodenal ligament and the leaves of the gastrohepatic ligament. No therapy is necessary, as these typically disappear following resolution of the pancreatitis.

MANAGEMENT OF ECHINOCOCCAL CYST DISEASE OF THE LIVER

[illegible] and D[illegible], MD, MRA, FAC[illegible], and Ibrahim Yakubu, MD, PhD

Human echinococcosis is a zoonosis caused by larval forms of tapeworms, cestodes found in the small bowel of carnivores. Hydatid cysts are most commonly caused by two species in humans, *E. granulosus* and *E. multilocularis*, which cause cystic and alveolar echinococcosis, respectively. The life cycle of the echinococcal parasite involves a definitive host (a dog or a cat) and an intermediate host (commonly a sheep). Humans become accidental intermediate hosts. Hence, the disease is endemic in sheep-grazing areas of the world such as Mediterranean, the Middle East, South America, Australia, and East Africa.

EPIDEMIOLOGY

Cystic Echinococcosis

Cystic echinococcosis is caused by the larvae of parasite *E. granulosus* (Table 1). The hydatid cyst is mainly located in the liver (60%) or lungs (30%), but occasionally also found in the kidney, spleen, and brain in about 2% of cases. The oncospheres (the larvae) transform into the metacestodes, which implant into the organ and grow into cysts with germinal, outer, and laminated layers. Echinococcal cysts are surrounded by pericyst (adventitia) from the peripancreatic tissue that surrounds the larval endocyst. The endocyst is composed of an outer acellular layer and an inner germinal layer that forms protoscolices and host capsules (Fig. 1). Protoscolices are infectious agents that develop into the adult tapeworm. A significant amount of these scolices floats freely in the hydatid fluid forming the so-called hydatid sand. The hydatid liquid is alkaline, with containing Na, K, Cl, and CO_3, similar to that of the host's serum.

Alveolar Echinococcosis

Echinococcus multilocularis is a small cestode (0.5–4.5 mm) that lives in wild carnivores (sylvatic cycle) or domestic dogs and cats (synanthropic cycle) (Table 1). The adult tapeworm reside in the small bowel of the definitive hosts, where gravid proglottids release eggs that are passed in the feces. Humans, aberrant intermediate hosts, become infected by ingestion of embryonated eggs. It can happen through direct contact with the definitive host or through indirect contamination of food or water. The parasite travels through the blood and settles in the liver in 70% of cases by developing an alveolar structure made up by several vesicles with the diameter range from less than 1 mm up to 15 to 20 cm. Each vesicle has a wall consisting of a germinal and a laminated layer. These lesions may be complicated by central necrosis, producing a cavity or pseudocyst after it liquefies. This disease is characteristic to the Northern Hemisphere, with the main endemic regions being Central Europe, Russia, Turkey, China, Japan, and North America. This form of disease clinically corresponds to a slow growing liver cancer with 75% of lesions located in the liver primarily. Alveolar echinococcosis (AE) is fatal in the absence of appropriate treatment, with 5 year mortality reaching 70% and 10 year mortality rate reaching 90% in untreated patients.

PRESENTATION AND DIAGNOSIS

The disease has characteristic long asymptomatic phase of growth. The larval growth averages about 1 to 15 years. It usually starts in the right lobe of the liver where metacestodes establish themselves. With time, the infection metastasizes via blood to lung, brain, and bones as well as becomes locally advanced to the abdomen, retroperitoneum, and diaphragm. In advanced stages, patients present with symptomatic disease with complaints of fatigue, weight loss, hepatomegaly, cholestatic jaundice, and abdominal pain. Occasionally, liver failure may occur resulting from portal hypertension, ascites, and splenomegaly from the compressive effect of the mass.

Clinical evaluation and noninvasive radiologic imaging are critical for decision making in the management of most patients with hydatid liver disease. Addition of the epidemiologic findings, exams, and detection and serology helps to provide a complete picture of disease.

Liver lesions are usually clinically silent and detected incidentally on abdominal ultrasonography (US) or computed tomography (CT) performed for other clinical reasons. Occasionally, in endemic areas, the disease can present with symptoms suggestive of the hydatid disease if there is a history of exposure to sheepdogs. Abdominal US is considered the gold standard for evaluation of the disease extent including the number of cysts, location, dimensions, and viability. The World Health Organization (WHO) established a standardized classification system for hepatic cysts based on US imaging (Table 2, Fig. 2). Color Doppler may be incorporated in ideal light on biliary connection or vascular infiltration.

US features of AE are consistent with a huge lesion with large central necrosis surrounded by a hyperechogenic ring corresponding to the parasitic fibrous tissue. AE also can present as a nodular homogeneous form of a hyperechogenic nature ("young AE") or as a pseudocystic form ("a huge AE with massive necrosis"). Abdominal CT confirms the morphologic aspects of AE. It is helpful to specify the number, size, and localization of the lesions in the liver. It is the best technique to identify the pattern of calcification and to delineate the mass precisely particularly the posterior border. It typically features a lesion with irregular borders, a heterogeneous content with a mosaic of various densities without significant enhancement with intravenous contrast administration. Magnetic resonance imaging is considered the standard to further delineate anatomy and adjacent structures as well as to ascertain cases with noncalcified lesions. The multifocal form is considered pathognomonic of AE. This is best visualized on T2 weighted sequences as a bunch of grapes of honeycomb-like pattern at the periphery corresponding to the parasitic vesicles. They are also the best to most closely differentiate between necrotic liquefactions and areas of fibrosis and parasitic tissue.

Preoperative cholangiography can be recommended in certain cases to assess the presence of communication between the biliary tree and the alveolar lesions. In cases with alveolar echinococcosis it is imperative to rule out extrahepatic involvement by obtaining a chest x-ray and CT scan of head. Recent studies also advise to obtain fluorodeoxyglucose positron emission tomography scanning to evaluate the parasite metabolic activity.

The WHO developed a so called PNM, microscopically recognized classification system to standardize disease diagnosis and treatment strategies in which P refers to the extent of parasite localization inside the liver, N establishes the involvement of neighboring organs, and M evaluates the absence (M0) or presence (M1) of distant metastases (Box 1).

Immunodiagnosis has a complementary role to a radiographic diagnosis that is used for initial diagnosis and a follow up of treatment. The enzyme linked immunosorbent assay replaced all other traditional immunodiagnostic methods such as Casoni intradermal test, complement fixation test, indirect hemagglutination test, indirect immunofluorescence antibody test, immunoelectrophoresis and latex agglutination test.

It is based on detection of the hydatid antigens extracted from the cyst such as fluid antigen B and antigen 5 (Ag5) from *E. granulosus*. It is more specific for *E. multilocularis* using Em2plus-enzyme linked immunosorbent assay which is based on Em2 antigen form metacestode and EMY-162 recombinant antigen. However, this test remains positive for years in inactive lesions after medical treatment because

TABLE 1 Hydatid Disease: Epidemiology and Characteristics

	Cystic Echinococcosis	Alveolar Echinococcosis
Causative agent	*Echinococcus granulosus*	*Echinococcus multilocularis*
Definitive hosts	Dogs and other canids (coyotes, dingoes, red foxes)	Red foxes, arctic foxes, coyotes, dogs, and cats
Intermediate hosts	Ungulates	Rodents
Geographic distribution	Worldwide	North America, northern and central Eurasia
Worldwide incidence	1–200/100,000	0.03–1.2/100,000
Organ localization	Mainly liver and lungs	Mainly liver
Characteristics of hydatid lesions	Large cysts, spherical, fluid filled, multilocular vesicles (diameter: 1–15 cm) Old cysts: internal septations, daughter cysts Three layered structure: germinal layer, laminated layer, pericyst	Alveolar-like pattern, with numerous vesicles (1–4 mm: 15 μm to diameter) and surrounding dense connective tissue; no cyst fluid, sometimes central necrosis
Type of growth in human organs	Concentric expansion	Tumor like, infiltrative behavior
Therapeutic options		Surgery, chemotherapy, endoscopic percutaneous interventions

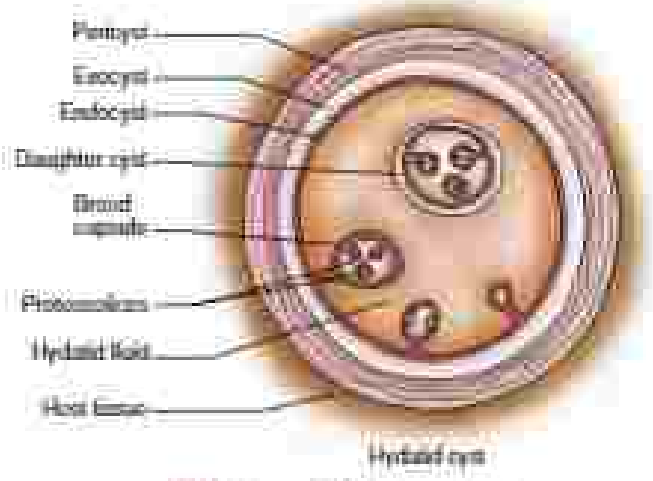

FIG. 1 Structure of echinococcal cyst.

8.6, coming from the laminated layer of the parasite, which persists in the calcified lesions. The surgical excision of the inactive lesion would unconvert a lesion to negative.

Em18 and Em18, new antigens, were developed to differentiate between active and inactive lesions. All lesions are classified into three groups based on serologic and US data: active hepatic lesions; calcified lesions; and without any evidence of hepatic lesions. Some studies identified elevated levels of immunoglobulin G1 and immunoglobulin G4 antibodies that become seronegative with treatment and recur with disease reactivation.

Liver needle biopsy can be performed in uncertain cases to help with histopathological diagnosis. Polymerase chain reaction of the specimen can identify DNA, whereas reverse transcriptase polymerase chain reaction can assess parasite viability with a good positive predictive value.

TREATMENT

There are several therapeutic modalities available to treat hepatic hydatid disease with the goal to achieve complete control of disease by eliminating the parasite and prevent recurrence. It involves chemotherapy, surgery, and percutaneous treatments. The recent development in chemotherapy and surgery improved life expectancy from 5 years in 1970s to 20 years in 2005.

Chemotherapy

The two benzimidazoles that are the most commonly used chemotherapeutic agents for hepatic hydatid disease are mebendazole and albendazole. Their mechanism is based on disruption of the absorption of glucose through the wall of the parasite, causing the glycogen depletion and degenerative changes in echinococcal mitochondria and endoplasmic reticulum. It is a parasitostatic treatment. Albendazole has better bioavailability because of better absorption in the gastrointestinal tract. It is recommended to be used alone in small CE1/3m liver cysts or for inoperable patients. More typically, it is used in combination with puncture, aspiration, injection, and respiration (PAIR) or surgery to prevent secondary disease. No medical treatment is recommended for the inactive or calcified asymptomatic cysts. The typical dose of albendazole is 10 to 15 mg/kg per day in two divided doses for patients weighing less than 60 kg and in a dose of 400 mg twice daily for patients weighing more than 60 kg. Mebendazole is given as a daily dose of 40 to 50 mg/kg in three divided doses administered continuously for 3 to 6 months. Their efficacy can be further enhanced with administration of praziquantel at 40 mg/kg once a week.

The size and stage of cysts are the key factors determining the duration of treatment and the likelihood of response to chemotherapy. Complete cure is observed to only about one-third of patients with chemotherapy alone. Treatment effect is evaluated both clinically and radiographically (reduction in cyst size >25%, membrane separation, or cyst calcification). The most common side effects include nausea, hepatotoxicity, neutropenia, alopecia, and leukopenia. Pregnancy, chronic hepatic disease and bone marrow depression are contraindications to chemotherapy. "Watch and wait" strategy is recommended for CE4 and CE5 cysts.

Surgical Management

PAIR

This approach was first proposed by a Tunisian team in 1987 as an alternative to the surgical treatment. Since its development, more

TABLE 2 World Health Organization Informal Working Groups on Echinococcosis Classification of Hepatic Echinococcal Cysts

Class	Ultrasound Features	Status	Fertility	Size	Treatment Approaches
CL	A unilocular active lesion with uniform anechoic content not clearly delimited by a hyperechoic rim, round or oval, usually small	Active	Nonfertile	CLa: <5.0 cm, CLm: 5–10 cm, CLE: >10 cm	Needs diagnosis
CE1	A unilocular simple active cyst with uniform anechoic content, may exhibit line echoes resulting from shifting of hydatid capsules called hydatid sand or *rive flake* sign, with visible cyst wall, round or oval	Active	Usually fertile	CE1a: <5.0 cm, CE1m: 5–10 cm, CE1E: >10 cm	<5 cm: ABZ >5 cm: ABZ + PAIR
CE2	A multivesicular, multseptated active cyst with separations producing *wheel like* structures, and daughter cysts (*rosette like* or *honeycomb like*)	Active	Usually fertile	CE2a: <5.0 cm, CE2m: 5–10 cm, CE2E: >10 cm	PT or surgery + ABZ
CE3	A unilocular transitional cyst that may contain daughter cysts, appears as an anechoic cyst with the detachment of laminated membrane from the cyst wall visible as floating membranes or as water lily sign, may be less rounded because of decreased intracystic fluid pressure	Transitional	Starting to degenerate	CE3a: <5.0 cm, CE3m: 5–10 cm, CE3E: >10 cm	PT, PAIR, or surgery + ABZ
CE4	A heterogeneous hyperechoic or hyperechoic multicystic cyst without daughter cysts, may show a *bull's eye* sign indicative of degenerating membranes	Inactive	Nonfertile	CE4a: <5.0 cm, CE4m: 5–10 cm, CE4E: >10 cm	Surgery + ABZ, or watch and wait
CE5	An inactive cyst with thick calcified wall that is arch shaped, with a cone shaped shadow, diagnosis is usually uncertain	Inactive	Nonfertile	CE5a: <5.0 cm, CE5m: 5–10 cm, CE5E: >10 cm	Surgery + ABZ, or watch and wait

ABZ, albendazole; *PAIR*, percutaneous intervention; *PAIR*, puncture, aspiration, injection, reaspiration; *PT*, percutaneous treatment.

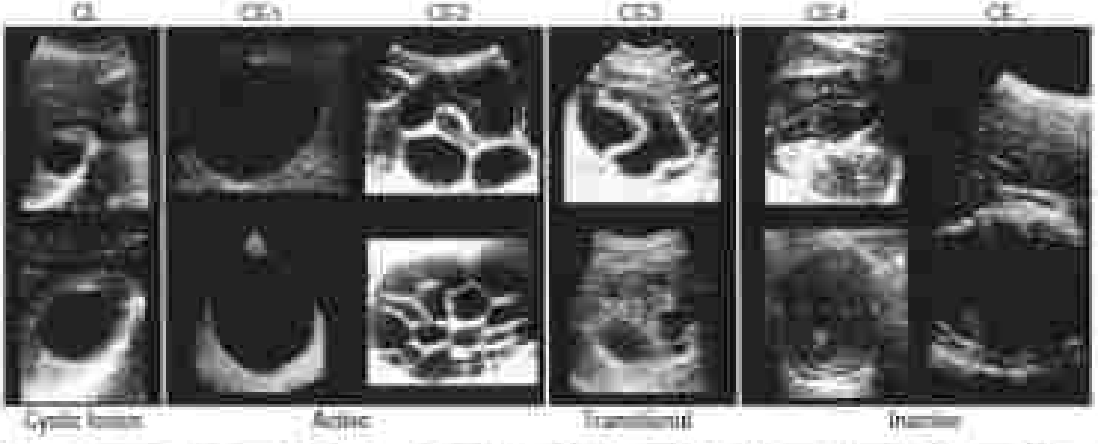

FIG. 2 [illegible]

than 3000 cases were published in the literature and discussed at the WHO Meeting during the XVIII International Congress of the Hydatidology Lisbon in 1997. It is a percutaneous drainage of echinococcal cysts located in the liver performed with a fine needle (for cysts <5 cm) or a catheter (for cysts >5cm), followed by the administration of a protoscolicidal agent in the cyst cavity for scolicidal effect. This technique can be further modified by placing and retaining the catheter in the cyst after the procedure for drainage or by curettage if numerous and large daughter cysts are present (percutaneous puncture with drainage and curettage). PAIR is usually performed under radiographic guidance using US or CT. Patients with the cystic echinococcal disease, with anechoic lesion 5 cm or greater in diameter

BOX 1 PNM Classification

PX Primary Tumor Cannot Be Assessed

1. P0 No detectable tumor in the liver
2. P1 Peripheral lesions without proximal vascular and/or biliary involvement
3. P2 Central lesions with proximal vascular and/or biliary involvement of 1 liver lobe
4. P3 Central lesions with bilateral vascular or biliary involvement of both lobes and/or with possible infiltration of 2 of 3 hepatic veins
5. P4 Any liver lesion with extension along the vessels (inferior vena cava, portal vein and arteries) and the biliary tree

NX Not Evaluable

1. N0 No regional involvement
2. N1 Regional involvement of contiguous organs or tissues like diaphragm, lung, pleura, pericardium, heart, gastric and duodenal wall, adrenal glands, peritoneum, retroperitoneum, parietal wall, muscles, skin, bone, pancreas, regional lymph nodes, liver ligaments, kidney

MX Not Completely Evaluable

1. M0 No metastasis to the lung and/or CNS (chest radiograph and cerebral CT negative)
2. M1 Metastasis to the lung and/or CNS

CNS, central nervous system; CT, computed tomography.

(CE1) in and 1) cysts with daughter cysts (CE2), and/or with detachment of membranes (CE3), multiple cysts and infected cysts are good candidates for PAIR. It is also recommended for pregnant women, children older than 3 years, patients who cannot undergo surgery, or those who fail to respond to medical treatment alone. The contraindications for PAIR are patients with lesions that are not accessible or to many locations in the liver, cysts communicating with the biliary tree, or open into the abdominal cavity, as well as inactive or calcified lesions.

PAIR has advantage of the minimally invasive approach, reduced hospitalization time and improved efficacy of chemotherapy. It comes, however, with the risk of anaphylactic shock, secondary echinococcosis associated with spillage of the protoscolices, chemical cholangitis, biliary fistulas resulting from the communication with the biliary tree, and systemic toxicity of scolicidal agent such as 95% alcohol or hypertonic saline (15% or more).

Chemical prophylaxis with albendazole is recommended 24 to 48 hours before intervention and 15 to 30 days after intervention to reduce the risk of disease recurrence and intraperitoneal seeding of infection. The procedure starts with aspiration of cyst fluid (1/3–1/5 mL) followed by the serologic tests for the presence of protoscolices and biochemical analysis of fluid. It is recommended to check bilirubin level in the cystic fluid on aspiration to rule out connection with the biliary tree before injection of the agent. Contrast medium is injected intracystically and confirmed by cystography. The solution is reaspirated after 5 minutes. The surveillance is performed using parasitologic, biochemical, serologic, immunologic, and US monitoring every week for the first month and every other month for the first year. Then, the interval is increased to every year for 10 years. Chest radiograph is recommended 1 year after PAIR and then every other year. CT scan of chest, abdomen, and pelvis should occur after 5 and 10 years. Endoscopic retrograde cholangiopancreatography with cystolithography is recommended if communication with the biliary tree is revealed during the procedure.

Surgical Resection

Surgery must be carefully evaluated for complicated cysts, particularly for: (1) large CE2 (CE3b) cysts with multiple daughter vesicles, (2) single liver cysts that may rupture spontaneously or as a result of trauma, (3) infected cysts, when percutaneous treatment is not available, (4) cysts communicating with the biliary tree, and (5) cysts exerting pressure on adjacent vital organs. It is contraindicated in inactive asymptomatic, difficult to access, and very small cysts.

Surgical options are further divided into radical and conservative approaches. Radical procedures include a total removal of the cyst, so-called pericystectomy. It carries an inherent higher operative risk but is associated with a lower risk of recurrence. A conservative approach with unroofing or capitonnage has a higher likelihood of recurrence, with ranges from 2% to 25%. Closed total pericystectomy removes the cyst in its entirety without spoiling the cyst. Open total pericystectomy encompasses procedure of sterilization of metacestodes with protoscolicidal agents, evacuation of the cyst content followed by removal of the pericystic tissue. Operative mortality varies from 0.2% to 4%. It is associated with major complications such as postoperative hemorrhage, cholangitis, sepsis, and fistula formation.

A benzimidazole agent is used to reduce the risk of anaphylaxis and secondary hydatid disease. It is administered 1 day before surgery to 1 month after surgery.

The first laparoscopic treatment was described in 1992. Since then, this approach has gained wider acceptance. It includes cystostomy and partial pericystectomy. The cystostomy involves aspiration of the cyst, instillation of a scolicidal substance, evacuation of the parasitic material, and partial resection of the pericyst. Several different methods are applied to the residual cavity; those most commonly described include marsupialization, capitonnage, omentoplasty, and internal drainage. The minimally invasive approach shortens the length of hospital stay to 1 to 8 days compared with open laparotomy; however, it is not different from the percutaneous drainage. The perioperative mortality varies from 0% to 0.5% for laparoscopic pericystectomy and 0% to 0.9% after percutaneous drainage. The most common complications are based on several factors, including age, size of the cyst, preoperative complications, and biliary cyst communication. The bile leak rate was reported to be about 6%, with most healed spontaneously without any additional intervention. The postoperative recurrence rate ranges from 0% to 11% for laparoscopic cases, 4.6% to 25% for open conservative surgery, and 0% to 0.63% to radical surgery.

The potential limitations of laparoscopic treatment are the fear of intraoperative spillage of cyst content, the possibility of anaphylactic shock, peritoneal seeding, and potential bleeding; however, clinical studies have showed a low incidence of intraoperative spillage. Despite that, laparoscopic approach suits better for peripherally and anteriorly location liver lesions.

The meta-analysis comparing laparoscopic to open approach showed no difference in cure rate, complications, mortality, and recurrences. The rate of conversion from laparoscopic to any type of open surgery ranges from 1.7% to 3.3%. The main reasons for conversion included a life-threatening bleeding, cystic rupture, irremovable residual daughter cysts, deep cystic locations or adjacent to the inferior vena cava, and intraoperative spillage of cyst contents. There are no prospective randomized trials directly comparing these two approaches.

A meta-analysis of 21 studies that compared 749 patients who received chemotherapy only and PAIR to 952 patients treated with surgery alone demonstrated that the former treatment approach is more effective than surgery. It was associated with lower morbidity and mortality, decreased recurrence risk, and a shorter hospital stay.

A small randomized trial on 50 patients that compared medical treatment with percutaneous drainage vs surgery alone concluded that percutaneous treatment is a safe and effective treatment choice for uncomplicated hydatid disease.

Management of Alveolar Echinococcosis

Approach to the alveolar echinococcosis differs from the *E. granulosus* as because it requires a multidisciplinary, more aggressive approach. Surgery is the first choice option for all qualified patients. Radical

resection of the entire hepatic lesion is the only curative approach. The likelihood of radical resection is determined by the WHO Informal Working Group on Echinococcus PNM classification system (Box 1). Unfortunately, only about 25% to 40% of patients have resectable disease. During the past 20 years, AE has become the fourth most common indication for liver transplant resulting from cholestatic disease in Turkey.

Palliative liver surgery is contraindicated; hence, liver transplant has been used since 1986 for advanced unresectable cases. The indications for liver transplant include the presence of liver failure and recurrent life-threatening cholangitis in the absence of extrahepatic manifestation of liver disease. Positron emission tomography is recommended to diagnose residual/recurrent lesions after liver transplantation. Presence of extrahepatic lesions before transplantation and prolonged immunosuppression are two main risks factors for recurrence. The suppression of cellular immunity leads to the uncontrolled growth of the parasite posttransplantation.

Chemotherapy should be carried out for at least 2 years after surgery and the patient should be monitored for at least 10 years because of high risk of recurrence in posttransplant immunosuppressed patients.

Therapy with benzimidazoles has resulted in an increased 10-year survival rate of approximately 80% compared with the 4% to 25% in historical untreated cohorts.

The largest study from one endemic center in Turkey reports results on 27 patients who underwent liver transplantation. The number of patients undergoing liver transplant for echinococcosis has decreased significantly in central Europe since early 2000s because of advances in imaging modalities. Recent systematic review (Abakhar- an et al., 2018) identified 36 studies describing their experience with liver transplantation. Of these patients, about 17% had undergone palliative partial hepatectomy before transplantation. Seventeen percent of patients had preoperative distant metastasis.

Six studies from China presented their experiences in ex vivo liver resection and autotransplantation for patients with end-stage disease that eliminates the need for immunosuppression. It usually involved the removal of the entire diseased liver with replacement of the infrahepatic vena cava by artificial blood vessels and transplantation of the normal liver tissue graft with reconstruction of hepatic artery and the portal vein.

Overall, earlier diagnosis for liver transplant, pretransplant and posttransplant benzimidazole therapy, minimal immunosuppression regimen, and close surveillance is crucial to achieve acceptable long-term results.

Management of Liver Hemangiomas

Ammar A. Jamil, MD, and Matthew J. Weiss, MD, FACS

Liver hemangiomas are the most commonly diagnosed solid benign tumors of the liver, with an incidence of approximately 20% in the general population. With advancements in imaging techniques and increased utilization of cross-sectional imaging, hepatic hemangiomas are now being diagnosed quite frequently. Females are most susceptible to having these tumors (female to male ratio of 5:1) and they tend to occur in the third to fifth decades of life. These tumors have a benign course, and therefore patient management is often driven by their symptomatology and the risk of complications.

PATHOGENESIS AND PATHOLOGY

The etiology of hepatic hemangiomas remains unclear. It is suggested that these tumors are either congenital lesions of the liver that are complicated with vascular ectasia or are an acquired abnormality of the normal hepatic vasculature resulting in atypical enlargement of these vessels. Though debatable, it has been proposed that angiogenic factors play an important role in the pathogenesis, which is supported by reports of tumor regression upon administration of antivascular endothelial growth factor antibodies. The strong predisposition for female incidence is also suggestive of a hormonal association. Estrogen receptors have been seen on the surface of hemangiomas and increased rate of growth has been observed when the patients are on steroid therapy, oral contraceptives, or during pregnancy. Currently, the mechanism by which these hormones contribute to the formation or progression of these tumors remains largely unknown.

Grossly, hepatic hemangiomas are well-defined, soft, and dark tumors, while microscopically they demonstrate a single layer of endothelium lining with dilated, cavernous, vascular channels surrounded by thin connective tissue containing occasional calcification and fibrosis. The most common location for hepatic hemangiomas is the right lobe of the liver; however, they can occur anywhere in the liver. At the time of diagnosis, a majority of these tumors are small (<3 cm) and are commonly referred to as capillary hemangiomas. A majority of these smaller tumors is diagnosed incidentally and only around 10% increase in size on follow-up. Symptomatic hemangiomas are more likely to be medium (3–5 cm) or giant (>5 cm) sized. Of note, large tumor size alone in the absence of symptoms is not an indication for surgical resection.

Clinical Presentation

The majority of hepatic hemangiomas are diagnosed incidentally on cross-sectional imaging (Figs. 1–4). Approximately 50% to 90% of patients are asymptomatic at the time of diagnosis. The likelihood of symptoms increases with the increased size of the lesion. Symptomatic lesions often present with vague, nonspecific symptoms including abdominal pain, nausea, vomiting, and early satiety. Giant hemangiomas can present with signs related to distortion of the hemangioma, stretching of a hepatic capsule, or diaphragmatic irritation including right shoulder pain or abdominal pain on deep inspiration. Additional symptoms due to mass effect on the stomach, duodenum, and the biliary tree include early satiety, gastric outlet obstruction, and obstructive jaundice. It is vital for the treating surgeon to evaluate these patients thoroughly for symptoms associated with the hemangioma, given that the symptomatic nature of the lesion is one of the most common indications for surgical resection.

One rare but life-threatening complication of large hepatic hemangiomas is a spontaneous rupture. It is associated with significant morbidity resulting from disseminated intravascular coagulopathy, hypovolemic shock, and a high mortality of over 30% has been reported. Another complication of large hepatic hemangiomas is Kasabach-Merritt (hemangioma thrombocytopenia) syndrome, which occurs when a large, rapidly growing lesion traps platelets, resulting in consumptive thrombocytopenia, which progresses to consumptive coagulopathy and eventually disseminated intravascular coagulation. Furthermore, when large liver lesions can lead to arteriovenous shunting that can lead to congestive heart failure.

resection of the entire hepatic lesion is the only curative approach. The likelihood of radical resection is determined by the WHO Informal Working Group on Echinococcus PNM classification system (Box 1). Unfortunately, only about 25% to 40% of patients have resectable disease. During the past 20 years, AE has become the fourth most common indication for liver transplant resulting from cholestatic disease in Turkey.

Palliative liver surgery is contraindicated; hence, liver transplant has been used since 1986 for advanced unresectable cases. The indications for liver transplant include the presence of liver failure and recurrent life-threatening cholangitis in the absence of extrahepatic manifestation of liver disease. Positron emission tomography is recommended to diagnose residual/recurrent lesions after liver transplantation. Presence of extrahepatic lesions before transplantation and prolonged immunosuppression are two main risks factors for recurrence. The suppression of cellular immunity leads to the uncontrolled growth of the parasite posttransplantation.

Chemotherapy should be carried out for at least 2 years after surgery and the patient should be monitored for at least 10 years because of high risk of recurrence in posttransplant immunosuppressed patients.

Therapy with benzimidazoles has resulted in an increased 10-year survival rate of approximately 80% compared with the 4% to 25% in historical untreated cohorts.

The largest study from one endemic center in Turkey reports results on 27 patients who underwent liver transplantation. The number of patients undergoing liver transplant for echinococcosis has decreased significantly in central Europe since early 2000s because of advances in imaging modalities. Recent systematic review (Abakhar-am et al., 2018) identified 36 studies describing their experience with liver transplantation. Of these patients, about 17% had undergone palliative partial hepatectomy before transplantation. Seventeen percent of patients had preoperative distant metastasis.

Six studies from China presented their experiences in ex vivo liver resection and autotransplantation for patients with end-stage disease that eliminates the need for immunosuppression. It usually involved the removal of the entire diseased liver with replacement of the infrahepatic vena cava by artificial blood vessels and transplantation of the normal liver tissue graft with reconstruction of hepatic artery and the portal vein.

Overall, earlier diagnosis for liver transplant, pretransplant and posttransplant benzimidazole therapy, minimal immunosuppression regimen, and close surveillance is crucial to achieve acceptable long-term results.

Management of Liver Hemangiomas

Ammar A. Jamil, MD, and Matthew J. Weiss, MD, FACS

Liver hemangiomas are the most commonly diagnosed solid benign tumors of the liver, with an incidence of approximately 20% in the general population. With advancements in imaging techniques and increased utilization of cross-sectional imaging, hepatic hemangiomas are now being diagnosed quite frequently. Females are most susceptible to having these tumors (female to male ratio of 5:1) and they tend to occur in the third to fifth decades of life. These tumors have a benign course, and therefore patient management is often driven by their symptomatology and the risk of complications.

PATHOGENESIS AND PATHOLOGY

The etiology of hepatic hemangiomas remains unclear. It is suggested that these tumors are either congenital lesions of the liver that are complicated with vascular ectasia or are an acquired abnormality of the normal hepatic vasculature resulting in atypical enlargement of these vessels. Though debatable, it has been proposed that angiogenic factors play an important role in the pathogenesis, which is supported by reports of tumor regression upon administration of antivascular endothelial growth factor antibodies. The strong predisposition for female incidence is also suggestive of a hormonal association. Estrogen receptors have been seen on the surface of hemangiomas and increased rate of growth has been observed when the patients are on steroid therapy, oral contraceptives, or during pregnancy. Currently, the mechanism by which these hormones contribute to the formation or progression of these tumors remains largely unknown.

Grossly, hepatic hemangiomas are well-defined, soft, and dark tumors, while microscopically they demonstrate a single layer of endothelium lining with dilated, cavernous, vascular channels surrounded by thin connective tissue containing occasional calcification and fibrosis. The most common location for hepatic hemangiomas is the right lobe of the liver; however, they can occur anywhere in the liver. At the time of diagnosis, a majority of these tumors are small (<3 cm) and are commonly referred to as capillary hemangiomas. A majority of these smaller tumors is diagnosed incidentally and only around 10% increase in size on follow-up. Symptomatic hemangiomas are more likely to be medium (3–5 cm) or giant (>5 cm) sized. Of note, large tumor size alone in the absence of symptoms is not an indication for surgical resection.

Clinical Presentation

The majority of hepatic hemangiomas are diagnosed incidentally on cross-sectional imaging (Figs. 1–4). Approximately 50% to 90% of patients are asymptomatic at the time of diagnosis. The likelihood of symptoms increases with the increased size of the lesion. Symptomatic lesions often present with vague, nonspecific symptoms including abdominal pain, nausea, vomiting, and early satiety. Giant hemangiomas can present with signs related to distortion of the hemangioma, stretching of Glisson's capsule, or diaphragmatic irritation including right shoulder pain or abdominal pain on deep inspiration. Additional symptoms due to mass effect on the stomach, duodenum, and the biliary tree include early satiety, gastric outlet obstruction, and obstructive jaundice. It is vital for the treating surgeon to evaluate these patients thoroughly for symptoms associated with the hemangioma, given that the symptomatic nature of the lesion is one of the most common indications for surgical resection.

One rare but life-threatening complication of large hepatic hemangiomas is a spontaneous rupture. It is associated with significant morbidity resulting from disseminated intravascular coagulopathy, hypovolemic shock, and a high mortality of over 30% has been reported. Another complication of large hepatic hemangiomas is Kasabach-Merritt (hemangioma thrombocytopenia) syndrome, which occurs when a large, rapidly growing lesion traps platelets, resulting in consumptive thrombocytopenia, which progresses to consumptive coagulopathy and eventually disseminated intravascular coagulation. Furthermore, when large these lesions can lead to arteriovenous shunting that can lead to congestive heart failure.

FIG. 1 Axial (A) and coronal (B) computed tomography demonstrating multiple hepatic hemangiomas in a 45-year-old woman. A large hepatic hemangioma is seen in the right lobe of the liver.

FIG. 2 Intraoperative images of a giant cavernous hepatic hemangioma in the right lobe of the liver extending into the caudate lobe. The patient was initially managed via surveillance; however the tumor grew significantly. On follow-up the patient reported epigastric pain, early satiety and was hypotensive and tachycardic upon lying down.

Physical examination is usually negative for findings unless the hemangioma is large enough that it becomes palpable in the right upper quadrant. Laboratory investigations including CA19-9 (carcinogenic antigen 19-9), carcinogenic embryonic antigen, and alpha-fetoprotein are generally within normal limits. If elevated, these lesions should be investigated further. In the case of Kasabach-Merritt syndrome, fibrinolysis can result in thrombocytopenia and coagulation abnormalities. Obstruction of the biliary tree can result in elevated bilirubin and alkaline phosphatase levels, although this is rare.

Diagnosis and Radiologic Findings

Accurate diagnosis of hepatic hemangiomas is imperative to avoid unnecessary procedures. Imaging-based diagnosis includes the use of ultrasound (US), contrast-enhanced computed tomography (CT) scan, magnetic resonance imaging (MRI), angiographic, and nuclear scans (scintigraphic studies with Technetium 99m labeled red blood cells). These modalities can help differentiate hepatic hemangiomas from other benign (adenoma) or malignant (hepatocellular carcinoma [HCC], cholangiocarcinoma, metastasis, dysplastic nodules) hepatic tumors.

Ultrasound is the first step in the evaluation of hepatic hemangiomas. On US, they present as hyperechoic, homogenous, and well-defined lesions with posterior acoustic enhancement. This hyperechoic appearance is due to the presence of numerous interfaces between the endothelial tissue septa and the blood within them. Larger hemangiomas can also develop central necrosis and fibrosis, which makes them appear to be heterogeneous with mixed echogenicity. On Doppler US, most hepatic hemangiomas demonstrate

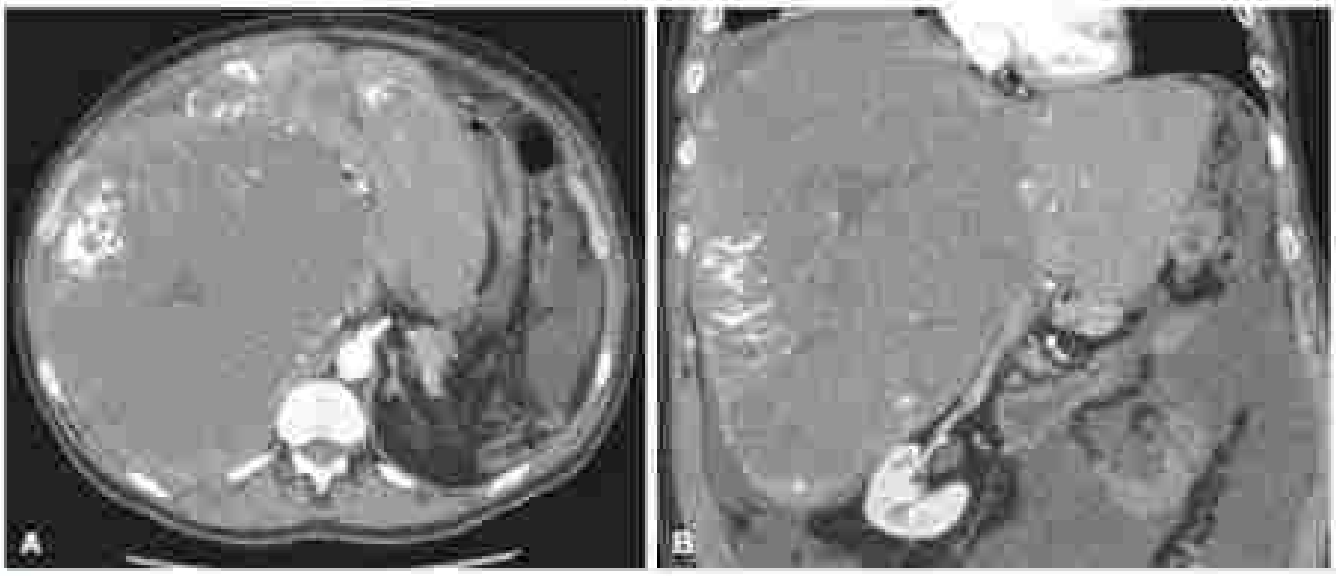

FIG. 3. Computed tomography of a 59-year-old male demonstrating a giant hepatic hemangioma in the right lobe of the liver. Axial (A) and coronal (B) view. The patient was initially managed via surveillance; however, the tumor grew and hepatic artery embolization was performed at an outside institution. Subsequently, he developed resulting bilateral pleural effusions and ascites requiring removal of 2 L abdominal fluid every 4 to 5 days. Additionally, he had lower extremity edema and pulmonary edema.

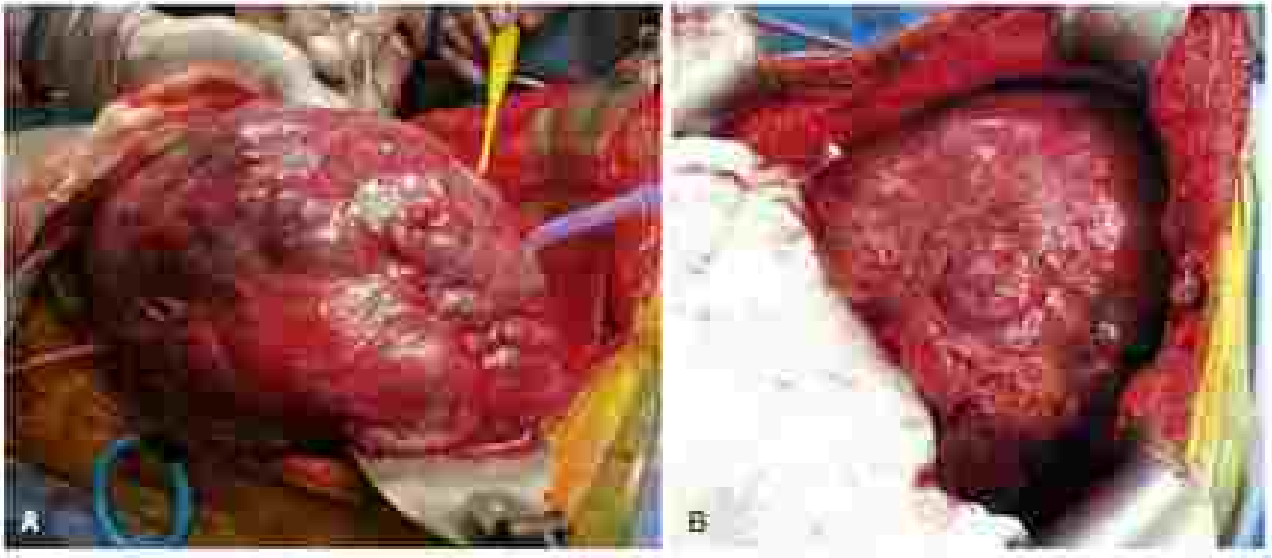

FIG. 4. Intraoperative image of a giant hepatic hemangioma in the right lobe of the liver.

minimal or no signal. The hyperechoic appearance on US can also represent other hepatic tumors; however, the absence of lesion blood flow on Doppler US can reliably differentiate hemangiomas from HCC, which frequently have intra- or peritumoral vascularity. The main limitations of using US are that it is highly operator and patient dependent, and when assessing a fatty liver a typical hemangioma can look hyperechoic relative to the liver parenchyma.

CT is the most commonly used modality for the diagnosis of hepatic hemangiomas. On unenhanced CT hepatic hemangiomas present as isodense liver lesions that are difficult to identify. However, contrast enhanced CT has a high sensitivity (98%) for diagnosing hepatic hemangiomas. On a noncontrast CT they are often hypoattenuating relative to the liver. On a contrast CT on the arterial phase, they show discontinuous, nodular, peripheral enhancement and in the portal phase they demonstrate progressive peripheral enhancement with centripetal fill in. Peripheral enhancement on the arterial phase, centripetal filling on venous phase, and contrast retention on the delayed phase, is highly suggestive of hepatic hemangioma. CT is particularly useful in differentiating hepatic hemangiomas from adenomas, focal nodular hyperplasia, hepatocellular carcinoma, or metastasis. The presence of these features is diagnostic; however, smaller lesions might not present with these findings. Giant lesions can present with central necrosis, thrombosis, or fibrosis, thus mimicking other hepatic lesions. When there is diagnostic uncertainty after CT other imaging modalities can be employed.

A dedicated hemangioma protocol MRI is the most specific (95%) and sensitive (99%) modality. Low signal intensity on T1 weighted imaging and bright signal on T2 weighted imaging with delayed relaxation times are characteristic of a hepatic hemangioma. This finding is known as a light bulb sign. CT can be equally effective in the diagnosis of hepatic hemangiomas and therefore MRI should only be performed when the diagnosis is unclear or when the patient cannot

undergo CT due to an allergy to contrast or renal disease. Additionally, MRI is the modality of choice for surveillance, as it reduces radiation exposure.

Percutaneous biopsies are contraindicated when hepatic hemangiomas are suspected, as it is associated with a high likelihood of serious complications and low likelihood of obtaining tissue for diagnosis. If diagnostic uncertainty exists after US, CT, and MRI, photon emission CT with technetium-labeled red blood cell scan or angiography can be used. Tagged red blood cell scans are limited for lesions located deeper in the liver parenchyma. Upon imaging a filling defect is observed in the liver, a finding similar to that in cases of other hepatic lesions. Therefore, the value of these modalities remains limited when diagnosing hepatic hemangiomas.

Management

Hepatic hemangiomas have a benign course; a majority remains stable on repeat imaging while 10% to 20% regress. The rate of hemangioma-related complications in patients managed via surveillance is similar to those undergoing surgical resection. Observation, therefore, can be an appropriate approach in patients with asymptomatic disease, even for women who are pregnant or are taking oral contraceptives.

Surgical resection is indicated when patients are symptomatic from their disease. These symptoms include extreme abdominal pain or signs related to mass effect leading to obstruction of the gastric outlet or the biliary tree. Other causes of these symptoms should be ruled out before proceeding with resection. If the patient presents with Kasabach-Merritt syndrome surgical resection is warranted despite the coagulopathy; many times resection results in reversal of the coagulopathy. Intensive care is often necessary to manage bleeding risk and prevent progression to disseminated intravascular coagulation. In the presence of hemangioma related complications, including intraperitoneal hemorrhage secondary to spontaneous or traumatic rupture, a surgery-first approach can be used. An alternative to a surgery-first approach is resection followed by embolization; however, if embolization is not successful emergent surgery should be performed.

Factors to be considered when a surgical approach is employed include the location and size of the tumor and the patient's comorbidities.

Surgical Approach

Surgical management of hepatic hemangiomas includes enucleation, anatomic or nonanatomic resection using an open or a minimally invasive approach. When performed by experienced surgeons these procedures are safe and feasible. The most common surgical approach is an enucleation, which is associated with reduced blood loss, shorter length of operation, lower risk of postoperative complications, and increased preservation of liver parenchyma. The minimally invasive approach has been shown to have similar outcomes when compared to open surgery; however, it may be challenging when resecting tumors on the right side of the liver.

To perform an enucleation, the hepatic artery inflow is controlled. For larger lesion ligation of the ipsilateral hepatic artery may be required, while for smaller lesions arterial flow can be controlled by ligation of more distal branches. A Pringle maneuver is useful to help attenuate the inflow in cases where the hemangioma is traumatically entered. It can also be used as a preoperative technique to decompress the tumor and facilitate resection. This maneuver is effective in cases of larger lesions. The maneuver is well tolerated if used for less than 30 minutes, and ischemic reperfusion injury is rare. If the enucleation requires more than 30 minutes periodic unclamping for 5 minutes is recommended. Clamping this portal permits pressure on the hemangioma limits the extent of resuspension of the lesion.

Upon entering the abdomen dissection begins with the incision of the Glisson's capsule to identify the plane of the pseudocapsule, which is relatively avascular. When the lesions are deep, an intraoperative US can be useful to identify them, and dissection of the normal parenchyma might be necessary to identify the pseudocapsule. Resection is then performed along the plane of the pseudocapsule, which reduces the risk of entering the hemangioma that can result in significant bleeding. In certain cases, the pseudocapsule may not be identifiable, making dissection difficult and parenchymal resection a more viable option.

Anatomic and nonanatomic liver resections are performed when there is diagnostic uncertainty, and there is a high suspicion for malignancy. Tumor size, location, and relationship with vasculature and biliary structures should be taken into account when selecting the appropriate surgical approach. Nonanatomic resection should be considered for smaller peripheral lesions. When performing liver resections inflow occlusion can be used to decompress the lesion, and assist with resection.

For unresectable tumors or patients with Kasabach-Merritt syndrome or coagulopathy, liver transplant can be the treatment of choice; however, this approach is employed infrequently.

Nonoperative Therapies

It is important to note that the majority of incidentally diagnosed hemangiomas require no intervention at all. The use of several nonoperative therapies has been described with limited success. Such therapies include transarterial embolization, percutaneous radiofrequency ablation, percutaneous ethanol ablation, and radiation therapy. Limited data are available on the use and outcomes of patients managed via these techniques. Elective embolization can result in transient pain relief, though tumor regression is rare and tumor recurrence and recurrent symptoms are common. Embolization is more effective for lesions that have actively identifiable arterial blood supply. Similarly, thermal ablation can result in transient relief in symptoms but complete ablation of the lesion is difficult due to the presence of nearby vessels and biliary structures. Ablation for giant tumors is typically associated with a high risk of complications and poor efficacy.

Nonoperative management of patients with hepatic hemangiomas should be considered in patients with symptomatic disease who are poor candidates for surgical resection due to comorbidities, or if the patients refuse resection. Additionally, a nonoperative approach can be adopted as the initial therapy in patients with spontaneous or traumatic rupture of the lesion to gain hemostasis.

Prognosis

Follow up using routine imaging is recommended for newly diagnosed hepatic hemangiomas that do not require surgical resection. The imaging modality of choice is an MRI due to reduced radiation exposure. It is recommended that an MRI is performed 3 months after the initial diagnosis followed by scans every 3 to 6 months for a year. If the lesion remains stable, imaging should be repeated annually, with less frequent follow up performed subsequently. Data on the impact of large hemangiomas on pregnancy are limited; however, follow up with ultrasounds is recommended.

Surgical resection is safe and feasible when performed by experienced surgeons and is associated with low morbidity and mortality. A majority of patients undergoing resection have reported a significant improvement in their symptoms postoperatively. Recurrence of tumors is rare and resection is almost always curative.

SUMMARY

Hepatic hemangiomas are the most common type of benign tumors of the liver that are now frequently being diagnosed due to an increase in the utilization of cross sectional imaging. The vast majority of hemangiomas present as small asymptomatic lesions, have a benign natural history, and can be observed with serial imaging. When under surveillance, larger lesions can very rarely develop spontaneous rupture, or result in Kasabach-Merritt syndrome, which should be diagnosed and managed in a timely manner, given the high rate

of morbidity and mortality associated with them. Surgical resection should be reserved for patients with symptomatic disease, or when there is a high risk of complications or an uncertainty in the diagnosis of disease. Surgical resection, performed via enucleation or nonanatomic or anatomic resection, is safe and feasible when performed by experienced surgeons. Resection is curative and long-term outcomes of all patients remain excellent.

Management of Benign Liver Tumors

Derek J. Erstad, MD, and Kenneth K. Tanabe, MD

Benign liver neoplasms occur in 7% to 20% of the population and include simple cysts, biliary cystadenomas, hemangiomas, adenomas, and focal nodular hyperplasia (FNH). Most lesions are incidentally discovered during imaging for other indications and can be managed expectantly with routine surveillance. Surgical resection may be required if symptoms develop or if there is risk of rupture, hemorrhage, or malignant transformation. Surgeons should be familiar with the clinical workup, radiographic features, and indications for intervention for these benign liver neoplasms.

Radiographic Evaluation of Liver Lesions

The use of axial abdominal imaging has increased more than 10-fold in the past four decades, resulting in the increased incidental identification of asymptomatic liver lesions. The vast majority of these lesions are benign, particularly when found in younger patients. With advances in axial imaging technology, most benign lesions may be definitively diagnosed with imaging alone and do not require further intervention, such as percutaneous biopsy. Making the correct diagnosis is critical to preventing unnecessary surgery or the mistaken diagnosis of liver metastases in patients with a known primary malignancy.

Ultrasound (US), computed tomography (CT), and magnetic resonance imaging (MRI) are the most commonly used modalities to image liver lesions. Each has advantages that may complement the others, and more than one modality is frequently used to secure a diagnosis. US is commonly used in emergency departments for patients with vague upper abdominal pain and has the advantages of ease of use, short duration, and absence of ionizing radiation. Fluid-filled cystic lesions are easily identifiable on US, whereas solid masses will have variable degrees of echogenicity. The main disadvantage of US is the inability to establish a diagnosis for most solid lesions resulting from limited specificity, which can be further confounded by conditions that reduce the quality of US imaging such as steatosis and fibrosis. For these reasons, follow-up imaging with CT or MRI is typically required to confidently diagnose benign liver lesions. The use of CT scanning as the first choice for follow-up to US has markedly increased in recent decades as a result of increased availability, short turnaround time, and high diagnostic sensitivity and specificity for many conditions. For accurate diagnosis of liver lesions, intravenous iodinated contrast is necessary and provides three distinct phases of enhancement: early hepatic arterial phase, portal venous phase, and delayed hepatic venous phase. The majority of benign liver lesions may be diagnosed with a high-quality, contrast-enhanced CT scan; however, the limitations of CT include radiation exposure and contraindications to iodinated contrast in patients with reduced kidney function or contrast allergy. MRI also provides excellent resolution of the liver and has a high sensitivity and specificity for diagnosing hepatic neoplasms. MRI, however, is limited by decreased availability, long examination time, certain metal implants such as cardiac pacemakers, and contraindications to gadolinium-based contrast agents, most notably reduced kidney function. Table 1 summarizes the common radiographic findings of benign liver lesions using these three modalities.

Benign Liver Cysts

Pathogenesis

Simple liver cysts are predominately congenital in nature, arising from aberrant bile ducts that lack communication with the biliary tree for drainage. Accumulation of serous, noninfectious fluid creates a spherical, nonseptated cyst lined by a single layer of cuboidal or columnar biliary epithelium with a surrounding fibrous stroma. Simple liver cysts are usually small (< 5 cm in diameter) and remain stable in size, although growth may be observed because of continued production of serous fluid. Simple cysts are rarely symptomatic and nearly universally benign.

Presentation

Simple liver cysts occur in approximately 18% of the population. They are most often observed in adults and are usually discovered incidentally after abdominal imaging for another indication. There is a slight female predominance (1.5:1), and although cysts may occur throughout the liver, they are found more often in the right lobe. Simple liver cysts are asymptomatic in the vast majority of cases, although patients may develop symptoms resulting from enlargement, infection, hemorrhage, or rupture of the cyst. Liver function tests are usually within normal limits. Cysts larger than 4 cm, which are most frequently observed in elderly women, may on rare occasion cause pain, shortness of breath, early satiety, nausea, or vomiting. In extremely rare cases, large cysts may compress nearby vascular or biliary structures, the latter resulting in jaundice. Occasionally, large cysts might be palpable on physical examination. A self-limiting bleed into a simple cyst is more common in patients on anticoagulation, and typically causes acute upper abdominal pain that spontaneously resolves over hours to days. On rare occasions, cholangitis may cause secondary infection of a cyst and transformation into an abscess. Increased cyst size is associated with increased risk of rupture or hemorrhage, which

of morbidity and mortality associated with them. Surgical resection should be reserved for patients with symptomatic disease, or when there is a high risk of complications or an uncertainty in the diagnosis of disease. Surgical resection, performed via enucleation or nonanatomic or anatomic resection, is safe and feasible when performed by experienced surgeons. Resection is curative and long-term outcomes of all patients remain excellent.

Presentation

Simple liver cysts occur in approximately 18% of the population. They are most often observed in adults and are usually discovered incidentally after abdominal imaging for another indication. There is a slight female predominance (1.5:1), and although cysts may occur throughout the liver, they are found more often in the right lobe. Simple liver cysts are asymptomatic in the vast majority of cases, although patients may develop symptoms resulting from enlargement, infection, hemorrhage, or rupture of the cyst. Liver function tests are usually within normal limits. Cysts larger than 4 cm, which are most frequently observed in elderly women, may on rare occasion cause pain, shortness of breath, early satiety, nausea, or vomiting. In extremely rare cases, large cysts may compress nearby vascular or biliary structures, the latter resulting in jaundice. Occasionally, large cysts might be palpable on physical examination. A self-limiting bleed into a simple cyst is more common in patients on anticoagulation, and typically causes acute upper abdominal pain that spontaneously resolves over hours to days. On rare occasions, cholangitis may cause secondary infection of a cyst and transformation into an abscess. Increased cyst size is associated with increased risk of rupture or hemorrhage, which

TABLE 1 Comparison of Imaging Findings for the Five Most Commonly Encountered Benign Liver Lesions

Lesion	US	CT	MRI
Simple cyst	Round, through-transmission, usually lacks septations Heterogeneity seen with hemorrhage	Well circumscribed, homogeneous, hypoattenuated Limited contrast enhancement	Well circumscribed, homogeneous T1: hypointense T2: very hyperintense Limited contrast enhancement
Biliary cystadenoma	Round, anechoic, ±thick cyst wall, internal septations May have mural and septal nodules	Well circumscribed, unilocular, unenhanced Mural and nodular enhancement with contrast	Well circumscribed, heterogeneous T1: hypointense T2: hyperintense Mural and nodular enhancement with contrast
Hemangioma	Homogeneous, hyperechoic, posterior acoustic enhancement Blood flow rarely observed	Well circumscribed, homogeneous Asymmetric peripheral pools of enhancement in arterial phase Centripetal enhancement and washout delayed phase	Well circumscribed, homogeneous T1: hypointense T2: very hyperintense Gadolinium enhancement pattern similar to CT
Adenoma	Well circumscribed, homogeneous, variable echogenicity	Isoattenuated noncontrast Hyperattenuated arterial phase, loss of contrast enhancement delayed phases (return to isoattenuation) Heterogeneous if necrosis or hemorrhage Hyperattenuated signal if active hemorrhage	T1: isointense to hyperintense T2: isointense to hyperintense Gadolinium enhancement pattern similar to CT Lesion not retained in delayed, hepatobiliary phase Fat saturation sequences demonstrate intracellular fat
Focal nodular hyperplasia	Variable echogenicity, central scar rarely observed Unreliable modality for diagnosis	Iso- or hyperattenuated noncontrast Hyperattenuated arterial phase, central scar remains enhanced during venous phase Loss of contrast enhancement in delayed phases (return to isoattenuation)	T2: hyperintense T2: hyperintense with hyperintense central scar Gadolinium enhancement pattern similar to CT Lesion retention in delayed, hepatobiliary phase

CT, computed tomography; MRI, magnetic resonance imaging; US, ultrasound.

can lead to shock, infection, and, in very rare cases, death. Polycystic liver disease is discussed in a separate chapter.

Imaging

In the majority of cases, US alone may be used to establish the diagnosis of a simple cyst, which appears as a circular or oval anechoic lesion with clearly defined smooth borders, posterior acoustic enhancement, internal septations, and absence of internal vascularity. Fluid layering, heterogeneity, and internal echoes mimicking septations may indicate cyst hemorrhage, whereas debris within the cyst fluid can be associated with infection or a prior bleed. The presence of internal septations or a thickened, irregular cyst wall with mural nodules and papillary projections or calcifications are concerning for biliary cystadenoma, which is associated with an increased risk of malignant transformation that requires surgical resection. In certain cases, CT or MRI imaging may be necessary to confirm the diagnosis of a simple cyst. On CT, simple cysts appear as well circumscribed, homogeneous, and hypoattenuated lesions that do not enhance with contrast injection (Fig. 1A). On MRI, simple cysts are hypointense with T1 weighted and hyperintense with T2 weighted imaging (Fig. 1B). Similar to CT, on MRI cysts lack contrast enhancement and appear as well circumscribed and homogeneous.

Management

The majority of simple cysts do not require intervention because most are asymptomatic. In cases in which the diagnosis is unclear (e.g., hemorrhage into simple cyst vs cystadenoma), follow-up scanning may be necessary. In the case of asymptomatic simple cysts, periodic surveillance imaging is not indicated. Surgical fenestration is recommended for symptomatic cysts. Sclerotherapy is an alternative for poor surgical candidates. Cyst aspiration is associated with a high rate of recurrence and is rarely indicated as definitive therapy for symptomatic cases in which the patient is unable to undergo other treatment modalities. Because it typically takes several days for cyst fluid to reaccumulate, however, cyst aspiration may be used as a diagnostic maneuver to determine whether symptoms are attributable to the cyst.

Surgical fenestration is a procedure to unroof a portion of the cyst to establish a permanent communication between the cyst and the peritoneal cavity for drainage. Fenestration can be performed by open or minimally invasive approach (laparoscopic or robotic). Cysts located in segments VII and VIII are more difficult to access by a minimally invasive approach. Laparoscopy is associated with reduced hospital stay, decreased postoperative pain, and reduced blood loss compared with an open procedure. Typically, the free wall of the cyst represented by the thinnest tissue is the resected portion. An energy device (e.g., harmonic scalpel) or surgical stapler is commonly used to cut through the cyst wall and liver tissue to minimize the likelihood of postoperative bleeding. In open operations, the resection margin can instead be oversewn with a running locked suture. The resected cyst wall is sent for pathologic evaluation to rule out malignancy. Securing a mobilized omental flap into the opened cyst helps reduce the likelihood of recurrence, which is a consequence of other tissue walling off the opened cyst (e.g., hemidiaphragm). Complete cyst wall excision

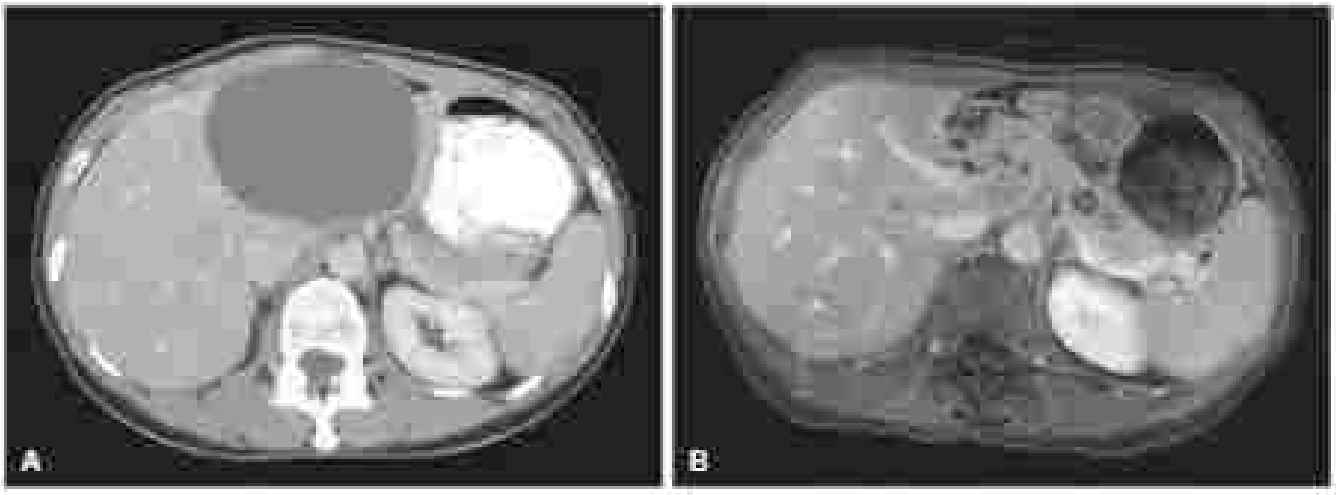

FIG. 1 (A) Axial computed tomography demonstrating a simple liver cyst in the left lobe of the liver in a 64-year-old woman. (B) Axial T1-weighted magnetic resonance imaging after cyst fenestration shows minimal hyperintense, residual fluid in the cyst cavity.

is rarely indicated and is reserved for instances when there is a high suspicion for biliary cystadenoma or cystadenocarcinoma. Complete resection can generally be performed with either a wedge or segmental resection. Recurrence rates are comparable between fenestration and complete resection, both approximately 10% to 15%. Morbidity for surgical fenestration or resection is approximately 15%, and mortality is less than 1%. Main complications include postoperative ascites, bile leak, hematoma, and surgical site infection.

For patients with multiple comorbid conditions who are unable to undergo a surgical procedure, sclerotherapy is an alternative treatment modality designed to destroy the biliary epithelial lining of the cyst wall, which is the source of fluid production. Sclerotherapy involves percutaneous placement of a drainage catheter into the cyst cavity under US guidance. Contrast is first injected to evaluate for communication with the biliary tree, which is a contraindication to proceeding. Other contraindications include intracystic bleeding and fistula to the gastrointestinal tract or peritoneum. Sclerosing agents include ethanol, tetracycline hydrochloride, and ethanolamine oleate. After an instillation duration of approximately 2 to 4 hours, the sclerosing agent is aspirated and the cyst cavity collapsed. Sclerotherapy is associated with a 20% recurrence rate within the first year, which is higher than surgical fenestration or resection, though is associated with lower morbidity and mortality. Postprocedural pain is common, though self-limiting.

BILIARY CYSTADENOMA

Pathogenesis

Biliary cystadenoma (BCA) is a cystic neoplasm of the biliary ductular system that may occur throughout the biliary tree, including both intrahepatic and extrahepatic locations. BCA is thought to arise from ectopic clusters of embryonic bile ducts, although a subset of lesions will also contain endocrine cells, indicating that BCA might also arise from intrahepatic peribiliary glands. BCA is typically a solitary, multilocular mass with fluid contents that is a distinct pathologic process from biliary intraductal papillary mucinous neoplasm. Unlike biliary intraductal papillary mucinous neoplasm, BCA lack papillary projections and a superficial spreading growth pattern, and histologically BCA have a cyst-in-cyst appearance characterized by multiple septa within the body of the lesion. BCA frequently contain ovarian-like stroma with estrogen and progesterone receptors and might therefore be hormone responsive. BCA has the potential for malignant transformation to biliary cystadenocarcinoma (BCAC) in approximately 20% of cases. BCAC is distinguished by the presence of proliferating, malignant-appearing epithelium on the tumor cystic layer.

Presentation

BCA typically occurs as a single mass, more often in the left lobe of the liver, and predominately affects women (90%) with a median age of diagnosis of 45 years. The majority of these tumors are identified incidentally and patients are asymptomatic, although some may present with abdominal pain or distension. Up to 20% of patients diagnosed with BCA will have elevated liver function tests, notably increased alkaline phosphatase and bilirubin. However, obstructive jaundice and cholangitis are rare and typically occur with extrahepatic disease. Cyst rupture and hemorrhage are reported but are also rare.

Imaging

On US, BCA appear anechoic with a thick cyst wall and internal septations. Intracystic debris is frequently observed, and mural and septal nodules may be present although are more common with BCAC, which contains foci of stacking malignant cells. On CT, BCA appear as well-circumscribed, multiseptated cystic lesions with mural and nodular enhancement on contrast injection. MRI provides similar architectural resolution, and BCA appear as low intensity on T1-weighted sequences and high intensity on T2-weighted sequences (Fig. 2A,B). The degree of T1 signal intensity in cyst fluid indicates the degree of protein and debris. Magnetic resonance cholangiopancreatography may aid in identifying cyst communication with the biliary tree. Although mural nodules, fluid debris, and wall thickening are more common with BCAC, there is currently no validated algorithm for reliably differentiating BCA from BCAC by imaging alone.

Management

Given the risk of malignant conversion of BCA to BCAC, surgical resection with negative margins is the current standard of care. Cyst aspiration, sclerotherapy, fenestration, and marsupialization leave behind premalignant or malignant tissue and are all associated with high recurrence rates (80%–90%) and should therefore be avoided when BCA is suspected. For extrahepatic BCA, complete removal of the cyst and surrounding bile duct followed by reconstruction with biliary diversion is required. For intrahepatic disease, technical factors including cyst location and size should determine the type and extent of resection. Peripheral lesions should be managed with segmentectomy or fenestration. For more central lesions near major vessels, formal resection may not be possible, in which case enucleation is an acceptable alternative. In extremely rare cases, orthotopic liver transplant has been used for BCA with good success.

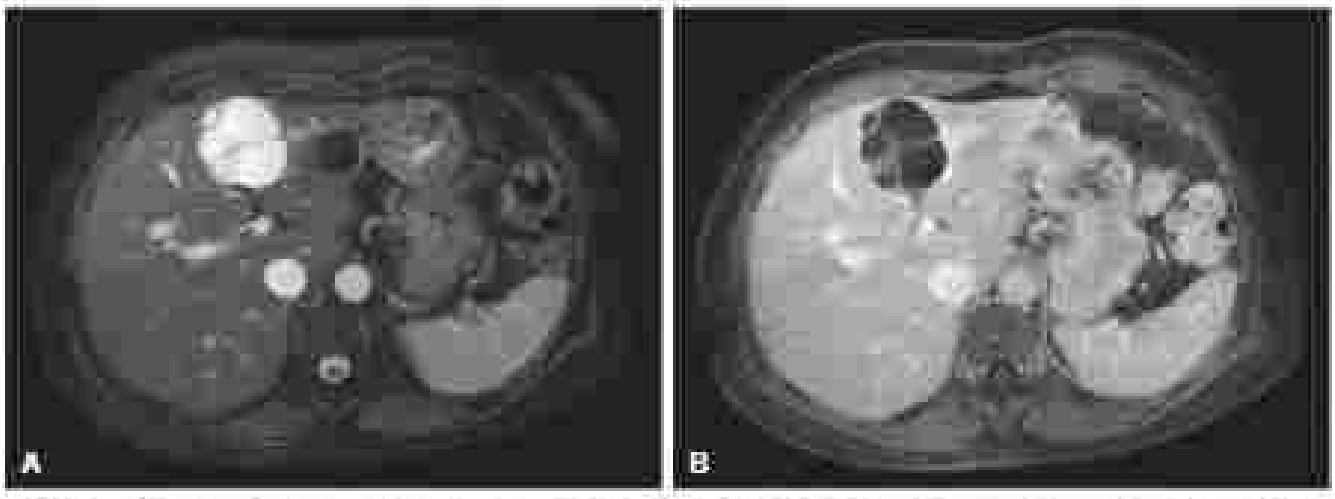

FIG. 1 (A) Axial T2-weighted image demonstrating a cystic mass in the left lobe of the liver in a 57-year-old woman. (B) Axial T1-weighted imaging of the same lesion reveals a hypointense, septated mass with clear borders.

HEPATIC HEMANGIOMA

Pathogenesis

Hepatic hemangiomas are the most common benign liver lesion, occurring in 5% to 20% of the population. They are congenital malformations comprising blood filled cavernous spaces lined by a single layer of endothelial cells and separated by fibrous tissue. They develop a round, well encapsulated shape and may grossly exhibit evidence of internal thrombosis or hemorrhage with calcifications. Hemangiomas have no potential for malignant transformation and, in contrast to adenomas, have an extremely low risk of spontaneous hemorrhage or rupture. Only a minority of lesions grow significantly over time.

Presentation

Hemangiomas occur predominately in women aged 30 to 50 years. Most patients present with a single lesion, though up to 10% of patients may present with multifocal disease throughout the liver. There is a slight predominance toward a peripheral location and the right lobe of the liver. In general, hemangiomas are small, ranging from several millimeters to several centimeters in diameter, although in rare cases lesions may be greater than 10 cm, which are referred to as giant hemangiomas. As with other benign lesions of the liver, hemangiomas are rarely symptomatic, and the majority of cases are incidentally diagnosed during abdominal imaging for other indications. With large hemangiomas, however, there is the potential for pain secondary to capsular stretch, or early satiety or nausea resulting from compression of the gastrointestinal tract. Giant hemangiomas in children may also result in a consumptive process called Kasabach Merritt syndrome, characterized by thrombocytopenia, hypofibrinogenemia, elevated fibrin degradation products, and coagulopathy.

Imaging

On US, hemangiomas appear as well demarcated, homogeneous, and hyperechoic lesions with posterior acoustic enhancement. On CT, hemangiomas appear as well circumscribed, hypodense lesions with postcontrast imaging. On MRI, hemangiomas appear as well demarcated, homogeneous lesions that are hypointense on T1 weighted imaging and markedly hyperintense on T2 weighted imaging (Fig. 3A). Following contrast injection, asymmetric peripheral pools of enhancement during the arterial phase followed by progressive centripetal enhancement and washout on delayed phases is pathognomonic for hemangioma (Fig. 3B). This enhancement pattern is similar to that observed with CT scan.

Management

The vast majority of hemangiomas are small and asymptomatic lesions that are managed nonoperatively. Indications for surgical resection include significant growth, significant symptoms that are unresponsive to analgesics and interfere with daily living, or, in exceedingly rare cases, rupture and hemorrhage. Perhaps the most difficult diagnostic challenge is to determine whether a patient's pain is caused by a known hemangioma. Unexplained abdominal pain are common, as are hemangiomas, and the two commonly coexist; therefore, it is important to carefully exclude other causes of abdominal pain before ascribing the pain to a known hemangioma. This task is challenging because pain caused by hemangiomas is typically nonspecific. The differential diagnosis commonly includes peptic ulcer disease, biliary colic, severe dyspepsia, and musculoskeletal pain. When choosing to operate for symptoms of pain, it is wise to inform the patient that his or her symptoms might not improve after surgery.

Resection can be completed by either open or minimally invasive approaches and involves tumor enucleation, wedge resection, or a limited segmental resection based on the size and location of the lesion in proximity to major biliary and vascular structures. Because of the large pseudocapsule often associated with hemangiomas, it is possible to perform an enucleation, sparing a parenchymal resection. Enucleation involves dissection in the plane between the normal liver parenchyma and pseudocapsule. Crossing vascular structures are individually identified and controlled with ties, clips, or an energy device. When operating on giant hemangiomas, a commonly used tactic is to first slowly squeeze the tumor to push out a majority of its blood. The tissue left behind is smaller and easier to grasp and manipulate. For large hemangiomas, preoperative hepatic arterial embolization has been used to mitigate intraoperative bleeding, though this is rarely necessary. Orthotopic liver transplant has also been used for large, unresectable lesions with good success. There are currently no effective medical therapies, though embolization and radiation therapy have been used for symptomatic patients who are not operative candidates.

HEPATIC ADENOMA

Pathogenesis

Hepatic adenomas are encapsulated tumors comprising sustained hepatocytes that exhibit minimal cellular atypia. Grossly, they appear as soft, tan lesions perfused by peripheral arteries on their outer surface, and necrosis may be observed centrally when the mass outgrows its blood supply. Because of their lack of encapsulation, adenomas are at increased risk of uncontrolled hemorrhage into the surrounding

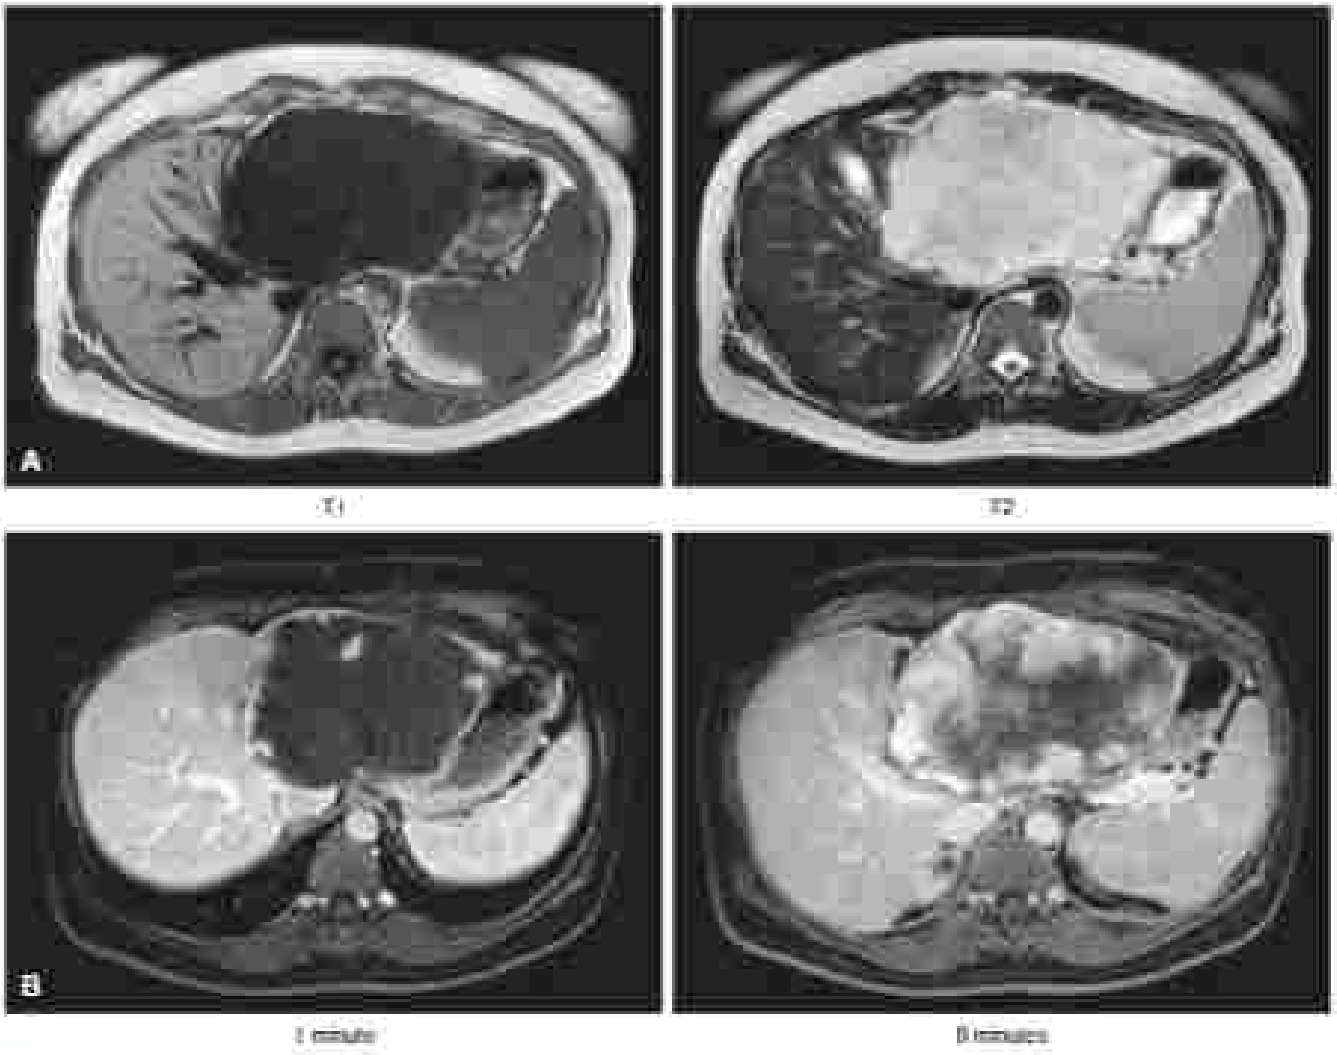

FIG. 2. (A) Homogeneous signal hyperintense on T1-weighted magnetic resonance imaging and hyperintense on T2-weighted images, as shown by this large left hepatic lobe mass in a 34-year-old woman. (B) Dynamic resonance imaging demonstrating centripetal contrast enhancement over time, which is pathognomonic for hemangioma.

liver tissue. Adenomas have a risk of malignant transformation. The risk is higher in men and for lesions larger than 5 cm in diameter. Adenomas generally occur in the absence of cirrhosis on a normal background liver, although steatosis and steatohepatitis are risk factors. Other risk factors include estrogens such as those in oral contraceptives, anabolic steroids, and type I and III glycogen storage diseases.

Adenomas may be categorized into four genetically distinct subgroups: HNF1 alpha–inactivated adenoma, inflammatory adenoma, beta-catenin–activated adenoma, and unclassified adenoma. The HNF1 alpha–inactivated subtype accounts for up to one third of all adenomas and is associated with spontaneous occurrence. These lesions exhibit macrovesicular steatosis and have a lower risk of malignant transformation. Inflammatory adenomas account for up to 60% of cases and are characterized by lymphocytic infiltrates, pseudoportal tracts, and abnormal activation of the JAK/STAT pathway. Inflammatory adenomas are associated with obesity-induced nonalcoholic steatohepatitis, which is rising in incidence in both men and women. The percentage of adenomas that are beta-catenin active is greater among men. These lesions exhibit greater cellular atypia than other subtypes, and their risk of malignant transformation depends on the type of beta-catenin mutation and the degree of constitutive downstream Wnt signaling. Finally, unclassified adenomas lack a clear mutational signature or inflammatory infiltrates. These lesions have been associated with the highest risk for spontaneous rupture.

Presentation

Adenomas can present as single or multiple simultaneous lesions and can range from a few millimeters to greater than 10 cm in diameter. The presence of 10 or more adenomas is referred to as adenomatosis. Adenomas occur most often in adult women aged 20 to 40 years, and less commonly in men. However, the epidemiology of adenomas has shifted in recent years. Historically, there was a significant association between adenoma formation and oral contraceptive use, which was determined by the duration of therapy and hormonal dosage; however, newer contraceptives have lower estrogen dosages, which has reduced the incidence of contraceptive-related adenomas. In contrast, obesity and the related metabolic disorders nonalcoholic fatty liver disease and nonalcoholic steatohepatitis are risk factors for adenoma formation with rising global incidence for both genders. Finally, glycogen storage disease–related adenomas most commonly occur in young males less than 20 years of age.

Most adenomas are asymptomatic and discovered incidentally with abdominal imaging for other indications. Some patients present with acute onset right upper quadrant or epigastric pain secondary

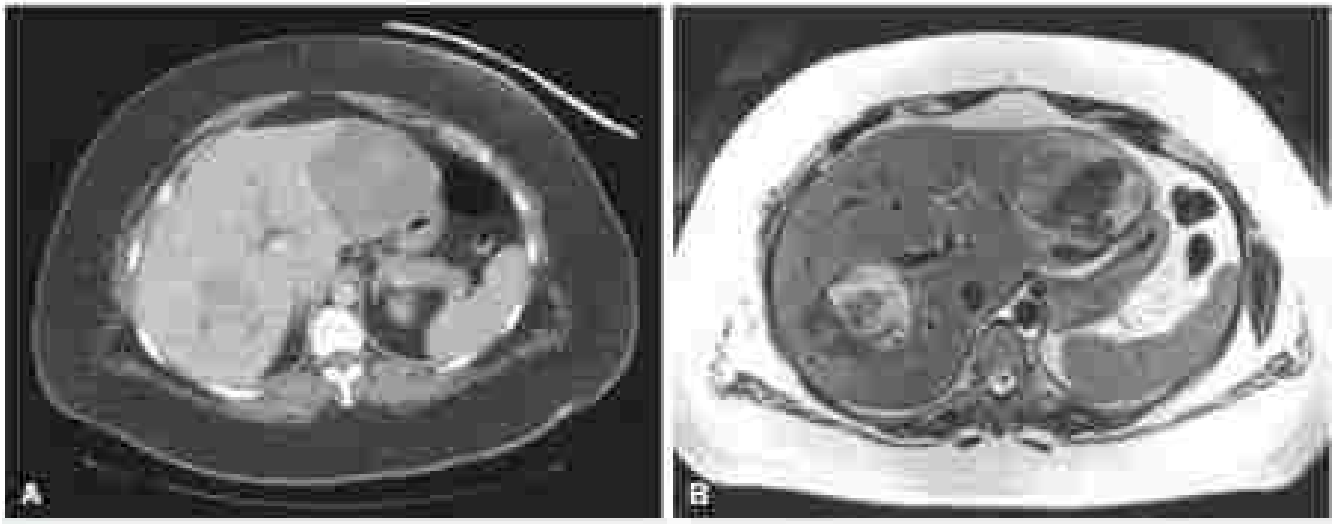

FIG. 4 (A) Axial computed tomography image of a 31-year-old female patient with two large adenomas with foci of hemorrhage. (B) Axial T2-weighted image of the same lesions shows mixed intensity signal that correlates with regions of hemorrhage.

to spontaneous adenoma hemorrhage. Bleeding is typically self-limiting; however, in rare cases, spontaneous hemorrhage and rupture may result in hypovolemic shock or death.

Imaging

Adenomas lack unique identifying radiographic features on US. They appear as well demarcated, heterogeneous masses with variable echogenicity, which can be difficult to differentiate from hepatocellular carcinoma or metastases. On CT scan, adenomas are hodgepodge relative to the surrounding liver parenchyma, and on contrast injection, will appear hyperattenuated during the early arterial phase with loss of signal during delayed phases. Depending on the degree of necrosis or hemorrhage, adenomas may have heterogeneous attenuation (Fig. 4A). On MRI, adenomas appear isointense to hyperintense on both T1- and T2-weighted sequences (Fig. 4B), with increased signal intensity on gadolinium contrast injection that is most prominent during the arterial phase. Gadoxetic acid contrast can help distinguish FNH from adenoma because FNH will typically retain contrast in the delayed hepatobiliary phase, whereas adenomas typically do not.

Management

The main risks of adenoma are bleeding and malignant transformation. For an adenoma less than 5 cm in diameter, the initial management strategy is cessation of hormonal contraceptives or anabolic steroids if present, followed by close surveillance. Weight reduction and improved dietary habits should be recommended for obese patients with fatty liver. The goal of cessation is to prevent further adenoma growth. In some cases, regression may occur although disappearance is unlikely and, if left in the liver, long-term surveillance is indicated. For patients in which the adenoma continues to grow or becomes symptomatic, or for adenomas greater than 5 cm, surgical resection is recommended. Ablative therapies have been used, but long-term follow-up data are lacking. The surgical approach to adenomas should be similar to that of a malignancy, with a goal of negative margins despite the benign nature of the lesion. The choice of an open or minimally invasive approach depends on technical factors and surgeon experience. Similarly, the decision between a formal anatomic resection versus a parenchymal-sparing approach should be determined by the size and location of the adenoma and the degree of suspicion of malignancy. For patients with multiple adenomas or unresectable lesions, close surveillance with MRI is the typical approach. Growth or worrisome changes on MRI of any specific lesion is an indication to resect that single lesion.

For patients who present with acute hemorrhage from a ruptured adenoma, treatment options involve vascular embolization or surgery, which depends on the stability of the patient. For patients with stable vital signs, the preferred approach involves selective arterial embolization by interventional radiology followed by elective surgical resection during the same hospitalization. For unstable patients or those not amenable to embolization, emergent laparotomy is indicated to control bleeding. The operation should be performed by an open laparotomy. Liver packing and inflow control with a Pringle's maneuver are used to gain control of the bleeding. If bleeding has been controlled before onset of hypotension, acidosis, hypothermia, or coagulopathy, resection may be performed at the same operation. Following hemorrhage into liver tissue, identification of the border between adenoma and liver can be difficult. In these situations, formal anatomic resection may be easier to perform than attempts to resect only the tumor. Finally, in cases in which bleeding cannot be controlled operatively despite Pringle, completing the operation leaving packing behind followed by selective embolization is indicated.

FOCAL NODULAR HYPERPLASIA

Pathogenesis

FNH is thought to be a hyperplastic response of normal liver tissue surrounding a congenital arteriovenous malformation and thus not a true neoplasm. Histologically, FNH appears as a proliferation of mature hepatocytes and bile ducts in a stellate pattern surrounding a central scar composed of fibrous tissue and malformed vessels. These lesions have no malignant potential and extremely low risk of bleeding or causing pain.

Presentation

FNH is the second most common benign liver lesion after hemangioma and occurs most often in reproductive age women aged 20 to 50 years. These lesions are typically discovered incidentally because they are nearly always asymptomatic, even when large; however, symptoms of vague right upper quadrant or epigastric pain may occur rarely. FNH usually presents as a single lesion, although multiple lesions may be observed in rare cases and are sometimes associated with a syndrome of vascular malformations. The majority of masses are less than 5 cm and approximately 80% will have evidence of a central scar.

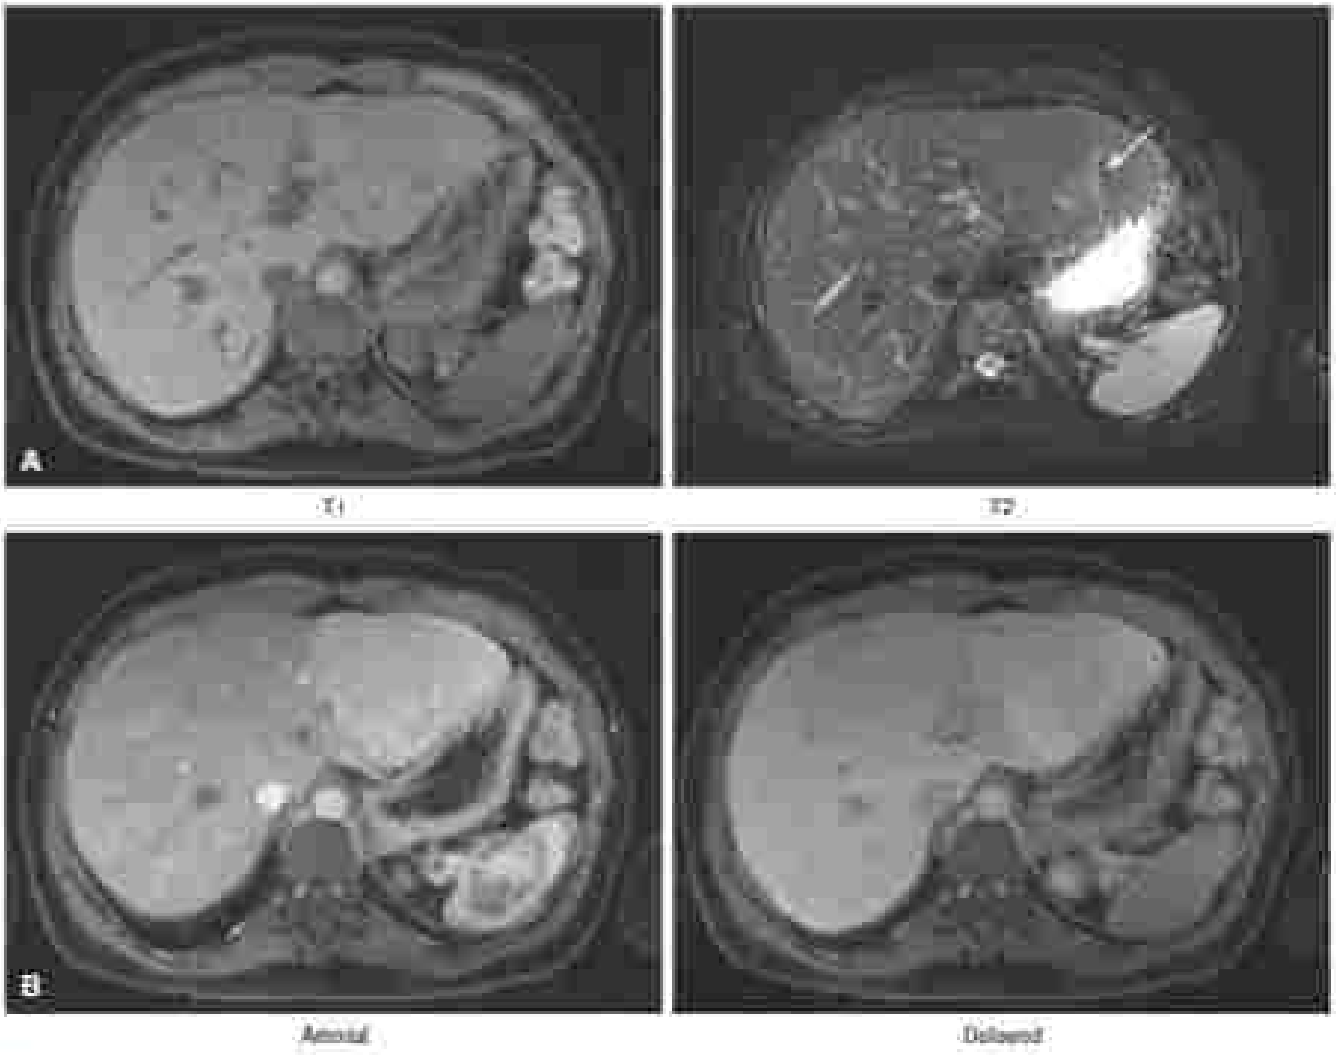

FIG. 3 (A) Focal nodular hyperplasia (FNH) appears hypointense throughout on T1-weighted magnetic resonance imaging whereas on T2-weighted sequence FNH is hyperintense with a hyperintense central scar (*left to right*). (B) FNH displays early arterial enhancement with rapid washout. During the venous phase, FNH is isointense with the central scar remains enhanced.

Twenty percent are "atypical" lesions that lack evidence of central scar and in rare cases, FNH greater than 10 cm has been reported.

Imaging

US is an available modality for the diagnosis of FNH, with an accuracy of approximately 80%. Multidetector CT and MRI are the standard of care for diagnosing FNH, which can be difficult to distinguish from other lesions, including adenoma or fibrolamellar carcinoma, particularly in the absence of a central scar. On noncontrast CT, FNH will appear isodense or hypodense relative to the surrounding liver parenchyma, and in some cases a hypodense central scar is visible. With contrast, FNH appears as a well-circumscribed, hyperattenuated mass during the arterial phase. During the venous phase, FNH is isodense, whereas the central scar remains enhanced. On T1-weighted MRI, FNH appears hypointense throughout, while on T2-weighted sequences, FNH is hyperintense with a hyperintense central scar (Fig. 3A). With gadolinium contrast, FNH will display early arterial enhancement (Fig. 3B). During the venous phase, FNH is isointense, whereas the central scar remains enhanced. Except for the findings of a central scar, these CT and MRI imaging characteristics are similar to those of hepatic adenomas, which is typically also in the differential diagnosis. Retention of gadoxetic acid on delayed hepatobiliary phase in FNH may be helpful in distinguishing it from adenoma. In some cases, biopsy is necessary to render a diagnosis, most notably when adenoma, fibrolamellar hepatocellular carcinoma, or metastases are possible diagnoses. There are no histologic features pathognomonic for a diagnosis of FNH, which often appears as fibrous and regenerative nodules, similar to cirrhosis.

Management

FNH almost never requires surgical intervention. There are extremely rare cases in which FNH causes pain unresponsive to analgesics that impairs quality of life, for which resection is indicated. Similar to the situation with purportedly symptomatic hepatic hemangiomas, ascribing symptoms of abdominal pain to an FNH can be fraught with inaccuracy. Both open and minimally invasive approaches are acceptable with a goal of negative margins. The extent of resection depends on technical factors, particularly the size and location of the lesion.

SUMMARY

There has been a substantial increase in frequency of incidentally discovered hepatobiliary masses because of increased usage of axial imaging modalities. The majority of these lesions are benign and

include simple cysts, HCA, hemangioma, adenoma, and FNH. Nonetheless, all incidentalomas require careful diagnostic evaluation to rule out malignancy or premalignant condition. Management of benign liver lesions does not typically require resection, with certain exceptions. Simple cysts should be observed unless symptomatic, in which case surgical fenestration is associated with the lowest rate of recurrence. HCA requires an oncologic surgical resection in all cases given the risk of malignant transformation. Hemangiomas have no malignant potential and harbor a low risk of hemorrhage; therefore, resection is not indicated except for rare cases of symptoms that adversely affect quality of life. Adenomas larger than 5 cm should be resected because of their risk of hemorrhage and malignant transformation. For smaller, asymptomatic adenomas, cessation of potential stimulants for growth including oral contraceptives, anabolic steroids, and obesity should be addressed in addition to observation with serial scans. Finally, FNH has no malignant potential and rarely requires surgical resection, except for cases of ongoing symptoms or inability to distinguish FNH from other potentially malignant lesions. The ability of surgeons to diagnose and appropriately manage benign liver lesions has taken on greater importance given the increasing frequency of incidentally identified liver lesions, now and likely in the coming decades.

Management of Malignant Liver Tumors

Jordan M. Cloyd, MD, and Timothy M. Pawlik, MD, MPH, PhD, FACS, FRACS(Hon)

The most common malignant liver tumors are hepatocellular carcinoma (HCC), intrahepatic cholangiocarcinoma (ICC), and metastatic colorectal cancer. In the Western world, metastatic liver tumors are more common than primary liver tumors.

Surgical resection is the mainstay of treatment for hepatic malignancies. Appropriate selection of patients for resection requires evaluation of the overall health status, oncologic appropriateness, and, finally, resectability of the disease. A lesion is considered resectable if negative margins can be obtained while leaving an adequate amount of functional liver parenchyma with intact hepatic arterial and portal venous inflow, venous outflow, and biliary drainage. If this cannot be accomplished, other liver directed therapies may be considered, such as tumor ablation, tumor embolization, and external radiation.

Tumor ablation can be performed with various techniques such as alcohol injection and thermal ablation with heat (microwave or radiofrequency ablation [RFA]) or cold (cryoablation). microwave and RFA are the most successful in hepatic malignancies. A newer technology called irreversible electroporation is emerging as an attractive alternative to thermal ablation for tumors near vascular structures. Irreversible electroporation uses short duration, high voltage pulses to create defects in the lipid bilayer that ultimately result in cell necrosis without the heat sink effect associated with thermal ablation when used near vascular structures. Tumor embolization includes transarterial blood embolization (TAE), transarterial chemoembolization (TACE), or radioembolization, typically using the radioactive isotope yttrium 90. Finally, external beam radiation therapy—either conformal or stereotactic—is emerging as another alternative for the treatment of malignant liver tumors not amenable to resection.

HEPATOCELLULAR CACINOMA

HCC is the most common primary malignant liver tumor worldwide. Although the incidence is highest in Asia and sub-Saharan Africa, the incidence in the United States has been increasing in recent years. Risk factors include cirrhosis of any cause, including hepatitis B and C. In the absence of cirrhosis, HCC usually is associated with hepatitis B, although a variant type, fibrolamellar HCC, occurs in patients with no underlying liver disease. HCCs are characterized by homogeneous enhancement in the arterial phase and washout of the contrast material in the portal venous phase on computed tomography (CT) scan and magnetic resonance imaging (MRI).

For patients with cirrhosis, liver transplantation will address both the HCC and the underlying liver disease. Because of limited organ availability and transplant associated risks, such as organ rejection and immunosuppression related complications, however, other treatment modalities often must be considered. The most widely used treatment modalities for HCC include TACE, ablation, and resection. Resection versus transplantation is addressed in a separate chapter.

Surgical resection of HCC is a good option when feasible. The presence and degree of fibrosis/cirrhosis correlates with the incidence of postoperative liver failure, as well as with long-term survival. Major liver resection is therefore generally limited to patients with no cirrhosis or cirrhosis classified as Child's A with no evidence of portal hypertension. In these patients, mortality rates are lower than 5%. Although 5-year survival rates range from 50% to 60%, recurrence rates are considerable among patients with cirrhosis, with recurrence noted in about one-third of patients within 5 years. Other factors negatively associated with long-term survival include invasion of major vessels, microvascular invasion, and both the number of tumors and tumor size; however, when adjusted for the presence of other prognostic features, tumor size is not a predictor of survival in patients with solitary lesions. Resection of tumors in patients with multifocal HCC and major vascular invasion are associated with poor prognosis and high recurrence rates (>85%) and should be considered only in highly selected cases.

In the appropriately selected patient, resection should be attempted only if negative margins can be obtained. Ideally, anatomic resections of portal territories, including sectionectomy, segmentectomy, and subsegmentectomy, should be performed, because HCC tends to spread via portal venous tributaries. Anatomic resections have been associated with reduced local recurrence and improved survival in patients with HCC in both randomized and observational studies. On the other hand, thermal ablation of small (<3 cm) HCC has been shown to have long-term outcomes that are equivalent to surgical resection in recent randomized trials, with less morbidity and mortality. These data should be interpreted cautiously, however,

include simple cysts, HCA, hemangioma, adenoma, and FNH. Nonetheless, all incidentalomas require careful diagnostic evaluation to rule out malignancy or premalignant condition. Management of benign liver lesions does not typically require resection, with certain exceptions. Simple cysts should be observed unless symptomatic, in which case surgical fenestration is associated with the lowest rate of recurrence. HCA requires an oncologic surgical resection in all cases given the risk of malignant transformation. Hemangiomas have no malignant potential and harbor a low risk of hemorrhage; therefore, resection is not indicated except for rare cases of symptoms that adversely affect quality of life. Adenomas larger than 5 cm should be resected because of their risk of hemorrhage and malignant transformation. For smaller, asymptomatic adenomas, cessation of potential stimulants for growth including oral contraceptives, anabolic steroids, and obesity should be addressed in addition to observation with serial scans. Finally, FNH has no malignant potential and rarely requires surgical resection, except for cases of ongoing symptoms or inability to distinguish FNH from other potentially malignant lesions. The ability of surgeons to diagnose and appropriately manage benign liver lesions has taken on greater importance given the increasing frequency of incidentally identified liver lesions, now and likely in the coming decades.

Management of Malignant Liver Tumors

Jordan M. Cloyd, MD, and Timothy M. Pawlik, MD, MPH, PhD, FACS, FRACS(Hon)

The most common malignant liver tumors are hepatocellular carcinoma (HCC), intrahepatic cholangiocarcinoma (ICC), and metastatic colorectal cancer. In the Western world, metastatic liver tumors are more common than primary liver tumors.

Surgical resection is the mainstay of treatment for hepatic malignancies. Appropriate selection of patients for resection requires evaluation of the overall health status, oncologic appropriateness, and, finally, resectability of the disease. A lesion is considered resectable if negative margins can be obtained while leaving an adequate amount of functional liver parenchyma with intact hepatic arterial and portal venous inflow, venous outflow, and biliary drainage. If this cannot be accomplished, other liver-directed therapies may be considered, such as tumor ablation, tumor embolization, and external radiation.

Tumor ablation can be performed with various techniques such as alcohol injection and thermal ablation with heat (microwave or radiofrequency ablation [RFA]) or cold (cryoablation). microwave and RFA are the most successful in hepatic malignancies. A newer technology called irreversible electroporation is emerging as an attractive alternative to thermal ablation for tumors near vascular structures. Irreversible electroporation uses short duration, high-voltage pulses to create defects in the lipid bilayer that ultimately result in cell necrosis without the heat sink effect associated with thermal ablation when used near vascular structures. Tumor embolization includes transarterial blood embolization (TAE), transarterial chemoembolization (TACE), or radioembolization, typically using the radioactive isotope yttrium 90. Finally, external beam radiation therapy—either conformal or stereotactic—is emerging as another alternative for the treatment of malignant liver tumors not amenable to resection.

HEPATOCELLULAR CACINOMA

HCC is the most common primary malignant liver tumor worldwide. Although the incidence is highest in Asia and sub-Saharan Africa, the incidence in the United States has been increasing in recent years. Risk factors include cirrhosis of any cause, including hepatitis B and C. In the absence of cirrhosis, HCC usually is associated with hepatitis B, although a variant type, fibrolamellar HCC, occurs in patients with no underlying liver disease. HCCs are characterized by homogeneous enhancement in the arterial phase and washout of the contrast material in the portal venous phase on computed tomography (CT) scan and magnetic resonance imaging (MRI).

For patients with cirrhosis, liver transplantation will address both the HCC and the underlying liver disease. Because of limited organ availability and transplant-associated risks, such as organ rejection and immunosuppression related complications, however, other treatment modalities often must be considered. The most widely used treatment modalities for HCC include TACE, yttrium 90, ablation, and resection. Resection versus transplantation is addressed in a separate chapter.

Surgical resection of HCC is a good option when feasible. The presence and degree of fibrosis/cirrhosis correlates with the incidence of postoperative liver failure, as well as with long-term survival. Major liver resection is therefore generally limited to patients with no cirrhosis or cirrhosis classified as Child's A with no evidence of portal hypertension. In these patients, mortality rates are lower than 5%. Although 5-year survival rates range from 50% to 60%, recurrence rates are considerable among patients with cirrhosis, with recurrence noted in about one-third of patients within 5 years. Other factors negatively associated with long-term survival include invasion of major vessels, microvascular invasion, and both the number of tumors and tumor size; however, when adjusted for the presence of other prognostic features, tumor size is not a predictor of survival in patients with solitary lesions. Resection of tumors in patients with multifocal HCC and major vascular invasion are associated with poor prognosis and high recurrence rates (>65%) and should be considered only in highly selected cases.

In the appropriately selected patient, resection should be attempted only if negative margins can be obtained. Ideally, anatomic resections of portal territories, including sectionectomy, segmentectomy, and subsegmentectomy, should be performed, because HCC tends to spread via portal venous tributaries. Anatomic resections have been associated with reduced local recurrence and improved survival in patients with HCC in both randomized and observational studies. On the other hand, thermal ablation of small (<3 cm) HCC has been shown to have long-term outcomes that are equivalent to surgical resection in recent randomized trials, with less morbidity and mortality. These data should be interpreted cautiously, however,

because these studies had small sample sizes and were not designed as noninferiority trials. Ablation can be accomplished percutaneously or through an open or laparoscopic operation. Finally, ablation of tumors larger than 4 cm or those close to major vascular structures should be avoided because this approach is associated with high rates of incomplete tumor destruction and recurrence, with local recurrence rates as high as 40%.

Embolization (bland, chemoembolization, or radioembolization) is used typically for patients who are not candidates for curative treatment by resection, transplantation, or ablation. Embolization also may be used as a bridge to liver transplantation or before ablation for tumors between 3 and 5 cm. In the latter group, the combination of TACE and RFA has been shown to improve survival when compared with either modality alone. Response rates with TACE are as high as 80%, but the treatment usually must be repeated every 3 to 4 months. A total bilirubin level greater than 3 mg/dL is a contraindication for these treatments. Portal vein thrombosis is a relative contraindication for TAE and TACE. These patients can be treated with radioembolization or external beam radiation. In the right setting, superselective embolization can be considered even if the ipsilateral portal vein is thrombosed. External beam radiation is an alternative for HCC with local control rates around 90%, although long-term data are limited.

Although surgical resection and transplantation are contraindicated in the presence of extrahepatic disease, liver-directed therapies may be used in the presence of limited extrahepatic disease, if the liver disease is thought to be rate limiting. For patients with significant extrahepatic disease, systemic therapy should be considered. Sorafenib, an oral multikinase inhibitor, remains first-line treatment, although the anti-PD1 agent nivolumab has recently been approved for second-line treatment of HCC.

INTRAHEPATIC CHOLANGIOCARCINOMA

ICC is the second most common primary malignant liver tumor, accounting for 10% to 20% of such cases. Its incidence has increased markedly over recent decades for unclear reasons. Risk factors for the development of cholangiocarcinoma include sclerosing cholangitis (10%–20% lifetime risk), choledochal cysts (15%–28% lifetime risk), and cirrhosis. Of the three gross subtypes of ICC—mass forming, periductal infiltrating, and intraductal—the periductal infiltrating type is associated with the worst prognosis and unfortunately is the most common. ICCs are typically low in attenuation on CT scan, with minor peripheral enhancement and upstream biliary dilation. Capsular retraction also may be noted. The diagnosis often is made when a liver lesion is found to be adenocarcinoma from biopsy and a workup for the primary (including upper and lower endoscopy and sometimes positron emission tomography scan) does not reveal a source.

Surgical resection with the goal of obtaining negative margins is the only curative option. The porta hepatis lymph nodes should be dissected formally because they are positive in about one third of patients. Survival rates for resected patients range between 40% and 60% at 5 years. Positive margins and positive nodes are associated with worse prognosis, and adjuvant chemotherapy and radiation may be beneficial in these cases. ICC is associated with a significant risk of peritoneal carcinomatosis, and diagnostic laparoscopy sometimes is considered in these patients. The presence of extrahepatic disease including lymph nodes beyond the porta hepatis is a contraindication for resection. Multiple liver lesions, which represent intrahepatic metastases, are associated with a poor prognosis, and resection should be considered only in highly selected patients. The presence of gross lymph node metastases in the hilum also is associated with worse prognosis, but some of these patients may benefit from resection and adjuvant therapy. For locally advanced tumors, TAE, TACE, or radioembolization can be used. Radiographic response can be seen in 25% of the patients. Whether regional therapy is better than chemotherapy in locally advance tumors remains to be determined.

METASTATIC COLORECTAL CANCER

Colorectal cancer is the third most frequent malignancy with approximately 150,000 new cases diagnosed every year in the United States. Synchronous or metachronous metastatic involvement of the liver will be diagnosed in about 50% of the patients with colorectal cancer. Consequently, colorectal liver metastases (CRLM) are far more common than primary liver tumors. These lesions are typically hypovascular and appear hypodense during the portal venous phase on CT scan. In this chapter, we focus on the resection of CRLM whereas other liver directed therapies are addressed in other chapters.

Surgical resection, when feasible, is the best curative option in patients with CRLM. The goal of the procedure should be to remove all metastases with microscopically negative margins. The optimal surgical margin width remains controversial but current recommendations are to aim for at least a 1 mm microscopic margin. Parenchymal sparing hepatectomies are preferred to major hepatic resections when applicable because these procedures are associated with decreased morbidity and increased rates of salvage ability in cases of recurrence, with no increase in recurrence rate or decrease in overall survival. For bilateral CRLM, major resection can be combined with wedge resection or ablation of the lesions on the contralateral side. These procedures may be performed at the same time or with staged operations, as dictated by the anticipated volume of the liver remnant. In patients with colorectal cancer and synchronous hepatic metastases, the primary tumor and the liver disease can be resected at the same time or separately. Concomitant liver and colorectal resection should be considered when only a minor liver resection is required or when the colon surgery is straightforward. Major liver resections should, however, be avoided when complex colorectal procedures are performed, such as those requiring extensive pelvic dissection or a low rectal anastomosis. In these situations, the hepatic metastases can be addressed first or after resection of the primary. Because the liver is usually the determining factor for complete disease resection, the "liver first" approach is an attractive option, especially for patients with extensive liver disease that may progress to unresectability and patients with rectal cancer that will require time between radiation and resection of the primary tumor. Occasionally, however, the primary tumor is symptomatic and must be addressed first. In contrast to patients with primary liver tumors, hepatic resection is often considered for patients with extrahepatic disease, as long as the extrahepatic disease is limited and resectable. This is a reflection of the very high response rates to the various systemic chemotherapy options currently available.

Preoperative chemotherapy is typically administered to assess tumor response and to address the potential micrometastatic disease not seen on imaging. A large randomized, controlled trial of perioperative chemotherapy for CRLM found improved progression-free survival compared with patients who received resection alone. However, prolonged, modern chemotherapy for colorectal cancer may be associated with significant injury to the liver, with increased risk of postoperative complications after liver resection. Specifically, irinotecan-based treatment is associated with steatohepatitis, whereas oxaliplatin-based chemotherapy is associated with sinusoidal congestion. Moreover, small (<2 cm) lesions may disappear with chemotherapy. If not surgically resected, these lesions will recur in up to 80% of the patients. The surgeon and the medical oncologist must work closely to determine optimal duration of preoperative chemotherapy and timing for the surgical procedure. In general, if preoperative chemotherapy is used, the duration should be limited to 4 to 6 cycles (i.e., 2–3 months).

Prognostic factors for patients who have undergone curative resection of CRLM include the disease-free interval between the diagnosis of the primary tumor and the metastatic disease, size of the largest hepatic tumor, presence of extrahepatic disease, mutation status (e.g., *RAS*, *BRAF*) and nodal status of the primary tumor. Overall and disease-free survival range from 30% to 60% and 20% to 40% at 5 years, respectively.

TABLE 1 Child-Turcotte-Pugh Score*

Measure	1 Point	2 Points	3 Points
Total bilirubin, mg/dL	<2	2–3	>3
Serum albumin, g/L	>35	28–35	<28
PT/INR	<1.7	1.71–2.30	>2.30
Ascites	None	Mild	Moderate to severe
Hepatic encephalopathy	None	Grades I–II (sup. present with medication)	Grades III–IV (refractory)

*The scores are for clinical measures: class A, 5–6 points; class B, 7–9 points; class C, 10–15 points.
PT/INR, prothrombin time/international normalized ratio.

PREOPERATIVE ASSESSMENT

Patients should undergo preoperative optimization and risk stratification according to the presence of medical comorbidities. Liver function is assessed with evaluation of total bilirubin, prothrombin time, albumin, presence of ascites, and history of encephalopathy. The Child-Turcotte-Pugh scoring system (Table 1) is associated with perioperative mortality rates of 0%, 10%, and 50% in patients with classes A, B, and C, respectively. Thrombocytopenia (platelets <100,000/mm^3), splenomegaly, and esophageal varices are indicators of portal hypertension, which is associated with prohibitive rates of perioperative mortality after major liver resections.

The location of the hepatic lesions and their relationship to the main hepatic vessels and the biliary tree are determined with high-quality, contrast-enhanced CT scan or MRI. The volume of the future liver remnant (FLR) is then calculated to estimate the risk of postoperative hepatic failure. The minimal recommended volume of the FLR varies according to the quality of the liver remnant. For patients with a healthy liver, the FLR should be at least 20% of the standardized total liver volume. Patients with some degree of liver dysfunction, such as those with chemotherapy-induced liver injury, should have an FLR of at least 30%, whereas those with evidence of cirrhosis should have an FLR of 40% or more depending on degree of dysfunction. Volumetry is calculated with three-dimensional CT scan or MRI. The volume of nonfunctional liver (parenchyma that is either tumor-burdened or replaced by tumor) is subtracted from the total liver volume, which is especially important for patients with large lesions. Alternatively, the estimated total liver volume can be calculated with the patient's body weight or body surface area (i.e., total liver volume in cm^3 = −794.41 + 1267.28 × body surface area in m^2). Patients with insufficient FLR volumes should undergo portal vein embolization of the branches of the segments planned for resection to induce growth of the contralateral side. Volumetry is repeated about 4 weeks after portal vein embolization and in a few more weeks if the minimal recommended FLR has not been achieved. The degree of hypertrophy of the remnant (at least a 5% increase in the volume of the FLR or an increase of 2% per week or more) has been associated with decreased rates of postoperative liver insufficiency.

OPERATIVE APPROACH TO RESECTION

Liver resections can be categorized into anatomic and nonanatomic. Anatomic resections include segmentectomies, sectionectomies, hemihepatectomies, and extended hepatectomies (also known as trisegmentectomy). Although small peripheral lesions are usually amenable to nonanatomic resections, lesions that are large or centrally located often require anatomic resections. These procedures can be performed either through an open technique or laparoscopically.

Positioning, Incision, and Exposure

Patients are placed supine in 15-degree Trendelenburg position to decrease the risk of air embolism with both arms extended at 90 degrees. Intravenous fluids should be restricted until transection of the parenchyma is completed to decrease bleeding from hepatic veins. Central venous cannulation is often unnecessary but should be considered in patients with extensive comorbidities. If used, a central venous pressure less than 5 cm H_2O should be maintained. Once the parenchymal transection has been completed, intravascular volume should be restored to achieve euvolemia.

In the open technique, a right subcostal incision with an upper midline extension provides adequate exposure for most tumors. Alternative incisions include a midline, an inverted "T" (Makuuchi incision), or bilateral subcostal with midline extension (Mercedes-Benz incision). The xiphoid should be removed to facilitate mobilization of the suprahepatic inferior vena cava (IVC). The abdominal cavity is explored for the presence of extrahepatic disease. The round ligament is ligated, the falciform ligament is dissected up to the anterior surface of the hepatic veins. The gastrohepatic ligament is opened to expose the caudate lobe with care not to injure an accessory or replaced left hepatic artery. Intraoperative US is performed to identify all known lesions—as well as any new lesions—and their relationship with vascular and biliary structures, as well as the position of the main hepatic vessels relative to the transection plane.

Inflow and Outflow Control

For major hepatic resections, artery and portal vein inflow vessels can be dissected and controlled in the hilum of the liver, intraparenchymally, or through small hepatotomies (Fig. 1). The latter approach should be avoided if the tumors are close to the hilum (<2 cm). Selective inflow control before the transection will result in a vascular demarcation line that will guide the correct transection plane. After inflow has been controlled, control of the hepatic venous outflow is performed. This also can be done outside the liver or within the parenchyma during the transection.

Parenchymal Transection

Multiple techniques have been described for parenchymal transection. Because randomized controlled trials have suggested no differences between the various methods, in general, it should be determined by the expertise and comfort of the surgeon. A simple and frequently used technique is the crush clamp method in which the liver substance is gently "crushed" with a Kelly clamp exposing small vessels that can be divided with an energy device (Fig. 2). An alternative method is the two-surgeon technique, in which the surgeon dissects using the Cavitron Ultrasonic Surgical Aspirator and an assistant provides exposure and divides vessels. In general, small vessels less than 3 mm can be divided using electrocautery, medium vessels are controlled with titanium clips, and vessels larger than 5 mm are divided between suture. Caution should be given to overuse of linear staplers for parenchymal transection, because although simple and efficient, the technique is relatively blind and may lead to inadvertent biliary or vascular injury.

Right Hepatectomy

If a right hepatectomy is to be performed, further dissection of the anterior surface of the hepatic veins is carried out to expose the right hepatic vein. The right coronary and triangular ligaments then are divided, exposing the bare area of the liver as the right liver is mobilized and rotated to the left and the short hepatic veins draining directly to the IVC are ligated. The retrocaval ligament (Makuuchi's

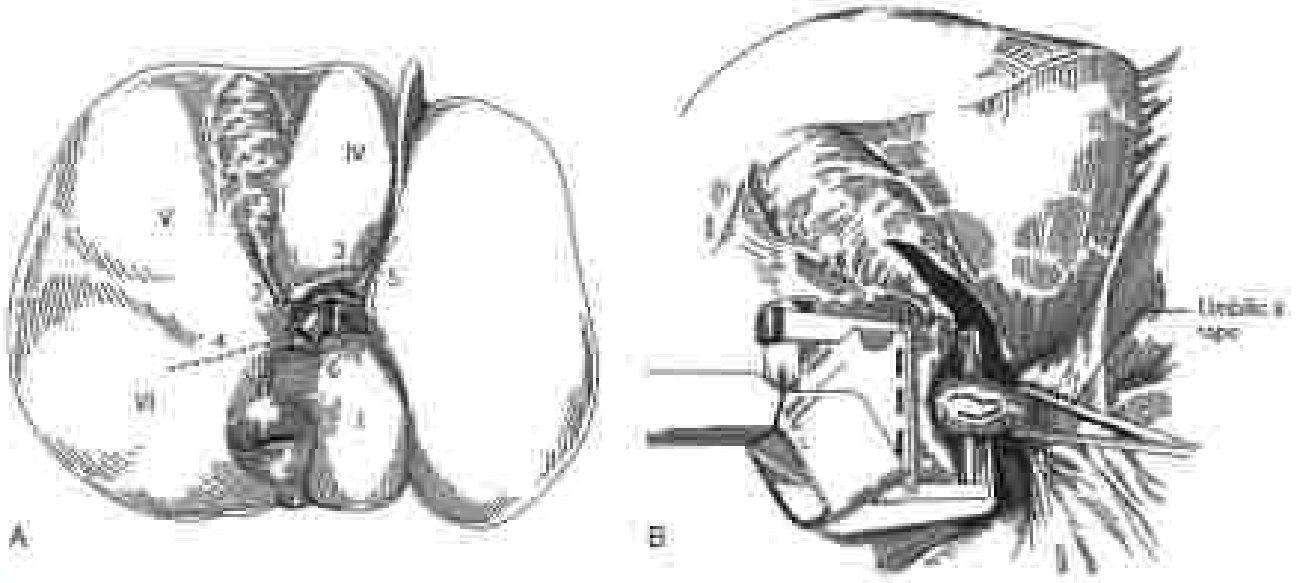

FIG. 1 (A) For the right portal pedicle to be accessed, hepatectomies are made in the gallbladder fossa (2) and in the caudate process (1). The pedicle is encircled with a metal pedicle clamp, and a vessel loop is passed around it. The vessel loop is used to retract the main portal vein/right portal vein to the left as a TA stapler is passed and fired. (B) to divide the right portal pedicle. [illegible]

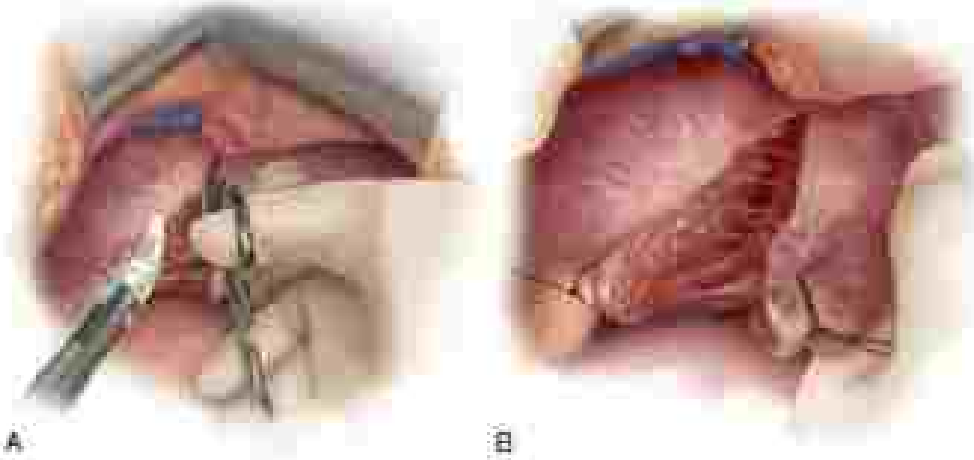

FIG. 2 (A) For division of the liver parenchyma, two stay sutures are placed for traction. The parenchyma is sequentially crush-clamped with a clamp. This demonstrates [illegible] (B) If the structure is <3 mm, the [illegible] are used. [illegible]

ligament) is identified and transected with a vascular stapler (Fig. 3). Further dissection between the liver and the IVC will expose the right hepatic vein, which is encircled. Attention is turned to the hilum, where the right hepatic artery and right portal vein are dissected and ligated. Alternatively, the right pedicle is controlled intraparenchymally as a large curved clamp is passed through an incision made in the left base of the gallbladder fossa, exiting through an incision at the junction of segment VII and the caudate process (Fig. 1). A clear line of vascular demarcation then can be identified. The right hepatic vein can then extraparenchymally be ligated with a stapler (Fig. 4). The transection plane follows the area of vascular demarcation leaving division of the right hepatic duct as the final step.

For large tumors in the right hemiliver that are adherent to the diaphragm and the retroperitoneum, an anterior approach can be used in which the parenchyma is divided before mobilization of the right liver. Inflow control initially is performed and the parenchyma is transected through the demarcated area until the anterior surface of the IVC is exposed. The right hepatic vein and short hepatic veins then are identified and ligated. The surgical maneuver, elevation of the liver by an umbilical tape passed between the anterior surface of the IVC and the liver, can facilitate this approach. The space between the right hepatic vein and the middle hepatic vein is initially dissected for 3 to 4 cm downward and a long clamp is passed gently 4 to 6 cm caudally from the anterior surface of the IVC to emerge between the right hepatic vein and the middle hepatic vein. An umbilical tape is passed behind the liver and is used as a guide to the transection plane.

Extended Right Hepatectomy

When indicated, segment IV can be resected along with the right liver. The initial steps are the same as previously described for a right hepatectomy. The transection plane is along the right side of the

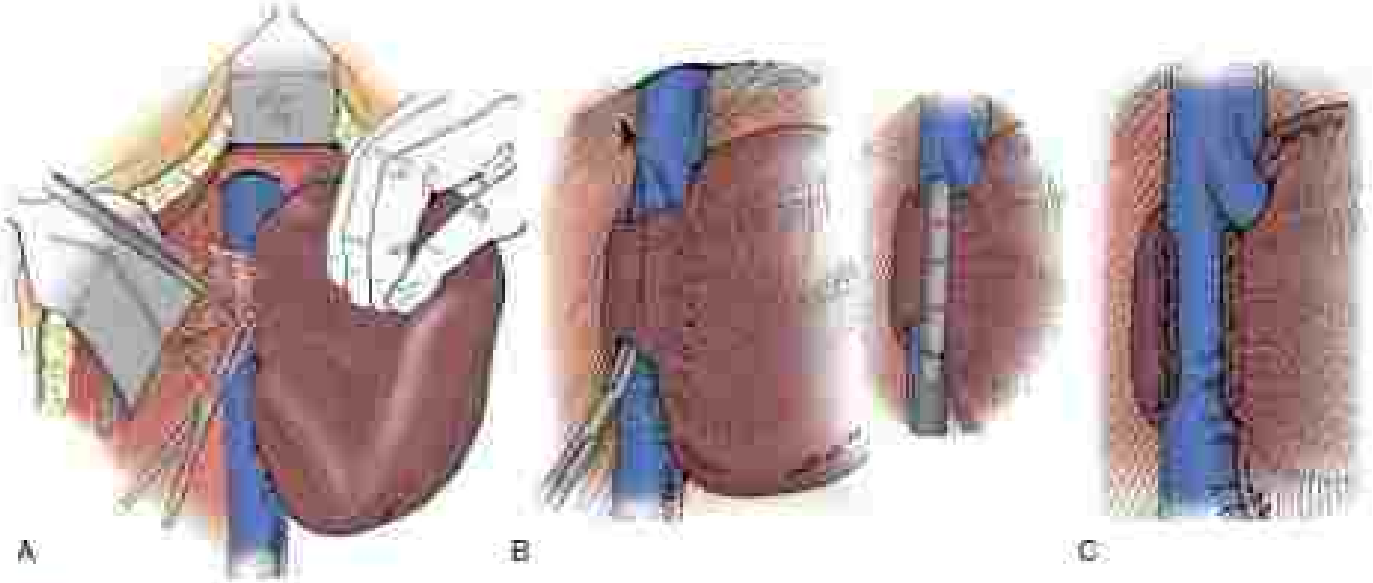

FIG. 3 (A) Division of the anterior vena cava ligament, (B) This ligament may contain liver parenchyma and/or a short hepatic vein and is therefore most safely transected with a stapler. (C) Transection will show exposure and control of the right hepatic vein. (From Blumgart LH, editor: *Surgery of the liver, biliary tract, and pancreas*, 4th ed. Philadelphia: WB Saunders; 2007. [194])

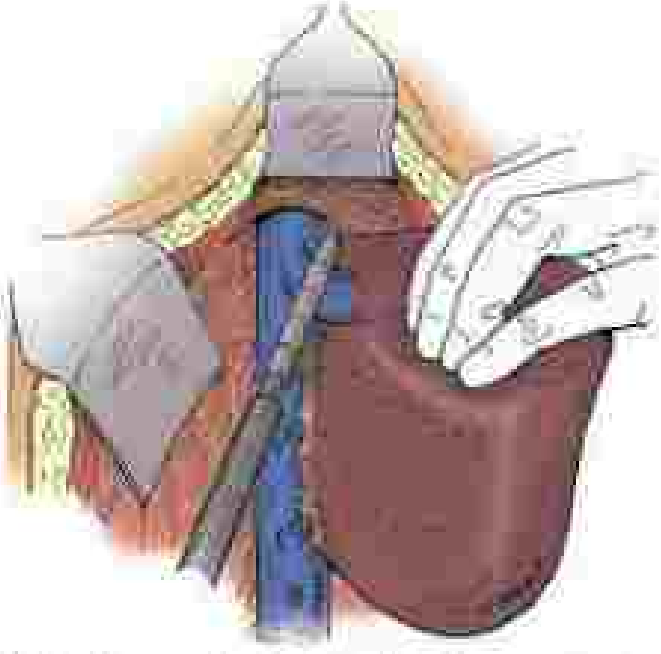

FIG. 4 Division of the right hepatic vein. With the liver retracted to the left, the right hepatic vein may be rapidly and safely divided using an Endo GIA stapler (Covidien) with a vascular load. (From Blumgart LH, editor: *Surgery of the liver, biliary tract, and pancreas*, 4th ed. Philadelphia: Elsevier; 2007. [194])

falciform ligament, from the groove separating the middle and left hepatic veins cranially to the right side of the umbilical fissure caudally, directed toward the medial aspect of the right hilar plate while avoiding the confluence of the left and right hepatic ducts. Inflow to segment IV is controlled during the transection, as is the middle hepatic vein as the surgeon moves cranially.

Left Hepatectomy

For a left hepatectomy, the triangular ligament is divided, exposing the IVC and the left hepatic vein. The round ligament is elevated and the parenchymal bridge between segments III and IVB is divided, exposing the left inflow at the base of the umbilical fissure. The left hepatic artery, portal vein, and hepatic duct are identified and ligated individually. For intrahepatic ligation of the pedicle, a curved clamp is passed through an incision that is 1 cm above the inflow to segment IVB to exit anterior to the caudate lobe (Fig. 1). The left lateral segment is rotated to the right, and the gastrohepatic ligament is divided. Exposure of the left hepatic vein is facilitated by dividing the ligamentum venosum at its insertion. The common trunk of the middle and the left hepatic vein is encircled as a clamp is passed between the left hepatic vein and the IVC, emerging between the right and middle hepatic veins. If the middle hepatic vein is to be divided because of tumor location, the common trunk is ligated with a vascular stapler. If the middle hepatic vein is to be preserved, the parenchyma between the left and the middle hepatic veins is transected and the left hepatic vein can be isolated. Alternatively, the left hepatic vein can be ligated intraparenchymally. The liver parenchyma is transected at the demarcated line. If oncologically feasible, the transection plane should run horizontally, approximately 1 cm above the hilum, from the area of transection of the left hilar plate to the left side of the gallbladder fossa, thus avoiding transection of an aberrant right anterior or posterior duct, and then turning vertical, parallel to Cantlie's line.

Extended Left Hepatectomy

When indicated, the right anterior sector (segments V and VIII) can be resected along with the left hemiliver. The initial steps are the same as those for a left hepatectomy. The main challenge is to define the transection plane, which is horizontal—extending from the right of the gallbladder fossa and anterior to the right hepatic vein toward the base of segment IV—without injuring the inflow to the posterior sector. The pedicle to the right anterior sector will be identified and ligated as transection of the parenchyma approaches the hilum.

Hepatic Malignancy: Resection Versus Transplantation

Jaime M. Iskandar, MD, and Andrew M. Cameron, MD, PhD

Hepatocellular carcinoma (HCC) is the most common primary hepatic malignancy worldwide. This aggressive and often lethal cancer frequently presents in the setting of underlying liver dysfunction. In 80% of cases, HCC is associated with cirrhosis or advanced fibrosis. It is three times more common in men and exhibits geographic variation, with the highest incidence seen in Asia and sub-Saharan Africa. The pathophysiology of HCC has been attributed to chronic inflammation secondary to cirrhosis. There is a pathologic progression from adenomatous hyperplasia to atypical hyperplasia and ultimately overt carcinoma. Risk factors for the development of HCC include viral hepatitis (hepatitis B infection even in the absence of cirrhosis), aflatoxin, aromatic amines, iron dysregulation, smoking, anabolic steroids, oral contraceptives, Budd-Chiari syndrome, α1-antitrypsin deficiency, hemochromatosis, alcoholic liver disease, and chronic Wilson's disease.

Incidences of HCC as well as the death rate related to the malignancy continue to increase in North America. As management of chronic liver disease improves, the number of patients living with compensated cirrhosis has risen. A recent study using the SEER (Surveillance, Epidemiology, and End Results) registry projects that the incidence of HCC will continue to rise until 2030. Metabolic disorders including nonalcoholic fatty liver disease and metabolic syndrome contribute more to the burden of HCC than the other risk factors including hepatitis C virus (HCV) infection. HCC is one of the leading indications for liver transplantation, with approximately 30% of patients awaiting liver transplantation in the United States carrying the diagnosis of HCC. The prognosis is poor if left untreated, with a 5-year overall survival of less than 10% and a median survival of under 6 months. Treatment options for HCC have expanded over the past few decades. In addition to liver transplantation and resection, locoregional therapies utilized as either monotherapy or as a bridge to surgical intervention have broadened the treatment options for patients. Unfortunately, only 20% to 30% of patients with HCC are candidates for either surgical or locoregional therapy at the time of presentation due to lack of adequate hepatic reserve or extent of disease. Tumor size, stage, number, location, patient's underlying liver function, and tumor pathology all must be measured when considering which treatment options to consider. Treatment mandates a multidisciplinary approach as multiple modalities may be used.

Evaluation

Patients who develop HCC are usually asymptomatic, outside of the sequelae of their chronic liver disease. Symptomatic patients may have upper abdominal discomfort, weight loss, early satiety, progression to decompensated cirrhosis, or a palpable abdominal mass. Paraneoplastic syndromes rarely occur but include erythrocytosis, polymyositis, hypoglycemia, hypercalcemia, and diarrhea. A thorough history and physical exam should focus on identification of underlying liver disease. History of ascites, gastrointestinal bleed, hepatic encephalopathy, and jaundice should be elucidated. Physical exam findings may include splenomegaly, caput medusa, ascites, gynecomastia, palmar erythema, and muscle wasting. Routine laboratory studies include coagulation factors, complete blood count, liver function tests, basic metabolic panel, alpha fetoprotein (AFP), and viral serologies.

The most common cause of death following resection for HCC is liver failure. Therefore, determining a patient's hepatic reserve preoperatively is essential for operative planning. The two commonly used measures of liver disease are the Child-Pugh classification and the Model for End-Stage Liver Disease (MELD) (Table 1). The Child-Pugh classification has been shown to be a better predictor of 30-day perioperative mortality following liver resection. Patients with class A cirrhosis are predicted to have perioperative mortality of less than 5% and can tolerate up to a 50% hepatectomy. Class B cirrhosis have a predicted mortality of 10% to 15% and should have no more than 25% of their liver volume resected. Class C cirrhosis is a contraindication to resection. The MELD score, which is comprised of bilirubin, international normalized ratio, and creatinine along with modifications for hyponatremia, prioritizes patients on the liver transplant wait list and predicts 90-day mortality. HCC patients with a MELD score higher than 9 benefit from liver transplantation.

Staging

A number of staging systems have been developed for HCC; however, no single system is universally accepted. Unlike other malignancies, tumor size and number do not adequately characterize the nature of the tumor nor do they capture the underlying liver dysfunction that accounts for significant morbidity. The American Joint Committee on Cancer Tumor Node Metastasis system provides prognostic information for patients with HCC following resection (Table 2). It

Hepatic Malignancy: Resection Versus Transplantation

Jaime M. Glorioso, MD, and Andrew M. Cameron, MD, PhD

Hepatocellular carcinoma (HCC) is the most common primary hepatic malignancy worldwide. This aggressive and often lethal cancer frequently presents in the setting of underlying liver dysfunction. In 80% of cases, HCC is associated with cirrhosis or advanced fibrosis. It is three times more common in men and exhibits geographic variation, with the highest incidence seen in Asia and sub-Saharan Africa. The pathophysiology of HCC has been attributed to chronic inflammation secondary to cirrhosis. There is a pathologic progression from adenomatous hyperplasia to atypical hyperplasia and ultimately overt carcinoma. Risk factors for the development of HCC include viral hepatitis (hepatitis B infection even in the absence of cirrhosis), aflatoxin, aromatic amines, iron dysregulation, smoking, anabolic steroids, oral contraceptives, Budd-Chiari syndrome, α1-antitrypsin deficiency, hemochromatosis, alcoholic liver disease, and chronic Wilson's disease.

Incidences of HCC as well as the death rate related to the malignancy continue to increase in North America. As management of chronic liver disease improves, the number of patients living with compensated cirrhosis has risen. A recent study using the SEER (Surveillance, Epidemiology, and End Results) registry projects that the incidence of HCC will continue to rise until 2030. Metabolic disorders including nonalcoholic fatty liver disease and metabolic syndrome contribute more to the burden of HCC than the other risk factors including hepatitis C virus (HCV) infection. HCC is one of the leading indications for liver transplantation, with approximately 30% of patients awaiting liver transplantation in the United States carrying the diagnosis of HCC. The prognosis is poor if left untreated, with a 5-year overall survival of less than 10% and a median survival of under 6 months. Treatment options for HCC have expanded over the past few decades. In addition to liver transplantation and resection, locoregional therapies utilized as either neoadjuvant or as a bridge to surgical intervention have broadened the treatment options for patients. Unfortunately, only 20% to 30% of patients with HCC are candidates for either surgical or locoregional therapy at the time of presentation due to lack of adequate hepatic reserve or extent of disease. Tumor size, stage, number, location, patient's underlying liver function, and tumor pathology all must be measured when considering which treatment options to consider. Treatment mandates a multidisciplinary approach as multiple modalities may be used.

Evaluation

Patients who develop HCC are usually asymptomatic, outside of the sequelae of their chronic liver disease. Symptomatic patients may have upper abdominal discomfort, weight loss, early satiety, progression to decompensated cirrhosis, or a palpable abdominal mass. Paraneoplastic syndromes rarely occur but include erythrocytosis, polymyositis, hypoglycemia, hypercalcemia, and diarrhea. A thorough history and physical exam should focus on identification of underlying liver disease. History of ascites, gastrointestinal bleed, hepatic encephalopathy, and jaundice should be elucidated. Physical exam findings may include splenomegaly, caput medusa, ascites, gynecomastia, palmar erythema, and muscle wasting. Routine laboratory studies include coagulation factors, complete blood count, liver function tests, basic metabolic panel, alpha fetoprotein (AFP), and viral serologies.

The most common cause of death following resection for HCC is liver failure. Therefore, determining a patient's hepatic reserve preoperatively is essential for operative planning. The two commonly used measures of liver disease are the Child-Pugh classification and the Model for End-Stage Liver Disease (MELD) (Table 1). The Child-Pugh classification has been shown to be a better predictor of 30-day perioperative mortality following liver resection. Patients with class A cirrhosis are predicted to have perioperative mortality of less than 5% and can tolerate up to a 50% hepatectomy. Class B cirrhosis have a predicted mortality of 10% to 15% and should have no more than 25% of their liver volume resected. Class C cirrhosis is a contraindication to resection. The MELD score, which is comprised of bilirubin, international normalized ratio, and creatinine along with modifications for hyponatremia, prioritizes patients on the liver transplant wait list and predicts 90-day mortality. HCC patients with a MELD score higher than 9 benefit from liver transplantation.

Staging

A number of staging systems have been developed for HCC; however, no single system is universally accepted. Unlike other malignancies, tumor size and number do not adequately characterize the nature of the tumor nor do they capture the underlying liver dysfunction that accounts for significant morbidity. The American Joint Committee on Cancer Tumor Node Metastasis system provides prognostic information for patients with HCC following resection (Table 2). It

TABLE 1 Child-Pugh Classification

Parameter	1 Point	2 Points	3 Points
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Bilirubin (mg/dL)	<2	2–3	>3
INR	<1.7	1.7–2.3	>2.3
Ascites	None	Slight	Moderate
Encephalopathy	None	1–2	3–4

Child-Pugh classification is calculated by summing the points per parameter. Class A = 5–6, class B = 7–9, class C = 10–15.
INR, international normalized ratio.

TABLE 2 AJCC UICC 2017 TNM Staging

Stage	Tumor	Node	Metastasis
I	T1	N0	M0
II	T2	N0	M0
IIIa	T3	N0	M0
IIIb	T4	N0	M0
IIIc	Any T	N1	M0
IV	Any T	Any N	M1

T1a: Solitary tumor ≤2 cm.
T1b: Solitary tumor >2 cm without vascular invasion.
T2: Single tumor with vascular invasion, ≥ 2 cm, or multiple tumors, none >5 cm.
T3: Multiple tumors, any >5 cm.
T4: Single or multiple tumors of any size involving a major branch of the portal or hepatic vein or tumor(s) with direct invasion of adjacent organs other than the gallbladder or with perforation of the visceral peritoneum.
N1: Regional lymph node metastases.
AJCC, American Joint Committee on Cancer; TNM, tumor node metastasis; UICC, Union for International Cancer Control.

incorporates vascular invasion, as well as local, regional, and distant metastasis. However, it fails to account for the severity of the underlying liver disease and patient's functional status. The Barcelona Clinic Liver Cancer staging system has emerged as a standard staging system for HCC. It has the advantage of including patients' functional status and liver function in addition to the tumor-related variables (Fig. 1).

Imaging

Imaging studies play an essential role in the diagnosis of HCC. For individuals with cirrhosis, the annual incidence of HCC is 2% to 5%. As HCC is amenable to curative surgical intervention when identified early, routine surveillance is recommended for these patients and has been shown to significantly improve mortality rates. The American Association for the Study of Liver Diseases recommends that individuals with cirrhosis undergo screening ultrasound (US) at 6-month intervals with or without AFP. For patients with Child class C cirrhosis, surveillance is only recommended if they are a transplant candidate. For suspected HCC identified on surveillance imaging, diagnostic evaluation with multiphasic computed tomography (CT) or magnetic resonance imaging (MRI) should be performed. Unlike many other malignancies, the diagnosis of HCC can be established noninvasively and tissue diagnosis is not required. The classic findings include arterial enhancement followed by venous washout. MRI is preferred in diagnosis of HCC, with a 91% specificity and 95% sensitivity compared to CT (83% and 91%, respectively). The Liver Imaging Reporting and Data System classification offers reliable probability of malignancy based on imaging findings and provides guidance for subsequent management. Cross-sectional imaging affords the advantage of visualizing tumor anatomy and assessing the potential liver remnant to assist with operative planning. If imaging findings are diagnostic for HCC, biopsy is not required to make the diagnosis due to the risk of bleeding, sampling error, and potential for seeding of the track.

Treatment

Liver Resection

The goal for hepatic resection of HCC is to resolve the patient cancer free while leaving them with an adequate functional liver remnant. Only 20% to 30% of patients have resectable tumors either due to underlying liver dysfunction or to the extent of disease. For patients who develop HCC without underlying liver disease, resection is the treatment of choice with 5-year survival reported to be as high as 70%. Imaging studies reviewed preoperatively determine resectability with regard to location, vascular involvement, and absence of distant metastases. Volumetrics can be obtained to estimate the liver remnant. If the liver remnant is thought to be inadequate (20%–30% for a healthy liver), portal vein embolization can be employed to induce hypertrophy of the future liver remnant. Intraoperative US is a useful adjunct to ensure negative margins can be secured and to evaluate for satellite lesions not seen on preoperative cross-sectional imaging. Due to the theoretical risk of intrahepatic metastases via the portal vein tributaries, anatomic resection is preferable to increase the likelihood of an R0 resection. Open or laparoscopic resection techniques are acceptable options. For patients with Child class A cirrhosis, no evidence of portal hypertension, and well preserved liver function, resection can be considered.

For patients that are referred for resection, it is important to identify prognostic factors. The main predictors of survival include tumor number, size, microvascular or macrovascular invasion, and grade. Vascular invasion is the strongest predictor of tumor recurrence and correlates with tumor number and size. For multifocal HCC with more than three nodules, Child Pugh status, microvascular invasion, and a positive margin were all negative prognostic factors, but tumor size was not. Approximately 70% of patients will develop disease recurrence within 5 years of resection; this is especially true for patients with cirrhosis.

Liver Transplantation

Liver transplantation is the gold standard for patients with HCC in the setting of Child-Pugh class B/C cirrhosis and limited hepatic reserve as it affords a significant survival advantage over liver resection. Transplantation allows for removal of the tumor and simultaneously corrects the extrahepatic manifestations of cirrhosis. Compared to partial hepatectomy, transplantation eliminates issues related to intrahepatic satellite lesions, margin status, and other anatomic limitations related to tumor location and future liver remnant volume that may otherwise deem an individual unresectable.

The outcomes for patients undergoing liver transplant for malignancy should be comparable to outcomes for patients with chronic liver disease without cancer. To ensure that this scarce resource is appropriately utilized, transplant criteria have been developed and validated. They include Milan, University of California San Francisco (UCSF), Barcelona Clinic Liver Cancer Group, Hangzhou, among others. These criteria are mostly based on size and tumor number; however, tumor biology remains an important factor. The Milan criteria have been the standard used in the United States; however, more expanded criteria, including UCSF, have demonstrated excellent results. Adherence to the Milan criteria (solitary tumor up to 5 cm or 3 tumors up to 3 cm each) has improved the 5-year survival rate to over 70% and decreased to post-transplant recurrence rate to less than 15%. The UCSF criteria include 1 tumor less than ≤5 cm or multiple tumors of which the largest is ≤3 cm and not exceeding 8

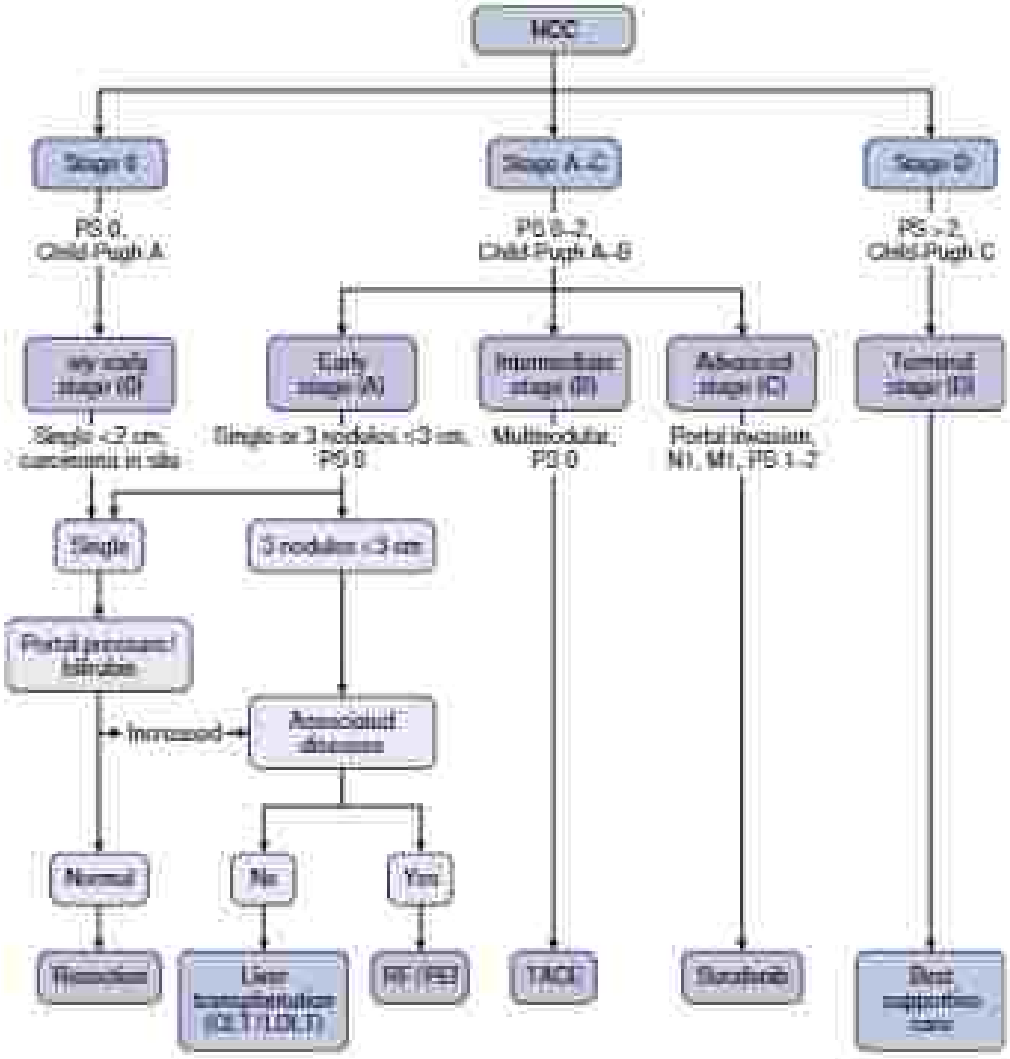

FIG. 1 Barcelona Clinic Liver Cancer staging system for hepatocellular carcinoma. (From Cleveland D, Hussain *. Locoregional therapies in the management of hepatocellular carcinoma. [URL]; [URL])

can treat. While the Milan criteria serve as a surrogate for tumor biology, it may exclude some patients with favorable biology. AFP, tumor growth and progression, and response to locoregional therapy can all serve as surrogates for tumor biology.

The major limitation of liver transplantation for HCC is the waiting time to transplant, which can result in disease progression. Approximately 20% of patients awaiting liver transplant with HCC fall off the waitlist. Conversely, waitlist time also selects out those patients with unfavorable tumor biology or unrecognized metastatic disease who would not benefit from transplant. Patients are granted exception points 6 months after their initial listing that allow them to move up the waitlist despite maintaining a low calculated MELD score. For patients with a T2 or larger lesion, bridging therapy is used to prevent further disease progression prior to transplant. Transarterial chemoembolization, radiofrequency ablation, and other local therapies are available and vary by institution. The modalities also serve to downstage tumors that are initially outside of Milan criteria with favorable survival and recurrence rates.

While there are no randomized control trials comparing resection versus transplantation for HCC, there are a multitude of retrospective studies. Overall, the two surgical options have similar 1-year survival, but 3- and 5-year survival favors transplantation. In addition, liver transplant has better disease-free survival compared to resection. The equivalent 1-year overall survival is likely related to the perioperative morbidity associated with liver transplantation, but the oncologic benefit of transplantation is clear.

One approach for management of HCC in patients with cirrhosis is utilizing transplantation as a salvage therapy for HCC recurrence after liver resection. A few series have shown comparable survival; however, many report higher operative mortality, higher recurrence rates, and worse 5-year survival compared to primary liver transplantation. Salvage liver transplant remains controversial based on the unfavorable results and limited organ supply.

Cholangiocarcinoma

Resection is the standard of care for patients with hilar cholangiocarcinoma. Resection includes excision of the bile duct and concomitant liver resection to decrease the risk for recurrence. Unfortunately, the majority of patients are deemed unresectable at the time of diagnosis due to the severity of parenchymal disease, the inability to preserve vascular inflow and outflow from the associated tumor involvement, or inadequate remnant liver volume. Liver transplantation can overcome the above barriers in appropriately selected patients. Individuals with hilar cholangiocarcinoma are candidates for liver transplant if they present with an unresectable tumor but have no evidence of nodal or metastatic disease. They undergo a protocol including induction chemoradiation followed by operative staging and transplant. One-, three-, and five-year survival is 90%, 80%, and 75%, respectively at high volume centers that follow this highly selective and strict protocol. Transplantation for intrahepatic cholangiocarcinoma remains controversial.

Ablation of Colorectal Liver Metastases

Kelly J. Lafaro, MD, MPH, and Yuman Fong, MD

The liver is the most frequent site of colorectal carcinoma metastases because of portal venous drainage. One-third of patients have liver metastases at the time of presentation, whereas more than half will develop liver metastases at some point during their disease course. Liver metastases are the leading cause of morbidity and mortality in cancer patients in the Western hemisphere. Surgical resection remains the mainstay of potentially curative treatment for liver metastases from colorectal carcinoma. New neoadjuvant chemotherapies, portal vein embolization, and multistaged resections together have expanded the indications for surgery in these patients. Despite these advances, a majority of patients with colorectal liver metastases are unresectable at the time of diagnosis. In addition, some patients are not surgical candidates because of prohibitive comorbid conditions or the need to preserve liver parenchyma to leave a sufficient amount to support posthepatectomy hepatic function.

Locoregional liver directed ablative therapies have emerged as a valuable adjunct to resection in patients with colorectal liver metastases who are otherwise unresectable and can even be curative for small tumors. Several ablation techniques have emerged starting in the 1980s and have evolved from cryoablation now to more effective and quicker techniques including radiofrequency ablation (RFA), microwave ablation (MWA), irreversible electroporation (IRE), and laser thermal ablation (LTA). This chapter summarizes the different ablation techniques and discusses patient selection, technical considerations, potential complications, and follow-up after ablation.

CRYOTHERAPY

First described in 1963, cryotherapy was initially introduced as a treatment for hepatocellular carcinoma; however, in the 1980s, its indication extended to colorectal liver metastases. At cryotherapy's inception, liquid nitrogen was used in direct contact with tumor surface, resulting in hypothermic cellular death. As the technology advanced, argon and helium gas replaced liquid nitrogen. High-pressure argon gas is passed through insulated probes followed by helium gas using the Joule-Thomson effect creating repeated freeze-thaw cycles resulting in protein denaturation, cellular dehydration, and ultimately tumor cell death. However, cryoablation is subject to substantial heat sink from surrounding hepatic vessels and has been linked to increased complications compared with other ablative techniques, including thrombocytopenia, disseminated intravascular coagulation, acute renal injury and "cryoshock," likely resulting from the repeated freeze cycles. As such, cryotherapy has largely been replaced by RFA and MWA.

RADIOFREQUENCY ABLATION

RFA has been the most widely used percutaneous liver ablative technology. It creates a closed-loop circuit between metal electrodes placed into the tumor, dispersive grounding pads placed on the patient, and the radiofrequency generator. This results in high-frequency alternating currents of 350 to 500 kHz and the friction from the agitation of ions within the tissue creates heat surrounding the probe and ultimately cell death from coagulative necrosis at temperatures higher than 60°C. If the tissue reaches greater than 100°C, carbonization or gas formation can char surrounding tissues and reduce ablative effectiveness secondary to high electrical impedance. Avoiding charring and high electrical impedance is important to maintaining more homogenous ablation zones and therefore avoiding incomplete tumor ablation and local tumor recurrence. Multiple commercial RFA electrode systems are available, including impedance controlled or temperature controlled systems. For example, the systems from Medtronic and Boston Scientific are impedance controlled, whereas AngioDynamics systems and Olympus CELON probes are temperature controlled.

RFA relies on passive conduction of heat into adjacent tissue, and the efficacy decreases with increasing tumor size. Multiple ablations can be performed for larger tumors; however, there is a risk of inadequate tumor destruction secondary to error in positioning the electrodes. Retrospective studies have shown similar rates for overall survival and disease-free survival in patients who underwent resection versus RFA for solitary colorectal liver metastases smaller than 3 cm; however, disease-free survival significantly decreased with RFA for tumors larger than 3 cm.

In addition to consideration of size, tissue composition and proximity of the lesion to hepatic vasculature are important factors influencing the outcomes of RFA. The flow of blood in large vessels creates a "heat sink," where the thermal energy created by the RFA probe dissipates and the cells surrounding the blood vessels remain at close to physiologic temperature, thus reducing the maximum temperature achieved and potentially leaving viable tumor cells.

There have been no prospective clinical trials comparing RFA with resection or other ablation techniques in the setting of colorectal liver metastases. Although retrospective studies show ablation site recurrences between 9% and 30%, the reader must keep in mind that such studies are easily susceptible to selection bias, and most frequently the data originate from patients who are not surgical candidates. Although initial retrospective data showed increased overall survival rates for patients who underwent surgical resection alone, compared with those who had a combination of surgical resection and RFA (65% vs 36%, respectively), more recent data comparing RFA in combination with resection showed comparable long-term outcomes to hepatectomy alone, with similar overall survival and disease-free survival rates. Thus, RFA is a useful tool when used alone in small tumors and complementary to surgical resection for patients with larger or bilobar tumors to achieve cure. To truly delineate the efficacy of RFA in comparison to other techniques, however, a prospective randomized clinical trial is necessary.

Ablation of Colorectal Liver Metastases

Kelly J. Lafaro, MD, MPH, and Yuman Fong, MD

The liver is the most frequent site of colorectal carcinoma metastases because of portal venous drainage. One-third of patients have liver metastases at the time of presentation, whereas more than half will develop liver metastases at some point during their disease course. Liver metastases are the leading cause of morbidity and mortality in cancer patients in the Western hemisphere. Surgical resection remains the mainstay of potentially curative treatment for liver metastases from colorectal carcinoma. Now, multiagent chemotherapies, portal vein embolization, and multistaged resections together have expanded the indications for surgery in these patients. Despite these advances, a majority of patients with colorectal liver metastases are unresectable at the time of diagnosis. In addition, some patients are not surgical candidates because of prohibitive comorbid conditions or the need to preserve liver parenchyma to leave a sufficient amount to support postoperative hepatic function.

Locoregional liver directed ablative therapies have emerged as a valuable adjunct to resection in patients with colorectal liver metastases who are otherwise unresectable and can even be curative for small tumors. Several ablation techniques have emerged starting in the 1980s and have evolved from cryoablation now to many ablative and quicker techniques including radiofrequency ablation (RFA), microwave ablation (MWA), irreversible electroporation (IRE), and laser thermal ablation (LTA). This chapter summarizes the different ablation techniques and discusses patient selection, technical considerations, potential complications, and follow-up after ablation.

CRYOTHERAPY

First described in 1963, cryotherapy was initially introduced as a treatment for hepatocellular carcinoma; however, in the 1980s, its indication extended to colorectal liver metastases. At cryotherapy's inception, liquid nitrogen was used in direct contact with tumor surface, resulting in hypothermic cellular death. As the technology advanced, argon and helium gas replaced liquid nitrogen. High-pressure argon gas is passed through insulated probes followed by helium gas using the Joule–Thomson effect creating repeated freeze–thaw cycles resulting in protein denaturation, cellular dehydration, and ultimately tumor cell death. However, cryoablation is subject to substantial heat sink from surrounding hepatic vessels and has been linked to increased complications compared with other ablative techniques, including thrombocytopenia, disseminated intravascular coagulation, acute renal injury and "cryoshock," likely resulting from the repeated freeze cycles. As such, cryotherapy has largely been replaced by RFA and MWA.

RADIOFREQUENCY ABLATION

RFA has been the most widely used percutaneous liver ablative technology. It creates a closed loop circuit between metal electrodes placed into the tumor, dispersive grounding pads placed on the patient, and the radiofrequency generator. This results in high frequency alternating currents of 350 to 500 kHz and the friction from the agitation of ions within the tissue creates heat surrounding the probes and ultimately cell death from coagulative necrosis at temperatures higher than 60°C. If the tissue reaches greater than 100°C, carbonization or gas formation can clear surrounding tissues and reduce ablative effectiveness secondary to high electrical impedance. Avoiding charring and high electrical impedance is important to maintaining more homogenous ablation zones and therefore avoiding incomplete tumor ablation and local tumor recurrence. Multiple commercial RFA electrode options are available, including impedance controlled or temperature controlled systems. For example the systems from Medtronic and Boston Scientific are impedance controlled, whereas Angiodynamics systems and Olympus CELON probes are temperature controlled.

RFA relies on passive conduction of heat into adjacent tissue, and the efficacy decreases with increasing tumor size. Multiple ablations can be performed for larger tumors; however, there is a risk of inadequate tumor destruction secondary to error in positioning the electrodes. Retrospective studies have shown similar rates for overall survival and disease free survival in patients who underwent resection versus RFA for solitary colorectal liver metastases smaller than 3 cm; however, disease free survival significantly decreased with RFA for tumors larger than 3 cm.

In addition to consideration of size, tissue composition and proximity of the lesion to hepatic vasculature are important factors influencing the outcomes of RFA. The "heat sink" effect is large vessels creates a "heat sink," where the thermal energy created by the RFA probe dissipates and the cells surrounding the blood vessels remain at close to physiologic temperature, thus reducing the maximum temperature achieved and potentially leaving viable tumor cells.

There have been no prospective clinical trials comparing RFA with resection or other ablation techniques in the setting of colorectal liver metastases. Although retrospective studies show ablation site recurrences between 8% and 20%, the reader must keep in mind that such studies are easily susceptible to selection bias, and most frequently the data originate from patients who are not surgical candidates. Although initial retrospective data showed increased overall survival rates for patients who underwent surgical resection alone, compared with those who had a combination of surgical resection and RFA (46% vs. 34%, respectively), more recent data comparing RFA in combination with resection showed comparable long-term outcomes to hepatectomy alone, with similar overall survival and disease free survival rates. Thus, RFA is a useful tool when used alone in small tumors and complementary to surgical resection for patients with larger or bilobar tumors to achieve cure. To truly delineate the efficacy of RFA in comparison to other techniques, however, a prospective randomized clinical trial is necessary.

MICROWAVE ABLATION

MWA uses high-frequency oscillating electromagnetic fields of either 915 mHz or 2.45 GHz delivered through antenna probes. This induces rapid realignment of polar molecules to a lesser, increasing kinetic energy and heating the tissue. Water molecules are particularly affected and thus lesions with higher concentrations of water are more susceptible to heating by microwave ablation.

There are multiple advantages to microwave ablation over RFA. Studies comparing MWA and RFA have shown (1) faster ablation time with faster heating, (2) larger tumor capacity, and (3) increased and more consistent ablation zones, and fewer ablation site recurrences with MWA.

1. MWA was shown to be capable of reaching temperatures as high as 150°C, much faster than RFA. MWA is also not as susceptible to heat sink as RFA, making it ideal for tumors in the liver, particularly those situated near vessels. Ablation times for MWA averaged between 2 and 5 minutes in three studies, with most being less than 10 minutes, which is less than that of most RFA treatments.
2. The heat produced with MWA can be propagated through charred tissue better than RFA, in part leading to the success treating larger lesions.
3. Single or multiple probes can be used simultaneously, contributing to the larger ablation zones observed with MWA. Finally, no grounding pad is needed, making the procedure more feasible.
4. Finally, a retrospective matched cohort study comparing MWA and RFA for colorectal liver metastases showed lower ablation site recurrence rates for those treated with MWA (6% vs. 20% for RFA).

Although there are several advantages of MWA over RFA, the cables are bulkier and have been prone to heating issues in some cases. General anesthesia is typically required for both MWA and RFA to decrease motion and improve patient comfort. MWA, like RFA, can be performed under both computed tomography (CT) and ultrasound (US) guidance. Although US allows for real-time imaging of ablation zones and often decreases the amount of time per ablation, CT is useful for lesions that are not well imaged by US. Percutaneous, laparoscopic, and open MWA are used depending on the patient. Percutaneous ablations are especially useful in patients who are not a surgical candidate, whereas laparoscopic and open ablations are ideal for patients who have tumors in areas that cannot be reached percutaneously, and for situations in which a combination of resection and ablation will render the patient without evidence of disease.

In studies reviewing complications of ablation technologies, MWA had a complication rate of 4.4% and a mortality rate of 0.26%, comparable to RFA. The most common complications noted for MWA were hemorrhage requiring blood transfusion, portal vein thrombosis, bile leak, liver abscess, and pleural effusion.

In a recently published series of more than 800 microwave ablations for small liver cancer, durable response can be seen in more than 90% of subcentimeter lesions. For tumors 1 to 3 cm in size, only 9% of tumors recurred in 3 years (Figs. 1 and 2). Ablations can indeed be curative in small tumors.

IRREVERSIBLE ELECTROPORATION

IRE is a newer, nonthermal ablation technology, which was approved by the US Food and Drug Administration in 2008 for tumor ablation. IRE uses multiple electrodes, which deliver 2 to 3 kV direct current pulses lasting up to milliseconds. These currents cause damage to the surrounding cell membranes. Initially, the damage to the cell membranes is reversible, however, with increased time, this damage becomes irreversible, leading to apoptosis. Compared with MWA and RFA, ablation time used for IRE is very short. Although this decreases overall ablation time, care must be taken to position probes accurately because they cannot be adjusted midablation.

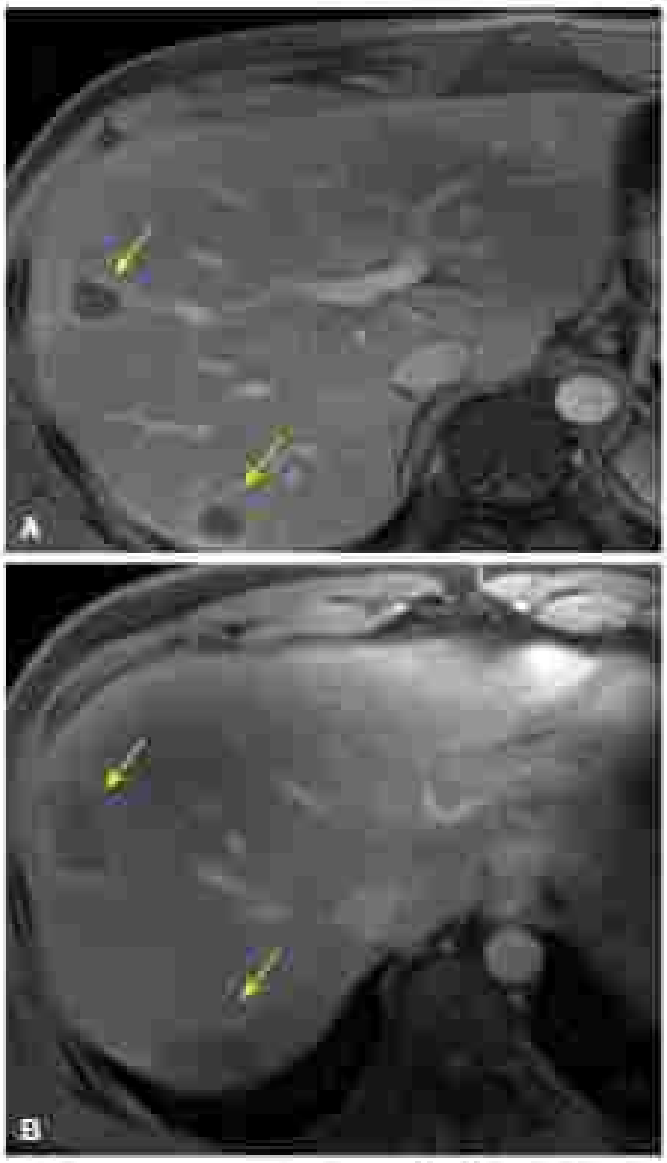

FIG. 1 Long-term appearance of microwave ablated lesions in the liver. (A) Classical portal venous phase appearance of metastatic colorectal cancer lesion (arrow): dark lesion with hypodense rim. (B) Unenhanced ablated area 3 years later.

Nonthermal technology has little destruction of surrounding tissues and adjacent tissue architecture is well preserved, and heat sink is not an issue with IRE. The combination of little destruction of surrounding tissues and lack of heat sink make IRE ideal for tumor situated near vessels or bile ducts. However, the multiple probes necessary to create the current are costly and can also be more technically challenging to position than other ablation probes (Fig. 3). The ablation zone created by IRE is often not evident by US for several minutes, making it difficult to ensure successful destruction of the tumor. In addition, IRE requires general anesthesia with paralysis because the currents can result in muscle spasms and arrhythmias. To decrease the chance of arrhythmias from IRE, the generator is linked to an ECG sensing triggering device, which signals pulses to be delivered in the cardiac refractory period.

IRE was first reported in the metastatic colorectal cancer patient population in 2014, when Silk et al. published a study of 22 metastatic lesions in 11 patients ranging from 1 to 4.7 cm in size. They reported an efficacy of 95% with local tumor recurrence in 1 of the 11 patients

FIG. 2 Durability of microwave ablation. Treatment of <1 cm tumor was 98%; treatment of 1- to 3-cm tumor was 91%. (From Hong CL, et al.: Long-term outcome following microwave ablation for liver malignancies. Br J Surg. 2015;102:982.)

by 9 months. A larger study of 81 metastatic lesions, although not all colorectal in origin, reported a 67% primary efficacy. More recently, Engstrand et al. reported on 29 metastatic colorectal as well as neuroendocrine lesions, in which a 7.5% local failure rate was seen, with a time to recurrence of 66 to 150 days.

A study reviewing complications of IRE used in multiple organ ablations reported a 14% complication rate with the most common complications being pneumothorax, portal vein thrombosis, biliary obstruction, pleural effusion, and cholangitis. Arrhythmias were reported in 6% of the patients in this study. Of note, no uncontrolled muscle spasms were reported in this study in patients who were under general anesthesia with paralysis.

LASER THERMAL ABLATION

LTA uses optical fibers to deliver high energy laser radiation to the tissue, which reaches temperatures of 150°C, leading to coagulative necrosis. The penetration of light is optimal near the infrared spectrum; therefore, neodymium:yttrium aluminum garnet (wavelength 1064 nm) and diode (800–980 nm) lasers are the most commonly used. Flexible quartz fibers deliver light and a spherical thermal lesion of 12 to 15 mm in diameter. Up to four fibers can be used simultaneously to increase the ablation zone.

Although LTA is not as robustly studied as other ablative techniques, Vogl et al. reported on 549 patients with colorectal liver metastases up to 5 cm in diameter treated with LTA. The 3- and 5-year survival was 29% to 74.2% and 19% to 37%, respectively, which is comparable to RFA and MWA. However, LTA has not become a mainstay treatment for colorectal liver metastases in most institutions. The placement of fibers can be difficult and the technology is also affected by heat sink. The major downfall of LTA is the small ablation zone, making it less ideal than other ablation techniques to address metastases from colorectal cancer.

PATIENT SELECTION

Whenever feasible, surgical resection should remain the standard treatment for colorectal liver metastases; however, in patients who are not surgical candidates because of comorbid conditions or extent of disease, a combination of systemic and ablative therapies should be used. Systemic chemotherapies have improved significantly, with some regimens resulting in 70% response rates. Long-term durable response remains an issue, however.

As with all cancer care, patients should be evaluated by a multidisciplinary team including medical oncologists, surgical oncologists, diagnostic radiologists, interventional radiologists, and pathologists. Each case should be reviewed to determine surgical feasibility and, if not, the possibility of ablation. Before consideration for ablation, several factors must be taken into consideration including response to chemotherapy, tolerance of systemic therapies, comorbid conditions, presence of extrahepatic metastases, baseline hepatic function, and tumor specific characteristics. Older patients or those with significant comorbid conditions who would not tolerate surgical resection with liver only disease should be considered for ablation. In addition, patients with bilobar disease who are otherwise surgical candidates should be considered for partial hepatectomy of the portion of liver with higher tumor burden and ablation of lesions in the remnant, assuming there are only a few lesions remaining. All lesions should be able to be addressed during the combined resection and ablation to make it a reasonable option.

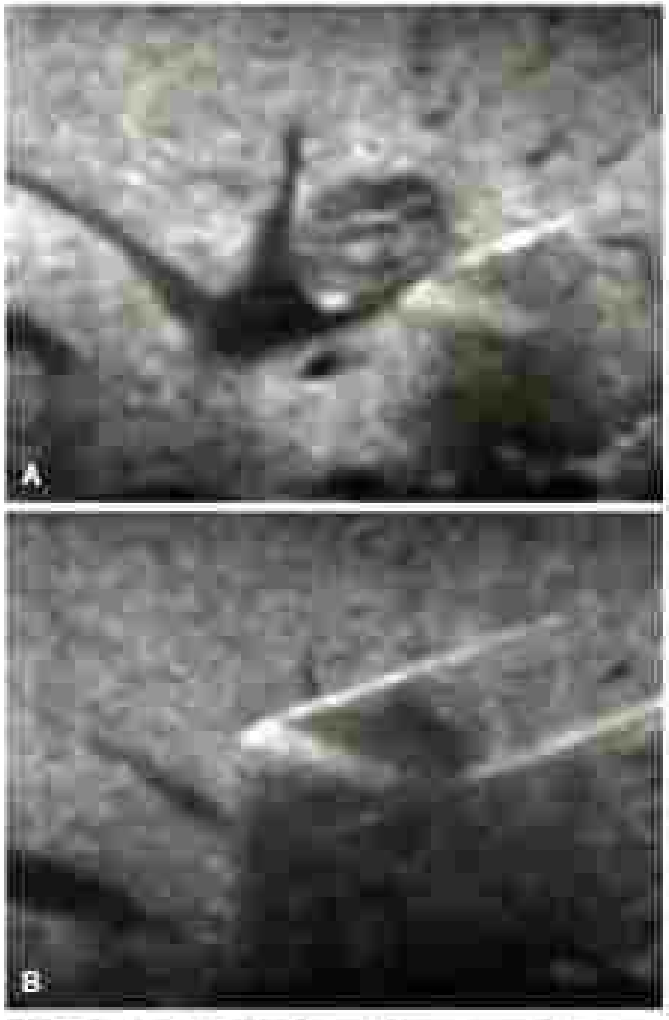

FIG. 3 Placement of needles for irreversible electroporation. (A) Tumors in a similar area were difficult to ablate with thermal ablation. Irreversible electroporation now allows perivascular ablation with good long-term outcomes. (B) Two needles are placed bracketing the tumor. Passage of needles into hepatic vein and vena cava is acceptable and will allow complete ablation.

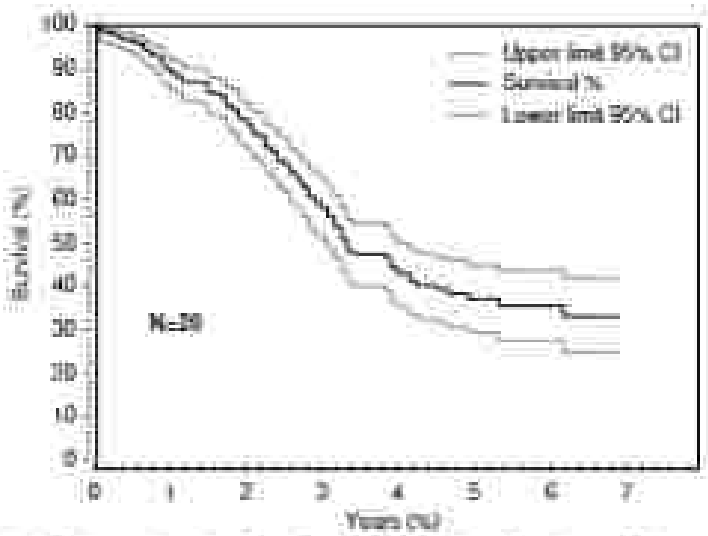

FIG. 4 Long-term survival after combined ablation and resection. Overall survival and 95% confidence interval (CI) curves for patients with liver metastases treated by resection in combination with intraoperative ablation. (From Hyun et al. Combined Ablation and Resection of Bilobar Colorectal Liver Metastases. PLoS One. 2016;11(1):e0147...)

BASELINE HEPATIC FUNCTION

In addition to a thorough metastatic workup, patients should also get a baseline evaluation of hepatic function before consideration of ablation. This hepatic liver function tests as well as evaluation of current radiologic scans for evidence of portal hypertension, cirrhosis or steatosis should be used. Chemotherapy-induced hepatic sinusoidal obstruction, which increases the risk of postresection liver failure, has not been shown to increase the risk of complications after liver ablation. However, portal hypertension and thrombocytopenia resulting from splenomegaly puts patients at increased risk of complications after ablation.

TUMOR-SPECIFIC CONSIDERATIONS

Radiologic studies including any CT or magnetic resonance imaging (MRI) scans should be evaluated and the size, number, distribution, and location of metastases within the liver noted. Ideal lesions for ablation include those smaller than 3 to 3.5 cm. Lesions larger than this require multiple probes or repeated ablations with overlapping ablation zones, which makes the tumor destruction less reliable and increases the chance of local recurrence. If there are multiple lesions within close proximity, surgical resection should be considered if the patient is a candidate. Lesions deep in the liver or within close proximity to major vessels or central bile ducts can be effectively ablated; however, the type of ablation technique should be chosen depending on location. If the lesion is close to major vessels, RFA should be avoided and MWA used to avoid substantial heat sink. Thus, ideal lesions for ablation remain small, deep lesions in the liver that do not lend themselves to surgical resection. While deciding whether to perform ablation percutaneously, laparoscopically versus open proximity to surrounding organs including the gallbladder, colon, stomach, diaphragm, and heart should be taken into account. When performed laparoscopically or open in combination with resection, these structures can be retracted to avoid thermal injury.

COMBINED ABLATION AND RESECTION

As surgeons have become more comfortable with intraoperative ablation, these procedures have extended the limits of surgical procedure for possible cure. When confronted with dominant disease on one side and small contralateral lesions, many surgeons now will perform a major liver resection along with ablation on the opposite side. Such experiences of combining ablation with resection from three different major centers were examined recently by Ward and colleagues. Such a combined procedure was found to be safe and produced very acceptable long-term survival given the bilateral liver disease (Fig. 4).

EXTRAHEPATIC METASTASES

According to current National Comprehensive Cancer Network guidelines, all patients diagnosed with colorectal cancer should undergo radiographic imaging to evaluate for extrahepatic disease, including a CT scan of the chest, abdomen and pelvis, and possible positron emission tomography CT. In terms of diagnosis of hepatic metastases, MRI with liver-specific contrast is the most sensitive modality. Similar to surgical candidates, patients with liver only disease remain the best candidates for ablation. Patients with pulmonary disease should be evaluated by a thoracic surgeon for possible lung-directed treatment. However, for small volume lung disease, the liver disease status dominates the clinical outcome. Thus, minimal lung metastasis is no longer a contraindication to liver tumor ablation. Patients with unaddressed peritoneal disease or bulky distant nodal disease should not be considered for ablation as it will add little benefit in this case.

TREATMENT APPROACH

Liver-directed ablative techniques can be performed under US, CT, or MRI using either percutaneous, laparoscopic, or open approach. For percutaneous procedures, patients generally require conscious sedation or general anesthesia for pain control as well as to minimize movement throughout the procedure. Prophylactic antibiotic usage has been debated and varies by institution. However, patients at high risk for liver abscesses, including those with a history of a biliary enteric anastomosis or biliary stents, should receive at least perioperative antibiotics and potentially a longer postprocedure course.

For those ablations performed laparoscopically or during laparotomy, a thorough intraoperative US of the liver should be used to identify any additional lesions present not seen on preoperative imaging. Up to 20% of patients are found to have extrahepatic disease not apparent on preoperative radiography. Once all the lesions are identified and mapped out, the placement of the ablation probes must be planned carefully to avoid major vessels and bile ducts, especially if using RFA. Surrounding organs should also be identified and retracted if possible. Cholecystectomy can be performed if the gallbladder is at risk of thermal injury. The probes should always be placed under US guidance into the lesion, taking into account where on the probe the particular ablation technique originates from. If multiple ablation zones are needed, the probe should be placed at the deepest portion of the lesion first. This is important as gas is created during the ablations, which is echogenic and can obscure the border of the tumors on US.

Once the probes are confirmed by US to be in position, the ablation is initiated. For RFA, tissue temperature is monitored to keep parenchyma between 100°C and 110°C to avoid charring, which affects impedance. For MWA, the frequency and time are chosen depending on the probe used and ablation zone necessary. Once the desired temperature and impedance for RFA or time duration for MWA are reached, the ablation is completed and probe is repositioned if necessary.

FOLLOW-UP

After liver ablation, liver function tests should be checked because they may acutely rise after ablation but should progressively return to baseline. Carcinoembryonic antigen should also be followed every 3 months as a rise in carcinoembryonic antigen is concerning for recurrence. Postablation imaging including CT scan or MRI should be obtained to determine efficacy of the ablation. Keep in mind that colorectal liver metastases are hypervascular in nature; therefore, it can be difficult to distinguish between residual tumor and necrosis resulting from the ablation. The current guidelines put out by the International Working Group on Image Guided Tumor Ablation recommend a baseline CT or MRI be obtained within 1 to 4 weeks postablation. The postablation and postablation imaging should be compared with look at size, shape, and location of the necrosis with ideally a 5- to 10-mm margin of ablation around the tumor. Once inflammation has subsided, positron emission tomography scans have been shown to be sensitive for detection of recurrent lesions. However, there must be at least 3 months allowed for inflammation to resolve. National Comprehensive Cancer Network guidelines recommend follow-up imaging every 3 to 6 months postablation for the first 2 years, followed by every 6 to 12 months.

COMPLICATIONS

For all the liver directed ablative techniques, complications range from minor skin burns to more serious ones including hemorrhage and bile leak. Historically, cryoablation has the highest complication rate, with some reports as high as 10% to 20%. Cryoablation has been linked to complications including thrombocytopenia, disseminated intravascular coagulation, acute renal injury, and cryoshock, likely because of the repeated freeze cycles. The high complication rates ultimately resulted in cryoablation being replaced to large part by RFA and MWA.

Both RFA and MWA have a lower rate of complications, ranging from 2.2% to 9.5%. The largest study evaluated 13,283 patients who underwent RFA of at least one liver lesion and had a complication rate of 3.3%, with the most common being hepatic infarcts, liver abscesses, bile duct injury, and bile leaks. Number complications include pleural effusions, burns to the skin, pneumothorax, intestinal injury, diaphragmatic injury, gallbladder injury, and cardiac tamponade. The most common complications reported with MWA were hemorrhage requiring blood transfusion, portal vein thrombosis, bile leak, liver abscess, and pleural effusion. Determinants of complication rates in RFA and MWA include tumor size, location, physician and institution experience, and approach (percutaneous vs. surgical). Reports of complications after IRE reach 16%, with the most common complications being pneumothorax, portal vein thrombosis, biliary obstruction, pleural effusion, and cholangitis.

SUMMARY

Surgical resection remains the mainstay of treatment of metastases from colorectal cancer. For patients who are not surgical candidates, ablation techniques offer significant disease free survival. In addition, ablation offers a potential cure for patients with small lesions that are located deep in the liver and would be technically difficult to resect. Ablation also allows us to extend resection criteria for patients with bilobar disease, which would previously have been deemed unresectable, such as a patient with a large left-sided lesion and two to three small ones in the right lobe. This patient may benefit from a left hepatectomy and ablation of the lesions on the right. Clinical trials are needed to better study patient selection and outcomes with current ablation technology. As current ablation techniques improve and new technology is introduced with larger, more consistent ablation zones, the indications for ablation of colorectal liver metastases will extend.

MANAGEMENT OF HEPATIC ABSCESSES

Henry A. Pitt, MD

Hepatic abscesses are uncommon but remain lethal if not promptly recognized or adequately treated. Liver abscesses may be categorized as pyogenic, fungal, amebic, or mixed. Pyogenic liver abscesses (PLA) have multiple etiologies, are frequently polymicrobial, and their management has evolved significantly over the past 2 decades. Fungal abscesses are the least common, but their incidence is increasing especially in immunocompromised patients with cancer or who have undergone a transplant. Amebic liver abscesses (ALA) are caused by *Entamoeba histolytica* and occur most commonly in tropical, developing countries.

Mixed bacterial and fungal abscesses may occur especially when patients have been exposed to multiple antibiotic courses and/or to broad spectrum antibiotics. In addition, amebic abscesses may become secondarily infected with bacteria, but this situation is uncommon. Management of pyogenic, fungal, amebic, and mixed hepatic abscesses varies considerably. As with many areas within surgery, nonoperative and minimally invasive treatment options have become the norm. However, hepatobiliary surgery may be lifesaving when an abscess ruptures or when less invasive approaches are unsuccessful.

PYOGENIC LIVER ABSCESS

Historically, PLAs were highly lethal and were most commonly caused by pylephlebitis secondary to appendicitis. With the advent of antibiotics in the mid twentieth century and advanced imaging techniques in the 1970s, diagnostic delays were shortened and

MANAGEMENT OF HEPATIC ABSCESSES

Henry A. Pitt, MD

Hepatic abscesses are uncommon but remain lethal if not promptly recognized or adequately treated. Liver abscesses may be categorized as pyogenic, fungal, amebic, or mixed. Pyogenic liver abscesses (PLA) have multiple etiologies, are frequently polymicrobial, and their management has evolved significantly over the past 2 decades. Fungal abscesses are the least common, but their incidence is increasing especially in immunocompromised patients with cancer or who have undergone a transplant. Amebic liver abscesses (ALA) are caused by *Entamoeba histolytica* and occur most commonly in tropical, developing countries.

Mixed bacterial and fungal abscesses may occur especially when patients have been exposed to multiple antibiotic courses and/or to broad spectrum antibiotics. In addition, amebic abscesses may become secondarily infected with bacteria, but this situation is uncommon. Management of pyogenic, fungal, amebic, and mixed hepatic abscesses varies considerably. As with many areas within surgery, nonoperative and minimally invasive treatment options have become the norm. However, hepatobiliary surgery may be lifesaving when an abscess ruptures or when less invasive approaches are unsuccessful.

PYOGENIC LIVER ABSCESS

Historically, PLAs were highly lethal and were most commonly caused by pylephlebitis secondary to appendicitis. With the advent of antibiotics in the mid twentieth century and advanced imaging techniques in the 1970s, diagnostic delays were shortened and

outcomes improved. During this time, surgical drainage was required but evolved from extraperitoneal to transperitoneal approaches. Over the past 30 to 40 years, however, the evaluation of image-guided aspiration, percutaneous catheter drainage (PCD) as well as percutaneous and endoscopic biliary procedures and eventually invasive surgery (MIS) have dramatically altered PLA management. With all these advances, the outcomes for most patients with PLA have continued to improve. However, the development of advanced hepatopancreatobiliary (HPB) surgery, liver transplantation, and various ablative techniques for managing liver tumors has created new etiologies and treatment challenges.

Pathophysiology

PLAs may arise by several mechanisms including: (1) via the bile ducts, (2) via the portal vein, (3) by direct extension, (4) via the hepatic artery, (5) as the result of trauma, or (6) without an obvious cause, *cryptogenic*. In recent years, especially at western tertiary referral centers, PLAs of biliary origin are most common. Frequently, these patients will have a biliary malignancy that is being managed with biliary stents. Patients with benign biliary strictures, those with a prior biliary enteric anastomosis, and Asian patients with hepatolithiasis also are prone to PLA formation. In the first half of the twentieth century, appendicitis was the most common cause of PLAs. Currently, diverticulitis is the most frequent underlying infection that reaches the liver via the portal vein.

Severe forms of cholecystitis may cause a liver abscess by direct extension. Bacterial endocarditis may lead to multiple liver and/or splenic abscesses with the infection transmitted via the hepatic artery. Liver trauma may result in an intrahepatic hematoma that can become secondarily infected. Segmental hepatic infarctions following hepatobiliary surgery or ablative hepatic arterial therapies also may result in bacterial colonization and abscess formation. These various etiologies of PLAs require multiple therapeutic options and also are associated with different types of bacterial or fungal contamination.

The organisms most commonly associated with PLAs of benign biliary origin are *Escherichia coli*, *Enterococcus*, and *Klebsiella* spp. (Table 1). In patients with cholangitis and severe cholecystitis, anaerobes including *Clostridium perfringens* may also be isolated. In patients with biliary malignancies who have been exposed to many antibiotics, *Pseudomonas* spp., vancomycin-resistant *Enterococcus* (VRE), multidrug-resistant (MDR) gram-negative aerobes, and yeast are also frequently cultured. In addition, these biliary PLAs often will be polymicrobial. In patients with diverticulitis or appendicitis, *Bacteroides fragilis*, other anaerobes and gram-negative aerobes are found most often in the associated PLA. The organisms isolated most frequently in patients with endocarditis are *Staphylococcus aureus* and *Streptococcus* spp. Similarly, if a liver abscess occurs as the result of a subcutaneous abscess, *Staphylococcus* spp., including methicillin-resistant *Staphylococcus aureus*, are cultured most often. Cryptogenic abscesses, especially in Asia, frequently grow *K. pneumoniae*, and anaerobes are also isolated more commonly in these patients.

Diagnosis

Almost all patients with PLAs present with liver and/or chills. Malaise and anorexia often are associated findings. The majority of patients will have some abdominal discomfort, frequently in the right upper quadrant. However, if diverticulitis or appendicitis is the underlying cause, the pain will be in the left or right lower quadrant, respectively. Nausea, vomiting, and weight loss also may be part of the presentation. In patients with a biliary etiology, jaundice may be present, but in those with biliary stents and cholangitis, PLAs may evolve without clinical jaundice. Physical examination will vary with etiology, but most patients will have no obvious abdominal findings.

The majority of patients with PLAs will have an elevated white blood cell count and some elevation of alkaline phosphatase. Mild increases of other liver function tests and hypoalbuminemia also are common. C-reactive protein usually is elevated, but serum lactate levels are normal unless the patient presents with septic shock. In some patients, pus may be seen in the liver on open abdominal surgery. Ultrasound (US) is helpful in screening for biliary pathology, but contrast-enhanced computed tomography (CT) is diagnostic in more than 95% of cases (Fig. 1). Magnetic resonance imaging (MRI) is equally sensitive and may provide additional useful information with respect to the biliary tree. In patients with indwelling biliary stents, direct cholangiography may also demonstrate the abscess(es) (Fig. 2). Culture of the bile in patients with abscesses of biliary origin will almost always be positive and can guide antibiotic therapy. In comparison, blood cultures will grow organisms in only half of the patients with PLAs.

TABLE 1 Typical Bacteria Associated With Underlying Etiologies of Pyogenic Liver Abscesses

Underlying Etiology	Typical Bacteria
Benign biliary	*Escherichia coli* *Enterococcus* spp. *Klebsiella* spp.
Cholangitis and severe cholecystitis	Anaerobes *Clostridium perfringens*
Biliary malignancies	*Pseudomonas* spp. VRE MDR aerobes Yeast
Diverticulitis, appendicitis	*Bacteroides fragilis* Other anaerobes Gram-negative aerobes
Endocarditis	*Staphylococcus* spp. *Streptococcus* spp.
Subcutaneous abscesses	*Staphylococcus* spp. MRSA
Cryptogenic	*Klebsiella pneumoniae* Anaerobes

MDR, Multidrug-resistant; MRSA, methicillin-resistant *Staphylococcus aureus*; VR, vancomycin-resistant *Enterococcus*.

TREATMENT

Antibiotics

As with any serious infection, blood cultures should be drawn before antibiotics are initiated. If the patient presents with sepsis or septic shock, a serum lactate should be sent, and aggressive fluid resuscitation should be initiated immediately. The choice of antibiotic(s) should be based on the suspected underlying etiology and therefore the likely bacteriology (Table 1). Patient factors such as a known penicillin allergy or altered renal function should also influence the choice of antibiotic(s).

For PLAs of biliary etiology, a broad-spectrum penicillin with good coverage for gram-negative aerobes and *Enterococcus* spp. is one option for an antibiotic-naïve patient. However, broader coverage for anaerobes, *Pseudomonas* spp., VRE, and MDR aerobes is indicated for patients with indwelling stents who have received multiple prior courses of antibiotics. Ideally, these patients will have prior bile cultures that will guide antibiotic choices. In patients with diverticulitis or appendicitis, metronidazole to adequately cover *B. fragilis* should be part of the antibiotic regimen. If endocarditis or a subcutaneous abscess is the suspected source, vancomycin should be included in the antibiotic regimen until sensitivities are available. As blood, aspirate, or percutaneous drainage culture data become available, the

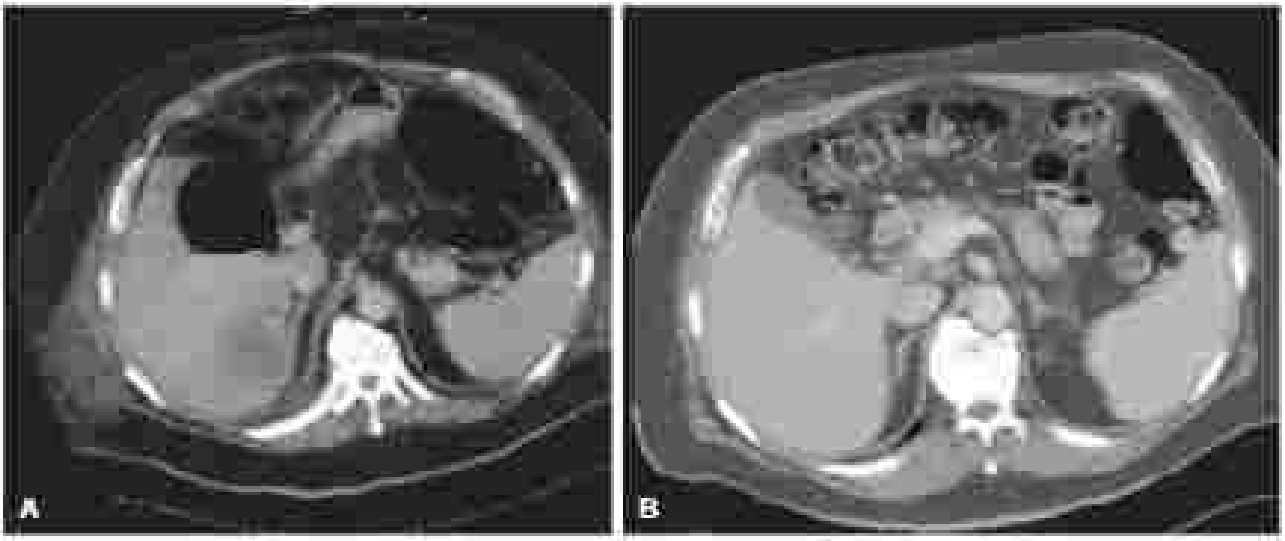

FIG. 1 (A) Computed tomography (CT) scan demonstrating a large pyogenic lung abscess (PLA) with an air-fluid level in segments [illegible] and 6. (B) CT scan 7 months later in the same patient, documenting complete resolution of the PLA after percutaneous catheter drainage.

FIG. 2 Tube cholangiogram demonstrating a pyogenic liver abscess that has been percutaneously drained in a patient with an unresectable biliary malignancy and intrahepatic biliary stones.

antibiotic regimen should be tailored to cover the sensitivities of the isolated bacteria. Most experts recommend a 4 to 6 week antibiotic course, but a shorter regimen may be appropriate if adequate drainage and a good clinical response have been achieved. Also, if oral antibiotics will cover the isolated bacteria, not all patients will require home intravenous antibiotics.

Aspiration

Percutaneous image-guided aspiration should be performed to confirm the diagnosis and to obtain samples for culture in selected patients with a small, solitary, easily accessible abscess; aspiration and appropriate antibiotics may be adequate therapy. In these patients, repeat aspirations may be indicated if clinical response is slow. However, many patients will have a large abscess, a multiloculated abscess, thick abscess rim, and/or multiple abscesses. In these patients, aspiration alone will not be adequate and should not be undertaken. An alternate for patients with a larger, multiloculated, and/or viscous abscess is PCD.

Percutaneous Drainage

Over the past 3 decades, a shift has occurred so that the majority of patients with PLAs are managed with PCD. This procedure can be performed under US or CT guidance. Most of these procedures can be accomplished under local anesthesia with minimal sedation. After aspiration of pus for culture, a guidewire is placed into the abscess followed by placement of an 8Fr to 14Fr pigtail catheter (Fig. 3). Contrast is injected to define the cavity, but care is taken not to aggravate sepsis by over injection. The catheter is left to gravity drainage, but frequently, small volume irrigations with sterile saline solution are indicated to ensure catheter patency. Subsequent procedures to increase catheter size and/or to interrupt loculations may be indicated.

In recent series of PLAs, approximately 80% of patients have been managed by PCD. In addition, in most reports the success rate for intravenous antibiotics and PCD has been 90% or greater. Factors that may lead to failure include a chronic abscess with thick, fibrous walls; a cluster of smaller abscesses as opposed to loculation within one abscess; or biliary communication with proximal obstruction. Bilateral abscesses or a difficult location, for example, high in segments VII or VIII, may be contraindications to PCD. In addition, a ruptured abscess or association with an intraabdominal problem that requires laparotomy, such as appendicitis or infected peripancreatic necrosis, are situations in which surgery is preferred.

Surgical Drainage

In the preantibiotic era, several intraperitoneal approaches to abscess drainage were described. In the 1960s and 1970s, a transperitoneal approach was preferred and was said to have the advantage of providing the opportunity for an exploratory laparotomy to find an undiagnosed abscess source. This strategy became less necessary as cross-sectional imaging improved in the 1980s and 1990s. Since then, the evolution of MIS and intraoperative US have led to these techniques being preferred when surgery is required.

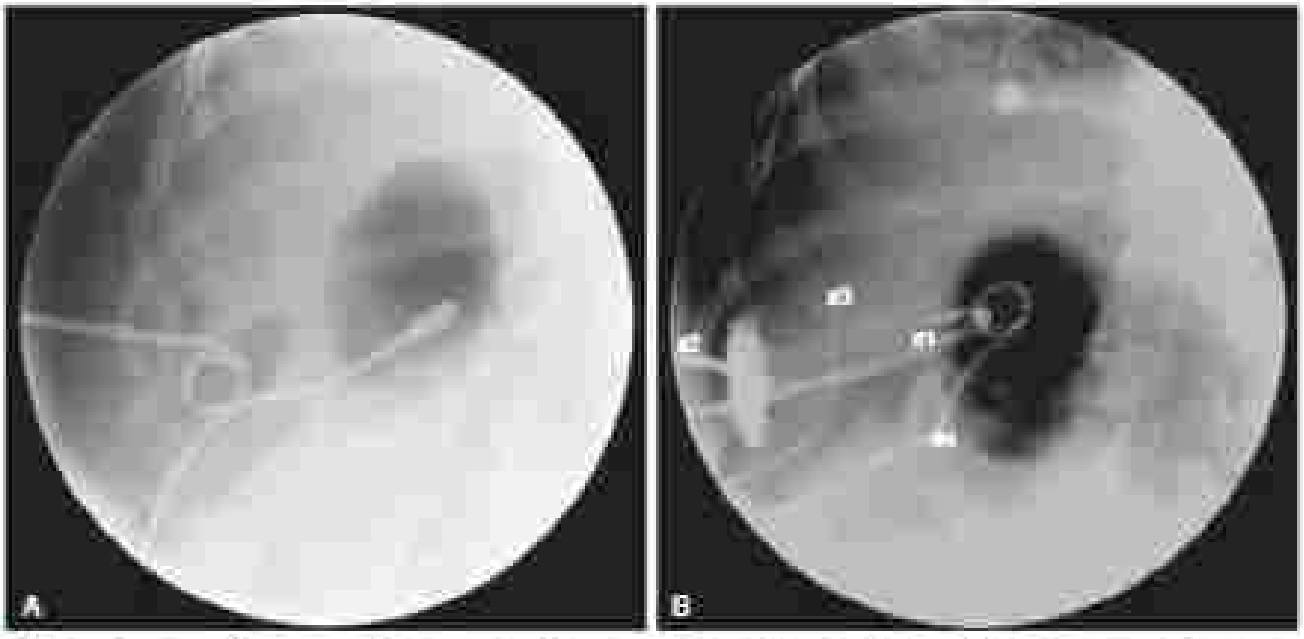

FIG. 3 (A) Initial placement of two percutaneous drainage catheters into the pyogenic liver abscess in the patient in Fig. 1. (B) Placement of two additional percutaneous catheters 4 days later to fully drain the large amount.

In those rare situations in which open surgery will be required, the choice of incision will depend on the abscess location. As these operations will be classified as "dirty," a wound protector should be used. The abscess should be localized with intraoperative US, and the adjacent peritoneum should be protected with laparotomy pads (Fig. 4). After aspiration for aerobic and anaerobic cultures, the liver capsule is incised. The cavity is then irrigated, and loculations can be disrupted gently with a finger being careful not to injure major vessels or bile ducts. Both soft Penrose and large suction drains are placed and brought out via a separate stab incision. In rare situations, hepatectomy of a very diseased segment or segments may be indicated. In performing these operations, care must be undertaken to avoid severe sepsis due to massive bacteremia caused by manipulation of the abscessed liver.

Outcomes

Historically, the majority of patients with PLAs died with outcomes being worst in patients with biliary abscess, malnutrition, and underlying malignancies. Currently, fewer than 10% of patients with PLAs die. However, patients with HPB malignancies and those who are immunosuppressed after liver transplantation are at greatest risk for mortality. For the remainder of patients with a relatively good prognosis, recent debate has centered around the relative risks and benefits of percutaneous needle aspiration (PNA) versus PCD. A recent systematic review and meta-analysis of five randomized controlled trials involving 306 patients clearly favored PCD. Compared to PNA, the success rate for patients with PCD was higher (96% vs 78%; $P < .01$); the time to clinical improvement was shorter ($< .001$); and the days to achieve a 50% reduction in abscess size was shorter ($P < .001$). Thus, when expert interventional radiologists are available, PCD should be performed.

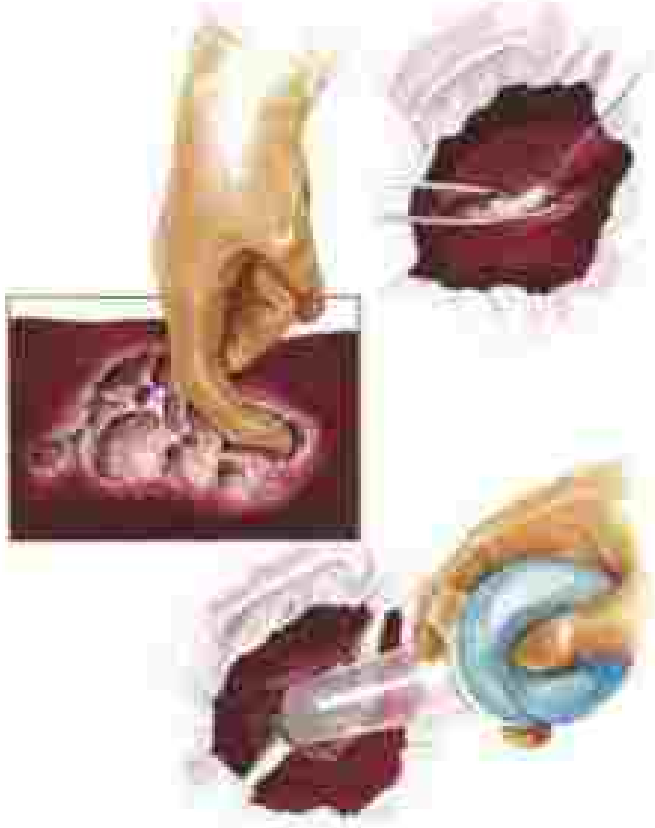

FIG. 4 Operative drainage of a PLA. Laparotomy pads are placed to prevent contamination when the abscess is incised and cultured (top). Loculations are gently disrupted with a finger (middle). The cavity is copiously irrigated (bottom) before large drains are placed. (From Lillemoe J, Jarnagin C. Atlas of Gastrointestinal Surgery v.2 E. 2nd ed. Shelton, CT: People's Medical Publishing; 2010.)

FUNGAL HEPATIC ABSCESS

Immunocompromised patients, including those receiving chemotherapy for an underlying malignancy and those who have undergone a liver transplantation, are more prone to develop a fungal liver abscess. Patients with biliary malignancies and indwelling stents, who receive multiple courses of antibiotics for recurrent cholangitis, also

ers at increased risk for mixed bacterial and fungal liver abscesses. Patients with hepatic tumors who undergo ablative procedures also have an increased risk for development of a fungal hepatic abscess.

Treatment

The principles outlined earlier for bacterial liver abscesses also apply to fungal hepatic abscesses. PCD should be undertaken as the preferred initial procedure. Biliary stent placement or change is also indicated when the underlying etiology is biliary obstruction. Approximately 80% of fungal abscesses will have *Candida* spp. In some patients, *Aspergillus* or *Cryptococcus* will be isolated. Historically, amphotericin B was the treatment of choice, but currently, micafungin and caspofungin should be utilized to treat these patients. Prolonged antifungal therapy is indicated, and oral fluconazole should be used only if *Candida* spp. are sensitive. In patients with mixed bacterial and fungal liver abscesses, appropriate antibiotic therapy also should be provided.

Outcomes

Patients with a pure or mixed fungal liver abscess are at high risk for mortality. Patients who receive adequate drainage and antifungal therapy still have a 20% risk of mortality. Patients who have fungemia and those with a delay in diagnosis who develop severe sepsis before adequate drainage and/or appropriate antifungal therapy is initiated are also at increased risk for mortality. As a result, approximately 50% of patients with a fungal liver abscess do not survive.

AMEBIC LIVER ABSCESS

Amebiasis is a common global parasitic infection caused by the protozoan *E. histolytica*. The vast majority of these infections occur in tropical and subtropical areas in the developing world including Africa, Indonesia, Central and South America. High risk groups in developed countries include immigrants, tourists who have travelled to endemic areas, sexually active homosexual men, institutionalized patients, and those with HIV. Amebiasis occurs with a bimodal age distribution, with one peak at age 2 to 3 years and the second peak in middle age. ALA is 10 times more common in men than in women. Low socioeconomic status and unsanitary conditions are independent risk factors for amebiasis.

Diagnosis

The vast majority of people who become infected with *E. histolytica* are asymptomatic. However, without symptoms, patients may shed amebic cysts for years. The most common form of invasive disease is colitis that presents with gradually worsening diarrhea, abdominal pain, and weight loss. In this setting, trophozoites may reach the liver via the portal system and cause focal hepatocytic necrosis and microabscesses. After coalescence, a single abscess will contain a thick liquid that typically is red/brown and has been described as "anchovy paste." Clinical presentation may be acute with fever and right upper quadrant pain or subacute with weight loss and intermittent fever and pain. Simultaneous presentation with colitis and an ALA is unusual. Clinical characteristics distinguishing patients with ALA from those with pyogenic hepatic abscesses are presented in Table 2.

Patients with an ALA will have a mild to moderate elevation of the white blood cell count. These patients also may have mild elevations of alkaline phosphatase and transaminases, but jaundice is rare. Stool samples for trophozoites may be positive in up to half of the cases. Chest radiographs will frequently demonstrate a pleural effusion, atelectasis, or elevation of the right hemidiaphragm. US, CT, and MRI are all excellent methods for detecting ALAs (Fig. 5). Approximately three fourths of ALAs appear as solitary lesions in the right lobe.

Another serology is highly sensitive and specific in differentiating ALA from PLA. Serum antibodies are positive in 99% of patients with ALA and in 80% of those with invasive colitis. Serologic data are usually available in 24 to 48 hours, therefore the need to aspirate a suspected ALA to establish a diagnosis is questionable. In addition, no level I data are available to demonstrate that aspiration of an ALA has a survival benefit. Thus, diagnostic aspiration is reserved for the rare patients with a negative serology or when secondary bacterial contamination is suspected.

TABLE 2 Clinical Characteristics of Patients With Pyogenic and Amebic Abscesses

Pyogenic	Amebic
Age >50 years	Age <50 years
Male/female 1:1	Male/female 10:1
No ethnic predisposition	Hispanic descent
No recent travel	Travel to endemic area
Underlying malignancy	No malignancy
High fevers	Fever
Pain unusual	Pain common
Tenderness uncommon	Tenderness common
No diarrhea	Diarrhea common
Jaundice occasionally	Jaundice rarely
Severe sepsis	Mildly septic

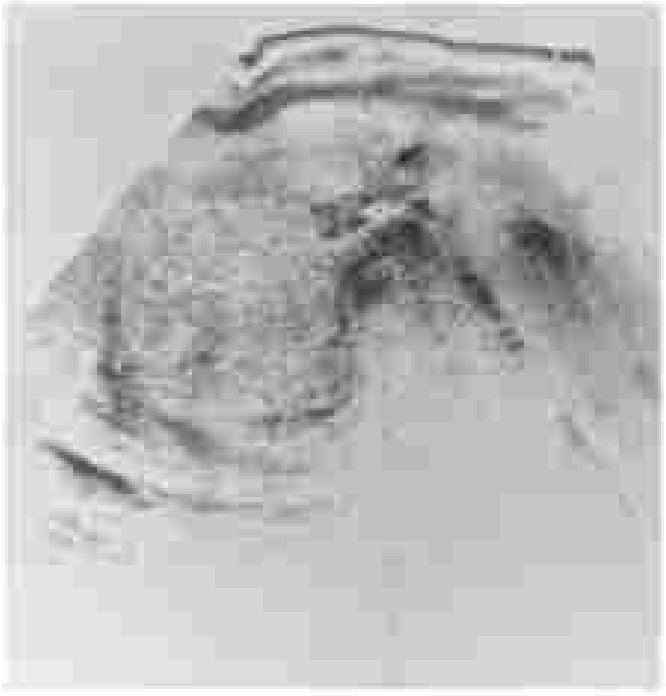

FIG. 5 Ultrasound demonstrating large amebic liver abscess in the right lobe.

TREATMENT

Antibiotics

Metronidazole is the antibiotic of choice for ALA. The oral dose is 500 to 750 mg three times a day for 7 to 10 days. The response to metronidazole is usually profound with symptomatic improvement in 3 to 4 days. At 5 days, 85% of patients with an ALA have responded and that rate increases to 95% at 10 days. Tinidazole 2 g orally for 5 days is an alternative for the rare patient with a metronidazole allergy. Another alternative

to metronidazole 2 g for 5 days to patients who do not tolerate the side effects of metronidazole. However, with metronidazole treatment, the parasites persist in the intestines in up to half of the patients. Therefore, an additional luminal agent such as paromomycin (35 mg/kg three times a day for 5 to 7 days), diiodohydroxyquin (650 mg orally three times daily for 20 days), or iliamycin furoate (500 mg orally three times a day for 10 days) should be utilized to eradicate intestinal colonization.

Therapeutic Aspiration

In 2003, Bennion and colleagues reported a prospective, randomized trial in patients with ALA, comparing oral metronidazole alone with US-guided aspiration plus oral metronidazole. ALA aspiration improved liver tenderness within the first 3 days, but no differences in other clinical findings or laboratory tests were observed between the two groups. The authors concluded that the minor clinical benefit was insufficient to justify routine needle aspiration. Thus, therapeutic needle aspiration is reserved for patients with (1) no clinical response after 5 to 7 days, or (2) a large abscess, especially in the left lobe, with increased risk for rupture into the peritoneum or pericardium.

Catheter and Surgical Drainage

In patients with a very large (>10 cm) ALA, PCD has been shown to be better than needle aspiration with respect to duration of clinical symptoms. PCD is useful in patients with pulmonary, peritoneal, or pericardial complications. However, large catheters are usually required because of the high viscosity of the amebic abscess fluid. Additionally, catheter drainage may lead to secondary bacterial contamination. Surgical drainage of ALAs is rarely required, and indications include (1) failure of response to more conservative measures, (2) erosion into neighboring organs including the stomach, duodenum, and colon, (3) sepsis related to secondary bacterial infection, or (4) life-threatening hemorrhage, not amenable to angiographic therapy.

OUTCOMES

The majority of patients with an ALA respond to oral antibiotics within 3 to 5 days. However, if the presentation is very late and subacute organ or free rupture has occurred, an ALA may be fatal. Factors associated with a poor prognosis include presentation with (1) encephalopathy, (2) a serum albumin of less than 2.0 g/dL, (3) a total bilirubin of greater than 3.5 mg/dL, (4) an abscess volume of greater than 500 mL, (5) multiple abscesses, (6) adjacent organ erosion, and (7) free rupture. Fortunately, these factors are present in only a small percentage of patients with ALA. The fact that most patients with an ALA, unlike many with PLA, are young, otherwise healthy, and unlikely to be immunosuppressed or have a malignancy, means that their likelihood for full recovery is excellent. Although clinical recovery is usually rapid, radiologic resolution of the abscess may take many months.

Transarterial Chemoembolization for Liver Metastases

Quang Nguyen, MD, and Christos S. Georgiades, MD, PhD

Transarterial chemoembolization (TACE) has become the standard of care for the treatment of unresectable hepatocellular carcinoma. In patients with hepatocellular carcinoma, catheter-based image-guided delivery of chemotherapy agents and embolization particles has been shown to result in significant improvement in objective tumor response, progression-free survival, cause-specific survival, and overall survival. TACE is also used to treat a number of secondary, liver-predominant malignancies. Studies have indeed shown many benefits for patients treated with TACE, including downstaging into resectability, improving survival and disease progression, and controlling symptoms. In this chapter, we describe how TACE can be incorporated into a multidisciplinary approach for the treatment of patients with metastatic malignancies to the liver. A variety of agents/transarterial modalities have been developed including bland transarterial hepatic arterial embolization (TAE), TACE, and selective internal radioembolization therapy. These therapies offer reduced systemic toxicity and more effective local tumor control. As a result, some procedures have been included in the National Comprehensive Cancer Network treatment guidelines.

CHEMOEMBOLIZATION OPTIONS

The efficacy of TACE relies on the fact that normal liver parenchyma is mainly supplied by the portal vein (~70%), whereas primary or secondary liver neoplasms are exclusively fed by hepatic artery branches (neo-angiogenesis) therefore, the intra-arterial delivery of a cytotoxic drug will primarily target neoplasms and spare liver parenchyma.

There are three slightly different options for treating patients using a catheter-based transarterial approach.

1. Bland embolization alone. Operators use embolic particles to effect complete stasis in the hepatic artery branch that feeds the target tumor. TAE is predicated on the assumption that all damage to the tumor is due to ischemia and that chemotherapy plays no role. Studies have shown TAE is nearly as effective as TACE; therefore, if chemotherapy administration is contraindicated (e.g., maximum lifetime doxorubicin amount reached, allergy), the patient may still benefit from TAE.
2. Lipiodol-based TACE. This is the originally described conventional TACE method. It involves the transcatheter delivery of a cocktail (chemotherapy and lipiodol) into the target tumor, followed by particle embolization. The chemotherapy cocktail consists of any combination of cisplatin 100 mg, doxorubicin 50 mg, and mitomycin C 10 mg. This is mixed with lipiodol (Ethiodol) in a 1:1 or a 2:1 volume ratio depending on flow characteristics. A 1:1 ratio is more viscous and used for high flow states, whereas 2:1 (chemo/lipiodol) is less viscous and used in low flow states.

to metronidazole 2 g for 5 days to patients who do not tolerate the side effects of metronidazole. However, with metronidazole treatment, the parasites persist in the intestines in up to half of the patients. Therefore, an additional luminal agent such as paromomycin (35 mg/kg three times a day for 5 to 7 days), diiodohydroxyquin (650 mg orally three times daily for 20 days), or diloxanide furoate (500 mg orally three times a day for 10 days) should be utilized to eradicate intestinal colonization.

Therapeutic Aspiration

In 2003, Bennion and colleagues reported a prospective, randomized trial in patients with ALA, comparing oral metronidazole alone with US-guided aspiration plus oral metronidazole. ALA aspiration improved liver tenderness within the first 3 days, but no differences in other clinical findings or laboratory tests were observed between the two groups. The authors concluded that the minor clinical benefit was insufficient to justify routine needle aspiration. Thus, therapeutic needle aspiration is reserved for patients with (1) no clinical response after 5 to 7 days, or (2) a large abscess, especially in the left lobe, with increased risk for rupture into the peritoneum or pericardium.

Catheter and Surgical Drainage

In patients with a very large (>10 cm) ALA, PCD has been shown to be better than needle aspiration with respect to duration of clinical symptoms. PCD is useful in patients with pulmonary, peritoneal, or pericardial complications. However, large catheters are usually required because of the high viscosity of the amebic abscess fluid. Additionally, catheter drainage may lead to secondary bacterial contamination. Surgical drainage of ALAs is rarely required, and indications include (1) failure of response to more conservative measures, (2) erosion into neighboring organs including the stomach, diaphragm, and colon, (3) sepsis related to secondary bacterial infection, or (4) life-threatening hemorrhage, not amenable to angiographic therapy.

OUTCOMES

The majority of patients with an ALA respond to oral antibiotics within 3 to 5 days. However, if the presentation is very late and subacute organ or free rupture has occurred, an ALA may be fatal. Factors associated with a poor prognosis include presentation with (1) encephalopathy, (2) a serum albumin of less than 2.0 g/dL, (3) a total bilirubin of greater than 3.5 mg/dL, (4) an abscess volume of greater than 500 mL, (5) multiple abscesses, (6) adjacent organ erosion, and (7) free rupture. Fortunately, these factors are present in only a small percentage of patients with ALA. The fact that most patients with an ALA, unlike many with PLA, are young, otherwise healthy, and unlikely to be immunosuppressed or have a malignancy, means that their likelihood for full recovery is excellent. Although clinical recovery is usually rapid, radiologic resolution of the abscess may take many months.

TRANSARTERIAL CHEMOEMBOLIZATION FOR LIVER METASTASES

Quang Nguyen, MD, and Christos S. Georgiades, MD, PhD

Transarterial chemoembolization (TACE) has become the standard of care for the treatment of unresectable hepatocellular carcinoma. In patients with hepatocellular carcinoma, catheter-based image-guided delivery of chemotherapy agents and embolization particles has been shown to result in significant improvement in objective tumor response, progression-free survival, cause-specific survival, and overall survival. TACE is also used to treat a number of secondary, liver-predominant malignancies. Studies have indeed shown many benefits for patients treated with TACE, including downstaging into resectability, improving survival and disease progression, and controlling symptoms. In this chapter, we describe how TACE can be incorporated into a multidisciplinary approach for the treatment of patients with metastatic malignancies to the liver. A variety of agents/transarterial modalities have been developed including bland transarterial hepatic arterial embolization (TAE), TACE, and selective internal radioembolization therapy. These therapies offer reduced systemic toxicity and more effective local tumor control. As a result, some procedures have been included in the National Comprehensive Cancer Network treatment guidelines.

CHEMOEMBOLIZATION OPTIONS

The efficacy of TACE relies on the fact that normal liver parenchyma is mainly supplied by the portal vein (~70%), whereas primary or secondary liver neoplasms are exclusively fed by hepatic artery branches (neo-angiogenesis) therefore, the intra-arterial delivery of a cytotoxic drug will primarily target neoplasms and spare liver parenchyma.

There are three slightly different options for treating patients using a catheter-based, transarterial approach.

1. Bland embolization alone. Operators use embolic particles to effect complete stasis in the hepatic artery branch that feeds the target tumor. TAE is predicated on the assumption that all damage to the tumor is due to ischemia and that chemotherapy plays no role. Studies have shown TAE is nearly as effective as TACE; therefore, if chemotherapy administration is contraindicated (e.g., maximum lifetime doxorubicin amount reached, allergy), the patient may still benefit from TAE.
2. Lipiodol-based TACE. This is the originally described conventional TACE method. It involves the transcatheter delivery of a cocktail (chemotherapy and lipiodol) into the target tumor, followed by particle embolization. The chemotherapy cocktail consists of any combination of cisplatin 100 mg, doxorubicin 50 mg, and mitomycin C 10 mg. This is mixed with lipiodol (Ethiodol) in a 1:1 or a 2:1 volume ratio depending on flow characteristics. A 1:1 ratio is more viscous and used for high flow states, whereas 2:1 (chemo/lipiodol) is less viscous and used in low flow states.

3. Drug-eluting beads (DEBs). The latest development are the introduction of sponge like particles that can be preloaded with chemotherapy. These particles are used to embolize the target tumor similar to conventional TACE, without the addition of lipiodol. Over a period of time, these particles elute chemotherapy, maintaining a high intratumoral dose and low plasma concentration. DEBs allow only one chemotherapy drug to be loaded, which is most commonly doxorubicin.

None of the three options has been shown to be superior to the others in terms of efficacy and the choice is operator dependent.

The secondary liver diseases most commonly treated with TACE are (in decreasing order of frequency):

1. Neuroendocrine cancer, if
   a. Symptomatic
   b. Results in clinically significant laboratory abnormalities such as hypoglycemia from metastatic insulinoma or hyperglycemia from metastatic glucagonoma
   c. Rapidly growing
   d. High Ki-67 index
2. Cholangiocarcinoma (CCA), if
   a. Systemic chemotherapy failed or in conjunction with systemic chemotherapy
   b. To target tumor portion along a precarious resection margin thus aiding surgery
3. Colon cancer
   a. If surgery or ablation is not an option and no systemic options left
   b. To maintain tumor size if planned surgery is significantly delayed
4. Other (breast, melanoma, pancreatic)
   a. TACE for such neoplasms is less well studied and should be tailored to each individual patient

A novel indication is the use of immunotherapy. TACE is believed immune response. Early studies suggest that circulating tumor related antigens after TACE, will result in augmented immune response. If checkpoint inhibitor administration is appropriately timed.

PATIENT PREPARATION

Patient selection is of paramount importance for patients with secondary liver disease as operator must coordinate with systemic options, consider potential drug interactions and potentiation of side effects and coordinate follow up and response evaluation, therefore a multidisciplinary input is necessary. In general, indications for liver-directed locoregional treatments for secondary malignancies include the following:

1. Liver predominant disease. TACE is reasonable if liver disease burden is the likely cause of the patient's demise should TACE be withheld. Minimal extrahepatic disease such as lymphadenopathy is not a contraindication to TACE.
2. Control of extrahepatic disease with systemic chemotherapy, with progression of liver disease.
3. To downstage or maintain a patient into criteria for resection. For example: a patient with resectable colon cancer metastases, whose surgery is delayed for other reasons. Or a patient with CCA with precarious surgical margin (i.e., tumor too close to a hepatic vein that must be preserved). Low level evidence suggests that incorporating aggressive locoregional treatments early in the treatment of CCA improves the chance for converting the patient into a candidate for resection.

A clinic visit is necessary during which the physician assess the patient's Eastern Cooperative Oncology Group status, explain the risk/benefit profile, set expectations, and answer the patient's questions. A complete blood count, comprehensive metabolic panel, and coagulation profile are reviewed to ensure there are no undue risks for TACE. A contrast-enhanced, cross-sectional study (preferably a magnetic resonance imaging [MRI] scan) is necessary for treatment planning and to evaluate for response after TACE. Contraindications to liver directed, locoregional therapies are summarized in Table 1 and aim to mitigate the risk of acute hepatic failure. Symptoms (encephalopathy, severe tumor related pain), signs (ascites) or labs (liver function tests [LFTs]), and poor performance status (hepatocellular carcinoma status >2) should prompt reconsideration of TACE.

TECHNIQUE/PATIENT CARE

1. Right lower fasting in preparation for conscious sedation or general anesthesia.
2. Premedication:
   a. Dexamethasone (20 mg intravenously), which reduces post-operative fever, anorexia, fatigue.
   b. Proton pump inhibitors, which reduce risk of gastric/duodenal ulcers and mitigate significance of nontarget embolization.
   c. Hydration, which reduces fatigue, nausea.
   d. Antibiotics. Not necessary unless sphincter of Oddi has been compromised. If prior biliary intubation or post Whipple, then antibiotic prophylaxis is necessary. Recommended regimen is moxifloxacin 400 mg by mouth daily beginning 3 days before and continuing for 17 days after TACE.
3. Vascular access. TACE can be performed either via common femoral arterial (CFA) or radial arterial (TRA) access. While still most TACEs use the CFA access, TRA which facilitates early patient ambulation is increasingly used. In both cases a 5Fr sheath is used. If TRA is performed, a Barbeau's test is performed first to minimize the risk of hand ischemia. Upon access, a cocktail of heparin and one or more vasodilators (nitroglycerin, verapamil, or nicardipine) is administered. The tumor is not necessary for CFA access.
4. Diagnostic arteriogram. The objective of diagnostic angiogram before delivery of chemotherapy is twofold:
   a. To delineate the vascular anatomy related to the tumor and how to best deliver the treatment
   b. To unmask any nontarget vessels at risk for inadvertent chemoembolization and plan approach to minimize the risk.

A superior mesenteric arteriogram is first performed. This excludes replaced/collateral vascular anatomy to the liver and shows whether the portal vein is patent or not. Then a celiac arteriogram is performed. This shows the target (hepatic artery branches) and nontarget vessels (i.e., left and right gastric artery, supraduodenal artery, cystic artery, umbilical artery) that must be protected (Fig. 1).

5. Treatment. Once the target arteries are clarified on, a microcatheter is used to obtain superselective access. The ideal location for the tip of the catheter is one that an infusion from that point would cover the entire tumor and, at the same time, spare as much of normal liver parenchyma as possible (Fig. 2). Once the catheter is in the optimum position, the treatment mixture is delivered. Whether lipiodol TACE or DEB TACE, this is done under continuous fluoroscopic observation. As the cocktail is given target arterioles embolize and flow dynamics may change. Over-aggressive embolization may result in antegrade reflux around the catheter and inadvertently reach nontarget organs. The ones most commonly at risk are the duodenum, stomach, and pancreas resulting from the proximity of their arterial supply to the hepatic artery. The technical objective is to deliver the entire treatment mixture into the target tumor and reach blood flow stasis within the artery that supplies it. Additional particle use may be necessary to achieve stasis. If multiple tumors are targeted, it is best to target each individual tumor as selectively as possible as

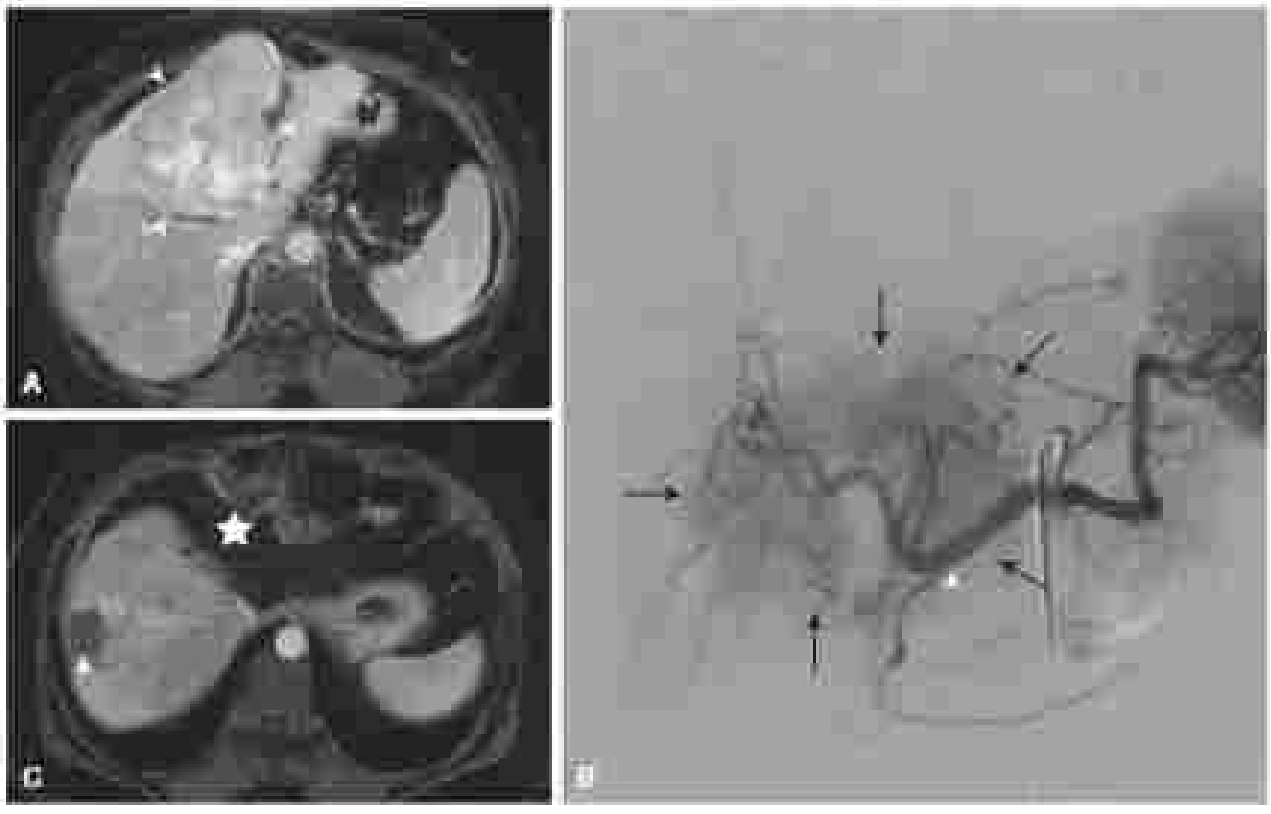

FIG. 1 A 51-year-old female with cholangiocarcinoma. (**A**) Axial contrast-enhanced magnetic resonance imaging shows a large hypervascular mass (arrow) in the liver with dominant unresectable tumors on the left of surgical margins. (**B**) Diagnostic angiogram during transarterial chemoinfusion after (TACE) shows the hypervascular mass (arrow) being fed by the hepatic artery (arrowhead). After a combination of locoregional treatments including many TACEs the patient became resectable. (**C**) Axial contrast-enhanced magnetic resonance imaging 2 years after initial diagnosis shows the remnant liver with no radiologic evidence of disease. A completely necrotic lesion (arrowhead) remains like after repeat TACE. See, Lin, h... [illegible]

opposed to treating an entire lobe. Though more time consuming and technically challenging, selective embolization carries a lower risk of liver injury and results in better response. Once the technical objective is reached, the catheters and sheath are removed and HOA hemostasis is obtained. The latter can be obtained by either a 15-minute manual compression or by the use of a vascular closure device. The use of vascular closure devices obviates the need for manual pressure and allow the patient to ambulate at 2 hours instead of at 6.

Note: In general, only one lobe (right or left) can be treated at any one time because TACE results in transient LFT elevation, with the treated liver recovering by approximately 2 weeks. During the recovery period, adequate remaining liver function must be ensured. In cases in which multiple subselective TACEs can be performed without affecting a significant portion of the normal liver parenchyma, bilateral lesions can be treated in one session.

6. Patient recovery. Patient recovery in short (<24 hours) and centered around symptom control and prevention. Postprocedure hydration, as-needed antiemetics, and pain control are the mainstay of recovery. The latter is optimized with patient-controlled analgesia pump. The most common symptoms include fatigue, fever, and abdominal pain, a triad that is termed the postembolization syndrome. They are reported in at least 40% of patients and gradually subside, on average, over 14 days. Other symptoms that could be encountered include nausea, anorexia, and rarer, alopecia (4%) and night sweats. Volume of embolization and degree of tumor necrosis are correlated with severity of symptoms. If lipiodol is used in the TACE mixture, a noncontrast computed tomography can be obtained after the procedure to indicate the distribution of treatment (Figs. 1, 2).
7. Patient follow-up. Irrespective of the embolization method used (conventional using lipiodol, Irinot, or with DEBs), follow-up protocol is usually preserved. It includes a repeat multiphasic MRI with intravenous gadolinium-based contrast, laboratory tests (comprehensive metabolic panel, complete blood count, international normalized ratio, relevant tumor markers) and a clinic visit to reassess the patient's performance status. Follow-up is generally at 3-month intervals but this must be tailored to each patient and according to treatment goals. There is no limit to the number of TACE treatments a patient can receive. Further treatment should be aborted, however, if any contraindications develop (Table 1), if the initial indication is no longer valid or if after 2 TACEs the targeted lesion failed to respond as expected. Studies have shown that failure of initial TACE does not predict failure of a second treatment, however, if two TACEs fail to result in tumor response, additional treatment is unlikely to have any benefit.
8. Toxicities/complications. Complications related to TACE are summarized in Table 2. A majority of patients (>60%) will have the described postchemoembolization syndrome. It is always self-limiting and only symptomatic care is indicated. The most feared complication is acute liver decompensation resulting from TACE-related acute liver injury. The related risk is small (<1%) and only considered when there is underlying liver disease (cirrhosis, severe steatohepatitis, significant history of systemic chemotherapy). Unilateral TACE all but eliminates this risk in cases of metastatic disease. Similarly, encephalopathy is also unlikely as TACE for secondary liver disease is usually

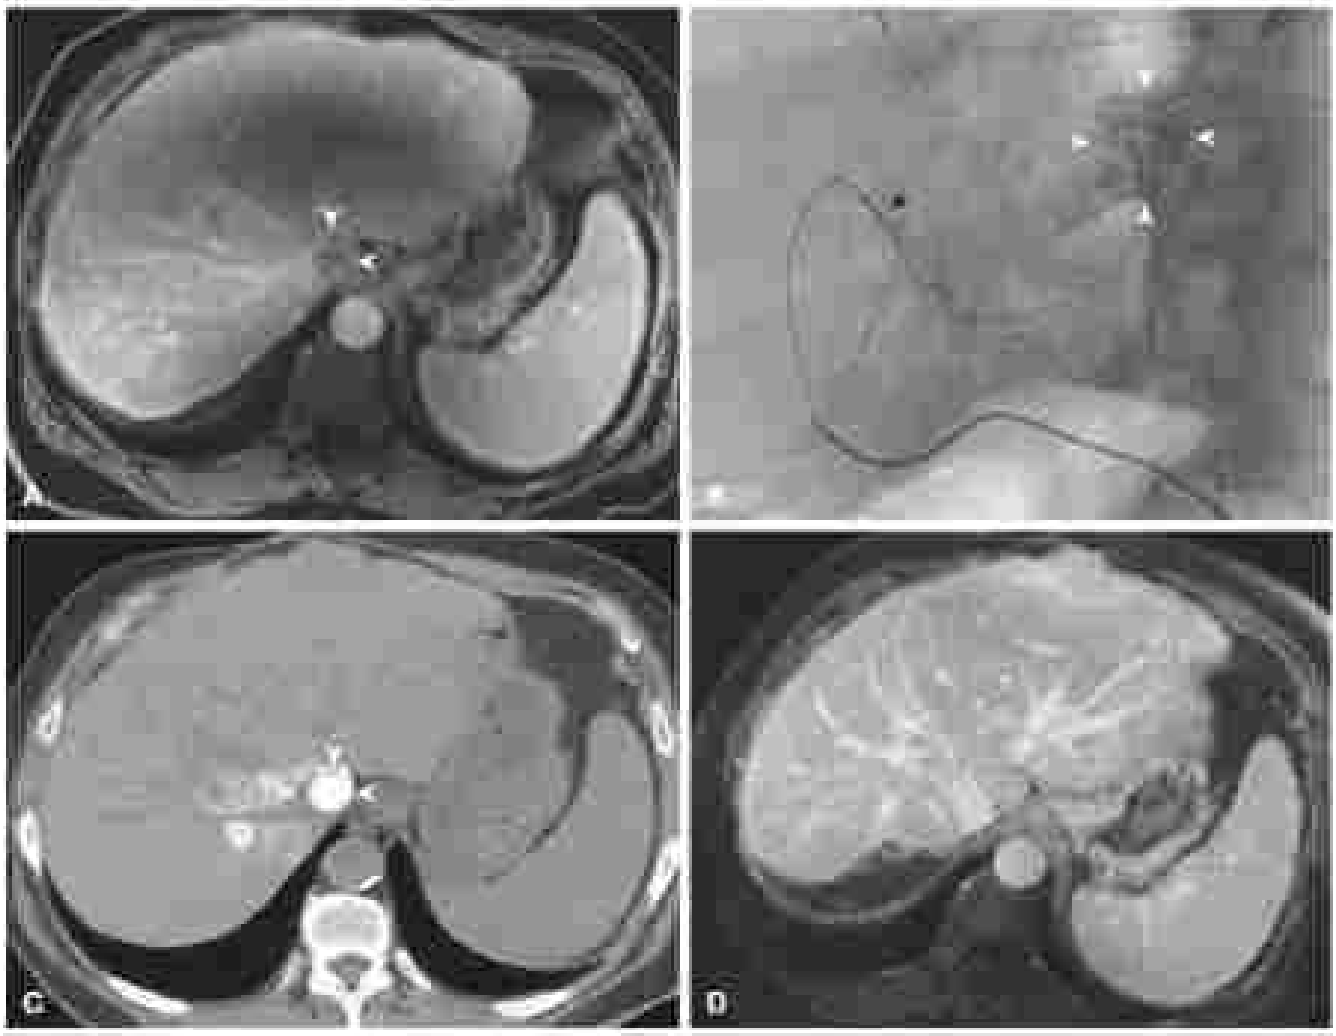

FIG. 2. A 64-year-old patient with history of colon resection for colon cancer. (A) Axial contrast-enhanced magnetic resonance imaging shows a single metastatic focal parenchymal abutting and compressing the inferior vena cava. The patient was deemed unresectable and had no extrahepatic systemic options. (B) Diagnostic angiogram during transarterial chemoembolization shows a subsegmental microcatheter (black arrowhead) and the hypervascular lesion (white arrowhead). (C) Noncontrast CT on postchemoembolization session 1 shows the dense lipiodol deposition in the targeted lesion (arrowhead). (D) Axial contrast-enhanced magnetic resonance imaging 3 years after treatment shows complete and persistent response with no radiologic evidence of disease.

performed in patients with intact liver function. Previous history of encephalopathy is the major risk factor for worsening encephalopathy. Both acute liver failure and encephalopathy risk can be further mitigated by selective treatments. Biliary complications include stricture and abscess formation. The biliary tree is supplied by the hepatic artery and overzealous embolization (especially with DEB) can result in ischemic strictures and hyperbilirubinemia. If the sphincter of Oddi has been violated (hepaticojejunostomy or biliary stent), there is a very high risk of intrahepatic abscess formation. Bacterial colonization translates into an abscess as a result of TACE-related biliary ischemia in more than 60% of such patients. Pre- (1 week) and post- TACE (2 week) treatment with broad-spectrum antibiotics (i.e., moxifloxacin 400 mg, by mouth every day) reduces the risk to less than 10%. Another potentially serious complication is inadvertent embolization of nontarget vessels. Performing a detailed diagnostic arteriogram before TACE and a selective TACE nearly eliminates this risk. Aberrant vascular anatomy further increases this risk with the vessels most at risk being left or right gastric arteries, supraduodenal artery, and the umbilical artery.

OUTCOMES

Colorectal Cancer

In a study by Vogl and associates in 2006, 863 patients with unresectable colorectal hepatic metastases that were refractory to systemic chemotherapy were treated with TACE (Fig. 2). By imaging characteristics, 68 patients (14.7%) had partial response, 223 patients (48.2%) had stable disease, and 172 patients (37.1%) had progressive disease. The 1- and 2-year survival rates after chemoembolization were 62% and 28%, respectively. Median survival times from date of diagnosis of liver metastases and date of first chemoembolization were 38 months and 14 months, respectively.

DEB-TACE as a new platform for intraarterial drug delivery in secondary liver tumors has been demonstrated in a retrospective analysis of 38 patients with metastatic colorectal cancer. Irinotecan-loaded DEBs were used and tumor response was assessed with modified Response Evaluation Criteria in Solid Tumor criteria in all patients. After an overall 47 procedures, 15% of the treated patients were classified as complete responders and 30% showed partial response, whereas 29% showed stable disease and 37% showed progressive disease. Most important, a median overall survival of 13.5

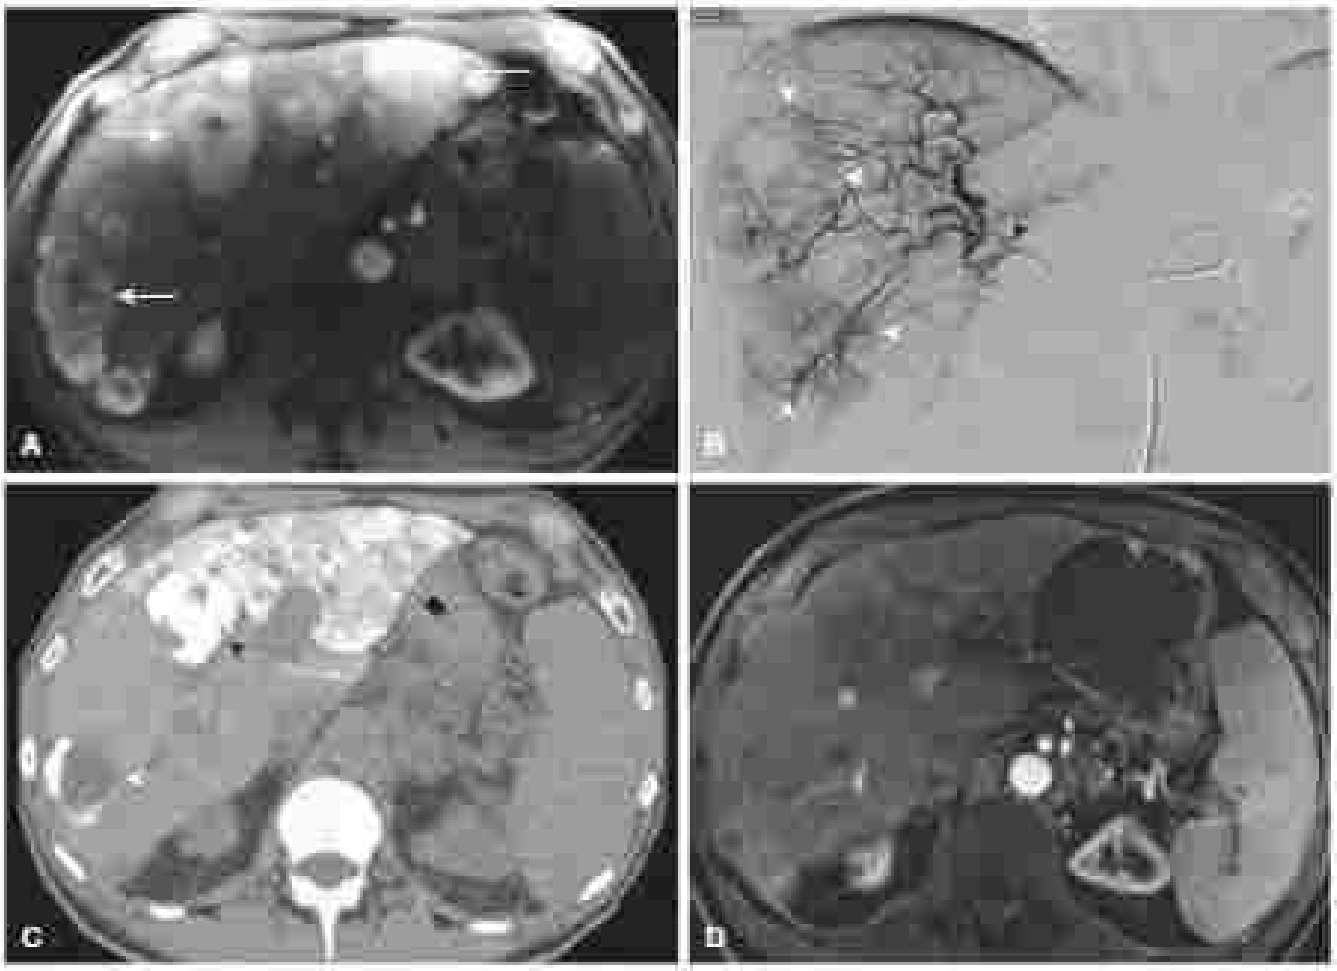

FIG. 3 A 70-year-old man with primary pancreatic neuroendocrine cancer (A) Axial contrast-enhanced magnetic resonance imaging shows extensive secondary neuroendocrine metastases in the liver (arrows). (B) Hepatic arteriogram of the right hepatic artery during segmental chemoembolization (TACE) shows the hypervascular tumor (arrowheads). The patient underwent a series of 4 TACEs over 6 months. (C) Abdominal computed tomography on post-TACE day 1 after left TACE shows dense lipiodol deposition in the hypervascular mass (black arrowhead) and a shrinking immediate proximity (curved) right hepatic lobe (white arrowhead). (D) Axial contrast-enhanced magnetic resonance imaging 2 years after treatment shows near-complete and systemic response with minimal radiologic evidence of disease.

TABLE 1 Contraindications to TACE

Contraindication	Comment
Total bilirubin >4	Superselective TACE can be performed
Rapidly rising total bilirubin	Deteriorating liver function
ECOG 3	Unlikely to benefit patient
Life expectancy <6 mo	Unlikely to benefit patient
Borderline liver function	Superselective TACE can be performed
Severe encephalopathy	Optimize medical treatment
Active bacterial infection	Treat and then TACE
Large tumor burden	
Renal insufficiency	Use CO_2 as contrast
Significant cardiopulmonary disease	
Biliary tube or hepaticojejunostomy	>40% risk of liver abscess ≤10% of prophylaxis is used

Contraindications to TACE are relative. A risk-benefit analysis must be applied to each patient, keeping the ultimate goal of treatment in mind. For example, if ECOG 3 status is temporary and unrelated to liver disease, TACE may be offered after recovery.
ECOG, Eastern Cooperative Oncology Group; TACE, transarterial chemoembolization.

TABLE 2 TACE-Related Toxicities

	Risk (%)	Mitigating Factors	Comment
Liver decompensation	<1	Selective embolization	Underlying cirrhosis increases risk
Encephalopathy	<1	Selective embolization	Underlying cirrhosis or prior encephalopathy increases risk
Liver abscess	2–4		If intact sphincter of Oddi
	10–20	If pretreated with antibiotics	If compromised sphincter of Oddi/colonized biliary tree
	>60	If not pretreated	
Cholangitis	10–15	Symptomatic treatment	Higher with drug-eluting beads
Renal failure	<2	Hydration	Worse if chronic renal insufficiency
Nontarget embolization	<1	Perform diagnostic arteriogram; selective TACE	Variant anatomy increases risk

Acute liver failure from TACE is rare and even rarer with secondary disease. This is because the noninvolved parenchyma is not cirrhotic (unlike hepatocellular carcinoma) and patients have preserved liver function. Only when signs of borderline liver function exist (elevated bilirubin levels, encephalopathy), further toxicity can be mitigated if subselective TACE is feasible. In general, TACE is very well tolerated and significant complications are rare and mitigated by meticulous technique and proper patient selection.

TACE, transarterial chemoembolization.

months was achieved with this treatment, yet again proving the potential of DEB TACE.

CCA

In a recent study Alberti and associates described results from treatment of intrahepatic CCA with DEB TACE (Fig. 1). They reported good disease control with more than 90% of patients having no disease progression. In a previous smaller study, the same group reported a median survival of 13 months and 100% response evaluation criteria in solid tumors response from DEC head treatment.

Metastatic Neuroendocrine Tumors

Metastatic neuroendocrine tumors represent approximately 10% of metastatic disease of the liver (Fig. 2). Carcinoid and pancreatic islet cells have a predilection to metastasize to the liver, and these patients with liver metastases have a poorer prognosis and quality of life. Surgical resection is curative but is possible only in less than 10% of patients. Progression to hepatic metastases is accompanied by hormonal synthesis and release into the circulation that can lead to a constellation of symptoms known as carcinoid syndrome (rash, flushing, diarrhea, and electrolyte disorders). With this development, treatment of the liver would be for palliation of the carcinoid syndrome symptoms. TACE can be used in patients with unresectable, hormonally active neuroendocrine tumors and strongly contribute to the elimination of hormonal symptoms. A report by de Monte et al. summarized the efficacy of TACE in the setting of neuroendocrine liver metastatic disease. The authors reported 74% chance of symptom control, a 56% chance of biomarker response, and a 50% chance of objective tumor response. TACE was very well tolerated and disease progression was delayed by 12 to 18 months.

SUMMARY

Level 1 evidence shows that transarterial chemoembolization is the mainstay for treatment for unresectable hepatocellular carcinoma as it results in significant prolongation of survival. Though lower level, evidence exists that selected patients with secondary liver disease may also benefit from TACE.

Patient and tumor selection are important and case specific. For example, TACE may help downstage patients into criteria for resection (colon cancer) or ensure disease stability while more definitive treatments must be delayed. Additionally, for hormonally active disease TACE has demonstrated a very high efficacy in both symptom and hormonal control, along with objective tumor response.

Finally, because of the complexity and variability of secondary disease and the continuously emerging novel therapies, a multidisciplinary approach is necessary to optimize outcomes.

PORTAL HYPERTENSION: ROLE OF SHUNTING PROCEDURES

Sharon R. Weber, MD, Shawn E. Ostrander, MD, and Mark S. Orloff, MD

APPROACH TO VARICEAL BLEEDING

β-Blockade is the primary therapy for prophylaxis against initial variceal bleeding from esophageal varices. In patients with acute variceal bleeding, endoscopic therapy is widely accepted for hemorrhage control and prevention of variceal rebleeding. Options include variceal sclerotherapy and band ligation. Both modalities are equally effective at controlling active bleeding, but ligation is preferred because of lower rates of complications, including esophageal stricture. Endoscopic therapies are augmented by pharmacologic vasoconstriction with octreotide or vasopressin. When endoscopic intervention is not readily available or is ineffective (as in 10% to 15% of patients with acute variceal bleeding), this pharmacologic vasoconstrictive can reduce portal flow with or without balloon tamponade (with a Sengstaken-Blakemore or Minnesota tube) as an effective temporizing measure.

For patients who have not responded to endoscopic and pharmacologic therapy, the TIPS procedure is typically the treatment of choice. Meta-analysis comparing TIPS with endoscopic treatment showed lower rebleeding rates in TIPS but higher rates of encephalopathy, with no ultimate difference in survival. The use of surgical shunts for refractory variceal bleeding has declined markedly with improving availability and long-term patency of TIPS.

In select patient populations, surgical procedures other than liver transplantation are used as salvage therapy when less invasive treatments fail. Surgical decompression may be considered for Child's class [illegible] and B patients who have recurrent bleeding after medical and endoscopic treatment, who have poor access to healthcare, or who have gastric varices. Surgical shunts also play a role for patients whose condition is refractory to medical and endoscopic treatment and who are not transplant candidates (nonabstinent patients, active alcoholics, elderly patients, and those with significant cardiovascular disease). Two groups of patients with compelling arguments for surgical shunts are (1) those with chronic noncirrhotic portal vein thrombosis, provided a patent and shuntable vessel can be identified (i.e., splenic vein or superior mesenteric vein [SMV]), and (2) those with Budd-Chiari syndrome with favorable anatomy. Patients with well-compensated cirrhosis and no ascites could benefit from a distal splenorenal shunt when they have limited access to interventional radiology, but these are very few patients in the current era.

TIPS

Widespread clinical utilization of TIPS began in the early 1990s. Transjugular access of the hepatic vein is performed under fluoroscopic guidance. The portal vein is then accessed through the liver parenchyma and a stent is placed in this channel. TIPS effectively relieves variceal hemorrhage, improves ascites, and prevents rebleeding. As a functional side-to-side portacaval shunt, it has

high rates of hepatic encephalopathy (reported to be about 25% in most studies), though this complication can usually be controlled with medical treatment and is nondebilitating for most patients. In many recent years, the introduction and ready availability of expanded polytetrafluoroethylene stents have decreased the need for acute intervention with improvement in patency rates and in several randomized controlled trials with 1- to 2-year outcomes have reduced rebleeding rates and improved survival compared with bare stents. The long-term effect of these stents on outcomes is not yet known. TIPS has the major advantage over surgical shunting procedures in that nonthrombotic placement permits in situ removal during liver transplant, whereas extrahepatic shunts must be ligated or resected at transplant should a patient be a suitable candidate for transplantation.

The role of TIPS as prevention for initial variceal bleeding has not been studied, and thus its indications is to treat acute variceal bleeding, prevent recurrent hemorrhage, and treat refractory ascites. Approximately 80% to 90% of TIPS procedures are performed electively, and treatment of ascites is the most common indication for TIPS. TIPS is also recommended for patients with Budd–Chiari syndrome who fail to improve with anticoagulation and have favorable anatomy. Contraindications to TIPS include moderate to severe pulmonary hypertension, occluded hepatic veins or portal veins, hepatic encephalopathy, Model for End-Stage Liver Disease score greater than 18, and bilirubin level greater than 5 mg/dL, all of which are significant predictors of poor outcomes.

The effectiveness and advantages of TIPS have been well reported. TIPS prevents rebleeding more effectively than endoscopic therapy, improves overall liver function, and effectively bridges patients to transplantation. Most episodes of rebleeding after TIPS have been linked to stenosis or thrombosis, necessitating follow-up care and intervention. In the setting of acute variceal bleeding, it has been suggested that TIPS may reduce treatment failure and mortality rate in high-risk patients, when compared with distal splenorenal surgical shunting procedures after bleeding, a randomized controlled trial showed no difference in variceal rebleeding, encephalopathy, shunt occlusion, and survival, although 80% of patients in the TIPS group required intervention to maintain patency. Long-term follow-up results from a randomized trial comparing TIPS with small-diameter prosthetic to graft portacaval shunt showed superior survival for Child's class A and B patients and longer time to shunt failure for those receiving surgical shunts. TIPS is currently indicated for patients with continued bleeding after failed medical and endoscopic management, prevention of rebleeding or ascites treatment in liver transplantation candidates, and prevention of rebleeding in patients who are not candidates for surgical shunt or liver transplantation.

TIPS is often follow up Doppler ultrasound to evaluate shunt function and frequently re-intervention to maintain shunt patency, with 1-year primary patency of 60% to 67%, 74% to 80% with revision of stenotic stents (assisted primary patency), and secondary patency rates of 95% to 100%. For this reason, it may not be the ideal treatment for patients with difficulty accessing medical care or with a history of poor compliance.

SURGICAL SHUNTS

The definitive surgical treatment for patients with variceal bleeding and underlying cirrhosis is liver transplantation. Before the advent of TIPS, patients who failed medical therapy were surgically shunted. In the TIPS era, surgical decompressive shunts remain a treatment option in those patients who (1) are not candidates for transplant because they have well preserved liver function and minimal hepatic encephalopathy; (2) are well-compensated cirrhotics without ready access to TIPS and without ascites; or (3) require bridging to transplantation resulting from variceal bleeding that has failed medical, endoscopic, and TIPS treatment.

Surgical shunts are classified by the extent of portal diversion and selectivity. Because variceal hemorrhage is the consequence of portal hypertension, these operative techniques are designed to shunt portal venous circulation to the systemic circulation to decrease hypertension. The anatomy of shunting can be nonselective or selective and the extent of diversion can be total or partial. Total nonselective shunts (e.g., end to side portacaval shunt) decompress all portal hypertension by diverting portal blood flow to the systemic venous system via the inferior vena cava (IVC) and thus are complicated by progressive liver failure and hepatic encephalopathy. Partial nonselective shunts, in contrast, preserve portal perfusion of the liver to minimize these effects and risk of liver failure. Selective shunts (e.g., distal splenorenal shunt, small caliber portacaval H graft) decompress a particular venous compartment to prevent variceal bleeding while maintaining portal perfusion to the liver, typically via the mesenteric circulation. A note for any selective shunt is the inevitable change in selectivity that occurs over time. Selective shunts are at risk of collateral development and subsequent loss of selectivity as portal systemic collaterals divert flow into a patent shunt. Conversely, selective shunts may narrow over time, thus decreasing the shunted blood flow and have been shown to have diminished primary patency compared to total shunts.

Total Nonselective Shunts

Total portal systemic shunts, or nonselective shunts, include any shunt greater than 10 to 12 mm in diameter between the portal vein (or its main tributaries) and the IVC (or feeding vessel thereof) because this likely results in total shunting of portal blood. This decompression of all portal hypertension results in excellent control of variceal bleeding at the cost of adverse effects on liver. Although bleeding and ascites are controlled in more than 90% of patients, total shunts can lead to hepatic encephalopathy in 30% to 40% of patients as well as progressive liver failure. The end to side portacaval shunt is the classic example of nonselective shunting and is the technique on which early studies are based. Today, it is largely of historical interest. Though complicated by hepatic encephalopathy this approach controls bleeding more effectively than medical therapy. Although studies showed no survival benefit with surgical shunting, results were biased by crossover to surgical management by patients who failed medical therapy.

A generous side to side portacaval shunt also acts as a total nonselective shunt. Early studies showed no differences in clinical outcomes compared with end to side portacaval shunts; however, it may play a role in select patient populations today. Specifically, it is indicated in patients with significant ascites and refractory variceal bleeding who are not transplant candidates, as well as in those with Budd–Chiari syndrome with ascites and portal hypertension without underlying or resultant cirrhosis. It should not be performed in patients who are potential liver transplantation candidates because the dissection in the porta hepatis complicates subsequent transplantation surgery with increased operative morbidity and intraoperative transfusions. In Budd–Chiari syndrome, in which a portacaval shunts cannot be performed because of caudate hypertrophy or hepatic IVC occlusion, a mesocaval shunt may be the more appropriate approach. Though mesocaval shunts have been described for this clinical scenario, they should be avoided because of shunt length leading to poor patency rates and inferior outcomes. Mesocaval and mesoatrial shunting procedures performed with prosthetic grafts suffer from 20% to 30% thrombosis rates; use of autologous internal jugular vein graft in the mesocaval setting may avoid this complication. In centers with extensive experience, TIPS for Budd–Chiari may be an effective treatment.

Budd–Chiari patients with a patent vena cava and relatively preserved liver function may best be served by a side to side portacaval shunt. The patient should be positioned with the right side elevated and explored through a right upper abdominal transverse incision. A self-retaining retractor and generous Kocher maneuver is required, as is complete mobilization of the vena cava and

portal. Care should be taken to avoid damage to the bile duct or any replaced hepatic vasculature. Generally, the anastomosis should be 2.5 cm in length and will require a side biting clamp, two right angle clamps, and 3- 0 or 4- 0 prolene suture. If it is not possible to perform the anastomosis without tension secondary to caudate hypertrophy, a side to side reconstruction can be performed with an 8- to 10- mm prosthetic graft beveled with the caval anastomosis oriented more inferiorly.

Partial Nonselective Shunts

Use of small diameter shunts, typically defined as 8 to 12 mm in diameter, results in a partial shunt and can be performed in the mesocaval or portacaval positions. Use of either polytetrafluoroethylene or Dacron grafts or vein autografts (e.g., internal jugular vein) acts as a conduit between portal or SMV and the IVC. The smaller shunt diameter compared with total shunts results in maintenance of portal perfusion in 80% of patients with equivalent bleeding control. These patients have lower incidence of hepatic encephalopathy and liver failure compared with total shunts. An interposition mesocaval shunt had no difference in clinical outcomes compared with side to side portacaval shunts in a randomized controlled trial. This approach suffers from a high thrombosis rate, but avoids portal hepatic dissection, an important consideration for future liver transplantation candidates.

In the setting of portal vein thrombosis with preserved liver function and a patent SMV and vena cava, the side to side mesocaval shunt provides effective decompression and a low rate of encephalopathy. A variety of incisions can be used. Visualization is aided by use of a self retaining retractor and the small intestine is retracted inferiorly and to the left with upward traction on the transverse mesocolon. Identification of the middle colic vein will direct the dissection to the SMV. Approximately 6 to 8 cm of the *SMV should be mobilized with ligation and division of small branches and vessel loop control of large branches. Lymphatics should be carefully tied. A window is made in the mesocolon, and the IVC is sufficiently dissected to allow clamping with a side biting clamp. The proposed conduit, either a 12 mm ringed polytetrafluoroethylene graft or autologous jugular vein, is sewn to the SMV with 5- 0 or 6- 0 prolene, suture line tested, and packed with heparinized saline. The graft will curve gently around the duodenum and should be tailored to be neither too short nor too long to prevent kinking when the retractors are released. Right angle vascular clamps are applied to the SMV, followed by a lateral venotomy, and the graft is beveled to run parallel with the venotomy (Fig. 11). The caval clamp is removed first and vented through the suture line before tying. The SMV clamps are removed and pressure used to control bleeding at the suture line. Sterile pressure tubing can be used to check pressures with the graft open and occluded (Box 2).

Selective Shunts

Selective shunts are designed to decompress esophageal varices while avoiding adverse effects of total diversion by selectively diverting blood flow to the liver, but maintaining portal perfusion. The canonical example is the distal splenorenal shunt (DSRS). Described by Warren and colleagues, it is commonly referred to as the Warren shunt. DSRS results in portal oxygen disconnection through an end to side anastomosis of the superior mesenteric end of the splenic vein to the left renal vein and ligation of collateral vessels. Decompression of the gastroesophageal venous system prevents bleeding, while the high pressure superior mesenteric venous system maintains perfusion of the liver. Variceal bleeding is well controlled in more than 90% of patients, but the risk of ascites persists and a DSRS may worsen ascites rather than relieve it. For this reason, it should be avoided in patients with advanced ascites. The preservation of hepatic function compared with total shunts remains debated, but selective shunting does result in a lower incidence of

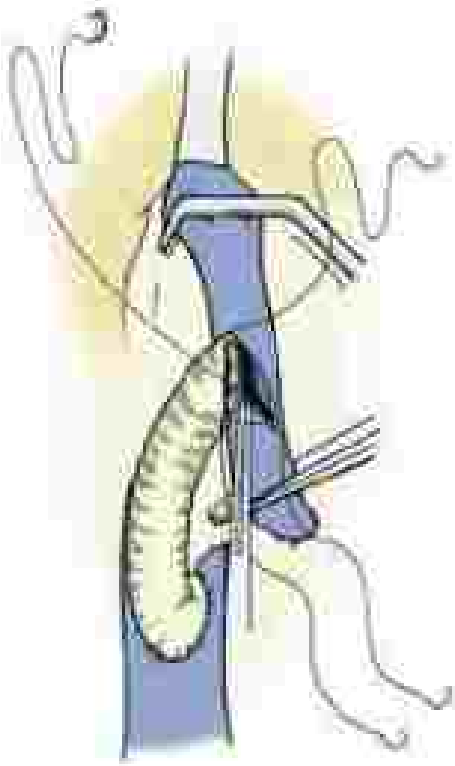

FIG. 1 After occlusion with vascular clamps, the superior mesenteric vein and splenic vein are transected at the confluence of the portal vein. (From Cameron JL, Zinner MJ, Ashley SW, Maingot's abdominal operations, ed 11, New York, 2013, McGraw-Hill Education.)

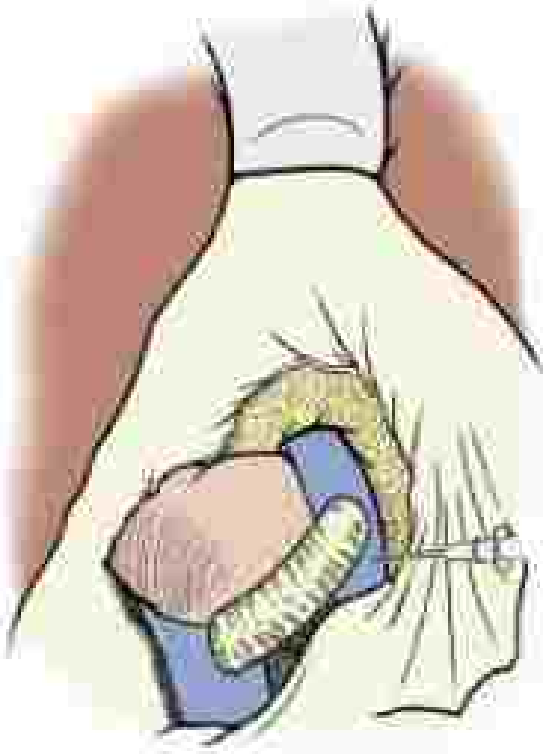

FIG. 2 After completion of the interposition mesocaval shunt, the portal splenic, and mesenteric veins are mobilized. The pancreas is mobilized from the superior mesenteric vein to the spleen by dividing the posterior parietal peritoneum along its inferior margin. (From Cameron JL, Zinner MJ, Ashley SW, Maingot's abdominal operations, ed 11, New York, 2013, McGraw-Hill Education.)

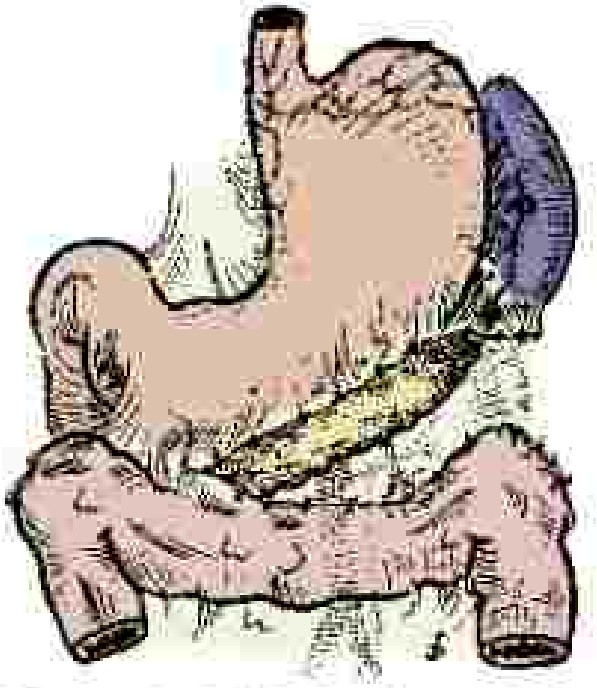

FIG. 3 The pancreas is mobilized from the superior mesenteric vein to the splenic by dividing the posterior parietal peritoneum along its inferior margin. (From Jarnagin W, editor: Blumgart's Surgery of the Liver, Biliary Tract, and Pancreas, 6th ed. Philadelphia: Elsevier, 2017.)

hepatic encephalopathy, at least in short term results. Some evidence suggests these shunts become nonselective over time, although published series on the long-term outcomes for these procedures remains elusive. One disadvantage of this shunt is that it can only be performed in well compensated cirrhotics on an elective basis. For this population, however, it remains an excellent proximalpant shunt that avoids dissection in the porta hepatis that may complicate later transplantation.

The DSRS can be performed with a generous midline incision or bilateral upper subcostal incisions. The lesser sac is opened. While preserving the short gastric vessels, the gastroepiploic vessels as well as the coronary vein should be disconnected from the portal system. Adequate exposure requires mobilization of the colon, including splenic flexure, as well as elevation of the pancreas off the retroperitoneum. The inferior mesenteric vein is divided and the pancreas carefully dissected away from the splenic vein, any small tributaries can be divided with fine ligature (Fig. 3). Next the renal vein is mobilized by dividing the adrenal branch while preserving the other major tributaries. The splenic vein is clamped and divided from the portal system, which may facilitate further mobilization, if necessary (Fig. 4). Finally an end-to-side anastomosis is fashioned between the renal vein and splenic vein after applying clamps and using the splenic vein (Fig. 5).

Other Surgical Shunts

A few shunting procedures for portal hypertension are worth mention, although they are outside the scope of this chapter. Of historical interest are the side-to-side splenorenal shunt and the proximal end-to-side splenorenal shunt with splenectomy. Additionally, pediatric specific shunts deserve special mention. The Clatworthy shunt was described in the 1950s and was historically the most common shunt used in pediatric populations. A nonselective mesocaval shunt, a completed hydrous of the distal IVC and anastomosis of the proximal end to the side of the SMV. It has been replaced by the H-type mesocaval shunt, in which an autologous internal jugular vein graft is used

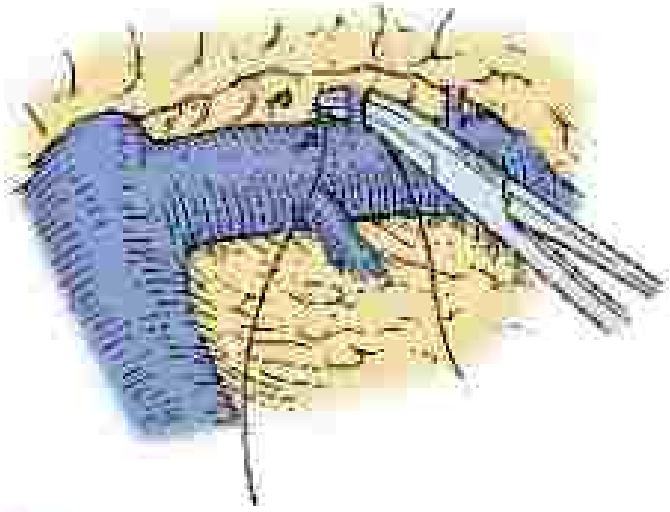

FIG. 4 Isolation of splenic vein from the pancreas near the splenic vein requires blunt dissection at right angles to the splenic vein. There are vein have this walls and require gentle dissection. (From Jarnagin W, editor: Blumgart's Surgery of the Liver, Biliary Tract, and Pancreas, 6th ed. Philadelphia: Elsevier, 2017.)

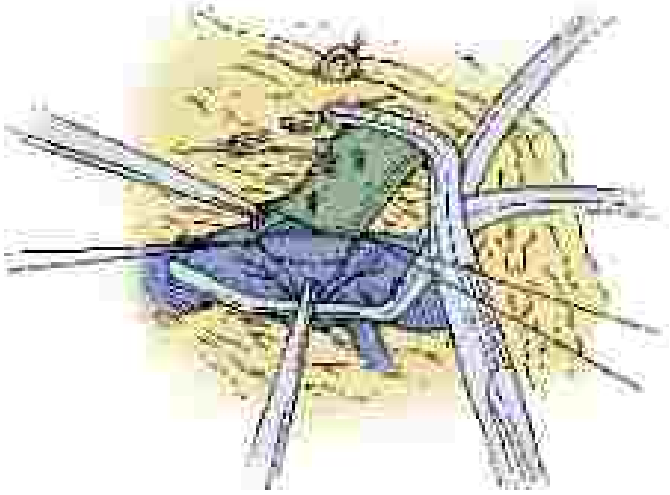

FIG. 5 This posterior anastomosis is made with a running suture. The clamps must be held for a tension-free anastomosis. (From Jarnagin W, editor: Blumgart's Surgery of the Liver, Biliary Tract, and Pancreas, 6th ed. Philadelphia: Elsevier, 2017.)

to connect the SMV and IVC. The mesenteric-left portal venous bypass, or Rex shunt, evolved as a salvage procedure for living donor pediatric transplantation. It is used to treat children with extrahepatic portal vein thrombosis with portal hypertensive complications by restoring blood flow to the liver. An autologous jugular vein graft, or transposition of the dilated coronary vein, is used to shunt the SMV to the intrahepatic left portal vein.

CONCLUSIONS

Our recommendations for a management approach to variceal bleeding in portal hypertension are summarized in Fig. 6. The initial approach comprises medical management and endoscopic therapy. Temporizing measures, such as Sengstaken-Blakemore or Minnesota tubes, play a role as needed to bridge to more definitive therapy. In recurrent bleeding, the management approach diverges based on underlying liver function. Cirrhotic patients should undergo a

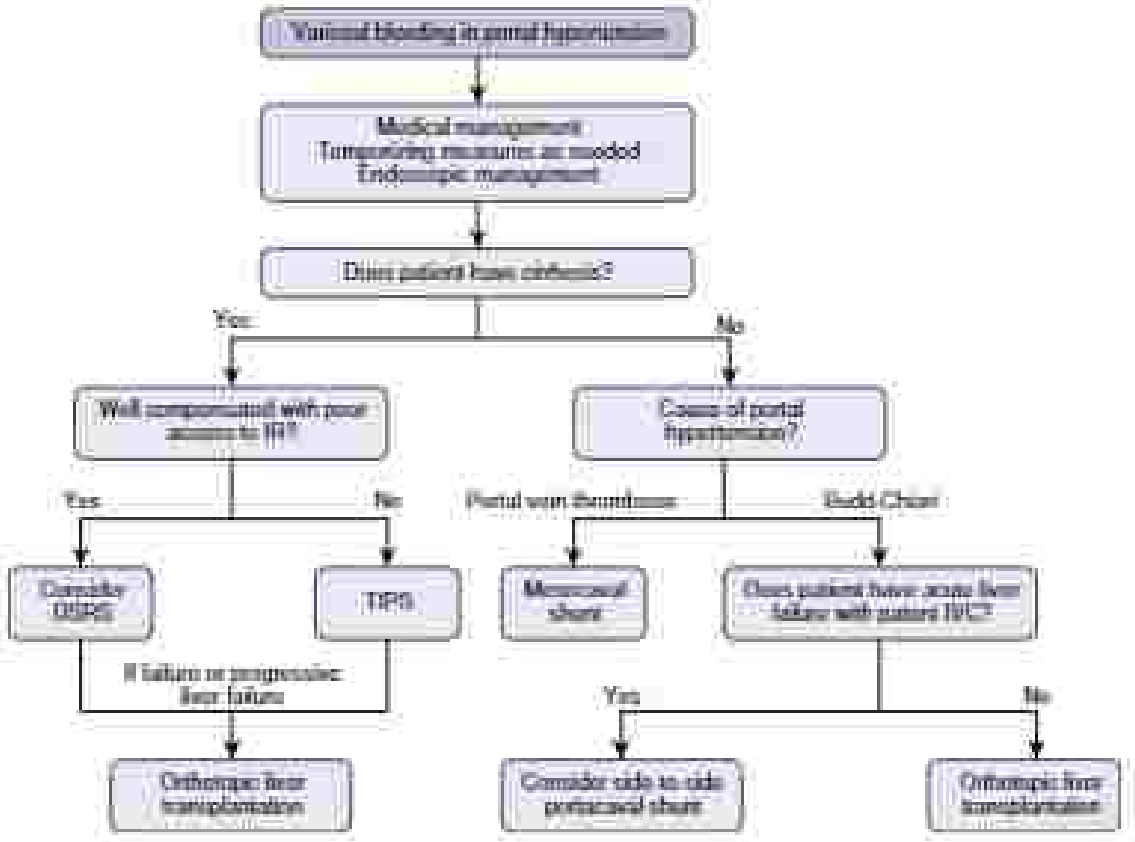

FIG. 8 *Management approach to variceal bleeding in portal hypertension. DSRS, Distal splenorenal shunt; IR, interventional radiology; IVC, inferior vena cava; TIPS, transjugular intrahepatic portosystemic shunt.*

shunting procedure as a bridge to orthotopic liver transplantation, either TIPS or, in those who are well compensated with poor access to care, a DSRS. In patients who do not have cirrhosis, the cause of portal hypertension dictates management. A mesocaval shunt is the appropriate therapy for those with portal vein thrombosis but with a patent mesenteric vein. Patients with Budd-Chiari syndrome should be managed with orthotopic liver transplantation, unless they have acute liver failure with a patent IVC, in which case a side-to-side portacaval shunt may be considered.

Role of Liver Transplantation in Portal Hypertension

Joseph DiNorcia, MD, and Ronald W. Busuttil, MD, PhD

Liver transplantation is a marvel of modern medicine, with the first successful transplant of the human liver performed by Thomas Starzl in 1967. Advances in surgical techniques, anesthesia and critical care, and immunosuppression have helped liver transplantation become the gold standard treatment for both adult and pediatric patients with decompensated cirrhosis and complications of portal hypertension.

INDICATIONS FOR LIVER TRANSPLANTATION

Although cirrhosis alone is not an indication for liver transplant, the presence of complications of portal hypertension suggests that the patient has decompensated cirrhosis, and liver transplantation can be lifesaving. Leading causes of cirrhosis in adults in the United States include nonalcoholic fatty liver disease, hepatitis C virus, and alcoholic liver disease, whereas chronic cholestasis from liver diseases such as biliary atresia is the most common cause of cirrhosis in children. Cirrhosis is late-stage fibrosis that results from repetitive injury and repair of the liver. This scarring impairs hepatocyte function, increases resistance to portal venous blood flow through the hepatic sinusoids, and ultimately leads to portal hypertension. Portal hypertension is defined by elevated pressure in the venous system draining the abdominal viscera. Although cirrhosis is the most common hepatic cause, obstruction of blood flow prehepatic (e.g., portal vein

Role of Liver Transplantation in Portal Hypertension

Joseph DiNorcia, MD, and Ronald W. Busuttil, MD, PhD

Liver transplantation is a marvel of modern medicine, with the first successful transplant of the human liver performed by Thomas Starzl in 1967. Advances in surgical techniques, anesthesia and critical care, and immunosuppression have helped liver transplantation become the gold standard treatment for both adult and pediatric patients with decompensated cirrhosis and complications of portal hypertension.

INDICATIONS FOR LIVER TRANSPLANTATION

Although cirrhosis alone is not an indication for liver transplant, the presence of complications of portal hypertension suggests that the patient has decompensated cirrhosis, and liver transplantation can be lifesaving. Leading causes of cirrhosis in adults in the United States include nonalcoholic fatty liver disease, hepatitis C virus, and alcoholic liver disease, whereas chronic cholestasis from liver diseases such as biliary atresia is the most common cause of cirrhosis in children. Cirrhosis is late-stage fibrosis that results from repetitive injury and repair of the liver. This scarring impairs hepatocyte function, increases resistance to portal venous blood flow through the hepatic sinusoids, and ultimately leads to portal hypertension. Portal hypertension is defined by elevated pressure in the venous system draining the abdominal viscera. Although cirrhosis is the most common hepatic cause, obstruction of blood flow prehepatic (e.g., portal vein

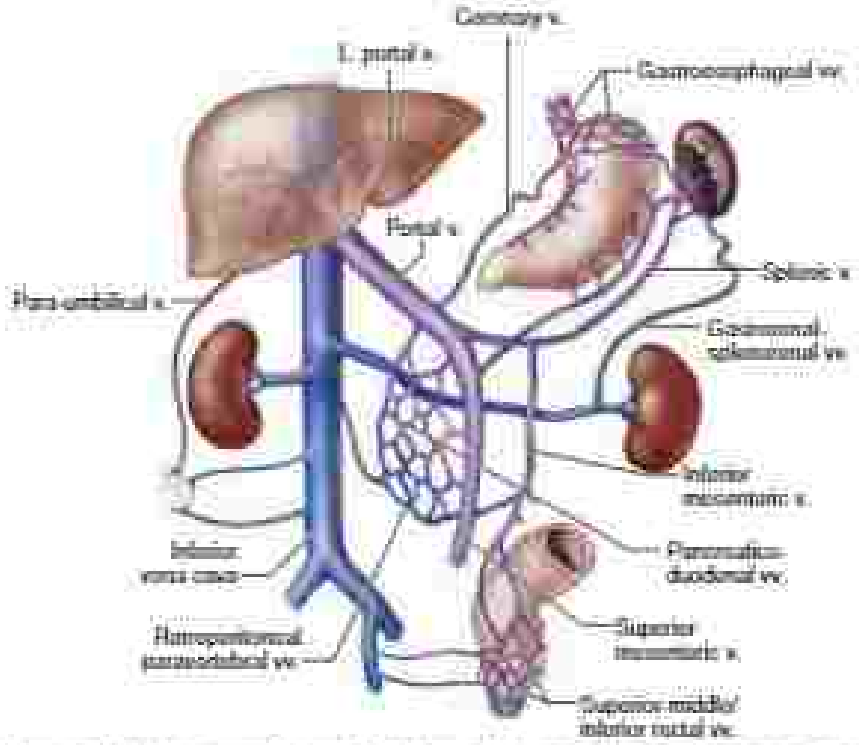

FIG. 1 Portal venous system. Anatomy of the portal venous system and the common portosystemic collateral pathways that develop in portal hypertension. (From Abbas [sic], Wilson CJ. Diagnostic Ultrasound Lab, Philadelphia, [source 20?]. p. 4 [6].)

thrombosis) and pathogens (e.g., Budd-Chiari syndrome) also can cause portal hypertension.

Normal portal venous pressure are 1 to 5 mm Hg greater than systemic venous pressure; in portal hypertension, portal pressures are 6 mm Hg or more above systemic venous pressure. This increased pressure in the portal system causes formation of portosystemic collateral venous pathways that manifest as prominent superficial abdominal wall veins, esophageal, gastric, retroperitoneal, and rectal varices; and portal hypertensive gastropathy, enteropathy, and colopathy (Fig. 1). Rupture of these varices can cause massive hemorrhage. The increased pressure also causes ascites, which can cross the diaphragm to form hepatic hydrothorax, and splenomegaly, which sequesters platelets to cause thrombocytopenia. The metabolic and hemodynamic effects of portal hypertension also can affect other organ systems, resulting in hepatic encephalopathy, cirrhotic cardiomyopathy, hepatopulmonary syndrome, portopulmonary hypertension, and hepatorenal syndrome.

The diagnosis of decompensated cirrhosis usually can be made by a thorough history and physical examination. Common manifestations of decompensated cirrhosis are outlined in ▬▬ 1. A history of confusion, memory loss, or personality change can indicate hepatic encephalopathy. Fetor hepaticus can be smelled on the breath, and asterixis can be elicited in the outstretched hands of patients with hyperammonemia. Temporal wasting and generalized sarcopenia suggest the protein wasting, catabolic state of advanced liver disease. Jaundice can be seen as scleral icterus and darkened skin. Spider angiomata or nevi, spider angiomata, and palmar erythema indicate dysfunction in the hepatic metabolism of estrogen and vasodilation. Decreased breath sounds at the lung bases may indicate hepatic hydrothorax, whereas low oxygen saturation or shunting of the fingers suggests significant hypoxemia from the intrapulmonary shunting of blood associated with hepatopulmonary syndrome. A history of hematemesis, hematochezia, or known bleeding esophageal varices suggests significant portal hypertension. Prominent superficial veins in the abdominal wall can form caput medusae around the umbilicus, and auscultation of a Cruveilhier-Baumgarten bruit over the umbilicus indicates recanalized umbilical or paraumbilical veins. Easy bruising or bleeding suggests coagulopathy or thrombocytopenia, and splenomegaly often can be palpated below the left costal margin. A history of diuretic use and paracentesis to control ascites or a history of spontaneous bacterial peritonitis are other common signs of decompensated cirrhosis. Uncontrolled, long-standing ascites can create umbilical or inguinal hernias that can incarcerate, leak, or bleed. Finally, hypoalbuminemia and fluid overload, due to chronic arterial, of end-stage liver disease can lead to marked peripheral edema. By the time patients present with any of these signs and symptoms, their liver disease is quite advanced, and these patients should undergo expeditious evaluation for liver transplant.

ALLOCATION OF LIVE ' ALLOGRAFTS

Liver transplantation is hampered by a limited supply of cadaveric liver allografts that cannot meet the demand. Approximately 14,000 patients are listed for liver transplantation annually, but only about 6000 to 7000 patients receive liver transplants per year in the United States. Currently, liver allografts are allocated based on a "sickest first" policy where the *Model for End-stage Liver Disease* (MELD) scoring system in adults (≥ 12 years old) and the *Pediatric End-stage Liver Disease* (PELD) scoring system in children (< 12 years old) provide objective assessments of 3-month mortality for patients with end-stage liver disease who do not receive liver transplant.

Originally developed to predict survival in patients undergoing elective placement of transjugular intrahepatic portosystemic shunts for complications of portal hypertension, the MELD score uses serum creatinine, total bilirubin, and international normalized ratio (INR) to provide a score ranging from ▬ to a maximum of 40. In 2016, serum sodium also was incorporated into the MELD score because decreasing sodium levels have been correlated with increasing mortality while on the liver transplant waitlist. The PELD score uses serum albumin, total bilirubin, and INR as well as growth failure (based on gender, height, and weight) and age at listing. Children with MELD/PELD scores higher than 25 and life-threatening complications of portal hypertension, such as severe encephalopathy or gastrointestinal bleeding requiring mechanical ventilation, red blood

cell transfusion of at least 30 mL/kg in 24 hours, or dialysis may be granted additional priority known as status 1B to expedite the allocation of an appropriate, size-matched liver allograft.

Patients are waitlisted according to blood type and ranked by MELD/PELD score and time on the list. The United States is formally divided into 11 regions made up of 58 local donor service areas, each of which is presided over by an organ procurement organization (Fig. 2). In general, liver allografts are allocated locally, regionally, and then nationally based on medical need (as determined by the MELD/PELD score) and distance from the donor hospital (to minimize cold ischemia time of the liver). For patients with MELD/PELD scores of ≥35 or higher, liver allografts are allocated regionally first, a policy known as "Share 35" to increase access to liver transplant and further decrease waitlist mortality for medically urgent patients. The current liver allocation system thus focuses on candidates with the greatest risk of pretransplant mortality (i.e., urgency) without consideration for maximizing patient survival after transplant (i.e., utility). In addition, disputes attempts to distribute the scarce resource of a liver allograft equitably, regional and national disparities in access to liver transplant persist. We can expect refinement and change to the current liver allocation system in the near future.

LIVER TRANSPLANTATION TECHNIQUES

Hepatectomy

The first phase of liver transplantation involves removing the diseased liver. The total hepatectomy can be broken down into four steps: incision and entry into the abdomen, mobilization of the ligaments of the liver, dissection of the porta hepatis, and dissection of the vena cava. We will discuss each step. Adequate exposure is essential, particularly in the setting of portal hypertension. Commonly used abdominal incisions include a bilateral subcostal incision with midline extension (the "Mercedes") and the inverted T incision. These large incisions provide excellent exposure but suffer from a weak point where the three lines of incision meet. Depending on the shape of the cirrhotic liver, degree of splenomegaly, and abdominal wall laxity, smaller incisions such as the "hockey stick," reverse L, or J shaped (the "Makuuchi") incisions also can provide good exposure (Fig. 3).

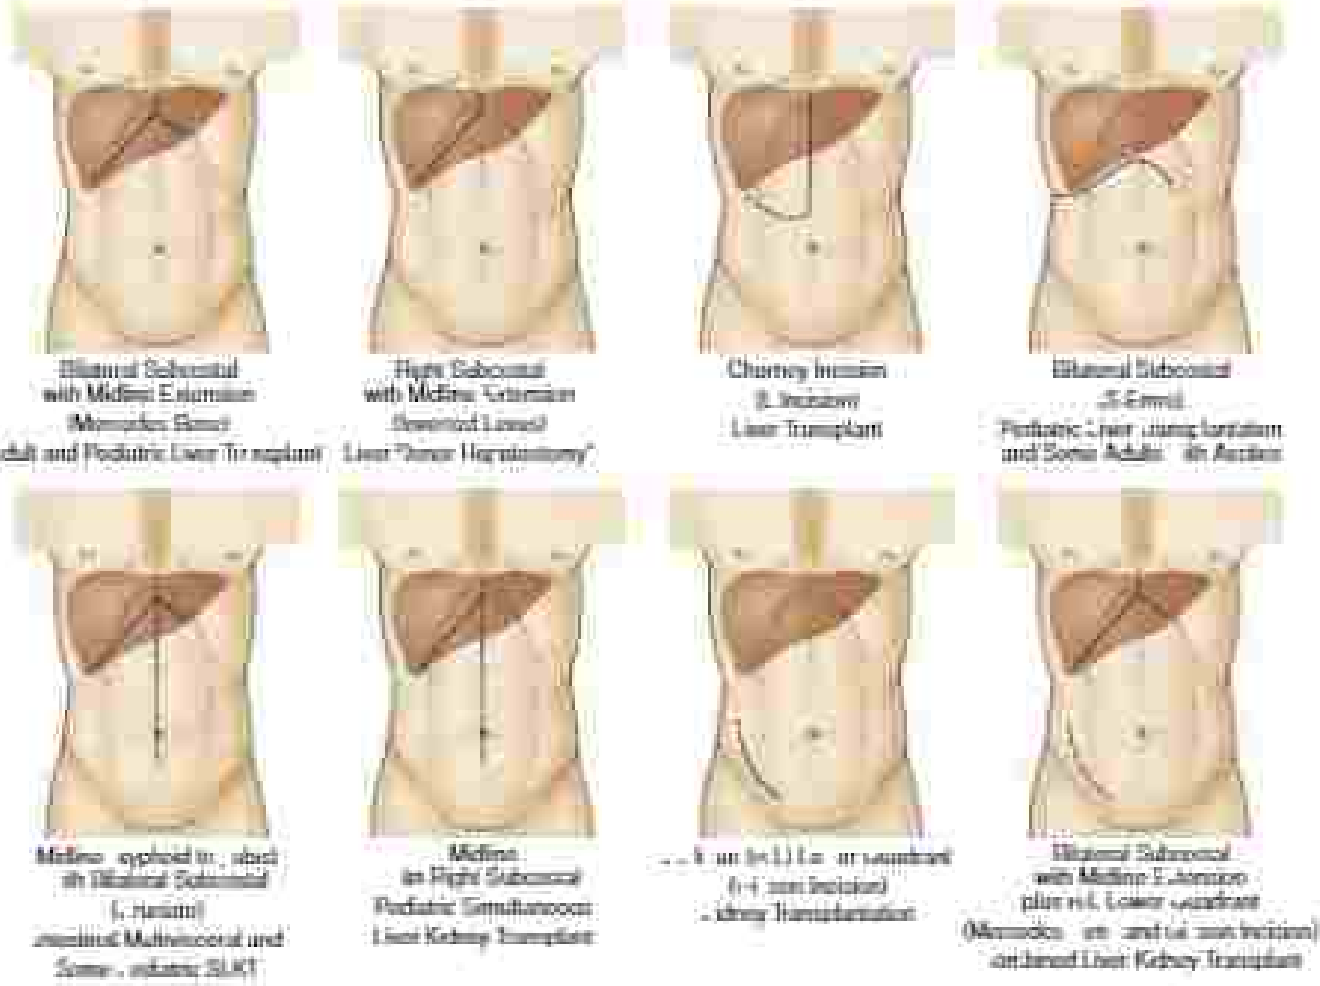
Sharp dissection through the subcutaneous tissue helps to identify, ligate, and divide prominent superficial veins to avoid bleeding early in the operation. Study of preoperative imaging can elucidate the point of entry into the abdomen to avoid recanalized paraumbilical veins or other large venous collaterals. Before entry, it is important to ensure there is adequate suction to evacuate ascites. Turbid or frankly purulent ascites should be cultured, offering the surgeon a moment to assess for active peritonitis, which should contraindicate liver transplant at that time. Patients with active peritonitis should be aborted and treated with appropriate intravenous antibiotics. They can be reexplored after 5 to 7 days of treatment when another liver allograft becomes available.

In portal hypertension, the ligamentum teres hepatis (i.e., round ligament of the liver) often carries recanalized paraumbilical veins that can become quite large as they shunt blood from the portal to systemic venous system. The ligamentum teres thus should be controlled securely with tie or stapler. The falciform ligament is divided to the hepatic vein followed by the left and right coronary and triangular ligaments to free the liver from the diaphragm and retroperitoneum. The gastrohepatic ligament may contain a replaced or accessory left hepatic artery and should be securely ligated and divided to expose the caudate lobe and left side of the vena cava.

The goal of dissection of the porta hepatis is to ligate and divide the bile duct, hepatic artery, and portal vein with minimal trauma and sufficient length for future anastomoses. These three structures are encased in nerves, lymphatics, and connective tissue, which must be dissected free. Particularly in cases of portal vein thrombosis, there can be large varices in the porta hepatis that require careful dissection to avoid significant bleeding. Although inflammation may distort the tissue planes, these planes provide safe passage around the vital structures and should be sought to allow efficient dissection.

After division of the cystic duct, the common hepatic duct is divided close to the biliary to maximize length. The bile duct is then sent down to the duodenum, taking care to preserve its blood supply. The hepatic artery is dissected with ligation and division of the right and left branches. The proper hepatic artery is carefully liberated, ligated and divided,[1] on the right gastric artery followed by the gastroduodenal artery, which is ligated with some length for the potential creation of a branch patch for later arterialization of the graft. The common hepatic artery is dissected free for a short distance along the superior border of the pancreas to provide space for clamping. A gentle vascular clamp can be placed on the common hepatic artery early in the dissection of the porta hepatis to prevent retrograde dissection of the artery. There can be large lymph nodes along the artery, which need to be handled with care to avoid bleeding. Finally, the portal vein is dissected free from the surrounding connective tissue from its bifurcation to the pancreas, which often requires division of the right gastric vein and superior pancreaticoduodenal vein. The portal vein is left intact until the dissection of the vena cava is complete.

In cases of portal vein thrombosis, it is necessary to remove the thrombus and ensure adequate portal flow before implantation of the liver. The thrombectomy requires control of the portal vein as close



* Some groups, including ours, have performed and published the use of a short (~ 10 cm) subcostal midline incision only or other MIS approaches for the donor hepatectomies.

as possible to the confluence of the superior mesenteric vein (SMV) and splenic vein (SV), depending on the degree and extent of clot. In cases of acute or nonocclusive thrombus, the clot usually can be lifted from the vein wall with minimal disruption to the intima of the vein. In cases of chronic, occlusive thrombus, the clot may be adherent and calcified and usually requires circumferential dissection to separate the clot and intima from the media of the vein to perform an adequate thrombectomy/endarterectomy. These maneuvers must be performed with the utmost care not to damage the portal vein. If the main portal vein is unusable because of complete thrombosis and cavernous transformation, it may be possible to excise the clotted portion of vein and sew an interposition graft of donor iliac vein to the SMV-SV confluence. If an interposition graft is not possible, the SMV should be dissected below the transverse mesocolon in preparation for a donor iliac vein bypass graft. In certain cases, large varices around the porta hepatis may provide adequate portal inflow to the liver allograft. Last resort options in cases of unusable portal vein, SMV, or collateral vein to usable portal inflow from the renal vein (if there is a large splenorenal shunt) or from the vena cava, known as cavoportal hemitransposition, but outcomes with such techniques are inferior (Fig. 6).

The dissection of the vena cava differs depending on the method of liver implantation. With the standard bicaval technique, the native liver is removed en bloc with the retrohepatic inferior vena cava (IVC) (Fig. 5). The retrohepatic IVC is completely mobilized as the suprahepatic and infrahepatic IVC are dissected free from the diaphragm and retroperitoneum to provide space for clamping. The right adrenal vein is ligated to allow adequate mobility of the infrahepatic IVC. With the dissection complete, the surgeon should alert anesthesia before clamping of the portal vein, suprahepatic IVC, and infrahepatic IVC. This complete clamping can cause hemodynamic instability as venous return decreases and the renal and splanchnic beds congest. In patients with severe portal hypertension who do not tolerate clamping, portocaval venovenous bypass may be necessary, which involves cannulation of the axillary, femoral, and portal veins to preserve venous return and decongest the splanchnic bed (Fig. 4). With the *piggy-back* technique, the native liver is dissected off of the IVC to remove the liver, thus preserving the IVC (Fig. 7). The hepatic veins are skeletonized anteriorly, and the short hepatic veins draining directly into the IVC are ligated and divided as the caudate lobe is mobilized off of the IVC up to the hepatic veins posteriorly. This piggy-back dissection requires division of the ligamentum venae (i.e., hepatic venal ligament) to completely liberate the liver from the IVC. The portal vein is clamped and divided high in the hilum before partially clamping the suprahepatic IVC and dividing the hepatic veins will take the liver to preserve length for future hepatic venous outflow reconstruction.

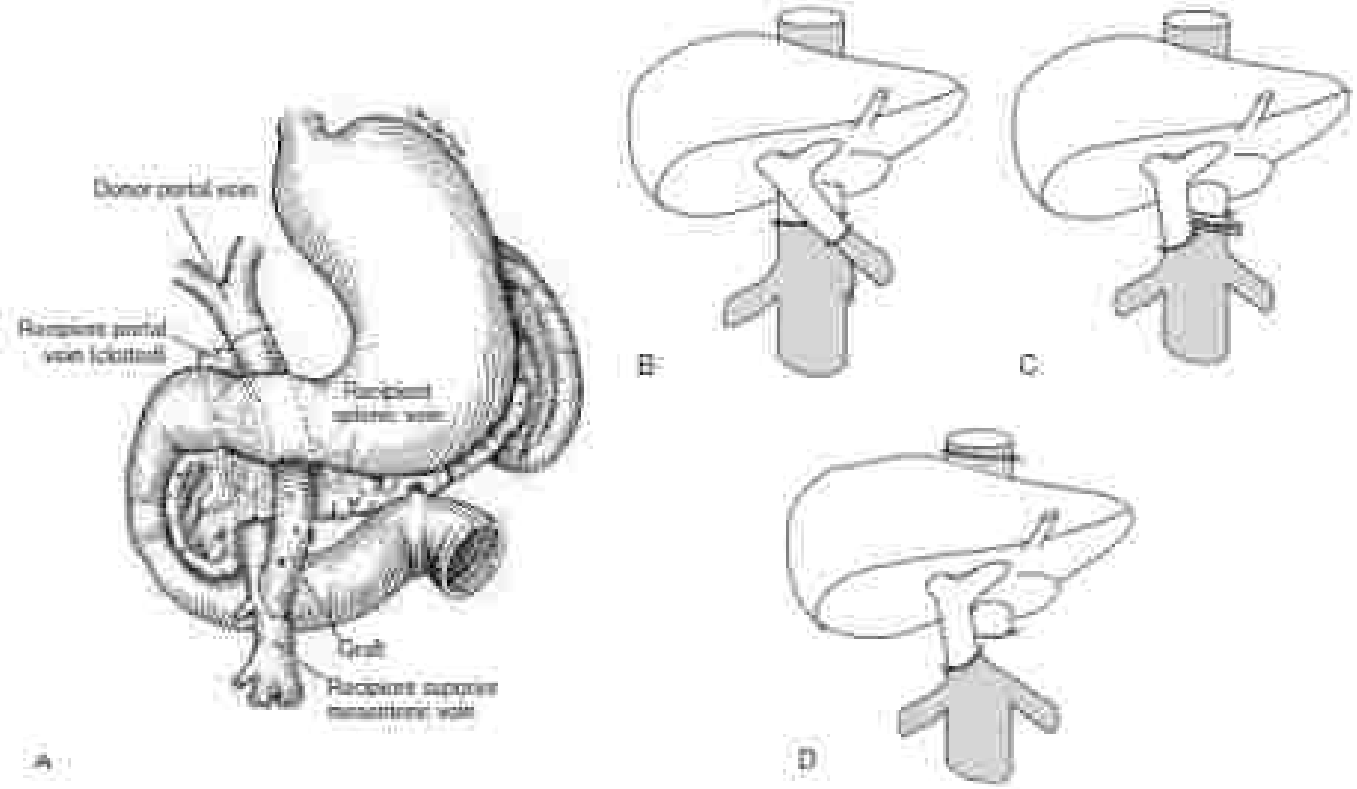


FIG. 9 Options for portal venous inflow in the setting of complex portal vein thrombosis. (A) As the vein graft from the donor can be sewn to the recipient superior mesenteric vein. (B) When a large splenorenal shunt is present, the recipient left renal vein can be sewn to the donor portal vein. As a last resort, the recipient inferior vena cava can be sewn to the donor portal vein. (C) donor iliac as side or (D) end to end, known as conjoint hemitransplantation. (Adapted from Abt, P. L., Crisalli, K. A., Martin, M., Reyes, J., Fontes, P., & Markmann, J. F. (2003). Liver transplantation in the setting of complex portal vein thrombosis. Liver transplantation, 9(6), 652–657. https://doi.org/10.1053/jlts.2003.50104)

Implantation

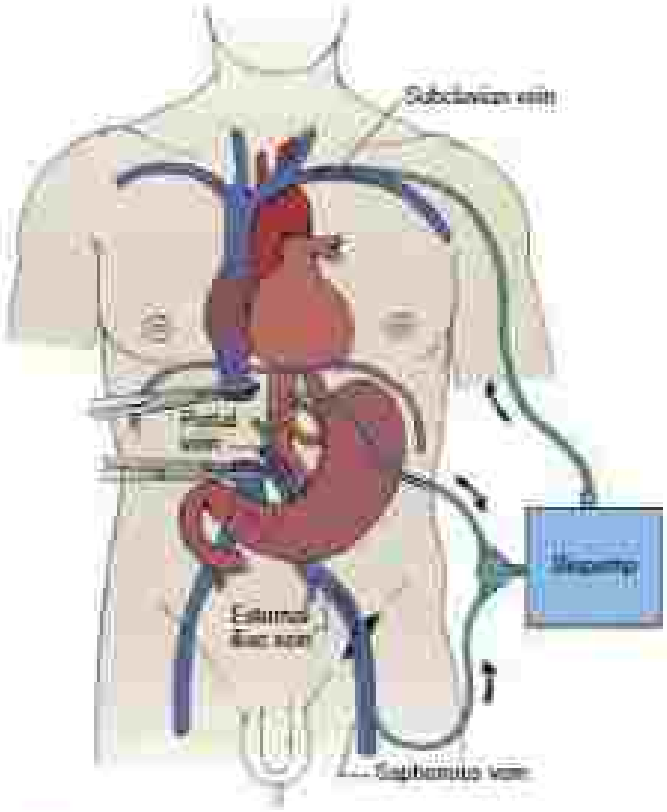

FIG. 6 Veno-venous bypass. Intracaval bypass is established before completion of the hepatectomy. The axillary, right atrium, and portal veins are cannulated. A centrifugal pump returns cystemic and portal venous blood to the heart via the axillary vein while the patient is anhepatic. (From Gilbert JD, Jaeg KM, Hug ... Oxford: ... J Int Pediatr Hepatol Gastroenterol. 2016;)

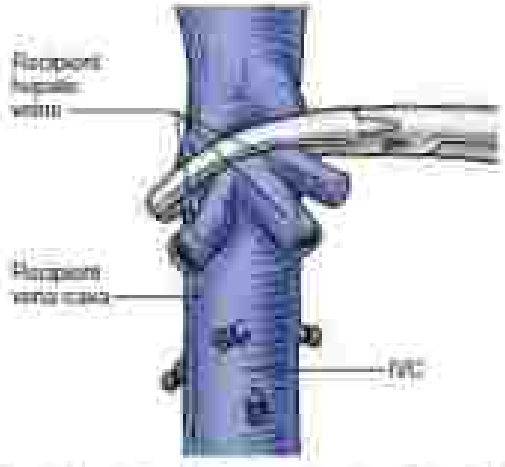

FIG. 7 Piggy-back technique for liver transplantation. During this hepatectomy, the diseased liver is freed from the recipient vena cava by ligating and dividing the short hepatic veins. The right, left, and middle hepatic veins are clamped and divided, and the liver is removed, thus preserving the vena cava. IVC, Inferior vena cava.

factor that allows for expansion of the portal vein after reperfusion to avoid stenosis. In cases of portal vein thrombosis described previously, anastomosis may involve donor portal vein to interposition graft between the ...eV – V confluence, the S...IV below the transverse mesocolon, large ... collaterals around the porta hepatis, left renal vein, or vena cava (Fig. 6). These techniques for portal inflow should be thoroughly analyzed and anticipated before reaching the operating room during study of preoperative imaging and undertaken with the utmost care. Occasionally in patients with significant portal hypertension, large portosystemic collaterals may continue to shunt blood away from the transplanted liver after reperfusion. It is important to find and ligate these collaterals to improve portal flow.

The liver allograft is reperfused once the portal vein reconstruction is complete. After a quick round of hemostasis to check for bleeding from the caval and portal anastomoses, the hepatic artery is reconstructed. The health of the biliary system is dependent on arterial tissue, and a perfect hepatic artery anastomosis is essential for excellent posttransplant outcomes. Common technical reasons for hepatic artery thrombosis include poor intimal apposition, dissection of the intima, misalignment of the artery lumens, entrapment of adventitia in the anastomosis, and narrowing of the lumen. The hepatic artery anastomosis thus should be sewn with meticulous handling of the artery and utmost precision to avoid these common pitfalls.

The donor hepatic artery usually includes the entire celiac axis with a patch of aorta. Aberrant donor arterial anatomy, such as a replaced right hepatic artery arising from the superior mesenteric artery, will require reconstruction during the back table preparation of the liver allograft. To prevent intraplasm thrombosis and retrograde bleeding that will interfere with the reconstruction, heparinized saline is instilled into the donor hepatic artery and the artery is gently clamped in the hilum. The hepatic artery is usually reconstructed in an end-to-end manner at a level where the diameters of donor and recipient arteries are well matched. Using fine polypropylene sutures, the donor celiac axis is commonly sewn to a branch patch of the recipient proper hepatic and gastroduodenal arteries, where they take off from the common hepatic artery. Branch patches can be fashioned at any major branch point along either the donor or recipient artery as length and quality of the artery allow (Fig. 5). A benefit of using branch patches in case of suturing a wider anastomosis without compromising the arterial lumen. If the donor hepatic artery is diseased or injured, it can be cleanly divided at a distal point of healthy arterial wall. If the recipient hepatic artery is not usable, more proximal dissection of the branches of the celiac axis can reveal a suitable segment of artery. Meticulous handling and preservation of length for both donor and recipient hepatic arteries during the organ procurement, back table preparation, and hepatectomy that are essential for an uncomplicated hepatic artery reconstruction.

Intimal dissection, atherosclerosis, or proximal stenosis are the most common reasons for poor hepatic artery inflow, which would require creation of a conduit directly from the recipient aorta to the donor artery using a donor iliac artery graft. The iliac artery conduit usually is sewn to the recipient infrarenal aorta because it is easier to access and safer to clamp. The conduit is then tunneled through the transverse colon mesentery behind the stomach to the porta hepatis. Alternatively, in cases of severe atherosclerosis of the infrarenal aorta or inaccessible retroperitoneal compartment, the iliac artery conduit can be sewn to the recipient supraceliac aorta. Exposure of and suturing to the supraceliac aorta can be challenging; clamping here temporarily occludes blood flow to the intestines and kidneys, which can be perilous. Rarely is it necessary to sew the donor iliac artery conduit to the recipient iliac artery for arterialization of the liver allograft.

The bile duct reconstruction is the final step in implantation of the liver. After the donor gallbladder is removed, the bile duct is reconstructed either by duct-to-duct anastomosis or ... hepaticojejunostomy or choledochojejunostomy using fine, absorbable sutures. The benefits of a duct-to-duct anastomosis (i.e., choledochocholedochostomy) include preservation of native anatomy and physiology and ease of access to the biliary system via endoscopy posttransplant. As with the portal vein, it is important to cut to appropriate length and align the donor and recipient bile ducts to avoid a redundant duct that might kink. Excision of the donor cystic duct and transection of the common hepatic duct ensures good blood supply to the end of the donor duct. Before cutting the donor duct, it is important to assess for aberrant duct anatomy, such as a right posterior sectoral duct draining directly into the common bile duct, to avoid cutting

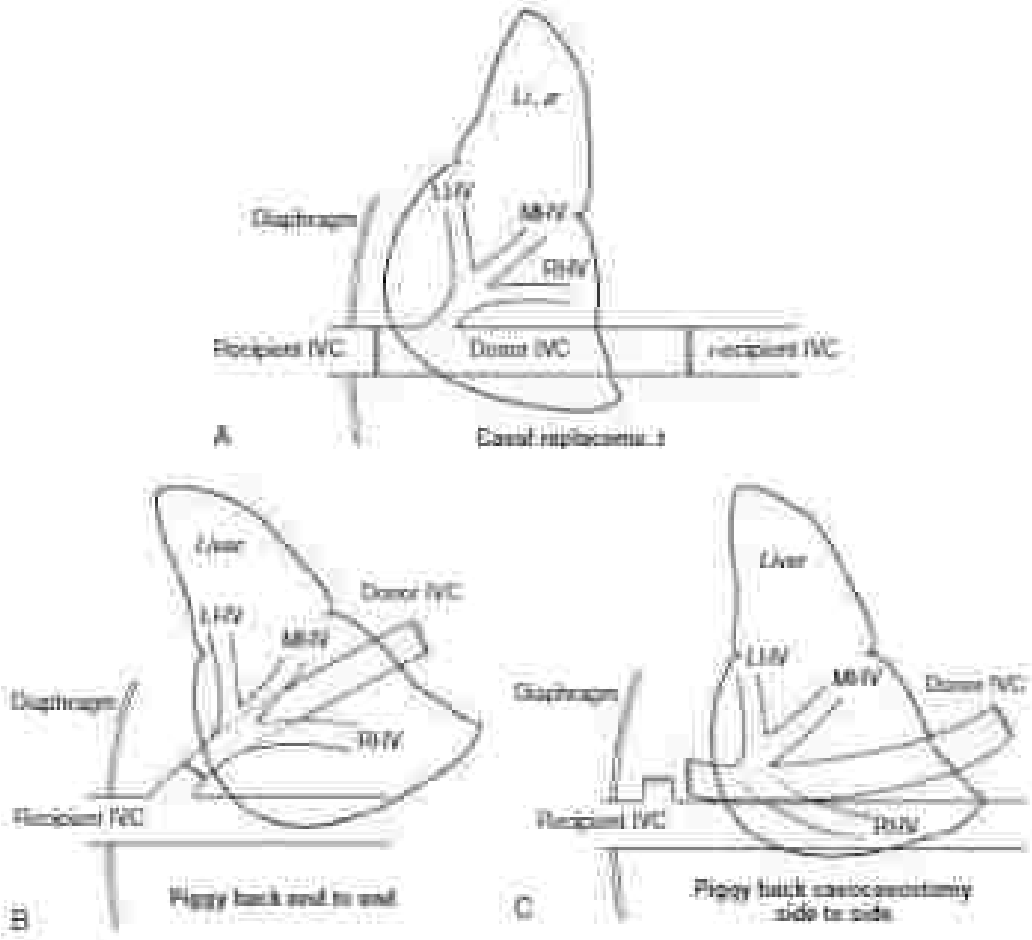

FIG. 8 Hepatic venous outflow reconstruction options. (**A**) The classic (orthotopic) technique of the donor and recipient supra- and infrahepatic vena cava (IVC) cuffs to reconstruct the hepatic venous outflow. (**B**) In the classic piggy-back (orthotopic) technique, the hepatic venous outflow is reconstructed by anastomosing the donor suprahepatic vena cava to a common orifice of the recipient hepatic veins. The donor infrahepatic vena cava is closed with a tie, suture, or stapler (—). In the modified piggy-back (orthotopic) technique, the hepatic venous outflow is reconstructed by anastomosing a cavotomy on the donor infrahepatic vena cava to a cavotomy on the posterior wall of the recipient vena cava. Both the suprahepatic and infrahepatic vena cava cuffs of the donor are closed. *IVC*, Inferior vena cava; *LHV*, left hepatic vein; *MHV*, middle hepatic vein; *RHV*, right hepatic vein.

above this insertion and creating two lumens that would need separate anastomoses. It also is important to probe the recipient bile duct to ensure that there is no distal obstruction or obvious problem at the ampulla of Vater. After trimming each duct to lumens with healthy, well-vascularized biliary epithelium, peri-duct vessels are controlled with fine polypropylene sutures before the reconstruction. In cases of mismatch of the diameters of the donor and recipient bile ducts, there are several options, including sewing down the larger duct (i.e., ductoplasty), creating a branch patch at the cystic duct insertion, or creating an anterior slit to widen the smaller duct on either the donor or recipient side (Fig. 10). When there is a significant size discrepancy, a side to side anastomosis can be performed between the donor and recipient ducts, though more commonly a Roux en Y hepaticojejunostomy anastomosis is performed. If the recipient bile duct is unusable for whatever reason (e.g., poor quality in patients with primary sclerosing cholangitis), Roux en Y hepaticojejunostomy anastomosis is performed.

Complications

The most common complications after liver transplantation are bleeding and infection. Complications specific to the liver transplant itself include problems with the liver allograft or with any of the anastomoses. These complications most often can be detected by clinical examination, serial monitoring of the hepatic function panel and INR, and liberal use of Doppler ultrasonography (DUS). If a problem is suspected, liver biopsy and cross-sectional imaging can confirm the diagnosis, whereas direct percutaneous venography/angiography can offer a chance for therapeutic intervention. Liver allografts can suffer from delayed graft function or primary nonfunction, the latter of which requires urgent retransplantation. Acute cellular rejection and antibody-mediated rejection also lead to graft dysfunction but can be managed with adjustments of immunosuppression.

Rarely, the hepatic venous outflow reconstruction can have thrombosis or stenosis, which may require hepatic venogram with angioplasty and possible stent placement. Portal vein thrombosis (“PVT”) and portal vein stenosis (PVS) are relatively rare outside of pediatric and living donor liver transplantation, in which size discrepancy and proper orientation lead to technical challenges, but can be catastrophic, resulting in early graft dysfunction and loss. Risk factors for PVT include technical issues (e.g., redundant vein), hypercoagulability, prolonged “cold” ischemia requiring intraoperative thromboendarterectomy, small portal vein diameter, and reconstruction with an interposition graft. Any PVT or PVS should be managed by reoperation to attempt graft salvage, if the graft is reversible. Reperfusion of an irreversible graft can cause massive cytokine release, coagulopathy, and hemodynamic instability; in these cases, retransplantation is contraindicated, and the patient should be relisted for liver transplant immediately. Late PVT or PVS may be amenable to percutaneous angioplasty with or without stent.

Hepatic artery thrombosis (“HAT”) is a dreaded complication of liver transplantation. Because the biliary system is dependent on arterial

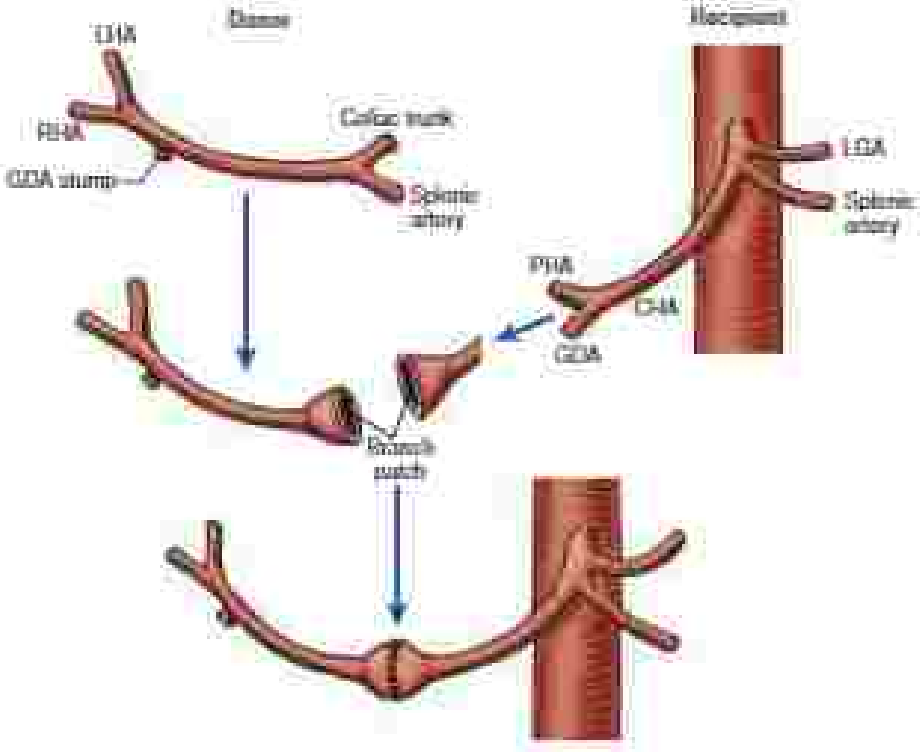

FIG. 9 Branch patch reconstruction of the hepatic artery. Branch patches can be created at points of bifurcation to maintain the diameter of an artery and facilitate suturing of an anastomosis without compromising the arterial lumen. CHA, Common hepatic artery; GDA, gastroduodenal artery; LHA, left hepatic artery; PHA, proper hepatic artery; RHA, right hepatic artery. *[From Gruessner R, Reed A: Surgical factors ... FIG. 10 Biliary reconstruction options. (A) When there is a size discrepancy between the donor and recipient bile ducts, an anterior slit can be made to maintain the diameter of the smaller duct. (B) When both bile ducts are small, slits can be made on both donor and recipient ducts to compensate for tissue that is ultimately lost in the suture line and to prevent stricturing. (C) Alternatively, the larger duct orifice can be partially sewn to create equal lumens for anastomotic leakage as a lateral duct-to-duct. *[From Busuttil RW, Klintmalm ... In Busuttil RW, Klintmalm GBG, eds: Liver and Pancreas Transplantation. Philadelphia, 2004, Saunders.]*

blood flow, arterial compromise leads to bile duct strictures, bile duct necrosis, liver abscesses, and, ultimately, graft dysfunction and loss. HAT thus requires a high index of suspicion and vigilance postoperatively to allow prompt recognition and management to ensure graft and patient survival. If HAT is diagnosed early enough, it is possible to salvage the graft by operative thrombectomy and revision or reconstruction of the hepatic artery. If diagnosed late, the patient most likely will need retransplantation. Hepatic artery stenosis (HAS) has a characteristic "parvus et tardus" (i.e., slow and late) arterial waveform on

IOUS and often presents clinically as unexplained, asymptomatic graft dysfunction. Early HAS may represent edema at the anastomosis and should be followed with serial IOUS until resolution. If HAS persists, surgical revision or percutaneous transluminal angioplasty with or without stent placement are options (Fig. 11). With advances in interventional radiology expertise, percutaneous transluminal angioplasty is first-line therapy for HAS at many institutions.

The two most common complications with the bile duct are bile leak and stricture. Many bile leaks will resolve without intervention as long as they are well drained. Abdominal pain, fever, and signs of peritonitis should prompt imaging to look for intraabdominal fluid collections. Fluid collections should be drained percutaneously and sent for bilirubin and culture. If the collection is indeed a biloma, the leak most often can be managed with intravenous antibiotics and endoscopic sphincterotomy and biliary stent placement. If the bile leak is severe, with suspected major disruption of the anastomosis, reoperation is necessary to revise the biliary reconstruction.

Bile duct strictures can be classified as anastomotic and nonanastomotic. Anastomotic strictures usually result from technical issues, including surgical technique, small caliber ducts, or thermal injury from electrocautery and can be managed with endoscopic balloon dilation and stent placement (Fig. 12). Short-duration internal biliary stenting for serial dilation and stent placement is very successful, and surgical revision is rarely needed. Nonanastomotic strictures can result from ischemia secondary to preservation injury or hepatic artery thrombosis, use of donors after cardiac death livers, rejection, or recurrent disease such as causes of autoimmune cholestatic liver disease. If the stricture involves the extrahepatic bile ducts, it may be possible to operate, excise the fibrotic segment, and convert to a Roux-en-Y hepaticojejunostomy. If the stricture involves the intrahepatic bile ducts, retransplantation usually is necessary.

Living Donor Liver Transplantation

We are able to perform living donor liver transplantation (LDLT) when a healthy person voluntarily donates part of the liver to a patient with indications for liver transplant, either an adult to a child or an adult to an adult. LDLT is founded on the principles of segmental anatomy and regeneration of the liver, which allow the procurement of partial liver allografts that will grow in the recipient while the remnant liver

FIG. 11 Hepatic artery stenosis. (A) Hepatic artery angiogram shows a stenotic lesion (arrow) distal to the anastomosis. (B) Balloon angioplasty corrected the stenosis. (From Goodall MD, Atkinson LAC. Transplantation in Focus. Mosby; Philadelphia; Elsevier; 2011.)

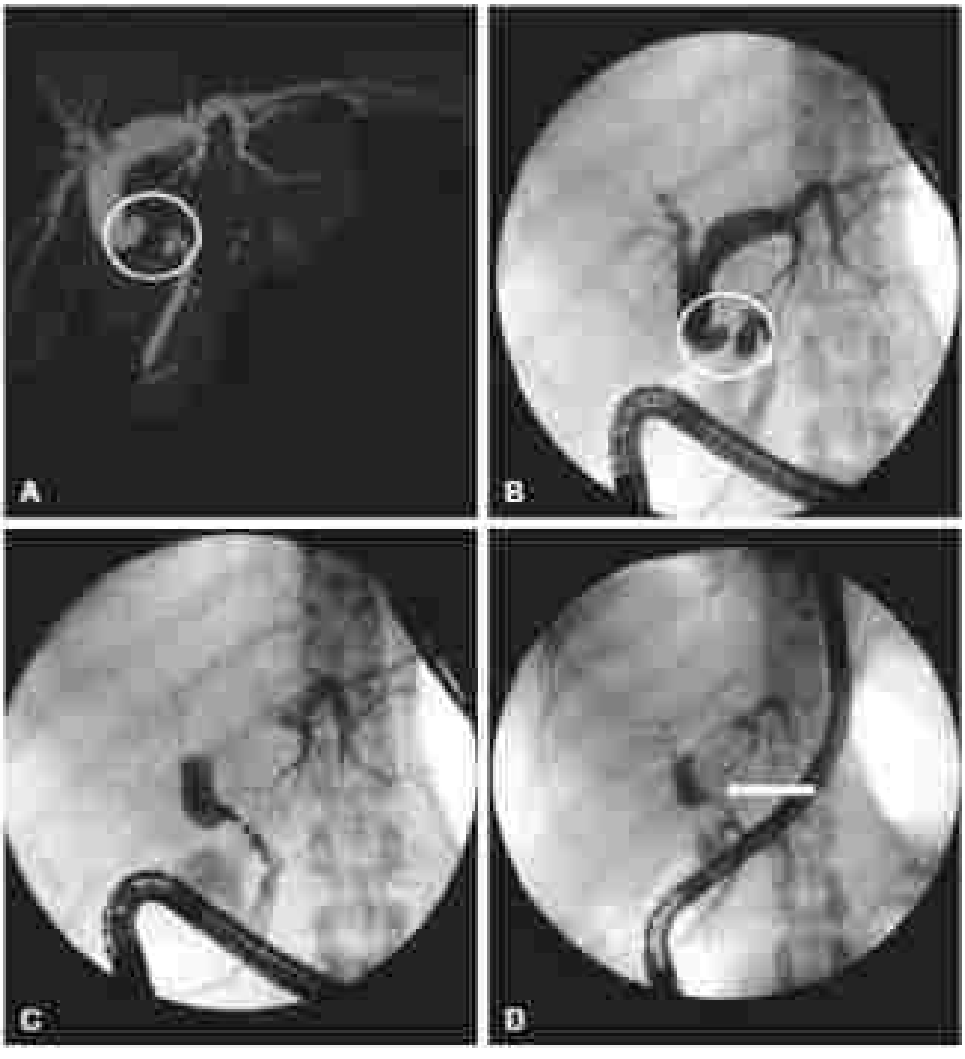

FIG. 12 Biliary stricture. Hepatic transverse cholangiopancreatogram (A) and endoscopic retrograde cholangiopancreatography (B) demonstrate high-grade anastomotic biliary stricture (arrow). Balloon dilation (C) and stent placement (D, arrow) ultimately resolved the stricture without surgical intervention.

registration and initiate life in the donor. LDLT was born from the scarcity of organs for transplant and the need for size appropriate liver allografts in children. Because of cultural, religious, and societal beliefs that restrict transplant of organs from deceased donors, LDLT has flourished in Asia and the Middle East. In contrast, brain death laws and the national promotion and organization of deceased donors have helped support deceased donor liver transplant (DDLT) in Western countries. Worldwide, about 20% of liver transplants performed are from living donors; in the United States, about 4% to 5% of liver transplants are from living donors. South Korea performs the most LDLTs at 34 LDLT per million people versus 9 DDLT per million people in 2[illegible]. Comparatively, the United States performs about 1 LDLT per million people versus 23 DDLT per million people in 201[illegible]. Milestones in the history of LDLT are listed in Table[illegible] 1.

The selection of donors and recipients for LDLT involves comprehensive, multidisciplinary medical, surgical, and psychosocial evaluation. Donor safety is paramount, and the donor evaluation must ensure absolute health, voluntary donation without coercion, and fully informed consent. Characteristics that maximize donor safety are listed in Box 2. Although experienced centers safely and successfully push these limits. In general, for recipients in the United States, all pediatric patients should be considered candidates, whereas adult patients should meet select criteria including MELD score of 25 or less with significant complications of cirrhosis or cholestasis. Liver disease. Adult patients with hepatocellular carcinoma who meet transplant criteria but face prolonged wait times or cannot receive locoregional treatment for control of the tumor also may be candidates for LDLT.

Once a donor and recipient have been thoroughly evaluated, cross-sectional imaging of the donor is necessary to determine liver size and anatomy and plan the partial liver allograft for donation. Standard partial liver allografts include the left lateral section, right hemiliver with or without the middle hepatic vein, and left hemiliver with or without the caudate lobe. For an adult to child LDLT, the graft to recipient weight ratio should be between 1% and [illegible]% to avoid large-for-size syndrome, which is characterized by abdominal compartment syndrome, insufficient graft perfusion, and graft dysfunction. For an adult to adult LDLT, a graft to recipient weight ratio of 0.8% or greater avoids small-for-size syndrome, which is characterized by persistent hyperbilirubinemia, coagulopathy, and ascites in the absence of technical problems in the early posttransplant period.

The donor hepatectomy is designed with donor safety foremost and a complete liver allograft second to none. Principles of the donor operation include avoiding unnecessary dissection of the hepatic hilum with limited use of cautery to isolate the hepatic artery, portal vein, and hilar plate containing the bile duct. Intraoperative cholangiography can be performed to ensure proper division of the bile duct. After dissection of the hilar structures, the hepatic parenchyma is divided with care to ligate biliary radicals and preserve all accessory hepatic veins 0.5 cm or greater in diameter. A 70% hepatectomy at maximum can be performed on the donor. The majority of donors do not regain donation and report preoperation quality of life scores that meet or exceed the general population. Most donors also note improved relationships with recipients. The estimated risk of morbidity for the donor is about 40% with serious morbidity (defined as Clavien-Dindo grade III or higher) occurring in 1%. The estimated risk of mortality for the donor is between 0.3% and 0.5%, with the highest risk in the first "1" days. One third of donors report lingering physical symptoms, one-third report financial burdens such as lost wages or unreimbursed expenses, and one-quarter report exacerbation of depression or anxiety. These challenges require further advocacy and research on the national level to optimize safety and security for living liver donors.

LDLT can be planned electively when recipients have better functional and nutritional status, before significant deterioration of liver function. Principles of the recipient operation include piggyback dissection of the vena cava, high hilar dissection to preserve branches and length of vessels and bile ducts for reconstruction options, and minimal dissection of the hepatic artery bile duct complex to preserve optimal blood supply for the biliary reconstruction. Adequate hepatic venous outflow is essential for proper allograft function, which may require augmentation of both donor and recipient hepatic vein orifices as well as separate reconstruction of major segmental veins. Microvascular techniques are used to reconstruct the smaller caliber hepatic arteries and bile ducts that come with partial liver allografts. In the setting of significant portal hypertension, portal venous flow may need to be modulated by splenic artery ligation or creation of portosystemic shunts to avoid graft dysfunction or failure from excessive portal blood flow. Although there is increased short-term morbidity compared with recipients of DDLT, particularly with hepatic artery and biliary problems, the overall complications and time to resolution of these complications in LDLT are equivalent to DDLT.

OUTCOMES

With advances in the perioperative care of patients with decompensated cirrhosis and complications of portal hypertension, patient and graft survival after liver transplantation continue to improve despite the high acuity of many recipients. Five-year patient survival for adult recipients of LDLT is greater than 75%, whereas 5-year patient

survival for pediatric recipients of DIRT is greater than 80%. In highly selected adult and pediatric patients, DIRT offers significantly superior and durable survival with improved liver allograft and fly compared with DIRT. Future challenges include addressing the shortage of liver allografts, mitigating the side effects of immunosuppression, and ensuring long-term living donor and recipient survival with excellent quality of life.

Endoscopic Therapy for Esophageal Variceal Hemorrhage

Anne Ag[illegible]

Varices are portosystemic venous collaterals that occur as a result of portal hypertension, most commonly in patients with cirrhosis. These collaterals protrude into the gastrointestinal lumen and their rupture with resultant hemorrhage is a complication with a high mortality rate (at least 20% at 6 weeks). Approximately 50% of patients with cirrhosis have varices and 8% of cirrhotic patients will develop them each year. Clinically significant varices are most commonly found in the distal esophagus and gastric cardia, which allows for easy detection and potential treatment with endoscopy.

MEDICAL MANAGEMENT

Patients who present with variceal hemorrhage will have signs of upper gastrointestinal bleeding (UGIB), such as hematemesis or melena. This may be accompanied by hemodynamic instability due to hemorrhagic shock or altered mental status. Variceal hemorrhage should be suspected in any patient with upper gastrointestinal hemorrhage and findings suggestive of portal hypertension or liver cirrhosis, including the presence of ascites, thrombocytopenia, elevated prothrombin time, or a history of cirrhosis.

The initial step in the assessment of any variceal bleed should be focused on ensuring adequate airway, breathing, and circulation in that order. Hematemesis can rapidly lead to aspiration of blood and respiratory failure, and so should prompt consideration of intubation to protect the airway. Patients with variceal hemorrhage are also at risk of developing encephalopathy due to shock or hyperammonemia, and so care should be given to ensure the patient is protecting their airway. If hypotension or the presence of shock physiology is present, attention must be paid to adequate resuscitation and consideration of vasopressor support to prevent hypoperfusion related end organ damage.

Care should be given to ensuring patients have adequate intravenous (IV) access, at least two large bore peripheral IVs or even large bore central access if necessary. Resuscitation via red blood cell transfusion is a necessity in almost all patients with variceal hemorrhage. Randomized control trials and a meta-analysis have demonstrated that a restrictive transfusion strategy with a transfusion threshold of 7 g/dL and a goal of 7 to 9 g/dL improves mortality and reduces rebleeding in patients with gastrointestinal ([illegible]) bleeding. Excessive transfusion and overload, by contrast, increases portal pressure and worsens bleeding. Notably, these studies typically exclude patients with massive exsanguinating hemorrhage—these patients may require blood transfusion at a rate that precludes waiting for confirmatory laboratory values. As cirrhotic patients often have a coagulopathy, patients may also require transfusion of platelets and fresh frozen plasma, particularly if they are receiving a large number of packed red blood cell transfusions. There is limited evidence to recommend a particular threshold for other platelets or the international normalized ratio (INR), particularly as INR is not a reliable indicator of coagulopathy in cirrhosis.

Broad-spectrum IV antibiotic prophylaxis should be administered as they have been shown to reduce mortality, rebleeding rates, and infections. Ceftriaxone is the most commonly used antibiotic and should be continued for prophylaxis for no more than 7 days. The use of vasoactive agents such as octreotide, vasopressin, somatostatin, or terlipressin has been shown to reduce 5-day all-cause mortality and lower transfusion requirements. Only one agent should be used. IV octreotide bolus and infusion is the only vasoactive agent available in the United States and should be continued for 2 to 5 days. Both antibiotic prophylaxis and a vasoactive agent should be started at the time of presentation and prior to endoscopic therapy.

The placement of a nasogastric tube for lavage is of limited utility in diagnosing variceal hemorrhage and has the theoretical risk of precipitating variceal rupture.

In patients for whom endoscopic therapy is delayed, balloon tamponade with a Sengstaken or Minnesota tube is highly effective at temporarily controlling bleeding. As it is associated with a high complication rate, including aspiration, migration, and necrosis/perforation of the esophagus, it should be used for no longer than 24 hours and as a bridge to definitive therapy.

Other nonendoscopic options to control acute variceal hemorrhage include the placement of a transjugular intrahepatic portosystemic shunt (TIPS) or, less commonly, a surgical portosystemic bypass. These techniques reduce the hepatic venous pressure gradient (HVPG) allowing for decompression of varices. TIPS placement involves the radiologically guided placement of a metal stent between the portal vein and hepatic vein by interventional radiology. Both these methods can be complicated by worsening hepatic

survival for pediatric recipients of DDLT to greater than 80%. In highly selected adult and pediatric patients, LDLT offers significantly superior and durable survival with improved liver allograft utility compared with DDLT. Future challenges include addressing the shortage of liver allografts, mitigating the side effects of immunosuppression, and ensuring long-term living donor and recipient survival with excellent quality of life.

Endoscopic Therapy for Esophageal Variceal Hemorrhage

Amarit Agarwalla, MD, and Vikesh K. Singh, MD, MSc

Varices are portosystemic venous collaterals that occur as a result of portal hypertension, most commonly in patients with cirrhosis. These collaterals protrude into the gastrointestinal lumen and their rupture with resultant hemorrhage is a complication with a high mortality rate (as high as 20% at 6 weeks). Approximately 40% of patients with cirrhosis have varices and 8% of cirrhotic patients will develop them each year. Clinically significant varices are most commonly found in the distal esophagus and gastric cardia, which allows for easy detection and potential treatment with endoscopy.

MEDICAL MANAGEMENT

Patients who present with variceal hemorrhage will have signs of upper gastrointestinal bleeding (UGIB), such as hematemesis or melena. This may be accompanied by hemodynamic instability due to hemorrhagic shock or altered mental status. Variceal hemorrhage should be suspected in any patient with upper gastrointestinal hemorrhage and findings suggestive of portal hypertension or liver cirrhosis, including the presence of ascites, thrombocytopenia, elevated prothrombin time, or a history of cirrhosis.

The initial step in the assessment of any variceal bleed should be focused on ensuring adequate airway, breathing, and circulation in that order. Hematemesis can rapidly lead to aspiration of blood and respiratory failure, and so should prompt consideration of intubation to protect the airway. Patients with variceal hemorrhage are also at risk of developing encephalopathy due to shock or hyperammonemia, and so care should be given to ensure the patient is protecting their airway. If hypotension or the presence of shock physiology is present, attention must be paid to adequate resuscitation and consideration of vasopressor support to prevent hypoperfusion related end organ damage.

Care should be given to ensuring patients have adequate intravenous (IV) access, at least two large bore peripheral IVs or even large bore central access if necessary. Resuscitation via red blood cell transfusion is a necessity in almost all patients with variceal hemorrhage. Randomized control trials and a meta-analysis have demonstrated that a restrictive transfusion strategy with a transfusion threshold of 7 g/dL and a goal of 7 to 9 g/dL improves mortality and reduces rebleeding in patients with gastrointestinal (GI) bleeding. Excessive resuscitation and overload, by contrast, increases portal pressure and worsens bleeding. Notably, these studies typically exclude patients with massive exsanguinating hemorrhage—these patients may require blood transfusion at a rate that precludes waiting for confirmatory laboratory values. As cirrhotic patients often have a coagulopathy, patients may also require transfusion of platelets and fresh frozen plasma, particularly if they are receiving a large number of packed red blood cell transfusions. There is limited evidence to recommend a particular threshold for other platelets or the international normalized ratio (INR), particularly as INR is not a reliable indicator of coagulopathy in cirrhosis.

Broad spectrum IV antibiotic prophylaxis should be administered as they have been shown to reduce mortality, rebleeding rates, and infections. Ceftriaxone is the most commonly used antibiotic and should be continued for prophylaxis for no more than 7 days. The use of vasoactive agents such as octreotide, vasopressin, somatostatin, or terlipressin has been shown to reduce 5-day all cause mortality and lower transfusion requirements. Only one agent should be used. IV octreotide bolus and infusion is the only vasoactive agent available in the United States and should be continued for 2 to 5 days. Both antibiotic prophylaxis and a vasoactive agent should be started at the time of presentation and prior to endoscopic therapy.

The placement of a nasogastric tube for lavage is of limited utility in diagnosing variceal hemorrhage and has the theoretical risk of precipitating variceal rupture.

In patients for whom endoscopic therapy is delayed, balloon tamponade with a Sengstaken or Minnesota tube is highly effective at temporarily controlling bleeding. As it is associated with a high complication rate, including aspiration, migration, and necrosis/perforation of the esophagus, it should be used for no longer than 24 hours and as a bridge to definitive therapy.

Other nonendoscopic options to control acute variceal hemorrhage include the placement of a transjugular intrahepatic portosystemic shunt (TIPS) or, less commonly, a surgical portosystemic bypass. These techniques reduce the hepatic venous pressure gradient (HVPG) allowing for decompression of varices. TIPS placement involves the radiologically guided placement of a metal stent between the portal vein and hepatic vein by interventional radiology. Both these methods can be complicated by worsening hepatic

encephalopathy as well as prolonged in those patients with right-sided heart failure, and so patients need to be carefully selected for these therapies. Surgical portosystemic bypass, while effective, has been limited due to concerns regarding the safety of intra-abdominal surgery in patients with decompensated cirrhosis.

ENDOSCOPIC MANAGEMENT

Esophagogastroduodenoscopy (EGD) remains the central therapy for acute variceal hemorrhage. Though endoscopic evaluation is beneficial in primary and secondary prevention as well as risk stratification for variceal hemorrhage, this chapter focuses on the endoscopic management of acute hemorrhage. In situations where endoscopic management is unable to control bleeding, methods such as TIPS placement or surgical portosystemic bypass are also options.

Prior to endoscopy, consideration must be given to several factors that will affect post-endoscopic outcomes. Patients should be intubated prior to the procedure to prevent aspiration during endoscopy. Patients should be transferred to an intensive care unit where post-procedure monitoring can be continued. Patients should also be hemodynamically stable and adequately resuscitated, to a hemoglobin of 7 to 9 g/dL and a systolic blood pressure of 100 mm Hg. Though it is generally agreed that endoscopy should be performed, the appropriate timing remains unclear. Evidence remains conflicted; some studies have shown emergency endoscopy in patients with portal hypertension and hemodynamic improves endoscopic outcomes, while others have shown it can be delayed in patients with stable vital signs and the absence of active ongoing bleeding. Current guidelines recommend endoscopy within 12 hours of presentation for cirrhotics with acute UGIB. Patients who have demonstrated hemodynamic instability should undergo EGD as soon as possible once resuscitated and ready for endoscopy. In the absence of instability, recent evidence suggests no difference in outcomes within the first 24 hours of presentation. In all patients, pharmacologic therapy should be paired with endoscopic therapy; this improves initial hemostasis as well as 5-day rebleeding rates when compared to either therapy alone.

Endoscopically, varices appear as dilated and serpiginous blood vessels that protrude into the gastrointestinal lumen. They are most commonly seen in the distal esophagus or, less commonly, in the gastric fundus. Variceal hemorrhage can be diagnosed if there is active bleeding or the stigmata of recent or remote bleeding, including red wale sign, white nipple, cherry red spots, or overlying clot. The presence of fresh blood without another clear cause is also suggestive of varices as the source of bleeding. Often there is clotted blood preventing adequate visualization; several strategies, such as positional changes of the patient and/or use of endoscopes with a large accessory channel for increased suctioning can allow for adequate visualization of the lumen.

Endoscopic Band Ligation

Endoscopic variceal ligation (EVL) is the gold standard for the treatment of acute esophageal variceal (EV) bleeding. In EVL, a circular band ligator is applied over an esophageal varix, obliterating blood flow and decompressing the varix. Other modalities are used for treating gastric or ectopic varices or cases that are refractory to band ligation. To perform EVL, the endoscope is inserted into the patient and used to confirm the presence of variceal hemorrhage (▶ Fig. 1), with attention paid to the distal most location of the relevant varix. The endoscope is then removed, and a multiband ligator with a clear cap is attached to the distal end of the endoscope. This cap allows for visualization (▶ Fig. 2) and suction of the varix into the cap prior to placement of a band ligator. Many devices are available, and the endoscopist should be familiar with the setup and troubleshooting of the band ligator device. The endoscope is then advanced again under direct visualization to the previously noted distal most location of the varix. This is often at the gastroesophageal junction, where the esophageal mucosa is thin, predisposing to bleeding. The endoscope is positioned so the entire width of the target varix is within the walls of the cap, typically with the endoscope tip being placed orthogonal to the luminal wall. Suction is applied and maintained until the varix is completely sucked into the cap. The goal is to capture the entirety of the variceal wall within the cap otherwise the band can fall off and result in an ulcer over the vessel with catastrophic rebleeding. With continuous application of suction (which could precipitate hemorrhage), the band is deployed (▶ Fig. 3). This technique is then repeated in a clockwise fashion moving distal to proximal until all high risk varices have been ligated. Care should be taken not to traverse previously placed bands as this may dislodge them and precipitate hemorrhage.

Ligation is performed distal to proximal, as this is also the direction of blood flow in distal EV. Rarely, patients may develop "downhill" EV located in the proximal esophagus in the setting of superior vena cava obstruction, typically due to mediastinal etiologies. In these proximal varices, ligation should be performed cephalad to caudal, with care to take not to dislodge a previously placed band. Nasogastric or orogastric tube placement should also be avoided or done with care to prevent dislodgment of a band. However, no consensus exists on how long one should wait before placing nasogastric access after EVL.

FIG. 1 Endoscopic view of esophageal varices.

FIG. 2 Visualization of the varix prior to placement of a band ligator.

FIG. 3 Placement of band ligator.

FIG. 4 Endoscopic view of a gastric varix.

EVL can be complicated by post banding ulcers that present with bleeding or chest pain. Patients should ideally undergo repeat banding to ensure complete eradication of esophageal varices, typically in 7- to 14-day intervals. Patients typically require 2 to 4 sessions to completely eradicate varices, after which they will require a repeat endoscopy in 3 to 6 months to evaluate for EV recurrence.

Endoscopic Injection Sclerotherapy

Prior to band ligation, endoscopic injection sclerotherapy (EIS) was the primary endoscopic management of acute EV hemorrhage. The advantages of EIS are its easy technique and high technical success. However, EIS appears to be associated with higher rates of complications, rebleeding, prolonged elevation in HVPG, and death. In general, EIS should not be used when EVL is available.

EIS is performed with ethanolamine, morrhuate sodium, or absolute alcohol, though no consensus exists on the ideal sclerosant or volume needed to inject. A 23- or 25-gauge endoscopic needle is inserted via the endoscope and injected into or between varices. Complications can include chest pain (seen in up to 40% of patients), or, less commonly, esophageal strictures or local necrosis.

Endoscopic Glue Injection

While EIS has generally fallen out of favor, endoscopic glue injection is increasingly used as a modality to treat gastric varices (Fig. 4). Cyanoacrylate, a liquid agent that polymerizes on contact with blood, is injected into the gastric varix with a similar technique as EIS. The procedure is often performed with the gastroscope in retroflexion to best visualize fundal varices. The needle is inserted into the varix orthogonal to the luminal wall, and 1 to 2 cc of cyanoacrylate are injected into the varix, followed by 1 cc of sterile water (Fig. 5). The needle should be withdrawn at the same plane as entry. The needle is retracted and a 1 cm length of catheter is left outside of the endoscope to avoid glue damage to the tip of the endoscope. Repeated injections may be necessary but increase complication rates, including the risk of embolization.

Glue injection may be enhanced by the guidance of endoscopic ultrasound (EUS). EUS can allow for identification of gastric varices and allow for antegrade injection. Coils can also be injected prior to glue injection to provide a structure for cyanoacrylate to polymerize, reducing the risk of embolization.

The most dreaded complication of glue injection is embolization, which can occur in 1% of patients. Other complications include transient fevers, chest or epigastric pain, or delayed onset bleeding due to ulceration at the injection site. In a poorly sedated patient, puncture

FIG. 5 Injection of cyanoacrylate into the varix.

of the gastric varix during treatment can also result in worsening hemorrhage.

Self-Expanding Metal Stent Placement

In patients with bleeding too rapid to allow for visualization and banding or for patients with bleeding that is refractory to EVL, the placement of a self-expandable metal stent (SEMS) can be used as a salvage therapy. A fully covered, removable esophageal SEMS, at least 25 mm in width, is deployed in the distal esophagus with or without the use of fluoroscopy. Successful placement provides tamponade and hemostasis. Once placed, these stents can remain in place for up to 7 days, allowing for resuscitation and plans for definitive therapy such as TIPS. One small trial comparing SEMS placement to balloon tamponade showed no difference in survival but did show SEMS had higher control of bleeding and fewer complications.

Gastric Varices

While the distal esophagus is the most common location of variceal hemorrhage, gastric varices are discussed in this chapter to highlight the similarities and differences in their treatment when compared to esophageal varices.

The location of gastric varices is important in determining the optimal treatment. Isolated gastric varices due to splenic

sion thrombosis should not be treated endoscopically as they rarely result in variceal hemorrhage. Varices that occur in both the esophagus and lesser curvature of the stomach (also known as GOVI) should be treated similarly to esophageal varices. Varices in the gastric fundus, however, rarely respond well to treatment with EVL, this is due to the difficulty in capturing the contralateral wall of the varix in the ligation cap, resulting in a high likelihood of band dislodgement, poor banding ulcer, and subsequent hemorrhage.

As mentioned above, the primary modalities for the treatment of acute gastric variceal hemorrhage is either the endoscopic injection of glue with or without coils, direct reduction in portal pressure with TIPS, balloon tamponade with a Sengstaken or Minnesota tube, or balloon occluded retrograde transvenous obliteration (BRTO). BRTO is transvenous obliteration performed by interventional radiology that instills sclerosants or embolic agents into a gastrorenal collateral through the left renal vein, aided by balloon occlusion. This requires the presence of an anatomic gastrorenal shunt, which is not present in all patients.

Ectopic Varices

Varices can occur anywhere in the GI tract, including in the duodenum, the remainder of the small bowel, colon, rectum, and enteric / colocutaneous stomas. The rates of bleeding from these ectopic locations is markedly lower than those from gastroesophageal varices, and so limited evidence is available as to which modality is optimal in their management. EIS, EVL, and glue injection have all been reported to be effective. Direct sutured ligation has also been reported for duodenal varices.

FUTURE DIRECTIONS

Two topical agents, Hemospray and Arkadia Hemostapler, have efficacy in early treatment in early gastric variceal hemorrhage as well as portal hypertensive gastropathy without the risk of embolization. However, the durability of hemostasis is unknown as these agents remain in the lumen for less than 24 hours, and their use is currently only approved for arterial bleeding and not for acute variceal hemorrhage.

SUMMARY

Esophageal variceal hemorrhage is a highly morbid complication of portal hypertension. The optimal management of variceal hemorrhage involves medical therapy with transfusion, vasoactive agents, antibiotics, as well as endoscopy, which remains the cornerstone of managing bleeding varices. Endoscopy allows for direct visualization, treatment, and risk stratification of patients with variceal hemorrhage. Endoscopic band ligation remains the gold standard therapy for esophageal varices, though other modalities including sclerotherapy, glue injection, and self-expandable fully covered metal stent placement remain part of the management toolbox. Endoscopy can be supplemented with other procedures, including TIPS, to treat acute hemorrhage or prevent rebleeding.

Transjugular Intrahepatic Portosystemic Shunt

Robert R. Liddell, MD*

Cirrhosis is the most common cause of portal hypertension, which often causes variceal bleeding, therapy refractory ascites/hydrothorax, and hepatorenal syndrome. Since the first description of transjugular intrahepatic portosystemic shunt (TIPS) insertion in dogs by Rösch et al. in 1969, the first successful TIPS insertion in patients was reported by Rössle et al. in 1989. TIPS is now regarded as an established procedure in the treatment of the previously mentioned consequences of liver cirrhosis, resulting in significantly reduced portal pressure.

The techniques used in TIPS formation are well established, involving portal vein access via a hepatic vein approach, and subsequent placement of a stent between them, essentially unchanged from when it was first described 20 years ago. There have been a number of significant improvements made in imaging equipment and devices used in the successful creation of a TIPS.

INDICATIONS

The list for causes of portal hypertension is lengthy and are summarized in Table 1. Whatever the causative pathophysiology, TIPS can reduce or normalize the portal pressure and attenuate the associated symptoms. As the technique for placing a TIPS has become more refined and more safe, and the imaging and catheter technologies become more advanced, the indications for TIPS have gradually expanded. Table 2 shows the indications and contraindications for TIPS.

VARICEAL BLEEDING

Portal hypertension can cause varices along the entire gastrointestinal tract, including the small bowel and colon (hemorrhoids). Varices are present in 30% of compensated cirrhotic patients and 60% of decompensated cirrhotic patients. Varices are more apt to bleed through the mucosa of the gastroesophageal junction, where the coronary vein is particularly prone to dilatation. Mortality from acute variceal bleeding is said to be approximately 33% in patients with cirrhosis.

The primary treatment of bleeding gastroesophageal varices has traditionally been medical, and/or endoscopic management. Despite the high success rate of endoscopic management in variceal bleeding, the progressive nature of chronic liver disease leads to rebleeding in more than 50% of patients. Unlike medical or endoscopic management, shunting procedures such as TIPS address the portal hypertension which causes the variceal bleeding. Portosystemic shunting is the only definitive treatment for portal variceal bleeding. Meta-analysis of the literature has shown that TIPS has a lower rate of both variceal rebleeding and death resulting from rebleeding with a strong trend toward increased survival (at the expense of increased hepatic encephalopathy). Most of the studies included in these meta-analyses predate the era of polytetrafluoroethylene (PTFE)-covered TIPS stent grafts that have improved long-term patency over bare metal stents with a trend toward better overall survival. Head-to-head comparisons of TIPS created with stent grafts to endoscopic and medical management are lacking.

Currently, the primary indication for TIPS is to control portal variceal bleeding refractory to medical and endoscopic management; however, there is evidence supporting the early use of TIPS in selected patients with advanced cirrhosis (Child–Pugh class B and C) and acute esophageal variceal bleeding (early TIPS). Additional studies are needed to confirm this finding before TIPS can be accepted as a first line therapy for bleeding esophageal varices in patients with advanced liver disease.

ASCITES

Ascites is the most frequent complication of cirrhosis. In addition to the severe limitations in lifestyle that often accompanies the development of ascites, it also poses a risk for bacterial peritonitis and other infections, renal failure, and has been seen to increase mortality. No single cause for cirrhosis related ascites has been identified; however, it is likely that a combination of causes, including decreased plasma albumin levels, increased bowel permeability, and cirrhosis related hemodynamic changes—such as increased cardiac output, vasodilatation, and increased plasma volume—factor together in the formation of ascites.

Initial management consists of sodium restriction and administration of loop diuretics (furosemide) and aldosterone antagonists (spironolactone). In advanced stages, ascites becomes refractory to medical management, and TIPS may be indicated. TIPS is very effective in eliminating ascites. Because the root causes are humoral/hormone related, response to TIPS is often not immediate. It may take 2 to 4 weeks after TIPS for ascites to resolve, during which additional paracentheses may be necessary. Randomized controlled trials, meta-analyses, and systematic reviews of the literature have demonstrated that TIPS significantly improves transplant-free survival compared with repeated paracentesis.

HEPATIC HYDROTHORAX

Hepatic hydrothorax is defined as the accumulation of at least 500 mL of pleural fluid in a patient with cirrhosis without cardiopulmonary disease. Even though this definition is not 100% specific to hepatic hydrothorax, additional signs, such as reduced right-sided hydrothorax and concurrent ascites, help confirm the diagnosis. It occurs in less than 10% of patients with cirrhosis as peritoneal fluid permeates via small diaphragmatic communications. As with ascites resulting from portal hypertension, initial management is sodium restriction and diuretics. In nonresponsive patients, TIPS will eliminate hydrothorax in most and decrease the frequency of thoracocentesis in the rest.

HEPATORENAL SYNDROME

Hepatorenal syndrome portends a poor prognosis for the cirrhotic patient because it generally occurs during the late stages of cirrhosis. Hemodynamic changes related to portal hypertension lead to the release of vasoactive hormones, resulting in splanchnic vasodilation, renal arterial vasoconstriction, and the opening of small intrarenal arteriovenous communications. This initially results in renal hypoperfusion and can eventually lead to renal failure.

Two distinct forms of hepatorenal syndrome (HRS) have been identified: type 1, which is rapidly progressing, and type 2, which evolves slowly. Type 1 is precipitated by an event that incites acute intrahepatic liver failure, an exaggerated systemic inflammatory response, and kidney dysfunction as part of broader multiorgan failure. Targeting the precipitating event is the hallmark of treatment for type 1. Type 2 results to large part from a reduction in effective arterial blood volume created by shift of fluid from the intravascular compartment to the extravascular compartment (i.e., ascites). Studies suggest that

TABLE 1 Causes of Portal Hypertension

Presinusoidal	Perisinusoidal	Postsinusoidal
Portal, splenic, or superior mesenteric vein thrombosis	Cirrhosis	Budd-Chiari syndrome
Idiopathic portal hypertension	Congenital hepatic fibrosis	Venoocclusive disease (sinusoidal obstruction syndrome)
Mass effect (i.e., tumor)	Cystic liver disease	Chronic passive congestion
Schistosomiasis	Sarcoidosis	Mass effect (i.e., tumor)
Preterminal stage, primary biliary cirrhosis		
Alcoholic central sclerosis		
Arterioportovenous fistula (traumatic or Osler-Weber-Rendu)		
Endofibrosis (liver transplant, radiation injury)		
Hyperdynamic splenomegaly (infectious or myeloproliferative)		
Nodular regenerative hyperplasia		
Congenital extrahepatic portal vein occlusion		

TABLE 2 Indications and Contraindications for TIPS

Indications			Contraindications	
	Emerging Indications			
Standard of Care	Supported by Controlled Studies	Supported by Noncontrolled Studies and Case Series	Absolute	Relative
Portal variceal hemorrhage refractory to medical/endoscopic management	Cirrhotic portal vein thrombosis caused by slow hepatic flow to the portal vein	Hepatorenal syndrome (more so type II than type I)	Severely elevated right heart pressure	Hepatic vein thrombosis
Ascites refractory to medical management	Child-Pugh B and C with acute esophageal variceal bleeding (simultaneously treated with medical and/or endoscopic interventions)	Hepatopulmonary syndrome	Severe tricuspid regurgitation	"Noncirrhotic" portal vein thrombosis caused by hypercoagulability or tumor thrombus
Budd-Chiari syndrome not responsive to anticoagulation		Portal gastropathy refractory to β blockers	Severe pulmonary hypertension	Poor liver function scores
Hepatic hydrothorax refractory to diuretics and salt restriction		Hepatic venoocclusive disease	Severe congestive heart failure	Polycystic liver disease
			Severe encephalopathy	Central liver mass
			Uncorrectable bleeding diathesis	Caution; arterial variceal source
			Active sepsis or hepatic bacterial infection	
			Obstructive biliary obstruction	

the reduction of ascites post-TIPS can improve renal function in type 2. However, the use of TIPS in HRS should be undertaken after serious consideration because of the contrast load and acute hemodynamic changes it involves.

BUDD-CHIARI SYNDROME

Budd-Chiari syndrome is caused by mechanical obstruction of the hepatic venous outflow and gradually results in cirrhosis and portal hypertension. Excluding a focal hepatic venous web, which can often be successfully treated with simple balloon angioplasty, treatment for the fulminant form of Budd-Chiari syndrome is liver transplantation, although anticoagulation may help stave off disease progression. TIPS has proven to be a valuable tool to bridge such patients to transplantation.

In the fulminant form of Budd-Chiari syndrome, anticoagulation is first-line therapy. When anticoagulation fails, TIPS is a reasonable and accepted next step, or direct intrahepatic portosystemic shunt (IHPS) if access to hepatic veins is completely occluded. The use of TIPS in this patient population was reported in a large retrospective study that showed 1- and 10-year transplant-free survival that was much greater than expected. The American Association for the Study of Liver Diseases now recommends creation of a TIPS in patients with Budd-Chiari syndrome who fail to improve with anticoagulation.

Technique

Patient Preparation

In nonemergent situations, patients needing a TIPS should be seen in a clinic in advance of the procedure. This provides an opportunity to explain and discuss the pathophysiology of portal hypertension as it relates to the patient and how a TIPS addresses this. The potential risks, benefits, and alternatives to TIPS are also to be discussed during the clinic visit and allows the patient to make an informed decision as to whether to proceed with TIPS. Review of any cross-sectional imaging and laboratory findings that may be pertinent to the TIPS procedure are done during the clinic visit. If necessary, additional imaging and laboratory testing can be ordered before the TIPS procedure. A pre-TIPS echocardiogram is often performed to

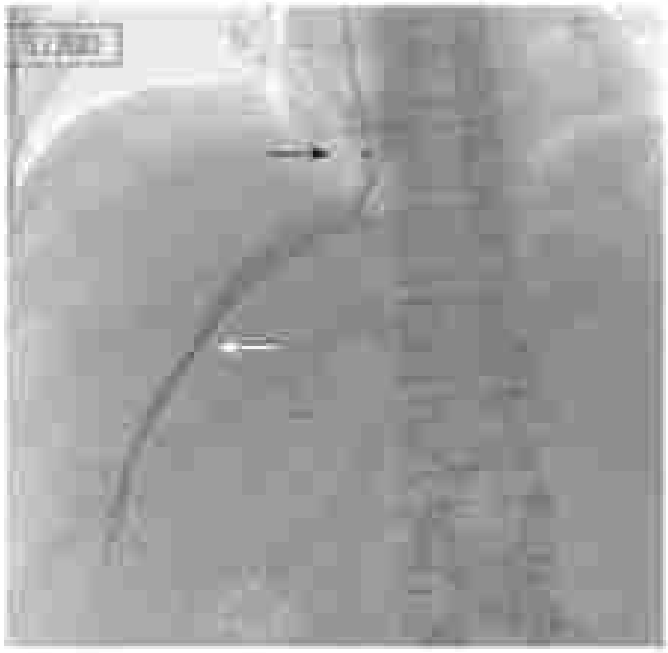

FIG. 1 Right hepatic venogram performed via a selective catheter (white arrow). The tip of the internal jugular sheath (black arrow) is below the diaphragm to avoid catheter/wire manipulations in the right atrium. The stages of transjugular intrahepatic portosystemic shunt insertion outlined in Figs. 1–9 are all from the same patient.

FIG. 2 Frontal digital subtraction views of a carbon dioxide (CO_2) hepatic venogram. CO_2 is injected via a balloon occlusion catheter to force the CO_2 retrograde into the portal system. The right portal vein and its intrahepatic branches, the left portal vein, and the main portal vein are easily visualized. The operator usually targets the right portal vein from the right hepatic vein with a long needle introduced via the right internal jugular sheath.

noninvasively evaluate cardiac function and exclude any evidence of right heart failure.

Many of the complications related to the placement of TIPS can be avoided by proper patient workup. Review of pertinent cross-sectional imaging will confirm a patent (nonthrombosed) portal vein, reveal the relative orientation and anatomic relationship of the hepatic and portal veins, and the presence or absence of varices. This minimizes the number of attempts to engage the portal vein and therefore decreases the associated bleeding risk. Good hydration will minimize the risk of acute renal failure, and initiation of metronidazole (Flagyl), rifaximin (Xifaxan), and/or lactulose mitigates the risk of encephalopathy. Type and cross of blood may prove lifesaving if a bleeding complication is encountered. Finally, all involved should be cognizant of related risks, especially the 30-day mortality, which ranges from less than 5% for elective procedures in well-compensated patients to 50% for emergent procedures in unstable patients with advanced liver disease.

Access

Access through the right internal jugular vein is preferred, although the left internal jugular vein can also be used. Access is maintained with a long, large vascular sheath positioned in the intrahepatic inferior vena cava to allow multiple catheter wire exchanges without recrossing the right atrium (Fig. 1).

Diagnostic Assessment

Optimizing TIPS outcomes requires not only a thorough anatomic assessment, but sometimes more importantly, a functional assessment of the patient's hemodynamic status. One of the contraindications to TIPS is an elevated right heart pressure. Unmasking the right atrial pressure is not severely elevated is mandatory before shunting the portal venous blood to an already overburdened right heart. Right atrial pressures below 15 mm Hg are generally safe, whereas pressures above 20 mm Hg predispose the patient to acute right heart failure. There are no specific guidelines, and sound clinical judgment is important. For example, a right atrial pressure of 16 mm Hg should not preclude creation of a TIPS in an unstable patient with ongoing variceal bleeding.

After selecting the right hepatic vein, free and wedged hepatic venous pressures are measured, which usually confirm portal hypertension. Normal corrected pressures should not necessarily terminate the procedure because these are not always accurate and are often inaccurate in cases of prehepatic portal hypertension (portal vein thrombosis, splenic vein thrombosis, primary biliary cirrhosis).

Delineation of the portal venous system is accomplished by injection of carbon dioxide (CO_2) via a catheter wedged into the hepatic vein. CO_2 is not nephrotoxic and can be given in virtually unlimited quantities. Frontal and lateral views show the anatomical relationships, so that the right portal vein can be targeted for access (Fig. 2).

In the vast majority of patients, the TIPS is placed from the right hepatic vein into the right portal vein as this is the shortest and most direct path for shunt creation. However, a recent randomized controlled trial found that using the left portal vein resulted in a significant reduction in the incidence of encephalopathy and rebleeding during 2 years of follow-up after TIPS creation. These data must be confirmed in additional studies before the standard approach of targeting the right portal vein is abandoned.

Shunt Placement

The next step in the cannulation of the right portal vein from the right hepatic vein. To accomplish this, a curved metallic sheath is advanced via the existing right internal jugular sheath in the right hepatic vein. The new catheter is rotated based on the anatomy revealed during CO_2 portography, so that it targets the right portal vein. When the operator judges the curved sheath to be directed toward the right portal vein, which is usually located anterior and inferior to the right hepatic vein, a long needle is advanced toward it. Aspiration of blood supports intravascular location, and contrast injection confirms the tip to be in the portal vein (Fig. 3). The use of ultrasound guidance during TIPS with intracardiac echocardiography is a new technique that may improve the technical success of portal vein access, decreasing procedure time and complications.

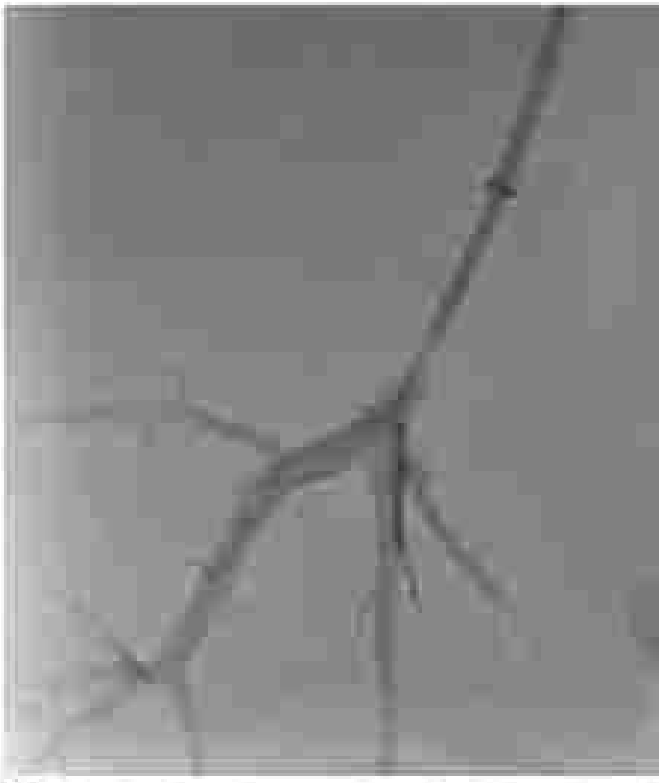

FIG. 3 Frontal unsubtracted venogram via a needle after it was advanced from the right hepatic vein through a catheter toward the right portal vein. Contrast dye injection of the right portal vein with hepatopetal blood flow.

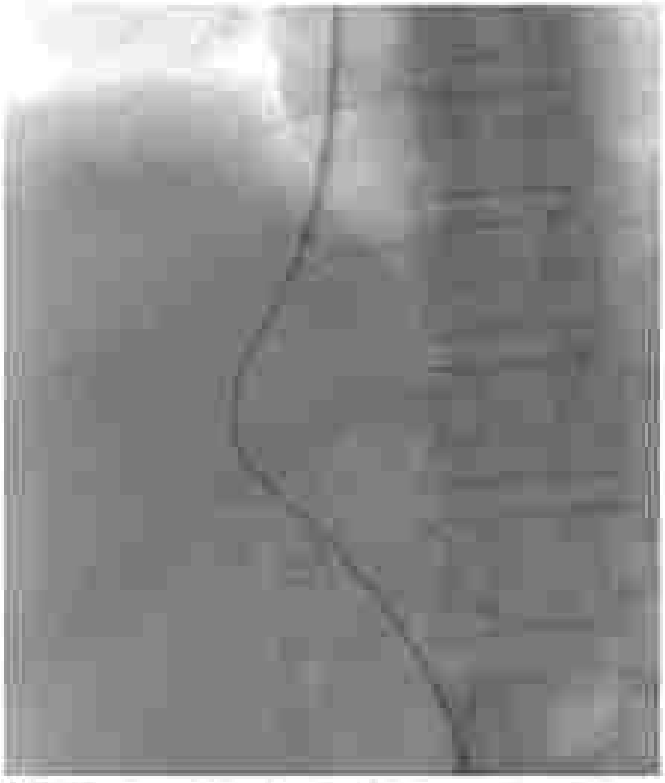

FIG. 4 After the needle is confirmed to be in the surgical portal vein branch, a wire is advanced through it into the portal vein. Note the location of the right internal jugular sheath. The wire crosses from the right hepatic vein, through a short segment of liver parenchyma, and into the right portal vein.

Once it is confirmed that the tip of the needle is in the right portal vein, an exchange length hydrophilic wire is passed distally through the main portal vein into the superior mesenteric vein or splenic vein for security (Fig. 4). In those patients with severe cirrhosis, the traversed liver parenchyma is often fibrotic and difficult to cross unless predilated. A small-caliber (4- to 6-mm diameter) balloon is used to predilate the liver parenchyma between the right hepatic and right portal vein created by the wire (Fig. 5). A marking catheter is then passed over the wire into the portal venous system. This allows for direct portal pressure measurement and a portal venogram. The venogram will be used to select the appropriate length stent to be placed (Fig. 6).

If the direct portal pressure and portosystemic gradient are within normal limits, TIPS creation is abandoned irrespective of the clinical picture. If a TIPS is not possible or is contraindicated, the gastroesophageal varices can be embolized via a catheter to stop the hemorrhage without placing a TIPS. Although this is very effective, it is nevertheless temporary. If present, the ongoing portal hypertension will likely cause new varices to form.

The stent is advanced through the larger sheath, which keeps it constrained and in position. The sheath is pulled back into the right atrium, uncovering the stent. The distal 2 cm of the stent is uncovered and flares out on withdrawal of the sheath. The rest of the stent is deployed once it is in the appropriate position (Fig. 7).

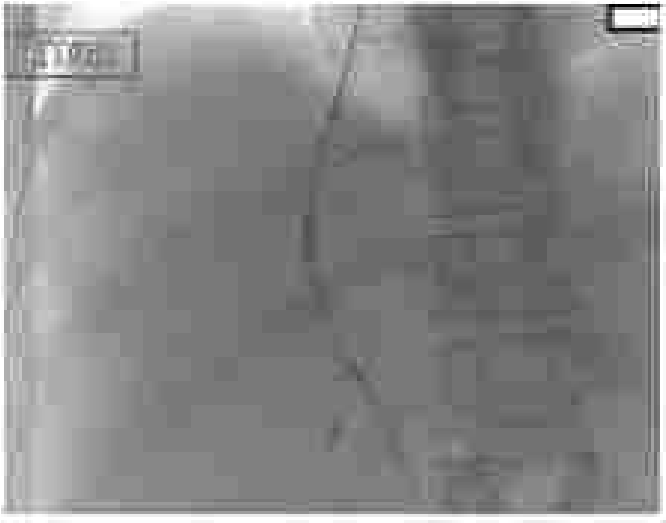

FIG. 5 Because cirrhotic liver is difficult to cross, it is predilated with a small balloon to facilitate the necessary shunt exchanges. The "waist" in the middle of the balloon reveals just how hard the liver parenchyma can be.

Shunt Evaluation

Usually, a 10-mm diameter stent is used and initially balloon dilated up to 8 mm in diameter. The direct portal pressure is measured again and, if it is not satisfactory, a 10-mm balloon is used to open the stent to capacity (Fig. 8). The smaller the stent diameter, the less the chance for encephalopathy postprocedure. A final portal venogram is performed to document flow and lack of variceal filling (Fig. 9). If at this point there are still varices present, coil embolization may be warranted.

Special Cases

Budd-Chiari Syndrome

The creation of a TIPS in a patient with Budd-Chiari syndrome is especially challenging because the hepatic veins are thrombosed. This shows as the classic spider vein appearance on a hepatic venogram (Fig. 10). Although it is true if the TIPS is placed from hepatic vein to portal vein, the lack of patent hepatic veins may necessitate an

FIG. 6 Frontal subtracted roadmap. Simultaneous manual injection via the right internal jugular sheath and marker catheter in the portal vein allows for calculation of the required length of the stent.

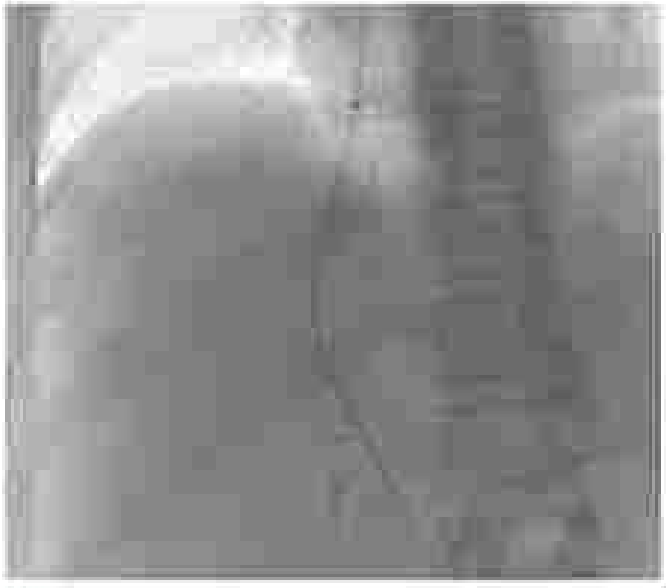

FIG. 7 Frontal view of the deployment sequence of a monojugular transhepatic portosystemic stent. The stent is first advanced via a sheath through the right hepatic vein, across the liver parenchyma, and into the portal vein. The stent's distal 2 cm are constrained only by the sheath and once the sheath is pulled back, a spotlight opens. The remainder of the stent remains unexpanded. The entire system is then gently withdrawn until the proximal end of the distal 2 cm lies the parenchymal tract. Once the operator judges the stent to be in proper position, the remainder of the stent is opened by pulling on the rip-cord.

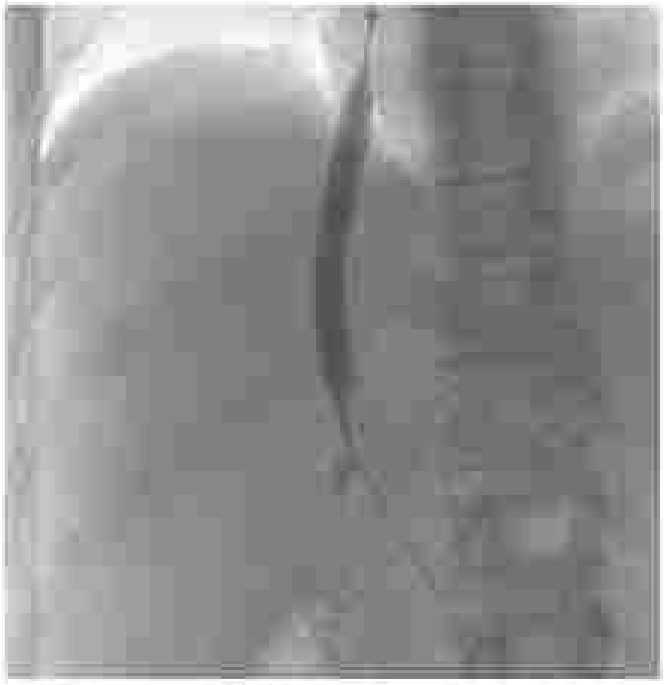

FIG. 8 After unwrapped monojugular transhepatic portosystemic shunt placement, a balloon is used to open the stent to the desired diameter. The objective is to open the stent to the minimum diameter required to reduce the portal pressure to the desired level.

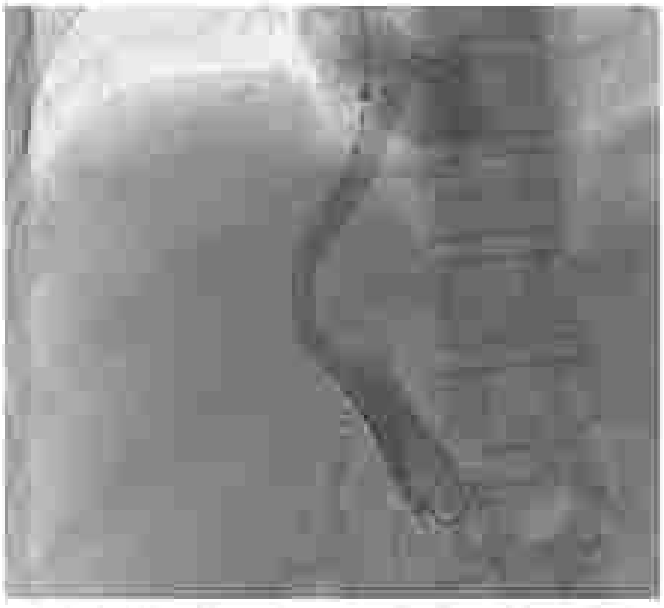

FIG. 9 Frontal view of a portal venogram via a catheter after monojugular transhepatic portosystemic shunt placement. Note the antegrade flow of contrast into the right atrium and no varices filling the varices and compare with Fig. 4.

inferior vena cava to portal vein TIPS through the caudate lobe, a so-called DIPS.

Parallel TIPS

Rarely, despite a previous TIPS, the patient's symptoms may not be completely alleviated. If portal hypertension and variceal bleeding are a persistent problem despite a TIPS, or if the first TIPS thrombooses, a second TIPS may be placed using the other hepatic and portal veins.

Transumbilical or Direct Portal Access

When access into the portal vein is challenging because of anatomy, the operator has two other options. First, access into the umbilical vein, which is usually dilated, provides a conduit into the left portal vein. A catheter then allows opacification of the portal venous system, which provides a better target for TIPS. Second, access through a

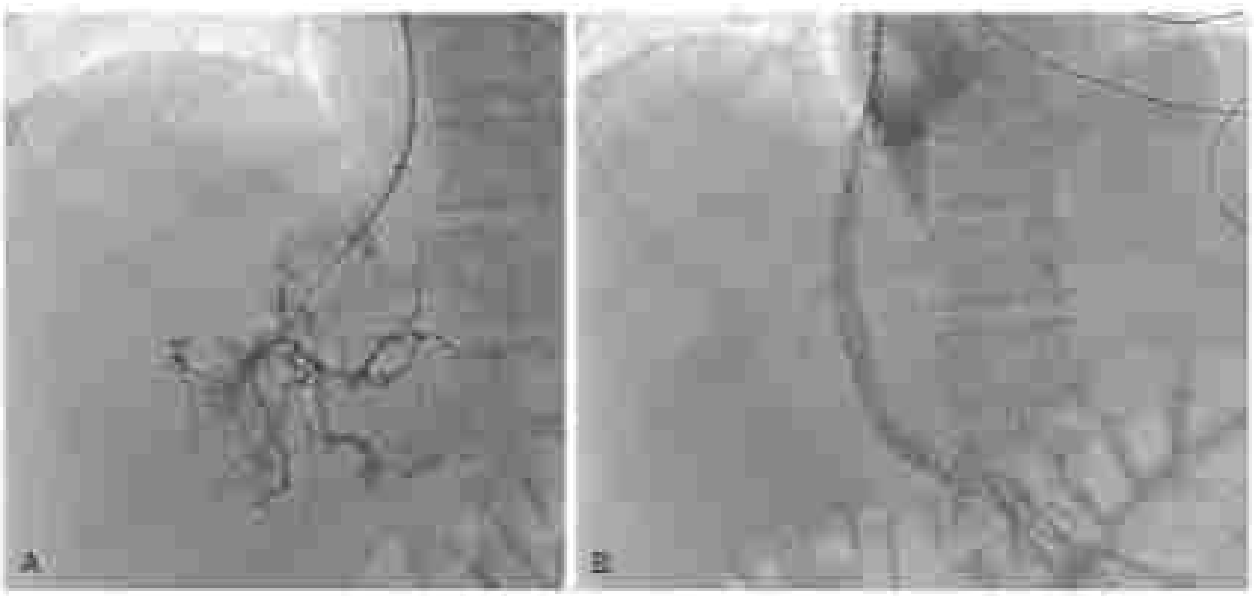

FIG. 16 (A) Frontal venous phase hepatic venogram in a patient with Budd–Chiari syndrome. Hepatic venogram shows the spiderlike appearance (arrow) of multiple small collateral draining veins. (B) Repeat unsubtracted portal venogram after placement of a direct intrahepatic portocaval shunt extending from the inferior vena cava to the right portal vein.

naturally occurring portosystemic shunt, such as a splenorenal shunt, can sometimes be used to gain access to the portal circulation. When the umbilical vein is not accessible and a natural portosystemic shunt does not exist, direct percutaneous access into the right or left portal vein can allow for contrast opacification and targeting.

TIPS Reversal/Revision

Occasionally, a TIPS reversal or revision is necessary. Limited liver reserve and/or overshunting may result in liver failure or intractable encephalopathy. In such cases, the interventionalist has the option to decrease the shunting or shut down the TIPS altogether. Several maneuvers exist to reduce shunting, including placing a stent within the TIPS, or two stents side by side, or even a "waisted" (hourglass-like) stent. If these interventions are not possible or are inadequate, then the entire TIPS can be shut down.

DIPS

DIPS is a recently developing modification to the TIPS procedure. Using intravascular ultrasound guidance, DIPS has been shown to decrease radiation dose and procedural time compared to TIPS. DIPS uses the caudate lobe as a parenchymal tract to create a side-to-side portocaval shunt, which alleviates the difficulties presented by significant hepatic vein stenosis. Portal access is accomplished by advancing a 21-gauge trocar needle through the caudate lobe into the main portal vein. After the inner trocar is removed, a guidewire (0.018-inch) can be advanced, followed by a 5Fr catheter. The needle and guidewire can then be removed, after which a 0.035-inch stiff guidewire can be advanced into the portal vein. Following portal vein access, a shunt can be created using a PTFE-covered stent graft (Fig. 18). In recent studies, DIPS creation was usually successful in entire patient cohorts and has produced higher patency and real-time imaging compared with TIPS. In some interventional radiology practices, DIPS has replaced TIPS as default procedure, especially in patients with occluded TIPS, challenging anatomy, calcification of the portal vein, or portal vein thrombosis resulting from hepatocellular carcinoma.

TIPS in Transplant Livers

TIPS has also been used to bridge liver transplants in patients in end-stage liver disease. Before transplant, TIPS is used to manage complications from portal hypertension and make sure that patients can remain transplant candidates. After transplantation, TIPS has a similar utility. The indications for TIPS in transplant livers are the same as those for pretransplant; studies have shown TIPS to be effective in addressing early complications such as portal vein thrombosis and delayed graft function. TIPS can be more complicated in liver transplant patients because of the altered anatomy of hepatic vessels. The piggyback technique for TIPS has been effective in addressing this challenge. In this technique, TIPS placement is done in the left intrahepatic portal vein rather than the right.

Results after TIPS in transplant patients are generally excellent but pose a different set of issues when compared with TIPS in non-transplant patients. Approximately 10% to 20% of stents in transplant patients require revision, whereas up to 70% do in nontransplant patients. Transplant patients undergoing TIPS have higher risks of infection, renal failure, and neurologic complications than nontransplant patients, however. For example, 30% to 50% of cases result in death by sepsis, the most common posttransplant TIPS complication. Interestingly, clinical success rate of TIPS in nontransplant patients is much higher than in transplant patients (93% vs 77%).

Balloon-Occluded Retrograde Transvenous Obliteration in Type I Gastric Varices

Isolated gastric varices often result from abnormal gastrorenal shunting of blood in response to portal hypertension. TIPS in these cases do not effectively address the splenorenal shunts that are the cause of the isolated gastric varices. Balloon-occluded retrograde transvenous obliteration (BRTO) was therefore developed and has been used to access the portosystemic gastrorenal shunt through the left renal vein via a transjugular or transfemoral approach. This procedure uses an occlusion balloon followed by injection of a sclerosing agent to control flow into the gastrorenal shunt and varices. BRTO has been reported to have excellent clinical success rates, ranging from 79% to 100%. Effectiveness of BRTO in controlling gastric varices ranges from 91% to 100%. The safety and efficacy of BRTO for managing varices has been established in many studies but is not as practiced in the United States as TIPS because of unfamiliarity of the procedure. Studies have shown BRTO to be as effective as TIPS and potentially more advantageous because it is less invasive. BRTO better supports portal blood flow, preserves liver function in patients with a poor hepatic functional reserve, and prevents encephalopathy.

TABLE 3 Complications Related to TIPS

Complication	Frequency	Predisposing Factors	Mitigating Factors
TIPS dysfunction	Occlusion/stenosis: 10%–70% Thrombosis: 10%–15%	Uncovered stents Smaller diameter stents Stent migration/suboptimal placement/positioning	Choice of stent Precise deployment Venography and/or ultrasound
Encephalopathy	In compensated liver disease: up to 12% In uncompensated liver disease: up to 50% Requiring TIPS reversal: 4%	History of encephalopathy High ammonia levels Limited reserve Increased age	Reduce or close the TIPS Metronidazole, rifaximin or lactulose
Bleeding	Hemolysis: <5% Intraperitoneal bleeding: 1%–2%	Difficult anatomy Abnormal coagulation profile	Correct coagulation profile
Sepsis	2%–10%	Active infection	Treat infection before TIPS
Renal failure	Highly variable	Elevated creatinine Dehydration Diabetes High contrast load	Hydrate Use carbon dioxide contrast
Liver failure/hepatic infarction	2%–4%	Limited reserve High filtration Overdiuresis	Reduce or close the TIPS

TIPS, Transjugular intrahepatic portosystemic shunt.

CLINICAL OUTCOMES

Clinical Response to TIPS

TIPS is the most effective option for treating gastroesophageal variceal bleeding. The rebleeding rate after TIPS placement is 4% per year, the lowest among all treatment options, including endoscopic management. TIPS is reserved after failure of endoscopic management only because of the greater risks associated with it, particularly encephalopathy. Cessation of bleeding is evident almost immediately after TIPS creation.

TIPS has also been shown to be very effective in treating ascites, and it reduces the risk of ascites by 50%–80% over the life of the patient. Additionally, TIPS has been shown to improve survival and transplant-free survival compared with other treatment options. Resolution of ascites may take up to 4 weeks after TIPS placement. TIPS improves renal function in 62% of patients with hepatorenal syndrome; however, it is occasionally difficult to distinguish noncirrhotic, related chronic renal insufficiency from hepatorenal syndrome.

Complications and Management

The complications related to TIPS are shown in Table 3. The most feared complication is liver failure, which usually results from excessive portosystemic venous shunting to a liver with limited baseline reserve. If patients with no liver reserve are appropriately excluded, the risk of liver failure is 2% to 4%.

Encephalopathy can be seen in up to 12% of patients with compensated liver disease and in up to 50% of patients with uncompensated liver disease. Metronidazole, rifaximin, and/or lactulose provide significant relief for such patients; however, a small percentage (~4%) will not respond and may require TIPS narrowing or occlusion.

Death from sepsis is rare (~4%) but very difficult to treat. Bacteremia results in TIPS stent seeding, which can be very challenging or impossible to treat. Broad-spectrum antibiotics may clear the bacteremia, but in some cases, it occurs after cessation of treatment because the seeded stent shields more bacteria. Active infection is an absolute contraindication to TIPS, and any infection must be cleared before intervention.

The overall post-TIPS 30-day mortality ranges from less than 10% to up to 40%. The higher mortality rate is seen in patients with poorly compensated liver disease who are having a TIPS created on an emergent basis, usually for life-threatening variceal bleeding. For patients with compensated liver disease who are having a TIPS created on an elective basis, mortality is less than 5%. It is therefore important to carefully select patients and refer for TIPS placement before it must be done on an emergency. Vasoactive drug therapy has been shown to reduce risk of mortality at 7 days, in addition to improving hemostasis and shorten length of stay.

The Model for End-Stage Liver Disease (MELD) score, routinely used to predict survival in patients with end-stage liver disease and allocate liver transplants, was initially developed to predict survival in patients after creation of a TIPS. The cutoff score for high-risk short-term mortality (expected survival less than 3 months after TIPS creation) in the initial MELD study was 18. The MELD-Na score, which incorporates serum sodium with the serum international normalized ratio, bilirubin, and creatinine of MELD, has been shown to be a more accurate predictor of risk post-TIPS. A MELD-Na score of 15 or greater is often associated with higher morbidity and mortality post-TIPS. Both versions of the MELD score are more accurate predictors of risk after TIPS than the Child-Pugh score.

Follow-up

TIPS follow-up is mostly based on clinical signs and symptoms. Ultrasound surveillance can be useful; however, false-positive reports (elevated velocities, occluded stent) can result if ultrasound is performed too soon after TIPS creation. The newly placed TIPS often has air trapped within it, which limits ultrasound penetration and can be mistaken for sonographic appearance of an occluded or narrowed TIPS. Waiting at least 2 weeks after TIPS for the air to be absorbed is generally adequate to avoid this problem. Recurrent variceal bleeding or ascites are very specific indicators of TIPS stenosis or occlusion and should prompt a diagnostic venogram and intervention if necessary. There is a 10% rate of reintervention for stenosed or occluded TIPS. The 1-year primary unassisted patency rate for expanded PTFE-covered stents is 80% to 90%. There is no role for the use of

uncovered bare metal stents because their restenosis rate after TIPS creation is unquestionably high.

SUMMARY

The most important determinant of clinical outcomes after TIPS placement is proper patient selection and preparation. Cirrhotic patients with portal hypertension should be evaluated by a hepatologist and should be referred for TIPS after conservative management fails, but before the complications of portal hypertension manifest into an emergency. This, along with optimal patient preparation, can help reduce the morbidity and mortality related to TIPS. Additionally, the introduction of expanded PTFE stents has improved the efficacy and patency rate of TIPS, and many patients survive with a TIPS for many years. The benefits of a TIPS include reduced drop in risk from the transplant list, improved lifestyle quality (i.e., resolution of ascites), as well as reduction in the many portal hypertension–related complications and future interventions to treat those complications. But most important, TIPS is often a lifesaving procedure for those with variceal hemorrhage.

Management of Refractory Ascites

Robin Min, MD, and Yo-Hung C. Lin, MD

Ascites, the accumulation of fluid in the peritoneal cavity, is one of the major complications of cirrhosis. Approximately 50% of patients with a new diagnosis of cirrhosis will develop ascites within 10 years. It is a common reason for hospital admission and can lead to other complications such as hepatorenal syndrome and spontaneous bacterial peritonitis. The development of ascites in cirrhosis is an important marker in its natural history. One half of all cirrhotic patients with ascites die within 5 years without a liver transplant.

Refractory ascites is defined as fluid that cannot be mobilized despite a 2 g sodium–restricted diet and high-dose diuretic treatment (160 mg of furosemide and 400 mg of spironolactone) or fluid mobilization rapidly after therapeutic paracentesis. Signs of diuretic failure include lack of weight loss, inadequate sodium excretion in the urine (<78 mEq/day), and development of complications such as progressive azotemia, hepatic encephalopathy, or progressive electrolyte imbalances. Less than 10% of decompensated cirrhotic patients with ascites are refractory to standard medical treatment.

uncovered bare metal stents because their restenosis rate after TIPS creation is unquestionably high.

SUMMARY

The most important determinant of clinical outcomes after TIPS placement is proper patient selection and preparation. Cirrhotic patients with portal hypertension should be evaluated by a hepatologist and should be referred for TIPS after conservative management fails, but before the complications of portal hypertension manifest into an emergency. This, along with optimal patient preparation, can help reduce the morbidity and mortality related to TIPS. Additionally, the introduction of expanded PTFE stents has improved the efficacy and patency rate of TIPS, and many patients survive with a TIPS for many years. Management of Refractory Ascites

Robin Min, MD, and Po-Hung Chan, MD

Ascites, the accumulation of fluid in the peritoneal cavity, is one of the major complications of cirrhosis. Approximately 50% of patients with a new diagnosis of cirrhosis will develop ascites within 10 years. It is a common reason for hospital admission and can lead to other complications such as hepatorenal syndrome and spontaneous bacterial peritonitis. The development of ascites in cirrhosis is an important marker in its natural history. One half of all cirrhotic patients with ascites die within 5 years without a liver transplant.

Refractory ascites is defined as fluid that cannot be mobilized despite a 2 g sodium–restricted diet and high-dose diuretic treatment (160 mg of furosemide and 400 mg of spironolactone) or recurrence later rapidly after therapeutic paracentesis. Signs of diuretic failure include lack of weight loss, inadequate sodium excretion in the urine (<78 mEq/day), and development of complications such as progressive azotemia, hepatic encephalopathy, or progressive electrolyte imbalances. Less than 10% of decompensated cirrhotic patients with ascites are refractory to standard medical treatment.

URINARY ELECTROLYTE MEASUREMENT

Patients who gain weight on maximum diuretics but excrete less than 78 mEq of sodium per day from the urine are refractory to diuretics. To measure urinary sodium excretion, the 24-hour urinary collection is necessary as an inadequate collection can underestimate the true value; however, it can be difficult to obtain an accurate 24-hour urinary collection in a real life setting. A random urinary sodium/potassium ratio can quickly estimate urinary sodium excretion. Approximately 90% of patients with a urine sodium/potassium ratio greater than 1 excrete more than 78 mEq/day of sodium in a 24-hour collection.

MEDICAL TREATMENT CONSIDERATIONS IN REFRACTORY ASCITES

β-Blockers

Cessation of β-blockers should be considered in patients with refractory ascites. Cirrhotic patients often receive nonselective β-blockers for prevention of variceal hemorrhage. Although refractory ascites is not an absolute contraindication to β-blocker treatment, high doses greater than 160 mg/day of propranolol or 80 mg/day of nadolol should be avoided, particularly in those with signs of low perfusion such as arterial hypotension and acute kidney injury. There is an association between β-blocker use and poor survival in these patients. In a prospective observational study over an 8-month period, median survival was 6 months in patients on propranolol versus 20 months in those not on a β-blocker. We propose that the difference in survival was due to a postparacentesis circulatory dysfunction secondary to the limitation of increased cardiac output, which leads to decreased arterial pressure and low perfusion of the kidneys. β-Blockers may be reintroduced if circulatory function improves or refractory ascites reverses.

Midodrine

Oral midodrine 7.5 mg three times daily has been shown in a randomized trial to increase urinary volume, sodium excretion, and mean arterial pressure after 1 month. Given that caregivers and nursing staff may feel reluctant to administer diuretics to severely hypotensive patients, the addition of midodrine may alleviate some of these concerns. Midodrine may in a sense convert diuretic-resistant patients to diuretic-sensitive patients. Cessation of β-blocker may also contribute to an increase in mean arterial pressure, which may allow more aggressive diuresis.

SPONTANEOUS BACTERIAL PERITONITIS

Diagnosis

Spontaneous bacterial peritonitis (SBP) is an infection of the ascitic fluid in the absence of an intra-abdominal, surgically treatable source. The diagnosis is made in the presence of an elevated polymorphonuclear leukocyte (PMN) count of 250 cells/mm^3 or higher in the ascitic fluid. SBP is associated with significant in-hospital mortality, which has decreased over the past decade with prompt recognition and treatment. Because the presentations can vary from asymptomatic to mild abdominal pain to severe, a diagnostic paracentesis is often justified in hospitalized patients with cirrhosis and ascites.

Empiric Treatment

When the ascitic fluid PMN count is 250 cells/mm^3 or higher, empiric antibiotic therapy is indicated. Delaying treatment to wait for the fluid culture to grow bacteria is not recommended because an overwhelming infection can develop rapidly. Patients who meet the PMN criterion but have negative ascitic fluid cultures have been labeled with culture-negative neutrocytic ascites. These patients have the same symptoms and mortality as those with SBP and thus require the same treatment as SBP. Patients may also have fewer than 250 cells/mm^3 of PMN in their ascitic fluid yet have positive bacteria fluid culture. This is labeled monomicrobial bacterascites. It may represent an early stage SBP before there is neutrophil response versus bacterial colonization. Although colonization has been shown to resolve more than half of the time without treatment, empiric treatment is still recommended for the cirrhotic patient with monomicrobic bacterascites and any coexisting symptoms of infection, including sepsis, fever, abdominal pain, and encephalopathy.

Choice of Antibiotics

Broad-spectrum antibiotic therapy is warranted for the treatment of SBP. Specifically, the treatment of choice is cefotaxime or a similar third-generation cephalosporin because it provides coverage against 95% of the three most common bacterial species that cause SBP. Treatment may be narrowed based on sensitivities of cultured organisms. Cefotaxime 2 g every 8 hours has been shown to achieve adequate drug levels in ascitic fluid. Five days of treatment has been shown to be efficacious. Oral antibiotics may be an option as well; ofloxacin 400 mg twice per day may be as effective as cefotaxime in patients without shock. Patients who have received fluoroquinolone as prophylaxis against SBP should be treated with nonfluoroquinolone regimens because they may harbor resistant organisms.

Intravenous Albumin Infusion

Albumin infusion (1.5 g/kg body weight on day 1 followed by 1 g/kg on day 3) in addition to antibiotic treatment has been shown to decrease mortality in SBP. A randomized trial showed that albumin infusion plus cefotaxime versus cefotaxime alone decreased mortality from SBP from 29% to 10%. The benefit of albumin largely stems from increased renal perfusion and preservation of kidney function during SBP.

Follow-up Paracentesis

A repeat paracentesis to document resolution of SBP is generally not necessary. Most cirrhotic patients with SBP and typical ascitic fluid analysis will show clinical response on antibiotic treatment. However, if symptoms persist or worsen, atypical organisms grow in culture, or suspicion of secondary peritonitis arises, then a repeat paracentesis can be performed to evaluate possible ongoing infection.

INTERVENTIONAL METHODS IN THE TREATMENT OF REFRACTORY ASCITES

Liver Transplantation

Liver transplantation is the best therapy for cirrhotic patients with refractory ascites. The development of refractory ascites confers a poor prognosis, with approximately half of patients dying within 1 year without transplantation; therefore, suitable candidates should be referred to a liver transplant center.

Paracentesis and Albumin Replacement

Paracentesis can offer expedited relief for patients suffering symptoms of large-volume ascites, such as abdominal distention, pain, dyspnea, and early satiety. For volume removals of 5 L or more, an infusion of albumin (6–8 g/L of ascites removed) at or around the time of paracentesis may reduce mortality, electrolyte abnormalities, and renal dysfunction. Serial paracentesis is not an optimal long-term solution because it depletes proteins and worsens malnutrition; therefore, liver transplantation and other options to reduce portal hypertension should be considered in those who have refractory ascites.

The preferred site for needle entry is 3 cm medial and 3 cm superior to the anterosuperior iliac spine on the left lower quadrant of the abdomen. The right lower quadrant is less desirable because the

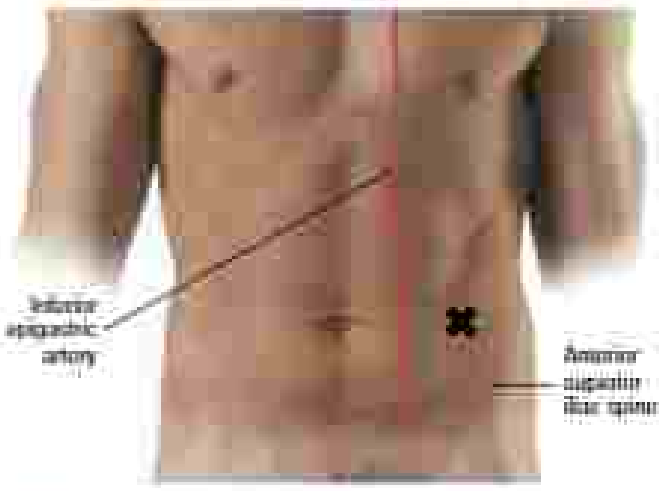

FIG. 1 Preferred needle entry site for paracentesis. (From Gilroy AM, Macpherson BR, Ross LM, et al. Atlas of Anatomy. Philadelphia: Thieme; 2016.)

cecum can become distended in patients who take lactulose. A distended cecum has a higher risk of perforation. The needle should avoid areas with cutaneous infection, abdominal wall hematomas, scars, or visibly engorged subcutaneous veins. Bedside ultrasound is useful in locating a safe site for needle entry away from vascular structures.

The paracentesis needle can be inserted with either the angular technique or the Z-track technique. In the angular technique, the needle is inserted obliquely from the cutaneous site into the peritoneum. In the Z-track technique, cutaneous tissues are pulled down and the needle is inserted straight into the peritoneum. These techniques ensure that cutaneous and peritoneal needle entry sites do not directly overlap each other, thereby minimizing postprocedure ascitic fluid leakage (Fig. 1).

Transjugular Intrahepatic Portosystemic Shunt

Transjugular intrahepatic portosystemic shunt (TIPS) is an artificial communication between the portal vein and hepatic vein usually placed by an interventional radiologist (Fig. 2). The direct result of TIPS placement is a significant reduction in portal pressure through the creation of an alternative pathway for portal venous flow. Before and after TIPS placement, the proceduralist can quantify the degree of portal hypertension by measuring the portosystemic gradient. The benefit of TIPS is in lowering portal hypertension, the cause of many complications of cirrhosis. After successful TIPS procedure, ascites may completely resolve along with portosystemic shunts (e.g., esophageal varices).

Under fluoroscopic guidance, the interventional radiologist accesses the liver through the internal jugular vein in the neck. Once venous access is confirmed, the radiologist inserts a guidewire and introducer sheath that enables access to the hepatic vein by gaining the superior vena cava and the inferior vena cava. Once the catheter enters the hepatic vein, the radiologist injects contrast to locate the portal vein and advances a needle through the liver parenchyma to connect the two veins. An inflated angioplasty balloon creates the channel for the shunt along the needle tract. Last, the shunt forms by placing a polytetrafluoroethylene covered stent to maintain the tract. The covered stent has been a standard for many years. It has a higher patency interval compared with the older uncovered stent.

Absolute contraindications for TIPS include heart failure, severe tricuspid regurgitation, and severe pulmonary hypertension. TIPS in the setting of these conditions can lead to severe cardiac volume overload because blood flow is diverted past the liver and into the right heart. Sepsis and biliary obstruction are other absolute contraindications to TIPS placement. The Model for End-Stage Liver Disease (MELD) score, now used to prioritize organ allocation in liver transplantation, was initially developed to predict the 3-month mortality after TIPS. A MELD score greater than 18 has been associated with poorer outcomes after TIPS. As procedural technology, including the stent itself improves, however, higher MELD scores may inform the decision for TIPS but are no longer absolute contraindications. Hepatic encephalopathy is a common occurrence after TIPS with an incidence of up to 45%. When mild, hepatic encephalopathy can be controlled through conservative medical management; however, severe baseline encephalopathy is another contraindication to TIPS.

Peritoneovenous Shunts

Peritoneovenous (shunt) drain ascitic fluid from the peritoneal cavity into systemic veins, such as the superior vena cava. The Denver shunt, popular in the 1970s, is the only peritoneovenous shunt still manufactured today. Although historically requiring an invasive approach, today it is placed percutaneously in a minimally invasive procedure through an internal jugular or subclavian route. The shunt is made of soft tubing connected to a pump chamber that lies subcutaneously over the lower ribs. Ascitic fluid flows spontaneously from the peritoneum to the superior vena cava, but manual pumping helps avoid buildup of proteinaceous material in the shunt. Nonetheless, because of poor long-term patency and complications such as coagulopathy, superior vena cava thrombosis, and sepsis, peritoneovenous shunts are infrequently used today.

Peritoneal Catheters

A peritoneal catheter (PleurX) inserted into the peritoneum can be an option for ascites removal in patients with the goal of palliation. Given the risk of introducing infection into the peritoneum, this option is typically reserved for patients who are near end of life. The catheter can be placed with minimal discomfort using a small incision. It is then tunneled in place to the skin and connected to a catheter bag. Patients may open the catheter to the bag at their convenience. This allows patients, who are likely less mobile, to avoid traveling to medical facilities for repeated paracenteses.

Experimental Options

Clonidine and Midodrine

Clonidine is an α_2-adrenergic receptor agonist that suppresses the renin-aldosterone system, which is activated in patients with refractory ascites. A randomized trial of 0.075 mg of oral clonidine twice daily versus placebo in cirrhotic patients with ascites showed faster mobilization of ascites with few complications. Midodrine is an oral vasopressor that acts through α_1-adrenergic activation. Midodrine (7.5 mg every 8 hours) or a combination of midodrine and clonidine (0.075 mg every 12 hours) plus standard medical therapy have been shown to be superior to standard medical therapy alone for the control of ascites.

Low-Flow Ascites Pump

European surgeons and radiologists have collaborated to develop a pump (AFEApump) that moves ascitic fluid from the peritoneal cavity into the urinary bladder. Several studies have shown a decrease in the need for large-volume paracenteses in those with refractory ascites, with most patients not requiring paracenteses after implantation of the pump system. The most commonly observed complications include blockage of the peritoneal catheter, infections, and bleeding. A multinational, randomized trial of the low-flow ascites pump versus TIPS versus therapeutic paracentesis is underway.

Endoscopic Ultrasound-Guided Placement of Gastric Stents

Gastric stents are placed under endoscopic ultrasound guidance into the stomach, creating a connection between the stomach lumen and

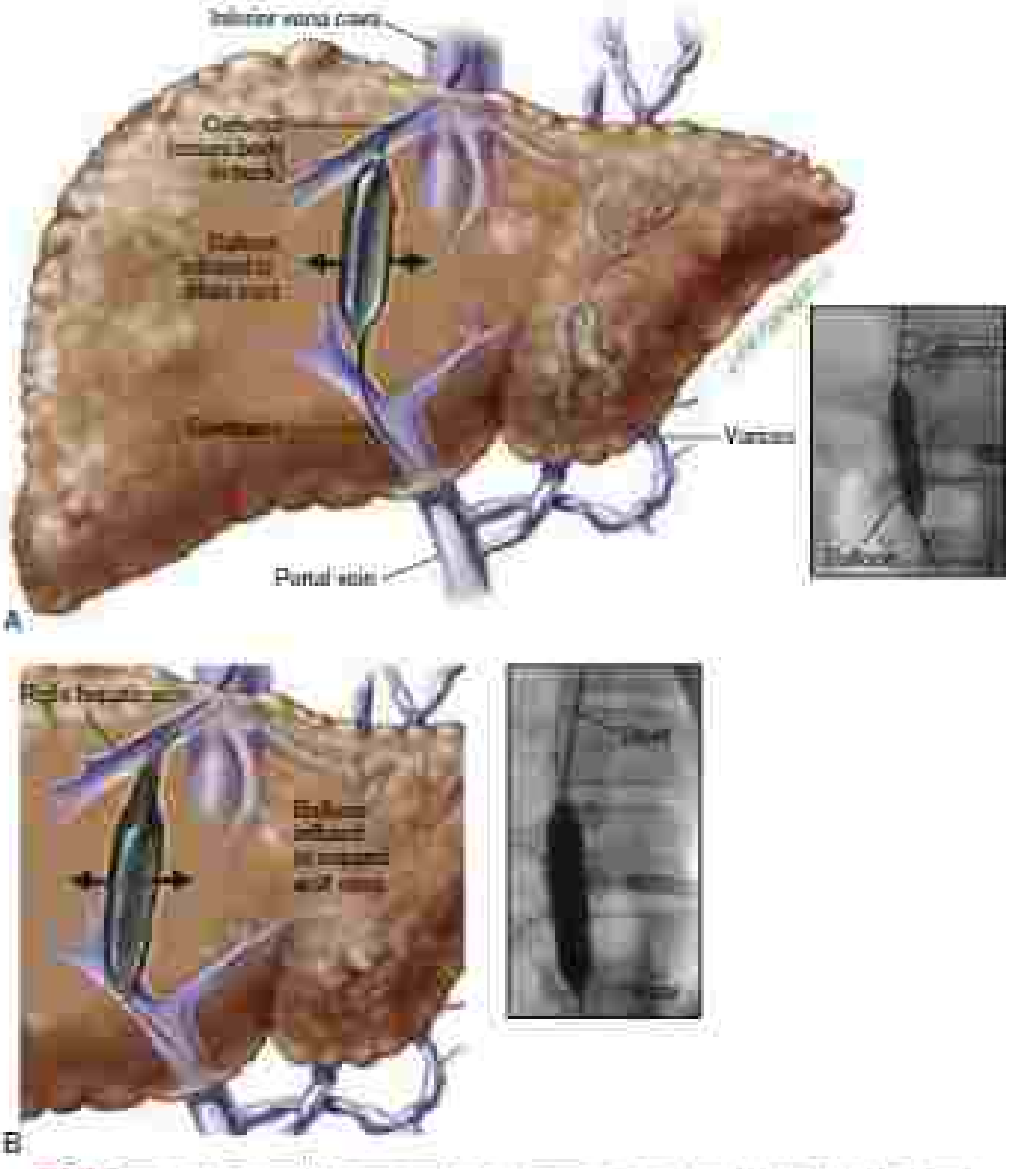

FIG. 2 Transjugular intrahepatic portosystemic shunt placement. (Courtesy Johns Hopkins Medical Institutions.)

the peritoneum. This is a relatively new method for controlling ascites that has two small case series. Complications included stent migration, stent occlusion by food, and leakage of gastric content into the peritoneum. The procedure has been studied only in malignant ascites. Symptomatic relief and technical success have been shown. By alleviating the need for paracentesis, patients may have improvement in their quality of life.

Management of Hepatic Encephalopathy

Tanay Wooreta, MD, MPH, and Aarya Sharma, MD, M c

Hepatic encephalopathy (HE) is a life-threatening and potentially reversible complication of liver disease that can be seen in cirrhosis, acute liver failure, and in the setting of portal systemic bypass.

PATHOPHYSIOLOGY

The pathogenesis of HE is multifactorial and incompletely understood, but the prevailing theory centers around the neurotoxic effects of ammonia and other toxins that are inadequately cleared because of liver dysfunction. Ammonia is produced mainly in the gastrointestinal tract by the bacterial metabolism of dietary protein and other nitrogenous compounds and subsequently enters the portal circulation where it is converted to urea by hepatocytes under physiologic conditions. Additional sites of ammonia detoxification include the kidneys and skeletal muscle.

Ammonia accumulates in the systemic circulation resulting from portal hypertension and cirrhosis, or as a consequence of a portosystemic shunt, and traverses the blood-brain barrier. Astrocytes convert ammonia and the neurotransmitter glutamate into glutamine, which is an active osmole, thereby precipitating intracellular swelling and cerebral edema. Myriad additional factors are suspected to play a role in central nervous system dysfunction in HE, including excessive activation of the neuroinhibitory γ-aminobutyric acid–benzodiazepine system, dysregulated cerebral blood flow, derangements in the gut microbiome of cirrhotic patients, inflammatory cytokines, neurosteroids, manganese, and manganese deposition in the basal ganglia.

CLASSIFICATION AND DIAGNOSIS

HE manifests as a broad spectrum of neuropsychiatric and motor disturbances. The diagnosis of overt HE is clinical and made after excluding other causes of acute brain dysfunction in a patient with liver disease or portosystemic shunt. The West Haven Criteria is the gold standard classification system for HE (Table 1). Of note, covert HE is a practical entity comprising minimal HE (sometimes referred to as grade 0) and West Haven grade 1 HE. Patients with chronic liver disease affected by minimal HE typically have abnormalities that are only detected through specialized psychometric or neuropsychologic testing. The presence of minimal HE is associated with impaired driving ability, increased falls, reduced quality of life, and an increased risk of progression to overt HE.

Extrapyramidal signs common in HE include muscular rigidity, parkinsonian-like tremor, and hypokinesia. Various other neuromuscular findings can be observed such as an upgoing Babinski reflex, hyperreflexia, and hypertonia, although deep tendon reflexes may become attenuated with progression to coma. On physical examination, asterixis is a loss of postural tone that can be elicited as a bilateral, flapping tremor with dorsiflexion of the wrists, but may be observed elsewhere, such as the tongue. Of note, asterixis is a nonspecific feature of other metabolic encephalopathies independent of liver disease, such as uremic encephalopathy.

The finding of focal neurologic deficits on examination, new-onset seizures, or relevant history of falls or trauma merits neuroimaging to evaluate for intracranial hemorrhage or structural brain lesions.

Electroencephalography typically demonstrates triphasic wave changes in patients with HE but may be helpful in excluding subclinical seizures.

Elevated circulating ammonia levels are observed in the majority of patients with HE; however, in cirrhotic patients, ammonia levels are not recommended as a diagnostic or staging test for HE and do not have prognostic value for HE. Moreover, in patients with end-stage liver disease who do not have clinical signs of HE, an elevated serum ammonia level is not an indication to begin treatment. Young patients presenting acutely with fulminant hyperammonemia (>1000 μmol/L) in the absence of acute liver failure should be evaluated for a urea cycle defect or other inherited hyperammonemia syndromes by a metabolic genetics expert.

PRECIPITATING FACTORS

The majority of patients with cirrhosis who present with an episode of overt HE will have an underlying precipitating factor and management aimed at correcting the underlying cause will usually reverse encephalopathy (Table 2).

Each episode of HE requires a thorough evaluation for active infection and sepsis, including diagnostic paracentesis to exclude spontaneous bacterial peritonitis in patients with ascites, which may be primary or secondary. Typical considerations also include evaluation of urinary tract, pulmonary, and skin and soft tissue sources of

TABLE 2 Common Causes of Hepatic Encephalopathy in Cirrhotic Patients

Infections (e.g., spontaneous bacterial peritonitis, urinary tract infection, pneumonia)	Drugs: sedatives (benzodiazepines, hypnotics), opiates, alcohol
Metabolic: hyponatremia, hypokalemia, metabolic alkalosis, hypovolemia	Portosystemic shunt (spontaneous or surgically or radiographically placed)
Constipation	Renal failure
Noncompliance with lactulose	Vascular (rare): portal vein thrombosis, hepatic vein thrombosis
Gastrointestinal bleeding	Hepatocellular carcinoma

infections. Empiric antibiotic therapy should be initiated promptly if there is high clinical suspicion for infection after collection of relevant cultures while awaiting results, in conjunction with initiation of lactulose therapy as outlined in the following section.

Gastrointestinal bleeding is a common precipitant of HE and may be suggested by an elevated blood urea nitrogen/creatinine ratio, presence of melena or hematochezia, and a known history of varices or portal hypertensive gastropathy. Gastrointestinal bleeding decreases perfusion to the key organs involved in ammonia clearance, the liver and kidneys, while concurrently depositing a large amount of protein substrate in the gut for formation of nitrogenous compounds.

Cirrhotic patients are vulnerable to electrolyte disturbances, particularly hypokalemia and hyponatremia, which can lead to decompensations of HE. The risk of hypokalemia is elevated in the setting of diuretic usage, lactulose therapy, and poor oral intake that worsens intravascular volume depletion. Rectifying hypokalemia is essential because this promotes renal ammonia production. Metabolic alkalosis and hypovolemia may be mediated by aggressive diuretics, nasogastric tube (NGT) suction, large volume paracentesis, or excessive diarrheal losses, which can be aggravated by lactulose therapy. The presence of a hypokalemic metabolic alkalosis further contributes to HE by facilitating ammonia transport through the blood brain barrier.

Hyponatremia is common in end stage liver disease because of impaired free water excretion, and the acuity and magnitude of the decrease in serum sodium relative to the patient's baseline must be carefully considered before invoking this as the main driver for HE.

Noncompliance with lactulose and resultant constipation is another common culprit. Sedative agents, in particular benzodiazepines, opiates, hypnotic agents, and alcohol, may precipitate HE. The sedative properties of valproic acid can cause an acute elevation in serum ammonia levels, although this agent is rarely used in end stage liver disease.

In parallel with the evaluation of precipitating factors for HE, it is important to initially consider a broad differential diagnosis in a patient presenting with an acute state of confusion, which can include complications related to diabetes such as hypoglycemia, ketoacidosis, or hyperosmolar state, drug or alcohol intoxication or withdrawal syndrome, Wernicke's encephalopathy, nonconvulsive seizures, or a primary psychiatric disorder. It is also prudent to maintain central nervous system sources of infection on the differential diagnosis for HE. Rarely, disseminated fungal infections such as cryptococcal meningitis may mimic HE in cirrhotic patients even in the absence of another cause of immunocompromise.

Finally, if the tempo of cognitive decline is more consistent with a subacute or chronic process, consideration of dementia due to a vascular or neurodegenerative disease, or another primary CNS process such as neoplasm or normal pressure hydrocephalus, may be appropriate.

TREATMENT

A central tenet of management of HE is the identification and reversal of any precipitating factors, particularly the treatment of underlying infection, correction of electrolyte abnormalities, and discontinuation of sedatives or opiate medications. In patients with chronic liver disease, pharmacologic therapies are aimed at lowering the blood ammonia level and reducing gut production of nitrogenous substances, irrespective of whether the serum ammonia level is indeed elevated (Table 3).

Nonabsorbable Disaccharides

Lactulose is considered first line therapy for the treatment of episodes of overt HE by the American Association for the Study of Liver Diseases (AASLD) and European Association for the Study of the Liver (EASL) guidelines. Lactulose is a nonabsorbable disaccharide metabolized to short chain fatty acids by colonic bacteria, thereby acidifying the bowel lumen, promoting the conversion of ammonia to ammonium, and stimulating fecal excretion of nitrogen containing compounds as a result of its osmotic laxative properties. Because of the relatively benign side effect profile, consisting of abdominal pain, flatulence, and diarrhea, we recommend maintaining a low threshold for the initiation of lactulose in patients with decompensated cirrhosis who exhibit early signs of HE.

Administration of lactulose to decompensated HE must be titrated to effect. Patients with clinically apparent HE should be initiated on scheduled lactulose 20 to 30 g (30–45 mL) every hour until defecation occurs, and the dose may be spaced to every 4 to 6 hours depending on clinical improvement. After the initial episode of HE, lactulose is recommended for prevention of recurrent episodes and titrated to achieve approximately two to three bowel movements per day. In patients unable to safely swallow (i.e., aspiration risk), obtain enteral access via NGT if appropriate for

TABLE 3 Treatment of Hepatic Encephalopathy

Initial Episode of Overt HE	
Lactulose	Oral: Start with 20–30 g (30–45 mL) every hour until defecation occurs. Reduce to 20 g (30 mL) every 4–6 hours until improvement. Maintenance: 20 g (30 mL) every 8–12 hours for goal 2–3 stools/day. Retention enema: Add 300 g (300 mL) of lactulose to 700 mL of tap water. Retain for 1 hour. Repeat every 4–6 hours.
Rifaximin[a]	Oral: 400 mg 3 times daily or 550 mg twice daily orally, up to 10 days.
Prevention of Recurrent Episodes of Overt HE	
Lactulose	Oral: 20 g (30 mL) titrated to goal 2–3 stools/day
Rifaximin	Oral: 550 mg orally twice daily
Second-line treatments for refractory cases	Supplementation with oral branched-chain amino acids. Evaluate and treat for zinc deficiency. Embolization of large portosystemic shunts.

[a]Consider adding if inadequate response to lactulose within 2–3 days.

lactulose administration. Alternatively, lactulose may be administered via retention enemas in patients with high grade HE who have contraindications to enteral access. Lactitol is a nonabsorbable disaccharide that may have comparable effectiveness to lactulose in the treatment of HE with fewer side effects; however, it is unavailable within the United States.

Polyethylene Glycol

The single-center Hepatic Encephalopathy: Lactulose vs Polyethylene Glycol 3350 Electrolyte Solution trial randomized patients to receive either lactulose or polyethylene glycol 3350 (PEG) electrolyte solution (GoLYTELY) and found a significantly faster improvement in HE within 24 hours among patients who received PEG compared with lactulose. The dose of PEG solution was 4 L orally or via NGT compared with three or more doses within 24 hours of lactulose 20 to 30 g orally or via NGT. In cirrhotic patients, PEG may be an effective alternative to lactulose therapy in the treatment of overt HE, presumably resulting from its potent cathartic effect on the colon; however, additional trials are needed before this treatment can be routinely recommended.

Low-Absorbable Antibiotics

Modulating the composition of gut flora to decrease ammonia production, which includes reducing the burden of urease-producing anaerobic bacteria, is the principle behind the use of poorly absorbed antibiotics in HE. Rifaximin, a semisynthetic nonaminoglycoside antibiotic, is recommended after the second episode of overt HE as secondary prophylaxis to prevent recurrences per AASLD and EASL guidelines. The prophylactic dose of rifaximin is 550 mg orally twice daily, and it cannot be administered via enema. Rifaximin can be initiated during the acute treatment of decompensated HE in patients with end-stage liver disease; however, it is not supported by the same strong recommendation as lactulose for this indication.

In one randomized trial, patients with overt HE receiving a short course (<10 days) of rifaximin 400 mg three times daily in addition to lactulose had significantly greater reversal of HE, decreased mortality, and length of stay compared with patients receiving lactulose alone. It is reasonable to add rifaximin in patients who have not improved despite lactulose monotherapy within 2 to 3 days of treatment. For limiting a recurrent episode of overt HE, secondary prophylaxis with a combination of lactulose and rifaximin is strongly recommended and may be continued indefinitely or until liver transplantation in select patients.

Neomycin, an aminoglycoside antibiotic, is no longer widely used in clinical practice for lowering of blood ammonia levels because of the adverse effects of ototoxicity and nephrotoxicity and unclear efficacy in clinical trials. Similarly, the use of metronidazole for the treatment of HE is currently limited because of the adverse effect profile and emergence of newer therapies.

Dietary Considerations

Although a high protein diet is associated with HE, cirrhotic patients have high rates of malnutrition and skeletal muscle catabolism, which further compromises extrahepatic ammonia detoxification. Cirrhotic patients with HE are recommended to receive 1.2 to 1.5 g/kg per day of protein intake and 35–40 kcal/kg (based on dry weight) according to the 2013 International Society for Hepatic Encephalopathy and Nitrogen Metabolism Guidelines. A standard nonprotein restricted diet is appropriate for most patients with mild to moderate HE that are able to take in nutrition orally.

ALTERNATIVE THERAPEUTIC OPTIONS IN REFRACTORY HE

A subset of patients with overt HE may prove refractory to conventional treatments for reasons that are incompletely understood. In this population, besides consideration of spontaneous portosystemic shunting as the etiology of intractable HE, there may be a benefit to attempting alternative therapies supported by varying degrees of evidence.

Supplementation with oral branched-chain amino acids (BCAA) is associated with a beneficial effect on HE but does not confer a survival benefit. Low levels of BCAA have been found in cirrhotic patients with sarcopenia; mechanistically, BCAA supplementation may promote ammonia detoxification by bolstering skeletal muscle anabolism. Per the 2014 AASLD/EASL practice guidelines, oral BCAA can be used as an alternative agent to treat patients unresponsive to conventional therapy.

Zinc, a cofactor for enzymes in the urea cycle, may facilitate ammonia clearance. We recommend evaluating for zinc deficiency, which is common in cirrhotic patients, and treating when indicated. A beneficial effect of empiric zinc supplementation in recurrent or chronic HE has not been established in large randomized trials; however, this is a relatively inexpensive and low-risk intervention.

L-ornithine is another supplement that may exert a modest benefit in HE, though robust data are lacking. In one randomized trial, acetyl-L-carnitine supplementation was associated with improvement in fatigue severity and other performance metrics in mild to moderate HE.

Administration of L-ornithine L-aspartate (LOLA) provides substrates to aid in the metabolism of ammonia and may have clinical benefit in overt HE on the basis of limited clinical trial data. Intravenous L-ornithine L-aspartate is currently not available in the United States.

The use of flumazenil, a benzodiazepine antagonist, has been associated with transient clinical improvement in HE in select patients in the absence of exogenous benzodiazepine exposure; however, it is not US Food and Drug Administration approved for the treatment of HE and rarely used for this purpose.

Probiotics, cultures of live microorganisms, may improve gut dysbiosis in cirrhosis and possibly improve recovery from overt HE and reduce recurrence relative to placebo or no intervention; however, current supporting data from clinical trials are low quality and insufficient to make a strong recommendation.

Glycerol phenylbutyrate and sodium phenylacetate are ammonia scavengers that may emerge as promising therapies to lower serum ammonia levels in patients with HE based on encouraging results from preliminary clinical trials.

Albumin infusion may be a useful adjunct to lactulose in the treatment of overt HE; however, supporting clinical trial data are very limited.

Fecal microbiota transplantation is another developing treatment that may be effective when combined with standard care to reduce HE recurrence; however, newer clinical trial data are needed. Ultimately, liver transplantation is the definitive therapy for end-stage liver disease associated with HE resistant to optimal medical therapy.

ADDITIONAL MANAGEMENT CONSIDERATIONS

Agitation may be a component of overt HE that is expected to improve with treatment. If patients are considered a hazard to themselves and caretakers, haloperidol is preferred over benzodiazepines because of the risk of accumulation of long-acting active metabolites with benzodiazepine therapy. If opiate therapy is required in the inpatient setting, we recommend avoiding hydromorphone for acute pain relief in cirrhotic patients because of the risk of accumulation of active metabolites in the setting of end-stage liver disease, in favor of judicious usage of fentanyl or oxycodone, resulting from the risk of precipitating or worsening preexisting HE.

Hepatic Encephalopathy Associated With Portosystemic Shunts

Cirrhotic patients who undergo a transjugular intrahepatic portosystemic shunt (TIPS) procedure for treatment of portal hypertensive complications are particularly vulnerable to the development of HE, with some studies estimating as high as 50% incidence of postprocedural encephalopathy. Routine prophylactic therapy with lactulose or rifaximin is not recommended for prevention of HE post-TIPS procedure on the basis of a randomized controlled clinical trial that failed to show benefit.

Management of HE post-TIPS involves similar principles of identifying and treating reversible precipitating causes, and initiating therapy with lactulose or combination lactulose and rifaximin. For the minority of patients who develop refractory HE post-TIPS, shunt diameter reduction, or even shunt closure, is an effective intervention to reverse HE in the majority of cases but may provoke complications related to increased portal hypertension and the original indication for TIPS placement.

Alternatively, the development of spontaneous portosystemic shunts, such as splenorenal shunts, may precipitate refractory HE in cirrhotic patients. In this circumstance, a radiographic procedure to identify and embolize the portosystemic collaterals may be indicated to facilitate resolution of HE in affected patients, although this strategy carries a potential risk of exacerbating portal hypertension.

Hepatic Encephalopathy Associated With Acute Liver Failure

The presence of HE is required for the diagnosis of acute liver failure (ALF) and the management is distinct compared with HE in patients with chronic liver disease. In patients with ALF, ammonia levels have a strong correlation with the presence and severity of HE, and the risk of cerebral herniation and death is highest with persistently elevated serum ammonia levels of 150 to 200 μmol/L or higher. Patients with ALF associated with grade 2 HE or higher benefit from close management in an intensive care unit and should be transferred to an institution with a liver transplant center. Patients with grade 3 HE or higher will require intubation for airway protection with neurologic checks performed every 1 to 2 hours to evaluate for signs of elevated intracranial pressure (ICP). A computed tomographic scan of the brain should be obtained in patients with ALF with a deterioration in neurologic examination to assess for cerebral edema. AASLD guidelines advocate maintaining a serum sodium between 140 and 145 mmol/L and the use of hypertonic saline infusion and intravenous mannitol boluses to reduce ICP. Additional measures include elevation of the head of the bed greater than 30 degrees, and maintenance of euglycemia and normothermia because mild hypothermia has not been shown to have a significant benefit in ALF. Using a ventilation strategy to lower partial pressure of carbon dioxide to 25 to 30 mm Hg may be desirable in the acute setting to promote cerebral vasoconstriction. Propofol is the preferred agent for sedation.

The use of invasive devices to monitor ICP is controversial and center dependent because ICP monitoring has not been shown to consistently improve outcomes in unselected patients with ALF and high-grade HE. Hemodynamically unstable patients should be empirically started on broad-spectrum antibiotics because of the high risk of sepsis in this population.

In patients with ALF and HE, there is not any specific pharmacologic treatment that has been clearly shown to improve overall outcomes. Lactulose may be attempted in the early stages of HE, although the benefit is unproven; rifaximin does not have a role in ALF management.

Preliminary clinical trial data have suggested a possible benefit of extracorporeal liver replacement devices, such as the *Molecular Absorbent and Recirculating System* in improving HE in patients with ALF. However, MARS and other bioartificial support systems do not appear to have a survival benefit and are not endorsed by guidelines.

MANAGEMENT OF BUDD-CHIARI SYNDROME

Kar-Ele Kesari, MD, Nicholas Nissen, MD, and Andrew Klein, MD, MBA, FACS

Initially noted by Carl Prosper von Baltzansky in 1842 and later formally described separately by the English physician George Budd in 1845 and the Austrian pathologist Hans Chiari in 1899, Budd-Chiari syndrome (BCS) remains a rare disease, a so-called orphan syndrome. As a result, most of the studies that deal with this condition have been small in numbers, often single institutional and retrospective in nature, and most of the recommendations regarding its management are from expert opinions and institutional biases rather than robust data. In this chapter, we summarize the most up-to-date information regarding the diagnosis and management of this disease.

Considered a form of splanchnic venous thrombosis, BCS is defined as hepatic venous outflow obstruction that can occur at any level from the small hepatic veins to the junction of the inferior vena cava (IVC) and the right atrium. Excluded from this definition are forms of outflow obstruction resulting from hepatic vein occlusive disease/sinusoidal obstruction syndrome (often from administration of toxic agents and seen almost exclusively in bone marrow transplantation) or cardiac disorders. BCS is a rare disease, occurring in roughly 4 patients per 1 million per year. Interestingly, the etiology of BCS often varies based on demography and geography; most Western patients suffer from venous outflow obstruction resulting from hepatic vein thrombosis, whereas Asian patients are more commonly found to have venous obstruction from a membranous web at the junction of the vena cava and hepatic veins. Considerable interest in associated hypercoagulability syndromes has led to the identification of a number of hematologic abnormalities associated with BCS, including myeloproliferative disorders (49%) or inherited thrombophilias (21%) such as Factor V Leiden (12%), protein C deficiency (9%), protein S deficiency (5%), G20210A prothrombin (3%) and antithrombin deficiency (3%). Acquired conditions such as antiphospholipid antibodies (25%), hyperhomocysteinemia (22%), paroxysmal nocturnal hemoglobinuria (19%), oral contraceptives (33%), pregnancy (6%), Behçet syndrome (2.5%) and sarcoidosis (1%) are also found in cohorts of patients with BCS. More than 80% of patients will be found to have at least one hematologic abnormality in BCS, and almost one half of patients will have multiple abnormalities.

Despite etiologic differences, there seems to be a common pathway in the downstream pathophysiology of BCS that involves liver congestion resulting from hepatic venous outflow obstruction, in turn leading to intrahepatic venous congestion with elevated sinusoidal pressure, erythrocyte extravasation in the hepatic parenchyma, and tissue hypoxia. This cascade ultimately leads to injury to surrounding perisinusoidal hepatocytes. Of note, the caudate lobe of the liver drains directly into the vena cava via multiple short veins that are usually spared in BCS. As a result, compensatory hypertrophy and hyperplasia in the unobstructed caudate lobe is manifest by caudate lobe enlargement, which is seen in most patients with BCS at the time of presentation. Without intervention, or if venous collateral systems do not develop early in the process, ongoing chronic tissue injury leads to the development of hepatic fibrosis, regenerative nodules, and possibly to cirrhosis.

CLINICAL PRESENTATION AND DIAGNOSIS

The dominant clinical feature of BCS is the development of ascites in an otherwise healthy person without preexisting liver disease or recognized risk factors for a liver disorder. Most patients with BCS present with ascites and/or abdominal pain, typically of less than 1 month's duration. Liver function is generally preserved, and liver function tests are normal or minimally deranged. A small fraction of BCS patients (<5%) develop fulminant hepatic failure with massive hepatocyte necrosis, rapidly progressive encephalopathy, and profound coagulopathy. In an equally small number of patients, hepatic vein occlusion is initially silent clinically, and BCS is identified only when an evaluation, including vascular imaging, is performed for a patient with cryptogenic cirrhosis. A prospective European study of 163 patients with BCS by Darwish Murad et al. identified esophageal varices in 58%, hepatic encephalopathy in 9%, portal vein occlusion on presentation in 18%, caudate hypertrophy in 77%, and involvement of all three hepatic veins in 75%. Histologically, 64% had sinusoidal congestion, 59% had fibrosis, 23% had hepatocellular necrosis, and 18% had cirrhosis.

Imaging continues to be the cornerstone of diagnosis and management of BCS and has three main roles: to establish the diagnosis; to plan care, especially endovascular intervention strategies; and to evaluate and distinguish commonly found benign regenerative liver nodules from rare primary liver malignancies. Initial evaluation with duplex ultrasonography of the liver is recommended and has a diagnostic sensitivity of greater than 85% in adults. In addition to ultrasound, triple-phase liver dedicated magnetic resonance imaging or rapid sequence computed tomography are ideal not only to establish the diagnosis of BCS, but also to assist the multidisciplinary team in therapeutic planning. Within the confines of multidisciplinary care, the inferior vena cavogram and hepatic venogram can add valuable information to the treatment planning by allowing the radiologist to measure venous pressures in the infrahepatic and suprahepatic vena cava, as well as in the right atrium.

Because of its high association, any patient with a known hematologic abnormality presenting with acute or chronic liver disease should be evaluated for presence of BCS. The converse is also true. Patients presenting with BCS should be thoroughly screened for hematologic abnormalities. History should include questions regarding use of oral contraceptives, personal and family history of hematologic abnormalities, and signs and symptoms of associated diseases. Laboratory workup should include evaluation for myeloproliferative neoplasia and several unique *JAK2* mutations, starting with *JAK2* V617F mutation. Discovered in 2005, the detection of *JAK2* V617F mutation will alleviate the need for bone marrow biopsy in up to 65% of patients who might otherwise require it to further delineate presence of myeloproliferative neoplasia. Other targets of investigation are continually being discovered, including *JAK2* exon 12 mutations, calreticulin, 5,10-methylenetetrahydrofolate reductase 2, and thrombopoietin receptor gene mutations. Because of the diversity and complexity of the various (and often rare) inherited thrombophilias and acquired conditions underlying BCS, inclusion of a hematologist in the multidisciplinary team is highly encouraged. Finally, a liver biopsy should generally be avoided as the initial presentation of the BCS patient, resulting from concerns for bleeding because anticoagulation is the mainstay of therapy at this stage. Furthermore, there does not appear to be a relationship between early liver pathology and survival in BCS.

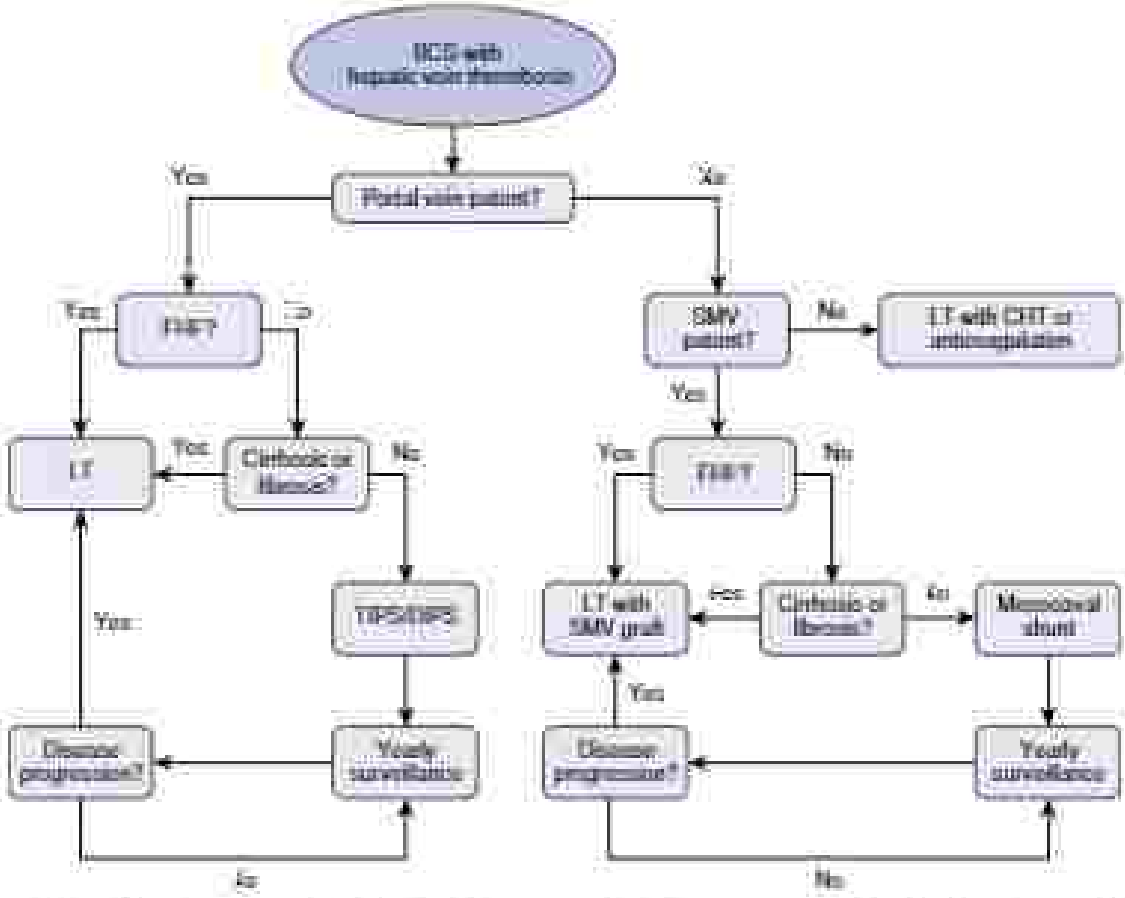

FIG. 1 Proposed algorithm for the management of Budd-Chiari Syndrome. CRT, Caval reconstruction; DIPS, direct intrahepatic portacaval shunting; FHF, fulminant hepatic failure; LT, liver transplantation; SMV, superior mesenteric vein; TIPS, transjugular portosystemic shunting.

TREATMENT

The natural history of untreated hepatic venous outflow obstruction is generally progressive hepatic fibrosis and cirrhotic changes. Cazenave and colleagues have demonstrated that persistent sinusoidal congestion leads to hepatocyte atrophy and impaired cellular regeneration. In fact, in a study reported by McCarthy and colleagues, 12 of 14 patients with BCS who were managed nonoperatively died within 6 months of diagnosis. An exception to this poor prognosis may be realized by the subset of patients determined to have incomplete hepatic venous obstruction. Preventing progressive liver dysfunction resulting from sinusoidal hypertension remains a central principle for managing BCS.

A multidisciplinary approach is key to the successful management of BCS. A stepwise strategy should focus on (1) preventing further venous occlusion; (2) managing the clinical sequelae of venous obstruction (such as ascites); and (3) portal decompression to prevent progression to cirrhosis. Anticoagulation is standard in BCS unless contraindicated by bleeding risk, but this serves only to prevent propagation of thrombosis and does not reverse established venous obstruction. Ascites and hepatic encephalopathy should be managed similar to other patients with end-stage liver disease with salt restriction, appropriate use of diuretics, and appropriate use of lactulose and rifaximin. Portal decompression is accomplished through implementation of one or more of the radiologic or surgical techniques discussed in the following section. A useful management algorithm for BCS is proposed in Fig. 1.

An important concept in the treatment of BCS that has evolved over the past decade is a stepwise approach to portal decompression. Liver transplantation (LT), which is the most radical solution for BCS, is rarely first-line therapy, and in recent years the use of portal decompressive surgery has waned and been replaced by minimally invasive interventional radiologic therapies. This strategy has led to overall survival rates of approximately 80% (Table 1). The primary goal of these interventional treatments for patients with BCS remains reduction of hepatic congestion and associated sequelae such as portal hypertension. In order of increasing invasiveness, the therapeutic options include pharmacologic agents such as diuretics and anticoagulants, thrombolysis, percutaneous transluminal angioplasty/stenting (PTAPS), transjugular intrahepatic portosystemic shunting (TIPS), direct intrahepatic portocaval shunting (DIPS), and the surgical options of portosystemic shunting and LT.

Anticoagulation should be viewed as a means to prevent clot progression or recurrent venous thrombosis, but it usually will not reverse established disease. Most patients with BCS will have to remain on anticoagulation therapy long term. In a follow-up to a large European study of patients with BCS (European Network for Vascular Disorders of the Liver [en-TAV-ble]) by Seijo and colleagues, about 40% of patients were treated with pharmacologic interventions only and did not undergo invasive treatments; 20 of the 69 patients treated without further intervention died within the 5-year follow-up. Because this represented 50% of the total mortality observed in the cohort, it begs the question of whether these patients should have had additional, and perhaps earlier, interventions for their BCS. Other studies have suggested that the percentage of patients with BCS that are well controlled on medical therapy alone are much lower. In more than one half of the cases of BCS in ex-USSR, the study continued to progress despite anticoagulation and required one or more interventions.

One option is to attempt thrombolytic therapy, angioplasty, and stenting. Thrombolysis and PTAPS seem to be more effective in the

Asian form of BCS compared with the Western form. This is likely related to the more frequent occurrence of hepatic venous web and venous stenosis in the former. Additionally, delivery of the thrombolytic agent "upstream" from the clotted hepatic veins is difficult or, in many cases, impossible. Nevertheless, thrombolysis and PTA/S can be an option in the rare patient who presents with BCS resulting from focal or short length segmental stenosis of a hepatic vein. In most reported series of the Western type of BCS, thrombolysis and PTA/S have played only a relatively minor role in the overall treatment of this disease.

TABLE 1 Comparison of Survival Outcomes for Endovascular vs Transplant Treatment of BCS

Study	N	Overall Survival	Need for Transplantation
TIPS			
Garcia-Pagan, 2008	124	79% 5 year OLT free	6.4% (8 of 124)
Senju, 2013	62	72% 5 year	4.3% (3 of 62)
Rössle, 2004	33	74% 5 year OLT free	6.1% (2 of 33)
TRANSPLANTATION			
Segev, 2007	510	80% 5 year (MELD era)	NA
Mentha, 2006	240	68% 10 year	NA
Singer, 1995	43	69% 10 year	NA

MELD, Model for End-Stage Liver Disease; NA, not available; OLT, orthotopic liver transplantation; TIPS, transjugular intrahepatic portosystemic shunting.

ENDOVASCULAR VERSUS SURGICAL SHUNTING

Given the disease progression in most patients treated with medical management alone and the limited effectiveness of thrombolytic therapy and PTA/S in the management of the Western form of BCS, the next intervention in the treatment algorithm is endovascular shunting via TIPS or DIPS (Fig. 2). Accumulated worldwide experience in the performance of TIPS, coupled with stent technology advancements (e.g., polytetrafluoroethylene-covered self-expanding stents) has led to excellent outcomes. In a retrospective analysis of 54 patients who underwent TIPS for primary BCS from 2004 to 2014, Hayek and colleagues reported the primary and secondary technical success rates to be 93% and 98%, respectively. During this study's mean follow up of 56 months, 42% of patients required shunt revision, but the secondary patency rate was 100%. Procedure related mortality was zero, and the overall 5- and 10-year survival rates of the cohort were 83% and 74%, respectively.

These results appear to be significantly better than those reported for surgical shunts performed for BCS. In the initial 1983 report of surgical shunts in treatment of BCS, only 8 of the 42 patients who underwent surgical systemic-venous shunt placement survived to discharge from the hospital. An additional patient died from sequelae of shunt thrombosis. Another two patients developed recurrent ascites immediately after surgery again from shunt thrombosis. Overall, only three patients had patent shunts and did not require reoperation. Interestingly, follow up liver biopsies in these three patients showed normalization of liver histology over time, which has been the basis for early decompressive intervention in newly diagnosed BCS, even in the absence of symptoms. Unfortunately, newer series have not shown any better outcomes for surgical shunting in the setting of BCS, as can be seen in the in hospital death of five of six patients who underwent surgical shunt placement for BCS between 1996 and 2011 at a major academic center with excellent and internationally recognized experts in performance of surgical portosystemic shunts. Furthermore, four multicenter retrospective multivariate analysis studies failed to show survival benefit of surgical portosystemic shunting after adjusting for independent prognostic factors.

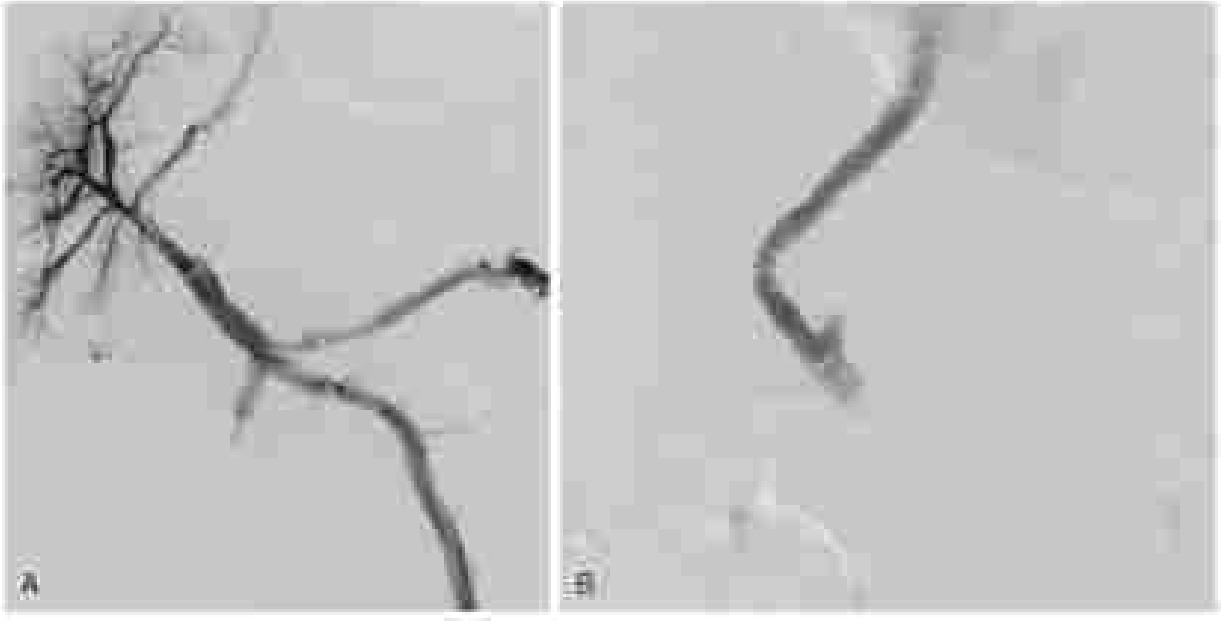

FIG. 2 Direct intrahepatic portosystemic shunt (DIPS) procedure. (A) Ultrasound-guided transhepatic portal venogram with guidewire ascending from splenic vein into portal vein, showing complete portal vein atresia/web with no evidence of hepatic vein runoff, consistent with BCS. (B) After placement of the metal stent, rapid flow through the stent into the vena cava is noted. No intrahepatic portal vein filling is noted because blood is shunted directly into the inferior vena cava from the main portal vein.

Given all these data, coupled with many of the diverse and declining technical expertise in portal systemic shunt surgery, routine use of surgical mesenteric-systemic or portal systemic shunting in the management of BCS cannot be recommended at this time. Surgical shunts should be reserved as an option in the uncommon situation where endovascular shunting is not possible (e.g., obstruction high in IVC not amenable to endovascular therapy).

The selection of which endovascular shunt approach is most appropriate in a BCS patient who progresses despite anticoagulation is driven largely by hepatic vein patency, the presence of which is required for performing a standard TIPS. In instances in which no adequately patent or suitable hepatic vein is present, recanalization of the vein may be attempted to allow subsequent TIPS. The development and evolution of TIPS provides an alternate endovascular approach to decompress the BCS liver. TIPS procedures involve creation of an endovascular shunt through the hepatic parenchyma which passes directly from IVC into the portal vein and does not require patency of the hepatic veins (Fig. 2). Successful TIPS has been greatly facilitated by intravascular ultrasound. Short- and long-term data on effectiveness of TIPS in management of BCS are limited, but the preliminary results are encouraging, with reported 100% technical success rate without complications and 83.3% overall clinical success rate, as reported by Hamdallah and colleagues. Several scoring systems have been proposed (e.g., Rotterdam classification III, Child, BCS-TIPS) as a way of predicting mortality in BCS and to determine urgency, and to some degree, the type of therapy to be used. Additional data are emerging but further validation is required. Of the patients in an FM Vic who received invasive therapies, up to 70% underwent TIPS. In that cohort, 22% received a liver transplant.

LIVER TRANSPLANTATION

For the rare patient who presents with fulminant hepatic failure secondary to BCS, LT is usually the only curative treatment option. In the 10% to 20% of patients who show progression of BCS despite all other therapies, LT is also the only remaining therapeutic option. In patients who develop hepatic venous thrombosis secondary to metabolic defects localized to the liver (e.g., antithrombin III deficiency, protein C deficiency), LT offers the singular benefit of being curative. The treatment options for patients with chronic hepatic venous outflow obstruction who have histologic evidence of cirrhosis are also limited to total hepatectomy and liver replacement because BCS patients with cirrhosis typically will do poorly with nontransplant treatment strategies. Newer advances in medicine such as use of the terminal complement inhibitor eculizumab have even opened the possibility for LT for paroxysmal nocturnal hemoglobinuria, once regarded as a definite contraindication to transplant because of high chance of recurrence in the liver allograft.

The first LT for BCS was performed in 1974. Over the next 15 years, 1- and 5-year posttransplant patient survival rates for BCS (~70% and 45%, respectively) were determined to be inferior to what was observed for adult liver recipients in general. The improved success reported in more recent series (5-year survival rates of 71%–89%) has been attributed to (1) a decreased interval between the onset of symptoms and initiation of therapy, (2) early institution of anticoagulants or antithrombotic therapy (or both) after transplantation, and (3) modern therapy of patients with a definable hypercoagulable state. Patients with BCS who undergo LT show survival rates and graft function that are equivalent to or better than those who undergo LT for most other reasons. Despite earlier concerns, BCS patients who undergo TIPS have not shown worse outcomes with LT; for this reason, endovascular shunting should not be considered a contraindication to LT.

Mentha and colleagues surveyed the European Liver Transplantation Registry between 1968 and 1999 and identified 205 patients transplanted for BCS. Complete follow-up data were obtained for 249 patients. The actuarial survival was 75.6%, 71.8%, and 68% at 1, 5, and 10 years posttransplant, respectively. Late mortality was low in this study; only 9 patients died after 1 year; however, 27 patients (11%) developed some form of venous thrombosis despite anticoagulation therapy. Six of these patients had recurrent hepatic venous thrombosis. In a more recent report by Segev and colleagues looking at 530 LTs that were done in the United States between 1987 and 2006, post-Model for End-Stage Liver Disease era graft and patient 3-year survival was found to be 81% and 83%, respectively.

Most series have suggested that early initiation of anticoagulation therapy has markedly reduced the incidence of recurrent BCS following LT. We would advocate for lifelong anticoagulation following LT for patients with BCS, even in the absence of an identifiable hypercoagulable state. This strategy is not without penalty. One series from Cambridge reported a 44% incidence of intestinal hemorrhage when a policy of early posttransplant anticoagulation was instituted. Nonetheless, there is evidence that complications secondary to bleeding are generally more amenable to treatment than are complications secondary to thrombosis. A European multicentre clinical series reported by Mentha and colleagues in 2006 identified risk of bleeding and thrombosis to both be around 11%, but the mortality from bleeding was 1%, whereas mortality after thrombosis was 40.2%.

LT poses specific technical challenges for patients with BCS. The obstructed liver is generally enlarged, firm, and difficult to mobilize during the hepatectomy. A diffuse fibrotic reaction to the retroperitoneum, perhaps related to the hepatic vein thrombotic process, increases the difficulty of identifying, mobilizing, and controlling the IVC. Because the caudate lobe is enlarged and the hepatic vein orifices are occluded, the "piggyback" technique of LT may be particularly challenging. Control of the vena cava may require incision of the diaphragm and isolation of the vena cava within the pericardial sac.

Not infrequently, BCS patients with hypercoagulable conditions present with thrombosis of other large vessels in their splanchnic circulation. Portal vein occlusion presents a particularly difficult problem because a plan for restoring portal venous inflow to the transplanted liver must be devised before proceeding with LT. If the portal vein is occluded but the superior mesenteric vein (SMV) is patent, preoperative transhepatic cannulation of the portal vein with thrombolysis and angioplasty has been shown to be successful in a small number of patients. Alternatively, direct thrombectomy of the SMV and portal vein can be used as a conduit from the recipient's SMV to the allograft portal vein. In cases in which both the portal vein and SMV are occluded, Ueda and colleagues have performed LT with cava bicavocaval anastomosis whereby the allograft portal vein is sewn end to side to the recipient's IVC. The IVC superior to this anastomosis is partially or totally ligated to preferentially direct systemic venous blood through the allograft portal vein. Patients treated with caval bicavocaval anastomosis have persistent portal hypertension as well as functional caval obstruction posttransplantation. Not surprisingly, morbidity and mortality are high in such patients, who arguably are best treated with anticoagulation alone with the hope that they will develop collateral splanchnic venous drainage and symptomatic improvement over time.

Despite a successful TIPS or less commonly a secondary systemic surgical shunt, persistent liver injury with histologic progression to fibrosis and cirrhosis has been documented in some patients. Shunt patency does not necessarily ensure complete decompression of the congested hepatic sinusoids. For this reason, lifelong follow-up and imaging of hepatic function is indicated in BCS patients treated with any form of portal venous decompression. The effect of radiologic therapies for BCS on a subsequent LT cannot be neglected. Intravascular stents become densely incorporated into their resident blood vessels. Should these stents migrate into the main portal vein, the suprahepatic IVC, or the right atrium, significant technical difficulties may be encountered during isolation of the hepatic vasculature and subsequent explantation of the liver.

There is little controversy that LT offers the most effective therapy for the minority of individuals with either fulminant hepatic failure or the chronic, cirrhotic form of BCS; however, most BCS patients present with acute or subacute manifestations of hepatic venous outflow obstruction. If long-term benefit were the sole benchmark by

which treatment was selected for these patients, who represent the majority of BCS patients, there is general agreement that, as a group, they will do best if given transplants. Unfortunately, from a practical standpoint, clinical outcomes alone cannot be used to determine whether LT is advisable for patients with BCS. A more restricted use of LT is mandated by (1) the widening gap between the number of patients who require a liver transplant and the static pool of donated organs, (2) the unpredictable availability of donor organs, (3) the need for and consequences of lifelong immunosuppression, and (4) the dramatically higher cost of transplant versus nontransplant therapies.

ASYMPTOMATIC GALLSTONES

Steven M. Strasberg, MD, FRCS(C), FACS, FRCS(Ed)

In the United States, 25% to [illegible] gallstones by age. More [illegible] people have gallstones [illegible] 80,000 patients [illegible] pregnancy [illegible] gallstones are found on routine [illegible] gallstones [illegible] gallstones are discovered when purposely searched for in asymptomatic persons with a strong family history of gallbladder cancer or in high gallbladder cancer endemic areas such as Chile and Alberta.

Clinical Stages of Cholelithiasis

Cholelithiasis has three clinical stages: the asymptomatic stage, the symptomatic stage, and the stage of complications. Complicated forms of cholecystolithiasis include acute cholecystitis and its complications, choledocholithiasis and its complications, gallstone ileus, and gallbladder cancer. Avoidance of these complications constitutes an important rationale for therapy in the symptomatic stage or under special circumstances in the asymptomatic stage.

Of importance in making recommendations about treatment is knowing the natural history of cholelithiasis, particularly the rate of conversion from the asymptomatic stage to the other stages. This information is necessary to weigh the risk of expectant management against the hazards of cholecystectomy. Historical series on the natural history of gallstones yielded controversial results, mainly because of the inclusion of patients with some biliary symptoms. This distorted the results toward a higher rate of symptomatic patients. Later, thinner studies with longer follow-up found that these gallstones most often remain silent or become symptomatic before causing complications and that expectant treatment of asymptomatic stones very rarely resulted in patient mortality. For these reasons, cholecystectomy is not recommended in asymptomatic patients with gallstones with some exceptions.

Types of Asymptomatic States

Asymptomatic gallstones may be identified in patients without any symptoms or in patients who have symptoms that are unconnected to the presence of gallstones. Although not usually made, this distinction is of practical importance.

Asymptomatic Gallstones in Asymptomatic Patients

Radiopaque gallstones, which make up about 15% of all gallstones, were commonly found on chest radiographs performed as part of an annual physical examination, but this is no longer a common practice. Another occasion for identifying a patient with asymptomatic gallstones is in the pregnant woman. Examination of the gallbladder is not part the standard obstetrical ultrasound examination, but stones may be identified on pregnant especially in the third trimester when the uterus enlarges into the upper abdomen. Based on the previously described natural history of gallstones, there is no indication for treatment of stones in this group of patients. However, there are some situations in which cholecystectomy may be indicated in asymptomatic patients.

Asymptomatic Gallstones in Symptomatic Patients

Several types of patient have symptoms at the time gallstones are discovered but whose symptoms are not connected to the presence of the gallstones. Some patients have symptoms clearly not of gastrointestinal origin. Common examples include those being investigated for symptoms based in nongastrointestinal organ systems (e.g., hematuria, cough). Although only a fraction of gallstones are radiopaque, computed tomography is so commonly used to diagnose chest and abdominal conditions that many patients are found to have gallstones by this route today. As previously stated based on the natural history of gallstones, there is no indication for treatment in such patients. Some patients have gastrointestinal symptoms but do not have abdominal pain. Bloating, belching, and nausea are common abdominal complaints. Such symptoms are no more frequent in patients with gallstones than in the general population, and their presence is not an indication for treatment of gallstones. Other patients have abdominal pain, which is the hallmark symptom of cholelithiasis, but their pain is not the result of gallstones. Decision making in this group of patients is more challenging because differentiating biliary from nonbiliary pain can be difficult. Understanding the characteristics of biliary pain and other gastrointestinal symptoms has been undertaken through the Rome Foundation, which has sponsored international conferences to define gastrointestinal function and dysfunction.

Rome Criteria for Biliary Pain

Pain of biliary origin in Rome I is defined as having the following characteristics:

1. Located in the epigastrium and/or right upper quadrant
2. Occurs at variable intervals (not daily)
3. Lasts at least ½ minutes
4. Severe enough to interrupt daily activities or lead to an emergency department visit
5. Builds up to a steady level
6. Is not significantly (<25%) relieved by bowel movements, postural changes, or acid suppression

Criteria supportive of biliary pain include pain that (1) is associated with nausea and vomiting, (2) radiates to the back and/or right infrascapular region, and (3) awakens the patient from sleep.

Gallstones are so common that it is not unusual for patients to have gallstones but another gastrointestinal problem actually responsible for the pain. Irritable bowel syndrome and peptic ulcer disease are examples of common problems in the differential diagnosis of abdominal pain in patients with gallstones. Both produce abdominal pain but usually have none or only one of the criteria of biliary pain. In some cases, the differentiation is straightforward. If the pain is in the lower abdomen and associated with constipation and/or diarrhea, irritable bowel syndrome is much more likely to be the diagnosis than symptomatic gallstone disease. Similarly, gnawing pain relieved by food and antacids will point to peptic ulcer disease. Cholecystectomy in these cases such as these is unlikely to improve symptoms. Conversely, persons with gallstones whose symptoms fit Rome IV criteria will need no further investigation to recommend cholecystectomy. It is an intermediate group that is more challenging because gallbladder pain may be atypical. For instance, the pain may be greatest in the left upper quadrant or in the back. It may be steady, especially when a stone is impacted. In this situation, when other Rome IV criteria are present, there is a definite possibility that the pain is of biliary origin. Once gallstones become symptomatic, the risk of conversion to complicated cholecystitis rises. If the pain is thought to be of biliary origin, cholecystectomy is advisable. Sometimes, when the pain is atypical, other diagnostic testing such as gastrointestinal endoscopy, abdominal computed tomography, chest radiograph, and cardiac evaluation should be considered before proceeding with cholecystectomy.

CHOLECYSTECTOMY FOR ASYMPTOMATIC GALLSTONES OR TO PREVENT STONE DEVELOPMENT

Cholecystectomy in Patients at an Increased Risk for Gallbladder Cancer

Porcelain Gallbladder

Porcelain gallbladder is believed to be due to heterotopic calcification of the gallbladder wall associated with chronic inflammation. There are two pathologic variations, focal calcium deposits in the mucosa of the gallbladder wall and diffuse infiltration of the muscularis of the gallbladder wall. Classically, porcelain gallbladder was an absolute indication for cholecystectomy because of purported high risk of development of gallbladder cancer. Rates as high as 60% were quoted. However, more recent data suggest that the incidence is much lower. There are no good studies of the natural history of the problem in part because it is quite uncommon. A modern estimate of the incidence of cancer and porcelain gallbladder is 6%. There is some evidence that the incidence of cancer is higher when the calcification is localized in the mucosa than when it is in the muscularis. Radiologically, when the calcification is in the muscularis, the gallbladder usually appears to be completely calcified (Fig. 1A), whereas when the calcification is in the mucosa it is incomplete (Fig. 1B) and often appears stippled. In considering whether to advise cholecystectomy, calcification type, patient age, comorbidities, and prior abdominal surgery need to be taken into account. Based on low-level evidence, it may be advised that younger healthier patients with mucosal type calcification should have cholecystectomy. Those who do not have cholecystectomy should probably be followed with serial imaging. Cholecystectomy in the presence of a porcelain gallbladder may be of increased difficulty. The gallbladder may be rigid from calcification and it may be a difficult to expose structures in the hepatocystic triangle because of the overhanging unyielding gallbladder. Laparoscopic cholecystectomy has been described in this disease but conversion to open surgery should be undertaken readily if there is operative difficulty displaying the anatomy.

Cholecystectomy in Populations With a High Risk of Gallbladder Cancer

Cholecystolithiasis is almost always present in patients who develop gallbladder cancer. However, in most populations in whom the incidence of gallbladder stones is high the incidence of gallbladder cancer is so low that as a public health strategy cholecystectomy in patients with stones is impractical. However, in Chile and India as well as northern India, gallbladder cancer is the most common form of gastrointestinal cancer, especially in women. The incidence is also high in Native (American) Indian women with gallstones. Although part of the explanation for the high incidence of gallbladder cancer in these populations may be a very high incidence of gallstones, the incidence of gallbladder cancer, which can reach 4% of gallstone-bearing women, exceeds that expected simply of the basis of the high incidence of gallstones.

Since 2006, the government of Chile has sponsored a program of prophylactic cholecystectomy for women with gallstones between the ages of 35 or 40 years. Approximately 40,000 patients had

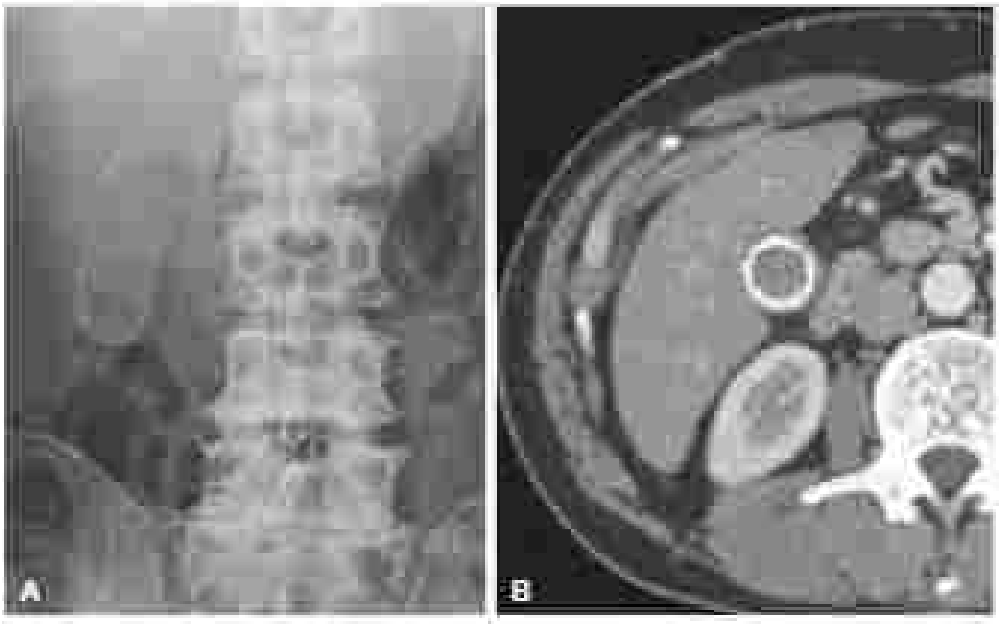

FIG. 1 [illegible] gallbladder wall.

cholecystectomy in the first 6 years of the program. It is too early to determine the overall effect on the incidence of gallbladder cancer, and the data are confounded by the fact that the incidence of gallbladder cancer overall in Chile has dropped in the past 10 years.

The risk of malignancy has been reported to be about 10 times greater in patients with stones larger than 3 cm than in those with stones of smaller than 1 cm and treatment may be indicated in this group of patients. However, the evidence is not as clear as it is in porcelain gallbladder, making a definitive recommendation impossible.

Occasionally a patient will be encountered who has a family history of gallbladder cancer and is asking for guidance, most simply when a close relative has recently been diagnosed with or has died of gallbladder cancer. Just such individuals have a fear of developing gallbladder cancer, which in some cases can be debilitating. Each one of these patients needs to be evaluated individually for the strength of the family history, presence of gallstones, and effect of the concern about developing cancer on the quality of life.

Cholecystectomy at the Time of Bariatric Surgery

Three questions are relevant to bariatric surgery and cholecystolithiasis: (1) What should be done at the time of bariatric surgery if the patient is symptomatic with cholecystolithiasis? (2) What should be done at the time of bariatric surgery if the patient has asymptomatic cholecystolithiasis? (3) Should cholecystectomy be done at the time of bariatric surgery in a patient with a normal gallbladder to avoid later formation of gallstones and the possibility of related problems?

Obesity is a major risk factor for the development of cholesterol gallstones; therefore, it is not surprising that many patients having bariatric surgery already have gallstones. There is general agreement that patients who have symptomatic gallstones should have a cholecystectomy at the time of bariatric surgery. This is not different from the recommendation for other patients with symptomatic gallstones. Although patients having Roux-en-Y gastric bypass are more likely to form gallstones in the postoperative period (see the following section), there is little evidence that patients with asymptomatic gallstones having bariatric surgery are more likely to develop symptoms postoperatively than other persons with asymptomatic gallstones. Consequently, prophylactic cholecystectomy is generally not recommended to patients with asymptomatic gallstones at the time of bariatric surgery. Another net-saving factor is that performing a cholecystectomy at the time of a laparoscopic gastric bypass is a significant addition to the duration of surgery and difficulty of cholecystectomy. The port placements for the typical laparoscopic gastric bypass are oriented toward the left upper quadrant and left abdomen and are not optimized for cholecystectomy; therefore, additional port placements may be needed. In addition, large liver weight and poor liver compliance make the cholecystectomy more difficult than that done in a lean individual or for a bariatric patient who is 3 months or more out from their procedure when liver fat is significantly reduced.

Rapid weight loss induced by Roux-en-Y gastric bypass is associated with a large increase in the amount of cholesterol excreted in bile with resultant increased gallbladder bile lithogenicity. Bariatric surgery may also interfere with gallbladder emptying, resulting in bile stasis in the gallbladder, which also is a risk factor for formation of gallstones. Gallstone formation rates of close to 60% within 6 months of Roux-en-Y gastric bypass have been reported. This problem can be largely avoided by treatment of patients with ursodeoxycholic acid for 6 months after surgery. As a result, prophylactic cholecystectomy in patients with normal gallbladders having Roux-en-Y gastric bypass is not recommended.

The preceding comments do not apply to the duodenal switch operation in which parts of the procedure are concentrated in the right upper quadrant very close to the gallbladder, making later surgery more difficult. This procedure induces the most rapid weight loss with consequent increase in gallstone formation. Therefore, the rationale for cholecystectomy in patients having this operation is stronger than in gastric bypass.

Cholecystectomy in Patients With Diabetes and Asymptomatic Gallstones

Controversy still exists about prophylactic treatment in patients with diabetes, in which those with asymptomatic stones do not seem more likely to become symptomatic than nondiabetic patients. It appears that once these patients become symptomatic, they are more likely to require emergency surgery for acute cholecystitis and surgery is attended by higher morbidity and mortality rates. On the other hand, the risk of elective surgery in patients with diabetes in the absence of other risk factors is similar to that in patients without diabetes. It therefore seems advisable to treat patients with diabetes with symptomatic gallstones but not to treat until symptoms develop.

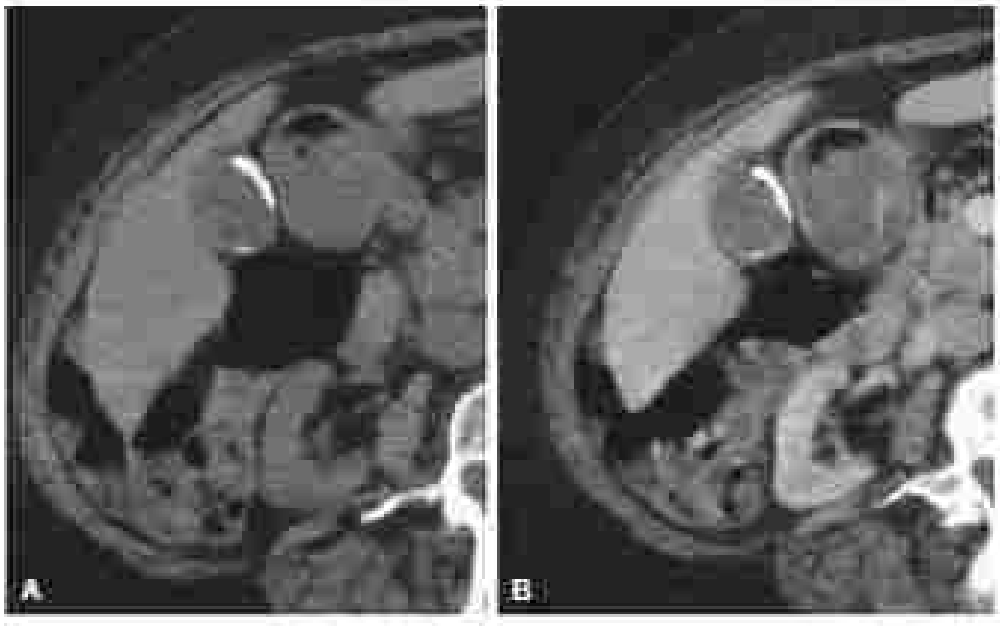

FIG. 4. Partial calcification of gallbladder wall. (A) Noncontrast computed tomogram. (B) Intravenous contrast computed tomography scan shown for comparison.

Cholecystectomy in Patients Having a Gastrectomy With and Without Asymptomatic Gallstones

The incidence of gallstones after gastrectomy is increased, especially gastrectomy for gastric cancer. Rates as high as 15% within 5 years have been reported. Formation of stones after gastrectomy has been associated with certain factors in different case series. These include total gastrectomy as opposed to partial gastrectomy, extensive lymph node dissection, and exclusion of the duodenum in the reconstruction. Obesity and male sex also have been reported as risk factors. Factors thought to be operative include rapid weight loss, gallbladder stasis from a lack of release of cholecystokinin and perhaps vagal denervation. Cholecystectomy has been advocated to avoid future gallstone formation after gastrectomy, but is not widely practiced.

There is a stronger argument for cholecystectomy in patients with gallstones already present at the time of gastrectomy because, similar to the situation with duodenal switch, cholecystectomy may be quite difficult following a prior gastrectomy especially after an N_2 node dissection.

Cholecystectomy in Patients With Hemolytic Anemias

Patients with sickle cell disease frequently form gallstones resulting from excessive excretion of bilirubin into bile. Gallstones are present in as many as 70% of adults with sickle cell disease. A key issue in this population is that sickle cell crisis may be very difficult to distinguish from biliary symptoms or biliary complications because these patients may have severe upper abdominal pain and leukocytosis. They may also become jaundiced. It has also been claimed that complications are more common after patients with sickle cell anemia become symptomatic. It seems reasonable to perform prophylactic cholecystectomy under circumstances in which it is not possible to distinguish between sickle crisis and biliary colic; however, the situation in other patients with asymptomatic gallstones is less clear. A large Jamaican study found that few patients with asymptomatic gallstones became symptomatic in follow-up. Patients with other types of hemolytic anemia such as spherocytosis and thalassemia may also develop symptomatic gallstones. Cholecystectomy in those groups is advocated only after the disease becomes symptomatic.

Cholecystectomy in Patients With Spinal Cord Injury

Patients with spinal cord injury are at increased risk of gallstone disease with an incidence of about 30%. In the great majority of patients with spinal cord injury, cholelithiasis presents with chronic pain rather than life-threatening complications. Presentation seems no more acute in patients with spinal cord injury than in the general population. Characteristic symptoms and signs are not necessarily obscured by spinal cord injury, regardless of the level. Expectant management should be the rule for patients with asymptomatic cholelithiasis. Cholecystectomy is indicated for patients with symptomatic gallstone disease.

Cholecystectomy in Short Bowel Syndrome

Patients with short gut syndrome are at increased risk of developing cholelithiasis if the intestinal remnant is smaller than 120 cm and particularly if the terminal ileum was resected and if the patient requires long periods of postoperative total parenteral nutrition. Long periods of fasting are associated with gallbladder stasis and the formation of sludge and gallstones. In a small series of five patients with short gut, all became symptomatic with acute cholecystitis or pancreatitis. Prophylactic cholecystectomy has been recommended in patients who have benign intestinal disease with short gut syndrome, especially when a laparotomy is being undertaken for another purpose.

Somatostatin interferes with gallbladder motility by interrupting the secretion of cholecystokinin. Consequently, its long-term use has been associated with the formation of gallstones. Asymptomatic gallstones form in about two-thirds of patients treated long term with somatostatin analogs. Seventeen percent of patients required cholecystectomy within 5 years of initiating treatment in one study; therefore, prophylactic cholecystectomy should be considered in these patients at the time that laparotomy is performed to remove the primary tumor.

Cholecystectomy in Transplant Patients

Expectant management is the preferred strategy for patients undergoing pancreas and/or kidney transplant with asymptomatic cholelithiasis based on a decision analysis. However, prophylactic posttransplantation cholecystectomy is favored for cardiac transplant recipients with asymptomatic cholelithiasis because in one study expectant treatment resulted in a mortality rate from complications of gallbladder disease of 44 in 1000 patients compared with 5 in 1000 for elective posttransplant cholecystectomy. Another study using the National In-Patient Sample database found that heart transplant patients are at an increased risk of inpatient mortality and morbidity after cholecystectomy compared with the general population. It was recommended that strong consideration be given to prophylactic cholecystectomy in such patients with asymptomatic gallstones.

Cholecystectomy in Patients With a Symptomatic Choledocholithiasis but Without Gallbladder Symptoms

Occasionally, patients will have stones pass into the bile ducts and become symptomatic with biliary pain, jaundice, or other consequences of choledocholithiasis without prior or concomitant symptoms from cholecystolithiasis. This situation may be described as asymptomatic cholecystolithiasis in the presence of symptomatic choledocholithiasis. There is good evidence that cholecystectomy should be performed in such patients, with the exception of very elderly or debilitated patients. For instance, in patients older than 75 years, once the bile duct stones are cleared by endoscopic means, it is unusual for patients to require a cholecystectomy for later symptoms arising from the gallbladder. However, it is advisable for such patients to have a protective endoscopic sphincterotomy at the time of stone clearance from the bile ducts by endoscopic retrograde cholangiopancreatography to prevent future symptoms arising from choledocholithiasis.

Cholecystectomy for Future Hostile Abdomen

As mentioned in regard to gastrectomy with extensive lymph node dissection and duodenal switch operation, cholecystectomy may be indicated for asymptomatic gallstones in circumstances in which a later cholecystectomy would encounter a hostile abdomen. In addition to the examples given, this situation would include operations on the head of the pancreas, duodenum, and certain liver operations.

Management of Acute Cholecystitis

Peter J. Fagenholz, MD, and [illegible] MD, PhD, MSEd

Acute cholecystitis (AC) is acute inflammation of the gallbladder usually resulting from obstruction of the cystic duct with gallstones. Diagnosis is based on a combination of clinical signs and physical examination findings (most important, right upper quadrant abdominal pain and tenderness) and imaging showing cholelithiasis and/or gallbladder wall inflammation. Standard treatment is prompt laparoscopic cholecystectomy, although selected patients may be managed medically or with percutaneous cholecystostomy (PC) tube placement. Surgeons should be prepared to convert planned laparoscopic cholecystectomy to open cholecystectomy and be familiar with various options for the sometimes difficult cholecystectomy encountered in patients with AC.

CLINICAL PRESENTATION, EVALUATION, AND DIAGNOSIS

Patients with AC typically experience upper abdominal pain that localizes to the right upper quadrant and lasts for more than 6 hours. A history of prior similar episodes that were shorter in duration or less severe often can be elicited. Patients may have a known history of gallstones either identified during evaluation for prior episodes of abdominal pain or identified incidentally on imaging studies performed for other reasons. Nausea and vomiting are frequently present, fever less so. The most common physical examination finding is right upper quadrant abdominal tenderness, Murphy's sign, inspiratory arrest with palpation over the gallbladder, is the classic physical examination finding. All of these signs and symptoms may be muted or absent in patients who are obese, have diabetes, are on steroids or otherwise immunosuppressed, or have impaired sensorium.

The most important differential diagnosis is between AC and other biliary tract disease, such as biliary colic or choledocholithiasis. A number of other intraabdominal diseases, such as pancreatitis, peptic ulcer disease, mesenteric ischemia, hepatitis, and colitis, and extraabdominal diseases such as myocardial ischemia and pneumonia occasionally may resemble AC. History taking and physical examination should focus on narrowing this list to appropriately direct further laboratory and imaging tests.

There are no diagnostic laboratory studies. Mild leukocytosis is common. Liver function tests are typically normal or only mildly elevated and are helpful primarily in differentiating AC from other forms of complicated gallstone disease, such as choledocholithiasis and cholangitis, or medical liver illness such as acute hepatitis. Marked abnormalities in serum bilirubin, alkaline phosphatase, or transaminases should prompt consideration of an alternative diagnosis. Serum amylase and lipase should be sent to evaluate for acute pancreatitis.

The optimal choice of imaging test depends primarily on the pretest probability for AC relative to other forms of intraabdominal pathology. Ultrasonography, computed tomography (CT), cholescintigraphy (HIDA scan), and magnetic resonance imaging are capable of identifying AC with variable sensitivity and specificity and have different levels of cost and availability. Using them correctly depends on the clinical scenario. For patients with a typical presentation and a high clinical suspicion for AC, transabdominal ultrasound is the current diagnostic test of choice. It is inexpensive, requires no ionizing radiation, is widely available, and is more than 90% accurate for detection of cholelithiasis. Signs of AC on ultrasound include pericholecystic fluid, gallbladder wall thickness greater than 4 mm, gallbladder distension, a gallstone lodged in the neck of the gallbladder, and a sonographic Murphy's sign. However, ultrasound, although very sensitive for the detection of gallstones, is only about 60% to 70% sensitive for detecting these "objective" signs of AC. Thus the scenario in which a patient has a convincing clinical presentation for AC, followed by an ultrasound showing gallstones, but no objective ultrasonographic signs of cholecystitis is a common one. In this scenario, for surgically low risk patients, we recommend proceeding to cholecystectomy, confident that the patient either has AC (as diagnosed clinically) or at least significantly symptomatic gallstone disease that merits cholecystectomy.

Scenarios frequently arise in which the orderly progression from history, to physical examination, to laboratory evaluation, to ultrasonography, to a diagnosis of AC does not occur. It is very common for surgeons to be consulted in patients who come to the emergency department with abdominal pain and after initial evaluation undergo CT scanning as the first radiologic test. When the CT scan shows evidence of AC, is a subsequent ultrasound necessary? We would argue rarely or never. Although not the first line test for AC and poorly sensitive for cholelithiasis, CT is actually more sensitive than ultrasound for detecting objective signs of AC, such as pericholecystic fluid or inflammation and gallbladder wall thickening (Fig. 1). It is also the most versatile test for evaluating the other entities usually considered in the differential diagnosis of AC. If a CT scan shows AC and no other diagnosis is suggested strongly by the clinical presentation or CT scan, there is little to no utility to performing ultrasonography just to demonstrate stones in the gallbladder.

Another common scenario is the patient with an atypical clinical presentation for AC, in whom ultrasonography demonstrates stones but no clear evidence of AC. Are these incidentally found stones in a patient with some other pathology, or are they the true source of the problem? After reviewing the patient and clinical data, the surgeon must decide whether there is a significant risk of intra-abdominal pathology not related to the biliary tract. If there is significant concern for other intraabdominal pathology as the source of the patient's symptoms, we usually perform abdominal CT scanning with intravenous contrast. It is the test most likely to either confirm the diagnosis of AC and rule out an alternative diagnosis or to provide an alternative explanation for the patient's symptoms. The other commonly used test to evaluate for AC when the diagnosis is unclear after clinical evaluation and ultrasonography is HIDA. Although HIDA is highly sensitive and specific for cholecystitis, it is not as widely available as CT and if negative for AC, it provides no useful information regarding other possible diagnoses. Thus we use it very selectively.

MANAGEMENT

Cholecystectomy is the standard treatment for AC and has the advantage of not only treating the current episode but also removing the risk of subsequent bouts of AC and other biliary tract complications related to gallstones. All patients diagnosed with AC should receive appropriate antibiotics. The decision regarding which of the following treatment options to use depends on the overall medical condition of the patient and the severity and duration of symptoms. Patients with minimal medical comorbidities presenting early in their disease generally should be managed surgically, those with significant comorbidities but mild AC may merit a trial of medical therapy, and those who are critically ill or have severe medical comorbidities and severe AC are managed best with PC.

Cholecystectomy

Cholecystectomy is standard treatment for patients with AC and should be performed within 72 hours of onset of symptoms, the sooner the better. Alternatives to cholecystectomy and when to apply

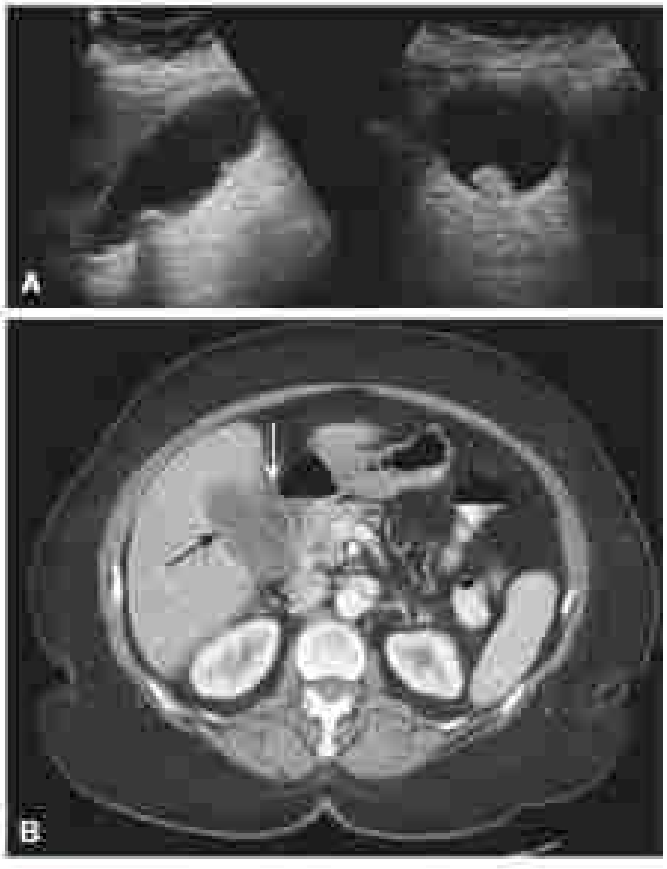

FIG. 1 Computed tomographic scan and its annotated image of a patient with acute cholecystitis. (A) Ultrasonic image. (B) Computed tomographic scan. The gallbladder is distended, with wall thickening and pericholecystic fluid. The gallbladder wall is thickened and edematous, and pathologic findings were consistent with acute cholecystitis.

them are discussed later. Once the decision to operate is made to operate, there is nothing to be gained by waiting, and prompt surgery provides quicker relief to the patient, limits overall hospital stay, and avoids peripheral inflammation that can worsen as days pass and make dissection more difficult. Laparoscopic cholecystectomy is the procedure of choice, but surgeons must be familiar with both laparoscopic and open techniques because the conversion rate in AC is 10% to 30%.

Laparoscopic Cholecystectomy

Laparoscopic cholecystectomy is the approach of choice to AC because multiple studies have demonstrated low morbidity, shorter hospital stays, less time until return to normal function, and lower costs with the laparoscopic approach. The technique of laparoscopic cholecystectomy for AC is fundamentally the same as for elective cholecystectomy—for other indications, the procedures are simply more difficult. The basic steps of patient positioning, equipment, abdominal access, exposure of the gallbladder and cystic structures, dissection of the cystic structures until a critical view of safety is obtained, and indications and use of cholangiography when needed to define the anatomy are the same and are described in detail elsewhere in this book. We discuss a few factors specific to cholecystectomy for AC.

Simply grasping an inflamed gallbladder may be problematic, and this often can be aided by decompression. Occasionally decompression can be accomplished with a purpose-made laparoscopic needle aspirator, but this is often too small to achieve effective decompression in AC. A 14-gauge angiocatheter needle placed through a tiny stab incision has a better chance of success. If this does not achieve adequate decompression, a 5-mm laparoscopic trocar can be thrust directly into the fundus of the gallbladder and a suction aspirator used to evacuate the gallbladder. If this technique is used, an endoloop can be used to close the cholecystotomy to prevent more spillage. Standard laparoscopic graspers may not be able to effectively grasp the thickened and edematous gallbladder wall in AC. This is not a minor nuisance, it is an actual danger because ineffective gallbladder retraction, especially laterally, is a risk factor for bile duct injury. Tripod graspers or large claw graspers may be able to effectively grasp an inflamed gallbladder when standard 5-mm toothed graspers cannot. It is worth identifying a piece of equipment at your home institution that is effective for this purpose.

Once the gallbladder is rendered graspable, the dissection begins. Adjacent structures, usually omentum, duodenum, and sometimes transverse colon or mesocolon, must be packed off the gallbladder. This is best done by identifying the plane where the structure meets the gallbladder and pushing bluntly downward parallel to the gallbladder wall rather than pulling outward. Adhesions to the adjacent liver capsule may be tougher than the capsule itself and so should be divided with scissors or electrocautery before this blunt dissection to avoid bleeding from a capsular tear. Once the gallbladder is exposed, the cystic dissection begins. As with any laparoscopic cholecystectomy, the peritoneum and fatty tissue surrounding the cystic structures must be cleared. Inflammation may pull the gallbladder in close to the porta hepatis, and so we often begin in cases of AC by retaining the gallbladder medially and bluntly stripping the peritoneum and tissue lateral to the cystic structures. This is a relatively safe area to work in initially because it is away from the portal structures, and relaxing this lateral peritoneum often improves the amount of lateral retraction that is possible when dissecting in Calot's triangle. Because of edema, electrocautery may be less effective in some cases of AC than in more elective cholecystectomies, and thus blunt dissection may be more useful. The suction irrigator or a laparoscopic probe dissector can be used for this. Some small capillary oozing may be seen in cases of AC, and this usually can be swept away bluntly as the dissection continues. It is critical to maintain the same standards of visualization as during an elective cholecystectomy. Although it may be harder to obtain the critical view of safety, the same standards of anatomic definition must be applied in cases of AC. Some authors have advocated a top-down laparoscopic dissection, beginning at the gallbladder fundus, when inflammation impairs the initial cystic dissection. We are not advocates of this technique unless it is used regularly in elective cases because it leaves the surgeon using an unfamiliar technique to only the hardest cases.

Occasionally the cystic duct may be foreshortened and/or thickened because of acute and chronic inflammation. If it is not safe to safely clip with standard clips, an endoloop or laparoscopic stapler may be used. In either case, when a duct appears too large to clip, the surgeon must be absolutely sure, either by dissection or cholangiography, that it is in fact the cystic duct. Once that is clear, the endoloop or stapler should be applied so as not to narrow the common bile duct. If stapling, we usually use a 30 mm long linear cutting stapler with 2.5 mm staples. Once the cystic structures are divided safely, the gallbladder must be removed from the liver bed. This is a commonly underdiscussed portion of the operation that can still result in problems if not done correctly. A significant portion of bile leaks after laparoscopic cholecystectomy are related to subvesical ducts, most of which course through the liver parenchyma just deep to the gallbladder fossa. Maintaining adequate tension with the retracting instruments and staying in the correct anatomic plane of dissection minimizes this complication and bleeding from the liver parenchyma.

Finally, although we have attempted to provide a few tips relevant to accomplishing laparoscopic cholecystectomy in cases of AC, when the anatomy cannot be defined clearly because of inflammation or other factors, there should be no hesitation to convert to an open procedure (described later). Although morbidity is increased somewhat

be an open approach, this small increase is nothing compared with the morbidity of a major bile duct or vascular injury, which may occur when persisting laparoscopically with inadequate exposure or dissection. It is very hard to find a surgeon who regrets converting a laparoscopic cholecystectomy to open, but there is no shortage of surgeons who regret persisting laparoscopically in cases of unclear anatomy with sometimes disastrous results.

Open Cholecystectomy

Because laparoscopic cholecystectomy is the standard procedure in cases of AC, most open cholecystectomies in this setting occur as a conversion from a laparoscopic procedure. There are very few conditions that mandate open cholecystectomy with no attempt at laparoscopy, but there are a number of risk factors for conversion to open cholecystectomy, including obesity, long duration of symptoms, cirrhosis, and male sex. Keeping in mind these risk factors, there are some theoretical advantages to performing planned open cholecystectomy rather than converting from a laparoscopic approach. Operating time and equipment costs can be reduced and planning for postoperative analgesia, including regional anesthesia, can be performed preoperatively. In some series, the highest complication rates are in cholecystectomies converted to laparoscopic to open, often after laparoscopic misadventure. It is possible that correctly identifying these difficult cases and starting with an open approach could limit some of these complications.

Both upper midline and right subcostal incisions provide excellent exposure for open cholecystectomy. We prefer a fundus-down technique, in which the fundus is grasped and separated from the liver edge with electrocautery. The medial and lateral peritoneal leaves overlying the gallbladder are incised with cautery, and the hepatic attachments are dissected either with cautery or bluntly with fingers or a suction catheter. When the infundibulum is reached, lateral retraction helps expose the cystic duct and artery, which are ligated.

Bailout Options

Even experienced surgeons will encounter gallbladders that cannot be removed safely. Options depend on when this is recognized. Ideally it will be recognized preoperatively, and patients will be treated nonoperatively as described later. If difficulties are recognized while the gallbladder is relatively intact or if the patient has medical instability early in the procedure, cholecystostomy tube is an excellent option. If the problem is that the gallbladder is fused to the liver and efforts to separate it result in repeated injury to the hepatic parenchyma with bleeding and associated risk of bile leak, then the back wall of the gallbladder abutting the liver can be wholly or partially left in place and the mucosa cauterized to reduce the risk of mucocele. If the cystic structures cannot be dissected safely out from a hostile porta hepatis, then subtotal cholecystectomy is acceptable and far preferable to risking significant injury to adjacent structures. If subtotal cholecystectomy is performed, we remove all stones from the gallbladder and then either oversew a small remaining cuff of infundibulum attached to the cystic duct, or if that is not possible because of poor tissue quality, we attempt to identify the cystic duct orifice from within the lumen of the gallbladder and oversew it from within. After performing any of these bailout maneuvers, we leave a closed suction drain.

Complications and Postoperative Care

Major bile duct injury is the most discussed, feared, and morbid complication of cholecystectomy, and is discussed at length in different sections of this book. We only can reiterate that the key to prevention is complete dissection of the cystic structures with judicious use of cholangiography as needed to help define the anatomy. If injury does occur, the key is to recognize it. Partially visualized clipping to control bleeding should be avoided and, if performed, should be followed by a careful postclipping analysis of the anatomy. The source of any bile leakage in the field should be identified clearly. If it is unknown from a small grasper-related tear in the gallbladder fundus, there is no cause for worry, but that should be ascertained clearly rather than assumed. After completion of the cholecystectomy, the area should be surveyed actively for any bile leakage and the source identified. Techniques for repair of bile duct injury are discussed elsewhere, but note: if the operating surgeon is not comfortable performing these, early identification, drainage, and transfer to a center of expertise for definitive management can limit morbidity.

Most bile leaks after cholecystectomy are not related to undiagnosed major bile duct injuries, but to leakage from the cystic duct stump or small subhepatic ducts. When the surgeon perceives a higher than average risk of this, closed suction drainage should be left. This can include cases in which the gallbladder was exceptionally adherent to the liver parenchyma so that subhepatic ducts may be at risk, cases with poor cystic duct tissue quality, or cases in which bailout maneuvers described earlier were used. Leaks in these scenarios may not be immediately apparent in the operating room. Because most patients undergoing such difficult cholecystectomies for AC will at least spend the night in the hospital, we remove these drains immediately before discharge if there is no evidence for bile leak. If a small leak is present, it usually will heal with drainage alone. If patients have biloma because of an unanticipated leak in an unplanned case, percutaneous radiologically guided drainage should be used. Once a bile leak is drained, the next decision is usually whether to perform endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy and/or common bile duct stent placement to decompress the biliary tree. The advantages of ERCP in this setting are that it can identify the source of the leak, reduce the volume of bile leakage, and reduce the time to healing and drain removal. The disadvantage is that it is yet another procedure with its own risks of complications. In general, we tend to avoid immediate ERCP if we have an anticipated low volume bile leak, that is adequately drained, such as may occur after any of the bailout maneuvers described earlier. If we have an unanticipated or high volume bile leak, then we tend to use ERCP to define the anatomy and decompress the biliary system.

Bile and gallstone spillage are common during cholecystectomy for AC. Bile should be irrigated and aspirated, and an effort should be made to retrieve any dropped gallstones. Sludge and small stones may be difficult to retrieve, but also pose the lowest risk of postoperative complication. Larger stones can result in abscess formation and a more extensive effort to retrieve them should be made. Postoperative drainage should be used infrequently, generally in cases in which there is significant concern for postoperative bile leak. Postoperative antibiotics should similarly be used very rarely, typically only in cases with ongoing systemic inflammatory response syndrome or sepsis. Pulmonary complications including pneumonia and retentions are not uncommon after open cholecystectomy. Strong consideration should be given to regional anesthesia with transversus abdominis plane block, paravertebral block, or epidural anesthesia both for patient comfort and to limit the risk of serious pulmonary complications.

Medical Management

As discussed earlier, medical therapy generally should be used for patients with moderate to severe medical comorbidities and mild AC. Antibiotics are the cornerstone of medical management for AC. Although only about half of patients with AC will have positive bile cultures, there is no reliable method for identifying who these patients are, and there is no other medical therapy specific for the disease. The most common organisms are enteric gram-negatives (*Escherichia coli*, *Klebsiella* spp., *Enterobacter* spp.), anaerobes (*Bacteroides fragilis*, *Clostridium* spp.), enterococci, and streptococci; antibiotic therapy should cover these all empirically. A number of antibiotic regimens can provide needed coverage. A typical duration of coverage is 7 to 14 days, although there are very few data regarding the optimal duration of treatment. As noted earlier in patients undergoing surgery, antibiotics generally should be discontinued postoperatively. Analgesia with

acetaminophen, nonsteroidal antiinflammatories, and opiates should be used until pain resolves and supportive intravenous fluids until adequate oral intake is tolerated. If patients do not improve clinically within 72 hours, strong consideration should be given to using percutaneous or surgical treatment. Studies report a greater than 85% response rate for medical therapy with most patients unimpeded by recurrent biliary events over short-term follow-up (1 to 3 years).

Percutaneous Drainage

PC should be used in patients who do not respond to medical therapy, have contraindications or are high risk for general anesthesia, have severe AC particularly with local complications such as adjacent liver abscess, or have a prolonged duration of symptoms (>3 to 4 days), which may increase the risk of cholecystectomy and the possibility of open conversion. PC is approximately 90% effective in relieving symptoms. It is usually performed under local anesthesia or light sedation with ultrasound guidance. Minor complications, such as catheter dislodgement or blockage, occur in approximately 15% of cases, more serious complications such as bleeding or bile leakage occur in fewer than 1% of cases.

We usually perform contrast injection of the tube at 4 to 6 weeks. If the cystic duct is patent, then the tube can be removed. The risk of recurrent AC or other biliary complications after PC is poorly defined, and reports range from 10% to 50%. How the decision about whether to perform interval cholecystectomy can be individualized on the basis of patient age and surgical risk. If the cystic duct remains occluded, we leave the tube in place until the time of cholecystectomy.

Endoscopic Therapy

Endoscopic therapy for AC can consist of transpapillary stenting or transmural drainage. Transpapillary stenting uses ERCP to place a stent into the gallbladder via the cystic duct. This is usually left to internally drain into the duodenum and eventually is removed endoscopically. Transpapillary stenting is technically successful in 80% to 90% of cases and is as effective (about 90%) as PC in resolving symptoms. The technique requires sphincterotomy and so incurs small risks of postsphincterotomy bleeding, perforation, and pancreatitis. Transmural drainage involves puncturing the gallbladder under endoscopic ultrasound guidance, dilation of the tract, and placement of a stent. Newer lumen-apposing covered stents may provide long-term internal drainage.

Special Situations

Pregnancy

The differential diagnosis of AC in pregnant patients includes all the entities mentioned earlier and several pregnancy-specific entities, such as HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count) and acute fatty liver of pregnancy. The traditional teaching that cholecystectomy should be avoided in the first and third trimesters of pregnancy is challenged by actual evidence suggesting that laparoscopic cholecystectomy is at least as safe as nonoperative management in all trimesters. Nonetheless, data less specific to cholecystectomy suggest that fetal organogenesis may be affected by laparoscopic surgery in the first trimester and that surgery during the third trimester may precipitate preterm labor. We typically pursue semi-elective cholecystectomy during the second trimester in low-risk patients (short duration of symptoms, medically low risk). In the first and third trimesters, we usually attempt medical management followed by PC if needed as a bridge to cholecystectomy in the second trimester or postpartum period, respectively.

Acalculous Cholecystitis

Acalculous cholecystitis is an inflammatory condition of the gallbladder not resulting from gallstones. It results from gallbladder stasis and ischemia, often leading to secondary infection, and typically occurs in critically ill patients. Treatment options are the same as for calculous AC. Because of the usually poor medical condition of patients with acalculous cholecystitis, and the fact that they are not at risk for recurrent complications of gallstones, PC is a much better option as "destination therapy" in acalculous than in calculous disease. We usually reserve cholecystectomy for patients who have evidence for perforation or who fail to improve after PC, which may be due to gallbladder necrosis.

Proper Use of Cholecystostomy Tubes

Amanda K. Arrington, MD, and Taylor S. Riall, MD, PhD

Cholecystostomy tubes have traditionally been considered for the treatment of acute cholecystitis (calculous or acalculous) when definitive treatment (cholecystectomy) is contraindicated secondary to high morbidity or mortality risk. This risk can be related to the severity of the underlying gallbladder pathology and/or comorbid conditions with decompensation. The Tokyo guidelines for the management of acute cholecystitis recommend cholecystostomy tubes in two specific situations. The data from multiple US reports indicate however that current practice patterns are not adherent to the Tokyo guidelines, with only a minority of patients receiving cholecystostomy tube placement. Though the Tokyo guidelines were revised in 2018 (TG18), and now factor in patient comorbidities and physiologic status, controversy still exists regarding the indications for placement of cholecystostomy tubes.

Once placed, the recommended management of cholecystostomy tubes based on TG18 is cholecystectomy within 3 months of initial tube placement. Cholecystectomy following cholecystostomy tube placement occurs rarely despite TG18 guidelines, leading to multiple tube-related complications and recurrent gallbladder pathology. Recommendations for management after cholecystostomy tube placement are not standard and primarily focus on the patency of the cystic duct and the patient's surgical risk. Clear indications for the use of cholecystostomy tubes and their subsequent management are imperative. This chapter reviews the current literature on cholecystostomy tube placement and provides recommendations based on the best current evidence.

INTRODUCTION

Gallstone disease is one of the most common gastrointestinal diseases encountered by general surgeons. Surgeons are increasingly presented with older patients with severe cholecystitis and associated

acetaminophen, nonsteroidal antiinflammatories, and opiates should be used until pain resolves and supportive intravenous fluids until adequate oral intake is tolerated. Though the Tokyo guidelines were revised in 2018 (TG18), and now factor in patient comorbidities and physiologic status, controversy still exists regarding the indications for placement of cholecystostomy tubes.

Once placed, the recommended management of cholecystostomy tubes based on TG18 is cholecystectomy within 3 months of initial tube placement. Cholecystectomy following cholecystostomy tube placement occurs rarely despite TG18 guidelines, leading to multiple tube-related complications and recurrent gallbladder pathology. Recommendations for management after cholecystostomy tube placement are not standard and primarily focus on the patency of the cystic duct and the patient's surgical risk. Clear indications for the use of cholecystostomy tubes and their subsequent management are imperative. This chapter reviews the current literature on cholecystostomy tube placement and provides recommendations based on the best current evidence.

INTRODUCTION

Gallstone disease is one of the most common gastrointestinal diseases encountered by general surgeons. Surgeons are increasingly presented with older patients with severe cholecystitis and associated

TABLE 1 Tokyo Guidelines Definition of Acute Cholecystitis Based on Disease Severity

Grade	Definition
I (mild)	• No findings of organ dysfunction and acute cholecystitis (does not meet criteria for grade II, III) • Clear [illegible] and no earlier risk and case • [illegible] duration of symptoms [illegible] 72 hours
II (moderate)	• Degree of [illegible] with operative difficulty if cholecystectomy is to be undertaken • [illegible] one of the following • Elevated white blood cell count (> 18,000/mm³) • A palpable tender mass in the right upper quadrant • Symptoms > 72 hours • Marked local inflammation (e.g., gangrenous cholecystitis, pericholecystic abscess, hepatic abscess, biliary peritonitis, emphysematous cholecystitis)
III (severe)	• Cholecystitis associated with organ dysfunction to include any of the following • Cardiovascular dysfunction (hypotension requiring treatment with dopamine ≥ 5 μg/kg/min, or any dose of norepinephrine) • Neurological dysfunction (decreased level of consciousness) • Respiratory failure (partial pressure of oxygen to arterial blood/fraction of inspired oxygen ratio < 300) • Renal failure (oliguria, creatinine > 2.0 mg/dL) • Hepatic failure (international normalized ratio > 1.5) • Hematologic dysfunction (platelet count < 100,000/mm³)

physiologic decompensation resulting from both underlying medical comorbidities and potential coexisting gallbladder pathology such as cancer. The preferred definitive treatment in patients with acute cholecystitis is laparoscopic cholecystectomy; however, when the cholecystitis leads to sepsis and hemodynamic instability, when baseline underlying comorbid conditions put the patient at high risk for surgery (e.g., severe cardiac disease, metastatic abdominal malignancy), or when cholecystitis has caused acute decompensation of otherwise stable comorbid illness, an emergent cholecystectomy is not always feasible as first-line treatment. In these cases, a cholecystostomy tube should be considered as a minimally invasive technique that avoids general anesthesia and controls the source of infection. The first ultrasound-guided cholecystostomy tube was performed and later described by Radder on a 54-year-old patient with gallbladder empyema.

The establishment of the Tokyo guidelines for cholecystitis and cholangitis in 2007 (TG07) and subsequent revisions in 2013 (TG13) and TG18 were developed to provide consensus regarding the diagnosis and management of cholecystitis. The TG07 and TG13 provide guidelines for the classification of the severity of cholecystitis, yet they did not account for a patient's medical comorbidities (Table 1). The Tokyo guidelines exclusively many cases based on a US study evaluating the sensitivity, specificity, and accuracy. Based on the grading classification defined in TG07 and TG13, an algorithm for cholecystostomy tube placement has been derived. The guidelines specifically recommend the use of cholecystostomy tubes in patients with grade II cholecystitis with symptoms lasting more than 72 hours who do not respond to antibiotic therapy or with grade III cholecystitis (Fig. 1).

The TG13 guidelines were revised in 2018 and now take into account patients' comorbidities in the form of Charlson Morbidity Index (CCI) and the American Society of Anesthesiologists (ASA) physical status classification system. TG18 guidelines recommend percutaneous cholecystostomy tube placement in grade II and III cholecystitis in those high surgical risk patients in whom antibiotics and supportive care fails (Fig. 1).

Although the use of cholecystostomy tubes in the United States has increased 2.5 -fold from 1998 to 2010 (2.8% to 9.2%) in grade III cholecystitis, the majority of patients with grade II disease are appropriately undergoing immediate cholecystectomy based on data regarding safety in this setting. Recent data reporting on Medicare beneficiaries with a diagnosis gallstone disease between 1998 and 2011 found only 6.4% of patients with a diagnosis of grade III cholecystitis and only 3% of those patients actually underwent a cholecystostomy tube.

Despite the move toward early cholecystectomy in all patients presenting with acute cholecystitis, there remains a subset of patients who present with a high surgical risk secondary to the severity of their cholecystitis, the complexity of their comorbid conditions, or both. It is in this subset of patients that cholecystostomy tube placement may be indicated; however, there remains controversy regarding indications, which may be addressed by the new TG18 guidelines.

KEY POINTS

- The TG18, adapted from the TG13, takes into account patient comorbidities and disease severity in the management of acute cholecystitis and placement of cholecystostomy tubes.
- Current practice in the United States is more aligned with TG18 treatment of grade II and III cholecystitis.
- After a cholecystostomy tube is placed, its subsequent management remains variable in literature, with multiple algorithms proposed.
- Cholecystostomy tubes have both short- and long-term complications; once placed, patients should undergo interval cholecystectomy if their underlying medical conditions can be optimized and cholecystectomy safely performed.

INDICATIONS FOR CHOLECYSTOSTOMY TUBE PLACEMENT

It is important to understand that cholecystostomy tube placement is driven by two main components: gallbladder pathology and patient-related factors. Gallbladder pathology primarily refers to the presence or absence of stones (calculous or acalculous cholecystitis), the severity of the inflammatory process, underlying malignancy, presence of sepsis or hemodynamic instability, and the duration of symptoms. The patient-related factors are more subjective and less well defined, typically based on physician judgment. Patient-related factors can include underlying cardiac, respiratory, renal, and other systemic disease that increase surgical risk. Such comorbid conditions in the setting of acute cholecystitis may lead to physiologic decompensation in the setting of manageable inflammation from the surgical standpoint. In the United States, cholecystostomy tube placement is performed in critically ill, debilitated, and/or high surgical risk with cholecystitis.

The TG18 guidelines attempt to define the group of patients at high risk for early operative intervention by including the CCI and ASA classifications. In TG18, for grade II disease, cholecystostomy tube is recommended in patients who have a CCI of 6 or greater or are ASA class III or greater in whom supportive care with antibiotics have failed.

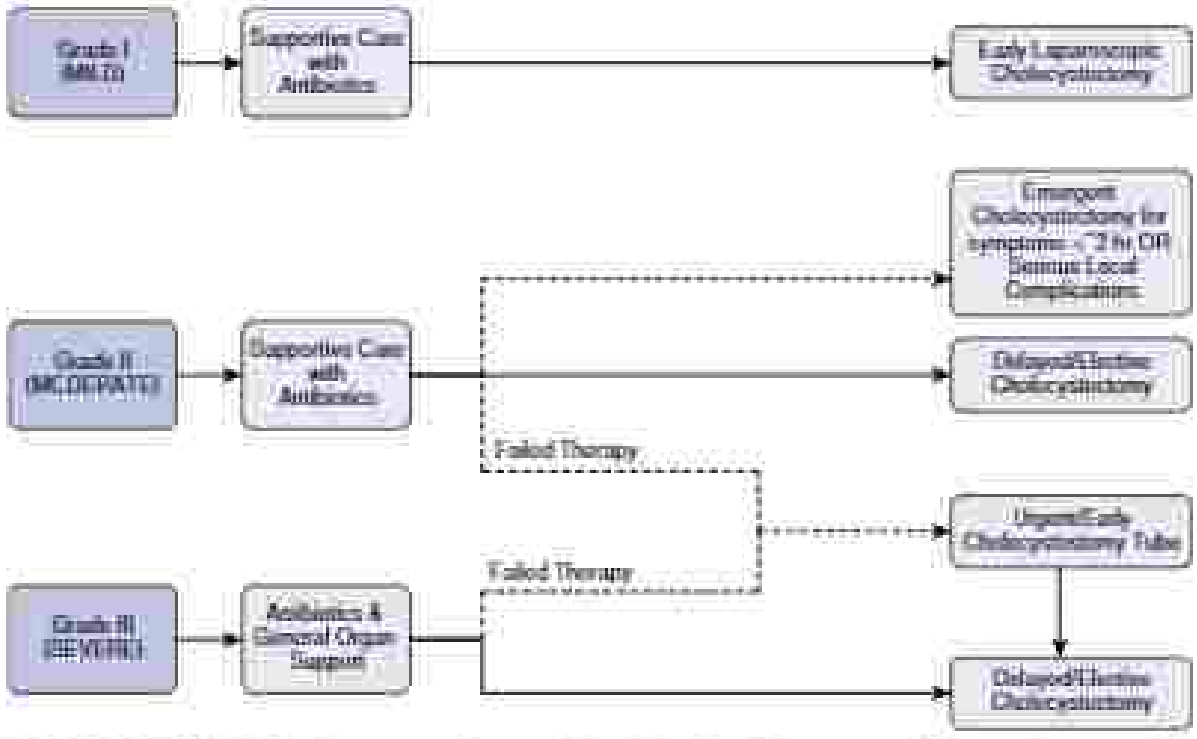

FIG. 1 Tokyo Guidelines 2013 algorithm for the management of acute calculous cholecystitis. Cholecystostomy tube placement is recommended in grade II and III disease when antibiotics and supportive care do not give the source control. Delayed elective cholecystectomy is recommended after tube placement. (From Mayumi T, Okamoto K, Takada T, et al. Diagnostic criteria for the diagnosis and treatment of acute cholangitis and cholecystitis. J Hepatobiliary Pancreat Surg. 2007;14:27–34.)

to control local inflammation. For grade III disease, a cholecystostomy tube is recommended in patients who fail supportive care with antibiotics, who are jaundiced and have neurologic or respiratory dysfunction, and whose associated organ system failure is not rapidly reversible with therapy. A cholecystostomy tube is also recommended in grade III disease, in which antibiotics and supportive care is effective, cardiovascular and renal organ system failure is reversed, but the patient has a poor performance status (ECOG >4 and ASA class V) (Fig. 2).

Acute Calculous Cholecystitis

Acute cholecystitis is most often related to gallstones. Complications from gallstones include acute calculous cholecystitis, choledocholithiasis, cholangitis, and gallstone pancreatitis. The pathophysiology of acute cholecystitis is obstruction of the cystic duct by an affected gallstone, which then leads to transmural edema and inflammation with potential necrosis. Cholecystostomy tube placement allows for gallbladder decompression in the setting of cystic duct obstruction without requiring a major anesthetic because the procedure can be done under ultrasound guidance, with local anesthetic and sedation. Decompression of the gallbladder reduces the inflammatory process allowing the patient to recover from the infectious process and any underlying systemic inflammatory response. Further, cholecystostomy tube placement provides a bridge to definitive therapy with an interval cholecystectomy.

Multiple studies in the United States have looked at the use of cholecystostomy tube decompression in the setting of acute calculous cholecystitis (Table 2). These studies indicate that the primary indications for tube placement are patient related and rather independent of the severity of cholecystitis, mostly including patient comorbidities making the risk of anesthesia and surgery prohibitive (Table 2). Some studies are nonspecific, simply recommending cholecystostomy tube in "poor surgical candidates" without clear definitions. Other studies report specific patient related factors as indications for cholecystostomy tube placement. In 2017, Hanks et al. reported in a retrospective analysis of 424 cholecystostomy tube patients that it was at the attending surgeons discretion whether a patient was considered a high risk surgical candidate; review of the data identified five risk factors for cholecystostomy tube placement: cardiac surgery within 3 months of symptom onset, pulmonary infection, end stage liver disease with cirrhosis, new diagnosis of pulmonary embolism, use of systemic anticoagulation, or hemodynamic instability. Other retrospective reviews have reported cholecystostomy tube indications such as stage IV terminal cancer and coronary artery disease.

Acalculous Cholecystitis

Other studies have reported cholecystostomy tube placement in patients with acalculous cholecystitis (Table). Acalculous cholecystitis primarily occurs in patients who are critically ill who cannot tolerate surgical intervention. Given the lack of cholelithiasis, this is not considered an obstructive process. One of the larger retrospective studies on acalculous cholecystitis found lower morbidity in the cholecystostomy tube group compared with the cholecystectomy group but mortality was similar. Mortality rates in those with acalculous cholecystitis and percutaneous cholecystostomy tubes remain relatively high according to the data, 30-day and in-hospital mortality ranges from 9% to 21%. Even though these data propose cholecystostomy tubes as definitive treatment for those with acalculous cholecystitis who cannot tolerate cholecystectomy, one-third of patients eventually undergoes definitive treatment with a cholecystectomy (Table).

Underlying Malignancy Precluding Definitive Surgery

A small subset of patients develop acalculous cholecystitis from an obstructive process secondary to underlying malignancy, as in the

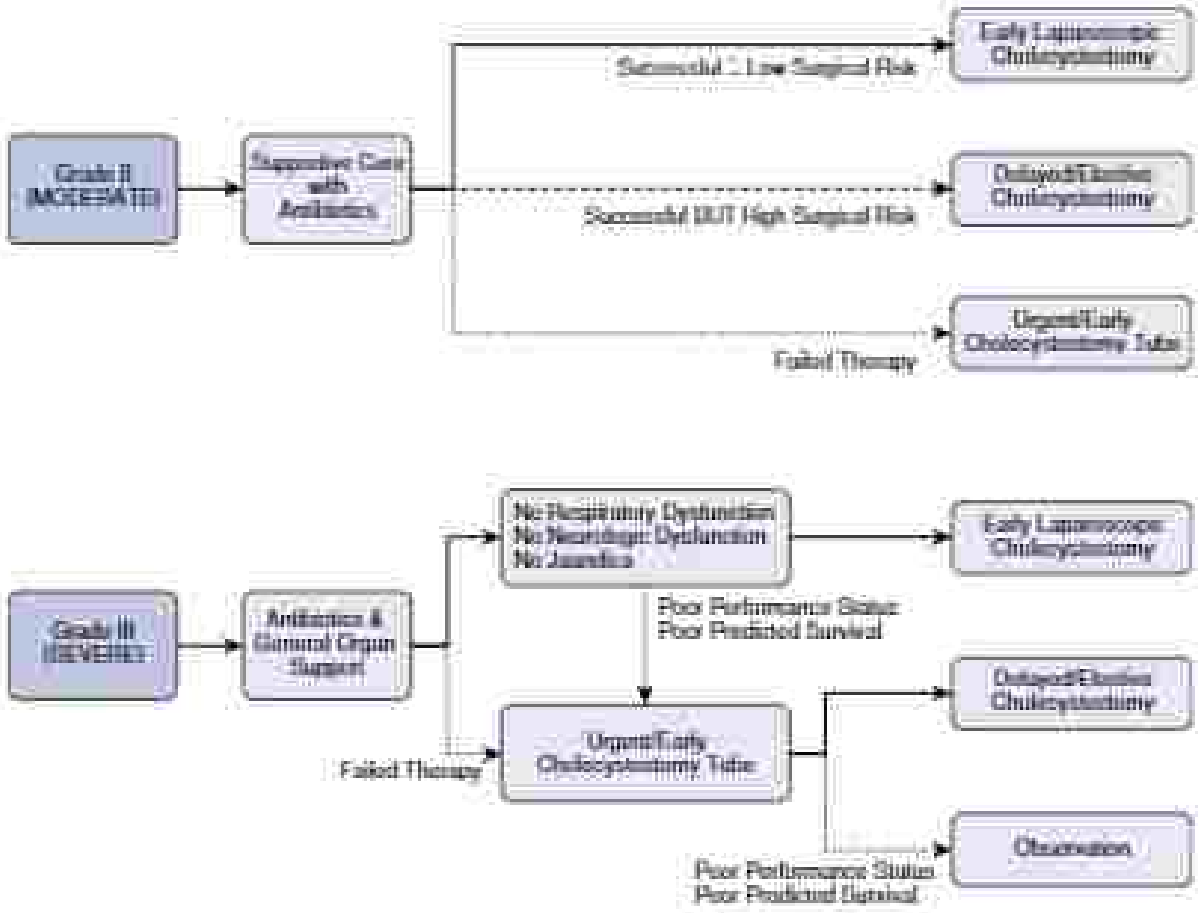

FIG. 2 Tokyo Guidelines 2018 algorithm for the management of patients with acute calculous cholecystitis. Cholecystostomy tube is now recommended in patients with grade II disease only if they fail antibiotics and supportive care and are not candidates for cholecystectomy based on poor performance status as measured by a Charlson Comorbidity Index >4 or American Society of Anesthesiologists class >3. In grade III disease, cholecystostomy is recommended in patients who (1) do not respond to antibiotics and supportive care, (2) have respiratory and/or neurologic dysfunction, and (3) do not rapidly resolve their cardiovascular and renal dysfunction. After cholecystostomy tube placement, cholecystectomy is recommended unless the Charlson Comorbidity Index is >4 and life expectancy is short, in which case patients can be observed. These management protocols assume advanced clinical centers with intensive care unit care, appropriate surgical expertise, and advanced endoscopy. [Adapted from Yokoe M, Takada T, Strasberg SM, et al. New diagnostic criteria and severity assessment of acute cholecystitis in revised Tokyo Guidelines. J Hepatobiliary Pancreat Sci. 2012;19(6):578–585.]

case of pancreatic cancer and cholangiocarcinoma. In this population, the malignancy itself can obstruct the cystic duct leading to cholecystitis or the intervention such as stenting of the bile duct to relieve a common bile duct obstruction can occlude the cystic duct. In both cases, the underlying malignancy may preclude a safe cholecystectomy and, in our opinion, a cholecystostomy tube is indicated. Multiple case reports and one retrospective study have shown that the use of a cholecystostomy tube in these instances decompresses the gallbladder and allows patients to recover and potentially proceed to treatment of their malignancy. In the case of resectable disease, the gallbladder can be addressed at the time of definitive therapy. In these cases, close tube management in a multidisciplinary team effort as patients will not be able to undergo definitive interval cholecystectomy.

TABLE 3 Studies Primarily Reporting Outcomes in Patients With AAC Who Undergo PC Placement

Study	Total AC (N)	Study Design	Outcomes
Hara (2015)	278	Retrospective	30 day mortality was 4.7%–54.7% of patients were definitively treated with PC with a follow up of 5 yr. 23.0% of patients were readmitted for recurrent cholecystitis; 29% underwent an LC at some point in the study period.
Kirkegard (2015)	56	Observational	30 day mortality was 16.7% with 80.4% being definitively treated with PC; 9% underwent LC at some point in the study period.
Anderson (2014)	8329	Retrospective	Decreased mortality in patients undergoing cholecystostomy vs PC (hazard ratio, 0.78; $P < .001$).
Simone (2013)	704	Retrospective	Compared with LC and OC, those who underwent PC had decreased LOS, mortality, ICU stay, and cost. No difference in mortality.
Chang (2012)	57	Retrospective	In-hospital mortality was 23% and 0% were managed nonoperatively; 19% underwent cholecystectomy; 2% had recurrent cholecystitis.

TECHNIQUE OF CHOLECYSTOSTOMY TUBE PLACEMENT

In 2018, the majority of cholecystostomy tubes are placed via a percutaneous approach. However, these tubes can also be surgically placed via an open or laparoscopic approach. Success rates of tube placement exceed 90% in most studies. Percutaneous cholecystostomy is most often performed by interventional radiologists in tertiary centers but can be done by a trained surgeon or physician. After localization by computed tomography (CT)/ultrasound (Figs. 1 and 4), the gallbladder is accessed percutaneously with radiologic guidance via either a transhepatic or transperitoneal approach. Traditionally, the transhepatic approach is preferred especially if it is possible to go through the liver area of a gallbladder to prevent the possibility of peritoneal spillage. This approach prevents bile leakage, especially in the setting of severe cholecystitis and a potentially necrotic gallbladder wall. In practice, however, there is the possibility of hepatic abscess and transient bacteremia with the transhepatic approach due to the direct connection with hepatic sinusoids. The transperitoneal approach is an alternative method which works best when the gallbladder wall is extremely inflamed and thickened because it is more likely to stick, and also more likely to contain a cutting wire without rupturing.

A long, hollow Yueh sheathed needle is placed to access the gallbladder through the liver and bile is aspirated (Fig. 3C, D). In many cases, the cystic duct is obstructed and this fluid will be clear secondary to the resolution hydrops. Once the gallbladder is accessed, a wire (short 35 cm Amplatz or Rosen curved tip wire) is placed into the gallbladder through the needle (Fig. 3C–D). A dilator is placed over the wire and an 8Fr pigtail catheter is then advanced and coiled in the gallbladder lumen (Fig. 3E and Fig. 4E, F). At the end of the procedure a CT and/or ultrasound are used to confirm the position (Fig. 4D, F). The drain is secured to the skin by a suture or proprietary adhesive device.

A cholecystostomy tube can also be placed surgically via a laparoscopic or open approach. This option should be kept in mind when the surgeon operates with the intent of performing cholecystectomy but finds inflammation so severe he or she feels dissection is unsafe for the patient to undertake and thus is aborted. In either approach, the gallbladder is directly visualized by the surgeon and the tube is can be placed under direct vision through a small cholecholecystostomy or transhepatically using the Seldinger technique. If placed directly into the gallbladder, the drain can be secured to the gallbladder wall to prevent bile leakage around the tube or slippage of the tube. If the gallbladder wall is necrotic, a frustrating partial cholecystectomy, removal of stones, and wide drainage may be a better option if cholecystectomy is not feasible.

Complications of Cholecystostomy Tube Placement

Although cholecystostomy tube placement is often not difficult and can avoid operation in poor surgical candidates, both immediate and long-term complications can occur. Immediate complications from cholecystostomy placement include failure of resolution/progression of acute cholecystitis, biliary peritonitis, sepsis, and tube dislodgement. Data on complications are largely derived from small, single institution retrospective studies. Although actual placement of the cholecystostomy tubes is 98% to 100% in most studies, some patients will not resolve their cholecystitis after placement of a cholecystostomy tube as measured by ongoing sepsis, leukocytosis, and/or right upper quadrant (RUQ) pain. In a study by Joseph et al., 32% of critically ill patients who had a cholecystostomy tube placed did not improve or declined clinically after cholecystostomy tube placement. Cha and colleagues reported a technical success rate was 100% in 82 patients undergoing cholecystostomy tube placement, with a clinical success rate of 98%, with one patient dying of cholecystitis-related complications. Across studies, 5% to 63% of patients underwent subsequent cholecystectomy; the timing of cholecystectomy is not clearly described, but most are delayed cholecystectomy for definitive management and not for failure to resolve immediate symptoms.

Overall complications specifically related to cholecystostomy tube placement ranged from 0% to 33% across studies and are primarily related to bleeding, or bile leakage/tube dislodgement. To prevent bleeding, especially in a transhepatic approach, the surgeon and/or interventional radiologist should ensure that any coagulopathy is corrected before tube placement. Bile leakage can occur if the tube is dislodged or the gallbladder wall is necrotic and the bile leaks around the tube itself. This can lead to sepsis, diffuse biliary peritonitis, or a biloma/abscess in the RUQ if the leakage is contained and

localized. This should be suspected when leukocytosis worsens or does not improve after tube placement or signs and symptoms initially improve and the patient subsequently develops sepsis, hemodynamic instability, fever, worsening leukocytosis, or worsening RUQ or abdominal pain.

In the long term, both readmission to the hospital and recurrence of acute cholecystitis are common after cholecystostomy tube placement if delayed definitive therapy with cholecystectomy is not performed. There is significant cost associated with frequent hospital visits, radiologic interventions, and overall increased hospital days, stressing the importance of definitive cholecystectomy when at all possible. Recurrence of acute cholecystitis after cholecystostomy tube placement ranges from 9% to 41% in small series and readmissions occur up to 41% of the time in some studies. Readmissions are most commonly related to inadvertent tube dislodgement or removal, tube occlusion, recurrent cholecystitis, or catheter site related pain.

In a study of long term outcomes in Medicare beneficiaries with grade III cholecystitis, 30-day, 90-day, and 1-year survival was significantly lower in patients who underwent cholecystostomy tube placement compared to propensity matched controls. Specifically, 1-year survival was 39% versus 61% in those with a tube compared to those without, respectively.

Long-Term Management of Cholecystostomy Tubes

Cholecystostomy Tube removal

The management of cholecystostomy tubes after initial treatment remains controversial. There are no published guidelines regarding tube management; however, the TG2018 clearly recommend delayed cholecystectomy after tube placement, regardless of initial grade of the cholecystitis. In the literature, several authors propose different algorithms for the management of cholecystostomy tubes, many of which involve cholangiography to assess the patency of the cystic duct and biliary tree. The duration of recommended tube drainage, the need for definitive cholecystectomy, the timing of tube removal, and the timing of cholecystectomy if performed remain topics of debate. The reported median length of time that the tube remained varies widely in the literature and depends on whether definitive cholecystectomy was performed. Times ranged up to 70 days if patients did not undergo definitive treatment with a cholecystectomy compared with only 10 days in those who eventually underwent cholecystectomy. Most studies recommend drainage for 3 to 6 weeks because this allows a tract to develop. Others recommend earlier removal and early definitive cholecystectomy, whereas others recommend a longer period of tube drainage in patients with uncontrolled diabetes, persistent infection, malnutrition, and those on steroids. Such conditions may hinder the healing process and tube drainage is recommended for a longer period.

In a study by Cha and colleagues, patients underwent a cholangiogram through the cholecystostomy tube to evaluate for patency of the cystic duct and biliary tract once their symptoms and clinical status improved. This was done during the index hospitalization. If patency was demonstrated via contrast emptying into the duodenum, the catheter was clamped. If, after clamping, patients developed recurrent cholecystitis, worsening laboratory values, or worsening symptoms the catheter placed back to external drainage for 7 days at which time patients were reassessed. If the patient tolerated clamping and had continued clinical improvement, the cholecystostomy tube was removed during the initial admission. If the cystic duct was not patent, patients were discharged with the cholecystostomy tube and draining externally.

Zamir and colleagues reviewed outcomes of 119 patients who underwent cholecystostomy tube placement for acute cholecystitis. In their study, all patients who underwent tube placement were discharged with the tube in place and draining externally. Follow-up cholangiogram 2 to 3 weeks later, if the duct was patent and the patient was deemed an appropriate surgical candidate the tube was clamped, left in place, and the patient subsequently underwent

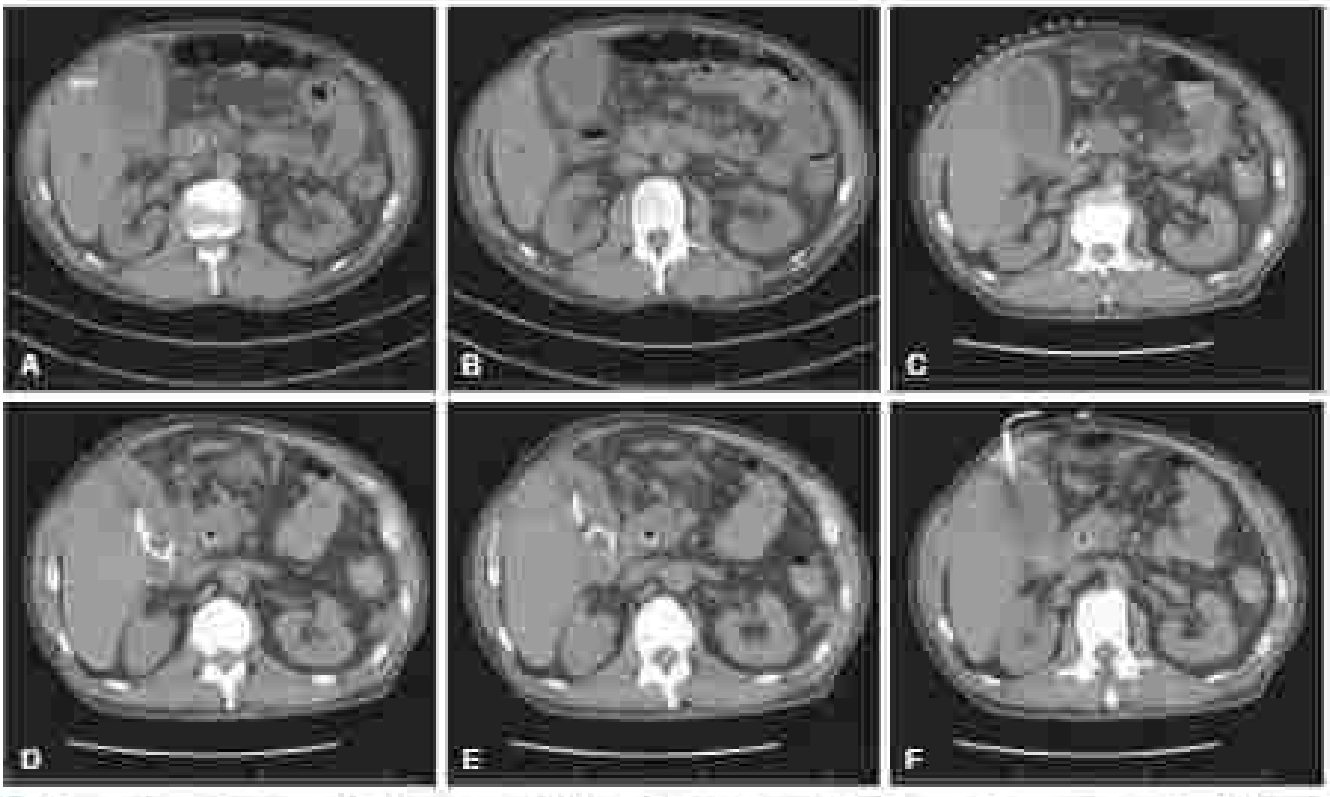

FIG. 4 Computed tomography placement of cholecystostomy tube. (*A–E*) Gallbladder is decompressed. (*C*) Computed tomography markers placed on abdominal skin on right upper quadrant to help with guidance. (*D–F*) Infiltration of pigtail catheter placement in gallbladder lumen.

cholecystectomy. In patients who were not deemed to be had biliary tract patency, the tube was removed.

Ultimately, tube removal is dependent upon resolution of the patient's symptoms, the presence or absence of cystic duct obstruction, and whether the patient is a candidate for cholecystectomy. This is done through evaluation of laboratory values, abdominal examination, and patient's report of resolved abdominal pain. In our opinion, if the patient's acute cholecystitis has resolved and he or she is a candidate for cholecystectomy, tube evaluation is not necessary. Cholecystectomy should be scheduled as soon as possible and the tube should be left in situ and draining externally until surgery is performed. This can be done laparoscopically or open, though conversion rates in this setting are higher than normal should not be unexpected. If the patient's clinical status improves and he or she is not a candidate for cholecystectomy, the patient should undergo a tube cholangiogram. Specifically, there must be patency of the patient's cystic duct or tube removal should not be considered as the likelihood of recurrent episodes of cholecystitis is extremely high. The timeline in which a cholangiogram is done in these patients varies in the literature, but we recommend 3 to 4 weeks to allow for a good track to form before tube removal. If cholangiogram demonstrates a patent cystic duct, the next step is clamping of the cholecystostomy tube, with removal in the absence of recurring symptoms after clamping.

Of note, the criterion of cystic duct patency does not necessarily apply to those with acalculous cholecystitis as the pathophysiology is different, but patients should at least undergo clamping trials before removal to reduce the risk of patient's having recurrent symptoms after tube removal and requiring an additional procedure.

Definitive Treatment With Cholecystectomy

Cholecystectomy remains the only definitive treatment for patients with acute cholecystitis. In patients who undergo cholecystostomy tube placement, the TG18 recommend delayed interval cholecystectomy after tube placement (Figs. 1 and 2), except for patients with initial grade III disease, poor performance status, and limited predicted life expectancy. These recommendations apply to those with calculous cholecystitis, but other reports on patients with acalculous cholecystitis agree that cholecystectomy may not be necessary. The recurrence of acute cholecystitis in those who do not undergo definitive therapy ranges from 11% to 41%; therefore, definitive therapy should be sought after if the patient's clinical status allows.

Despite the Tokyo guidelines and recommendation for cholecystectomy, cholecystectomy rates vary widely, with 15% to 80% of patients undergoing cholecystectomy after cholecystostomy tube placement across small retrospective series. Ideally, cholecystectomy should be done in the elective setting after the patient's clinical status has improved. Cholecystectomy may be required more urgently if cholecystostomy tube placement fails to control local inflammation and systemic sepsis or recurs acutely. Data published in Medicare beneficiaries undergoing cholecystostomy tube placement for grade III cholecystitis demonstrate that only one third of these patients undergo definitive treatment with a delayed cholecystectomy.

PROPOSED ALGORITHM FOR CHOLECYSTOSTOMY TUBE PLACEMENT AND MANAGEMENT

The proper use of cholecystostomy tubes includes temporary treatment for patients with cholecystitis, calculous or acalculous, who cannot tolerate surgery according to the TG18 guidelines. The severity of cholecystitis or the duration of symptoms are not absolute contraindications for cholecystectomy and do not mandate cholecystostomy tube placement. Potential reasons for a patient's inability to tolerate surgery includes severe systemic disease including cardiovascular disease, underlying malignancy, and any condition that precludes general anesthesia.

The TG18 algorithm for management of patients with acute cholecystitis is shown in Fig. 2. Initial evaluation should include assessment of patients' clinical status and severity of their gallbladder disease. If patients are hemodynamically stable and able to tolerate a general anesthetic, cholecystectomy should be performed as soon as possible during the index admission regardless of the Tokyo grade. Cholecystostomy tubes should be reserved for patients who do not rapidly respond to antibiotics and supportive care and are not candidates for cholecystectomy due to underlying comorbidity and/or physiologic decompensation resulting from acute illness. In cases of grade III disease, if a patient improves with antibiotics and organ support, reevaluation should be undertaken during his or her index hospitalization for possible cholecystectomy. If not performed on the index admission, then delayed or elective cholecystectomy should be done should on patients who have a life expectancy of greater than a year as recurrence rates are high. Incorporating models that predict patient survival into the treatment algorithms for patients with grade II and III cholecystitis may help guide decision making. Regardless, as with all interventions, there are risks and benefits, therefore, physicians must consider the risks and benefits of this intervention and its long-term consequences.

Management of Common Bile Duct Stones

Cecilia T. Ong, MD, and Theodore N. Pappas, MD, FACS

Choledocholithiasis refers to the presence of gallstones in the common bile duct. If choledocholithiasis is suspected preoperatively, it is usually managed via endoscopic retrograde cholangiopancreatography (ERCP) to prevent complications such as cholangitis, obstructive jaundice, and pancreatitis. Because common duct stones can often go unrecognized before surgery however, it is imperative for surgeons, especially those who routinely perform laparoscopic cholecystectomy, to know the surgical approaches to cholangiography and common bile duct exploration for stone extraction.

EPIDEMIOLOGY AND PRESENTATION

Most cases of choledocholithiasis are clinically asymptomatic and thus, the true incidence of disease is unknown. Choledocholithiasis may be identified in 10% of cholangiograms routinely performed at the time of cholecystectomy. Retained stones are also discovered following 1% to 2% of cholecystectomies despite normal preoperative liver function tests. When not clinically silent, common duct stones may present as right upper quadrant pain that is more prolonged than typical episodes of biliary colic; as symptoms of obstructive jaundice such as dark urine, acholic stools, or as ascending cholangitis. Charcot's triad, the constellation of fever, right upper quadrant pain, and jaundice, is considered pathognomonic for cholangitis; however, the full triad is only present in approximately 15% to 20% of patients with the condition. Progression to hypotension and mental status changes which comprise Reynold's pentad indicates shock from a biliary source and requires emergent biliary decompression.

Pathophysiology

Common duct stones are classified by their point of origin. Primary stones arise in the bile duct and comprise a precipitate of bile pigments and cholesterol. These so called brown pigment stones are more common in Asian populations and are associated with bacterial infection of the bile duct and/or biliary stasis. Secondary stones travel from the gallbladder and lodge in the common bile duct and are the major etiology of calculous biliary disease in the United States.

Diagnosis

Patients with symptomatic cholelithiasis routinely undergo liver function tests and transabdominal ultrasonography; these can suggest the potential for choledocholithiasis or other variants of biliary disease. Elevated liver function tests and common bile duct dilation warrant further evaluation for choledocholithiasis.

Abnormalities in the hepatic function panel indicating a cholestatic picture include elevated total bilirubin, alkaline phosphatase, and amylase. Though these are commonly present in choledocholithiasis and can help differentiate this condition from uncomplicated gallstone disease, functional gallbladder disorders, or acute cholecystitis, such enzymatic derangements are neither sensitive nor specific for choledocholithiasis.

Ultrasound is the initial imaging study of choice for a diverse array of suspected biliary issues due to its noninvasive nature and low cost. It may demonstrate the presence of common duct stones. In the absence of visualized stones, though, biliary ductal dilation (>6–8 mm) in the setting of right upper quadrant pain, gallstones, and/or jaundice is highly suggestive of choledocholithiasis. Transabdominal ultrasound has poor sensitivity for stones in the distal common bile duct as views can be obscured by overlying bowel gas. Findings on ultrasound can assist in the decision to pursue further imaging or management of suspected choledocholithiasis.

ERCP offers an opportunity for diagnosis and management of common duct stones. It is a highly sensitive and specific method of diagnosis and, when paired with sphincterotomy or balloon dilation and stone extraction, is an effective method of treatment for choledocholithiasis. ERCP is currently used in more than 90% of cases of common duct stones and can provide therapeutic clearance of stones in 75% of patients at the first procedure, and in 90% if a repeat procedure is required. This modality is preferred for patients with high risk or suspicion of choledocholithiasis, ascending cholangitis, biliary pancreatitis, limited surgeon/center experience, and patients with multiple medical comorbidities and/or contraindications to surgery. ERCP can also be pursued postoperatively when incidentally discovered choledocholithiasis cannot be managed by common duct exploration or for retained stones. ERCP can fail, however, when stones are large, intrahepatic, multiple, or impacted, or if there is altered gastric or duodenal anatomy or duodenal diverticula. Failure of ERCP necessitates operative intervention. Furthermore, as it is an invasive procedure, ERCP is not without complications including pancreatitis, bleeding, and perforation.

Endoscopic ultrasound (EUS) and magnetic resonance cholangiopancreatography (MRCP) are both highly sensitive and specific methods of imaging the biliary tree which have replaced ERCP as the diagnostic modalities of choice in patients at intermediate risk for choledocholithiasis. When EUS demonstrates stone disease, the endoscopist can proceed immediately to therapeutic ERCP. When the EUS is negative, the potential risks of post-ERCP complications, including pancreatitis, can be avoided. MRCP is an attractive noninvasive option but has the potential to miss biliary sludge and stones smaller than 4 mm.

Percutaneous transhepatic cholangiogram similarly offers a route of diagnosis and management of choledocholithiasis. It has similar complication rates to ERCP and is most effective in patients with a dilated biliary system.

General Considerations in the Management of Choledocholithiasis

If choledocholithiasis is determined preoperatively, postoperatively, or in patients with symptoms of cholangitis, every attempt should be made for endoscopic sphincterotomy and stone extraction. Successful ERCP with stone extraction does not eliminate the risk of recurrent biliary stone disease, however, and 30% will have recurrence of symptoms after successful ERCP. Thus, in good surgical candidates, interval cholecystectomy with intraoperative cholangiogram is generally recommended following ERCP duct clearance.

Patients who failed endoscopic therapy or who are determined to have choledocholithiasis intraoperatively can receive intraoperative ERCP, intraoperative common bile duct exploration (discussed later), or postoperative ERCP. The choice between these approaches largely depends on equipment availability and surgeon comfort with intraoperative exploration.

Patients at intermediate risk for choledocholithiasis, such as those with dilated common bile duct without visualized stone or clinical gallstone pancreatitis, can undergo EUS- or MRCP or can proceed to laparoscopic cholecystectomy with intraoperative cholangiogram.

Endoscopic Common Bile Duct Clearance

The endoscopic methods for bile duct clearance include sphincterotomy, balloon dilation of the ampulla, and basket or balloon extraction techniques. Sphincterotomy involves severing the deep muscle layers of the sphincter of Oddi with electrocautery to relieve the anatomic barrier to stone passage and to facilitate stone extraction.

sphincterotomy is the procedure of choice for patients with dilated common bile ducts. A sphincterotomy of adequate length to completely unroof the papilla decreases the risk of papillary stenosis. Balloon dilation can be used if the patient has contraindications to sphincterotomy such as anticoagulant or antiplatelet use. It can also aid in the removal of large stones if the sphincterotomy cannot be extended; however, it does increase the risk of post-ERCP pancreatitis relative to sphincterotomy.

Following sphincterotomy or balloon dilation, stones smaller than 1 cm can pass spontaneously. Larger stones can be extracted using balloon or basket retrieval devices. Basket devices are helpful with a dilated duct or when multiple stones are present. The successful extraction of multiple or large stones can be improved with mechanical lithotripsy. Balloons, commonly can be used in normal-sized ducts or single-free floating stones.

Short-term complications of ERCP with sphincterotomy include pancreatitis, perforation of the duodenum or bile duct, bleeding, and infection and occur in fewer than 10% of patients. Long-term, stone recurrence is the most commonly cited complication, hence the recommendation for cholecystectomy in appropriate surgical candidates. Surgery is recommended within 2 weeks after the endoscopic clearance to decrease the risk of recurrent biliary events and conversion to open cholecystectomy. Other long-term but infrequent complications of sphincterotomy include papillary stenosis and cholangitis.

Young patients or those at a high risk of bleeding have an increased risk of developing such long-term complications. They are thus candidates for endoscopic methods that do not require sphincterotomy such as balloon dilation of the ampulla with stone extraction.

Intraoperative Cholangiography

Intraoperative cholangiography (IOC) should be performed before any attempt at laparoscopic common bile duct exploration. The equipment and setup required for IOC can include a 0.035-inch guidewire, 30- or 50-cc biliary Fogarty's catheters, wire baskets, balloons (8-mm outer diameter) or mechanical (7Fr–12Fr) dilators, 3- to 5-mm choledochoscope with 1.1 mm or larger working channel, loop ligatures, and T tubes. Additional cholangioscopic equipment and support includes a separate light source, an adapter to allow simultaneous irrigation via the biopsy channel, a second camera and monitor, picture-in-picture display with video switcher, C-arm, and fluoroscopy support. The C-arm is brought in from the patient's left side and its position should be taken into account when positioning video monitors, the operating surgeon, and the assistant.

To perform laparoscopic IOC, the critical view of safety is obtained as in a standard laparoscopic cholecystectomy. An additional 5-mm port can be placed in the right midclavicular line to facilitate access to the cystic duct. The gallbladder is left in situ to provide liver retraction and countertraction on the cystic duct. The critical view is obtained, and before opening the cystic duct, a clip is applied across the cystic duct–infundibulum junction above the site of the planned ductotomy. This prevents contrast passage into the gallbladder and further translocation of stones. A transverse ductotomy is created, and the contents of the duct are milked toward the incision. A 14-gauge transhepatic angiocatheter is placed in the right upper quadrant, through which a 4Fr–5Fr cholangiogram catheter with a reinforced tip is introduced. The cholangiogram catheter is guided laparoscopically into the cystic duct and secured using clips, cholangiogram clamps, or other devices. Water-soluble contrast is injected and fluoroscopy is used to evaluate the biliary anatomy including the junction of the cystic and common bile ducts and the size of the common duct, and filling defects impeding contrast flow into the duodenum or into the liver (Fig. 1).

If routine contrast administration does not adequately visualize the proximal or distal ductal system, pharmacological adjuncts can be employed. Visualizing the proximal bile ducts including the intrahepatic system can be aided by intravenous morphine to contract the sphincter of Oddi, directly occluding the distal bile duct, or repositioning the patient in Trendelenburg. To visualize the distal duct and confirm contrast passage into the duodenum, intravenous glucagon can be used to relax the sphincter of Oddi. Dilated ducts, filling defects, or failure of contrast flow into the duodenum can suggest the presence and position of choledocholithiasis. The successful and accurate completion of cholangiography is highly operator dependent and may be unfeasible in patients with a severely inflamed gallbladder or a small or inflamed cystic duct.

Laparoscopic Common Bile Duct Exploration

Despite the widespread adoption and performance of laparoscopic cholecystectomy, surgeon experience with laparoscopic common bile duct exploration is much more infrequent. However, for surgeons comfortable with the approach, it offers an attractive option to manage biliary stone impaction and prevent future recurrence of choledocholithiasis in one procedure. Access to the common duct is achieved through either the transcystic approach or directly through a choledochotomy.

Transcystic Approach

A transcystic approach is generally performed in patients with stones smaller than 1 cm, common duct diameter less than 8 mm, stone location distal to the junction of the cystic and common duct, and cystic duct diameter larger than 4 mm. It is contraindicated if the stones are in the common hepatic duct, numerous (>8), or large (>1 cm), or if the patient has a small friable cystic duct not amenable to instrumentation.

Following cholangiography, the duct is cannulated with a wire. The ductotomy already made for the cholangiogram can be used, or an incision closer to the junction with the common bile duct in a less tortuous segment of the duct can be made. If the patient has a narrow cystic duct, a flexible dilator or balloon catheter is passed over the wire via the Seldinger technique to dilate the duct (Fig. 2).

The initial maneuver to clear the duct is to flush the distal common bile duct with saline. Flushing of the proximal duct should be avoided; if stones are pushed into an intrahepatic location, they may be irretrievable. If the stone cannot be flushed through the duct, a balloon catheter is the next step in stone retrieval. A 3Fr–5Fr Fogarty balloon catheter is advanced through the ductotomy into the duodenum. Positioning of the catheter in the duodenum is confirmed

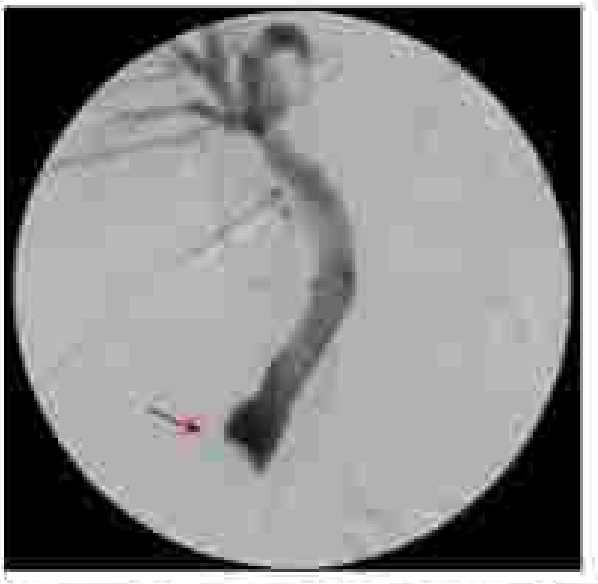

FIG. 1 Intraoperative cholangiogram shows obstruction of biliary drainage distally with a characteristic meniscus sign (arrow) indicating the presence of an obstructing common bile duct stone.

FIG. 2. Transcystic common bile duct exploration and stone extraction can be facilitated by balloon dilation of the duct, as explored here. The balloon catheter is advanced over a guidewire, which has been advanced from the cystic duct into the duodenum.

fluoroscopically then by inflating the balloon and withdrawing the catheter until the resistance of the ampulla is met. The balloon is deflated, withdrawn slightly, and inflated again. These steps are repeated until the stones are pulled retrograde through the ductotomy. Care should be taken to withdraw the catheter superiorly along the axis of the common duct, to increase the tension on the ductotomy. This procedure is generally effective but carries the risk of propagating stones into the common hepatic duct. If balloon catheter retrieval is unsuccessful, wire basket retrieval through a cholangiogram catheter is performed. The choledochoscope aids in visualization of the stone and reduces the trauma to the common bile duct, although it does require dilation of the cystic duct to accommodate the scope. A wire basket is advanced through the working channel of the scope, and once the stones are extracted, the basket is usually withdrawn together with the choledochoscope.

Following stone removal through the transcystic approach, the duct is irrigated again with saline and completion cholangiography performed to ensure duct clearance. The cholecystectomy is completed, paying particular attention to closure of the cystic duct stump to avoid bile leakage. This can be performed by clip or loop ligature; however, the latter is preferred due to the trauma of cystic duct dilation and instrumentation.

Direct Choledochotomy

Laparoscopic direct choledochotomy is indicated in the event of failure of the transcystic approach, in a narrow or tortuous cystic duct, in a dilated common duct (> 10 mm), large (>10 mm) or multiple stones, or stones located proximal to the cystic/common bile duct junction. Compared with the transcystic approach, choledochotomy has equivalent stone clearance rates but longer operative time and hospital length of stay. There are reports of lower postoperative bile leak rates following the transcystic approach, likely resulting from the additional laparoscopic suture applied to the cystic duct stump and lack of direct violation of the common duct wall.

To perform a direct choledochotomy, the gallbladder is again left in situ and the cystic duct is dissected down to the level of the common duct junction. The tissue overlying the anterior common duct is cleared, taking care to avoid excessive dissection which could compromise the peritubular blood supply and impair healing. Two stay sutures are placed on either side of the planned incision. A 1-cm incision into the common bile duct is made below the cystic duct takeoff. The orientation of the ductotomy is dependent on the planned method of closure: if T tube drainage is planned, the incision should be oriented longitudinally, whereas if a primary repair is planned, the incision is best oriented transversely. The stone can be directly extracted if its location is amenable; otherwise, similar techniques including saline flush, balloon, or wire basket capture can be performed as described previously.

At the completion of exploration, the common ductotomy can be closed with monofilament absorbable suture in a continuous or interrupted fashion primarily or around a 12Fr 14Fr T tube. Permanent suture should be avoided as this can promote further stone formation. Historically, routine T-tube drainage was performed after choledochotomy to provide biliary decompression while edema or spasm of the sphincter resolved, and to provide postoperative access to the bile duct for cholangiography or further intervention for retained stones; however, T tubes increase the risk of biliary leak, duct obstruction, and infection. Primary closure has been found to be feasible and safe with equivalent bile leak rates, shorter operative times, and hospital length of stay. The posterior attachments of the common bile duct preclude the mobilization necessary to close a longitudinal ductotomy transversely; thus, transverse closure of a transverse choledochotomy minimizes narrowing of the duct.

Open Common Bile Duct Exploration

Although the frequency of open common bile duct exploration has decreased with the greater utilization of endoscopic and laparoscopic approaches, the open approach is still required when these other measures have failed or are not possible, as in the case of previous gastric bypass, or when biliary drainage is required; thus, surgeons who perform laparoscopic cholecystectomy should be prepared to convert to open common bile duct exploration if needed. Open exploration is indicated in patients who have failed laparoscopic exploration, those with choledocholithiasis who have other indications for open cholecystectomy, and those with severe inflammation of the triangle of Calot that precludes dissection. The critical view of safety required in a laparoscopic approach is often unattainable when the open procedure is required. Thus, the gallbladder is usually dissected in a dome-down fashion to facilitate access to the cystic and common bile ducts.

Choledochotomy

To gain access for an open direct choledochotomy, a midline or right upper quadrant subcostal incision is made. The liver is retracted superiorly using a broad-bladed, curved retractor. The duodenum is retracted inferiorly, and the omentum and stomach to the patient's left to facilitate visualization. A Kocher maneuver is performed to expose the distal common bile duct. Gentle palpation of the duct can localize the stone and milk it back from the ampulla toward the eventual extraction point. After placement of stay sutures, a longitudinal, 1.5-cm choledochotomy in the distal common bile duct is made (Fig. 3). Stones can be milked to the incision and extracted manually, or balloon catheters can be used to clear the proximal then distal duct. Care must be taken to avoid crush injuries to the duct. If a flexible choledochoscope is available, it may be useful in extracting stones that are otherwise difficult to retrieve from the distal common bile duct.

Postclearance cholangiography via an 18Fr T tube is performed before duct closure. The ends are trimmed obliquely so the proximal limb does not obstruct the hepatic ducts and the distal limb terminates before the ampulla. The posterior wall of the T tube is excised to improve its flexibility and aid in eventual removal. The T tube is brought out through the skin of the abdominal wall under the costal margin and secured. Completion cholangiogram through the T tube is performed to confirm proper tube position and to verify there are no residual stones. The T tube can be removed about 2 weeks postoperatively after repeat T-tube cholangiography demonstrates patent distal flow. If a T tube is placed, a closed suction drain should also be placed next to the common duct; it can be removed in the first 2 days after surgery if a cholangiogram demonstrates a patent biliary system without biliary leakage around the T tube.

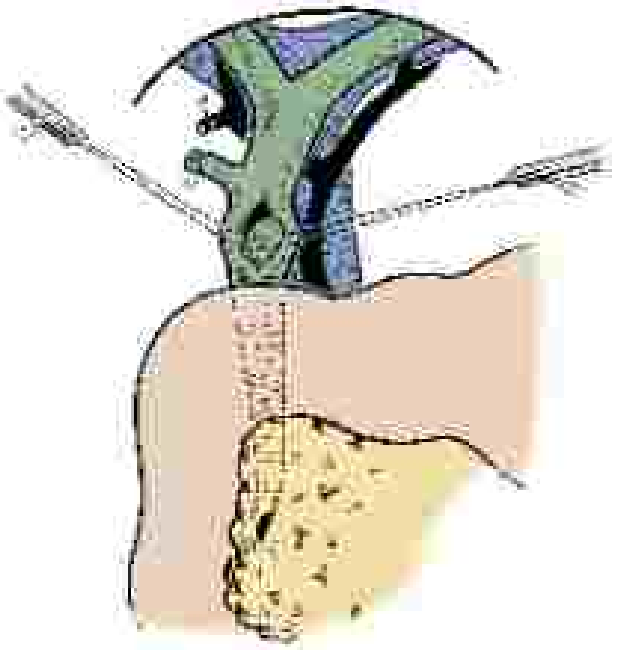

FIG. 3 Stay sutures are applied to either side of the planned choledochotomy to elevate the common bile duct and minimize the risk of injury to the posterior wall of the duct. From Jarnagin WR, Blumgart LH. Surgery of the bile ducts and the liver. In: Blumgart LH, ed. Surgery of the Liver, Biliary Tract and Pancreas. 4th ed. Philadelphia, PA: Elsevier; 2007.

Transduodenal Sphincteroplasty

A transduodenal sphincteroplasty may be necessary to provide drainage for patients with a nondilated biliary tree and stones impacted at the ampulla. This is contraindicated if there is a long supraphincteric stricture or severe periampullary inflammation. This procedure can be performed open or laparoscopically, although the latter should only be attempted by the most skilled laparoscopic surgeons. Lower linear placement than that for routine cholecystectomy suffices placing an additional port in the right lower quadrant can assist in the visualization of the ampullary reconstruction.

After Kocherization of the pancreas and duodenum, a longitudinal incision in the lateral aspect of the second part of the duodenum is made using electrocautery. The longitudinal orientation of the incision, when closed transversely, decreases the likelihood of stricture and potential duodenal obstruction. The papilla is then located and a 4Fr–5Fr flexible catheter, such as a Nélaton probe, is introduced into the ampulla. This provides a guide for the sphincterotomy, which is made using electrocautery to the 11 o'clock position to avoid injury to the pancreatic duct. Fine absorbable sutures are then placed between the duodenal wall and the common bile duct to suture open the sphincteroplasty. The total length of the sphincteroplasty should be approximately 10–12 mm to open the entire length of the common duct of the sphincter of Oddi. Adequate sphincterotomy allows the passage of angled Randall's forceps and stone extraction using these forceps, Fogarty's catheter, or wire baskets. Following successful stone removal, the longitudinal duodenotomy is closed transversely with absorbable sutures such as Vicryl or Maxon.

Biliary-Enteric Drainage

Certain patients should be considered for biliary-enteric drainage such as those with stones not amenable to endoscopic or surgical removal, or to prevent future recurrence of choledocholithiasis. Such procedures are indicated in elderly patients, those at risk for primary stone formation, or those with multiple, large duct stones, dilated ducts, intrahepatic stones, or benign distal bile duct stricture.

Choledochoduodenostomy

Choledochoduodenostomy is the most physiologic reconstruction and allows endoscopic access to the entire biliary tree; however, it may not be possible if the duodenum is inflamed or cannot be completely mobilized. In the laparoscopic approach, trocar placement is similar to that for transduodenal sphincterotomy as is the initial Kocherization and exposure of the distal common duct. A complete circumferential dissection of the duct is required if planning an end-to-side anastomosis. A 1.5 cm longitudinal supraduodenal choledochotomy is made in the anterior wall of the duct. A 1 cm longitudinal duodenotomy is made in the adjacent duodenum and is made shorter as the choledochotomy will stretch. The choledochoduodenostomy is then sewn in a side-to-side fashion with absorbable suture in a single layer, interrupted fashion.

Potential complications include sump syndrome, or emetic reflux into the common duct causing inflammation and recurrent cholangitis. This complication is seen more frequently in diabetic patients with side-to-side anastomoses as the bile duct distal to the anastomosis does not drain well and thus collects debris which could obstruct the anastomosis.

Roux-en-Y Choledochojejunostomy

The Roux-en-Y choledochojejunostomy is the most common surgical reconstruction for biliary obstruction. It provides superior drainage of the biliary tree but does not allow for postoperative endoscopic evaluation of the hepatic duct.

The jejunum is mobilized and divided with a stapler approximately 20 cm distal to the ligament of Treitz to create a 50- to 70-cm Roux limb. Enough mesentery is divided to allow the reach of the limb to the duct with care taken not to devitalize the limb. The Roux limb can be passed retrocolic or antecolic. The anastomosis can be created in an end-to-side or side-to-side fashion. For an end-to-side anastomosis, the bile duct segment is transected, and the stump is sutured with 3-0 absorbable sutures. A jejunotomy is created on the antimesenteric side of the bowel approximately 2 cm from the staple line. The anastomosis is constructed in a single layer with interrupted sutures of 4-0 absorbable sutures. A side-to-side anastomosis has a lower risk of bile duct devascularization. The anterior surface of the duct is exposed and a 2.0 cm ductotomy is created and the anastomosis to the jejunum is made as previously described. Finally, the jejunojejunostomy is created 40 cm distal to the choledochojejunostomy.

Approach to a Patient With Prior Cholecystectomy

Choledocholithiasis can occur following cholecystectomy resulting from a dropped stone at the time of cholecystectomy or to de novo stone formation within the duct. Retained stones are usually found within 2 years of cholecystectomy. Stones found longer than 2 years from cholecystectomy are attributed to primary stone formation. These brown pigment stones are more commonly seen in Asian countries, likely resulting from recurrent pyogenic cholangitis. However, primary choledocholithiasis can also occur in conditions associated with biliary stasis such as strictures, cysts, fibrosis, periampullary diverticuli, parasitic infections, choledochal cysts, or sclerosing cholangitis.

Transabdominal ultrasound is less helpful in diagnosing choledocholithiasis following cholecystectomy as postcholecystectomy patients can have physiologic dilatation of the duct up to 10 mm. In such patients, EUS or MRCP can confirm the presence of stones or, alternatively, in the absence of stones, may suggest sphincter of Oddi dysfunction. In either circumstance, ERCP is still indicated although, in the latter circumstance, additional measures such as biliary stents may prevent recurrence of symptoms.

Management of Acute Cholangitis

Leigh Anne Dageforde, MD, MPH, and
Keith D. Lillemoe, MD

Acute cholangitis, most commonly presenting as fever and right upper quadrant pain, results from either obstruction of the common bile duct (CBD), leading to bile stasis with the development of infection or from iatrogenic introduction of bacteria through biliary intervention. Severity of the disease can range from mild to severe and even life threatening when the infection becomes systemic and is not promptly diagnosed and treated appropriately.

EPIDEMIOLOGY

The most common cause of acute cholangitis is choledocholithiasis (30%–70%) usually secondary to cholelithiasis. Other etiologies of acute cholangitis in patients without prior intervention are benign stricture (5%–30%) or malignancy (10%–30%). Patients with prior intervention either from biliary stents, indwelling drains, or postoperative complications from biliary reconstruction are also at risk for acute cholangitis. In the recent era, this is an increasing cause of cholangitis. Although endoscopic retrograde cholangiopancreatography (ERCP) is the primary technique of biliary drainage for treatment of acute cholangitis, the procedure itself can result in cholangitis in up to 3% of patients undergoing therapeutic ERCP procedures. In addition, as many as 20% of patients are bacteremic postintervention of biliary endoscopy without developing symptoms of sepsis or cholangitis. Acute cholangitis occurs most commonly in patients aged 50 to 70 years and with equal prevalence in men and women. Risk factors include prior medical or surgical intervention on the biliary tree and the presence of choledocholithiasis; thus, risk factors for choledocholithiasis are also related to risks for acute cholangitis.

Relevant Anatomy/Pathogenesis

Acute cholangitis results from obstruction of the common bile duct. Bile is inherently sterile due to the continuous flow of bile, immunoglobulin A secreted in the biliary tree, and bile salts, which contain a bactericidal mechanism. Biliary stasis results in development of infection when bacteria enter the biliary tree through the sphincter of Oddi (ascending cholangitis) and proliferate often with the presence of a stone or stent to act as the nidus for infection. Systemic spread causing bacteremia and sepsis occurs via translocation into the portal vein into the systemic blood supply. Direct inoculation of the biliary tree via intervention and placement of biliary stents can also lead to acute cholangitis. Finally, an increasing occurrence occurs when existing stents or drains become malpositioned or develop partial or complete obstruction resulting from sludge or tumor ingrowth leading to biliary stasis and subsequent cholangitis.

Although the bacterial profile in acute cholangitis is polymicrobial, gram-negative rods are the most prominent bacteria present in acute cholangitis (Table 1). *Escherichia coli* is present in 25% to 50% of cases. Initial empiric antibiotic treatment should cover gram-positive and gram-negative bacteria as well as anaerobes. After culture sensitivities are determined, the antibiotic regimen can be narrowed to appropriate coverage. Patients should be treated 7 to 14 days with at least 2 weeks of treatment for patients with bacteremia and sepsis.

The obstruction can be intrinsic (stone, stricture, polyp, tumor, blood clot, infectious parasite, food impaction) or result from external compression on the duct. Similarly, causes can be benign or malignant. Benign structure can be inflammatory (from chronic pancreatitis or Mirizzi syndrome with compression by a stone filled gallbladder) or iatrogenic resulting from ischemia or injury. Benign iatrogenic strictures can develop following prior surgery without biliary reconstruction (most commonly cholecystectomy) or with biliary reconstruction following pancreaticoduodenectomy, liver transplant, or Roux-en-Y or other forms of biliary bypass. Malignant obstruction can be intrinsic to the common bile duct such as cholangiocarcinoma, or extrinsic from any malignancy causing compression of the common bile duct such as pancreatic, ampullary, gallbladder, or duodenal adenocarcinoma; however, malignant obstruction alone does not often result in cholangitis, and most patients with malignancy develop acute cholangitis only following prior intervention and manipulation of the biliary tree.

Biliary obstruction of the common bile duct can be at all levels but most commonly occurs distally resulting from a stone lodged at the sphincter. Obstruction from stricture or cancer leading to cholangitis can occur at any location from proximally at the right and/or left hepatic ducts duct to distally at the ampulla. The location of the obstruction along the CBD traditionally has affected treatment strategy; although currently nonoperative techniques are successful for managing obstructions at any location. Patients with biliary obstruction and previously placed stents will have infection proximal to the level of the stent and require exchange of the stent to reestablish free biliary drainage.

CLINICAL PRESENTATION

Fever and right upper quadrant pain are the most common symptoms, occurring in more than 80% of patients with acute cholangitis. Less than 20% of patients have all three symptoms of Charcot's triad: right upper quadrant pain, fever, and jaundice. Addition of altered mental status and hypotension (Reynold's pentad) are seen in patients with severe cholangitis. Immunocompromised and elderly patients may present with hypotension or altered mental status only. Severe acute cholangitis can progress to sepsis and multisystem organ failure, requiring admission to the intensive care unit.

Charcot's triad of symptoms are commonly seen in patients presenting with acute cholangitis but are not sensitive or specific enough for definitive diagnosis. In 2006, an International Consensus Meeting was held in Tokyo to better define diagnostic criteria for acute cholangitis. Since then, multiple iterations of the Tokyo Guidelines have been published, most recently in 2018. The Tokyo Guidelines classify patients as having three different grades of acute cholangitis and give recommendations to adjust treatment guidelines according to severity of illness.

Diagnosis

The differential diagnoses for patients presenting with acute cholangitis includes acute cholecystitis, Mirizzi syndrome, liver abscesses, right lower lobe pneumonia, or empyema.

Examination

Patients presenting with acute cholangitis range from mildly ill with mild right upper quadrant pain to severe tenderness on examination. Almost 60% of patients present with jaundice. Some patients may have high fever, hypotension, tachycardia, and altered mental status consistent with sepsis.

Laboratory Values

Most commonly, patients have elevated white blood cell count consistent with infection and elevated bilirubin (conjugated more than unconjugated) with associated elevations in alkaline phosphatase and transaminases. The tumor marker Ca 19-9 can be elevated because of the biliary obstruction but does not necessarily indicate the presence

TABLE 1 Most Commonly Isolated Bacteria From Bile and Blood Cultures in Acute Cholangitis

Organism	Bile Culture Isolates (%)	Blood Culture Isolates (%)	
		Community Acquired	Healthcare Associated
GRAM-NEGATIVE BACTERIA			
Escherichia coli	31–44	35–42	23
Klebsiella species	8–28	12–28	16
Pseudomonas species	0.5–19	4–14	17
Enterobacter species	5–8	2–7	7
Serratia species	—	1	7
Citrobacter species	—	2–6	5
GRAM-POSITIVE BACTERIA			
Enterococcus species	3–14	19–23	28
Streptococcus species	2–10	6–8	5
Staphylococcus species	0	2	4
Anaerobes (usually associated with polymicrobial infections)	8–20	1	2
Other (fungal, worms, flukes)	—	17	11

of malignancy. Ca 19-9 should be ordered in patients with malignant obstruction once the bilirubin normalizes and the obstruction is resolved. Bile cultures are positive in approximately 60% to 90% of cases, although they are not obtained in all cases of acute cholangitis and reported rates of positive blood cultures in acute cholangitis have ranged from 20% to 70%.

Imaging

Noninvasive imaging is necessary to distinguish cholangitis from other differential diagnoses and identify the underlying etiology of obstruction for therapeutic intervention guidance. Invasive imaging techniques, such as endoscopic ultrasound (EUS), often have better success at identifying common bile duct stones and the level of the obstruction along the biliary tree, but these studies are often not the best first test to perform in the setting of acute infection. If suspicion is very high for acute cholangitis, some may proceed with urgent ERCP if available so as not delay treatment. Patients with prior biliary tree interventions, especially with stents or drains, may proceed directly to repeat ERCP or interventional radiology as appropriate.

Abdominal Ultrasound

The first imaging test that should be obtained after stabilizing the critically ill patient and initiating broad-spectrum antibiotics is an abdominal ultrasound. Findings on ultrasound commonly show biliary dilation (can be isolated intrahepatic or both intra- and extrahepatic depending on the level of obstruction). Cholelithiasis and gallbladder sludge are a common finding in cholangitis, but the presence of gallbladder stones alone is not sufficient for diagnosis of cholangitis. Choledocholithiasis is often not appreciated even when biliary dilation is appreciated and can be diagnosed on ultrasound in only 30% of cases.

Cross-Sectional Imaging

Computed tomography (CT) scans document biliary dilation and even the location of the obstruction, but similar to ultrasound, CT is often not effective in identifying the source of obstruction (stricture vs stone vs mass). CT is only effective in identifying stones in the CBD in 40% of cases. MRCP is the best test for characterizing biliary structure and the underlying etiology. MRCP is about 80% accurate in diagnosing choledocholithiasis with stones greater than 6 mm. For smaller stones, MRCP is not as accurate in identifying the presence of stones but is still the best noninvasive test for demonstrating the location and nature of biliary stricture.

TREATMENT ALGORITHM

The primary treatment for acute cholangitis is urgent biliary drainage with appropriate antibiotic coverage followed by definitive surgical management to address the underlying etiology of the cause of obstruction (Fig. 1). Treatment of acute cholangitis requires a multidisciplinary team approach often involving interventional endoscopists and radiologists, and intensivists as well as infectious disease specialists if necessary. All patients should be promptly started on appropriate empiric antibiotic coverage. Single agent options for treatment include carbapenems or piperacillin-tazobactam. Metronidazole with the addition of cephalosporins or fluoroquinolones are options for dual therapy. For severe or hospital-associated cholangitis, vancomycin should be added and fungal coverage considered. Appropriate definitive antibiotic coverage is dependent on drug resistance patterns, patient allergies and comorbidities, and final culture data from blood and bile cultures (Box 1).

Patients with severe acute cholangitis should be admitted to an intensive care unit with fluid resuscitation, broad-spectrum antibiotics, correction of any electrolyte abnormalities, critical care monitoring, and any support necessary such as pressors or intubation. Patients with prior biliary intervention with external drains should have those drains placed to gravity drainage and have any obstructed drains flushed or exchanged if necessary. Those with indwelling stents will require urgent endoscopic intervention to potentially relieve any stent obstruction and/or exchange the obstructed prosthesis.

Seventy-two patients with symptoms of sepsis should undergo biliary drainage as soon as they are adequately resuscitated and stabilized. Moderate acute cholangitis requires biliary drainage, although with less urgency than severe disease. Patients with mild disease may respond to antibiotics and not require biliary drainage (Box 2). Recent literature indicates less urgency is required for biliary drainage in severe cholangitis than formerly recommended;

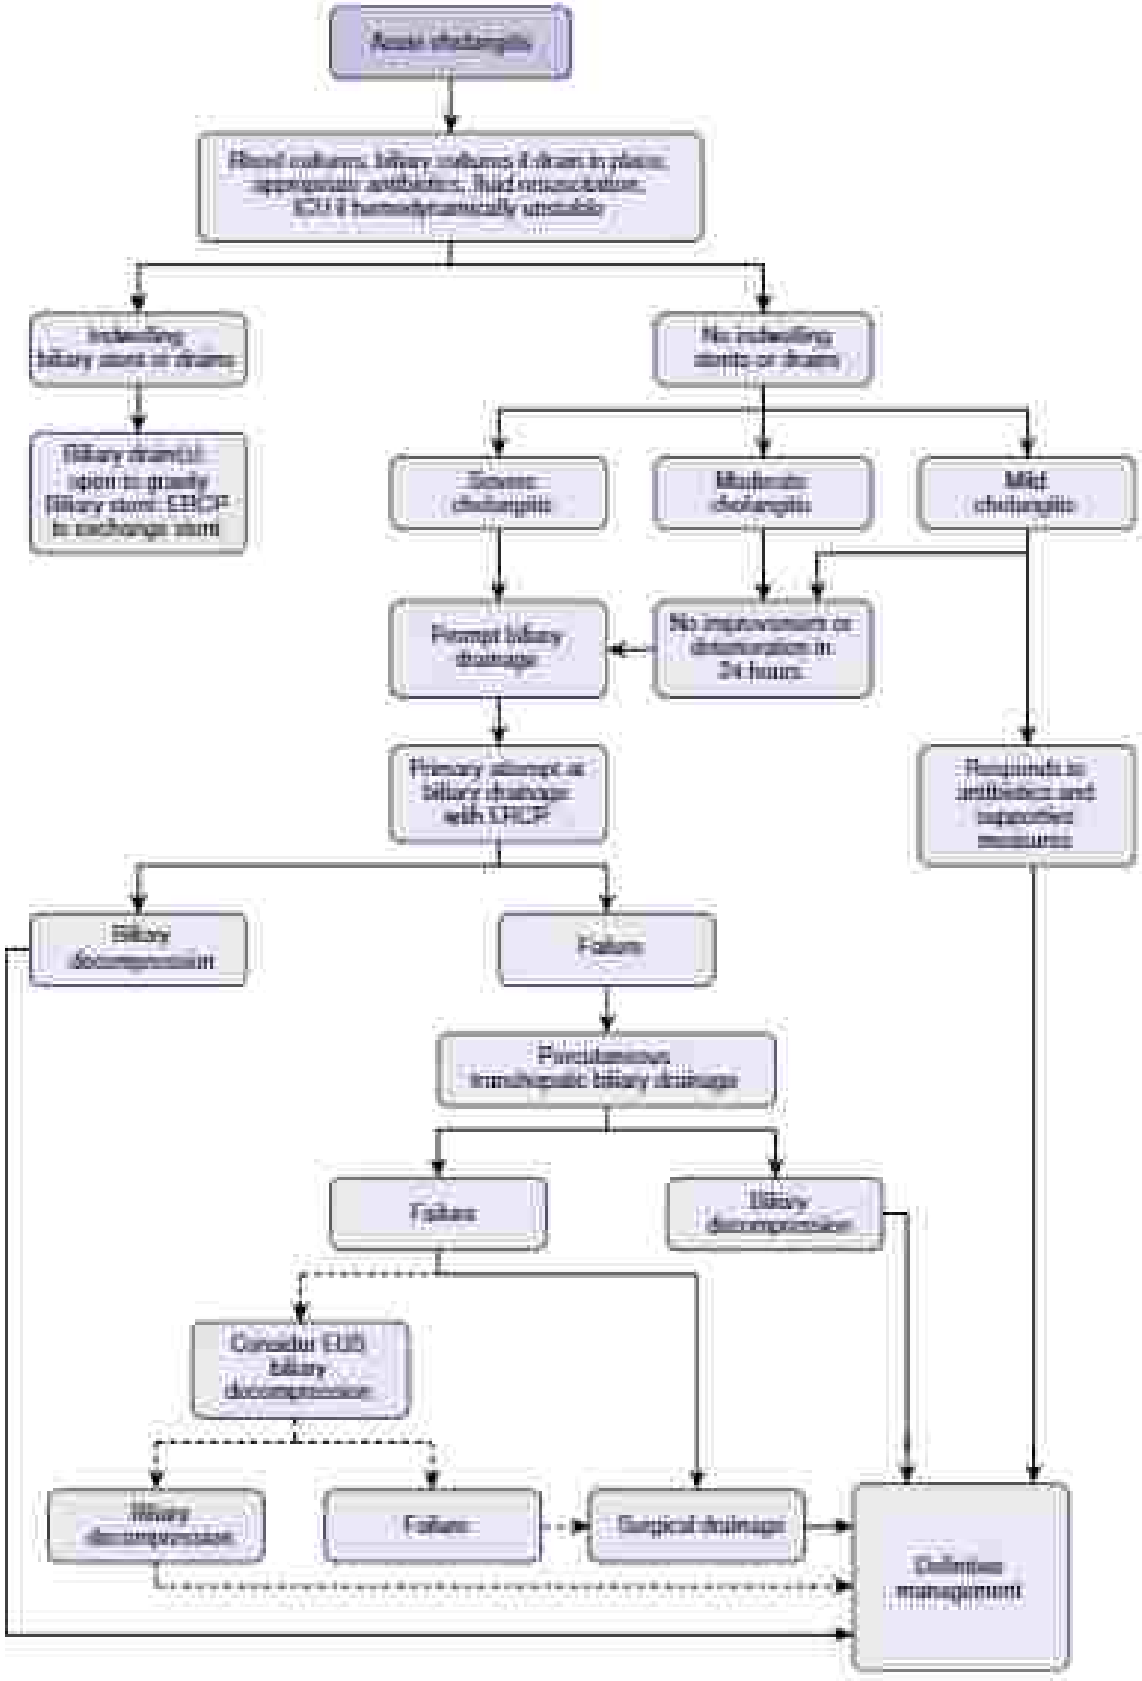

FIG. 1 Management algorithm for patients with acute cholangitis. Dotted lines represent optional progression to EUS biliary decompression, however the priority is prompt biliary drainage and some patients may require surgical drainage without attempted EUS biliary decompression. ERCP, endoscopic retrograde cholangiopancreatography; C.T, endoscopic ultrasound.

BOX 1 Options for Antibiotic Regimens*

Single Agent

- Carbapenem
- Ertapenem (mild or moderate)
- Meropenem (consider for severe hospital associated)
- Piperacillin/tazobactam
- Ampicillin/sulbactam (>20% resistance rate)

Combination Therapy

- Metronidazole, PLUS one of the following:
  - Cephalosporin (moderate to severe or hospital associated, use fourth generation)
  - Fluoroquinolone (mild or moderate)
- For hospital associated infection, severe cholangitis additional coverage with:
  - Vancomycin (daptomycin if vancomycin resistant enterococcus cultured)
  - Consider fungal coverage

*Antibiotic coverage depends on severity of acute cholangitis and history of prior biliary tract medical or surgical interventions.

Modified from Gomi H, Solomkin JS, Schlossberg D, et al. Tokyo Guidelines 2018: antimicrobial therapy for acute cholangitis and cholecystitis. *J Hepatobiliary Pancreat Sci*. 2018;25(1):3–16.

however, timely drainage is still indicated as a function of source control.

Nonoperative Approaches

First-line preferred biliary drainage is via ERCP. ERCP is both diagnostic and therapeutic, but at the time of initial procedure, particularly in patients with systemic sepsis, decompression of the obstructed biliary tree is the top priority. Nasobiliary tube drainage effectively decompresses the biliary tree but the tube is prone to dislodgement and its use has gone out of practice. Other diagnostic or therapeutic interventions can follow when sepsis is controlled. Ultimately, transoral endoscopists can remove any obstructing stone or sludge, perform a sphincterotomy, if appropriate, to allow future stones to pass, and place a stent for drainage. Additionally, for benign structures and potential malignant disease, a cholangiogram can be performed to better elucidate the extent of disease. Brushings can be performed if a structure is suspicious for cancer and sent for cytology and pathology. ERCP is successful in treating distal bile duct obstructions in 90% to 95% of cases. Complications of ERCP occur in 5% to 15% of cases and include bleeding from the sphincterotomy in coagulopathic patients, intestinal perforation, pancreatitis and infecting or worsening cholangitis; thus, supporting a conservative approach at any initial procedure in septic patients is advisable.

Some patients may not be able to have an ERCP because of their anatomy, such as those with prior surgical reconstruction (Roux-en-Y hepaticojejunostomy, Roux-en-Y gastric bypass, pancreaticoduodenectomy, or gastrectomy), difficult access to the ampulla, or duodenal obstruction. Severe pancreatitis may also limit endoscopic biliary drainage secondary to external compression. If patients have intrahepatic biliary dilation, an alternative approach to biliary drainage is percutaneous transhepatic cholangiography (PTC) and percutaneous transhepatic biliary drainage (PTBD). Similar to ERCP, PTC is diagnostic, providing images and details about the location of the obstruction as well as giving a way to perform brushings if malignancy is a concern. As with ERCP, the goal of any initial procedure is to establish biliary drainage, not full diagnostic or therapeutic procedures. PTBD is successful about 90% of the time and is contraindicated in ascites and can be difficult in patients with intrahepatic strictures where multiple drainage catheters may have to be placed.

BOX 2 Tokyo Guidelines 2018: Grades of Acute Cholangitis 2018 and Recommended Treatment

Grade I (Mild)

Definition: not meeting criteria for moderate (grade II) or severe (grade III) cholangitis

Treatment: allow empiric antibiotics and supportive care. Only requires biliary drainage if inadequate response to resuscitation and antibiotics.

Grade II (Moderate)

Definition: At least 2 of the following 7 criteria:
- WBC >12,000/mm³ (or <4000/mm³)
- Temperature >39°C
- Age ≥75 years
- Total bilirubin ≥5 mg/dL
- Albumin less than the lower limit of normal value (<0.73 g/dL)

Treatment: antibiotics, supportive care plus endoscopic or percutaneous drainage in >48 hours

Grade III (Severe)

Definition: cholangitis as above + sepsis and organ damage in cholangitis and one of the following markers of end organ damage:
- Cardiovascular dysfunction (requiring the use of dopamine >5 mg/kg/min or norepinephrine)
- Altered mental status with decreased consciousness
- Respiratory dysfunction (partial pressure of oxygen in arterial blood/fraction of inspired oxygen ratio <300)
- Renal dysfunction (oliguria or serum creatinine >2.0 mg/dL)
- Hepatic dysfunction (prothrombin time international normalized ratio >1.5 or platelet count <100 ($\times 10^9$/L)
- Hematologic dysfunction: platelet count <100,000/mm³

Treatment: intensive care unit admission, appropriate support for interventions (e.g., intubation, pressors), prompt initiation of broad-spectrum antibiotics, and urgent biliary drainage via endoscopic retrograde cholangiopancreatography or percutaneous transhepatic cholangiography when able.

Surgical intervention in the management of acute cholangitis is rare, but definitive surgical management of the underlying etiology of biliary obstruction to allow necessary once the acute episode has resolved.

WBC, White blood cells.

Modified from Miura F, Okamoto K, Takada T, et al. Tokyo Guidelines 2018: initial management of acute biliary infection and flowchart for acute cholangitis. *J Hepatobiliary Pancreat Sci*. 2018;25(1):31–40.

Complications of PTBD include biliary fistulas, bleeding, recurrent cholangitis, and hepatic abscesses.

In select cases when ERCP has failed and there is not significant intrahepatic biliary dilation to perform PTBD, an alternative is EUS-guided biliary drainage (EUS-BD). A covered metal stent can be placed via EUS-guided choledochoduodenostomy or hepaticogastrostomy in an urgent setting. This has been a successful strategy for nonoperative biliary drainage, even in patients with ascites and hilar strictures. When compared with patients undergoing operative management with biliary drainage resulting from ERCP and PTBD failure, some studies have shown similar long-term survival, but fewer complication rates and better quality of life for EUS-BD. Similarly, when comparing EUS-BD to PTBD following ERCP failure, some report fewer adverse events and reintervention in patients undergoing EUS-BD. One limitation of this technique is that it requires advanced endoscopic skills often limited to tertiary centers. This intervention may also complicate definitive operative strategies for underlying etiologies of cholangitis and therefore is most often used in unresectable malignancy.

Finally, placement of a percutaneous cholecystostomy tube may be beneficial if all other nonoperative techniques have failed and the patient is a poor surgical candidate or there is concern for simultaneous cholecystitis, which is rare. For a percutaneous cholecystostomy tube to be successful, the cystic duct must be patent and the obstruction must be distal to where the cystic duct joins the CBD. We emphasize that the sole priority in any management algorithm for acute cholangitis, especially in the setting of sepsis, is urgent biliary drainage.

Surgical Options

Urgent surgical intervention has been the traditional method of treatment for obstructive jaundice since the days of Halsted; however, therapeutic options have changed with ERCP now that the optimal treatment and preferred management of acute cholangitis, followed by PTBD if ERCP is not technically possible. Surgery is now a last option because it is associated with high morbidity and mortality for patients with severe acute cholangitis. Surgical management, however, must still be considered if the patient's condition is deteriorating without a nonoperative means of biliary decompression.

If all other biliary drainage options have failed, and the patient is sick enough to require surgical intervention, the primary goal of this operation is simple, uncomplicated biliary drainage, with definitive management strategies being pursued later. In mild and moderate cholangitis that resolves with antibiotics, after resolution of acute illness, definitive management at the time of initial presentation can be considered. In severe acute cholangitis, we recommend complete resolution of the cholangitis before attempting definitive management of the underlying etiology of disease.

The best operative intervention to achieve safe and efficient surgical biliary decompression in severe disease is limited common bile duct exploration (CBDE) via choledochotomy, stone removal if easy to accomplish, and T tube placement. If the gallbladder has stones, a straightforward cholecystectomy can be performed if the patient is stable. Skilled laparoscopic surgeons may perform the CBDE laparoscopically, but the open approach remains safe and appropriate. In all cases, the experience level and comfort of the surgeon must be considered when the best approach is discussed.

For laparoscopic CBD exploration, stone retrieval, and T tube placement, laparoscopic port sites are placed in similar positions as for laparoscopic cholecystectomy. For small stones or sludge, some may consider the transcystic approach, but because that approach would necessitate cholecystectomy, this option is best reserved for stable patients with mild to moderate cholangitis. In patients with severe illness, the best approach would be directly via choledochotomy as long as the duct is at least greater than 6 mm in diameter to prevent future stricture. The technique involves an approximately 1-cm longitudinal choledochotomy made in the middle of the anterior surface of the common bile duct. A choledochoscope can then be advanced into the distal common bile duct. A stone seen via direct visualization through the choledochoscope can be retrieved using a wire basket passed through the operating channel of the choledochoscope. Once the stone is removed, a 12F–14Fr T tube can be placed through the choledochotomy and the duct closed with 4-0 or 5-0 monofilament absorbable suture.

Recent literature advocates for primary closure of the common bile duct after elective CBDE because of complications from T tube placement; that is, patients with cholangitis, placement of a T tube is necessary for biliary decompression and allows easy access for future cholangiograms if the obstruction does not resolve. T tube drainage has been associated with bile leak and requires externalization of the tube for several days until postoperative cholangiography demonstrates resolution of obstruction. Primary closure can lead to stricture and bile leak and result in no direct access to the biliary tree for future investigations.

To perform the open common bile duct exploration, the anterior surface of the common bile duct is exposed and stay sutures are placed in the 2 and 10 o'clock positions of the CBD (avoiding the blood supply at 3 and 9 o'clock). A 1 to 1.5 cm longitudinal choledochotomy is made between the stay sutures, and a sterile four French biliary Fogarty balloon catheter is passed into the distal common bile duct. Small stones or sludge may be cleared from the duct by direct flushing. Administration of glucagon will relax the sphincter of Oddi. A choledochoscope can also be used through this open approach to directly visualize and clear the stone. Similar to the laparoscopic approach, a T tube should be placed, and the choledochotomy is closed transversely with 4-0 or 5-0 absorbable monofilament sutures (Fig. 2). A closed suction drain should be left to place near the choledochotomy. A cholangiogram should be obtained 4 to 5 days postoperatively through the T tube to show patency of the CBD prior to capping the tube and then again 4 to 6 weeks later before T tube removal.

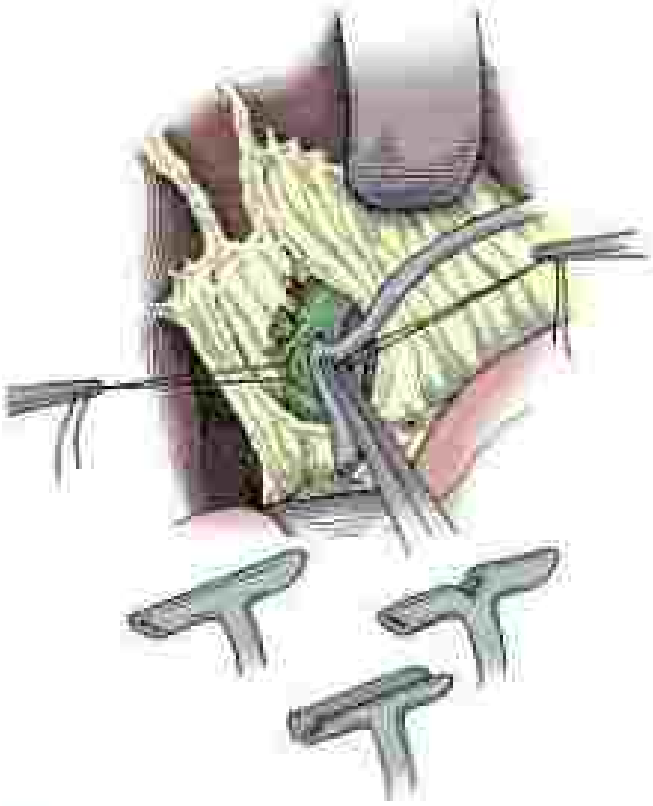

FIG. 2 Insertion of a T tube in the common bile duct with subsequent closure using absorbable monofilament suture (4-0 or 5-0). The T tube is prepared in one of the ways shown. (From Aldrete JM, Johnson DG, Shorvon PJ, et al. Operative Endoscopy and Ultrasound of the Biliary Tract and Pancreas. 2nd ed. New York: Taylor & Francis; 2007.)

The best acute surgical management for an impacted stone at the ampulla in the setting of acute cholangitis is T tube drainage, decompression of the biliary tree, and treatment of infection. If further endoscopic attempts including lithotripsy are not successful at clearing the stone from the ampulla, definitive surgical management with transduodenal sphincteroplasty can be pursued after resolution of the acute cholangitis. Complications from transduodenal sphincteroplasty include duodenal leak and recurrent pancreatitis.

Other surgical interventions such as formal biliary enteric bypass, liver resection, transduodenal sphincteroplasty, and pancreaticoduodenectomy are all definitive treatment options depending on the etiology of the biliary obstruction causing acute cholangitis. Such procedures should be performed following resolution of the acute infection and illness. The most common biliary enteric anastomosis used for a bypass of proximal biliary obstruction resulting from benign strictures is a Roux-en-Y hepaticojejunostomy.

Choledochoduodenostomy, another biliary bypass option, requires an anastomosis involving the duodenum and results in the biliary system being in continuity with the gastrointestinal tract. This eventually can lead to recurrent cholangitis through ascending, when a dysfunctional sphincter of Oddi results in bile and stone stasis in the distal common bile duct; therefore this procedure is not considered the ideal operative bypass strategy by the authors.

Because manipulation and flushing of the biliary system for either the nonoperative or operative approaches may lead to increased biliary pressure and lead to translocation of more bacteria systemically, it is not uncommon for even patients who were stable before intervention to show signs of sepsis or even systemic inflammatory response syndrome postoperatively. Broad antibiotic coverage should continue for at least 48 to 72 hours following the intervention, narrowing the antibiotic selection once sensitivities are available, and some patients may even require transfer to an intensive care unit.

OUTCOMES

Most cases of acute cholangitis resolve with antibiotics and nonsurgical biliary drainage (~ 85%); however, morbidity and mortality can be high when patients are immunocompromised or elderly. Reported overall mortality remains at 2% to 10%, with higher mortalities in patients with advanced unresectable malignancy often on chemotherapy. Overall, with better nonsurgical drainage techniques and fewer cases requiring operative intervention, the mortality rate has decreased significantly in the past 30 years. The primary treatment goal is early broad-spectrum antibiotic coverage, adequate resuscitation, and appropriate biliary drainage. After resolution of the acute episode, underlying disease must be addressed. If the severity of the acute cholangitis is mild or moderate, definitive management with cholecystectomy or biliary bypass may be considered during the same admission, but the priority is resolution of infection.

MANAGEMENT OF BENIGN BILIARY STRICTURES

Irada Ibrahim-zada, MD, PhD, and Steven A. Ahrendt, MD

Benign biliary strictures are most commonly caused iatrogenically, usually after cholecystectomy, or after liver resection or transplantation. Benign biliary strictures also occur in a wide variety of conditions, including chronic pancreatitis, primary sclerosing cholangitis, acute cholangitis, several autoimmune diseases, or following either blunt or penetrating abdominal trauma. Most injuries are recognized either intraoperatively or in the early postoperative period, and with appropriate management the long-term results are acceptable. However, with unrecognized or inappropriately managed biliary strictures, recurrent cholangitis, secondary biliary cirrhosis, and portal hypertension may eventually develop.

IATROGENIC BILIARY INJURIES

Biliary Injury at Laparoscopic Cholecystectomy

Mechanism of Injury/Risk Factors

Before the widespread use of laparoscopic cholecystectomy, bile duct injuries were relatively infrequent, occurring in about 1 in 200 open cholecystectomies. The rate of bile duct injury with laparoscopic cholecystectomy is greater than with open cholecystectomy. Several large studies have estimated the rate of injuries at about 0.3%. The incidence of major bile duct injuries is about 0.2% and the incidence of bile leaks or minor injuries is 0.3%.

Several factors have been implicated in the occurrence of bile duct injury during laparoscopic cholecystectomy. Local operative factors can increase the difficulty of the procedure and, therefore, the risk of injury. The bile duct injury rate is increased in patients with complications of gallstones including acute cholecystitis. Significant inflammation obscures normal anatomical relationships and is more likely to be present when symptoms have been present for more than 3 days, when the white blood cell count is higher than 10,000, and with a palpable gallbladder. Additional factors associated with injury include obesity, poor exposure, and bleeding obscuring the operative field. Furthermore, increased patient age, male gender, a long period of symptoms before cholecystectomy, and number of attacks all are associated with increased difficulty of the procedure.

Aberrant biliary anatomy is also often cited as a factor in biliary injuries. A common anomaly that increases the risk of bile duct injury is an aberrant right hepatic duct coursing through the triangle of Calot and entering the common hepatic duct. Occasionally the cystic duct enters a small aberrant right hepatic duct, which is mistaken for the cystic duct and ligated and/or divided.

Intraoperatively, several factors have been implicated and biliary injuries. The classic laparoscopic injury involves the misidentification of the common duct for the cystic duct (Fig. 1). This injury occurs from excessive cephalad retraction of the gallbladder fundus or inadequate lateral retraction on the infundibulum. The common bile duct is mistaken for the cystic duct, with subsequent clipping and transection. As the dissection proceeds cephalad, the common hepatic duct is divided a variable distance from the hilus, and often the right hepatic artery is injured as well. Other intraoperative factors implicated in bile duct injury include excessive traction on the cystic duct, which can lead to clip placement on the common bile duct; dissecting too deep in the liver parenchyma, which can injure intrahepatic ducts; poor clip placement on the cystic duct; or injudicious use of cautery.

Biliary injuries can occur in combination with vascular injuries. The right hepatic artery may be erroneously misidentified as the cystic artery and lead to the most common type of injury. Arterial injuries usually happen most commonly from transection, followed by occlusion by clips, and thrombosis of the vessel. The vessel is often damaged while attempting to control bleeding during the dissection; hence, it is important to address hemorrhage with tamponade rather than by blind application of clips or considering conversion to open operation. Finally, vessel occlusion may occur due to biliary peritonitis.

Choledochoduodenostomy, another biliary bypass option, requires an anastomosis involving the duodenum and results in the biliary system being in continuity with the gastrointestinal tract. This eventually can lead to recurrent cholangitis through ascending, when a dysfunctional sphincter of Oddi results in bile and stone stasis in the distal common bile duct; therefore this procedure is not considered the ideal operative bypass strategy by the authors.

Because manipulation and flushing of the biliary system for either the nonoperative or operative approaches may lead to increased biliary pressure and lead to translocation of more bacteria systemically, it is not uncommon for even patients who were stable before intervention to show signs of sepsis or even systemic inflammatory response syndrome postoperatively. Broad antibiotic coverage should continue for at least 48 to 72 hours following the intervention, narrowing the antibiotic selection once sensitivities are available, and some patients may even require transfer to an intensive care unit.

OUTCOMES

Most cases of acute cholangitis resolve with antibiotics and nonsurgical biliary drainage (~80%); however, morbidity and mortality can be high when patients are immunocompromised or elderly. Reported overall mortality remains at 2% to 10%, with higher mortalities in patients with advanced unresectable malignancy often on chemotherapy. Overall, with better nonsurgical drainage techniques and fewer cases requiring operative intervention, the mortality rate has decreased significantly in the past 30 years. The primary treatment goal is early broad-spectrum antibiotic coverage, adequate resuscitation, and appropriate biliary drainage. After resolution of the acute episode, underlying disease must be addressed. If the severity of the acute cholangitis is mild or moderate, definitive management with cholecystectomy or biliary bypass may be considered during the same admission, but the priority is resolution of infection.

MANAGEMENT OF BENIGN BILIARY STRICTURES

Iruda Ibrahim-zada, MD, PhD, and Steven A. Ahrendt, MD

Benign biliary strictures are most commonly caused iatrogenically, usually after cholecystectomy, or after liver resection or transplantation. Benign biliary strictures also occur in a wide variety of conditions, including chronic pancreatitis, primary sclerosing cholangitis, acute cholangitis, several autoimmune diseases, or following either blunt or penetrating abdominal trauma. Most injuries are recognized either intraoperatively or in the early postoperative period, and with appropriate management the long-term results are acceptable. However, with unrecognized or inappropriately managed biliary strictures, recurrent cholangitis, secondary biliary cirrhosis, and portal hypertension may eventually develop.

IATROGENIC BILIARY INJURIES

Biliary Injury at Laparoscopic Cholecystectomy

Mechanisms of Injury/Risk Factors

Before the widespread use of laparoscopic cholecystectomy, bile duct injuries were relatively infrequent, occurring in about 1 in 200 open cholecystectomies. The rate of bile duct injury with laparoscopic cholecystectomy is greater than with open cholecystectomy. Several large studies have estimated the rate of injuries at about 0.3%. The incidence of major bile duct injuries is about 0.2% and the incidence of bile leaks or minor injuries is 0.3%.

Several factors have been implicated in the occurrence of bile duct injury during laparoscopic cholecystectomy. Local operative factors can increase the difficulty of the procedure and, therefore, the risk of injury. The bile duct injury rate is increased in patients with complications of gallstones including acute cholecystitis. Significant inflammation obscures normal anatomical relationships and is more likely to be present when symptoms have been present for more than 3 days, when the white blood cell count is higher than 10,000, and with a palpable gallbladder. Additional factors associated with injury include obesity, poor exposure, and bleeding obscuring the operative field. Furthermore, increased patient age, male gender, a long period of symptoms before cholecystectomy, and number of attacks all are associated with increased difficulty of the procedure.

Aberrant biliary anatomy is also often cited as a factor in biliary injuries. A common anomaly that increases the risk of bile duct injury is an aberrant right hepatic duct coursing through the triangle of Calot and entering the common hepatic duct. Occasionally the cystic duct enters a small aberrant right hepatic duct, which is mistaken for the cystic duct and ligated and/or divided.

Intraoperatively, several factors have been implicated and biliary injuries. The classic laparoscopic injury involves the misidentification of the common duct for the cystic duct (Fig. 1). This injury occurs from excessive cephalad retraction of the gallbladder fundus or inadequate lateral retraction on the infundibulum. The common bile duct is mistaken for the cystic duct, with subsequent clipping and transection. As the dissection proceeds cephalad, the common hepatic duct is divided a variable distance from the hilus, and often the right hepatic artery is injured as well. Other intraoperative factors implicated in bile duct injury include excessive traction on the cystic duct, which can lead to clip placement on the common bile duct; thermal injury too deep in the liver parenchyma, which can injure intrahepatic ducts; poor clip placement on the cystic duct; or injudicious use of cautery.

Biliary injuries can occur in combination with vascular injuries. The right hepatic artery may be erroneously misidentified as the cystic artery and lead to the most common type of injury. Arterial injuries usually happen most commonly from transection, followed by occlusion by clips, and thrombosis of the vessel. The vessel is often damaged while attempting to control bleeding during the dissection; hence, it is important to address hemorrhage with tamponade rather than by blind application of clips or considering conversion to open operation. Finally, vessel occlusion may occur due to biliary peritonitis.

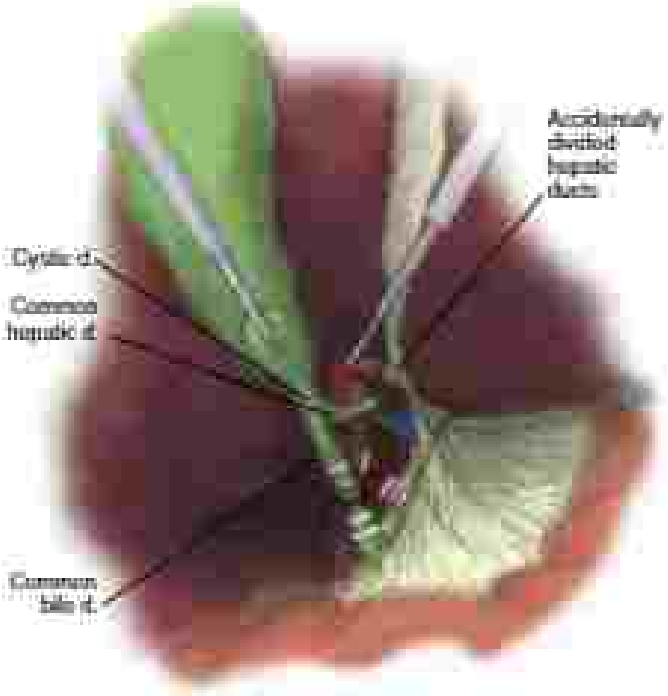

FIG. 1 Classic laparoscopic misinterpretation of bile duct injury. The cystic duct and common bile duct are aligned by traction on the gallbladder. The common bile duct is mistaken for the cystic duct leading to ligation of the common bile and common hepatic ducts at duct. (From Strasberg S, Hertl M, Soper N. An analysis of the problem of biliary injury during laparoscopic cholecystectomy. *J Am Coll Surg*. 180:101–125, 1995.)

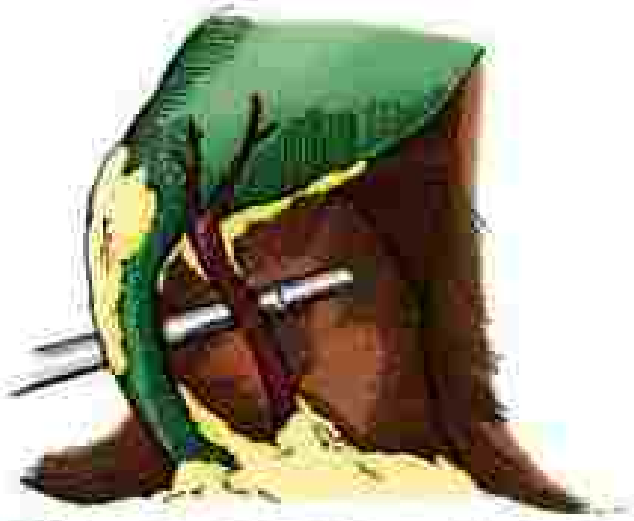

FIG. 2 The critical view to safety: (1) the hepatocystic triangle was dissected free of all tissue except for putative cystic duct and artery; (2) the lower one-third of the gallbladder was dissected off the cystic plate; and (3) two (and only two) structures are seen to be attached to the gallbladder. (From Strasberg SM, Hertl M, Soper NJ. An analysis of the problem of biliary injury during laparoscopic cholecystectomy. *J Am Coll Surg*. 180(1):101–125, 1995.)

Additional factors also implicated in the occurrence of bile duct injuries include surgeon training. The number of surgeon cases and the learning curve were recognized as factors in early reports of laparoscopic bile duct injuries. Single incision cholecystectomy has also been reported to be associated with a higher rate of common bile duct injury.

Several strategies have been advocated for lowering the risk of bile duct injury. Routine intraoperative cholangiography may define the biliary anatomy, increase the intraoperative recognition of bile duct injury, and limit the extent of biliary injury; however, its use has not been conclusively demonstrated to lower the overall risk of bile duct injury. Obtaining the critical view of safety is an important step described by Soper and Strasberg in the 1990s. It allows the surgeon to proceed safely with the clipping and transection once it is achieved. The critical view (Fig. 2) includes (*1*) the hepatocystic triangle is dissected free of all tissue except for putative cystic duct and artery; (2) the lower one-third of the gallbladder has been dissected off the cystic plate; and (3), two (and only two) structures are seen to be attached to the gallbladder.

Anatomic Classification

The appropriate management of biliary tract injuries depends on the type, extent, and level of injury. The most common anatomical classification in use currently was developed by Strasberg et al., adapting the Bismuth classification for commonly seen laparoscopic injuries (Fig. 3). This system classifies bile duct injuries based on the most distal level at which healthy biliary mucosa at the proximal site of the injury or stricture is available for anastomosis. It has been created to assist in choosing the appropriate technique for repair and has a good correlation with the final outcome. Type A injuries are cystic duct leaks or leaks from small ducts in the liver bed. Types B and C injuries involve aberrant right hepatic ducts. Type D injuries are lateral injuries to major bile ducts. Type E injuries are strictures in the hepatic ducts and are further defined by proximal extent. Type E_1, common hepatic duct division, is more than 2 cm from bifurcation. Type E_2, common hepatic duct division, is less than 2 cm from bifurcation. Type E_3 is a common bile duct division at bifurcation. Type E_4, bile stricture, includes involvement of confluence and loss of communication between right and left hepatic duct. Type E_5 is involvement of aberrant right hepatic duct with concomitant stricture of the common hepatic duct.

Presentation

Intraoperative

Patients with bile duct injuries can present intraoperatively, in the early postoperative period, or may present months or years after the initial injury. Only a minority of cases of biliary duct injuries (8%–15%) are recognized immediately during laparoscopic cholecystectomy. An injury is usually suspected from ongoing biliary drainage or late recognition of the anatomy. An intraoperative cholangiogram is imperative once biliary injury is suspected and helps to delineate the biliary anatomy and to avoid any additional dissection. Once an injury is confirmed, the surgeon must decide whether to repair the injury or refer the patient to a specialized hepatobiliary center. An intraoperative consultation with an experienced biliary surgeon may be helpful in making this decision. Immediate repair should only be attempted if the reconstruction involves techniques commonly used by the operating surgeon. If the patient is to be referred to a tertiary care center, a closed suction drain should be placed laparoscopically in the subhepatic space. If immediate repair is selected, the procedure should be converted to an open laparotomy.

If an experienced surgeon is available, then primary repair or reconstruction will be based on the type of injury. Lateral bile duct (type D) injuries recognized at the time of cholecystectomy should be managed with placement of a T-tube. A T-tube can be placed at the site of the injury if it is similar in size to a choledochotomy. If the biliary defect is more extensive, the injury is repaired primarily and stented with a T-tube placed through a proximal or distal choledochotomy. If a significant thermal injury is present, a hepaticojejunostomy may be necessary. Isolated hepatic ducts smaller than 3 mm and draining a single hepatic segment can be safely ligated. Ducts larger

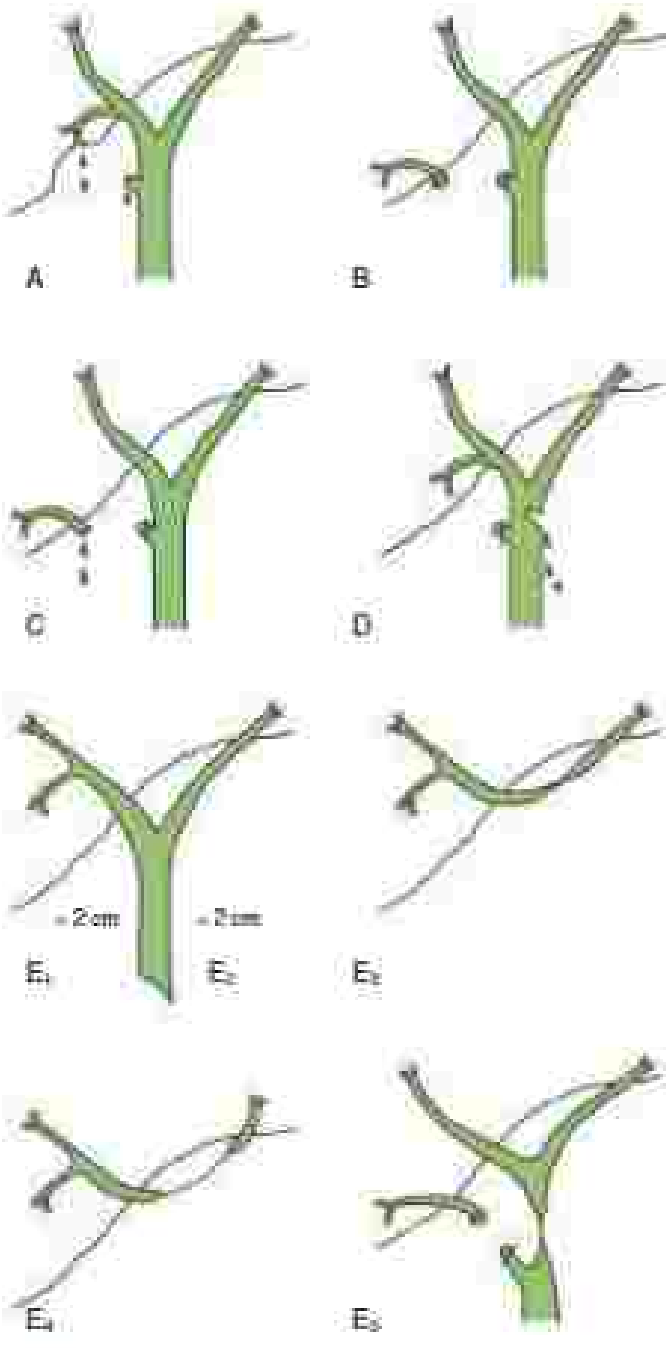

FIG. 1 Strasberg-Bismuth classification of laparoscopic bile duct injuries. Type A injuries are cystic duct leaks or leaks from small ducts in the liver bed. Type B and C injuries involve aberrant right hepatic ducts. Type D injuries are lateral injuries to major bile ducts. Type E injuries are strictures to the hepatic ducts and are further defined by proximal extent. Type E_1, common hepatic duct division, are >2 cm from bifurcation. Type E_2, common hepatic duct division, are <2 cm from bifurcation. Type E_3 is a common bile duct division at bifurcation. Type E_4, hilar stricture, involves confluence and loss of communication between right and left hepatic duct. Type E involves aberrant right hepatic duct with concomitant stricture of the common hepatic duct. (From Strasberg SM, Hertl M, Soper NJ, et al: An analysis of the problem of biliary injury during laparoscopic cholecystectomy, *J Am Coll Surg* 180:101, 1995.)

than 3 mm are more likely to drain several segments or an entire lobe and need to be reimplanted. Bile duct connections should be reconstructed with a Roux-en-Y hepaticojejunostomy. Primary repair with a choledochocholedochostomy is rarely feasible because of the loss of bile duct length from thermal injury, excision and/or devascularization, and associated with a high rate of postoperative stricture.

Postoperative

Approximately 75% of injuries are diagnosed at some point in the postoperative period. Patients usually present with a stricture diagnosed on imaging, with deranged liver function tests or recurrent bouts of cholangitis. In some cases, patients present with secondary biliary cirrhosis, which has been reported on average at about 4 months after the biliary injury. It has been reported to occur on average at about 8 months.

Clinical Presentation

Patients can present with a variety of symptoms based on the anatomy of the injury. Patients with a bile leak from the cystic duct stump, a connected aberrant right hepatic duct, or a lateral injury to the main bile duct usually present within 2 weeks of cholecystectomy with pain, fever, and/or bilious hypersalivation from a biloma or bile peritonitis. The degree of pain and physical findings may be quite subtle initially. Occasionally, bile begins leaking externally through a drain or surgical incision. Type E injuries involve occlusion of the common hepatic or bile duct without an intraperitoneal bile leak. With these injuries, jaundice with or without abdominal pain is the common mode of presentation. A persistent increase in bilirubin or alkaline phosphatase after cholecystectomy should prompt the assessment of a bile duct injury.

Evaluation

For patients with a suspected bile leak, an abdominal computed tomography (CT) scan or ultrasound identifies peritoneal fluid, a biloma or abscess. A CT has higher sensitivity (96% vs. 70%) in detecting fluid collections. Perihepatic or other intraabdominal fluid collections should be drained percutaneously. Ongoing biliary drainage through a percutaneous catheter establishes an active bile leak. The anatomy of the bile leak can be established with a cinegram through an existing drain if a fibrous tract has been established. An endoscopic retrograde cholangiogram (ERC) can also define the location of the injury and can often treat the leak effectively by placement of a biliary endoprosthesis.

For patients presenting with jaundice, the evaluation proceeds somewhat differently. A magnetic resonance cholangiogram is useful to evaluate for intrahepatic bile duct dilatation, level of injury, any cholangitic liver abscesses and liver atrophy. In addition, it can provide information on associated fluid collections. The postoperative common bile duct (CBD) should measure minimally 12 mm, and taper slowly. If a dilated or ligated hepatic or CBD is present, intrahepatic biliary ductal dilation will extend to the level of the occlusion with an abrupt cutoff. An ERC is often limited in defining the proximal biliary anatomy if the duct is occluded. In these patients a percutaneous transhepatic cholangiogram should be obtained and a catheter placed to decompress the intrahepatic biliary tract. The cholangiogram should define the proximal extent of the injury, which is critical in defining treatment. It is important to confirm integrity of all ductal bile ducts. For patients with E_3, E_4 injuries, more than one transhepatic catheter may be necessary. There is no role for diagnostic exploratory laparotomy or laparoscopy to delineate biliary anatomy.

All patients with a bile duct injury should undergo either a magnetic resonance or CT angiography to identify the presence of a concomitant arterial or portal venous system injury. The most common finding is represented by the nonenhancement of the right lobe during the arterial phase. Duplex ultrasound is less reliable method but useful for intraoperative assessment.

Management

The appropriate management of bile duct injuries depends on the time of diagnosis following the initial laparoscopic cholecystectomy.

the level and extent of injury, and the patient's general condition. A leak from the cystic duct or bile duct, a lateral injury, or a minor confluential stricture (type A and D injuries) can be diagnosed and managed by endoscopic retrograde cholangiography. Endoscopic treatment includes placement of a biliary endoprosthesis across the ampulla and proximal to the cystic duct or lateral injury site. The stent increases transpapillary flow, reduces the pressure gradient across the injury and, hence, reduces the extravasation out of the biliary tract. The bile leak and symptoms usually resolve fairly promptly. Stents are removed 4 to 6 weeks later. Endoscopic stents are quite effective in management of cystic duct leaks and minor main duct lacerations (<25% of the circumference). The presence of a bile leak in the peritoneal cavity may provoke a severe systemic response and all biliomas should be drained percutaneously. Percutaneous drainage and endoscopy have about 90% success rate for minor bile leaks.

Patients with strictures of the common bile or common hepatic duct with an intact duct may be amenable to endoscopic therapy. These injuries usually follow partial transections, partial clip placement, or thermal injury. Strictures are managed with serial dilations and multiple simultaneous biliary stents until the stricture is no longer present. The success rate of endoscopic therapy approaches 75% in this setting, with approximately 25% of patients developing recurrent strictures requiring surgical intervention.

Surgical intervention will be necessary in patients with a transected or occluded bile duct. Preoperative preparation is essential to maximize the chance of success. The goals for adequate preoperative preparation in these patients are to decompress the obstructed biliary tract with transhepatic catheters, define the anatomical extent of the injury, control sepsis by adequately draining any perihepatic fluid collections, and restore homeostasis by correcting any fluid and electrolyte abnormalities and optimizing nutritional status. CT imaging and cholangiograms must be reviewed together to ensure that all hepatic segmental ducts are defined so that all hepatic segments are included in the repair. Patients referred within days of the injury with good drainage and without any physiologic derangements may be able to proceed with surgery once the preoperative evaluation is complete. Patients referred weeks to months after the initial injury may benefit from decompression and drainage for several months while the acute inflammatory changes in the subhepatic space improve.

The goal of surgical repair is a tension-free anastomosis to ensure duct-enteric anastomosis. A Roux-en-Y hepaticojejunostomy using a 40 cm Roux limb will provide a tension-free repair and is superior to a choledochojejunostomy. In patients with E_1 and E_2 injuries (intact hepatic duct confluence) an end-to-side repair is constructed with interrupted 4-0 absorbable sutures. If inadequate length of the common hepatic duct remains for reconstruction, the left hepatic duct can be opened anteriorly and a side-to-side anastomosis fashioned to the proximal end of the Roux limb. In E_3 injuries with a partially intact confluence, a wide anastomosis is constructed including both left and right hepatic ducts. For more proximal injuries, separate hepaticojejunostomies may be required. Transhepatic catheters placed preoperatively are useful technical aids to identify the hepatic ducts particularly with more proximal strictures and are placed across the anastomosis and left in postoperatively for several months to stent the anastomosis and provide access for imaging.

Results

The morbidity and mortality from bile duct leaks and injuries is substantial. Patients with a bile duct leak or injury at laparoscopic cholecystectomy are more likely to die than patients without an injury. This risk is greatest in patients older than 50 years who have a greater than twofold increase in mortality. The morbidity and mortality occur both after the initial injury when the risk of sepsis and multisystem organ failure is high and following repair of the injury. In most large series of operative repair of bile duct injury, more than 90% of patients are free of jaundice and cholangitis with short-term follow-up. Operative mortality is low (<1%) and significant complications occur in about 30% of patients. Recurrent strictures develop in 10% to 15% of patients with long-term (>10 years) follow-up. Two-thirds of these will develop within 2 years of the initial repair. The majority of recurrent strictures following hepaticojejunostomy can be successfully managed with percutaneous dilating and dilation. Factors contributing to recurrent strictures include proximal injury, multiple repairs, and male gender.

After Liver Transplant Strictures

Several biliary complications may arise following orthotopic liver transplant (OLT), including the formation of strictures, bile leaks, and biliary filling defects. Benign biliary strictures may present anytime from days to years after the original OLT. Early strictures (<30 days after OLT) may be the result of ischemic anastomosis between donor and recipient and are often located at the anastomosis. Hepaticojejunostomies are more prone to early strictures than duct-to-duct anastomoses. Late strictures (>30 days after OLT) are most often associated with ischemic injury and mandate longer and more aggressive management which can often lead to retransplantation or revision.

Posttransplant strictures are classified into anastomotic strictures and nonanastomotic strictures. Anastomotic strictures comprise about 80% of all post-OLT strictures. Anastomotic strictures present with a single, short segment in the middle portion of the CBD. It usually develops within the first 1 to 2 months after OLT and is managed with endoscopic dilation and stent placement. The late presentation often requires stent exchange every 3 months to ensure a durable response to therapy.

Nonanastomotic strictures usually are numerous, diffuse, and proximal to the anastomosis involving the hilum and intrahepatic biliary ducts. These strictures are often associated with donor-recipient ABO blood type incompatibility or prolonged ischemic time. The patients at the highest risk are the recipients of the liver from donor after cardiac death (37% at 3 years of follow-up vs. 12% in patients after brain death). The presence of nonanastomotic strictures should prompt an evaluation of hepatic artery flow by Doppler ultrasound and/or CT angiography. They typically present later than anastomotic strictures (a mean time of 10 months) and are less responsive to endoscopic therapy. Biliary dilation and stenting are recommended and is often a bridge to retransplantation. Twenty-five to 50% of patients with nonanastomotic strictures undergo retransplantation.

Biliary-Enteric Strictures

Biliary-enteric strictures can occur after Roux-en-Y hepaticojejunostomy, partial liver resection, or pancreaticoduodenectomy (Whipple's procedure). The incidence of benign bile duct strictures following pancreaticoduodenectomy is about 4% and is more common in patients with a small caliber (<3 mm), thin-walled bile duct. Endoscopic management of this strictures can be more challenging due to modified anatomy; however, most (75%) of these strictures can be managed successfully with endoscopic stenting.

OTHER BENIGN BILIARY STRICTURES

Chronic Pancreatitis

Biliary strictures may develop in 3% to 23% of patients with severe chronic pancreatitis secondary to fibrosis of the intrapancreatic portion of the common bile duct or due to compression from a pseudocyst. In addition, up to 40% of cases, patients with autoimmune pancreatitis develop biliary strictures. Patients most commonly present with jaundice, abdominal pain, and acute cholangitis and less frequently secondary biliary cirrhosis. Benign biliary strictures from chronic pancreatitis are usually smooth, tapered and 2 to 4 cm in length. Both a pancreas protocol CT scan and an endoscopic retrograde cholangiopancreatography (ERCP) provide useful information in selecting the appropriate management. The CT scan can identify a pseudocyst, which may be contributing to the biliary obstruction.

Relief of the pancreatic compression with internal drainage may lead to resolution of the biliary stricture. The CT scan can also identify a mass or other features suspicious for malignancy. Further evaluation with ERCP and/or endoscopic ultrasound–guided fine needle aspiration or core biopsies and serum CA19-9 levels can help differentiate between benign and malignant strictures. Furthermore, the presence of numerous immunoglobulin G4–positive plasma cells confirms the diagnosis of autoimmune pancreatitis.

The clinical presentation guides the selection of therapy. In patients without significant pain and with a low suspicion of malignancy, endoscopic therapy is appropriate. For most distal strictures, placement of either multiple, side-by-side plastic biliary stents or a covered self-expandable metallic stent have produced excellent results. Both treatments have led to resolution of the biliary stricture in about 90% of patients after 1 year of stenting. Two-year stricture-free rates of 90% have been reported. Fewer ERCPs are needed with the use of the covered self-expandable metallic stent. Surgical therapy with a Roux-en-Y hepaticojejunostomy is reserved for patients with persistent or recurrent strictures following endoscopic management.

In patients with significant pain, management of the biliary stricture is part of a more extensive procedure to relieve pain. The Frey procedure may relieve compression on the obstructed distal bile duct or can be combined with a hepaticojejunostomy. A pancreaticoduodenectomy will also relieve the biliary obstruction and is the preferred procedure if malignancy cannot be excluded.

Strictures From Gallstone Disease

Mirizzi's syndrome results from obstruction of the common hepatic duct by a gallstone impacted within the gallbladder infundibulum or cystic duct. Inflammation from the impacted stone can lead to fibrosis, ulceration, and erode into the common hepatic duct. Most patients with Mirizzi's syndrome present with pain and jaundice. The diagnosis can be made by CT or magnetic resonance cholangiopancreatography and confirmed by ERCP. Open cholecystectomy is warranted with careful dissection of the gallbladder infundibulum from the common hepatic duct or a small portion of the gallbladder wall can be left in place to avoid injury to the duct. If a fistula to the common hepatic duct is present, a Roux-en-Y hepaticojejunostomy may be necessary.

Ortneal cholangiohepatitis results from chronic, parasitic infections. *Clonorchis sinensis* and *Opisthorchis viverrini* that lead to inflammatory and fibrotic changes in the bile duct walls that eventually result in stricturing, bile stasis, and stone formation. The disease is characterized by the presence of intra and extrahepatic lesions and black pigment stones and recurrent attacks of pyogenic cholangitis. The goal of treatment is to prevent or minimize the long-term consequences of the disease such as biliary cirrhosis and cholangiocarcinoma. Key aspects of management include treatment of the parasitic infection, stone removal and biliary drainage. ERCP is effective for extrahepatic biliary tree. However, surgical resection is an option in patients with limited left-sided intrahepatic disease. In high-risk patients with extensive stone disease, percutaneous transhepatic drainage and stone removal is often effective. Long-term outcomes of recurrent pyogenic cholangitis include progression to secondary biliary cirrhosis (7%–10%) and development of cholangiocarcinoma (2%–10%).

Strictures From Noniatrogenic Bile Duct Injuries

Noniatrogenic injuries to the bile ducts from penetrating or blunt abdominal trauma are rare but can be a source of significant morbidity. Penetrating injuries are often accompanied by injuries to the hepatic artery or portal vein, resulting in significant hemorrhage and devascularization of the bile duct. Biliary tract injuries in blunt trauma can be challenging and complicated because of multiple associated injuries and are often overlooked. The evaluation and management of these injuries is similar to iatrogenic injuries.

Benign Inflammatory Pseudotumors

Biliary inflammatory pseudotumors (IPTs) represent an exceptional benign cause of obstructive jaundice. IPTs are rare, idiopathic, benign mass lesions composed of fibrous tissue with marked nonspecific inflammatory infiltrate, mainly consisting of spindle cells, plasma cells, lymphocytes, eosinophils, and macrophages. Patients with IPT usually present with painless jaundice. Their clinical presentation and imaging features are nonspecific and are indistinguishable from those of cholangiocarcinoma, making their preoperative diagnosis extremely difficult. Most IPTs involve the proximal intrahepatic biliary tree. These lesions are often mistaken for cholangiocarcinoma and are treated with major resections, because their final diagnosis can be achieved only after formal pathologic examination of the resected specimens.

Management of Cystic Disorders of the Bile Ducts

Sudeep Ramarjan, MD, MAS, Bryan Clary, MD, MBA, and Jason K. Sicklick, MD, FACS

Choledochal cyst is a rare dilatation of the extrahepatic and/or intrahepatic biliary tree. Although choledochal cysts usually develop during infancy and childhood, the disease is commonly diagnosed in adults.

Epidemiology

The incidence of choledochal cyst ranges from 1 to 15 per 100,000 people in Western countries, but their incidence is as high as 1 in 1000 in select East Asian countries. Furthermore, choledochal cysts are four times more common in women than men. Although the exact incidence remains unknown, choledochal cysts predispose individuals to developing cholangiocarcinoma.

Etiology

The frequent presentation of choledochal cysts in infancy supports a congenital origin. An anomalous pancreaticobiliary ductal junction (APBJU) is one purported mechanism for the development of choledochal cysts. In APBJU, the pancreatic duct joins the common bile

duct more than 15 mm proximal to the ampulla, resulting in a long common channel with free reflux of pancreatic secretions into the biliary tract. In turn, this reflux of pancreatic juice results in increased biliary pressure and inflammatory changes within the biliary epithelium. Ultimately, it is hypothesized that these effects are related to the formation of choledochal cysts. Initial studies cited APBJD rates as high as 100% in patients with choledochal cysts, whereas more recent series identify only 25%. This wide range suggests that multiple etiologies likely underlie the pathogenesis of these lesions.

Classification

The current classification of choledochal cysts was initially proposed by Alonso Lej (1959) and subsequently modified by Todani (1977) (Fig. 1). Type I cysts (i.e., dilations of the extrahepatic biliary tract) are the most common and comprise 70% of choledochal cysts. Type I cysts are more prevalent in children (80%) than adults (65%) and further subdivide into cysts (Ia) (Fig. 2), focal (Ib), and fusiform (Ic) subtypes. Type IV cysts (i.e., cystic dilation of both the intrahepatic and the extrahepatic biliary tract) are the second most common (20% of patients) and are more frequently diagnosed in adults (30%) than children (12%). They further subdivide into the common case of multiple intrahepatic cysts and a single extrahepatic cyst (IVa) (Fig. 3) or, more rarely, as only multiple extrahepatic cysts (IVb). Type II (i.e., saccular diverticulum of the extrahepatic bile duct), type III (i.e., bile duct dilation within the duodenal wall [also known as a choledochocele]), and type V cysts (i.e., intrahepatic cysts [also known as Caroli's disease]) are much less common, with each type being diagnosed in 1% to 3% of choledochal cyst patients.

Clinical Presentation

The clinical presentation differs somewhat among children and adults. The classic clinical triad includes right upper quadrant pain, jaundice, and an abdominal mass; however, this presentation occurs very rarely. In both children and adults, abdominal pain is the most common symptom with frequencies of 41% and 72%, respectively. Children also present with jaundice (32%), pancreatitis (24%), and/or early satiety (11%). Adults may also develop symptomatic cholelithiasis (18%), pancreatitis (16%), and/or jaundice (12%). Less common symptoms or clinical findings include early satiety (11%), cholangitis (10%), or a palpable abdominal mass (1%). Prior biliary surgery is common in adults with choledochal cysts, with 32% having undergone cholecystectomy and 8% having undergone common bile duct resection. Finally, asymptomatic or incidental diagnoses account for 10% of pediatric and 18% of adult presentations.

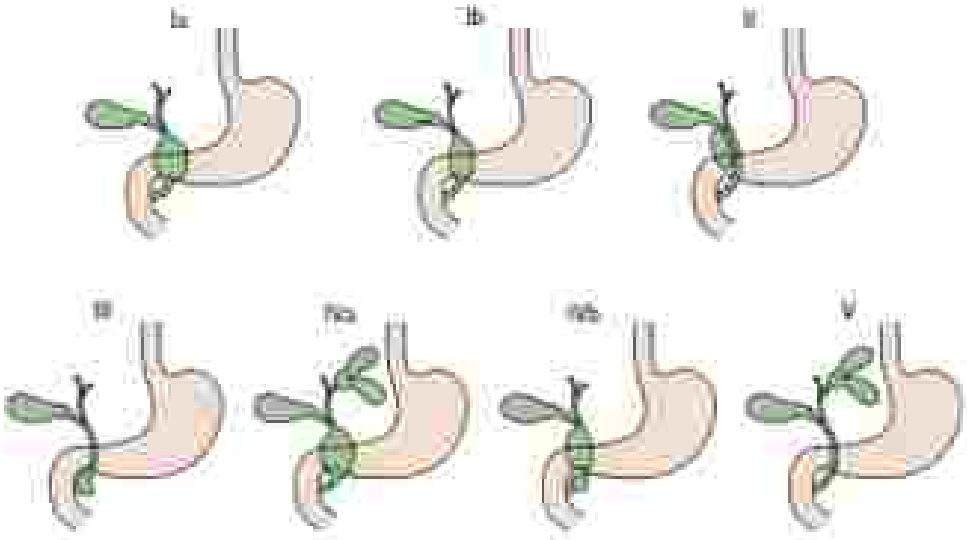

FIG. 1 Choledochal cysts: Alonso-Lej classification of choledochal cysts. Type Ia, choledochal cyst; type Ib, segmental choledochal dilation; type II, extrahepatic duct diverticulum; type III, choledochocele; type IVa, multiple intrahepatic and extrahepatic duct cyst; type IVb, multiple extrahepatic duct cysts; type V, intrahepatic duct cyst (Caroli's disease). (From Sanjai A, et al. Video article: Laparoscopic excision of choledochal cysts. *Surg Endosc*. 2008.)

Diagnosis

Laboratory evaluation most frequently demonstrates normal levels of transaminases, amylase, prothrombin time and tumor markers, including CA 19-9 and carcinoembryonic antigen. The most common imaging modalities used for diagnosis include ultrasound (US, 42%), computed tomography (CT, 57%), magnetic resonance imaging (MRI, 13%) and magnetic resonance cholangiopancreatography (MRCP, 58%). In the pediatric population, US is historically the preferred diagnostic modality and remains a commonly used imaging modality. US therefore remains a commonly used imaging modality. Moreover, there are well established criteria for suspicion of choledochal pathology. A common bile duct diameter exceeding 1 cm in an adult suggests a distal obstruction from a stone, periampullary neoplasm, or the presence of cystic dilation of the biliary tract. The presence of a right upper quadrant cyst distinct from the gallbladder is also suggestive of a choledochal cyst. MRCP is equally becoming the preferred technique given its high sensitivity (76%–100%) and specificity (90%–100%), as well as avoidance of radiation associated with CT. Likewise, with improved experience and technologies, MRCP is becoming more commonly used in children. Although more invasive, endoscopic retrograde cholangiography (ERCP) and percutaneous transhepatic cholangiography are the most sensitive techniques, allowing for clear visualization of both intra- and extrahepatic biliary cysts with the added benefit of potential for therapeutic interventions such as biliary drainage or biopsy. Importantly, APBUD is not readily identified using US, whereas both MRCP and ERCP are accurate in defining this anatomic finding. Preoperative interventions (i.e., ERCP, percutaneous transhepatic cholangiography) are common in adults (45%) and children (31%). Modern protocols that reduce radiation exposure and contrast agent volume permit more frequent usage in the pediatric population.

Management

The indication for definitive surgical management of choledochal cysts is based on an observed increase in the risk of cholangitis and pancreatitis, as well as malignant degeneration into cholangiocarcinoma. Historically, choledochal cysts were managed with internal drainage procedures (e.g., cystoenterostomy) and cholecystectomy; however, this approach led to persistent biliary stasis and a high rate of cholangitis, pancreatitis, recurrent strictures, and liver fibrosis. More significantly, the risk of cholangiocarcinoma in the remaining biliary cyst was unacceptably high (range, 12%–16%). The current-day approach includes cholecystectomy, complete resection of the choledochal cyst whenever possible to minimize the risk of malignant transformation, and a biliary enteric anastomosis to prevent further reflux of pancreatic juice into the biliary tract. Patients initially managed with cystoenterostomy should undergo resection as outlined in the following sections because of the increased risk of malignancy.

TYPE I: EXTRAHEPATIC BILE DUCT CYST

Treatment of type I choledochal cysts, the most common type of choledochal cyst, centers around resection of the common hepatic duct, common bile duct, and the gallbladder. Following cholecystectomy, a Kocher maneuver should be performed. The anterior wall of the choledochal cyst can then be dissected distally until it narrows at the tubular portion of the cyst. The distal CBD is then ligated at this level and divided, taking care not to injure the pancreatic duct. The cyst is then reflected anteriorly to allow dissection off of the portal vein. The cyst is mobilized to the level of the confluence of the left and right hepatic ducts. The common hepatic duct is divided just distal to hepatic duct confluence. Frozen sections of the proximal and distal bile duct margins should be obtained to exclude the presence of cholangiocarcinoma at the margin. Biliary enteric continuity is restored with an end-to-side Roux-en-Y hepaticojejunostomy. This type of reconstruction is preferred to hepaticoduodenostomy, which has a higher risk of postoperative bile reflux, gastritis, and gastric cancer. In cases in which the cyst extends to the head of the pancreas, pancreaticoduodenectomy should be performed. Laparoscopic resection with biliary enteric anastomosis has been shown to have equivalent success rates in experienced centers and is frequently the preferred approach in the pediatric population.

TYPE II: EXTRAHEPATIC BILIARY DIVERTICULUM

Type II cysts usually can be managed by simple diverticulectomy with closure of the common bile duct at the cyst neck. These cysts are typically not associated with an APBUD and do not have a high risk of malignant transformation.

TYPE III: CHOLEDOCHOCELE

The majority of choledochoceles are small and can be managed with endoscopic sphincterotomy. These cysts also do not carry an elevated risk of cholangiocarcinoma. Larger cysts have been managed successfully with transduodenal excision.

TYPE IV: INTRAHEPATIC AND EXTRAHEPATIC BILE DUCT CYST

The management of type IV choledochal cysts, the second most common type of choledochal cyst, is challenging. Diffuse involvement of the intrahepatic bile ducts can make complete excision impossible. The extrahepatic component is treated with cyst excision and biliary enteric reconstruction, similar to type I choledochal cysts. Partial hepatectomy is recommended when only one lobe is involved, and when technically and clinically feasible. Importantly, subtotal resection is associated with high rates of biliary complications; therefore, confidence in complete surgical resection is paramount. Patients with

bilobar disease should be aggressively surveilled for malignant degeneration with serial imaging and serum CA 19-9. The development of complicated bilobar disease should prompt evaluation for orthotopic liver transplantation.

TYPE V: CAROLI'S DISEASE

Treatment of Caroli's disease is predicated on management of cholangitis with antibiotics, biliary drainage procedures, and stone extraction. Asymptomatic patients with uni- or bilobar disease should undergo aggressive biochemical and imaging surveillance for cholangiocarcinoma. Patients developing symptoms from unilobar disease, or those with localized intrahepatic cysts are best managed with hepatic resection. Patients with complicated bilobar disease (despite maximal medical therapy), portal hypertension, or suspicion of early cholangiocarcinoma may be candidates for orthotopic liver transplantation.

SHORT-TERM AND LONG-TERM MORBIDITY

Perioperative morbidity and mortality in patients undergoing choledochal cyst resection are comparable to other major hepatobiliary procedures. Common morbidities include hepatobiliary complications (e.g., bile leak, peritonitis, abscess, cholangitis; 17%), wound infection (11%), and gastrointestinal complications (e.g., bowel obstruction, pancreatitis, ileus; 11%). Long-term complications are common, with 29% of patients requiring readmission within 2 years of surgery. Reasons for readmission include anastomotic stricture, cholangitis, and cholangiocarcinoma. The management of complications requires biliary procedures in 17% of cases and a second operation in 15% of cases. Despite resection, choledochal cysts can recur in 3% of patients, and 82% (i.e., 5.7% of all patients) present with recurrent symptoms.

PROGNOSIS

The rate of cholangiocarcinoma at the time of surgical resection is approximately 11%, with a median age of 42 years at diagnosis. Overall, the 5-year survival rate of patients with choledochal cysts managed with resection and biliary reconstruction is 96%, however, those patients with incidental cholangiocarcinoma have a far worse prognosis, with a median survival of 29 months. Finally, across all subtypes, the risk of cholangiocarcinoma remains elevated after choledochal cyst resection with 11% of patients developing cancer after 10 years therefore, patients with resected choledochal cysts should undergo long-term surveillance. In summary, these operations are often done for risk reduction, although in a small subset of cases, they may be curative. Given the poor prognosis of cholangiocarcinoma and risk of recurrent disease, aggressive surgical management remains warranted.

Management of Primary Sclerosing Cholangitis

Nazeen Ghanekar, MD, and Steven C. Cunningham, MD, FACS

Primary sclerosing cholangitis (PSC) is a chronic idiopathic inflammatory disease affecting the intrahepatic (IHB) or extrahepatic (EHB) biliary tree or both (75%), which causes chronic cholestasis and eventual liver failure. The etiology of PSC is unknown but is believed to be due to a combination of genetic and environmental factors that cause chronic inflammation of the bile ducts resulting in stricture formation and upstream dilatation. It is a rare disease with a prevalence between 0.22 to 14.2 per 100,000 persons, with increased prevalence in northern European countries compared with the United States. It affects males more than females, usually in the fourth to fifth decade of life, and progresses to end-stage liver disease with a median survival of 12 to 18 years after diagnosis.

It is essential to distinguish PSC from secondary sclerosing cholangitis because many of the primary causes of secondary sclerosing cholangitis, including infectious, obstructive, immunologic, ischemic, and congenital etiologies may respond to specific therapies to which PSC does not respond. Similarly, it is important to recognize that an overlap syndrome exists between autoimmune hepatitis and PSC in 35% of pediatric and 9% of adult patients because these patients may respond well to systemic steroids.

PSC has strong associations with inflammatory bowel disease (IBD) especially ulcerative colitis, which develops in 68% to 75% of PSC patients, whereas Crohn's disease develops in only 5% to 10%. Although a majority of patients with PSC have IBD, only 3% to 5% of patients with IBD have PSC. Other autoimmune diseases commonly associated with PSC include celiac disease, diabetes mellitus type 1, hypothyroidism, ankylosing spondylitis, and autoimmune hepatitis.

PSC is a major risk factor for the development of cholangiocarcinoma (CCa), which occurs in 10% to 20% of PSC patients and is the second leading cause of death. In addition, CCa is found incidentally in up to 10% of explanted livers at the time of transplantation for PSC and up to 40% of PSC patients at autopsy.

PRESENTATION AND DIAGNOSIS

PSC has an indolent course, and the majority of patients are diagnosed while asymptomatic, generally during the evaluation of an abnormal liver panel, particularly with elevated alkaline phosphatase, although bilirubin and transaminase may also be elevated less commonly. A large variety of autoantibodies have been detected in PSC patients, but specificity is generally low. One of the most prevalent is perinuclear antineutrophil cytoplasmic antibody, present in 26% to 94% of cases. In symptomatic patients, pruritus, abdominal pain, diarrhea, jaundice, fatigue, and fever are common. Delayed presentations may be in the form of decompensated liver failure with manifestations of portal hypertension such as ascites, variceal bleeding, jaundice, and splenomegaly. Dominant biliary strictures may occur anywhere but commonly affect the hepatic confluence, usually presenting with recurrent cholangitis, and raising suspicion for CCa.

Cholangiography with endoscopic retrograde cholangiopancreatography (ERCP) has been considered the gold standard for diagnosing PSC but has been largely replaced by magnetic resonance

bilobar disease should be aggressively surveilled for malignant degeneration with serial imaging and serum CA 19-9. The development of complicated bilobar disease should prompt evaluation for orthotopic liver transplantation.

TYPE V: CAROLI'S DISEASE

Treatment of Caroli's disease is predicated on management of cholangitis with antibiotics, biliary drainage procedures, and stone extraction. Asymptomatic patients with unifocal or bilobar disease should undergo aggressive biochemical and imaging surveillance for cholangiocarcinoma. Patients developing symptoms from unifocal disease, or those with localized intrahepatic cysts are best managed with hepatic resection. Patients with complicated bilobar disease (despite maximal medical therapy), portal hypertension, or suspicion of early cholangiocarcinoma may be candidates for orthotopic liver transplantation.

SHORT-TERM AND LONG-TERM MORBIDITY

Perioperative morbidity and mortality in patients undergoing choledochal cyst resection are comparable to other major hepatobiliary procedures. Common morbidities include hepatobiliary complications (e.g., bile leak, peritonitis, abscess, cholangitis; 17%), wound infection (11%), and gastrointestinal complications (e.g., bowel obstruction, pancreatitis, ileus; 11%). Long-term complications are common, with 29% of patients requiring readmission within 2 years of surgery. Reasons for readmission include anastomotic stricture, cholangitis, and cholangiocarcinoma. The management of complications requires biliary procedures in 17% of cases and a second operation in 15% of cases. Despite resection, choledochal cysts can recur in 3% of patients, and 82% (i.e., 3.7% of all patients) present with recurrent symptoms.

PROGNOSIS

The rate of cholangiocarcinoma at the time of surgical resection is approximately 11%, with a median age of 42 years at diagnosis. Overall, the 5-year survival rate of patients with choledochal cysts managed with resection and biliary reconstruction is 96%, however, those patients with incidental cholangiocarcinoma have a far worse prognosis, with a median survival of 29 months. Finally, across all subtypes, the risk of cholangiocarcinoma remains elevated after choledochal cyst resection with 11% of patients developing cancer after 10 years therefore, patients with resected choledochal cysts should undergo long-term surveillance. In summary, these operations are often done for risk reduction, although in a small subset of cases, they may be curative. Given the poor prognosis of cholangiocarcinoma and risk of recurrent disease, aggressive surgical management remains warranted.

Management of Primary Sclerosing Cholangitis

Nazeen Gowaman, MD, and Steven C. Cunningham, MD, FACS

Primary sclerosing cholangitis (PSC) is a chronic idiopathic inflammatory disease affecting the intrahepatic (IHB) or extrahepatic (EHB) biliary tree or both (3%), which causes chronic cholestasis and eventual liver failure. The etiology of PSC is unknown but is believed to be due to a combination of genetic and environmental factors that cause chronic inflammation of the bile ducts resulting in stricture formation and upstream dilatation. It is a rare disease with a prevalence between 0.22 to 14.2 per 100,000 persons, with increased prevalence in northern European countries compared with the United States. It affects males more than females, usually in the fourth to fifth decade of life, and progresses to end-stage liver disease with a median survival of 12 to 18 years after diagnosis.

It is essential to distinguish PSC from secondary sclerosing cholangitis because many of the primary causes of secondary sclerosing cholangitis, including infectious, obstructive, immunologic, ischemic, and congenital etiologies may respond to specific therapies to which PSC does not respond. Similarly, it is important to recognize that an overlap syndrome exists between autoimmune hepatitis and PSC in 35% of pediatric and 9% of adult patients because these patients may respond well to systemic steroids.

PSC has strong associations with inflammatory bowel disease (IBD) especially ulcerative colitis, which develops in 68% to 75% of PSC patients, whereas Crohn's disease develops in only 5% to 10%. Although a majority of patients with PSC have IBD, only 3% to 5% of patients with IBD have PSC. Other autoimmune diseases commonly associated with PSC include celiac disease, diabetes mellitus type 1, hypothyroidism, ankylosing spondylitis, and autoimmune hepatitis.

PSC is a major risk factor for the development of cholangiocarcinoma (CCa), which occurs in 10% to 20% of PSC patients and is the second leading cause of death. In addition, CCa is found incidentally in up to 10% of explanted livers at the time of transplantation for PSC and up to 40% of PSC patients at autopsy.

PRESENTATION AND DIAGNOSIS

PSC has an indolent course, and the majority of patients are diagnosed while asymptomatic, generally during the evaluation of an abnormal liver panel, particularly with elevated alkaline phosphatase, although bilirubin and transaminase may also be elevated less commonly. A large variety of autoantibodies have been detected in PSC patients, but specificity is generally low. One of the most prevalent is perinuclear antineutrophil cytoplasmic antibody, present in 26% to 94% of cases. In symptomatic patients, pruritus, abdominal pain, diarrhea, jaundice, fatigue, and fever are common. Delayed presentations may be in the form of decompensated liver failure with manifestations of portal hypertension such as ascites, variceal bleeding, jaundice, and splenomegaly. Dominant biliary strictures may occur anywhere but commonly affect the hepatic confluence, usually presenting with recurrent cholangitis, and raising suspicion for CCa.

Cholangiography with endoscopic retrograde cholangiopancreatography (ERCP) has been considered the gold standard for diagnosing PSC but has been largely replaced by magnetic resonance

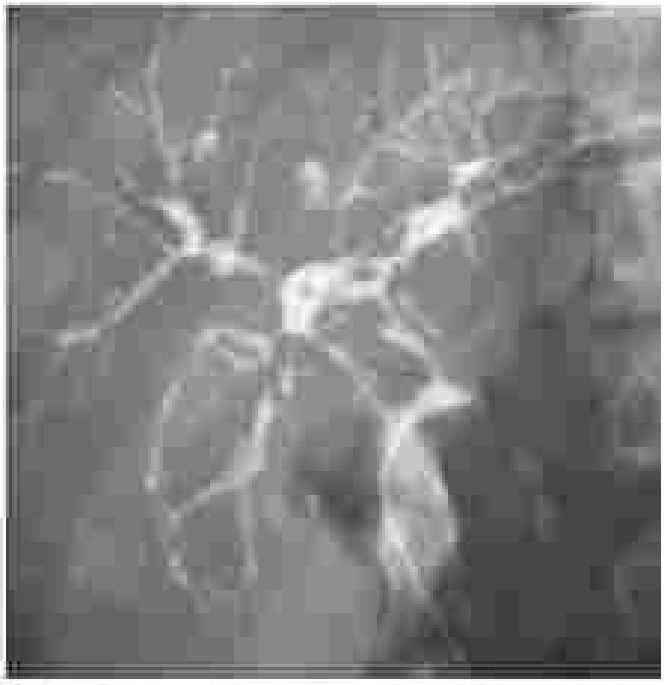

FIG. 1 Typical characteristic primary sclerosing cholangitis on cholangiography showing stricturing and beading.

cholangiopancreatography (MRCP) (Fig. 1). ERCP, however, retains the advantage of being not only diagnostic for both PSC and for CCa, but also potentially therapeutic. Any patient with a typical picture of dominant strictures and/or persistently elevated CA 19-9 should be considered for ERCP with brushings or directed biopsy to assess for CCa, ideally in a high volume center with access to and expertise in cholangioscopy. Although the diagnostic yield of endobiliary brushings is unfortunately low, newer brushes recently available have increased the sensitivity of brushed specimens. Benign strictures may be treated at ERCP with balloon dilatation, with or without placement of stents.

Other imaging modalities include abdominal ultrasound, contrast-enhanced computed tomography, and magnetic resonance imaging to detect masses concerning for malignancy. Liver biopsy is indicated in appropriate patients to quantify the degree of fibrosis, as this impacts future decisions for resection versus transplantation, and may also show cholestasis, recurrent cholangitis, and ductular proliferation.

MANAGEMENT

There are several different but overlapping aspects of PSC that warrant specific management considerations, including dominant strictures, CCa, gallbladder disease, liver failure, hepatocellular cancer, related systemic symptoms and diseases (such as pruritus, vitamin malabsorption, and hepatic osteodystrophy), and IBD and the attendant risk of colorectal cancer, as delineated in the following section. An algorithm for the management of the primary manifestations of PSC is shown in Fig. 2. Medical therapy, although shown to normalize laboratory values, is largely ineffective at retarding disease progression or extending survival and is therefore first reserved for clinical trials.

Recurrent Cholangitis and Dominant Strictures

Dominant strictures are defined by a diameter of 1.5 mm or less in the common bile duct or 1.0 mm or less in the common hepatic duct and are concerning for their propensity to cause recurrent cholangitis and to harbor or develop CCa.

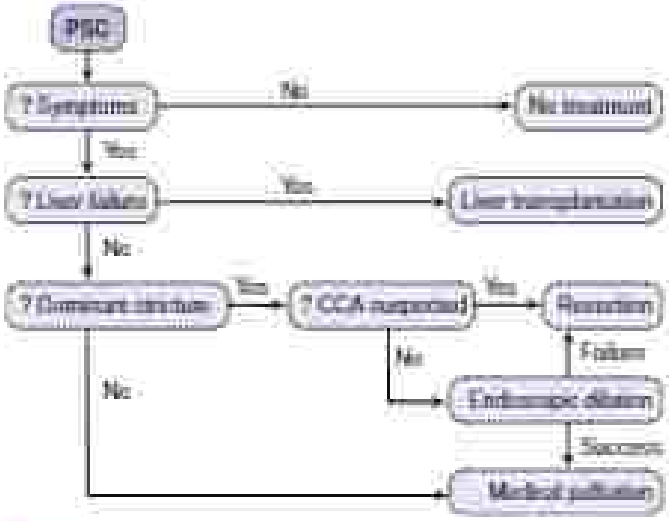

FIG. 2 Management algorithm for primary sclerosing cholangitis. CCA, cholangiocarcinoma.

Multiple modalities have been described for treating patients with biliary strictures, including percutaneous, endoscopic, and surgical modalities. ERCP is currently the most useful in managing strictures with balloon dilatations and stents. Endobiliary stents are typically reserved for patients who fail balloon dilatation. Not uncommonly, repeat ERCP is needed for recurrent strictures. Percutaneous interventions are also available but are falling out of favor given advancements in ERCP. Nevertheless, percutaneous transhepatic drainage remains a useful intervention in cases where endoscopic therapy is not available or technically feasible. Perprocedural antibiotic coverage is very important in PSC patients, especially in those previously instrumented or with recurrent cholangitis. Some patients who continue to suffer from recurrent cholangitis despite successful treatment of strictures benefit from rotating antibiotics to mitigate recurrent cholangitis episodes.

Resection for dominant extrahepatic or hilar strictures often durable results, delays the development of cirrhosis, and offers an opportunity to exclude CCa, ideally in high volume centers for selected patients with preserved liver function and no or only early fibrosis or compensated cirrhosis. Resection in these patients typically includes the entire extrahepatic biliary tree with a Roux-en-Y hepaticojejunostomy reconstruction over transhepatic stents. Preoperative placement of percutaneous bilateral transhepatic stents not only aids in dissection of the biliary confluence but also allows creation of a hepaticojejunostomy over stents, which are often left in place significantly longer than in non-PSC patients.

The operation may be performed through an upper midline or right subcostal incision. After entry in the abdomen, careful examination of the peritoneal cavity, liver, and porta hepatis is performed to identify any metastatic disease. Intraoperative ultrasound is used to examine the intrahepatic stones. A wide Kocher maneuver is performed to expose the distal common bile duct, which is transected, biopsied by frozen section, ligated as close to the pancreas as possible, and then reflected cephalad and anterior to facilitate dissection of the bile duct from the portal vein(s) and hepatic artery(ies) (Fig. 3). The right and left hepatic ducts are transected and biopsied by frozen section. The transhepatic stents are exchanged in a retrograde fashion with fiberoptic guidance and the hepaticojejunostomy performed using 2-0 PDS in a running or interrupted fashion to a Roux limb of jejunum, which is brought through the base area of the transverse mesocolon just to the right of the middle colic artery. The Silastic drains are brought through the abdominal wall in the right upper quadrant, taking care to avoid kinking. Closed suction drains are placed around the hepaticojejunostomy.

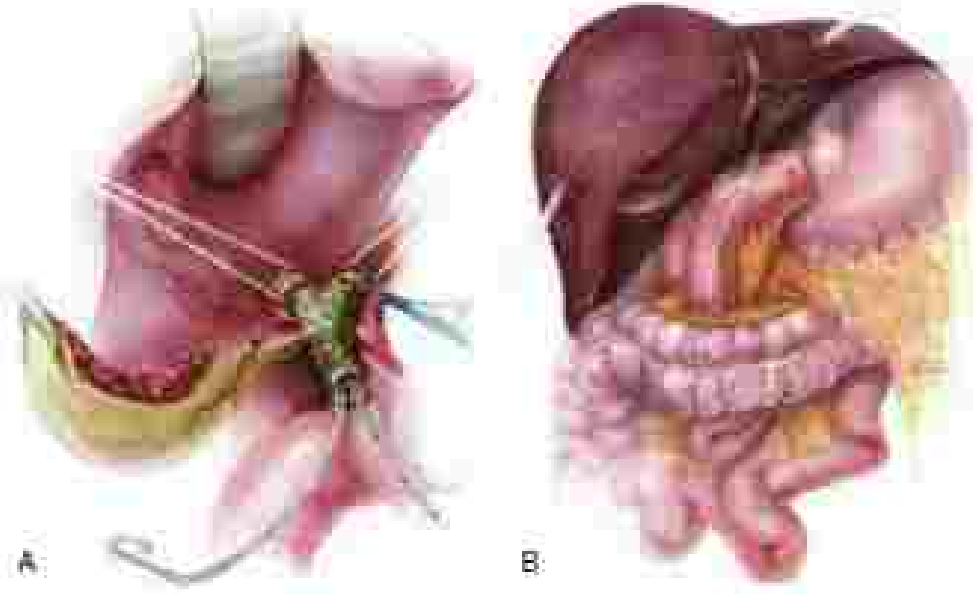

FIG. 3 (A) Resection of extrahepatic biliary tree with (B) reconstruction by Roux-en-Y hepaticojejunostomy over endoprosthesis biliary stents. (Courtesy Carlos Galdino, Mark Clements, Lecture C. Atlas of Gastrointestinal Surgery, 2nd Ed. [2]. Hamilton, Ontario: BC Decker Inc.)

In selected patients, this surgical approach offers good long-term results as compared to endoscopic or percutaneous modalities with a 5-year survival of 85%, similar to liver transplantation (Figs. 4 and 5). In the presence of cirrhosis, however, liver transplantation is the preferred treatment modality. Following liver transplantation for PSC, however, recurrent biliary strictures are more common than after transplantation for other diseases. Nonanastomotic recurrent biliary strictures have been diagnosed in up to 25% of patients after transplant (median follow-up, 5–10 years) and are more common in males than females, and in the presence of IBD, especially with an ileostomy. Other transplant considerations specific to PSC patients are discussed below.

Cholangiocarcinoma

Diagnosing CCa in patients with PSC is challenging because it is difficult to differentiate from inflammatory strictures, even with a biopsy. Patients with suspicious strictures on magnetic resonance cholangiopancreatography or elevated CA19-9 should undergo ERCP with brushings or biopsy of dominant strictures. Although the sensitivity of brush biopsies is traditionally very low, the addition of fluorescence in situ hybridization of brush cytology looking for polysomy increases the sensitivity. Cholangioscopy with directed biopsies has also been shown to increase sensitivity compared to traditional cytology brushings.

Surgical resection for CCa in the setting of PSC is ill-advised in patients with advanced cirrhosis or poor liver function because it is usually associated with prohibitively high postoperative mortality. In patients with findings suspicious for CCa or diagnosed CCa in the absence of extrahepatic disease or metastatic spread liver transplant after neoadjuvant chemoradiation is increasingly recommended. This approach has shown good outcomes with a 5-year survival of 70% (Fig. 6). Patients with suspicious looking strictures should be followed closely with repeat imaging and referral to a transplant center.

Gallbladder Disease

Given that PSC has been associated with an increased risk for developing both benign and malignant gallbladder disease, special consideration of the gallbladder is warranted in PSC patients. For example, not only is the threshold for cholecystectomy for gallbladder polyps lower in PSC than in non-PSC patients because the observation of gallbladder adenocarcinoma in even polyps smaller than 1 cm, but also some experts recommend that patients with PSC undergo annual ultrasound screening to look for gallbladder polyps and masses, and that cholecystectomy be considered in any patient with gallbladder

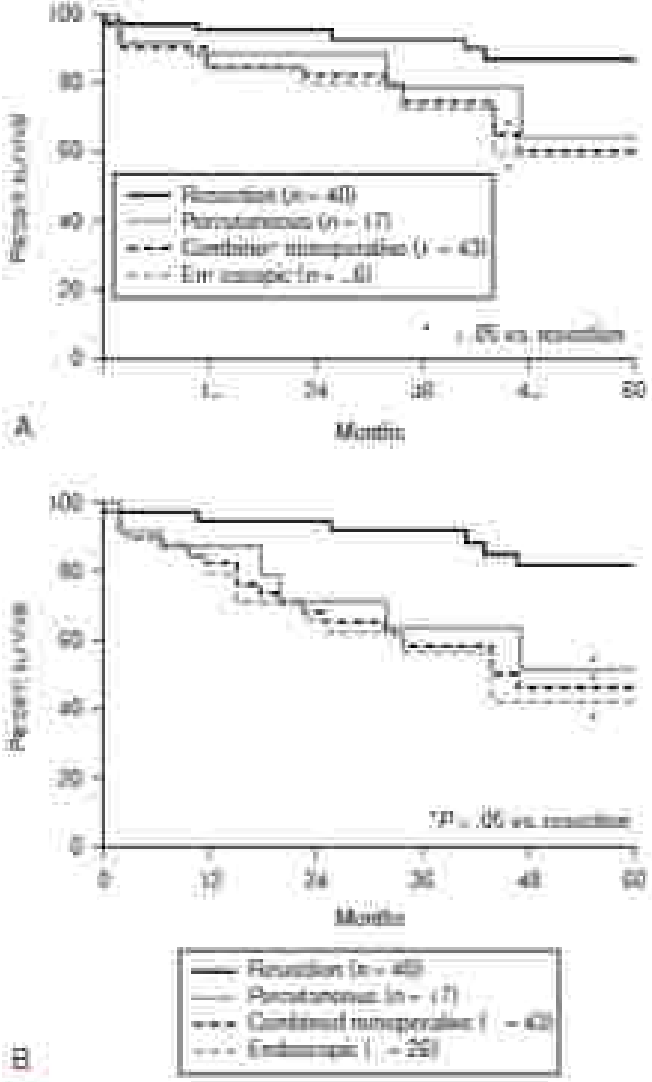

FIG. 4 (A) Overall and (B) transplant-free survival curves for nonoperative patients undergoing resection, endoscopic and percutaneous treatment for dominant biliary strictures. FIG. 6 Survival after start of medical therapy (A) and survival following transplantation (B). (From Lerner MR, Hochwald SN, Hochwald SN, et al: Surgery of the bile ducts and pancreas. Adv Surg 2010;44:193–210.)

polyps (~3% of patients with PSC). Patients with PSC are also at a higher risk (25%) of developing benign gallstone disease and are at increased risk to develop acalculous cholecystitis resulting from diffuse lymphoplasmacytic infiltration of the gallbladder, in which cases cholecystectomy may be indicated.

Liver Failure and Hepatocellular Carcinoma

PSC is the fifth most common indication for liver transplant in the United States and the most common indication for transplant in Scandinavia. As with other diseases warranting transplantation, the indication for liver transplant in PSC with liver cirrhosis is based on the model for end-stage liver disease (MELD) score. Patients with PSC usually have lower MELD scores because of preserved liver function but suffer from complications related to the disease from recurrent cholangitis to lifestyle limiting pruritus. These patients may get additional exception MELD points after evaluation by regional review board.

Hepatocellular carcinoma is observed in 2% to 6% of cholangiocytes in the setting of PSC. Abdominal ultrasound screening for hepatocellular carcinoma, typically every 6 months, with or without alpha fetoprotein should be performed for patients with PSC and evidence of liver cirrhosis.

During liver explant, excision of the entire biliary tree should be performed down to the head of the pancreas. Biliary reconstruction is then performed as a Roux en Y choledochojejunostomy. Following liver transplant, survival in patients with PSC is similar to liver transplant for other indications with 1- and 5-year survival rates of 83% and 87.3%, respectively, and graft survival rates of 87% and 79.2% at 1 and 5 years, respectively.

Post-transplant, PSC patients are at risk for disease recurrence, acute rejection, and chronic rejection. It is difficult to differentiate between ischemic strictures versus recurrence of disease versus chronic rejection. Recurrence of PSC is observed in 20% to 25% of patients following liver transplant, and male patients with IBD and an intact colon are at greatest risk of PSC recurrence.

Pruritus, Vitamin Malabsorption, and Hepatic Osteodystrophy

Pruritus is a common symptom that develops in patients with cholestatic liver disease. Dilatation of dominant strictures usually leads to relief of symptoms but some patients continue to suffer from severe pruritus despite resolution of jaundice. Several medications have been used for management of pruritus, including antihistamines, ursodeoxycholic acid, rifampicin, cholestyramine, naltrexone, and sertraline reuptake inhibitors. Patients with severe and refractory symptoms may receive MELD exception points after approval by a regional review board.

Patients with cholestasis also suffer from malabsorption of fat-soluble vitamins (A, D, E and K), putting them at risk to develop associated diseases such as osteoporosis and coagulopathy. Supplementation with fat soluble vitamins should therefore be offered to appropriate PSC patients.

IBD and Colon Cancer

As discussed previously, PSC is strongly associated with IBD. In most cases, the diagnosis of IBD precedes the diagnosis of PSC, but IBD can be diagnosed at any point during the course of PSC. Given that risk of colon cancer in PSC patients appears to be even higher after liver transplantation, patients with an intact colon should undergo screening colonoscopy during transplant evaluation and an aggressive screening regimen should be continued after transplantation.

SUMMARY

PSC is a progressive cholestatic disease that eventually results in liver failure. It is strongly associated with IBD. No medical therapy has shown evidence to alter the natural history of the disease. Endoscopic and percutaneous interventions are the main modalities in managing patients with dominant biliary strictures. In very selected patients with preserved liver function, intrahepatic bile duct resection with hepaticojejunostomy reconstruction over transhepatic stents offers good long-term results and prolonged survival. Patients with evidence of liver disease should be referred to a transplant center. Patients diagnosed with or suspected to have CCA should be offered a multimodality therapy including preoperative chemoradiation and possible liver transplant.

Management of Intrahepatic, Hilar, and Distal Cholangiocarcinomas

Michele M. Gage, MD, Mohammad Al Efishat, MD, and Richard A. Burkhart, MD

Cholangiocarcinoma, or bile duct cancer, originates from the epithelial lining of the biliary tree, and accounts for approximately 3% of all gastrointestinal tumors. They are the second most common primary liver tumor after hepatocellular carcinoma (HCC). The overall incidence of cholangiocarcinoma has been rising, though incidence varies by geographical location resulting from environmental and genetic differences. Incidences range from 113 per 100,000 person-years in Thailand, where liver flukes are endemic, to 0.5 to 1.5 per 100,000 person-years in the Western Hemisphere. The best chance for long-term survival and cure is surgical resection with a negative margin; however, cholangiocarcinoma is often diagnosed late, and only one-third of patients qualify for curative resection at diagnosis. Even after surgical resection, disease recurrence is common and the 5-year survival can range from 10% to 50% or more depending on disease stage.

Cholangiocarcinoma typically affects patients in the sixth or seventh decade of life and has a slightly higher predominance in men than women. Most cholangiocarcinomas in the Western population are likely sporadic in nature. There have been several risk factors recognized across populations, including biliary tract disorders (such as primary sclerosing cholangitis), parasitic infections (such as liver flukes Opisthorchis viverrini and Clonorchis sinensis endemic in Southeast Asia), hepatic toxins, and hepatitis B and C. Genetic polymorphisms, inflammatory bowel disease, choledochal cysts, cirrhosis, diabetes, obesity, hepatolithiasis, cholecholithiasis, and alcohol abuse have also all been linked to cholangiocarcinoma.

Cholangiocarcinoma is a diverse disease that is clinically grouped according to anatomical location within the biliary tree: intrahepatic, hilar (also known as Klatskin tumors), or distal. Intrahepatic tumors arise within the liver parenchyma and account for less than 10% of all cholangiocarcinomas. Hilar tumors are located in the extrahepatic biliary tree above the cystic duct and are the most commonly seen disease (60%–70%). Distal tumors are those that are centered in the extrahepatic biliary tree below the cystic duct takeoff and account for 20% to 30% of all cholangiocarcinomas. Cholangiocarcinomas commonly propagate longitudinally along the bile ducts resulting in disease that can overlap these anatomic landmarks.

The dominant histopathology is adenocarcinoma, and there are three classical subtypes of disease on microscopy: sclerosing, nodular, and papillary. The most common subtype is sclerosing cholangiocarcinoma, which is thought to extend in a subepithelial plane and cause thickening of the duct without a significant obstructing intraluminal mass. These are often detected clinically only after significant growth, and in many cases, discovered at a stage of disease that precludes resection. Nodular cholangiocarcinomas also result in thickening of the duct, but the radial growth pattern can clinically result in early biliary obstruction allowing for earlier diagnosis in some patients. Papillary cholangiocarcinomas consist of approximately 10% of all cholangiocarcinomas and typically arise in the distal bile duct. Papillary tumors are typically polypoid and expand the lumen of the duct. In all subtypes, perineural and lymphovascular invasion of the hepatoduodenal structures are also frequently seen.

INTRAHEPATIC BILE DUCT CANCER

Presentation and Preoperative Evaluation

Similar to many intrahepatic tumors, intrahepatic cholangiocarcinoma (ICCA) is often discovered incidentally on imaging obtained for an unrelated reason. When symptomatic, patients can present with a variety of symptoms including abdominal pain, fatigue, weight loss, poor appetite, and fever. Physical examination findings range from an asymptomatic patient to jaundice and signs of chronic liver disease. Rarely, patients may develop paraneoplastic dermatologic syndromes such as Sweet's syndrome, erythema multiforme, or porphyria cutanea tarda. Laboratory evaluation includes a liver chemistry panel, which may reveal an elevation in liver enzymes with an obstructive (direct) hyperbilirubinemia and an elevated alkaline phosphatase. Cancer antigen 19-9 (CA19-9) is the most likely tumor marker to be elevated (>129 units/mL) but it is neither highly specific nor sensitive for cholangiocarcinoma and can be falsely elevated in cholangitis or cholestasis. Workup should also include tumor markers

Patients with cholestasis also suffer from malabsorption of fat-soluble vitamins (A, D, E and K), putting them at risk to develop associated diseases such as osteoporosis and coagulopathy. Supplementation with fat soluble vitamins should therefore be offered to appropriate PSC patients.

IBD and Colon Cancer

As discussed previously, PSC is strongly associated with IBD. In most cases, the diagnosis of IBD precedes the diagnosis of PSC, but IBD can be diagnosed at any point during the course of PSC. Given that risk of colon cancer in PSC patients appears to be even higher after liver transplantation, patients with an intact colon should undergo screening colonoscopy during transplant evaluation and an aggressive screening regimen should be continued after transplantation.

SUMMARY

PSC is a progressive cholestatic disease that eventually results in liver failure. It is strongly associated with IBD. No medical therapy has shown evidence to alter the natural history of the disease. Endoscopic and percutaneous interventions are the main modalities in managing patients with dominant biliary strictures. In very selected patients with preserved liver function, intrahepatic bile duct resection with hepaticojejunostomy reconstruction over transhepatic stents offers good long-term results and prolonged survival. Patients with evidence of liver disease should be referred to a transplant center. Patients diagnosed with or suspected to have CCA should be offered a multimodality therapy including preoperative chemoradiation and possible liver transplant.

Management of Intrahepatic, Hilar, and Distal Cholangiocarcinomas

Michele M. Gage, MD, Mohammad Al Efishat, MD, and Richard A. Burkhart, MD

Cholangiocarcinoma, or bile duct cancer, originates from the epithelial lining of the biliary tree, and accounts for approximately 3% of all gastrointestinal tumors. They are the second most common primary liver tumor after hepatocellular carcinoma (HCC). The overall incidence of cholangiocarcinoma has been rising, though incidence varies by geographical location resulting from environmental and genetic differences. Incidences range from 113 per 100,000 person-years in Thailand, where liver flukes are endemic, to 0.5 to 1.5 per 100,000 person-years in the Western Hemisphere. The best chance for long-term survival and cure is surgical resection with a negative margin; however, cholangiocarcinoma is often diagnosed late, and only one-third of patients qualify for curative resection at diagnosis. Even after surgical resection, disease recurrence is common and the 5-year survival can range from 10% to 50% or more depending on disease stage.

Cholangiocarcinoma typically affects patients in the sixth or seventh decade of life and has a slightly higher predominance in men than women. Most cholangiocarcinomas in the Western population are likely sporadic in nature. There have been several risk factors recognized across populations, including biliary tract disorders (such as primary sclerosing cholangitis), parasitic infections (such as liver flukes Opisthorchis viverrini and Clonorchis sinensis endemic in Southeast Asia), hepatic toxins, and hepatitis B and C. Genetic polymorphisms, inflammatory bowel disease, choledochal cysts, cirrhosis, diabetes, obesity, hepatolithiasis, cholecholithiasis, and alcohol abuse have also all been linked to cholangiocarcinoma.

Cholangiocarcinoma is a diverse disease that is clinically grouped according to anatomical location within the biliary tree: intrahepatic, hilar (also known as Klatskin tumors), or distal. Intrahepatic tumors arise within the liver parenchyma and account for less than 10% of all cholangiocarcinomas. Hilar tumors are located in the extrahepatic biliary tree above the cystic duct and are the most commonly seen disease (60%–70%). Distal tumors are those that are centered in the extrahepatic biliary tree below the cystic duct takeoff and account for 20% to 30% of all cholangiocarcinomas. Cholangiocarcinomas commonly propagate longitudinally along the bile ducts resulting in disease that can overlap these anatomic landmarks.

The dominant histopathology is adenocarcinoma, and there are three classical subtypes of disease on microscopy: sclerosing, nodular, and papillary. The most common subtype is sclerosing cholangiocarcinoma, which is thought to extend in a subepithelial plane and cause thickening of the duct without a significant obstructing intraluminal mass. These are often detected clinically only after significant growth, and in many cases, discovered at a stage of disease that precludes resection. Nodular cholangiocarcinomas also result in thickening of the duct, but the radial growth pattern can clinically result in early biliary obstruction allowing for earlier diagnosis in some patients. Papillary cholangiocarcinomas consist of approximately 10% of all cholangiocarcinomas and typically arise in the distal bile duct. Papillary tumors are typically polypoid and expand the lumen of the duct. In all subtypes, perineural and lymphovascular invasion of the hepatoduodenal structures are also frequently seen.

INTRAHEPATIC BILE DUCT CANCER

Presentation and Preoperative Evaluation

Similar to many intrahepatic tumors, intrahepatic cholangiocarcinoma (ICCA) is often discovered incidentally on imaging obtained for an unrelated reason. When symptomatic, patients can present with a variety of symptoms including abdominal pain, fatigue, weight loss, poor appetite, and fever. Physical examination findings range from an asymptomatic patient to jaundice and signs of chronic liver disease. Rarely, patients may develop paraneoplastic dermatologic syndromes such as Sweet's syndrome, erythema multiforme, or porphyria cutanea tarda. Laboratory evaluation includes a liver chemistry panel, which may reveal an elevation in liver enzymes with an obstructive (direct) hyperbilirubinemia and an elevated alkaline phosphatase. Cancer antigen 19-9 (CA19-9) is the most likely tumor marker to be elevated (>129 units/mL) but it is neither highly specific nor sensitive for cholangiocarcinoma and can be falsely elevated in cholangitis or cholestasis. Workup should also include tumor markers

that are associated with primary liver and gastrointestinal tumors such as alpha-fetoprotein in HCC, carcinoembryonic antigen (CEA) in colorectal liver metastasis, chromogranin A in carcinoid tumors, and immunoglobulin profiling in patients with findings suspicious for autoimmune disease.

Cross-sectional imaging with a liver-protocol multiphase, contrast-enhanced magnetic resonance imaging (MRI) or multiphasic contrast-enhanced multidetector computed tomography (CT) is a mainstay of the diagnostic evaluation and can aid in differentiating intrahepatic cholangiocarcinoma from HCC or focal nodular hyperplasia. It is also useful for operative planning by identifying aberrant ductal anatomy. Radiographic features of intrahepatic cholangiocarcinoma vary depending on tumor type: mass-forming, periductal infiltrating with intrahepatic ductal dilation, or annular type. On multiphasic contrast-enhanced multidetector CT, intrahepatic cholangiocarcinoma usually appears as a well-defined or infiltrative hypodense lesion with biliary dilatation, often with capsular retraction, and exhibits rim enhancement throughout both arterial and venous phases. On liver-protocol multiphase, contrast-enhanced MRI, it appears as a hypointense lesion on T1-weighted images and heterogeneously hyperintense on T2-weighted images. Primary liver cancer can arise with a histologic subtype of mixed HCC-ICC. These often appear as an irregular mass with rim enhancement on gadoxetic acid–enhanced MRI, whereas mass-forming ICCA appear as lobulated lesions with a weak rim and a target appearance. Of note, these mixed tumors are staged as ICCA rather than HCC.

Classic findings on history, physical examination, and cross-sectional imaging can often obviate the need for biopsy. When doubt about the underlying etiology of disease exists, metastatic disease from another primary malignancy should be kept in mind. In these instances, a search for a primary tumor can be sought with upper and lower endoscopy, chest CT, and mammography in female patients. For ICCA presenting with typical imaging characteristics and high-quality data, positron emission tomography scan is infrequently used. In patients with resectable disease, many surgeons advocate for a staging laparoscopy during the workup to evaluate for occult peritoneal dissemination.

Surgical resection is the primary treatment modality in localized disease as summarized by guidelines summarized by the National Comprehensive Cancer Network. Characteristics of disease that preclude resection include metastatic disease on preoperative staging and lymph node metastasis beyond the porta hepatis. Although disease spread to locoregional (portal) lymph nodes is not a contraindication to resection, the prognosis of patients with gross disease in this location is generally poor. Multifocal hepatic disease is a strong indicator of systemic disease spread and, although not an absolute contraindication to resection, patients presenting with this pattern of disease are poor candidates for a surgery first approach to management. Additional poor prognostic factors include the presence of small localized satellite lesions and portal hypertension. Technical resectability is defined as the ability to completely remove the disease while leaving an adequate future liver remnant (FLR). Unresectable local disease is most commonly noted for tumors that involve either inflow or outflow bilaterally. Other technical resectability can only be determined by intraoperative exploration and attempt at extirpation.

An assessment of liver volumes and function should be performed as part of preoperative planning. The volume of the FLR should, at the least, be estimated from cross-sectional imaging. When major hepatectomy is planned, CT volumetrics can assist with preoperative risk assessment. An FLR of at least 20% to 40% of normal hepatic parenchyma (two contiguous Couinaud's segments) should be maintained postresection with an intact arterial and portal inflow, hepatic venous outflow, and biliary enteric drainage. If cirrhosis is present or suspected, the FLR needed is increased, with most surgeons targeting 40% to 50%. The Child-Turcotte-Pugh score and the Model for End-Stage Liver Disease score are commonly used to indirectly assess liver function and degree of cirrhosis. Other hepatic functional assessment using a variety of techniques, including indocyanine green kinetics, is also selectively used when considering major hepatectomy.

In preparing for surgical resection, preoperative global functional assessment is ideal given the morbidity (30%–50%) and mortality (5%–10%) of major hepatic resections in this patient population. Common tools used for functional assessment include Eastern Cooperative Oncology Group performance status (range, 0–5), G8 geriatric screening tool (range, 0–17, with a score of 14 or less identifying at-risk individuals), and the American College of Surgeons Surgical Risk Calculator (http://riskcalculator.facs.org).

Staging

Historically, staging guidelines for ICCA were identical to those used for HCC. In 2010, however, the seventh edition of American Joint Committee on Cancer (AJCC) tumor node metastasis (TNM) staging system introduced a unique staging system for ICCA. Though prognosis was better stratified in the context of this unique system, long-term survival was not different in patients with stage II and stage III disease. The AJCC eighth edition revised guidelines were published in 2017 (Table 1) and have incrementally improved prognostic capacity, particularly in the ability to separate survival between T1b2 disease and T3 disease. This is a result of the T1 category being divided to reflect the prognostic importance of tumor size, and the T2 category now takes into account the prognostic values of vascular invasion and tumor multifocality. Despite the improvements in the staging of T stage, it is important to note that survival differences across several of the clinical stages remain small (stage IIa, II, and IIIa, for example, have similar rates of 5-year overall survival).

Management

Resection

Liver resection achieving negative margins offers the only chance for cure and should be attempted in the cohort of patients who are otherwise healthy and share goals of care that are in line with early, aggressive surgical management. Historically, curative resection with tumor-negative margins can be achieved in less than 30% of patients. This number appears to be improving as advances in intraoperative ultrasound imaging and resection techniques continue to evolve. Portal lymphadenectomy is recommended, and these lymph nodes are positive in approximately one-third of patients. The benefit of lymphadenectomy is controversial and likely limited to prognostic value. Positive resection margins and positive nodes are associated with worse prognosis. Adjuvant gemcitabine-based chemotherapy and fluoropyrimidine-based chemoradiation may be beneficial, although high-quality data are lacking. Extent of resection depends on tumor size and the expected residual volume of the liver, which could range from nonanatomic wedge resection for small tumors to formal anatomic resections, such as extended hepatectomy, for large tumors. If the FLR is too small, preoperative unilateral portal vein embolization can result in contralateral hypertrophy of the FLR and help to define, and at times mitigate, the risk of postoperative liver failure. Major liver resection combined with portal and/or caval resection and reconstruction has been performed safely in highly selected patients who are otherwise healthy, but these operations should only be performed in high-volume or liver transplant centers.

In an open operative approach, a right subcostal incision, which can be extended bilaterally to a chevron incision with or without a vertical midline extension, provides excellent exposure. A midline incision may be used for selected lesions, or when a liver resection is combined with curative abdominal surgery. Based on suspicion from preoperative imaging, diagnostic laparoscopy may precede open operation to assess for carcinomatosis or assess the extent of multifocal disease if suspected. Increasingly complex hepatectomies for malignant disease are successfully performed laparoscopically or robotically, and the decision on an open versus minimally invasive approach is surgeon dependent. The safety of minimally invasive

TABLE 1 Tumor-Node-Metastasis Staging System for Intrahepatic Cholangiocarcinoma, Eighth Edition

PRIMARY TUMOR (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor

surgery in hepatic resections is increasingly demonstrated by high volume surgeons in the literature.

Surgery typically begins with exploration, often laparoscopically, to rule out metastatic disease in the abdomen. For a hemihepatectomy or extended hepatectomy, the liver is mobilized by incising the coronary, triangular, and falciform ligaments. Intraoperative ultrasound is helpful in localizing the tumor, ruling out occult liver lesions, and delineating the parenchymal anatomy. A cholecystectomy is typically performed. Inflow is controlled in the hilum, and venous outflow is controlled by isolating the corresponding hepatic vein(s), generally extrahepatically, before parenchymal transection. In selected cases, the vein can be transected before parenchymal dissection to decrease blood loss. A flamed tourniquet can be positioned around the hilar vasculature in preparation for a Pringle's maneuver, should it become necessary. When used, Pringle's inflow occlusion can vary between surgeons. One common strategy is to maintain occlusion for periods of 15 minutes with 5 minute periods of reperfusion. Parenchymal transection is also surgeon dependent with the more commonly used techniques being the clamp crush technique, stapled hepatic resection, and transection with ultrasonic dissection or energy devices. Practically, a combination of the above is used as the situation demands with ties, titanium clips, and cautery used for hemostasis and biliary ligation. Direct pressure, Prolene suture, and topical hemostatic agents can also be used to control bleeding from the raw surface of the liver. The use of drainage catheters following major liver resection is surgeon dependent and our use is largely confined to patients requiring multivisceral resections, biliary-enteric reconstruction, or diaphragmatic repair.

Other Treatments

Unfortunately, many patients with intrahepatic cholangiocarcinoma present with unresectable disease, and even for those who undergo surgical resection, many recur either locally in the liver (25%–70%) or outside the liver (10%–30%) and are thus managed with palliative intent. Survival rates for resected patients are generally between 20% and 50% at 5 years (depending on stage). Patients who underwent R0 resections with node negative tumors can have 5 year survival rates that exceed 60% in some series. Adjuvant chemotherapy using a gemcitabine/cisplatin (per the ABC trial) or capecitabine/gemcitabine followed by FU based chemoradiotherapy (per the adjuvant Southwestern Oncology Group 50800 trial) should be considered in high risk patients with R0 resection. These adjuvant therapies are strongly recommended in R1 resection or positive lymph nodes, as these patients are managed similar to those with unresectable disease. Stereotactic body radiotherapy is an alternative to FU based chemoradiotherapy and is starting to gain favor in high volume centers.

Liver transplantation has yet to become widely accepted for ICCA and is most commonly considered in those with HCC or perihilar cholangiocarcinoma, however, transplantation may be considered in the context of a clinical trial for highly selected patients with severe liver disease or primary sclerosing cholangitis with ICCA, usually following neoadjuvant chemoradiation. Survival data suffer from selection bias and the inclusion of perihilar cholangiocarcinoma, with some experienced centers reporting 5 year survival of up to 53% following liver transplantation in ICCA.

Patients with unresectable tumors because of poor functional status, inadequate FLR, or locally advanced disease, may still be candidates for external beam radiotherapy, transarterial chemoembolization (TACE), transarterial radioembolization, or ablation. TACE and selective radioembolization with radioactive isotopes (e.g., iodine 131 labeled lipiodol or yttrium 90 tagged glass or resin microspheres) are appealing options given that most of the tumor blood supply is derived from the hepatic artery rather than the portal vein. Large unresectable tumors can sometimes be converted to resectable disease following TACE or radioembolization. Ablative techniques for ICCA include radiofrequency ablation, microwave ablation, irreversible electroporation, and photodynamic therapy (PDT). Several limited studies have demonstrated the safety and efficacy of these local therapies, but there are no high quality data to support the use of one approach over another in ICCA.

HILAR CHOLANGIOCARCINOMA

Presentation and Preoperative Evaluation

Early diagnosis of hilar cholangiocarcinoma most commonly presents with symptoms of jaundice and pruritus, which is present in up to 90% of patients. Other symptoms are relatively nonspecific and include abdominal pain, fatigue, weight loss, and anorexia. The diagnosis can also be made following work up of abnormalities on routine laboratory tests, or imaging obtained to diagnose vague symptoms. Despite a relatively early presentation commonly driven by clinically apparent symptoms, in comparison to ICCA, the proximity of the hilum to critical structures does raise the specter of involvement of critical vascular structures that can preclude resection.

Once hilar cholangiocarcinoma is suspected, a thorough evaluation is recommended. This typically includes high-quality cross-sectional imaging with CT of the chest, abdomen, and pelvis. MRI is a commonly used modality for imaging of the liver in this setting and anatomic delineation of the disease can be clarified by formal magnetic resonance cholangiopancreatography. In the absence of need for decompression of biliary biopsy, magnetic resonance cholangiopancreatography has been shown to be equivalent to endoscopic retrograde cholangiopancreatography (ERCP) in the diagnosis of hilar cholangiocarcinoma. The chest imaging is used to rule out metastatic disease, whereas abdominal imaging assists in evaluating the degree of local and distant invasion, particularly vascular invasion, portal lymphadenopathy, hepatic atrophy, and biliary dilatation. Invasion of the right hepatic artery is more commonly observed than the left because of the right hepatic artery's proximity to the ductal confluence. Laboratory profiling should include, at a minimum, liver function tests and tumor markers CA19-9 and CEA. Sensitivity and specificity of CA19-9 and CEA vary widely, and these values should not be used to a diagnostic capacity in the setting of jaundice and biliary mass. Tissue diagnosis is often difficult to obtain and is not necessary if laboratory and imaging findings are pathognomonic for disease.

The approach to disease in the hilum mimics that for HCC with resection as a primary modality when technically achievable. Criteria for unresectable disease include main portal vein involvement, bilateral spread to secondary biliary radicals, bilateral hepatic artery and/or portal venous branch involvement, unilateral hepatic artery involvement with contralateral ductal spread, and/or presence of distal metastases (Box 1). Clinical staging paradigms, as discussed further in this chapter, have been developed to assist surgeons in patient selection.

The preparation of a patient for resection in hilar cholangiocarcinoma requires careful preoperative planning. The underlying principle of resection is an attempt to achieve R0 resection. As historical data have demonstrated that rates of R0 resection are improved in the setting of concomitant hepatectomy, the standard of care dictates a major hepatectomy in conjunction with extrahepatic biliary resection and reconstruction. For patients with obstructive jaundice and cholestasis, preoperative biliary drainage has been associated with decreased postoperative complications and mortality. There is currently not a standard optimal preoperative bilirubin level, though cutoffs of 5 to 10 mg/dL are frequently used to trigger biliary intervention. Both endobiliary prosthesis and percutaneous biliary drainage catheters can be used to relieve hepatic congestion, and the debate about an ideal approach is ongoing.

Before surgery, all patients should undergo a thorough review of general functional and medical status, particularly in regards to their likelihood of tolerating a major liver resection. Due to frequent intrahepatic or vascular involvement in hilar cholangiocarcinoma, major hepatectomy is the standard of care, and the ability of the patient to tolerate this procedure and the remaining FLR should be carefully assessed. Portal vein embolization, as described for intrahepatic cancers above, should be considered for patients who are estimated to have less than 25% to 30% FLR.

BOX 1 Local Tumor-Related Criteria for Unresectability

- Hepatic duct involvement up to secondary biliary radicals bilaterally
- Encasement or occlusion of the main portal vein proximal to its bifurcation*
- Atrophy of one hepatic lobe with contralateral encasement of portal vein branch
- Atrophy of one hepatic lobe with contralateral involvement of secondary biliary radicals
- Unilateral tumor extension to secondary biliary radicles with contralateral vein branch encasement or occlusion

*Relative criterion. Portal vein resection and reconstruction may be possible.

Staging

The three most commonly used staging systems for hilar cholangiocarcinoma are the Bismuth Corlette, AJCC TNM, and the Blumgart staging system. Bismuth and Corlette published one of the first anatomical classification systems for hilar cholangiocarcinomas. Based on tumor location and ductal infiltration, tumors are classified into four categories (Fig. 1). This system is useful for stratifying patients based on the degree of involvement through the biliary tree but does not provide information regarding resectability or survival since vascular, lymphatic, and hepatic parenchymal findings are not noted. The AJCC TNM system (Table 2) is one of the most commonly used, and considers size, presence of the tumor, regional nodal involvement, and metastases. This staging system, commonly used in the preoperative period, has limitations in both the assessment of technical resectability and in prognostic stratification (sharing many of the same concerns as the BCLC system described previously). The Blumgart system expands on the Bismuth Corlette system by classifying patients into three T stages based on longitudinal and radial extent of the tumor, as well as vascular involvement, and liver atrophy (Table 3). Increased T stage has been associated with decreased likelihood of R0 resection and associated worse survival (Table 3 and Box 1). The unique characteristics of the Blumgart system have resulted in a facile tool for surgical patient selection.

Management

Surgical Resection

Surgical resection is the best chance of cure and long-term survival. Resection is often challenging and options include hepatectomy, pancreaticoduodenectomy, or liver transplantation in attempts to achieve R0 resection. As many as 80% of patients are found to have metastatic or unresectable disease at time of exploration, and some surgeons use exploratory laparoscopy before laparotomy as a matter of routine. A right subcostal incision, often with midline extension, is commonly

and the exposure. Other options for selected tumors include a chevron, Mercedes, or midline laparotomy. The steps of the operation can vary according to surgeon preference and patient disease. One common approach is outlined briefly herein.

The hepatoduodenal ligament is dissected and the portal triad is skeletonized in keeping with the principles of a formal lymphadenectomy. Tumor tissues are often left intact with the main specimen during the course of the early dissection. The bile duct is transected distally and a margin is sent for frozen section. This assists in operative planning because it determines if a pancreaticoduodenectomy is necessary for a negative margin. Next, the bile duct is reflected anteriorly and the portal vein and hepatic artery are dissected free and assessed for tumor involvement. The gallbladder may be removed at this time or maintained for use as retraction. Resectability is assessed by evaluating local tumor invasion to the surrounding vasculature. Cases are deemed unresectable in the event of unreconstructible main portal vein involvement, bilateral hepatic artery involvement, involvement of the artery or vein on the contralateral side in relation to apparent involvement of the biliary tree, or a positive margin at the common bile duct along its entry into the pancreas in a patient who would not tolerate concomitant pancreaticoduodenectomy with their resection. Here, preoperative risk stratification and judgment on surgical risk assumed by more advanced technical maneuvers are required of the operating surgeon. Practically, involvement of bilateral biliary secondary radicals is often unknown until division of the ducts and committing to operative extirpation.

If the tumor is deemed unresectable, local excision of the bile duct should be completed at this time (if feasible) with creation of a Roux-en-Y hepaticojejunostomy for palliation. If resectable, proceeding with hilar resection in the context of hepatectomy is appropriate. The choice of hepatectomy (right vs. left, standard vs. extended) is dictated by intraoperative findings and informed by preoperative staging as discussed previously. Caudate resection is typically performed for all patients with hilar disease. Commonly, transection of the hepatic artery and portal vein supplying the specimen side of the liver is completed as the next step. The hepatic vein to the corresponding liver can then be transected and hepatectomy is performed. The transection of the hepatic ducts is often the last maneuver to be undertaken, as this margin would dictate R (resection) status of the surgery. The proximal margin should also be assessed by frozen section analysis and a positive result should prompt a further dissection of the biliary tree, if possible, in attempt to reach a negative margin. There are reports of extrahepatic biliary tree resection without hepatectomy in the absence of vascular involvement and relatively low lying tumors without preoperative evidence of disease extending into the second-order biliary radicals. If this approach is to be taken, both the right and left hepatic ducts should be assessed for local involvement of disease prior to leaving the operating room. In the context of historical data demonstrating increased rates of R1 resection, caution should be used before adopting this approach.

Following resection, a Roux-en-Y hepaticojejunostomy is commonly performed for reconstruction. Commonly, more than one biliary radical is found that requires anastomosis. In these cases, it may be considered to join two adjacent lumens with sutures to make a

common wall, enabling creation of a single enteric anastomosis (Fig. 2). Drains are universally used in our practice for combined hepatectomy with bile duct reconstructions.

Additional Treatments

Chemotherapy and radiation are typically offered to patients with unresectable disease, postoperative patients as adjuvant therapy, or preoperative patients as neoadjuvant therapy. While studies are limited, gemcitabine-based combination chemotherapies have demonstrated prolonged overall survival when used as adjuvant therapy. Routine chemoradiotherapy is also being studied with prospective trials under way. There is an expanding experience with transplant in hilar cholangiocarcinoma after neoadjuvant chemoradiation. Initial data demonstrate that long-term survival is possible in this highly selected cohort. PDT is also being explored as a palliative modality in unresectable cases of hilar cholangiocarcinoma but is not routinely performed in all high-volume centers. This involves intravenous administration of a photosensitizing agent, such as porphyrin, which accumulates in cancer cells. Phototherapy is then delivered, intraluminally by cholangioscopy, generating oxygen free radicals and tumor cell death. There is some evidence PDT may increase survival by up to 3 months compared with biliary stenting alone.

DISTAL CHOLANGIOCARCINOMA

Presentation and Preoperative Evaluation

Distal cholangiocarcinoma, or cholangiocarcinoma arising between the cystic duct and the ampulla of Vater, commonly presents with painless jaundice and other nonspecific abdominal symptoms including nausea, anorexia, fatigue, and weight loss. Liver enzymes are typically elevated, with a bilirubin elevated more than 10 mg/dL being highly suggestive of a malignant process. Initial ultrasound performed for jaundice will typically reveal both intrahepatic and extrahepatic biliary ductal dilatation, compared with only intrahepatic dilatation in hilar cholangiocarcinoma. High-quality imaging with CT or MRI of the chest, abdomen, and pelvis is helpful in assessing invasion of surrounding structures, anatomical abnormalities, and regional or distant metastases. Pancreatic atrophy or pancreatic ductal dilatation may be present based on location of the tumor. These tumors can be very small and difficult to characterize on imaging. Preoperative laboratory values and tumor markers (CA19-9 and CEA) should also be evaluated.

Though not always necessary, invasive studies such as ERCP with EUS may be utilized to further characterize the tumor and obtain a tissue diagnosis. In cases of cholangitis or severe hepatic congestion, ERCP and stent placement can also provide therapeutic drainage; however, routine ERCP with stenting is not recommended unless necessary because it increases the risk of postoperative infection resulting from colonization of the biliary tree. Relief of jaundice is not as critical as in hilar cholangiocarcinomas because hepatectomy is rarely necessary in distal cholangiocarcinomas. Preoperative assessment should similarly evaluate the patient's ability to tolerate local excision of the biliary tree and/or a pancreaticoduodenectomy.

Staging

Distal cholangiocarcinoma is most often staged by the AJCC TNM system (Table 4). The TNM staging shares some similarities with the system for proximal bile duct cancers. For example, T1 and T2 are confined (T1) or invade through (T2) the bile duct wall, whereas T3 includes invasion of adjacent organs and T4 includes invasion of adjacent vasculature. The nodal staging system differs, however, with two classifications (N1, N2) as opposed to three (N1, N2, N3) for perihilar bile duct cancers. The nodal staging is performed at the time of surgery with the sampling of at least 12 nodes, analogous to the management of pancreatic cancer.

Management

Surgical Resection

The goals of resection are as follows: remove the tumor, relieve obstruction, and provide accurate staging information to direct selection of further therapies. Resection of distal cholangiocarcinomas requires pancreaticoduodenectomy in the majority of cases. Resectability is assessed intraoperatively by confirming the absence of distant metastatic disease and evaluating for unresectable vascular invasion. The procedure may be performed open, laparoscopically, or robotically. In proceeding with open resection, an upper midline incision provides excellent visualization. Unlike hilar cholangiocarcinomas, distal cholangiocarcinomas are frequently identified relatively early in their disease course and metastatic disease not identified on CT is less likely (5%–10%). For this reason, many surgeons forego routine staging laparoscopy and opt to begin with a multidisciplinary.

As discussed by several chapters, there is variation in the order of maneuvers done for pancreaticoduodenectomy. One common approach is as follows. After exploration for metastatic disease, the duodenum, head, and uncinate process of the pancreas are mobilized out of the retroperitoneum with wide lymphadenectomy. The course of the superior mesenteric artery is assessed. The superior mesenteric vein is identified along the inferior border of the pancreatic neck and the portal vein is inspected in the porta hepatis. Also, in and around the porta, the common hepatic artery, gastroduodenal artery, and proper hepatic artery are inspected for resectability. The gastroduodenal artery is identified, dissected free, and ligated. A permissive pulse in the porta hepatis should be verified. At this point, if all critical structures are verified to be free of tumor involvement the case may proceed. Venous involvement of the tumor may not preclude resection so long as the operative team is prepared and experienced with vascular resection and reconstruction. Arterial resection and reconstruction remain controversial in the setting of periampullary malignancy.

The stomach is transected with a linear cutting stapler approximately 4 to 6 cm proximal to the pylorus. Alternatively, a pylorus-preserving pancreaticoduodenectomy spares the pylorus. The gastroduodenal artery is then transected with silk ties, and the common stump is reinforced with Prolene suture. The common bile duct is then transected with electrocautery, and a bulldog clamp is used to control bile spillage. A frozen section of the duct is sent to ensure a negative margin. A Penrose drain is placed through the previously established tunnel behind the pancreas, and the neck of the pancreas is divided with electrocautery or scalpel. Next, the transverse mesocolon is elevated and the ligament of Treitz (LOT) is identified. The LOT is incised and the first portion of the jejunum is mobilized. The jejunum is then transected with linear cutting stapler approximately 10 to 20 cm from the LOT. The proximal jejunum is separated from the mesentery and passed into the right upper quadrant through the LOC. Last, the dissection is completed by separating the head and uncinate process of the pancreas from the portal vein, superior mesenteric vein, and superior mesenteric artery using a combination of sharp dissection, silk ties, and energy devices. This from the Whipple specimen to be sent off as specimen.

For reconstruction, a pancreaticojejunostomy, hepaticojejunostomy, and gastrojejunostomy are performed. First, the LOT defect is closed with running Prolene suture. The cut surface of the jejunum is then passed through a defect created in a bare area of the transverse mesocolon to the right of the middle colic artery. The staple line of the jejunum is removed and laid onto the pancreas without tension. An end-to-side pancreaticojejunostomy (PJ) is created in two layers. There are myriad techniques to construct the PJ with few demonstrating superiority. In our center, we commonly use a two-layer duct-to-mucosa technique. Next, for the hepaticojejunostomy, an end-to-side hepaticojejunostomy is created with absorbable suture. The jejunum is tacked to the transverse mesocolon at the point of passage through the transverse colon mesentery to secure the afferent limb and close this defect. The jejunum is then traced approximately 40 cm to a point where it may easily approximate the stomach. An antecolic gastrojejunostomy (or duodenojejunostomy if a pylorus preserving pancreaticoduodenectomy was performed) is then constructed. Similar to the PJ, a variety of techniques have been demonstrated to function well for these anastomoses. At creation of the operative, closed suction drainage is employed routinely after a Whipple operation in our practice.

Other Treatments

Similar to hilar cholangiocarcinoma, chemotherapy and radiation are typically offered to patients with unresectable disease or perioperative patients as adjuvant therapy. Because of the rarity of disease, the role of adjuvant chemotherapy and chemoradiotherapy in patients with resected distal cholangiocarcinomas is poorly defined. Many studies investigating adjuvant therapy in cholangiocarcinoma have combined distal and hilar cholangiocarcinomas as one entity, extrahepatic disease, and at times have often included gallbladder cancers. As such, the true benefit of adjuvant disease is difficult to ascertain. Most adjuvant chemotherapy and chemoradiation regimens demonstrating benefit have been fluoropyrimidine or gemcitabine based. However, there is limited clinical trial data to define a standard regimen. In the metastatic setting, a 2010 randomized, controlled, phase III trial (ABC-02 study) demonstrated improved overall survival of gemcitabine and cisplatin combination therapy compared to gemcitabine alone. More recent studies have demonstrated similar findings, and combination gemcitabine-cisplatin is considered first line chemotherapy for patients with advanced or metastatic biliary tract cancers. PDT may also be considered as a palliative modality in unresectable cases of distal cholangiocarcinoma.

SUMMARY

Cholangiocarcinomas are a diverse group of tumors with evaluation and initial management considerations based largely on location in the biliary tree and the extent of local disease or evidence of dissemination. Surgical resection is the cornerstone of treatment in a curative paradigm. Thorough preoperative evaluation for resectability, operative candidacy, and likelihood of R0 resection are required in all cases. For patients requiring liver resection, the estimated FLR should be carefully evaluated before surgery and consideration for biliary decompression should be assessed. The best chance of survival is R0 resection, and frozen sections should be used liberally in the operating room. Though the use of adjuvant therapies is common, definitive evidence of benefit from adjuvant chemotherapy and chemoradiation is mixed at this time. Unfortunately, many cases are diagnosed late, and palliation of symptoms, chemotherapy, and chemoradiation are commonly utilized in these cases. As with all complex oncologic care, management of these cases can often be optimized by multidisciplinary input at high volume centers.

MANAGEMENT OF GALLBLADDER CANCER

Akhil Chawla, MD, and Cristina R. Ferrone, MD

Gallbladder cancer is one of the rarest and most aggressive gastrointestinal malignancies. Surgical resection offers the best chance at long-term survival. Patients generally have a poor prognosis, except those with early stage disease, which is most often found incidentally. The current available systemic therapy is not effective in the majority of patients with high rates of distant metastases. In the United States, patients are often diagnosed after elective cholecystectomy for cholelithiasis–related disease. Alternatively, patients may present after imaging findings suspicious for malignancy are found during workup for symptomatic gallstone disease. In patients found to have disease amenable to resection, only a select group of patients will benefit from an aggressive operation. The surgeon is most often the diagnostician of this rare malignancy. Therefore, an in-depth knowledge of the appropriate workup and management of such patients is mandatory. This chapter focuses on the staging, appropriate evaluation, workup, and treatment of patients with gallbladder cancer.

EPIDEMIOLOGY AND PATHOGENESIS

There is strong variability in the incidence of gallbladder adenocarcinoma that parallels the geographic prevalence of cholelithiasis. The highest rates of malignancy are seen in South American countries including Chile, Bolivia, and Ecuador as well as South Asian and Southeast Asian countries including India, Pakistan, Japan, and Korea, with rates of gallbladder adenocarcinoma in excess than 10 of every 100,000 people. In the United States, gallbladder cancer is rare, with an incidence of just over 2 per 100,000 people.

The median age of diagnosis is 72 years, with a female to male predominance of 2:1 to 4:1. Increasing age as well as the presence of cholelithiasis are both independent predictors of malignancy. These data support the rationale that chronic mucosal inflammation may lead to dysplastic changes and eventual malignant transformation. Further supporting this hypothesis are data which demonstrate metaplasia in nearly one half of examined gallbladder specimens found to have gallstone disease. The adenoma to carcinoma progression seen in various gastrointestinal malignancies may also play a role in the pathogenesis given the increased incidence of adenocarcinoma in gallbladder polyps greater than 10 mm, particularly if solitary.

STAGING AND SURVIVAL

TNM Staging

The eighth edition of the American Joint Committee for Cancer (AJCC) TNM Cancer Staging system for gallbladder adenocarcinoma is shown in Table 1. The T stage, which describes the depth of invasion, has importantly been changed in the latest AJCC staging system. There are strong data demonstrating poorer prognosis of tumors that are located on the hepatic interface of the gallbladder as opposed to the peritoneal side. Tumors invading the perimuscular tissue on the hepatic side, without any extension into the liver parenchyma are now designated as T2b. T2b tumors demonstrate an increase in intrahepatic as well as nodal recurrence after curative radical resection compared with T2a tumors, and therefore portend a worse prognosis. In addition to these changes, the newest edition of the AJCC staging system reclassifies N stage based on the number of nodes involved, rather than the anatomic location of involved nodes. The eighth edition of the AJCC for gallbladder cancer has been validated using the National Cancer Database (Lee et al.) (Fig. 1).

Survival

Historically, the median survival time for patients with gallbladder adenocarcinoma was less than 6 months. There has been an increase in median overall survival to 12 months for all cancers in recent years. This can be attributed to improved surgical technique, lower perioperative morbidity, and the key understanding that improvement in survival is particularly dependent on the final margin status. Incidentally found gallbladder cancers have a far better survival rate than those that are symptomatic. The 5-year survival in patients who are found to have malignancy on final pathology after routine cholecystectomy is 50%. This is more than twice the 5-year survival of unincidentally identified cancers, which are often a more advanced stage of disease at diagnosis. Similar to other cancers, nodal metastases are also an independent predictor of survival. The 5-year survival rate is 65% for patients with early-stage disease (stages I and II) and drops to 20% for patients with stages III and IV disease.

Benefit of an Operation

The true survival benefit of performing a curative minor resection for gallbladder cancer is strongly contingent on the pathologic stage of the tumor. Those with carcinoma in situ tumors (Tis) or tumors invading the lamina propria (T1a) derive no additional benefit from extended cholecystectomy over simple cholecystectomy. Therefore, patients who have incidentally found Tis or T1a malignancies after routine cholecystectomy should not undergo a more aggressive operation. However, it is imperative that such cases are reviewed by an expert pathologist to ensure proper staging.

Depth of invasion (T stage) is an independent predictor of survival in patients with gallbladder adenocarcinoma; therefore, T3 and T4 tumors should be approached with caution, as these cancers have been shown in numerous series to carry a significantly worse prognosis with a marginal benefit from an aggressive operation. T3 and T4 cancers have an increased rate of nodal metastasis and distant metastasis. Historical series do not demonstrate any benefit in resection of these tumors; however, contemporary data indicate a potential benefit for the fit and properly staged patient with a T3 adenocarcinoma. Improved surgical outcomes and modern chemotherapy may account for this discrepancy.

The involvement of nodal disease signifies a significantly worse prognosis. Only 8% of such patients will survive 5 years. Appropriate surgical staging involves portal lymphadenectomy inclusive of recovering at least six lymph nodes, evaluation of the anatomical nodal basin, as well as recovery of any suspicious regional nodal tissue. Patients who are found to have nodal involvement of the aortocaval, celiac, or superior mesenteric artery nodes do not seem to benefit from an operation because they already have disseminated disease disease.

Taken together, patients with a noninvasive malignancy with clinical findings suggestive of locally advanced disease (T3, T4, or N+) should be evaluated by a multidisciplinary team with a strong consideration for neoadjuvant therapy.

PRESENTATION

Incidentally Discovered Gallbladder Cancer

Incidental gallbladder adenocarcinomas are most often identified during or after routine cholecystectomy for gallstone disease. The rate of gallbladder carcinoma after cholecystectomy is less than 0.2%. Outcomes of patients with incidentally identified gallbladder cancers are superior to those in which adenocarcinoma was diagnosed nonincidentally, provided appropriate staging and resection is performed.

Patients who have undergone open cholecystectomy are 17 times more likely to harbor a malignancy than those who underwent laparoscopic cholecystectomy. This is most likely because of the increased difficulty of the operation resulting from the cancer.

TABLE 1 Staging of Gallbladder Cancer

Definition of Primary Tumor (T)	
T Category	**T Criteria**
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor invades the lamina propria or muscular layer
T1a	Tumor invades the lamina propria
T1b	Tumor invades the muscular layer
T2	Tumor invades the perimuscular connective tissue on the peritoneal side, without involvement of the serosa (visceral peritoneum) Or tumor invades the perimuscular connective tissue on the hepatic side, with no extension into the liver
T2a	Tumor invades the perimuscular connective tissue on the peritoneal side, without involvement of the serosa (visceral peritoneum)
T2b	Tumor invades the perimuscular connective tissue on the hepatic side, with no extension into the liver
T3	Tumor perforates the serosa (visceral peritoneum) and/or directly invades the liver and/or one other adjacent organ or structure, such as the stomach, duodenum, colon, pancreas, omentum, or extrahepatic bile ducts
T4	Tumor invades the main portal vein or hepatic artery or invades two or more extrahepatic organs or structures

Definition of Regional Lymph Node (N)	
N Category	**N Criteria**
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastases in one to three regional lymph nodes
N2	Metastases in four or more regional lymph nodes

Definition of Distant Metastasis (M)	
M Category	**M Criteria**
M0	No distant metastasis
M1	Distant metastasis

AJCC Prognostic Stage Groups			
When T is...	**And N is...**	**And M is...**	**Then the Stage Group is...**
Tis	N0	M0	0
T1	N0	M0	I
T2a	N0	M0	IIA
T2b	N0	M0	IIB
T3	N0	M0	IIIA
T1–3	N1	M0	IIIB
T4	N0–1	M0	IVA
Any T	N2	M0	IVB
Any T	Any N	M1	IVC

Noninicidentally Discovered Gallbladder Cancer

Patients may present with symptomology similar to those with biliary colic, or with unintentional weight loss or vague abdominal pain. Rarely jaundice can be the presenting symptom which portends an extremely poor prognosis, as this a sign of biliary tree involvement. The presence of jaundice is an indicator of increased risk for a margin positive resection and aggressive disease with a disease specific survival of only 6 months. Therefore, for these patients an operation should not be considered, but rather a strategy involving neoadjuvant chemotherapy to treat tumor biology, followed by diagnostic laparoscopy before attempt at curative intent resection.

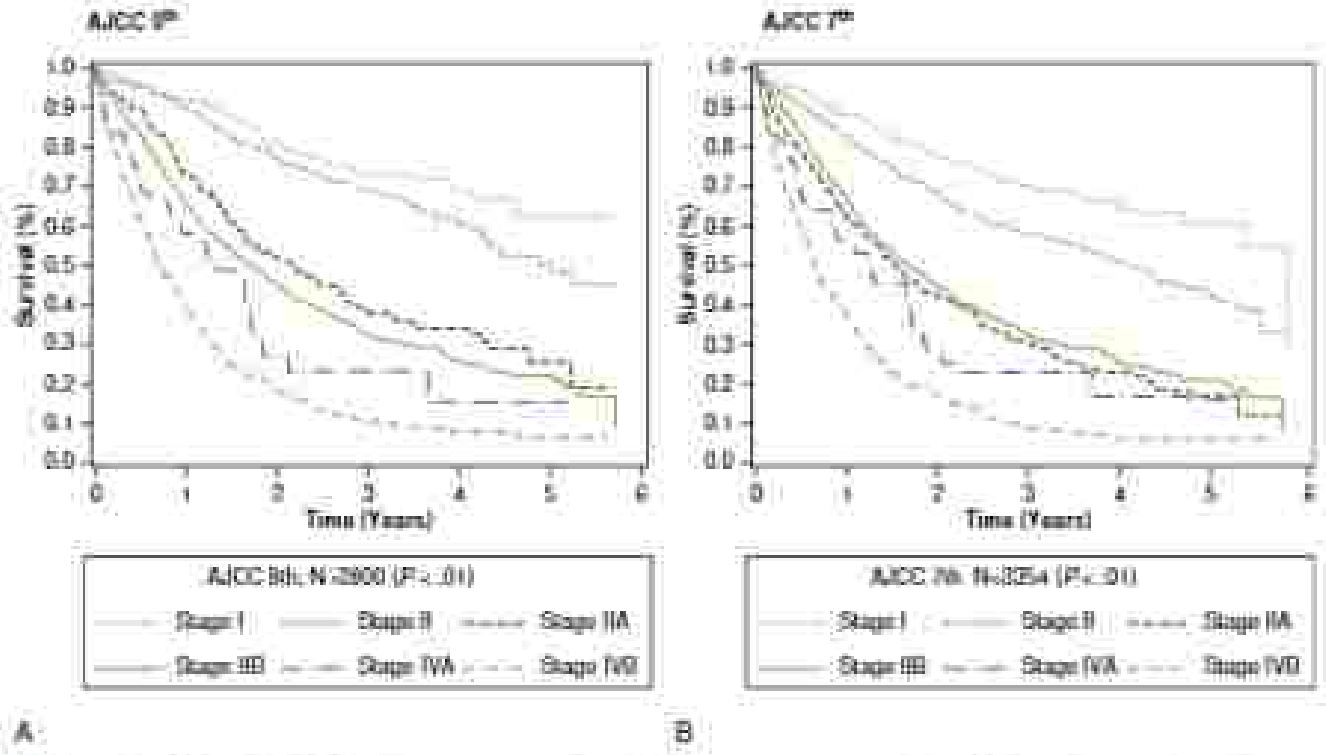

FIG. 1 Comparison of American Joint Committee on Cancer seventh and eighth edition staging system. Although both staging systems have similar c-statistics overall, when evaluated with patients compared, American Joint Committee on Cancer eighth edition was superior to separation of higher stages. (From [A] Chang JS, Tsai CR, Chen LT, et al. Validation of American Joint Committee on Cancer eighth staging system for gallbladder cancer and its prognostication patterns. J Surg Res. 2016;202(2):493–499.e1.)

WORKUP

Patients should have a detailed workup involving tumor markers including carcinoembryonic antigen and CA19-9, as well as expert review of pathology if malignancy is incidentally discovered. In addition, high-resolution cross-sectional imaging is mandatory.

Ultrasonography is the most frequent modality used to image the gallbladder; therefore, it is important to understand the imaging characteristics that increase the probability of a malignancy. High-risk ultrasonography findings that should be further evaluated with cross-sectional imaging include a mass greater than 1 cm, a gallbladder wall with irregular thickening, imaging suggestive of direct extension of the soft tissue in the pericholecystic space or within the liver, biliary obstruction with ductal dilation, lymphadenopathy, as well as nearby liver lesions.

Magnetic resonance imaging (MRI) with gadolinium enhancement allows for enhanced visualization of the biliary anatomy, as well as better definition of small liver lesions, especially in patients with steatosis or cirrhosis. Contrast-enhanced computed tomography (CT) of the abdomen allows excellent visualization of the post-operative resection bed, potential gross margin status from a previous operation, local vascular invasion, lymphadenopathy, variant vascular anatomy for preoperative planning, and evaluation of distant peritoneal or intrahepatic metastases. Both CT and MRI are useful to evaluate for lymphadenopathy with a detection rate of nodal disease in nearly a quarter of patients.

The role of 18-FDG positron emission tomography (PET)-CT continues to be elucidated. If there is a high suspicion of a gallbladder malignancy in the setting of a suspicious gallbladder mass, the sensitivity of a PET scan to detect occult peritoneal, omental, and nodal metastases is only 50%. PET-CT is most useful in those patients with a high risk of distant disease based on initial cross-sectional imaging, as well as in those patients who have a mass incidentally discovered malignancy. PET-MRI is a modern imaging modality that has the advantages of delivering higher spatial resolution in combination with enhanced functional information. Its role in gastrointestinal and biliary tract malignancies continues to be investigated. In our practice, we use PET-MRI to characterize suspicious lymph nodes or intrahepatic nodules that may indicate unresectable disease.

MANAGEMENT

Incidentally Discovered Gallbladder Cancer

Incidentally discovered malignancy may be found either intraoperatively or on postoperative pathology after cholecystectomy. Intraoperative discovery of a gallbladder malignancy during laparoscopic or open cholecystectomy should prompt closure and, if needed, subsequent referral to a hepatobiliary center. This allows for complete staging, a full discussion with the patient and family, pathologic evaluation with regard to depth of tumor invasion, as well preoperative planning for oncologic resection. Patients who undergo a suboptimal positive margin resection fare from shorter to numerous series to have a far worse survival in comparison to those who undergo an oncologically sound margin-negative resection. There is no oncologic detriment to returning to the operating room at a later time.

Cases that are incidentally found to be gallbladder cancer on final pathology after routine cholecystectomy should undergo review by an experienced pathologist (Fig. 1). In our practice, all patients after any diagnosis of gallbladder cancer undergo either staging CT scan or MRI, if not already performed. No additional operation, other than cholecystectomy, is necessary for Tis and T1a lesions. Those with T1b to T3 lesions should be evaluated further for a radical re-resection. T3 lesions with imaging suggestive of nodal involvement or T4 cancers should selectively be offered radical resection based on tumor biology and functional status after consideration of neoadjuvant therapy. T1b and above lesions should be appropriately staged with CT scan of the chest,

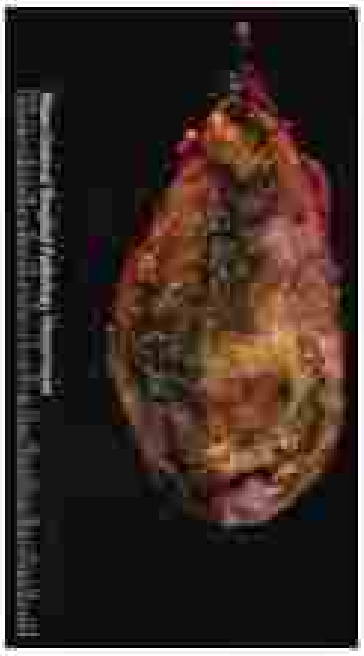

FIG. 2 Incidentally discovered gallbladder cancer. (Courtesy Hatice Gulec, MD, PhD.)

Nonincidentally Discovered Gallbladder Mass

Patients discovered to have imaging suspicious for gallbladder malignancy should be referred to a hepatobiliary center. Before cholecystectomy, patients should undergo appropriate staging including serum tumor markers, cross-sectional imaging including evaluation of the chest for distant disease. Patients with locally advanced disease should be strongly considered for an approach involving neoadjuvant therapy followed by, if appropriate, staging laparoscopy prior to radical resection.

RADICAL RESECTION

The appropriate oncologic operation for a gallbladder adenocarcinoma involves portal lymphadenectomy and partial hepatectomy yielding a microscopically negative (R0) resection margin. Bile duct resection may be performed to achieve negative margins if necessary. There are various facets to this operation which are discussed in detail below and highlighted in Box 1.

Diagnostic Laparoscopy

Currently, the American Hepato-Pancreato-Biliary Association consensus statement recommends the use of staging laparoscopy prior to laparotomy for all patients with suspected gallbladder cancer based on cross-sectional imaging, as well as those with a confirmed diagnosis of gallbladder cancer after a previous operation. Laparoscopy affords the ability to evaluate for distant disease in this aggressive malignancy. Contrary to these recommendations, surgeons often forego redo laparoscopy after a recent cholecystectomy unless the peritoneal cavity was not inspected thoroughly during the index procedure.

Portal Lymphadenectomy

Portal lymphadenectomy is mandatory for a comprehensive staging of gallbladder adenocarcinoma. At a minimum, six portal lymph nodes should be harvested, as survival of patients with node-negative disease is inferior to those who have less than six nodes harvested as compared to those that have six or more harvested, thus indicating that suboptimal lymphadenectomy misses occult nodal metastases.

BOX 1 Important Considerations for the Oncologic Resection of Gallbladder Cancer

- Diagnostic laparoscopy to evaluate for distant disease
- Extended cholecystectomy en bloc resection of gallbladder with hepatic resection of segments IVB/V with frozen section analysis of the hepatic parenchymal margin and cystic duct margin
- Portal lymphadenectomy with harvesting of at least six lymph nodes
- Bile duct excision and reconstruction in the setting of a microscopically positive cystic duct margin

Portal lymphadenectomy should include cystic, pericholedochal, hepatoduodenal, retroportal, posterior pancreaticoduodenal, common hepatic, and right sided celiac nodes. Aortocaval nodes should be considered as distant disease.

Hepatic Resection

Historically, a formal segment IVB/V anatomic liver resection was performed for gallbladder cancer. This has fallen out of favor because this operation has been associated with an increase in perioperative morbidity in comparison to a nonanatomic partial hepatectomy to achieve a negative margin surrounding the gallbladder bed (extended cholecystectomy). Numerous series have demonstrated no oncologic compromise in nonanatomic versus anatomic resection. Therefore, extended cholecystectomy should be performed for any malignancy invading the muscular layer of the gallbladder (T1b).

The operation generally begins with an intraoperative ultrasound evaluation of the liver to exclude distant hepatic metastases and to evaluate the cancer. Ultrasound helps guide the resection by identifying important vascular structures, including the middle hepatic vein and its branches that generally intersect the transection plane. Surgical dissection begins with the porta hepatis and identification of the cystic duct and artery. A formal portal lymphadenectomy is then performed followed by a 2 cm wedge resection of the gallbladder fossa. The thickness of the liver resection should be tailored to the extent of invasion seen by imaging. Frozen section analysis should be performed to maximize the chance of an R0 resection.

Bile Duct Resection

The cystic duct margin should be sent for frozen section analysis early in the operation. Bile duct resection may be necessary when the cystic duct margin is positive. Involvement of the hepatic or common bile duct portends a poor survival with a high rate of nodal metastases; therefore, bile duct excision with reconstruction should be reserved only for carefully selected patients with a microscopically positive margin. Patients who present with gross direct extension into the bile duct identified preoperatively should be treated with neoadjuvant chemotherapy to further test the biology of the tumor. Empiric bile duct resection outside of this setting should not be performed as it has been associated with an increase in perioperative morbidity without an increase in survival. In addition, it does not provide superior portal lymphadenectomy for staging.

Bile duct resection is performed after mobilization of the duodenum followed by transection of the bile duct at the level of the pancreas after confirming margins. Additional hepatic resection or pancreatic resection to obtain a negative margin should not be performed because these do not provide benefit given the increased morbidity of such procedures. Completion of the portal lymphadenectomy is then followed by Roux-en-Y hepaticojejunostomy for reconstruction.

Open Versus Laparoscopic

The safety of the laparoscopic approach has been demonstrated in a retrospective series. However, to date, there have been no randomized studies that have identified the laparoscopic approach to gallbladder cancer as noninferior to an open approach from an oncologic standpoint. Regardless of the approach, the correct oncologic operation needs to be performed with a margin negative hepatic resection and adequate portal lymphadenectomy.

Resection of Previous Port Sites

The practice of resecting previously used laparoscopic cholecystectomy port sites to reduce the chances of recurrence has not been validated and is of historical interest. This practice has been shown to provide no survival benefit, while also increasing the rates of postoperative incisional hernia.

ADJUVANT TREATMENT

Scarce high-quality data currently exist for the optimal systemic strategy in the adjuvant setting for gallbladder adenocarcinoma. Although adjuvant chemotherapy and chemoradiation have been associated with an increase in survival, these modalities seem to be most beneficial to patients with nodal metastases.

Systemic treatment of gallbladder adenocarcinoma is oftentimes guided by the investigation of treatment regimens used in metastatic biliary tract tumors. Two landmark randomized controlled trials evaluating patients with advanced biliary cancers have demonstrated that the combination of gemcitabine and cisplatin is superior to gemcitabine alone in terms of survival. A subgroup analysis has shown the benefit of this regimen in patients with gallbladder adenocarcinoma. Other commonly used regimens include fluorouracil based chemotherapy with the addition of oxaliplatin.

There is currently no level one evidence to support the use of adjuvant chemotherapy over surgery alone or any standard adjuvant regimen over another. An analysis of the National Cancer Database demonstrated a more than 50% increase in survival in favor of adjuvant chemotherapy over surgery alone in patients with T1 to T3 gallbladder adenocarcinomas. However, this population of patients is likely highly selected for in this large retrospective analysis. The landmark BILCAP phase III trial evaluated the benefit of capecitabine in the adjuvant setting over observation after an operation in all biliary tract cancers. Unfortunately, less than 8% of patients included in this trial had a diagnosis of gallbladder adenocarcinoma. The results of this trial suggest a modest improvement in disease free survival rate with the addition of chemotherapy. The complete results of this trial have not yet been published. We await the results of a subset analysis of gallbladder adenocarcinomas, which may shed light as to the true benefit of adjuvant chemotherapy in this rare disease. Likewise, there are no strong data regarding the use of radiation therapy. Ongoing and future clinical trials enrolling patients with gallbladder cancers along with other biliary malignancies will help to guide the care of such patients.

Current guidelines are based on retrospective data as well as expert opinion. The National Comprehensive Cancer Network guidelines state that adjuvant therapy with chemotherapy or chemoradiotherapy should be considered for patients, in particular those with residual disease after resection and as well as patients with nodal metastases.

In patients with locally advanced, potentially resectable tumors, neoadjuvant chemotherapy and chemoradiation should be strongly considered. This strategy provides the opportunity to allow for evaluating response to therapy with the hopes of avoiding a potentially futile operation. If jaundice or biliary obstruction is present, patients should undergo biliary decompression with stenting. Neoadjuvant regimens are similar to those described in the adjuvant setting. If there is a response to therapy, careful selection of patients is required to identify those that are likely to benefit from radical resection which carries a nontrivial rate of perioperative morbidity and mortality.

SUMMARY

Gallbladder cancer is an aggressive malignancy, most often discovered incidentally. The management of incidentally identified gallbladder cancer during elective cholecystectomy should mandate closure followed by appropriate staging before definitive resection. The minimally acceptable of a comprehensive oncologic operation for gallbladder adenocarcinoma include a margin negative resection and portal lymphadenectomy of six or more nodes. Adjuvant therapy should be guided by margin status and involvement of nodes on final pathology. Patients found to have locally advanced disease on presentation should be considered for neoadjuvant chemotherapy with or without chemoradiation. Clinical trials are desperately needed to identify effective systemic strategies for patients with gallbladder adenocarcinoma.

Management of Gallstone Ileus

Nicholas J. Zyromski, MD

Gallstone ileus is a misnomer; this condition is not a physiologic ileus at all, but a mechanical obstruction of the intestinal lumen (most commonly the small bowel) by a large gallstone that has passed through a cholecystoenteric fistula. Cholecystoenteric fistulae may occur from the gallbladder to the adjacent luminal viscera: duodenum (most common), stomach, or colon. Gallstone obstruction of the stomach at the pylorus is known as Bouveret's syndrome. Cholecystocolic fistula is less common. Colonic obstruction in this situation typically occurs at the sigmoid colon. Most common is cholecystoduodenal fistula, with a large (usually >2 cm) gallstone passing through the small bowel and becoming lodged in the terminal ileum. Cholecystoenteric fistula is felt to be caused by a combination of pressure necrosis and inflammation with chronic longstanding gallstone disease. Up to 25% of patients who develop gallstone ileus will harbor multiple stones in the alimentary tract; therefore, a close inspection of the entire intestine is important at the time of operation.

EPIDEMIOLOGY

Until the year 2000, only about 1000 cases of gallstone ileus had been reported in the medical literature. Over the past few years, however, the incidence of gallstone ileus has been shown to be greater than previously thought. Several recent large population-based series have found that gallstone ileus accounts for approximately 0.1% of all small bowel obstructions. The disease usually affects women (70%) and those in the seventh or eighth decade of life.

Clinical Presentation and Diagnosis

Most patients present with bloating, crampy abdominal pain, and vomiting, symptoms typical of mechanical small bowel obstruction. A careful history may reveal earlier episodic colicky right upper quadrant abdominal pain consistent with gallstone disease. The classic finding on plain abdominal radiograph is that of Rigler's triad (pneumobilia, dilated small bowel loops with air-fluid levels, and a large calcified gallstone in the lumen of the small bowel). Currently, computed tomography (CT) is used nearly exceptionally. CT has 90% accuracy for diagnosing gallstone ileus. Typical CT findings include pneumobilia, dilated loops of small bowel with air-fluid levels consistent with small bowel obstruction, and transition point with the ectopic stone almost always visible radiologically (Fig. 1).

MANAGEMENT

Operation is required for nearly all patients with gallstone ileus, as spontaneous passage of these large stones is rare once the patient has become symptomatic. It is crucial to optimize the patient physiologically as much as possible in this emergent situation, with the understanding that the majority of gallstone ileus patients are elderly and commonly have numerous medical comorbidities. A nasogastric tube should be placed to decompress the small bowel. Vigorous intravenous fluid resuscitation is necessary to replete electrolytes and ensure hydration. Cardiopulmonary optimization should be undertaken to the best of the clinician's ability, without delaying operation.

A significant clinical question related to operation lies in whether to simply address the small bowel obstruction by

Management of Gallstone Ileus

Nicholas J. Zyromski, MD

Gallstone ileus is a misnomer; this condition is not a physiologic ileus at all, but a mechanical obstruction of the intestinal lumen (most commonly the small bowel) by a large gallstone that has passed through a cholecystoenteric fistula. Cholecystoenteric fistulae may occur from the gallbladder to the adjacent luminal viscera: duodenum (most common), stomach, or colon. Gallstone obstruction of the stomach at the pylorus is known as Bouveret's syndrome. Cholecystocolic fistula is less common. Colonic obstruction in this situation typically occurs at the sigmoid colon. Most common is cholecystoduodenal fistula, with a large (usually >2 cm) gallstone passing through the small bowel and becoming lodged in the terminal ileum. Cholecystoenteric fistula is felt to be caused by a combination of pressure necrosis and inflammation with chronic longstanding gallstone disease. Up to 25% of patients who develop gallstone ileus will harbor multiple stones in the alimentary tract; therefore, a close inspection of the entire intestine is important at the time of operation.

EPIDEMIOLOGY

Until the year 2000, only about 1000 cases of gallstone ileus had been reported in the medical literature. Over the past few years, however, the incidence of gallstone ileus has been shown to be greater than previously thought. Several recent large population-based series have found that gallstone ileus accounts for approximately 0.1% of all small bowel obstructions. The disease usually affects women (70%) and those in the seventh or eighth decade of life.

Clinical Presentation and Diagnosis

Most patients present with bloating, crampy abdominal pain, and vomiting, symptoms typical of mechanical small bowel obstruction. A careful history may reveal earlier episodic colicky right upper quadrant abdominal pain consistent with gallstone disease. The classic finding on plain abdominal radiograph is that of Rigler's triad (pneumobilia, dilated small bowel loops with air-fluid levels, and a large calcified gallstone in the lumen of the small bowel). Currently, computed tomography (CT) is used nearly exceptionally. CT has 90% accuracy for diagnosing gallstone ileus. Typical CT findings include pneumobilia, dilated loops of small bowel with air-fluid levels consistent with small bowel obstruction, and transition point with the ectopic stone almost always visible radiologically (Fig. 1).

MANAGEMENT

Operation is required for nearly all patients with gallstone ileus, as spontaneous passage of these large stones is rare once the patient has become symptomatic. It is crucial to optimize the patient physiologically as much as possible in this emergent situation, with the understanding that the majority of gallstone ileus patients are elderly and commonly have numerous medical comorbidities. A nasogastric tube should be placed to decompress the small bowel. Vigorous intravenous fluid resuscitation is necessary to replete electrolytes and ensure hydration. Cardiopulmonary optimization should be undertaken to the best of the clinician's ability, without delaying operation.

A significant clinical question related to operation lies in whether to simply address the small bowel obstruction by

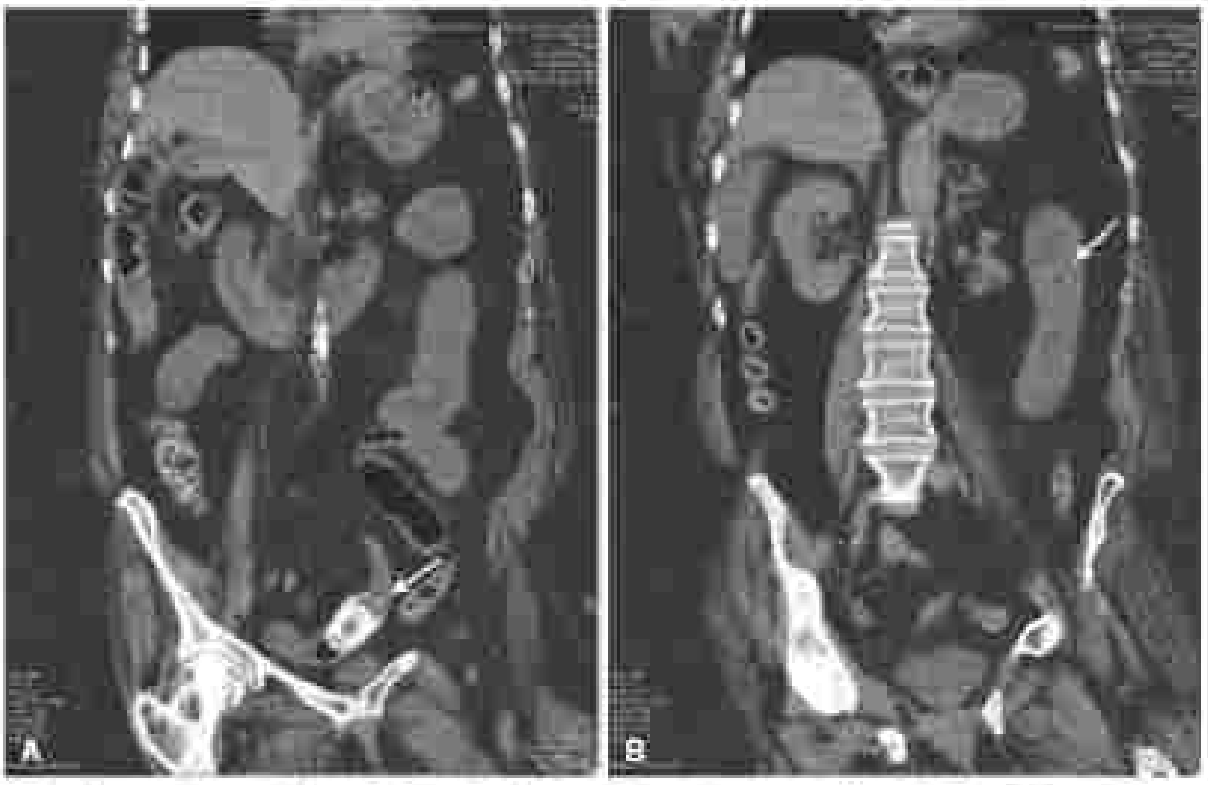

FIG. 1 (A) Coronal computed tomography image of gallstone ileus demonstrating obstructing stone (arrow) in terminal ileum. (B) Second gallstone (arrow) in the upstream small bowel of the same patient.

evacuating the gallstone (enterolithotomy) or to deal with the right upper quadrant biliary pathology at the same operation (i.e., by closing the biliary fistula and performing cholecystectomy). Historically, substantial perioperative mortality has been associated with addressing the biliary pathology. These findings have led to the current general practice of managing the small bowel obstruction during the primary operation and addressing biliary pathology selectively.

When making this clinical decision, the surgeon must consider several factors. First and foremost is the patient's acute and chronic physiologic state. Again, elderly patients with medical comorbidities and acute small bowel obstruction are often best managed with staged operative procedures. A second significant consideration is surgeon experience. The cholecystoduodenal fistula is often associated with a substantial right upper quadrant inflammatory response. Experienced operating on complex hepatobiliary pathology is ideal when addressing the pathology of cholecystoduodenal fistula.

The question of whether to intervene on the biliary pathology at all is reasonable; however, a significant number of patients will have recurrent biliary symptoms if the problem is not addressed. Multi-institutional single-institution series, which can provide longitudinal follow-up, have documented nearly 30% recurrent biliary symptoms such as right upper quadrant pain, cholecystitis, and/or choledocholithiasis when the cholecystoduodenal fistula is left in situ.

Technical operative considerations include the ability to address gallstone ileus laparoscopically. Current nationwide sample registry data show that approximately 10% of gallstone ileus patients were approached initially laparoscopically; however, 30% of these patients underwent conversion to open operation. Should laparoscopy be considered, the surgeon should take into account the presence of dilated small bowel loops. Open access to the abdominal cavity by Hasson approach may be most prudent. The laparoscopic ports should be positioned to address the entirety of the small bowel, as a careful search for additional intraluminal stones competes as important part of the operation.

The small bowel should be evaluated along its length. At the stone and point of obstruction is identified, enterotomy is created upstream from the stone, typically in a longitudinal orientation to the bowel. The stone is then gently evacuated (Fig. 2), and the enterotomy is closed transversely to prevent luminal narrowing. Intraoperative ultrasound is quite useful to identify additional stones in the bowel, gallbladder, or biliary tree. Such findings may influence the surgeon's decision to address biliary pathology at the index operation. A large series of gallstone ileus patients was recently reported in the *Annals of Surgery*. These authors studied the National Inpatient Sample, identifying 3268 patients over the 6 year period between 2004 and 2009. An interesting finding from this study was that patients requiring small bowel resection (presumably for ischemic bowel) had poorer outcomes in terms of mortality and length of stay relative to those who did not require bowel resection.

OUTCOMES

Two contemporary series of registry data have expanded our understanding of gallstone ileus. This condition was once thought to be relatively rare; however, the National Inpatient Sample study identified 3268 gallstone ileus patients, which accounts for approximately 0.1% of all patients admitted to the hospital with mechanical small bowel obstruction during this time period. In this series, overall hospital mortality was substantial at 6.7%. Mortality was significantly higher in patients who underwent cholecystectomy and closure of the biliary fistula compared to those who simply had small bowel obstruction addressed by cholecystolithotomy. Overall, 77% of the 3268 patients had small bowel obstruction palliatively treated and the remaining 23% had biliary fistula closed and cholecystectomy at the same operation. An interesting finding was the substantial incidence of postoperative renal insufficiency, or approximately 30% in the entire group of patients. The latter finding highlights the need for preoperative resuscitation and close attention to perioperative fluid management.

FIG. 2 Intraoperative view of distal ileum.

A second smaller series was reported from National Surgical Quality Improvement Project data collected between 2005 and 2010. These authors identified 127 patients with gallstone ileus. The overall mortality in this series was also fairly high at 5.5%. In this group of 127 patients, 11% had biliary pathology addressed at the same operation as bowel obstruction. Although the operative mortality was higher in this group (7.1% vs. 5.3%) this difference did not reach statistical significance, possibly because of smaller sample size. Patients who underwent cholecystectomy did have a significantly longer length of stay relative to those who simply had the small bowel obstruction pathology addressed.

SUMMARY

Gallstone ileus is a mechanical obstructive problem related to the underlying pathology of biliary enteric fistula. Gallstone ileus commonly affects elderly patients, with a female predominance of 70%. Surgical intervention is indicated to address the small bowel obstruction. At the time of operation careful search for additional enteric stones should be undertaken as these stones are present up to 25% of patients. The surgeon must consider carefully feasibility of same operation intervention to repair biliary pathology. It is safe to defer biliary operation to a later date with a second staged operation. When this strategy of two stage operation is selected, surgeon should consider and counsel their patient regarding the substantial incidence of recurrent biliary symptoms.

TRANSHEPATIC INTERVENTIONS FOR OBSTRUCTIVE JAUNDICE

John Filton, MD, and Clifford R. Weiss, MD

The patient with obstructive jaundice should be managed with a multidisciplinary team approach. This may involve the combined expertise of multiple healthcare providers and specialties, including primary care physicians, gastroenterologists, surgeons, and interventional radiologists. Percutaneous transhepatic techniques used in the treatment of obstructive jaundice, secondary to both benign and malignant etiologies (Box 1), is the focus of this chapter.

The interventional radiologist uses advanced diagnostic imaging techniques, providing percutaneous image-guided access into the bile ducts and offering multimodal therapies. Since the introduction of percutaneous transhepatic dilation in 1978, percutaneous techniques have become alternatives to surgical and endoscopic treatments. Long-term data on percutaneous treatments are limited, but studies have reported 5-year success rates between 50% and 70%. Imaging modalities include fluoroscopy and ultrasound guidance, and also, less commonly, computed tomography (CT), endobiliary cholangioscopy, and magnetic resonance (MR) imaging (Figs. 1–3). Such therapies may include percutaneous management of benign biliary strictures, biliary ductal injuries and leaks, biliary decompression of cholangitis, biliary duct biopsy, stone removal (using fluoroscopy or cholangioscopy), palliation of malignant biliary obstruction with endoprosthesis, and occasional endobiliary therapies, such as radiation, photodynamic therapy, and drug infusion. Therapy may also include the use of physiologic parameters, such as a biliary manometric perfusion test, to help decide when a biliary drainage catheter may be removed. A dialog among gastrointestinal endoscopists, interventional radiologists, internal medicine specialists, oncologists, primary care physicians, nurses, and other team members is required to manage such patients effectively.

NONINVASIVE IMAGING

Biliary anatomy in the patient with obstructive jaundice is usually defined using noninvasive imaging techniques. Many centers use cross-sectional imaging techniques, and many have multidetector CT

FIG. 2 Intraoperative view of distal ileum.

A second smaller series was reported from National Surgical Quality Improvement Project data collected between 2005 and 2010. These authors identified 127 patients with gallstone ileus. The overall mortality in this series was also fairly high at 5.5%. In this group of 127 patients, 11% had biliary pathology addressed at the same operation as bowel obstruction. This patient presented with signs and symptoms of obstructive jaundice. Note the lack of contrast in the common bile duct.

scanners that allow for rapid patient evaluation and reformatting of images in multiple anatomic projections. Ultrasound (US) is an inexpensive and generally available imaging modality that provides confirmation of dilated intrahepatic and extrahepatic ducts. It is operator dependent, but, in skilled hands, it provides important information about the possible etiology. For example, it is useful in confirming the presence or absence of dilated biliary ducts and detecting stone disease (choledocholithiasis, cholelithiasis, etc.). It is also advantageous in children because it does not use ionizing radiation. It may also be used at bedside in the critically ill patient to drain the gallbladder (percutaneous cholecystostomy).

When using US to evaluate the liver, the addition of color flow Doppler easily differentiates vascular tubular structures (dilated biliary ducts) from vessels (hepatic artery, hepatic vein, portal vein). Intrahepatic anatomy may not be adequately visualized in patients with extensive bowel gas (ileus or bowel obstruction), or it may not be technically feasible because of a limited "sonic window" for imaging, such as in a patient with multiple drains, wound dressings that cannot be removed, open abdominal incisions with a silo barrier, and so on.

As mentioned earlier, thin-section helical CT images, especially those obtained with newer multidetector scanners, allow rapid evaluation of abdominal anatomy. Studies are reproducible, and axial images may be reformatted to provide anatomic detail of the liver, the biliary anatomy, and other adjacent organs, such as the pancreas and duodenum. CT is more expensive than US, does use ionizing radiation, and generally requires the administration of oral and intravenous contrast; however, initial images without contrast may be useful in detecting bile duct stones. Because of the greater sensitivity of CT to density differences, poorly calcified or noncalcified stones or plaque illness may be readily detected on CT. On the downside, CT is not portable, thus, ill patients must be transported to and from the scanner.

Magnetic resonance imaging is useful in this context, especially given the ability to reformat axial images and produce an MR cholangiogram. The technique requires a significant amount of time, but when performed well it can result in a detailed representation of bile duct anatomy. In some centers, magnetic resonance cholangiopancreatography has replaced routine endoscopic retrograde cholangiopancreatography (ERCP) for defining bile duct anatomy. Because it uses no ionizing radiation, MR is helpful in children; however, in such instances, sedation or anesthesia support may be required to complete the MR examination.

ENDOSCOPIC AND PERCUTANEOUS EVALUATION

After clinical evaluation, laboratory blood work, and cross-sectional imaging, the patient must be evaluated endoscopically. ERCP is often the first invasive procedure performed in patients who require biliary surgery and/or intervention. An ERCP is especially useful in patients with coagulopathies, marked ascites, or in whom intrahepatic lesions, such as multiple hepatic cysts, preclude a safe transhepatic approach. The limitations of ERCP in patients with obstructive jaundice include the inability to cannulate the biliary system because of surgically altered anatomy (biliary enteric anastomosis) and technical limitations to the treatment of intrahepatic or hilar lesions from an endoscopic retrograde approach.

For the patient to be considered an operative candidate for biliary reconstruction, such as with choledochoduodenostomy, precise anatomic definition of the intrahepatic and extrahepatic bile ducts is essential to planning the surgical reconstruction. When ERCP is unable to completely opacify the biliary system, percutaneous transhepatic cholangiography (PTC) is the preferred procedure. PTC accurately depicts the intrahepatic biliary tree, lesion length, and lesion number, and it defines whether the biliary disease involves the bifurcation. Should a bifurcation lesion be found, bilateral (right and left) PTC and biliary drainage procedures may be performed. At our institution, the placement of one or more transhepatic biliary drainage catheters facilitates biliary reconstruction, assisting us in creating one or more biliary enteric anastomoses.

In a clinical situation in which the intrahepatic biliary system has been injured, such as with inadvertent complete clipping of the common hepatic or common bile duct, PTC alone may not fully define the distal intrahepatic bile duct anatomy. ERCP may be required to define distal anatomy up to the clip, and PTC and external percutaneous biliary drainage (PBD) may be used to define anatomy superior to the clipped duct. In this context, precise anatomic detail is demonstrated for eventual biliary reconstructive surgery. At times, combined ERCP and percutaneous transhepatic procedures are required to bridge and reconstruct biliary disruptions (endoscopic procedure) when access points are insufficient to clearly define the entire biliary tree.

PTC is the first step to PBD. The only absolute contraindication to PTC/PBD, performed as a means of access into the biliary system

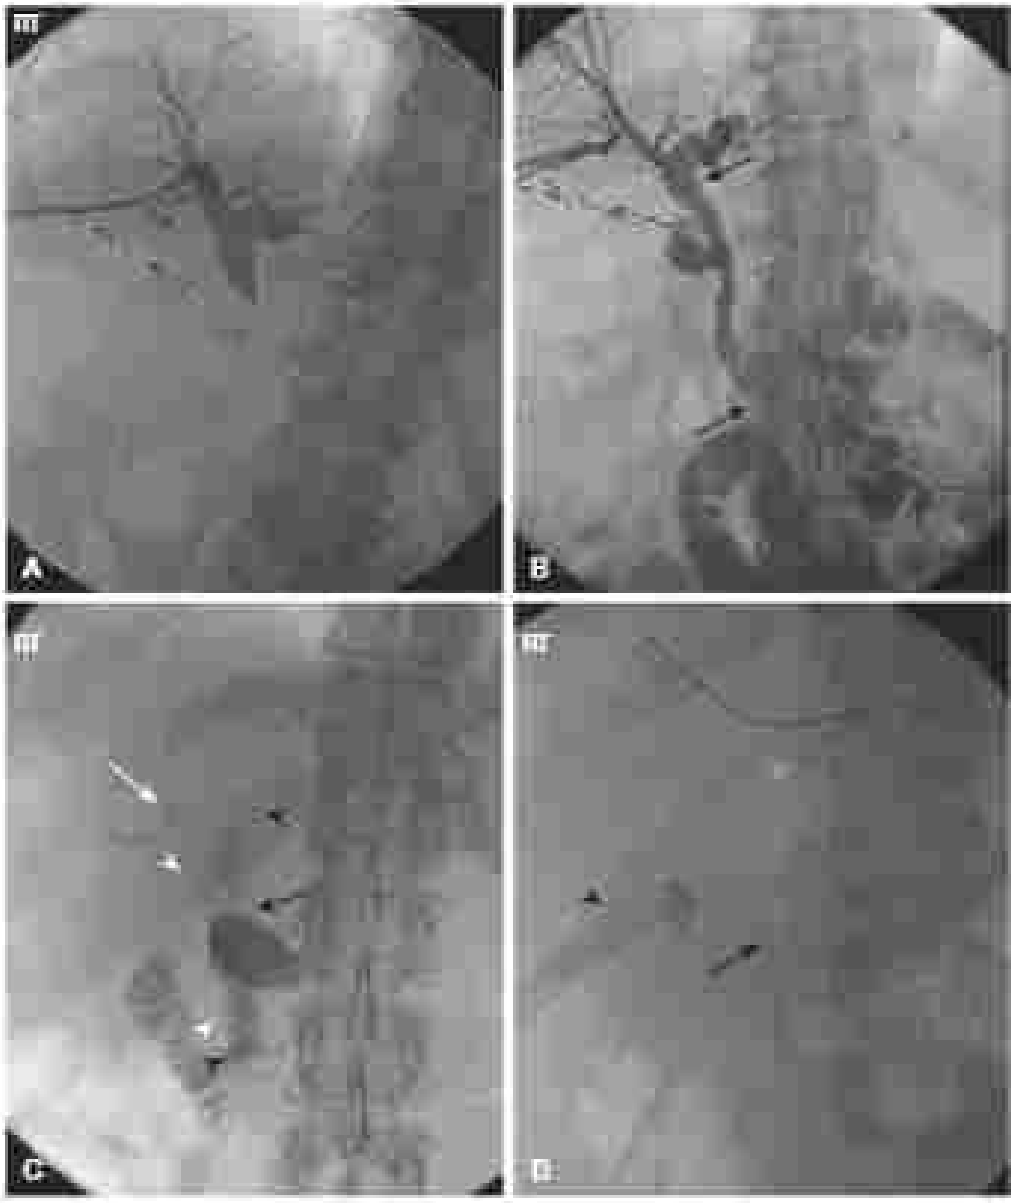

FIG. 2. (A) Digital spot fluoroscopic image of the right upper quadrant in the right anterior oblique projection showing abrupt cutoff of contrast in the common hepatic duct. There is no opacification of the duodenum. Note the contrast injection via a pre-existing right-sided external biliary drainage. (B) Digital spot fluoroscopic image of the right upper quadrant in the same patient. Cholangiogram performed after placement of an expanded polytetrafluoroethylene (ePTFE) endoprosthesis (Viabil; W.L. Gore) shows rapid flow of contrast through the endoprosthesis into the duodenum (arrows mark the ostium of the endoprosthesis because the pancreatic head mass was unresectable, so ePTFE endoprosthesis was placed). (C) Another patient with cholangiocarcinoma who underwent bilateral ePTFE endoprosthesis placement. Note the metallic stent "distractor" (black arrow) and radiopaque rings indicating the edges of the ePTFE covering (underneath). Also seen are associated metallic side adjuncts to the radiopaque rings (white arrow) and anchoring. (D) Another patient with a pancreatic head mass who underwent stented hepatic jejunostomy for common bile duct obstruction. Note the three overlapping 6-cm metal stents (arrows) outlining the common bile duct. Also seen is a jejunostomy tube (arrowhead).

for the treatment of patients with obstructive jaundice, is a significant coagulopathy that cannot be corrected. PBD should also be avoided in patients with diffuse polycystic liver disease or in patients with hepatic cysts due to parasitic infestation (e.g., Echinococcus). Occasionally, cross-sectional imaging and PBD under CT or US imaging guidance may be useful to determine an appropriate, safe window for access into the biliary system in those patients with multiple hepatic lesions.

Ideally, the patient with obstructive jaundice who is undergoing PBD/PBD should not have a coagulopathy. At our institution, PBD is generally not performed if the platelet count is below 50,000 or if the international normalized ratio is greater than 1.2. If the platelet count or international normalized ratio parameters are significantly altered, blood products—such as platelets, fresh frozen plasma, and vitamin K—may be administered to the patient for the biliary drainage procedure.

The presence of active jaundice challenges the percutaneous transhepatic drainage. Should biliary drainage be required in a patient with active, PBD with stent placement is the preferred means of drainage (i.e., internal drainage). The patient with significant ascites who requires a percutaneous transhepatic drainage catheter will often be plagued with leakage of ascitic fluid around the tube, which makes

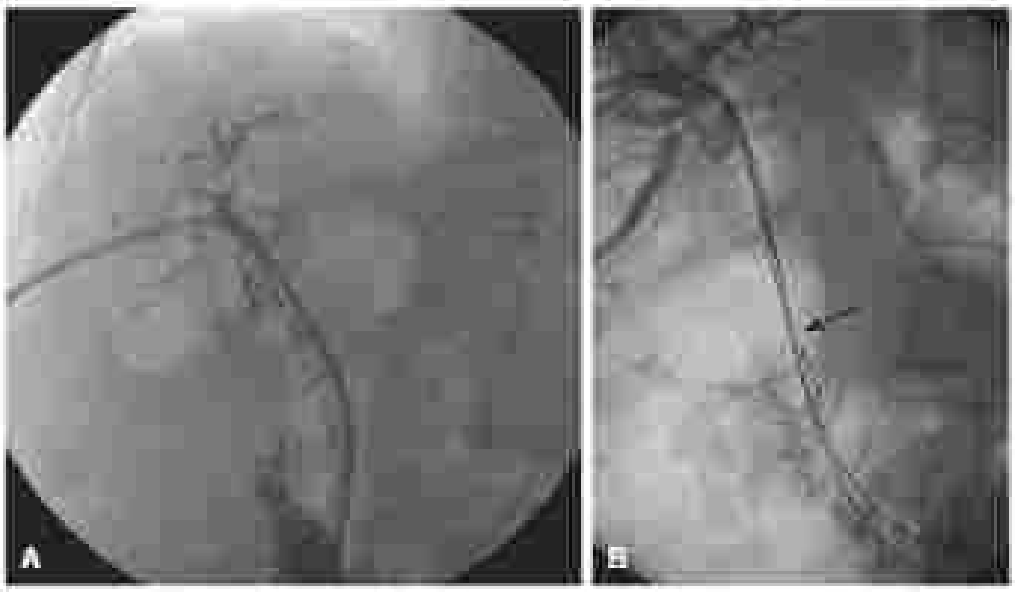

FIG. 7 (A) Digital spot fluoroscopic image of an adult patient who presented with obstructive jaundice, percutaneous transhepatic cholangiography demonstrated biliary findings included numerous intrahepatic filling defects in both intrahepatic and extrahepatic bile ducts. (B) Endoscopic brush biopsy (arrow) performed to confirm the diagnosis through a preexisting right-sided access. Pathologic analysis of the specimen later confirmed this to be a metastatic colon adenocarcinoma.

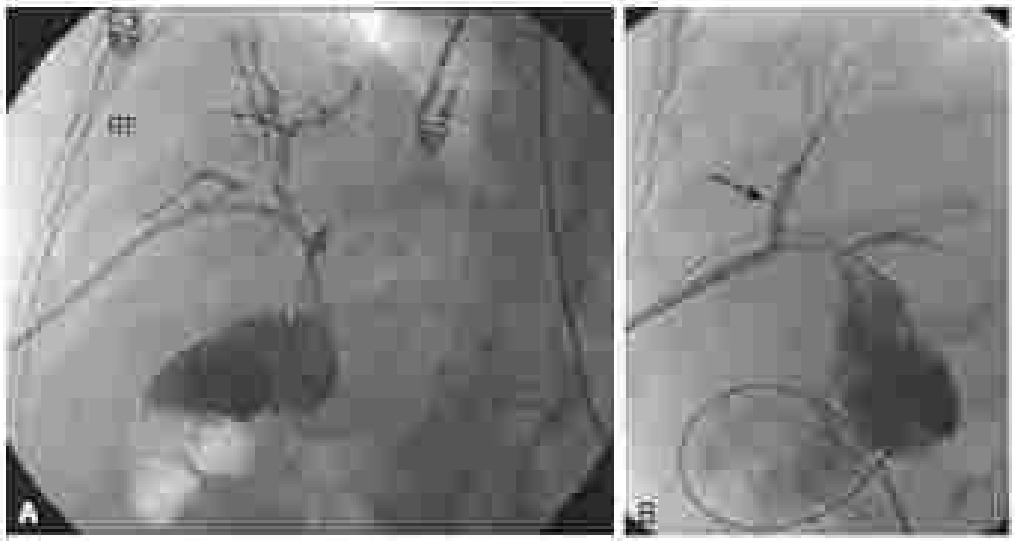

FIG. 8 (A) Digital spot fluoroscopic image of the right upper quadrant in the right anterior oblique projection showing multiple intrahepatic biliary tortuosity in an adult patient who had undergone previous choledocholithotomy. This patient has primary sclerosing cholangitis. (B) Digital spot fluoroscopic image of the right upper quadrant in a right anterior oblique projection in the same patient. Patient underwent balloon cholangioplasty (arrow) for treatment of intrahepatic biliary strictures. RAO, right anterior oblique.

dressings, causes skin irritation and inflammation, and theoretically places the patient at risk of bile leakage into the peritoneum (bile peritonitis). Technically, the presence of ascites can also make percutaneous biliary drain placement difficult. Because the liver floats in fluid, it is easily moved during needle placement. This can make it difficult to accurately access the liver capsule with the needle.

PTC/PBD TECHNIQUE SUMMARY

The technique of PTC/PBD is well described and outlined in the following section; it is a minimally invasive procedure. Intravenous antibiotics are started immediately on admission if a patient has clinical signs and symptoms of biliary sepsis or cholangitis. In patients who are not septic, intravenous antibiotics are administered on the day of the procedure and are generally continued for 24 hours afterward. As mentioned, the complete blood count, coagulation studies, and liver function tests are obtained as part of our routine preprocedure laboratory analysis.

After counseling as to the risks of the procedure, informed consent is obtained. The patient is placed in the supine position, intravenous sedation and analgesia are administered under an institutional conscious sedation protocol, and physiologic monitoring of blood pressure, pulse, and oxygen saturation is recorded frequently. In patients with hypotension and biliary sepsis, the help of an anesthesiologist can be invaluable because he or she can secure the airway and actively manage blood pressure and pain control, allowing a safe, reliable procedure. Although most interventional radiologists prefer initial biliary access from the left subcostal approach, in our institution, a right mid-axillary approach is generally used.

The first step is to anesthetize the skin and subcutaneous tissues inferior to the level of the cutaneous angle and above the level of the colon hepatic flexure. A thin needle (22G Chiba, Cook, Inc.) is advanced under fluoroscopic guidance, entering at the mid-axillary line parallel to the tabletop. The needle is directed medially and superiorly. After removing the stylet, the hub of the needle is connected through tubing to a syringe containing diluted contrast (1:1 dilution of saline to contrast). As the needle is withdrawn, contrast is injected slowly under fluoroscopic guidance. If the tip of the needle is in a bile duct, contrast is seen to flow away from it. On opacification of the biliary anatomy, multiple images are obtained to accurately define anatomy.

Should PBD be considered, and if a peripheral duct has not been entered or the point of duct entry is unfavorable for the advancement of a guidewire, a second thin needle (we use a 21-gauge fascar needle)

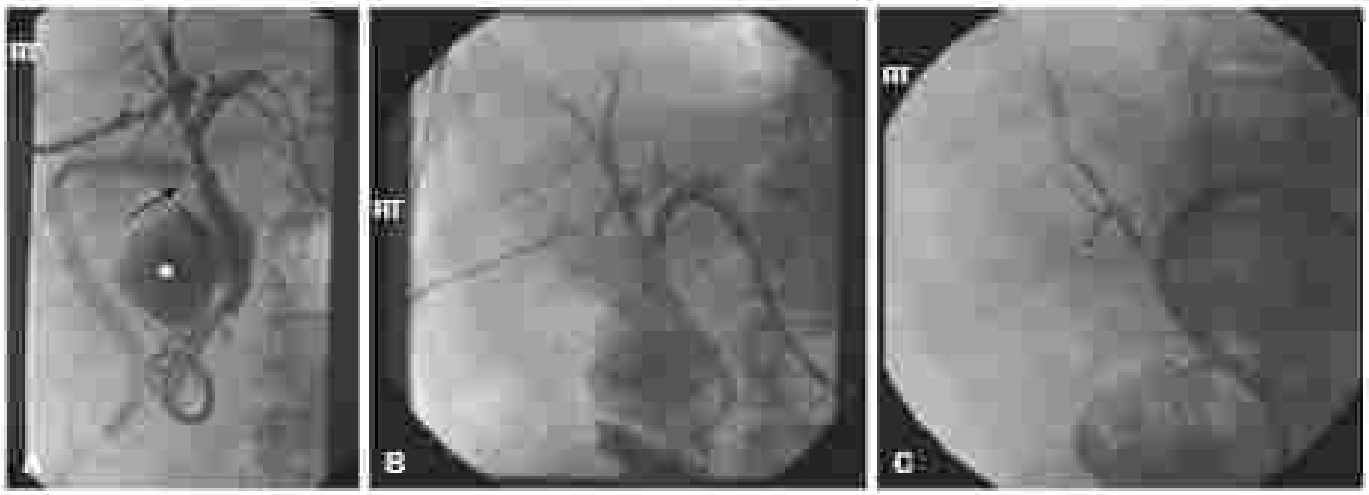

FIG. 8 (A) Digital spot fluoroscopic image of the right upper quadrant in a patient who had undergone cholecystectomy. A postoperative cystic duct stump leak (arrow) was managed by bilateral percutaneous transhepatic internal/external drainage catheter placement to divert bile. The internal/external biliary drainage catheters were left in place for 4 weeks. Note contrast within the duodenal bulb (arrow). (B) Digital spot fluoroscopic image of the right upper quadrant in the right anterior oblique projection in the same patient as that was performed by keeping the catheter distal side proximal to the confluence of the right and left main ducts allowing for internal drainage without the assistance of drainage catheters across the site of postoperative bile leak. (C) Digital spot fluoroscopic image of the right upper quadrant in the left anterior oblique projection showing adequate flow of contrast into the right main duct and common bile duct from a left-sided injection. External biliary drainage catheters were removed after two weeks. The patient remained asymptomatic at the 6-month follow-up.

may be used to select a more peripheral right duct. Having placed the needle in a more peripheral location, a coaxial system that consists of a small caliber, platinum tipped, steerable guidewire and a dilator/allowing cannula is advanced and used to secure biliary access. Using this system, the initial small-caliber guidewire is exchanged for a larger, stiffer guidewire, and a biliary drainage catheter may then be advanced to achieve drainage across a specific bile duct lesion.

In those patients with a high-grade biliary stricture at the bifurcation that isolates the right and the left ductal systems, a left PTC/PBD may be required. Anatomic depiction of the left biliary system requires access from a subxiphoid approach. As part of planning the left PTC/PBD approach, it is important that cross-sectional imaging studies be reviewed to determine whether major organs, such as the transverse colon, are interposed between the subxiphoid skin entry site and the left lobe of the liver. Imaging should also be reviewed to determine whether the left lobe is atrophic due to chronic left-sided biliary obstruction. If the left lobe is atrophic and requires drainage, an approach that is more medial than the standard left-sided subxiphoid percutaneous approach may be required.

When percutaneous transhepatic access to the patient with obstructive jaundice has been achieved, biliary catheter maintenance is required. Initially, the catheter is placed to external (bag) drainage. This is especially true for the patient with septic shock/ill from infected bile.

If the patient is critically ill and hemodynamically unstable, placement of an external drainage catheter alone will achieve biliary decompression (placement of a simple, locking perforated drainage catheter as an external drain). Once hemodynamically stable, the patient may return for a conversion either to an external/internal biliary drainage catheter (biliary stent) or an internal drainage catheter made of plastic or metal (internal biliary stent, or biliary endoprosthesis). The latter is generally reserved for patients with surgically unresectable disease and a limited life expectancy who are receiving palliative care. Specifics on the use of endoprostheses are covered later in this chapter.

Transhepatic internal/external biliary drainage catheter placement in the patient with obstructive jaundice requires crossing the obstructing lesion(s). The ultimate goal is to eventually reestablish the biliary enteric circulation. If left to external drainage alone—that is, given the inability to advance the multiple side hole drainage catheter into the small bowel—the loss of bile may result in significant morbidity to the patient, including dehydration and electrolyte disturbances. In such patients, replacement with intravenous electrolyte-rich fluid (e.g., lactated Ringer's solution) is recommended, or oral ingestion of an electrolyte-rich sports drink if the patient is able to tolerate oral fluids.

Biliary drainage catheters are generally flushed once or twice a day, especially in patients with viscous or infected bile. The patient and healthcare providers must be instructed as to the technique. In the patient with an external/internal biliary drainage catheter, the importance of flushing into the lobe, forward flushing, taking care not to aspirate fluid back into the syringe, must be emphasized. Forceful aspiration with a syringe may rapidly bring bacteria from the gastrointestinal tract into the biliary system (i.e., under pressure), and sepsis may result.

If left in place on a chronic basis, external/internal biliary drainage catheters require a periodic exchange. Generally, catheters are exchanged over a guidewire on an outpatient basis approximately every 2 to 3 months. For this procedure, the patient receives a single dose of intravenous antibiotics before the cholangiogram and biliary catheter exchange. If conscious sedation is required, the patient returns from the interventional suite to the recovery room (usually for 1 hour). During this time, the newly exchanged biliary drainage catheter is connected to an external drainage bag. If the patient is afebrile, he or she is discharged home with instructions to "cap" the biliary tube after 24 hours (i.e., the bag is removed). Should the patient become febrile after a tube exchange, a decision is made as to the subsequent course of therapy. The patient may be observed and later discharged on oral antibiotics with the biliary catheter left to external drainage until the patient is afebrile. The patient is told to return if symptoms worsen. Should an outpatient become septic, the patient should be admitted to the hospital and continue intravenous antibiotics with the biliary drainage catheter left to external (bag) drainage. The clinical presentation of sepsis is fortunately infrequent after routine outpatient catheter exchanges.

Internal Drainage (Biliary Endoprostheses)

The patient who has undergone transhepatic biliary drainage for obstructive jaundice resulting from surgically unresectable malignant disease may receive a palliative biliary endoprosthesis (internal

biliary stent). If the patient is clinically stable at the time of initial biliary drainage, the biliary endoprosthesis may be placed in a single step. This allows rapid treatment and reduces costs, compared with placement of an external/internal drainage with later conversion to a completely internalized catheter system (i.e., a multistage procedure).

The endoprosthesis used is either polymer (plastic) or metallic (bare metal stent mesh or a covered stent). The plastic endoprosthesis are larger in caliber and require transhepatic tract dilation to 10 or 12 Fr. This can cause considerable pain to the patient, and there is a theoretical risk of increased bleeding. Although inexpensive compared to metallic endoprostheses, there are few manufacturers of plastic endoprosthesis for transhepatic deployment. The majority of plastic endoprostheses are placed endoscopically.

In contrast, metallic endoprostheses are smaller in caliber at deployment, but have significantly larger luminal diameters. For example, self-expanding bare metal stents used as biliary endoprostheses may be deployed through a 6 or 7Fr sheath system and expand to 1 cm in diameter. These types of stents provide longer patency times and greater cost effectiveness compared to plastic stents; thus, for palliation, a patient could undergo PTC/PBD followed by placement of a metallic endoprosthesis in a single step.

For malignant biliary obstruction, placement of flare self-expanding bare metal stents should be considered because the location of the stent can be a significant predictor of pancreatitis. To reduce the chances of pancreatitis, the literature suggests supraampullary rather than transampullary placement.

After endoprosthesis placement, the patient's transhepatic access may be removed if there is no significant bleeding. Should bleeding occur, such as with a friable tumor, a temporary external drainage catheter should be initiated for the patient's transhepatic access tract. This maintains access in the event that the endoprosthesis becomes acutely occluded with thrombus. Once thrombus has cleared, generally in 1 to 2 days, the catheter may be removed after a final cholangiogram confirms patency of the metallic endoprosthesis.

PBD followed by metallic biliary stent placement is extremely important in managing hilar biliary obstruction, but deciding whether to decompress the obstructed ducts to one or both hepatic lobes still must be considered. Very few data on unilobar versus bilobar drainage exist in the literature; however, one study showed no difference in survival or stent patency between the two procedures.

Biliary endoprostheses used for palliation are considered permanent implants with patency periods generally limited to 6 to 12 months; thus, they are used in patients with limited life expectancy. Patients should be warned of this and told that should the endoprosthesis occlude, repeat endoscopic or transhepatic access may be required to relieve the obstruction.

Covered biliary endoprostheses have been developed that have improved the long-term patency for palliation of malignant biliary obstruction. Percutaneous transhepatic placement of expanded polytetrafluoroethylene (ePTFE)-covered stent grafts has been approved (Viabil biliary endoprosthesis; W.L. Gore). These stent grafts have been modified to include perforations or fenestrations in the ePTFE covering to avoid occlusion of biliary branches that may otherwise be obstructed by a continuous covering. Such stent grafts also have anchor barbs that prevent migration.

A recent meta-analysis has shown that covered, self-expandable biliary endoprostheses have a longer patency compared to uncovered, self-expandable stents (mean, 61 days). Greater long-term patency of stent grafts provides an additional therapeutic option to enhance the quality of life in patients with unresectable malignant biliary disease. Although covered and uncovered biliary endoprostheses show similar rates of stent dysfunction, the mechanisms of stent dysfunction differ. Covered stent dysfunction usually involves tumor overgrowth around the stent edges, sludge formation, or stent migration. Uncovered stent dysfunction is more commonly the result of tumor ingrowth through the interstices of the stent. Available data show no statistically significant increase in episodes of cholecystitis or pancreatitis with covered biliary endoprostheses.

The relationship between stent occlusion and stent coating material remains undetermined. When plastic stents are used, however, stent diameter relates to stent patency such that 10Fr stents show longer stent patency duration compared to 8Fr stents; a smaller diameter predisposes to occlusion by biliary sludge.

Patients with benign disease and covered stent grafts, regardless of material used (e.g., ePTFE), may be considered for endoscopic removal. This is not the preferred treatment for benign disease, but it may be used as an alternative to patients who could otherwise not undergo biliary reconstructive surgery or percutaneous transhepatic catheters. One study suggests a protocol of staged uprating of internal/external biliary catheters, balloon dilation (8 mm), and prolonged stent treatment at maximum catheter size (10Fr) for benign biliary strictures. Results from this study showed stricture patency probabilities of 84%, 78%, and 74% at 1, 2, and 5 years, respectively.

COMPLICATIONS OF PTC/PBD

The technical success rates of PTC/PBD are high, and major complication rates are generally low (3%–8%). Some reported major complications include hemobilia or hemorrhage, sepsis, biloma, peritonitis, pancreatitis, pleural effusions, and, rarely, death. Another complication is cholangitis, which is found in up to 20% of patients. Fortunately, these episodes of cholangitis are usually brief and not associated with hypotension.

Hemobilia/Hemorrhage

Hemobilia occurs when blood enters the bile duct during catheter exchange. This complication has been reported in 2% to 8% of patients who undergo PTC/PBD. It is usually a result of injury to one of the major vessels, either a hepatic artery or vein or portal vein. These patients generally are seen with bleeding from the biliary drainage catheter and right upper quadrant pain. The patient may also present with melena or hematochezia.

Hemobilia can occur from either the venous or arterial system. If it occurs from the hepatic or portal vein, it is generally nonpulsatile and dark in color; this is generally managed either by repositioning or upsizing the biliary drainage catheter.

If the bleeding occurs from injury of an arterial branch, emergency consult should be obtained for hepatic arteriography. The bleeding is generally bright red and pulsatile and may be due to a hepatic artery–bile duct fistula or a pseudoaneurysm of the hepatic artery with communication to the biliary system. The treatment requires transcatheter arterial embolization, generally with embolic coils. The injured vessel is occluded by advancing a catheter distal to the injury site and coiling across the site. After hepatic artery branch embolization, the transhepatic access need not be abandoned.

Sepsis

If the patient develops a fever, rigor, and hypotension, sepsis should be suspected. Sepsis can arise even with prophylactic antibiotic treatment, and it can be treated with intravenous antibiotics, expansion of intravascular volume, and pressor support. Identification of the causative agent by bacterial culture is imperative to tailor antibiotic use.

Pericatheter Leakage

Transhepatic access may result in leakage of bile around the catheter. This is often due to occlusion of the catheter lumen, and the problem may be addressed by catheter exchange. Occasionally, ascites may also leak around the catheter and may resemble bile leakage. The optimal way to drain the biliary system of a patient with ascites may be with an internal stent (endoprosthesis). If an endoprosthesis is not possible, the catheter may be upsized in an attempt to temporarily tamponade the site, allowing time for tract maturation. A purse-string suture on the skin placed around the catheter may also be used to reduce leakage of ascitic fluid.

BILIARY CATHETER REMOVAL

In addition to the routine biliary exchange every 8 to 12 weeks, the decision about when to remove the biliary drainage catheter in a patient who has undergone treatment for benign biliary strictures is based on clinical and laboratory parameters and on biliary flow dynamics. As mentioned, the duration of stenting is controversial. Most interventionalists will leave a stent in place for at least 3 months before determining whether it can be removed. In our institution, we often have biliary stents in place for 6 to 12 months. Before removing a biliary drain, an over the wire cholangiogram is performed by pulling the biliary drainage catheter back over a guidewire. If the site of the stented stricture looks patent based on an injection of contrast through the tube, the decision may be made to initiate a clinical trial. For this, a shortened biliary drainage catheter is reintroduced over the guidewire, but the tip is placed above the biliary stricture. This functions to maintain percutaneous access and to allow bile to flow across the newly dilated, previously stented stricture. The tube is capped for 1 to 2 weeks, and any signs or symptoms of cholangitis, right upper quadrant pain, fever, jaundice, or leakage around the biliary drainage catheter indicates a probable failure of the trial. Because percutaneous access has been maintained, the stricture can be easily redilated and restented; alternatively the patient may require surgery.

If the patient remains asymptomatic during the clinical trial and there is documented evidence of flow across the stricture on follow-up cholangiography, a biliary manometric perfusion test may be performed. Dilute, iodinated contrast is infused in a stepwise manner via the shortened PBD. Biliary pressure less than 20 cm of H_2O are considered normal. In patients with an asymptomatic clinical trial and normal pressures during the biliary manometric perfusion test, the positive predictive value for biliary duct patency at 1 year approaches 90%. Patients are followed carefully, with follow up liver function tests obtained at periodic intervals after tube removal.

To the medical literature, published data for the results of percutaneous dilation and stenting indicate long term patency of 53% to 76% with follow up periods of 5 and 3 years, respectively. However, most of the data are retrospective in nature. Long term patency rates for surgical repair of similar lesions are 89% at 72 months of follow up. Initial reports of percutaneous balloon dilation showed significant complications that included hemobilia, mainly resulting from clot, angle or transhepatic access. More recently, cutting balloon dilation has been shown to be safe for the treatment of biliary enteric anastomotic strictures that are resistant to conventional balloon techniques.

In patients with malignant biliary obstruction, the biliary drainage catheter may be removed after placement of an internal stent (endoprosthesis), either plastic or metallic. Patients with advancing cholangitis require a combined approached that may involve ipsilateral resection of the dominant stricture, PTC followed by drainage, and balloon dilation of intrahepatic strictures until periodic biliary catheter exchanges. A recent study has shown that percutaneous transhepatic biliary drainage and subsequent metallic stent placement are viable, palliative treatment options in patients with metastatic gastric cancer; subsets of patients with differentiated histology of primary gastric cancer and serum bilirubin levels greater than 7 mg/dl, after biliary drainage, may benefit from the combination therapy of metallic stent placement and chemotherapy.

OTHER INTERVENTIONS

Cholangioscopy

As previously mentioned, the use of cholangioscopy is not as common in biliary interventions, but it is becoming increasingly used in the assessment and treatment of biliary disease. Cholangioscopy was first described in the 1970s but is rarely used because of the high costs. Now, with recent developments, it is starting to become feasible. There are two types of cholangioscopy currently: indirect and direct. Indirect cholangioscopy uses a catheter with an optical probe inside that is inserted within the accessory port of a duodenoscope.

FIG. 8 Cholangioscope. (A) The most generation of mother-therapeutic cholangioscope (CHF-CB30 LA, Boston Scientific) has an outer diameter of 8.9 mm and a working length of 45 cm (5 type) or 70 cm (type shown). This endoscope provides 120-degree angulation in the up or down direction, and a depth of view ranging between 2.5 and 50 mm. (B) Two access ports on the cholangioscope feed into a single channel. One irrigation system is attached to the anterior port (single arrow), while the posterior port (paired arrow) is used for passage of wires and instruments.

Direct cholangioscopy is most often used and uses a very thin upper endoscope percutaneously and transhepatically positioned within the biliary system. The diagnostic uses of percutaneous transhepatic cholangioscopy (PTCS) include visualization of indeterminant biliary structure, verification of bile duct stone clearance, and for staging cholangiocarcinoma. For simple diagnostic PTCS, we allow the tract to mature for 2 weeks after placement of an 8 to 10Fr biliary drain. Cholangioscopy (Fig. 8) is then performed with either a 10Fr access sheath or a bare tract technique without a sheath. This method works for diagnostic visual inspection with or without the use of 3Fr disposable biopsy forceps.

Studies have shown cholangioscopy to have a higher sensitivity and positive/negative predictive value than ERCP. PTCS has been considered a safe procedure, with low incidences of complications (in less than 8% of patients). The most common complication reported was cholangitis (14% of cases in one study), with an overall complication rate of 7.5% (in an international multicenter study). PTCS has also been shown to be effective in providing guidance for numerous tasks that involve occluded metal stents.

Cholangioscopy can be used to treat obstructive stones in the biliary system as well (Fig. 7). Stones small enough to pass through the access sheath can be removed with a retrieval basket. Retrieval baskets consist of wires fused at both ends and are available in a variety of sizes and shapes. We prefer to use the 4.0Fr 90 cm Segura Hemisphere stone retrieval basket (Illusion Scientific), which has a rounded tip to minimize trauma to the biliary tree. To engage the stone for removal or mechanical pulverization, the basket needs to be positioned slightly beyond the target stone. A magnified view of the stone through the endoscope may suggest that it is too large for basket removal when in reality it can fit through the access sheath.

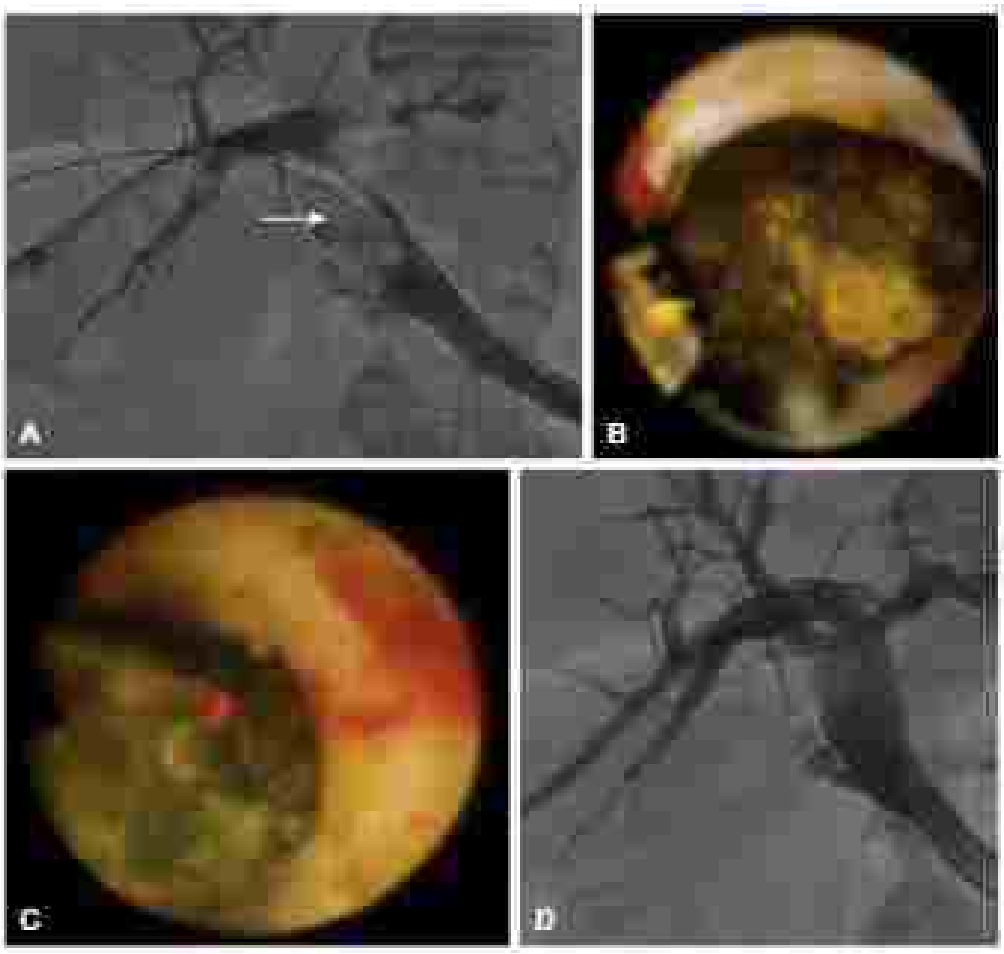

FIG. 7 Laser lithotripsy. (A) Diagnostic cholangiogram demonstrates a large filling defect (arrow) near the hepatic hilum. (B) A large stone is visualized on cholangioscopy, partially covered with yellow mucus. (C) The laser fiber is positioned just proximal to the stone, which allows the laser light to reflect off the stone surface. Laser lithotripsy is performed with care to avoid extraneous firing. Stone fragments are either removed with a basket or flushed down the biliary tract to allow passage through the ampulla. (D) Postprocedure cholangiogram demonstrates complete removal of the large stone with restoration of bile flow.

fluoroscopy with this technique allows the operator to become more adept at accurately judging the size of the stone.

Open-ended graspers, such as alligator forceps, may be used when limited space precludes appropriate positioning and expansion of a retrieval basket. Graspers are usually situated just proximal to the stone and the prongs are closed around the stone for gentle retraction through the access sheath. Graspers, however, provide poor gripping force and there is a risk of dropping the stone before removal through the sheath, which may result in multiplied calculi. The prongs of the grasper are generally hooked at the ends to capture the stone, which increases the risk of damage to the bile duct walls. Graspers should be reserved for small stones or stone fragments. At our institution, we use this instrument only rarely because of its technical limitations.

Lithotripsy is used to fragment stones that are too large to fit into a basket or pass through the access sheath, which is often the case in patients with chronic biliary obstruction. This has been traditionally accomplished with mechanical lithotripsy; however, biliary calculi may resist mechanical fragmentation resulting from stone composition (e.g., bilirubin stones), or anatomical location (e.g., high within the hepatic parenchyma). Electrohydraulic and laser technologies have been used successfully for lithotripsy. Although less expensive than laser, electrohydraulic lithotripsy has a higher risk of duct damage because of poor targeting. In addition, its 10-F probe is usually too large to pass through the working channel of a smaller endoscope. Laser lithotripsy offers several advantages, including greater precision in targeting stones and much smaller caliber probes, and is our technique of choice. The two main categories of lasers used for lithotripsy are flashlamp-pumped, pulsed dye lasers (e.g., coumarin dye and rhodamine 6G dye) and pulsed solid-state lasers (e.g., holmium: YAG and q-switched neodymium: YAG). We use a 20-W holmium: YAG laser (VersaPulse PowerSuite 20W, Boston Scientific) with a starting pulse energy of 0.8 J per pulse and a pulse frequency of 10 Hz for a power between 8 and 10 W, never for more than 5 seconds per pulse. The laser is delivered through a flexible fiber that is available in various sizes, including 200 and 365 μm. The most commonly used fiber is of 365 μm in size, which requires a working channel of 2.2 F or greater. The depth of penetration from the holmium: YAG laser is less than 0.5 mm. In contrast to neodymium: YAG lasers, the holmium laser does not cause forward scatter.

PTCS-guided removal of biliary stones is highly successful, with complete stone removal from the bile ducts occurring in 80% to 100% of cases. The number of stones, stone location, and presence of biliary strictures may have a significant effect on procedural success. Complete clearance of intrahepatic stones tends to be more challenging than clearance of extrahepatic stones, but technical success rates of more than 90% for treating hepatolithiasis have been reported in the literature. Recurrence is reported in up to one third of patients with intrahepatic stones, most commonly when intrahepatic strictures are also present. Complex cases of choledocholithiasis with multiple stones often require more than one session for complete clearance.

Irreversible Electroporation

Irreversible electroporation (IRE) is a nonthermal ablation technique that induces cell death via pulsed direct current. Thermal ablation techniques have increased the 5-year survival rate of hepatocellular carcinoma from under 1% to 33% to 54%, however, most patients are considered ineligible for these procedures because there are tumors in close proximity to the main biliary tracts. IRE induces cell death via formation of nanopores in the cellular membrane, while leaving the extracellular matrix intact so bile ducts can retain function. One study has shown IRE to be effective in treating centrally located liver tumors adjacent to bile ducts, but more studies need to be done to assess safety.

Intraductal Radiofrequency Ablation

Intraductal radiofrequency (RF) ablation has been used to treat malignant tumors that involve the bile duct using endoscopy. More recently, there have been a few studies that have investigated this type of ablation being used with PTC. One study showed that PTC and intraductal RF ablation, followed by biliary stent placement, was safe and effective in the short term. At 6 months postoperation, two of 11 patients in an experimental group (PTC/RF) developed recurrent jaundice and received repeat procedures. In the same study, recurrent jaundice was observed at three months in the control group (without RF ablation).

SUMMARY

Transhepatic access for obstructive jaundice provides several therapeutic options for patients with both benign and malignant obstructions. A range of therapeutic options is available, including emergent drainage, endohepatobiliary biopsy, biliary stricture dilation, long-term stenting, and endoprosthesis for palliation (Figure 1.5). In addition, direct visualization using endoscopic techniques (cholangioscopy) may assist in the treatment of retained intrahepatic stones and may allow a significant reduction in radiation exposure for the patient, the interventional radiologist, and the personnel in the room.

Improvements in the percutaneous transhepatic cholangiography techniques, biliary drainage, and adjunctive biliary interventions provide the interventionalist with ready access to the biliary system to assist in the multidisciplinary management of patients with complex biliary disease. The team approach is warranted because such patients often require management by surgeons, interventional radiologists, gastroenterologists, and primary care physicians.

The minimally invasive treatment of patients using transhepatic interventions for obstructive jaundice continues to expand. It is hoped that this information will assist readers in understanding some of the options available to such patients.

Obstructive Jaundice: Endoscopic Therapy

Olaya I. Brewer Gutierrez, MD, and Anthony N. Kalloo, MD

Obstructive jaundice is a manifestation of cholestasis, which in turn is an impairment in the bile flow out of the parts hepatic through the biliary ducts and into the duodenum. Symptoms may include fatigue, pruritus, and pale-colored or acholic stools. Abdominal pain may or may not be present, depending on the underlying cause. Cholestasis can be intra or extrahepatic and there are multiple causes. The main causes of extrahepatic cholestasis are summarized in Table 1. Overall, common bile duct stones are the most common cause of obstructive jaundice.

Cholestasis is identified through abnormal findings on biochemical tests of the liver, such as elevated alkaline phosphatase (AP), 5′-nucleotidase, γ-glutamyl transferase levels, and variable levels of bilirubin and prothrombin time. However, elevated AP levels are not completely specific for cholestasis and do not help in identifying the underlying cause. In general, values of AP greater than three times the upper limit is suggestive of extrahepatic biliary obstruction. Different imaging techniques can be performed to identify the cause of obstructive jaundice with variable sensitivities and specificities, such as transabdominal ultrasound, cross-sectional imaging (magnetic resonance cholangiopancreatography [MRCP] or computed tomography), and endoscopic ultrasound (EUS) or endoscopic retrograde cholangiopancreatography (ERCP), both of which can be diagnostic and therapeutic, the latter mainly therapeutic.

This chapter focuses on the different endoscopic techniques available for the treatment of obstructive jaundice. Overall, endoscopic techniques for the management of obstructive jaundice are ERCP guided approaches and EUS guided biliary drainage (EUS-BD).

ERCP

ERCP is one of the most technically demanding and high-risk procedures in gastroenterology, requiring significant training and experience to maximize success and minimize poor outcomes. Currently, ERCP is predominantly a therapeutic procedure. ERCP is effective in the nonsurgical management of a variety of pancreaticobiliary disorders, most commonly removal of bile duct stones and relief of malignant obstructive jaundice. Selective cannulation of one or both ducts can usually be accomplished in more than 90% of the cases. At least 100 procedures are required for a trainee to acquire a level of competence in diagnostic and therapeutic ERCP, defined by deep cannulation of the bile duct in 70% to 80% of cases. ERCP can be accurate in establishing the location, character, and length of strictures in the bile and/or pancreatic ducts, as well as accomplishing drainage in the same session. Failure to drain an obstructed bile duct when performing an ERCP carries a high risk of infection even with the use of antibiotics.

During ERCP, a specialized side-viewing endoscope, called a duodenoscope, is advanced to the descending duodenum to identify the major papilla. Then, dedicated instruments are passed into the bile and pancreatic ducts. The ducts are opacified by injection of an iodine contrast medium permitting their radiologic visualization and therefore allowing for a variety of therapeutic interventions.

The main indications of an ERCP are mentioned in Box 1.

Preprocedure coagulation studies are not routinely indicated but should be considered in selected patients, such as those with a history of coagulopathy or prolonged cholestasis. Endoscopists should consider correction of coagulopathy if sphincterotomy is anticipated, but specific international normalized ratio thresholds for this intervention have not been established. Antibiotic prophylaxis is indicated in the setting of suspected biliary obstruction with incomplete drainage (including primary sclerosing cholangitis [PSC]), postanastomotic bile biliary strictures, or ductal leaks.

The American Society for Gastrointestinal Endoscopy (ASGE) recommends preprocedure testing in the following settings.

- Pregnancy testing for women of childbearing potential who provide an uncertain pregnancy history or who have a history suggestive of a current pregnancy.
- Coagulation studies for patients with active bleeding, known or suspected bleeding disorder (including history of abnormal

Intraductal Radiofrequency Ablation

Intraductal radiofrequency (RF) ablation has been used to treat malignant tumors that involve the bile duct using endoscopy. More recently, there have been a few studies that have investigated this type of ablation being used with PTC. One study showed that PTC and intraductal RF ablation, followed by biliary stent placement, was safe and effective in the short term. At 6 months postoperation, two of 11 patients in an experimental group (PTC/RF) developed recurrent jaundice and received repeat procedures. In the same study, recurrent jaundice was observed at three months in the control group (without RF ablation).

SUMMARY

Transhepatic access for obstructive jaundice provides several therapeutic options for patients with both benign and malignant obstructions. A range of therapeutic options is available, including emergent drainage, endohepatoscopy, biliary stricture dilation, long-term stenting, and endoprosthesis for palliation (Figs. 1–5). In addition, direct visualization using endoscopic techniques (cholangioscopy) may assist in the treatment of retained intrahepatic stones and may allow a significant reduction in radiation exposure for the patient, the interventional radiologist, and the personnel in the room.

Improvements in the percutaneous transhepatic cholangiography techniques, biliary drainage, and adjunctive biliary interventions provide the interventionalist with ready access to the biliary system to assist in the multidisciplinary management of patients with complex biliary disease. The team approach is warranted because such patients often require management by surgeons, interventional radiologists, gastroenterologists, and primary care physicians.

The nonsurgical treatment of patients using transhepatic interventions for obstructive jaundice continues to expand. It is hoped that this information will assist readers in understanding some of the options available to such patients.

Obstructive Jaundice: Endoscopic Therapy

Olaya I. Brewer Gutierrez, MD, and Anthony N. Kalloo, MD

Obstructive jaundice is a manifestation of cholestasis, which in turn is an impairment in the bile flow out of the parts hepatic through the biliary ducts and into the duodenum. Symptoms may include fatigue, pruritus, and pale-colored or acholic stools. Abdominal pain may or may not be present, depending on the underlying cause. Cholestasis can be intra or extrahepatic and there are multiple causes. The main causes of extrahepatic cholestasis are summarized in Table 1. Overall, common bile duct stones are the most common cause of obstructive jaundice.

Cholestasis is identified through abnormal findings on biochemical tests of the liver, such as elevated alkaline phosphatase (AP), 5′-nucleotidase, γ glutamyl transferase levels, and variable levels of bilirubin and prothrombin time. However, elevated AP levels are not completely specific for cholestasis and do not help in identifying the underlying cause. In general, values of AP greater than three times the upper limit is suggestive of extrahepatic biliary obstruction. Different imaging techniques can be performed to identify the cause of obstructive jaundice with variable sensitivities and specificities, such as transabdominal ultrasound, cross-sectional imaging (magnetic resonance cholangiopancreatography [MRCP] or computed tomography), and endoscopic ultrasound (EUS) or endoscopic retrograde cholangiopancreatography (ERCP), both of which can be diagnostic and therapeutic, the latter mainly therapeutic.

This chapter focuses on the different endoscopic techniques available for the treatment of obstructive jaundice. Overall, endoscopic techniques for the management of obstructive jaundice are ERCP guided approaches and EUS guided biliary drainage (EUS-BD).

ERCP

ERCP is one of the most technically demanding and high-risk procedures in gastroenterology, requiring significant training and experience to maximize success and minimize poor outcomes. Currently, ERCP is predominantly a therapeutic procedure. ERCP is effective in the nonsurgical management of a variety of pancreaticobiliary disorders, most commonly removal of bile duct stones and relief of malignant obstructive jaundice. Selective cannulation of one or both ducts can usually be accomplished in more than 90% of the cases. At least 100 procedures are required for a trainee to acquire a level of competence in diagnostic and therapeutic ERCP, defined by deep cannulation of the bile duct in 70% to 80% of cases. ERCP can be accurate in establishing the location, character, and length of strictures in the bile and/or pancreatic ducts, as well as accomplishing drainage in the same session. Failure to drain an obstructed bile duct when performing an ERCP carries a high risk of infection even with the use of antibiotics.

During ERCP, a specialized side-viewing endoscope, called a duodenoscope, is advanced to the descending duodenum to identify the major papilla. Then, dedicated instruments are passed into the bile and pancreatic ducts. The ducts are opacified by injection of an iodine contrast medium permitting their radiologic visualization and therefore allowing for a variety of therapeutic interventions.

The main indications of an ERCP are mentioned in Box 1.

Preprocedure coagulation studies are not routinely indicated but should be considered in selected patients, such as those with a history of coagulopathy or prolonged cholestasis. Endoscopists should consider correction of coagulopathy if sphincterotomy is anticipated, but specific international normalized ratio thresholds for this intervention have not been established. Antibiotic prophylaxis is indicated in the setting of suspected biliary obstruction with incomplete drainage (including primary sclerosing cholangitis [PSC]), postsurgical anastomotic biliary strictures, or ductal leaks.

The American Society for Gastrointestinal Endoscopy (ASGE) recommends preprocedure testing in the following settings:

- Pregnancy testing for women of childbearing potential who provide an uncertain pregnancy history or who have a history suggestive of a current pregnancy.
- Coagulation studies for patients with active bleeding, known or suspected bleeding disorder (including history of abnormal

TABLE 1 Causes of Extrahepatic Cholestasis

Mechanism	Cause
Intraluminal or intramural	Cholangiocarcinoma Choledocholithiasis Primary/secondary sclerosing cholangitis Benign biliary stricture Choledochal cyst Parasites Hemobilia

Extraluminal or intramural	Pancreatic head mass Gallbladder carcinoma Pseudotumoral chronic pancreatitis
Obstruction at the ampulla of Vater	Duodenal diverticulum Ampullary mass Ampullary stenosis

bleeding), an increased risk of bleeding resulting from medications use (ongoing anticoagulation, prolonged antibiotic use), prolonged biliary obstruction, malnutrition, or other conditions associated with acquired coagulopathies.

- Chest radiograph for patients with new respiratory symptoms or decompensated heart failure.
- Hemoglobin/hematocrit for patients with preexisting significant anemia or active bleeding, or in case of high risk of significant blood loss during the procedure.
- Blood typing for patients with active bleeding or anemia who may likely need a blood transfusion.
- Serum chemistry testing for patients with significant endocrine, renal, or hepatic dysfunction when medications are to be used that may further impair function.

Equipment

A side viewing duodenoscope allows a better view of the major duodenal papilla, making cannulation easier. In patients with altered anatomy, such as Billroth II gastrectomy, Whipple or Roux-en-Y reconstruction, a forward viewing endoscope, such as a pediatric colonoscope or a single or double balloon enteroscope with a cap, is a reasonable alternative in these circumstances, where afferent loop intubation would be easier. Papillary cannulation would be more challenging given the absence of the elevator, only available in the duodenoscope. Different accessories such as sphincterotomes, guidewires, balloon or catheter dilators, extraction balloons, baskets, and stents (plastic vs. metallic) are part of the ERCP armamentarium necessary to treat obstructive jaundice, depending on the cause.

Choledocholithiasis

The most common cause of biliary obstruction is choledocholithiasis. Gallstone disease affects more than 20 million American adults. A subset of these patients will also have choledocholithiasis, including 5% to 10% of those undergoing laparoscopic cholecystectomy for symptomatic cholelithiasis, and 10% to 33% of patients with acute biliary pancreatitis.

ASGE published a risk stratification scoring system where a score is assigned to patients with suspected choledocholithiasis, taking into account patient age, liver function tests, and abdominal ultrasound findings (Table 2). Moreover, based on this proposed scoring system, the same group suggested a management algorithm (Fig. 1).

The sensitivity and specificity of ERCP for detecting common bile duct stones is greater than 90%, although small stones can be missed.

BOX 1 Indications of ERCP

Indications for ERCP

- Jaundice thought to be the result of biliary obstruction
- Clinical and biochemical or imaging data suggestive of pancreatic or biliary tract disease
- Signs or symptoms suggesting pancreatic malignancy when direct imaging results are equivocal or normal
- Pancreatitis of unknown etiology
- Preoperative evaluation of chronic pancreatitis or pancreatic pseudocyst
- Sphincter of Oddi manometry (surgical biliary sphincteroplasty without sphincter of Oddi manometry is not recommended in patients with suspected type III sphincter of Oddi dysfunction)
- Endoscopic sphincterotomy
- Choledocholithiasis
- Papillary stenosis or sphincter of Oddi dysfunction causing disability
- Facilitate biliary stent placement or balloon dilation of biliary structures
- Sump syndrome
- Choledochocele involving the major papilla
- Ampullary carcinoma in poor surgical candidates
- Access to pancreatic duct
- Stent placement across benign or malignant strictures, fistulae, postoperative bile leak, or large common bile duct stones
- Balloon dilation of ductal strictures
- Nasobiliary drain placement
- Pseudocyst drainage in appropriate cases
- Tissue sampling from pancreatic or bile ducts
- Ampullectomy of adenomatous neoplasms of the major papilla
- Therapy of disorders of the biliary and pancreatic ducts
- Facilitation of cholangioscopy and/or pancreatoscopy

ERCP Not Indicated

- Evaluation of abdominal pain of obscure origin in the absence of objective findings that suggest biliary or pancreatic disease. Magnetic resonance cholangiopancreatography and endoscopic ultrasound are safe diagnostic procedures that can obviate the need for ERCP.
- Evaluation of suspected gallbladder disease without evidence of bile duct disease
- As further evaluation of proven pancreatic malignancy unless management will be altered

ERCP, endoscopic retrograde cholangiopancreatography.

Careful injection of contrast and early fluoroscopy may help detect stones and avoid overfilling of the ducts or proximal advancement of stones into the intrahepatic ducts.

ERCP with biliary decompression is the procedure of choice for the treatment of acute cholangitis. The role and timing of ERCP in acute gallstone pancreatitis remains controversial. A systematic review comprising 448 patients concluded that in patients with acute gallstone pancreatitis, there is no evidence that early routine ERCP significantly affects mortality and local or systemic complications of pancreatitis, regardless of predicted severity. Nevertheless, results favored early ERCP in patients with acute biliary pancreatitis and cholangitis.

Endoscopic sphincterotomy and stone extraction are successful in more than 90% of cases, being the treatment of bile duct stone clearance. Stone removal is usually accomplished with extraction balloon catheters or wire baskets. In case of difficult bile duct stones (>1.5 cm), impacted, difficult cannulation, altered anatomy), sphincterotomy and endoscopic papillary large balloon dilation can result in high success rates of complete clearance. When this combined approach is used, a large endoscopic sphincterotomy is not required. Patients with

TABLE 2. ASGE Proposed Strategy to Assign Risk of Choledocholithiasis in Patients With Symptomatic Cholelithiasis Based on Clinical Predictors

Clinical Predictors of Choledocholithiasis
Very strong
CBD stone on transabdominal US
Clinical ascending cholangitis
Bilirubin >4 mg/dL
Strong
Dilated CBD on US (>6 mm with gallbladder in situ)
Bilirubin level 1.8–4 mg/dL
Moderate
Abnormal liver biochemical test other than bilirubin
Age older than 55 years
Dilated CBD on US/cross-sectional imaging

Likelihood of Choledocholithiasis Based On Clinical Predictors	Probability
Presence of any very strong predictor	High (>50%)
Presence of both strong predictors	High (>50%)
No predictors present	Low (< 10%)
All other patients	Intermediate (10%–50%)

ASGE, American Society for Gastrointestinal Endoscopy; CBD, common bile duct; US, ultrasound.

prior biliary sphincterotomy do not need extension of the sphincterotomy before endoscopic papillary large balloon dilation. The diameter of the dilating balloon ranges from 12 to 20 mm (about 3–5.5 cm esophageal, pyloric, or colonic dilating balloons), and is chosen based on the diameter of the stone or stones and the maximal diameter of the bile duct. There are other techniques that can be used for stone extraction of difficult bile duct stones such as mechanical lithotripsy using a basket and the digital single operator cholangioscopy system with electrohydraulic lithotripsy or laser lithotripsy, the latter with more than 90% rate of stone clearance with low rate of adverse events. If stone removal is unsuccessful, biliary decompression should be accomplished by placement of a biliary stent or nasobiliary drain.

Endoscopic sphincterotomy and stone extraction without subsequent cholecystectomy may be appropriate in some patients with comorbidities and high surgical risk. Nevertheless, biliary symptoms recur twice as commonly in patients whose gallbladder remains in situ with a 5-year risk of significant biliary adverse events leading to cholecystectomy as high as 15%.

Benign Biliary Strictures

ERCP is indicated in the evaluation and treatment of benign biliary strictures, congenital bile duct abnormalities, and postoperative adverse events such as anastomotic strictures and biliary leaks. Biopsies and brushings can help define the etiology of benign biliary strictures and diagnostic yield may increase with cholangioscopy directed biopsies.

Biliary injury is rarely recognized during surgery; symptoms appear most often in the early postoperative course or months or years after surgery. Benign biliary strictures may be dilated with bidirectional balloons (maximum biliary dilator diameter 10 mm) or graduated catheters passed over a guidewire. Benign biliary strictures amenable to endoscopic dilation include those secondary to chronic pancreatitis, dominant strictures in PSC, postoperative

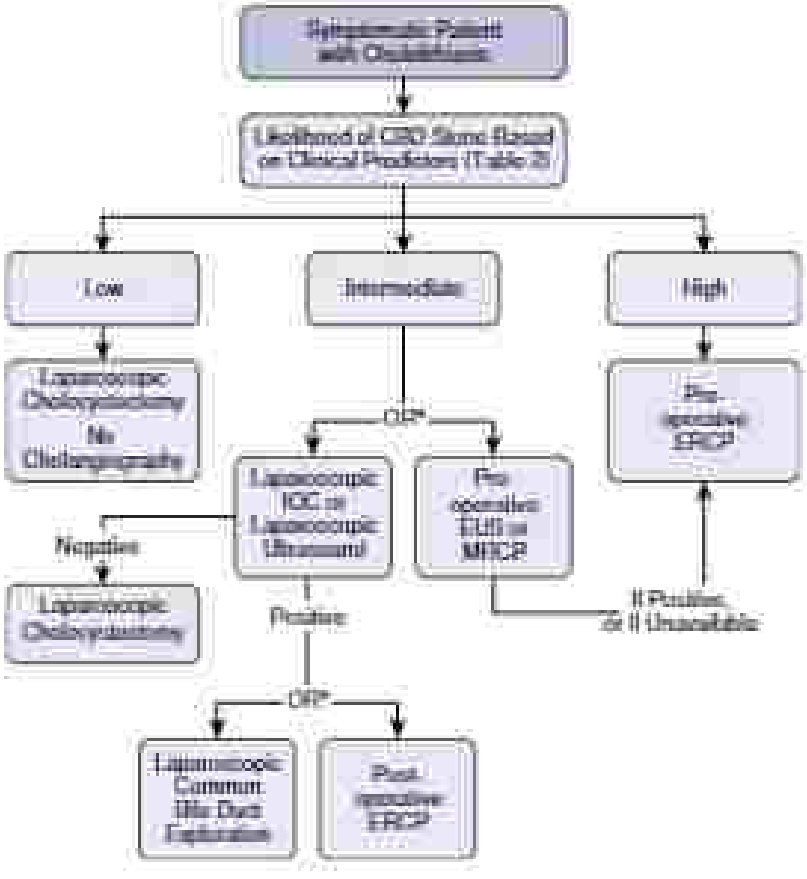

FIG. 1 American Society for Gastrointestinal Endoscopy suggested management algorithm for patients with symptomatic cholelithiasis based on the risk of probability for choledocholithiasis. *Depending on costs and local expertise. (Modified from Tse F, Barkun JS, Barkun AN. Risk stratification of patients with suspected choledocholithiasis undergoing laparoscopic cholecystectomy. Can J Gastroenterol. [year]; [volume]:[issue]:[pages].)

TABLE 3 Bismuth Classification for Benign Biliary Strictures

Type	Criteria
I	Low common hepatic duct stricture with a length of common hepatic duct stump greater than 2 cm
II	Proximal common hepatic duct stricture with a common hepatic duct stump less than 2 cm
III	Hilar stricture, no residual common hepatic duct, but the hepatic ductal confluence is preserved
IV	Hilar stricture with involvement of hepatic ductal confluence and loss of communication between right and left hepatic duct
V	Involvement of an aberrant right sectorial duct alone or with concomitant stricture of the common hepatic duct

strictures, and strictures caused by stone disease. Single or multiple plastic stents may be used to maintain patency after initial dilation. Serial endoscopic dilation and maximal caliber stent placement can be used to achieve prolonged ductal patency in most benign postoperative strictures. Despite high success rates, this approach is technically demanding and requires an average of five ERCPs. Fully covered self-expandable metal stents (cSEMS) are an alternative approach to benign biliary strictures. The cSEMS expand to lumen sizes larger than those of plastic stents, without the risk of tissue ingrowth and embedding such as in uncovered and partially covered metal stents, allowing an indwell time up to 12 months if necessary, and without compromising the ease of removal.

Chronic pancreatitis accounts for 10% of all common bile duct strictures. Treatment is indicated for patients with jaundice and/or cholangitis, those with significant biliary dilation (12 mm), pruritus, and/or strictures, and with abnormal liver function tests (ALP >3 times the normal value for 6 months or longer). In patients with bile duct strictures resulting from chronic pancreatitis the use of multiple plastic stents over a long period (24 months) compared with a single stent increases the chance of long-term overall success of 61.2% with a high risk of relapses (17%).

In patients with PSC, ERCP is no longer indicated for diagnosis in a routine basis. An MRCP is a noninvasive imaging test with comparable diagnostic accuracy to ERCP in the diagnosis of dominant strictures. A dominant stricture is defined as a lumen diameter of 1.5 mm or less in the common bile duct and 1 mm or less in the common hepatic duct and it is seen in 47% to 50% of patients with PSC. In case of unclear results of an MRCP or clinical deterioration of a patient with prior diagnosis of PSC (worsening cholestasis, pruritus, or cholangitis), ERCP can aid in the diagnosis of a dominant stricture. Benign strictures in PSC patients respond well to endoscopic therapy with balloon dilation with or without stent placement. Limited data suggest that balloon dilation is often sufficient and that the use of stents may be associated with an increased risk of adverse events and cholangitis.

Postsurgical strictures occur after orthotopic liver transplantation and laparoscopic cholecystectomy in 3% to 13% and 0.2% to 0.7%, respectively. Also, strictures at bile enteric anastomosis are seen more often every day in clinical practice. Strictures recognized early in the postoperative/operative period are often associated with a bile leak caused by direct trauma, whereas delayed presentation is commonly associated with ischemic injury and resultant fibrosis. A commonly used classification for postoperative strictures is the Bismuth classification, based on location of the stricture within the bile tree (Table 3). Clinical presentation (elevation of liver function tests, pain, jaundice) depends on the degree of bile duct obstruction. Endoscopic treatment usually involves serial placement of multiple large bore plastic stents over a 1-year period, with exchange every 3 to 4 months. Balloon dilation of anastomotic biliary strictures within the first 4 weeks of surgery carries an increased risk of anastomotic dehiscence and thus a less aggressive approach is suggested in this setting. Success rates for this approach range from 74% to 90%, with recurrence rates as high as 30% within 2 years of stent removal. Distal postoperative biliary strictures (Bismuth I and II) are associated with better success rates compared to proximal hilar strictures (Bismuth III). A 2008 randomized control trial comparing plastic stents versus cSEMS in benign biliary strictures concluded that patients with benign biliary strictures and a bile duct diameter 6 mm or more in whom the cSEMS would not overlap the cystic duct, cSEMS should be considered an appropriate option. The main potential benefit of cSEMS in the management of refractory benign biliary strictures is their large caliber and longer duration of patency allowing them to be left in place longer, resulting in fewer procedures for serial dilations and placement of multiple plastic stents.

Malignant Biliary Strictures

The most widely recognized cause of malignant distal biliary obstruction is pancreatic head cancer. Other causes of malignant obstructive jaundice are cholangiocarcinomas (CCA), gallbladder cancer, and metastatic tumors compressing the biliary system. ERCP is the most accepted and widely used method for biliary decompression in these scenarios. In those patients with unresectable malignant biliary obstruction, effective biliary decompression improves symptoms and enables patients to undergo palliative therapies. On the other hand, in those patients who are surgical candidates, routine preoperative biliary intervention may worsen outcomes. In a randomized control trial comparing preoperative biliary drainage using plastic stents versus early surgery without drainage in resectable pancreatic cancer showed that endoscopic preoperative biliary drainage with placement of a plastic stent did not have a beneficial effect on the surgical outcome. In a recent published meta-analysis including 33 studies showed that the available evidence argues against preoperative biliary drainage in patient with resectable pancreatic head adenocarcinoma. With the advent of neoadjuvant chemotherapy used to downstage potentially unresectable tumors in the hope of improving the outcome, preoperative biliary drainage is clinically relevant. Preoperative biliary drainage during the period of neoadjuvant treatment might be best achieved with metal stents, which have a higher patency rate than plastic stents.

In patients with unresectable pancreatic head adenocarcinoma and obstructive jaundice, ERCP with SEMS are superior to plastic stents in the palliative setting. A recent meta-analysis of 19 studies involving 1985 patients, cSEMS were associated with significantly lower occlusion rates, less therapeutic failure (7% vs 15%), less need for reintervention and lower rates of cholangitis (8% vs 21%) than plastic stents. In distal malignant biliary obstruction, there is the option of cSEMS vs uncovered SEMS, each of which have its advantages and disadvantages. A meta-analysis involving eight studies concluded that the group of patients with cSEMS had lower incidence of adverse events, with no significant difference in dysfunctions, however, cSEMS tends to be better, with no difference in stent patency, patient survival, and complications.

Malignant hilar strictures are categorized according to the Bismuth-Corlette classification (Table 4). At the time of presentation, only a minority (<50%) of patients with hilar CCA are candidates for resection or transplantation. The goal of palliative stenting of hilar CCA is drainage of adequate liver volume (50% or more), irrespective of unilateral, bilateral, or multisegmental stenting. Endoscopic stenting in hilar obstructions can be done with plastic or metal stents. Plastic stents are less expensive with easier insertion, removal, and exchange. Nevertheless, they have limited stent patency. On the other hand, metal stents have prolonged stent patency, do not occlude side branches, and have easier passage across biliary strictures because

TABLE 4 Bismuth-Corlette Classification for Malignant Hilar Tumors

Type	Anatomic Location
I	Common hepatic duct distal to the hepatic confluence
II	Involves the biliary confluence
IIIa	Biliary confluence + right hepatic duct
IIIb	Biliary confluence + left hepatic duct
IV	Extends to the bifurcation of the left and right hepatic ducts or multifocal

of relatively smaller delivery sphincterotomes. However, greater cost and difficulty to removal once blocked are the limitations. In those patients with predicted survival greater than 3 months, uncovered cSEMS are superior to plastic stents for palliation with respect to outcome and cost effectiveness. Adequate biliary drainage can be achieved with unilateral, bilateral side by side, or bilateral stent to stent approaches, with evidence currently lacking as to which of these approaches is optimal. The Asian Pacific consensus supports that patients with low grade hilar obstruction (Bismuth I and II), endoscopic stenting is considered a less invasive approach with acceptable outcome. In contrast, patients with advanced hilar obstruction (Bismuth III and IV), endoscopic stenting had a lower success rate of cholestasis palliation and a higher rate of post ERCP cholangitis, making percutaneous stenting a better approach for these patients. In patients with potentially resectable hilar CCA, the Asia Pacific consensus recommendations are to not perform routine preoperative biliary drainage. Nevertheless, in case of hepatectomy or hepatic vein embolization some experts prefer to achieve drainage via percutaneous approach.

ERCP Adverse Events

Post ERCP pancreatitis (PEP) is the most common serious adverse event attributed to the procedure. An elevation in the serum amylase or lipase concentration is common after ERCP, occurring in up to 75% of patients, by comparison, acute clinical pancreatitis (defined as a clinical syndrome of abdominal pain and elevated amylase or lipase more than 3 times the upper value requiring hospitalization) is much less common. The reported rate of PEP varies widely from 1% to 40%, with an average rate of 5% to 7%. In a systematic review of 108 randomized controlled trials, including 15,296 patients undergoing both diagnostic and therapeutic ERCP, the overall rate of PEP was 9.7%, with a mortality rate of 0.7% in the control group (placebo or no pancreatic duct stent arm). Most episodes of PEP are mild and require only a short hospital stay for bowel rest and intravenous hydration. Patients who develop severe pancreatitis may require prolonged hospitalization in the intensive care unit with total parenteral nutrition. The management of patients with PEP is the same as for patients with pancreatitis from other causes. The endoscopist must perform a meticulous technique, and patients deemed to be at high risk for PEP should receive aggressive intravenous hydration using lactated Ringer's solution, rectal indomethacin, and pancreatic stenting.

Bleeding is a serious adverse event after ERCP and is most commonly the result of endoscopic biliary and/or pancreatic sphincterotomy. The rate of postsphincterotomy bleeding after ERCP is estimated to be 0.3% to 2%. Initial management of postsphincterotomy bleeding includes adequate fluid resuscitation, reversal of coagulopathy, and blood transfusion as needed. Endoscopic therapy includes diluted epinephrine injection at the sphincterotomy site (0.5–1 mL), thermal therapy such as multipolar electrocautery or argon plasma coagulation, clipping at the sphincterotomy site, which might be challenging using the duodenoscope; balloon tamponade mostly during intraprocedural bleeding, and cSEMS, which have shown excellent results in multiple series. A recently US Food and Drug Administration approved inert powder developed for endoscopic hemostasis (Hemospray; Cook Medical) has a potential role in postsphincterotomy active bleeding. It is a noncontact, nonthermal, atraumatic technique that will induce hemostasis when in contact with an active bleeding site, the powder absorbs water and adheres to the bleeding site forming a mechanical barrier. It could act as a primary hemostatic or as a bridge to a more definitive hemostatic technique during intraprocedural bleeding. There are no data to support its use in a nonactive bleeding site. Angiographic embolization or surgery is reserved for bleeding unresponsive to endoscopic therapy.

Cholangitis is the most common infectious adverse event associated with ERCP, occurring in 0.5% to 3% of cases. The risk of cholangitis is highest in patients with incomplete biliary drainage (hilar CCA and PSC) and a history of liver transplantation, therefore, periprocedural antibiotics and meticulous biliary drainage techniques are essential in these patients. Other potential infectious events include cholecystitis, duodenoscope related transmission of infections, and infective endocarditis.

Perforations associated with ERCP are rare and can occur in 0.08% to 0.6% of patients. Perforations can occur with the endoscope, after a sphincterotomy, and transmural secondary to the passage of guidewires or stents. ASGE guidelines state that in case of suspected periampullary or instrument related perforations from ERCP without evidence of peritonitis or systemic inflammatory response syndrome, these can be managed nonoperatively.

EUS-BD

In cases where bile duct access cannot be obtained as a result of failed ERCP cannulation, altered anatomy, ampullary distortion or diverticulum, gastric outlet obstruction, or in situ duodenal stents, EUS-BD is increasingly being used as an alternative to interventional radiology or surgery.

EUS-BD is performed by using one of three basic approaches that include the rendezvous (RV) technique, transluminal (TL) stenting, or EUS-guided antegrade transpapillary (or transduodenal) biliary stent placement.

Any of the three approaches is performed using a linear therapeutic endoscopic ultrasound, and in case of the RV approach a combination of a linear echoendoscope and a standard duodenoscope is used. Other instruments needed are a 19-gauge fine needle aspiration needle, a 0.025-inch guidewire (most frequently used), and plastic or metal stents.

The echoendoscope is positioned within the gastric fundus or duodenal bulb to access the intrahepatic and extrahepatic bile duct, respectively. A 19 gauge fine needle aspiration needle is used to puncture the bile duct, and then access is confirmed with EUS or with contrast injection and fluoroscopic confirmation. The 0.025-inch guidewire is advanced into the bile duct and under fluoroscopy is advanced transpapillary into the duodenum (in the RV technique) or proximally into the intrahepatic ducts (TL technique). In the RV approach, once the guidewire is properly placed, the echoendoscope is removed, and a standard duodenoscope is inserted to retrieve the guidewire by using a biopsy forceps or snare, thereby allowing standard ERCP and stent placement (over the wire technique). In the TL approach, once the guidewire is properly placed, the puncture site is dilated using a catheter or biliary balloon dilator creating a fistula. The two common TL approaches are a choledochoduodenostomy or hepaticogastrostomy. The initial puncture in the choledochoduodenostomy technique is done in the duodenum and in the hepaticogastrostomy from the gastric cardia or gastric body into the dilated intrahepatic ducts, liver segment 2 or 3. In both approaches, cSEMS are favored over plastic stents to decrease the risk of bile leak.

In the antegrade stenting technique, the initial steps are the same as in the other techniques. Then, the intrahepatic stent placement is performed by advancing the stent through the echoendoscope over

the guidewire to traverse the stricture and does the papilla (transpapillary) or anastomosis (transanastomotic).

It is important to obtain informed consent from all patients for possible EUS-BD at the time of ERCP, in particular those at high risk of failed biliary cannulation (surgical altered anatomy, previous failed ERCP, periampullary cancer with duodenal invasion on imaging, duodenal tumor covering the ampulla). The consent requires a thorough discussion regarding the potential indications, benefits, and risks after possible failed cannulation and available alternatives such as repeated ERCP versus percutaneous or surgical drainage.

Data mostly from small retrospective series suggest that EUS-BD can be performed with high therapeutic success (87%) but is associated with a 10% to 20% risk of adverse events, most of which are mild to moderate in nature. Many endoscopists favor the RV technique because it avoids the creation of a permanent bilioenteric fistula and luminal tract dilation, which may result in bleeding, pneumoperitoneum, or pneumomediastinum. Data published to date are from tertiary high volume centers. These procedures should be done by experienced endoscopists in both ERCP and EUS and carried out at institutions with backup surgery and radiology to manage failed interventions or adverse events.

Data directly comparing EUS-BD with PTBD are limited, leaving uncertainty about how best to manage patients after failed ERCP. Some studies have reported similar efficacy in both approaches, but EUS-BD may offer more safety at a significantly lower cost with fewer interventions. A potential advantage of EUS-BD is the ability to access various sites of the biliary system, allowing drainage even in the setting of duodenal obstruction or duodenal bypass surgeries. In addition, EUS-BD may also be performed in patients with ascites and liver metastasis, scenarios in which percutaneous approaches may be difficult. Indications and methods for EUS-BD are yet to be standardized, moreover, the approach should be individualized for each patient based on the endoscopist's expertise and the patient's anatomy.

MANAGEMENT OF ACUTE NECROTIZING PANCREATITIS

Zhi Wei Feng, MD, MPH ... Christopher L. Wu, MD, FACS, FRCSed(A) (Orth) and Peter J. Pappas, MD

DIAGNOSIS AND EVALUATION

PRESURGICAL TREATMENT

Resuscitation

The resuscitation strategy should be tailored to the severity of the disease. In moderately severe and severe pancreatitis, a significant amount of intravenous fluid resuscitation is typically required because most patients with pancreatitis present with intravascular hypovolemia from poor oral intake, vomiting, and third-space sequestration. Prospective studies have demonstrated that ... around Ringer's solution is the preferred fluid of choice over other crystalloid solutions such as normal saline for resuscitation. In general, goal-directed intravenous fluid resuscitation at 5 to 10 mL/kg per hour should be used initially. Under-resuscitation results in worse overall outcomes, more end-organ damage such as acute kidney injury and may result in more pancreatic necrosis because of hypoperfusion. On the other hand, over-resuscitation can lead to acute lung injury and abdominal compartment syndrome. Striking the right balance between over- and under-resuscitation is difficult. Current guidelines call for ongoing fluid resuscitation to be guided by frequent reassessment of fluid responsiveness using urine output, blood pressure and hematocrit levels, or dynamic variables such as pulse pressure and stroke volume variation. When a patient is deemed euvolemic but is persistently hypotensive, vasopressor support should be used, with norepinephrine as the first line agent. Ultimately, the way we conceptualize this is that there are responders and nonresponders to initial fluid resuscitation. ...responders can benefit greatly from rapid, aggressive intravenous fluid administration in accordance with the guidelines presented. ...caution in patients who remain in persistent

organ failure with SIRS, tachycardia, hypotension, and renal failure, additional fluid resuscitation beyond the initial effort will not reverse this underlying process, but may accrue severe complications such as abdominal compartment syndrome from visceral edema and ascites. In patients with persistent hypotension and organ failure in spite of early aggressive fluid resuscitation, we ask, "What will the tenth liter of fluid accomplish that the first nine did not." Usually, nothing beneficial. Although this tipping point from helpful resuscitation to harmful over resuscitation is difficult to identify clinically, it does exist, and avoiding harmful excessive crystalloid administration is as important as providing adequate early crystalloid resuscitation.

TABLE 1 Etiology and Diagnosis of Acute Pancreatitis

Etiology	Diagnostic Options
Gallstone	Ultrasound, MRI
Alcohol	History taking, serum alcohol levels
Hypertriglyceridemia	Serial serum triglyceride levels
Hypercalcemia	Serum PTH
Idiopathic*	Postpancreatitis imaging to assess for mass lesion
Neoplasm	Postpancreatitis imaging to assess for mass lesion
Iatrogenic (ERCP)	Recent history

ERCP, endoscopic retrograde cholangiopancreatography; MRI, magnetic resonance imaging; PTH, parathyroid hormone.

TABLE 2 Contemporary Severity Assessment of Acute Pancreatitis

Mild	Moderately Severe	Severe
Complete absence of systemic inflammatory response syndrome *and* No local pancreatic complications such as necrosis *and* No end organ failure	Local pancreatic complications such as necrosis and acute fluid collections *or* Transient organ failure (resolution within 48 hr)	Persistent organ failure (>48 hr)

Nutrition

Historically, patients with pancreatitis were kept without food or water for prolonged periods on the premise of decreasing stimulation of pancreatic secretion and release of digestive enzymes. Recent evidence has demonstrated that this practice is not beneficial. In patients with mild pancreatitis, oral feeding of a low fat solid diet should be initiated as soon as abdominal pain and inflammatory markers start improving. Feeding as tolerated has been shown to accelerate recovery and to shorten hospital stay. In patients with more severe pancreatitis who are unable to tolerate oral intake, enteral nutrition should be provided within 2 to 3 days of presentation, preferably through nasogastric or nasojejunal tube feedings with an aspiration precaution protocol in place. Enteral feeding has been shown to preserve the gastrointestinal mucosal barrier, which in turn may reduce bacterial translocation and infection of damaged tissues. It is preferred over total parenteral nutrition, which is associated with higher incidences of organ failure, infectious complications, and mortality. Parenteral nutrition should be reserved for patients not meeting nutritional goals via an enteral route after 5 to 7 days. Fig. 1 details our approach to nutritional support in patients with acute pancreatitis.

Infection and the Role of Antibiotics

Prophylactic antibiotics are not indicated in patients with no signs of infection. Historically, prophylactic antibiotics were given on the premise of preventing the progression of sterile pancreatic and peripancreatic necrosis to infected necrosis. However, studies have shown that prophylactic antibiotics confer no benefits, predispose to multidrug resistant and fungal infections, and should not be administered unless there is clear evidence of infection (cholangitis, bacteremia, proven infected pancreatic necrosis). However, it may be difficult to be sure if infection is present because patients with acute pancreatitis often manifest signs and symptoms of SIRS such as fever, tachycardia, and leukocytosis, all of which can mimic infection. When infection is suspected, CT imaging is indicated. Infected necrosis can be diagnosed by imaging demonstrating gas within the areas of pancreatic necrosis. Although this finding is highly specific, it is not sensitive. Until recently, percutaneous sampling by needle aspiration of the necrotic collection for culture was routinely advocated to assess

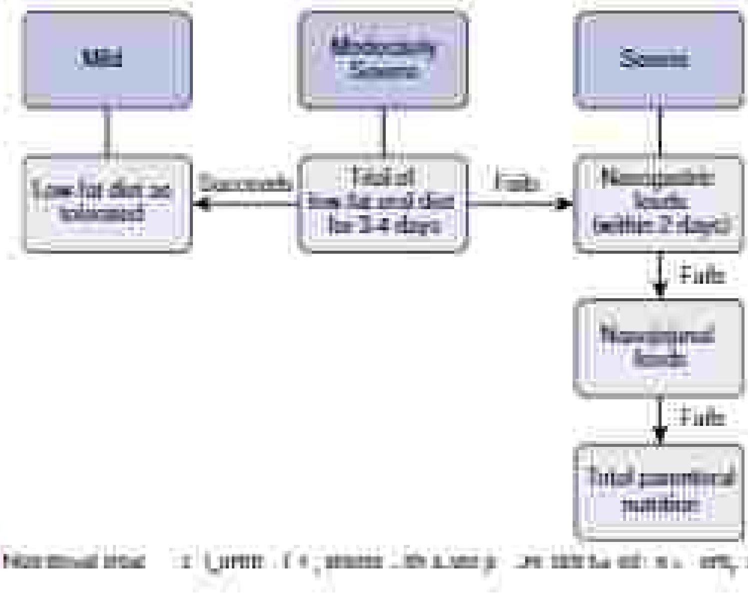

FIG. 1 Nutritional [illegible]

for infected necrosis when there was clinical suspicion for infection but no definitive evidence on imaging. However, it has a relatively high false-negative rate of approximately 20% and should be used selectively. It should be performed if there is no clear cut evidence of infection (i.e., gas bubbles on CT) and prolonged surveillance, and a positive aspirate culture will prompt initiation of antibiotics. If the patient has ongoing inflammatory signs and a negative needle aspiration will not change the treatment plan, a decision to treat empirically based on the clinical diagnosis is justified. Patients with necrosis and "persistent unwellness" (failure to thrive) over a period of weeks often harbor occult infection. Our studies have shown that 46% of these patients have infected necrosis when cultures are obtained, many times after negative needle aspirates.

If infection is suspected or confirmed, antimicrobial therapy should be initiated. The majority of infections are caused by enteric organisms. Empiric antibiotic treatment should consist of a regimen with an appropriate spectrum of antimicrobial activity and known to penetrate pancreatic necrosis such as a carbapenem or gram-negative agent (quinolone or third- or fourth-generation cephalosporin) plus metronidazole. If drainage or debridement is performed, a sample should be taken for culture to guide treatment. If patients are started on antibiotics for infected necrosis in the absence of microbiologic data and continue to clinically deteriorate, the regimen should be empirically broadened to include gram positive, fungal, and multidrug-resistant organisms in addition to performing other maneuvers to achieve source control (e.g., drainage, debridement) and considering extrapancreatic sources of the clinical deterioration.

KEY COMPLICATIONS

Choledocholithiasis and Cholangitis

In patients presenting with pancreatitis caused by gallstones, routine ERCP should not be performed. The majority of tiny stones will pass into the duodenum spontaneously. However, retained stones or cholangitis may occur in parallel with the ongoing pancreatitis. In cases of suspected persistent choledocholithiasis without any concern for cholangitis, a period of watchful waiting of 72 to 48 hours with serial liver function tests and clinical monitoring is reasonable as spontaneous passage of gallstones is common and results in resolution of the obstruction without the need for intervention. These patients should be managed like any other patients with possible choledocholithiasis, which is discussed elsewhere in this text. In cases of suspected cholangitis, blood cultures should be drawn, followed by the initiation of broad spectrum antibiotics and urgent ERCP to relieve the biliary obstruction.

Abdominal Compartment Syndrome

Abdominal compartment syndrome occurs when organ dysfunction, most prominently oliguric acute kidney injury and respiratory failure with high peak inspiratory pressures, is caused by intraabdominal hypertension. Although intraabdominal hypertension is defined as intraabdominal pressure exceeding 12 mm Hg, abdominal compartment syndrome rarely occurs with intraabdominal pressures less than 20 mm Hg. The intraabdominal pressure is measured by instilling a small volume of fluid into the bladder via a urinary catheter and transducing the catheter. Three main factors can contribute to the development of abdominal compartment syndrome in acute pancreatitis: (1) visceral edema from large volume crystalloid resuscitation, (2) ascites similarly related to fluid resuscitation and occasionally to portal venous thrombosis, and (3) space occupying retroperitoneal and peripancreatic necrosis and fluid collections. This complication typically occurs early in the course of illness when the inflammatory response is at its height amid active fluid resuscitation. Initial treatment is the cessation of unnecessary volume infusion, volume removal if possible via diuresis, administration of ultrafiltration, interventions to decrease hollow viscus volume (nasogastric decompression, rectal drainage, prokinetics), and sedation and neuromuscular blockade to increase abdominal wall compliance. In patients with a significant volume of ascites, percutaneous drainage can sometimes result in a dramatic decrease in intraabdominal pressure and should be attempted before decompressive laparotomy is considered. When all other strategies fail, decompressive laparotomy is the definitive treatment for abdominal compartment syndrome. It is critical to note that debridement of pancreatic necrosis should not be performed at the time of abdominal decompression as very early debridement increases mortality. There are a variety of techniques for managing the open abdomen. We prefer to use a vacuum assisted abdominal closure, with closure beginning 24 to 48 hours after the initial decompression and proceeding in a staged fashion every 24 to 48 hours thereafter if primary closure is not possible.

Pseudoaneurysm

Pseudoaneurysms occur when enzyme rich pancreatic fluid autodigests and weakens the walls of pancreatic and visceral arteries, leading to wall defects. The most commonly involved arteries are the splenic, branches of the gastroduodenal arcade, and the hepatic artery (Fig. 2A). These pseudoaneurysms are life threatening because of their potential for major hemorrhage. Pseudoaneurysms are typically asymptomatic until they bleed, and are often incidentally identified during CT or magnetic resonance imaging in the course of serial evaluations. We recommend aggressive angioembolization of virtually all pseudoaneurysms found in pancreatic fields because there is no reliable means of clinical monitoring and the consequences of hemorrhage are potentially grave. When pseudoaneurysms do rupture, they may present initially with a small volume "sentinel" bleed that, if recognized, can provide a window for intervention before massive hemorrhage ensues. In patients with external drainage catheters, any bleeding from the drain must be taken seriously and considered a possible pseudoaneurysm until proven otherwise. Similarly, pseudoaneurysm should be in the differential diagnosis when upper gastrointestinal bleeding occurs in a patient with transgastric stents or a gastric anastomosis to the necrotic cavity (discussed later). In stable patients, CT angiography (CTA) can effectively assess for pseudoaneurysm, provide a picture of any surrounding local complications (such as necrosis or pseudocyst), and provide a road map for angioembolization. In hemodynamically unstable patients with clinical suspicion for a bleeding pseudoaneurysm, there may not be time for CTA; immediate angiography may be required. Surgical control of a bleeding pseudoaneurysm within a bed of pancreatic necrosis is extremely challenging, and operative intervention should be reserved for patients with severe hemodynamic instability when angiography is not immediately available or when angiographic interventions have failed.

Pseudocyst

Acute pancreatic and peripancreatic collections are common local complications of acute pancreatitis. These collections usually do not require intervention, with a minority of them progressing to walled off necrosis or pseudocyst when they are not evacuated. Pseudocysts are organized collections of pancreatic fluid that have a connection to the pancreatic duct system, and persist more than 4 weeks after the index pancreatitis episode. Most pancreatic pseudocysts resolve spontaneously or remain asymptomatic, without intervention. In symptomatic cases, symptoms typically develop as a result of pressure symptoms on adjacent structures (usually stomach or duodenum), resulting in pain or early satiety. Less commonly, infection, rupture, or hemorrhage, may occur (Fig. 2B). In symptomatic patients, standard management consists of internal drainage into the gastrointestinal tract. This is most commonly performed endoscopically. Surgical drainage, which may have a higher rate of resolving the pseudocyst in a single procedure, should be considered when patients have failed endoscopic drainage, when there is a disconnected pancreatic duct (by gaining internal drainage or resection), for larger pseudocysts in dependent locations (i.e.,

parasitic pattern), or when other intraabdominal procedures are indicated (i.e., laparoscopic cystogastrostomy at the time of laparoscopic cholecystectomy to prevent recurrent biliary pancreatitis). For patients with hemorrhage into the pseudocyst, a CTA should be performed to determine the appropriate next steps. Bleeding may be from a single adjacent visceral artery branch or from a small unnamed vessel in the pseudocyst wall. If CTA demonstrates a significant arterial bleed, the bleeding should be treated akin to a pseudoaneurysm and managed as detailed in the previous section. If CTA demonstrates no clear evidence of an arterial bleed, the bleed seen on initial imaging is likely a sidewall bleed within the pseudocyst, and the pseudocyst can be managed without directly addressing the culprit vessel. Be cognizant of the fact that cystic neoplasms can also manifest as pseudocyst, especially in cases in which a prior history of pancreatitis is unclear.

Portal System Thrombosis

Portal system thrombosis is often asymptomatic and is typically found incidentally on imaging (Fig. 2.3). Long-term sequelae are the result of chronic portal hypertension, the most obvious of which is the formation of varices although these are rarely complicated by bleeding. Complete superior mesenteric or portal vein thrombosis can occasionally have more dramatic presentation however, including massive ascites, propagation into the mesenteric venous tributaries with bowel infarction, and encephalopathy. Good evidence for the management of portal system thrombosis in pancreatitis is lacking. We typically anticoagulate with intravenous unfractionated heparin or subcutaneous low molecular weight heparin, with a bridge to oral anticoagulation for 3 to 6 months when no further invasive procedures planned. Anticoagulation seems to be effective, with partial recanalization of the portal venous system occurring in ~3% to ~8% of patients, and complete recanalization in 34% to 87%. If recanalization occurs, it typically happens within the first 6 months, and anticoagulation beyond that point is unlikely to be effective. In case of acute symptomatic thrombosis, endovascular thrombectomy or thrombolysis can be considered, and in the very rare case with associated bowel infarction requiring laparotomy, surgical thrombectomy is an option.

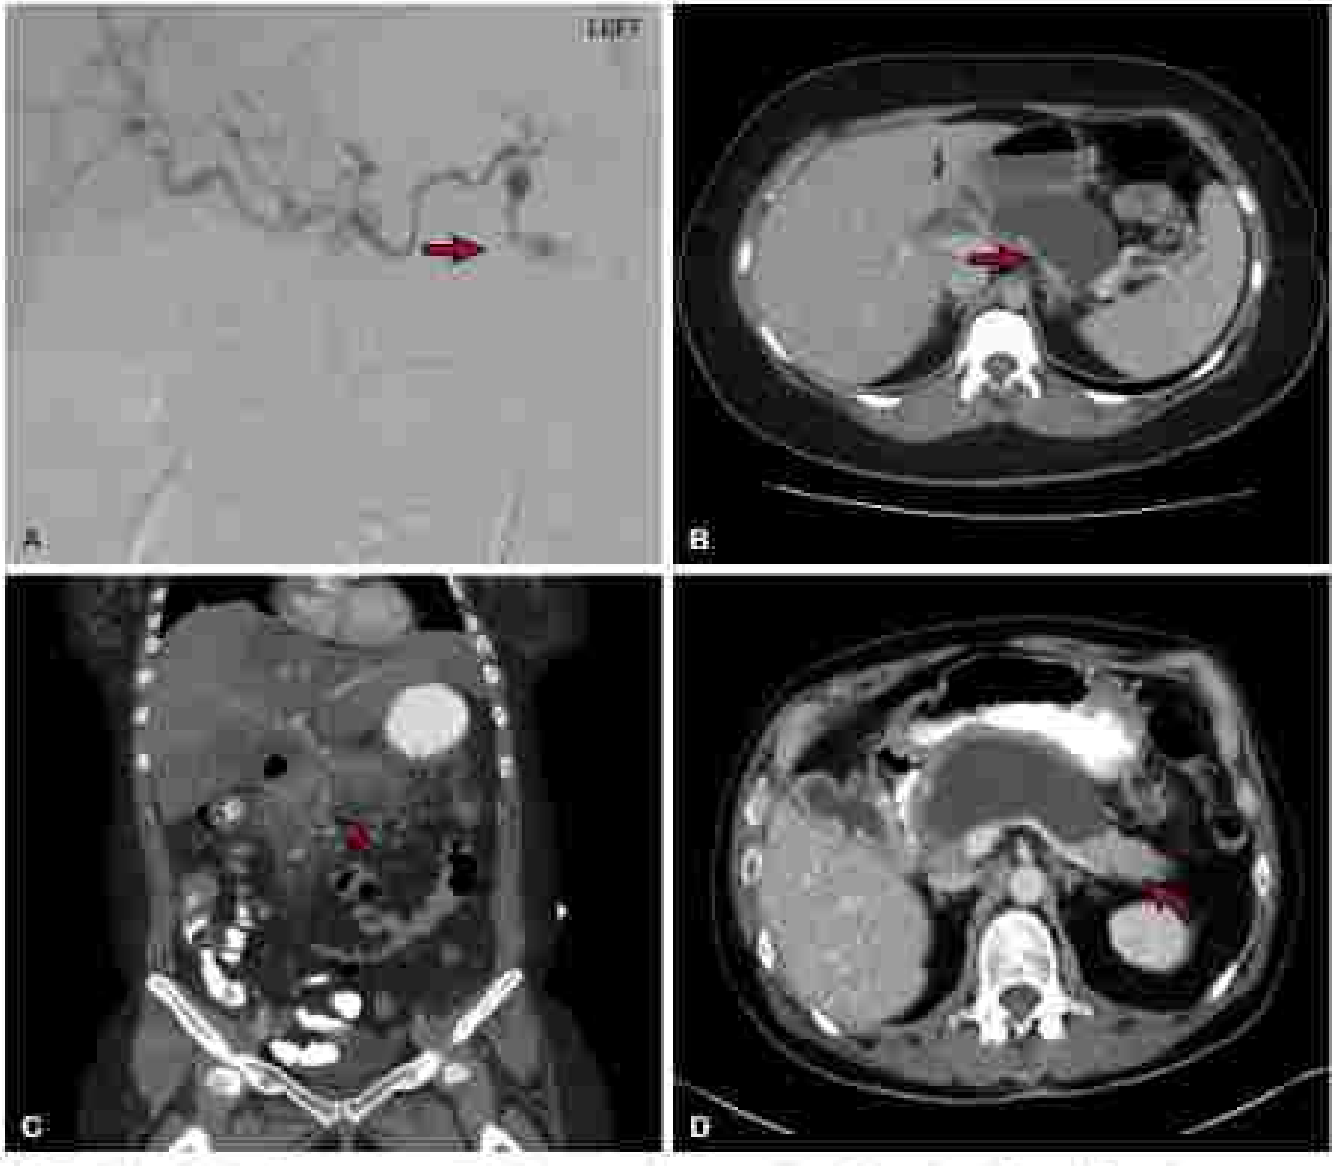

FIG. 2 Potential complications of acute pancreatitis. (A) Splenic artery pseudoaneurysm with a tiny hemorrhage [red arrow] into the stomach pseudocyst [green arrow] posterior to the stomach [red arrowhead]. (B) Superior mesenteric vein thrombosis [red arrow]. (C) "Disconnected duct syndrome." An out of the notation a "tube" segment of pancreatic tissue disconnected from the tail with a cyst at the end of a pancreatic ductal

Disconnected Duct Syndrome

The disconnected duct syndrome refers to complete necrosis of a central portion of the pancreas with associated disruption of the main pancreatic duct such that a viable tail segment is "disconnected" from any drainage pathway to the ampulla of Vater (Fig. 27). After resolution of the necrosis, this can present a number of problems including external pancreatic fistula if external drainage is in place, recurrent pseudocyst, or chronic recurrent pain resulting from obstructive pancreatitis because the disconnected segment produces exocrine secretions that have nowhere to go. If a disconnected duct is identified early in the course of pancreatitis, then the management strategy for the necrosis should incorporate some form of internal drainage (see the sections on endoscopic and surgical transgastric necrosectomy and dual modality therapy later in this chapter) to avoid prolonged external drainage. If endoscopic therapy is chosen, then soft plastic transgastric stents should be left in place indefinitely. In case of recurrent obstructive pancreatitis in the disconnected tail, endoscopic pancreatic duct stenting may be able to reestablish drainage to the ampulla. Surgical options include minimal drainage, usually into a Roux limb of jejunum, or resection of the disconnected distal segment. Distal pancreatectomy has a slightly higher rate of successful symptomatic management (90% vs 80% in one recent series) but at the cost of more intraoperative blood loss, worse long-term endocrine function, and usually splenectomy. One of the most important aspects of this syndrome is to recognize it. In our experience, many patients referred with this problem have been told "this is life after a bad episode of acute pancreatitis," sometimes for years, when in fact therapeutic options may be available.

INTERVENTIONAL MANAGEMENT

The primary indication for operative intervention in necrotizing pancreatitis is known or suspected infected pancreatic necrosis. Patients with sterile necrosis with gastric outlet or intestinal obstruction or persistent failure to thrive beyond 8 weeks may also benefit from necrosectomy and, as mentioned previously, a significant minority of them may also have occult infection. When intervention is required, it should ideally be delayed for a minimum of 4 weeks whenever possible to allow for encapsulation and demarcation of the necrosis. This waiting period applies to all of the techniques described later. The strategy for intervention for infected necrosis typically involves a step-up approach. Patients undergo percutaneous or endoscopic drainage of the infected cavity as the first intervention, with necrosectomy reserved for those who fail to improve after the initial drainage. The step-up approach is associated with less major morbidity and in some studies lower mortality rates compared with primary open necrosectomy. In 30% to 40% of cases, percutaneous or endoscopic drainage alone may obviate the need for necrosectomy. The question of when to step up should be tailored to the individual patient depending on the extent and location of the necrosis and clinical progress after initial drainage, but there are no hard criteria established for when to step up. It is worth emphasizing that the majority of patients with infected necrosis require some form of necrosectomy, not just drainage and antibiotic treatment alone. Because the step-up approach has been popularized and the number of facilities capable of percutaneous and endoscopic intervention has proliferated, it has been our impression that the misconception that drainage suffices for the management of infected necrosis has grown in parallel. This frequently results in cases in which an appropriate initial intervention (such as percutaneous drainage) is undertaken, but patients are inappropriately allowed to languish because of a failure to recognize the need to step up and debride. A complete strategic plan should be established before the initial intervention because the route and method of percutaneous drainage may dictate or limit subsequent options. Fig. 1 depicts our algorithm for selecting the optimal method of intervention. Table 3 depicts their relative strengths and weaknesses.

Video-Assisted Retroperitoneal Debridement

Video-assisted retroperitoneal debridement (VARD) is the technique most closely associated with minimally invasive necrosectomy because it was used almost exclusively in the landmark 2010 study

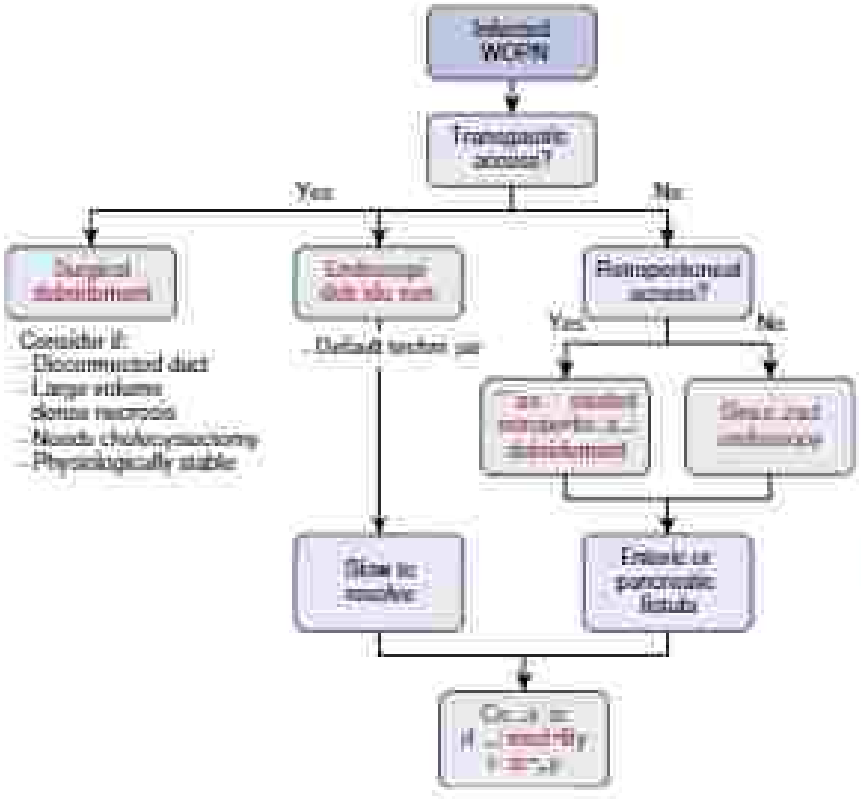

FIG. Decision algorithm for selecting the optimal interventional approach in patients with infected walled-off pancreatic necrosis. Surgical debridement refers to transgastric debridement, which can be performed open or laparoscopically. Dual modality therapy refers to a combination of endoscopic transgastric drainage and a single necrosectomy via video-assisted retroperitoneal debridement or direct endoscopy. WOPN, walled-off pancreatic necrosis.

TABLE 3 Advantages and Disadvantages of Different Approaches to Necrosectomy

	Open Transperitoneal Necrosectomy	Transgastric Necrosectomy	Video-Assisted Retroperitoneal Debridement	Sinus Tract Endoscopic Debridement
Advantages	Flexibility to access	Lacks external drainage system Endoscopic approach has decreased morbidity when compared to open necrosectomy Surgical approach allows rapid debridement and simultaneous cholecystectomy	Does not require a transgastric window Decreased morbidity compared with open transperitoneal necrosectomy Uses equipment familiar to surgeons	Flexibility to access (transperitoneal, retroperitoneal, intramural) Decreased wound morbidity compared with open necrosectomy or video-assisted retroperitoneal debridement
Disadvantages	High rates of morbidity and mortality	Requires a clear anatomic window with posterior stomach Endoscopic approach usually requires multiple reintervention	Increased wound complications compared with sinus tract endoscopic debridement Requires a retroperitoneal drainage route Pancreatic fistula	Requires familiarization with equipment (right nephroscope, intraoperative fluoroscopy) Often requires multiple interventions Pancreatic fistula

that established the step-up approach as the usual standard of care. VARD relies on a retroperitoneal drain placement as the initial intervention. This is most commonly placed via the left flank in the window between the left kidney and descending colon. If drainage alone does not resolve the infected necrosis, the drain is used as a guide for the VARD procedure. Thus, careful attention to the exact route of placement is critical and should be discussed in detail with the radiologist performing the drainage procedure.

When the decision is made to proceed with VARD, the patient is placed in a partial lateral decubitus position at a 30- to 45-degree angle, with the percutaneous drain propped into the field. A 4- to 5-cm lateral flank incision is made over the drain, and electrocautery is used for the dissection along the tract through the retroperitoneum into the necrotic cavity. It is critical for the surgeon to have diligently studied the preoperative CT scan to understand the relationship of the surrounding structures (colon, kidney, splenic vessels) to the course of the drain tract to avoid injury to them (Fig. 4). Retractors and a laparoscope are used to provide visualization. On entering the cavity, suction and irrigation are used to clear liquid debris. If the cavity is superficial enough, ring forceps can be used to excavate the necrotic material. For deeper cavities, longer right retractors are used to create a working space, and laparoscopic graspers can be used for debridement. Once debridement has been completed, drains are placed. We typically bring the drain(s) out through a separate stab incision(s) and close the initial wound in multiple layers to reduce the risk of leakage through the wound. A video of the procedure can be found at https://youtu.be/9SrPSAuwOA4.

VARD uses equipment familiar to surgeons, such as a laparoscope for visualization, as well as ring or laparoscopic forceps for debridement. Similar to open necrosectomy, VARD allows rapid and large-volume debridement of necrosis, and complete debridement is usually achievable in a single procedure. VARD has a number of limitations, however. First, there is a relatively high rate of external pancreatic fistula. Second, wound complications, although generally minor, are fairly common. Finally, it requires a retroperitoneal window that is wide and safe enough for a cadaver along the drain tract into the cavity.

Sinus Tract Endoscopic Debridement

Sinus tract endoscopic debridement (STD) is another step-up option when percutaneous drainage fails to resolve pancreatic necrosis. STD is relatively free of anatomic requirements because any necrotic collection that can be accessed percutaneously can be accessed by STD. Thus, STD is an especially good option when the optimal drainage routes into the necrosis are transperitoneal, intercostal, or through very small windows between vital structures. As with VARD, planning for STD should begin at the time of percutaneous drainage in collaboration with interventional radiology. The path of the percutaneous drain should be chosen in a manner that allows access to the entire necrotic cavity, typically by entering at one end. Positioning of the patient on the table can be supine or in partial decubitus position based on the location of the drain. The drain is cut at the skin level, and propped and draped into the surgical field (Fig. 5).

Under fluoroscopic guidance, a guidewire is threaded through the percutaneous drain into the necrotic cavity, and the drain removed over the wire. A nephrostomy balloon dilator catheter is then introduced over the wire until the tip of the balloon is within the cavity, and the balloon inflated with contrast to a pressure of 10 psi. The balloon is kept inflated for 1 minute to allow for tract dilation. Subsequently, a 30Fr working sheath is inserted over the balloon dilator catheter, and a rigid nephroscope then inserted with continuous irrigation of the cavity to facilitate visualization. A grasper is then introduced through the nephroscope and debridement performed in a systematic manner to develop a working space within the cavity. The goal is to debride until a healthy circumference of granulation tissue is identified. However, it is unnecessary and dangerous to debride necrotic tissue that is tightly adherent to the walls of the cavity because of the risk of bleeding. During sinus tract endoscopy, even minor bleeding can be problematic because it impairs visualization in the relatively small working space, especially when swirling to the irrigant. In this circumstance, the bleeding areas can be managed by packing the cavity with a half inch gauze packing strip through the sheath for a few minutes. This is often enough to allow the procedure to proceed. Advancing the sheath past the point of bleeding to "plug" and tamponade the bleeding tissue can also be effective and allow debridement to continue at a different point in the cavity. An alternative is to stop the continuous irrigation and continue the debridement in a dry fashion, so that the blood can pool on the floor of the cavity (instead of swirling in the irrigant (pictured in the video)). If complete debridement cannot be achieved at the time of the first STD, it is always safer to irrigate the cavity and return in 2 to 3 days to repeat the debridement, at which time the necrosis is typically much less adherent. Once the debridement procedure is completed, a new drainage catheter is placed over the wire before it being removed. If a repeat procedure is planned, a separate 7Fr catheter is placed adjacent to the drainage catheter to allow for continuous irrigation, which loosens tightly adherent necrotic tissue within the cavity. The drain is

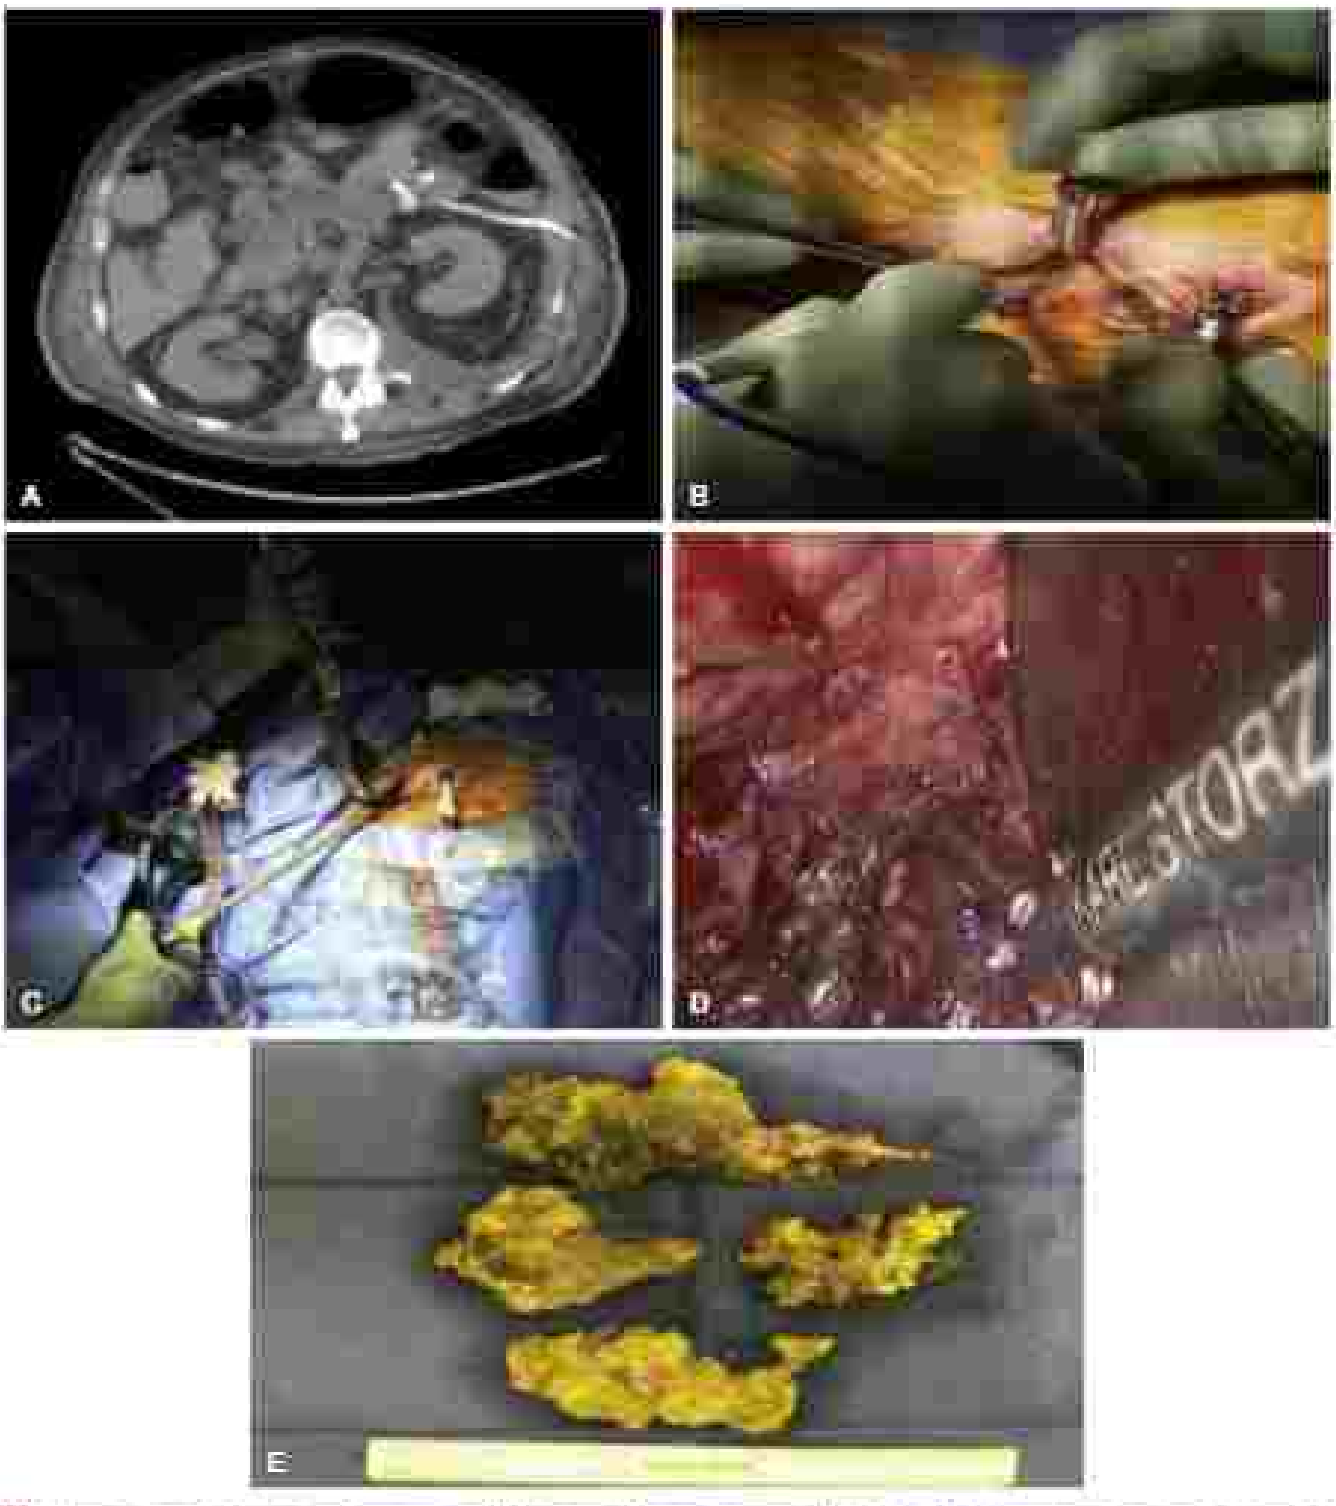

FIG. 4 Operative steps for video-assisted retroperitoneal debridement of pancreatic necrosis. (A) Axial view of the percutaneous catheter that is used as a guide as the dissection is carried out into the retroperitoneum. (B) The cut down on the percutaneous drain tract out through the bowel with electrocautery. (C) Retractors and a laparoscope are inserted through the incision into the necrotic cavity. (D) A laparoscope is used for better cavity visualization and laparoscopic graspers are used to manually debride and remove necrotic material. (E) Necrotic specimen at the end of the procedure.

FIG. 1. Operative steps for step-up minimally invasive debridement of pancreatic necrosis. (A) An Amplatz wire is inserted through the cut end of the drain into the necrotic cavity. (B) A 30Fr nephrostomy balloon dilator catheter is inserted over the wire until the tip of the balloon is within the cavity of the necrotic tissue. (C) A balloon dilator is inflated with contrast for dilation of the tract. (D) A 33Fr working sheath is inserted over the balloon into the cavity. (E) A right nephroscope is advanced into the cavity through the sheath and a grasper is passed through the nephroscope for debridement of the necrotic cavity.

then according to the skin, concluding the procedure. A full video of the procedure can be found at https://youtu.be/ed5S3-1 [1].

Aside from versatility in allowing access to almost any intra-abdominal collection, the other main advantage of STE is that wound complications are uncommon because the drain entry site is the only incision. However, STE requires familiarization with equipment not frequently used by surgeons, such as fluoroscopically guided dilators and the rigid nephroscope, and the relatively small graspers mean multiple procedures are usually required for full debridement of larger necrotic collections.

Endoscopic Transluminal Necrosectomy

Endoscopic transluminal necrosectomy is typically performed through the gastric wall but can also be done through the duodenal wall. Endoscopic transgastric necrosectomy is our preferred approach for the majority of cases where there is a clear transgastric window into the necrotic cavity, and where the burden of pancreatic necrosis is in continuity with the posterior stomach. A lumen-apposing metal stent can be placed to facilitate transluminal drainage after the initial debridement and to simplify reintervention. The primary benefits of this approach are the resultant low rate of new onset organ failure, minimal pain, and absence of an external drain, thus obviating any pancreatic fistula. The primary drawbacks are that it can only be applied to necrotic collections that are accessible through the gastrointestinal tract, and that it usually requires multiple re-interventions. Outcomes of these interventions in the Pancreatitis, Endoscopic Transgastric Versus Primary Necrosectomy in Patients With Infected Necrosis trial1 and occasionally requires other modalities to complete debridement (20% in the same trial).

Surgical Transgastric Necrosectomy

Operative transgastric necrosectomy can be performed in an open or laparoscopic fashion. It accrues the main benefit of endoscopic transgastric necrosectomy—namely the lack of external drains or pancreatic fistula—but typically does not require multiple procedures as surgical instrumentation generally allows for a more complete debridement at the initial operation. Additionally, it allows for a simultaneous cholecystectomy to be performed when required to reduce the risk of recurrence in patients with gallstone pancreatitis. By combining transgastric debridement with what essentially is a cystgastrostomy, it also allows for more durable control of high-grade pancreatic fistulas such as that with a disconnected distal remnant. As with the endoscopic approach, surgical transgastric necrosectomy should be reserved for patients whose main necrotic burden lies in the lower sac posterior to the stomach.

Dual-Modality Drainage

Dual-modality drainage consists of combining endoscopic transgastric drainage with percutaneous drainage. In the initial description, this was performed as drainage alone without necrosectomy by either approach. The result was a low mortality and low rate of external fistula but a long duration of external drainage. Combining this approach with either transgastric or minimally invasive surgical necrosectomy may reduce the overall duration of drainage. We use this combined approach in two scenarios. (1) When planned transgastric endoscopic necrosectomy reveals a large volume of dense necrosis which will require multiple endoscopic necrosectomies, but which could be efficiently and effectively managed with the larger instrumentation available surgically. (2) When a large volume of necrosis tracks away from the stomach inferiorly through the retroperitoneum or down the retrocolic gutters, which can be most efficiently addressed via a surgical retroperitoneal approach, but we wish to incorporate internal drainage to minimize the duration of external drainage and the risk of prolonged pancreatic fistula. Incorporation of internal drainage minimizes the duration of external drainage and the risk of prolonged pancreatic fistula. Essentially, dual-modality drainage accrues the main benefit of endoscopic drainage (the low rate of external fistula formation and the main benefits of surgical necrosectomy), larger instrumentation that allows more rapid debridement and the ability to access portions of the necrosis that are difficult to reach endoscopically.

Transperitoneal Necrosectomy

Although the benefits of minimally invasive approaches to necrosectomy have been largely adopted by centers managing patients with necrotizing pancreatitis, it is important to remember that open operative debridement still represents a useful tool in appropriately selected patients. Most trials supporting the use of the step up approach only enrolled patients with necrosis anatomically amenable to these interventions, and also report an unusually high mortality rate with patients undergoing open debridement (~40%), which limits the generalizability of the results to the operative group. In these studies, surgical necrosectomy was not used as part of a step up approach (there was no preoperative drainage), but using it only if percutaneous drainage failed would likely improve outcomes. A contemporary series from our institution analyzing 48 patients who underwent open necrosectomy demonstrated an in-hospital mortality rate of 8.8% despite severe disease by prognostic indices on admission. This suggests that, in part owing to advances in critical care and better understanding in the timing and indications for operative intervention, surgical transperitoneal necrosectomy remains a useful tool, especially if the expertise and resources for minimally invasive necrosectomy are not available. We still occasionally use it for patients with widespread necrosis that is not completely accessible endoscopically and percutaneously. Because the necrosis in this scenario is typically multifocal and/or encysted between vital structures, it is typically difficult to access laparoscopically, and so most of our surgical necrosectomies are done open.

RECURRENCE PREVENTION

The recurrence prevention strategy for pancreatitis is dependent on its etiology. Almost one half of all cases of acute pancreatitis are caused by gallstones, with the true prevalence likely even higher because some pancreatitis with undefined etiology may be due to unrecognized biliary sludge or microlithiasis. The risk of recurrent biliary complications from gallstones after an episode of biliary pancreatitis nears 35%; the most effective mitigation strategy is cholecystectomy, which reduces recurrence rates to 0% to 5%. In mild biliary pancreatitis, same admission cholecystectomy is the standard of care. In cases in which there are peripancreatic fluid collections, current guidelines recommend waiting until peripancreatic collections resolve, or ≥4 weeks from the onset of pancreatitis to allow the collections to organize. Cholecystectomy can generally be performed safely at the time of laparoscopic or open necrosectomy unless the biliary tree is obscured by the inflammatory mass. When using a minimally invasive step up approach to necrosis, we typically wait until the necrosis is fully treated to perform cholecystectomy; however, this delay may expose the patient to the risk of further biliary tract complications. If necessary, choledocholithiasis or cholangitis can be treated endoscopically, and acute cholecystitis can be treated with endoscopic or percutaneous decompression as a bridge to eventual cholecystectomy. In patients who are poor surgical candidates, an endoscopic sphincterotomy may be adequate prophylaxis as it reduces biliary complication rates significantly. An unknown proportion of apparently idiopathic pancreatitis cases may be caused by undetected gallstones or biliary microlithiasis. One randomized trial demonstrated a reduced incidence of recurrent pancreatitis after cholecystectomy in patients who had been evaluated for typical causes of pancreatitis, did not have an etiology identified, and were randomized to cholecystectomy or watchful waiting. The odds ratio for recurrence was 5 in the nonoperative group compared with the cholecystectomy group, and the number needed to treat was 5 to prevent an episode of recurrent pancreatitis. In patients who initially present with idiopathic pancreatitis, the decision to perform a cholecystectomy should be individualized. We currently offer cholecystectomy to idiopathic pancreatitis patients who are good surgical candidates and avoid it in poor surgical candidates when we believe the risks outweigh the potential benefits.

For patients presenting with alcoholic pancreatitis, the root cause needs to be addressed: alcohol dependence. Alcoholic acute pancreatitis is usually a result of 5 to 10 years of overconsumption of alcohol and it rarely lives an isolated binge. As such, it is prudent for surgeons to recognize that it may be beyond their means to successfully achieve behavioral change to a deep-seated habit cultivated over years. Randomized controlled trials have shown that behavioral interventions that include counseling and longitudinal assistance for associated psychosocial issues significantly decrease alcohol consumption and dependency scores. Such patients should be enrolled in institutional programs that provide the necessary support to minimize the risk of future recurrences.

Hypertriglyceridemia can typically be successfully managed with diet modification and fibrate therapy. As noted in the section on etiology, hyperparathyroidism is the most common cause of hypercalcemia-induced pancreatitis and is most commonly treated with parathyroidectomy. Finally, surgeons should be wary of the possibility of a pancreatic neoplasm as a possible etiology, especially in elderly patients or patients with "idiopathic" pancreatitis. Early stage pancreatic adenocarcinoma or ampullary neoplasms can obstruct the pancreatic duct and cause pancreatitis. Detecting them in follow up imaging may provide an opportunity to intervene and treat at an early stage.

SUMMARY

Acute pancreatitis is a common but potentially life-threatening disease. Imaging is not always necessary to establish a diagnosis and is more helpful in delineating the demarcation of necrosis from healthy tissue later in the disease process. Patients should be expeditiously fluid resuscitated early in the course of disease while remaining conscious of the potential complications of over resuscitation. Institution of an oral diet early in the course of mild pancreatitis and enteral tube feeding in severe disease form the foundation of nutritional support; parenteral nutrition being reserved for patients who cannot tolerate enteral feeding. Antibiotics should not be administered prophylactically in the absence of clinical suspicion or evidence for infection. Infected necrosis is the primary indication for nonclinical intervention in acute pancreatitis. Infection is usually diagnosed by a combination of radiographic and clinical factors. Intervention, when indicated, should be initiated with a step-up approach; decisions about the best modality and route for intervention should optimally be made by a multidisciplinary group of surgeons, interventional radiologists experienced with percutaneous drainage, and interventional endoscopists capable of endoscopic transluminal intervention. A variety of techniques are now available for interventional management of necrotizing pancreatitis and its sequelae with the different strengths and weaknesses of the alternatives as described previously. An individualized approach based on patient anatomy, physiology, and preference should be used to choose the best technique in each case to obtain optimal results.

GALLSTONE PANCREATITIS

John C. Alverdy, MD, FACS, Richard A. Jacobson, MD, and Fenna van den Esker, MD

Acute pancreatitis (AP) remains a leading cause of emergency department visits, hospital admissions, and healthcare costs worldwide. In the United States, the incidence has risen concordantly with an aging population and the increased prevalence of obesity. AP resulting from gallstones is the most common etiology in the developed world, followed by alcohol ingestion, although locoregional rates vary based on population characteristics.

In patients with mild disease, cholecystectomy should be performed during the same admission to prevent complications of recurrent disease. Twenty percent of all patients admitted with a diagnosis of AP develop severe disease for which minimally invasive therapy and interventional procedures other than cholecystectomy may be appropriate. In this latter population, the surgical community has been slow to fully adopt more minimally invasive techniques that are associated with lower morbidity and improved survival.

EPIDEMIOLOGY

AP accounts for more than 300,000 emergency department visits and contributes to roughly 3400 deaths per year in the United States. More than US$2.5 billion are spent annually on the treatment of AP and its complications. Gallstone pancreatitis (GSP) is the most common etiology, accounting for up to 60% of all cases, followed by alcoholic AP. Risk factors for GSP are patient related, stone related, or anatomic. Factors such as age, female gender, gallstones smaller than 5 mm, biliary sludge, 20 or more gallstones, and a large cystic duct diameter have been demonstrated to influence the incidence, course, and outcome of the disease.

PATHOPHYSIOLOGY

The molecular pathophysiology of GSP is defined by inappropriate and excessive activation of intrapancreatic processes that lead to autodigestion of the pancreatic tissue. The subsequent inflammatory response results in local and systemic complications of AP as outlined in the following section. Anatomically, it is recognized that obstructive biliary events incite this cascade of pancreatic inflammation and autodigestion; however, the full process is incompletely understood. Three leading theories include: (1) obstruction of the sphincter of Oddi leading to back pressure and stasis in the pancreatic duct; (2) bile reflux into the pancreatic duct; and (3) duodenal contents refluxing into the pancreatic duct. Irrespective of these mechanical events, the burst of protease activation that follows is what damages the pancreatic acini, which in some cases leads to ductal disruption, local inflammation, secondary infection, and all subsequent complications.

Infection of a peripancreatic fluid collection or necrotic pancreatic parenchyma is the leading cause of morbidity and mortality in AP. Importantly, these are not primary necrotizing infections that destroy pancreatic tissue, but rather secondary infections by translocated bacteria presumed to originate from the gastrointestinal tract. The morbidity and mortality associated with infected pancreatic necrosis has resulted in several attempts to prevent the translocation of intestinal bacteria with prophylactic intravenous antibiotics, selective digestive decontamination with oral antibiotics, or probiotic regimens. The timing, dose, route, and utility of such antibiotic-altering regimens remains controversial in GSP.

CLINICAL PRESENTATION

Patients presenting with AP appear constitutionally similar to those in septic shock. They often appear unwell and complain of acute onset, constant visceral type pain in the epigastrium, usually

SUMMARY

Acute pancreatitis is a common but potentially life-threatening disease. Imaging is not always necessary to establish a diagnosis and is more helpful in delineating the demarcation of necrosis from healthy tissue later in the disease process. Patients should be expeditiously fluid resuscitated early in the course of disease while remaining conscious of the potential complications of over resuscitation. Institution of an oral diet early in the course of mild pancreatitis and enteral tube feeding in severe disease form the foundation of nutritional support; parenteral nutrition being reserved for patients who cannot tolerate enteral feeding. Antibiotics should not be administered prophylactically in the absence of clinical suspicion or evidence for infection. Infected necrosis is the primary indication for mechanical intervention in acute pancreatitis. Infection is usually diagnosed by a combination of radiographic and clinical factors. Intervention, when indicated, should be initiated with a step-up approach; decisions about the best route and route for intervention should optimally be made by a multidisciplinary group of surgeons, interventional radiologists experienced with percutaneous drainage, and interventional endoscopists capable of endoscopic transluminal intervention. GALLSTONE PANCREATITIS

John C. Alverdy, MD, FACS, Richard A. Jacobson, MD, and Fons van der Berg, MD

Acute pancreatitis (AP) remains a leading cause of emergency department visits, hospital admissions, and healthcare costs worldwide. In the United States, the incidence has risen concordantly with an aging population and the increased prevalence of obesity. AP resulting from gallstones is the most common etiology in the developed world, followed by alcohol ingestion, although locoregional rates vary based on population characteristics.

In patients with mild disease, cholecystectomy should be performed during the same admission to prevent complications of recurrent disease. Twenty percent of all patients admitted with a diagnosis of AP develop severe disease for which intensive care therapy and interventional procedures other than cholecystectomy may be appropriate. In this latter population, the surgical community has been slow to fully adopt more minimally invasive techniques that are associated with lower morbidity and improved survival.

EPIDEMIOLOGY

AP accounts for more than 300,000 emergency department visits and contributes to roughly 3400 deaths per year in the United States. More than US$2.5 billion are spent annually on the treatment of AP and its complications. Gallstone pancreatitis (GSP) is the most common etiology, accounting for up to 60% of all cases, followed by alcoholic AP. Risk factors for GSP are patient related, stone related, or anatomic. Factors such as age, female gender, gallstones smaller than 5 mm, biliary sludge, 20 or more gallstones, and a large cystic duct diameter have been demonstrated to influence the incidence, course, and outcome of the disease.

PATHOPHYSIOLOGY

The molecular pathophysiology of GSP is defined by inappropriate and excessive activation of intrapancreatic processes that lead to autodigestion of the pancreatic tissue. The subsequent inflammatory response results in local and systemic complications of AP as outlined in the following section. Anatomically, it is recognized that obstructive biliary events incite this cascade of pancreatic inflammation and autodigestion; however, the full process is incompletely understood. Three leading theories include: (1) obstruction of the sphincter of Oddi leading to back pressure and stasis in the pancreatic duct; (2) bile reflux into the pancreatic duct; and (3) duodenal contents refluxing into the pancreatic duct. Irrespective of these mechanical events, the burst of protease activation that follows is what damages the pancreatic acini, which in some cases leads to ductal disruption, local inflammation, secondary infection, and all subsequent complications.

Infection of a peripancreatic fluid collection or necrotic pancreatic parenchyma is the leading cause of morbidity and mortality in AP. Importantly, these are not primary necrotizing infections that destroy pancreatic tissue, but rather secondary infections by translocated bacteria presumed to originate from the gastrointestinal tract. The morbidity and mortality associated with infected pancreatic necrosis has resulted in several attempts to prevent the translocation of intestinal bacteria with prophylactic intravenous antibiotics, selective digestive decontamination with oral antibiotics, or probiotic regimens. The timing, dose, route, and utility of microbiome-altering regimens remain controversial in GSP.

CLINICAL PRESENTATION

Patients presenting with AP appear constitutionally similar to those in septic shock. They often appear unwell and complain of acute onset, constant visceral type pain in the epigastrium, usually

radiating to the back. Associated symptoms include nausea and vomiting. The pain is exacerbated by oral intake and may be relieved when the patient leans forward. Other diagnoses to be considered are acute cholecystitis, choledocholithiasis, and peptic ulcer disease.

On examination, patients can present with tachycardia driven, in part, by the pain associated with AP in mild cases or by severe hypovolemia in more moderate to severe cases. Low grade fevers are common and not necessarily indicative of an acute infectious process. Abdominal tenderness can be a prominent finding on physical examination. The presence of bruising in the flank areas, umbilicus, or inguinal regions indicates hemorrhagic pancreatitis that has resulted in dissection of blood along the retroperitoneal planes. The presence of fever, jaundice, or scleral icterus may indicate obstructive choledocholithiasis or cholangitis.

DIAGNOSIS

The diagnosis of GSP is generally made in the emergency setting and is based on clinical, radiographic, and biochemical factors. Blood chemistries suggestive of AP in the setting of gallstones documented by ultrasound usually confirm the diagnosis. The pancreatic enzymes amylase and lipase are usually elevated in patients with AP. Sensitivity and specificity of these assays depends on the specific enzyme measured and the threshold used to define a positive test. Amylase is considered nonspecific, whereas lipase is considered specific for AP, but neither delineates GSP from other etiologies. Most centers use a threshold of positivity defined as three to four times the normal value; however, the duration of symptoms should be considered when interpreting levels of these enzymes. Other circulating factors such as C-reactive protein and interleukin-6 have been validated as useful markers of the severity of AP, but they do not discriminate AP from other inflammatory or infectious processes. Elevated alanine aminotransferase or lymphocyte/neutrophil ratio may distinguish GSP from other etiologies of AP; however, this distinction is generally based on the absence of a history of alcohol abuse and evidence of obstructing biliary stones or sludge on imaging. Other markers of the acute phase response induced by AP such as interleukin-8 have been validated to rise in the setting of AP but are uncommonly used in clinical practice.

Ultrasound is the initial imaging test of choice as it is a noninvasive and highly sensitive test to detect the presence of gallstones. Because patients with GSP may present with a significant ileus, the sensitivity of ultrasound may be decreased by overshadowing of bowel gas. A limitation of ultrasound in this setting, however, is that it cannot assess the severity of pancreatic inflammation and therefore contrast-enhanced computed tomography (CT) is the test of choice to determine the extent of the AP. Ideally, a pancreas protocol CT with arterial and portal phases is most useful to delineate the degree of inflammation and disruption of the pancreatic parenchyma and main duct. Most authors recommend a CT scan at least 72 hours after the onset of symptoms because radiographic signs of local complications may not be evident before this and therefore are not actionable. On CT, peripancreatic edema (in the anterior pararenal space, transverse mesocolon, or small bowel mesentery), fat stranding, or nonenhancement of the pancreatic parenchyma (indicating necrosis) are indicative of AP.

Severity

The severity of GSP is a function of the degree of acute cholecystitis and the degree of pancreatic necrosis and inflammation that is present. Most often, the gallbladder is not inflamed because the disease is more of a consequence of the migration of gallstones into the common bile duct than acute gallbladder inflammation. However, it is important to recognize the severity of both as an important aspect of the treatment strategy. Stratification by severity is of prognostic value and predicts which patients will require intensive care and invasive drainage procedures. The severity of systemic inflammation generally dictates the need for intensive care monitoring and can usually be assessed on admission. Although most patients present with mild or moderate disease, up to 20% of patients can present with severe AP as defined by the 2012 revision of the Atlanta criteria (Table 1). This revision classifies organ dysfunction as transient (<48 hours) or persistent. When organ failure develops, the systems most commonly affected are the respiratory, renal, and cardiovascular systems (to this order). Dysfunction is defined by the Marshall criteria (Table 2).

TABLE 1 Severity of AP According to 2012 Revision of the Atlanta Criteria

Severity	Characteristics
Mild	No organ failure No local or systemic complications
Moderately severe	Transient organ failure (<48 hours) Local or systemic complications without persistent organ failure
Severe	Persistent organ failure

TABLE 2 Organ Failure as Defined by the Marshall Criteria

Organ system	Criteria for failure
Pulmonary	PaO_2/FiO_2 ratio ≤300
Renal	Serum creatinine >1.9 (if normal at baseline)
Cardiovascular	SBP <90 mm Hg, not responsive to fluids

From Marshall JC. A scoring system for multiple organ failure (or dysfunction). *Arch Surg*. 1995;130:871–872.
SBP, systolic blood pressure.

As many as 20% of patients with severe AP (SAP) will progress to develop necrotizing disease of the pancreas or peripancreatic tissues. Up to 70% of these patients can develop infected necrosis, which will significantly complicate their course and worsen their prognosis. This so-called rule of 20s (20% of all AP is severe, 20% of SAP is necrotizing, 20% of necrotizing disease develops infection) is a useful clinical pearl.

MANAGEMENT: INITIAL TREATMENT

Patients diagnosed with GSP are admitted to the hospital and, if determined to have severe disease, will require monitoring in an intensive care unit. Aggressive fluid resuscitation, preferably with lactated Ringer's solution, remains the cornerstone of initial management and is recommended for all patients. Pain should be managed adequately with standard-of-care protocols. Patients presenting with mild AP should resume oral intake as early as is feasible once the pain is resolving. Initiation of enteral feeding, be it with oral intake or nasoenteric feeding of a chemically defined diet, has been shown to have an adverse effect on the natural history of pancreatitis even when the feeding is jejunally tolerated, at which point it can be discontinued. The Pancreatitis, Very Early Compared with Selective, Delayed Start of Enteral Feeding trial compared very early with on-demand enteral feeding in patients with predicted severe pancreatitis and found no difference in infectious complications or death. Tube feeding, either nasogastric or nasojejunal, should be reserved for patients that do not respond to a trial of oral nutritional intake.

An absolute indication for an emergency endoscopic retrograde cholangiopancreatography (ERCP) with endoscopic sphincterotomy (ES) is acute cholangitis. Evidence indicates that mild GSP does not warrant ERCP. The risks of the procedure itself coupled with the likelihood of spontaneous passage of gallstones and/or sludge diminishes enthusiasm for an aggressive approach using ERCP in GSP. Whether ERCP with ES should be applied in cases of severe

GSP remains controversial and will require further research before it is recommended.

SYSTEMIC COMPLICATIONS OF GSP

In severe GSP, persistent multiple organ failure is a dreaded complication that warrants admission to an intensive care unit and treatment by both critical care specialists and pancreatic surgeons. Persistent organ failure in the first 2 weeks of admission is a function of a dysregulated systematic inflammatory response, an altered microbiome, and thus immune dysregulation. Late onset sepsis associated with highly resistant and virulent pathogens generally occurs after 2 weeks when necrotizing organ dysfunction mandates dialysis, ventilator support, vasopressors, total parenteral nutrition, and multiple antibiotics. The initial hyperinflammatory response can develop into an immunosuppressive state, allowing highly resistant healthcare associated pathogens opportunity to cause life threatening infected pancreatic necrosis, pneumonia, urinary tract infections, catheter-associated bloodstream infections, and spontaneous bacteremias. Continuous vigilance is imperative for these infections and application of multiple infection control measures such as daily chlorhexidine baths, oral hygiene, and enteral nutrition are useful.

Necrotizing Gallstone Pancreatitis

Patients who develop necrotizing GSP should be managed in specialty centers where an experienced interdisciplinary team of surgeons, gastroenterologists, and interventional radiologists are available. Secondary bacterial infections that invade the necrotic pancreas can arise from multiple sources and can lead to infected pancreatic necrosis (IPN), a dreaded and often fatal complication with mortality rates as high as 30% and reaching nearly 100% when endoscopic, radiologic, or surgical services are not immediately available. The diagnosis of IPN is made by the presence of gas in the peripancreatic collections seen on CT scan, ultrasound, or endoscopic ultrasound with or without fine needle aspiration confirming the presence of bacteria. Clinical suspicion of IPN is based on new onset of organ failure after 2 weeks of hospital admission combined with fever and rising inflammatory markers in the absence of other infectious foci. Confirmed infection by fine needle aspiration is not mandatory for treatment but is useful to guide antibiotic treatment. ...ost antibiotic treatment targets presumptive organisms because cultures often do not represent all pathogens present in a given sample. It is preferable to use antibiotics with a known penetration profile into the pancreatic parenchyma and necrotic pancreatic collections.

Because the gallbladder per se is noninflamed in most cases of GSP, treatment strategies are largely similar to those of nonbiliary AP. The past several decades of experience have taught surgeons that the longer surgery can be safely delayed, the more favorable the outcome. Aggressive, early surgical intervention for SAP is no longer recommended because of the attendant high mortality rates associated with this approach. The step-up approach (first described in the Pancreatitis, Necrosectomy versus Step-up Approach [PANTER] trial in 2010) is recommended and follows international guidelines that have become the standard of care. Briefly, management of IPN consists of percutaneous catheter drainage, followed by video assisted retroperitoneal debridement (VARD) and failing that, necrosectomy. The PANTER trial showed that the step-up approach significantly decreased mortality and major complications, including new onset multiple organ failure, perforation of a visceral organ, bleeding, and/or the development of an enterocutaneous fistula. Aggregate complications were decreased from 69% for open necrosectomy to 40% for patients in the step-up group. A management algorithm based on step-up therapy is illustrated in Fig. 1. The more recent Transluminal Endoscopic Step-up Approach Versus Minimally Invasive Surgical Step-up Approach in Patients With Infected Pancreatic Necrosis superiority trial compared an endoscopic with a surgical step-up approach, with the former consisting of endoscopic ultrasound guided transluminal drainage followed by endoscopic necrosectomy. There was no difference in mortality and major complications; however, the endoscopic step-up was associated with a reduced incidence of pancreatic fistulas and a reduction in length of hospital stay. Centers with immediate access to interventional endoscopists experienced in this procedure are encouraged to use this approach. The optimal timing of intervention is still unclear; the ongoing Postponed or Immediate Drainage of Infected Necrotizing Pancreatitis trial is comparing early with postponed drainage until the infected collections are completely walled off, which is the current standard of care.

The first step in surgical step-up management is CT guided percutaneous catheter drainage, preferably through the left retroperitoneum to later facilitate thorascopic access for the VARD procedure, if indicated. Furthermore, because the catheter remains in the retroperitoneal space, it avoids contamination of the abdominal cavity. If sepsis persists and drainage is deemed to be inadequate, drains should be upsized to the largest size available. Repeat imaging and the clinical course should dictate whether further drainage is indicated. In this circumstance, a VARD procedure can be performed to facilitate more complete source control. A 5 cm incision is made to the left flank at the drain site and the retroperitoneal space is accessed for debridement of necrotic tissue under direct vision. Laparoscopic instruments are introduced in the cavity for debridement, irrigation, and suction. The catheter drain is removed, replaced by two surgical drains, and lavaged as needed. This hybrid minimal invasive procedure reduced major complications and mortality to 35% and 13%, respectively, compared with 54% to 95% and 11% to 39% in open necrosectomy.

Although open and retroperitoneal laparoscopic necrosectomy were once considered standard of care, today these approaches have become outdated in favor of VARD. However, if indicated during an intraabdominal emergency, an open or an intraabdominal laparoscopic approach can be used. Several endoscopic techniques have been described, and the major interventions for IPN are increasing in popularity owing to their minimally invasive nature. The first step is the endoscopic ultrasound guided placement of transgastric or transduodenal stents to provide temporary decompression and drainage. If further intervention is needed, the stents can be used as guides to facilitate endoscopic necrosectomy. Recent innovations in stents, such as the lumen-apposing metal stent, make it possible to safely drain collections even when the distance between the gastric or duodenal wall and necrotic collection exceeds 1 cm. The established tract can be used for endoscopic debridement of the necrotic cavity.

Prophylactic Interventions for Infectious Complications

The mechanism by which pancreatic collections and parenchymal necrosis become infected remains speculative, but it is hypothesized to occur from intestinally derived bacterial and fungal pathogens. Clinically, bacteremia does not occur in most cases and therefore the route by which pathogens travel from the gut to the necrosis remains unknown. The "Trojan horse" hypothesis suggests that pathogens enter neutrophils or macrophages, which then silently home to pancreatic tissues. These conditions of the pancreas with pancreatitis or necrosis are receptive to these bacteria carrying immune cells, which can lodge and release their infectious payload into pancreatic tissue, causing infection. Such processes may explain why many patients develop infected necrosis late after the acute inflammatory process has abated and when blood cultures are negative. Further work will be needed to establish causality of such a mechanism. The gut is considered the origin of pathogens that cause IPN. However, attempts to preemptively eliminate potentially translocating pathogens have been tested with controversial results. In general, neither selective digestive decontamination nor aggressive intravenous antibiotics are recommended to achieve this because of the inability to completely delineate the gut and for fear of emergence of antibiotic resistance. Thus, the role of prophylactic

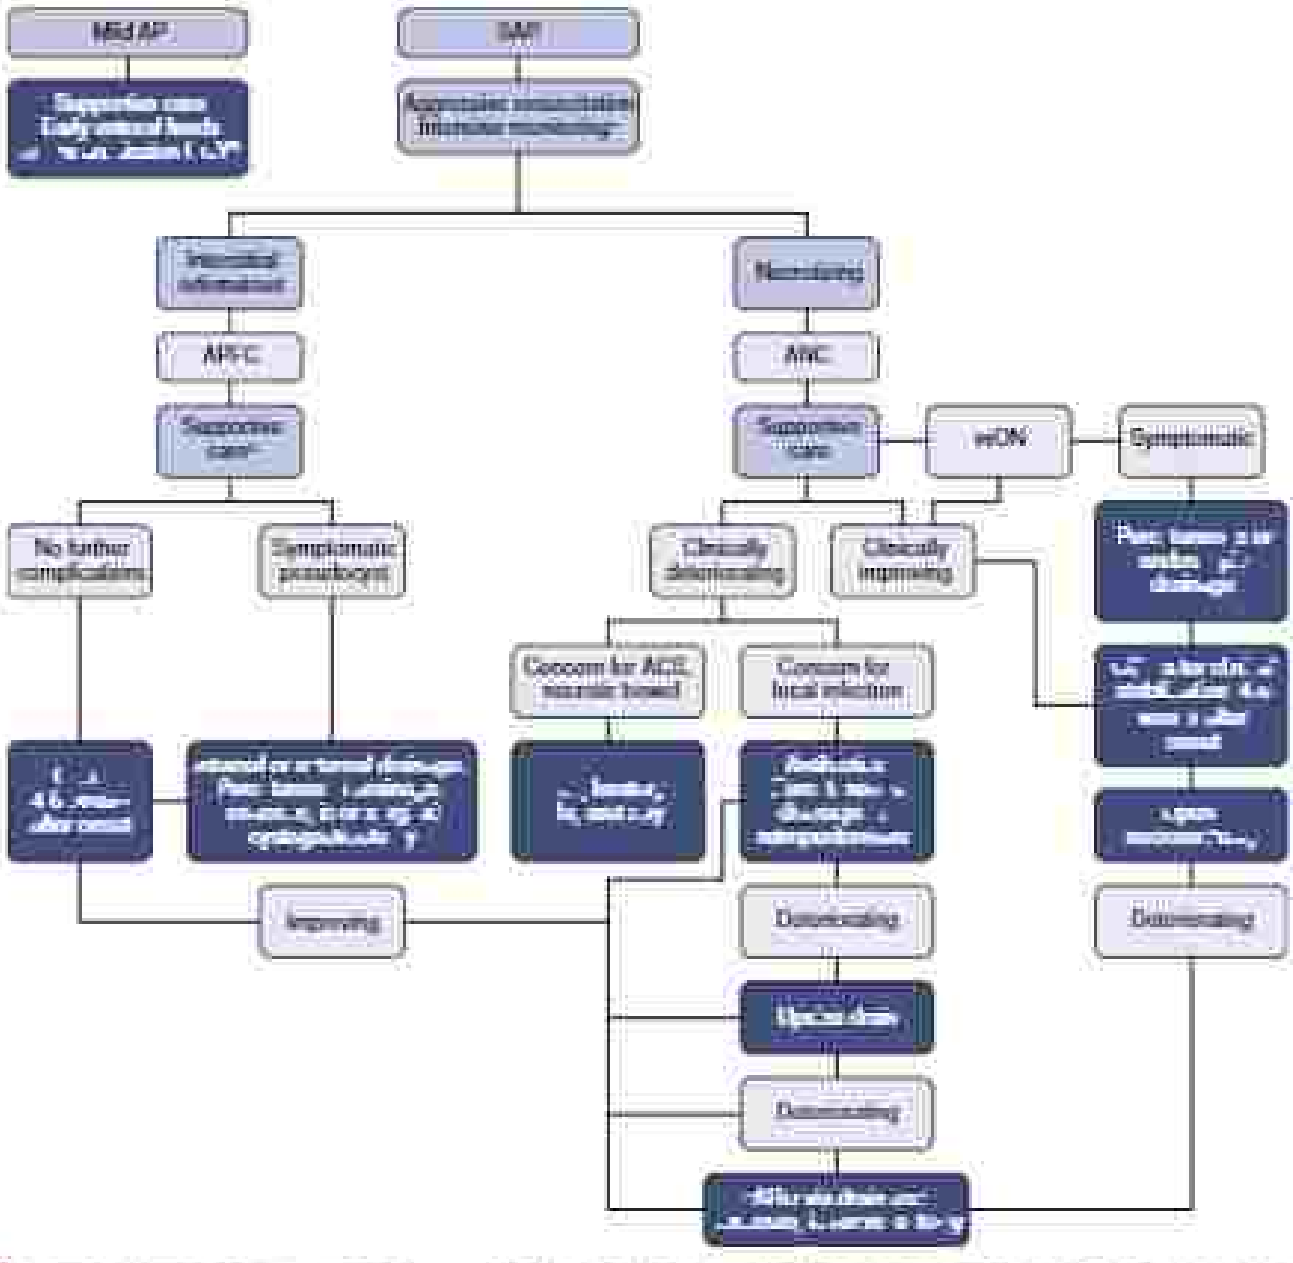

FIG. [illegible]

antibiotics in SAP or GSP in the absence of cholangitis remains debated. Once infected SAP is confirmed or suspected, antibiotics are indicated.

Probiotics have been tested in severe AP as a strategy to contain potential pathogens that drive systemic inflammation, translocate, and cause IPN. The use of probiotics has been shown to have a beneficial effect on the outcome of pancreatitis in animal models and small human studies. However, a randomized controlled trial designed to evaluate the efficacy of Prophylactic Probiotics in Patients With Predicted Severe Acute Pancreatitis demonstrated an increase in mortality in the treatment group presumed to be due to bowel ischemia. Prophylactic treatment with probiotics is therefore contraindicated in the treatment of pancreatitis. Possible explanations for these paradoxical results may involve the choice of bacteria in the probiotic mixture, the route of administration (oral feeding) or an inappropriate metabolic microenvironment. Fecal microbiota transplantation is an emerging research field and could potentially be applied to prevent infections in SAP.

FOLLOW-UP

Among the most contentious aspects of the treatment of GSP beyond halting the progression of the pancreatitis is the timing of the cholecystectomy. If the presentation of GSP is mild and the

TABLE 3 Current Trials

Population	Intervention	Outcomes	Country
Mild AP	Rectal indomethacin	Systemic inflammatory markers, organ failure, disease progression	UK
Mild AP	Cholecystectomy within 72 hours of onset	Hospital stay, perioperative complications	Chile
All AP	Contrast-enhanced CT with additional image processing	Microvascular permeability markers as predictors of severe disease	France
SAP	Early percutaneous drainage of sterile acute peripancreatic collections	Mortality, secondary infection, hemorrhage, fistula formation	China
SAP	Goal-directed fluid resuscitation based on PiCCO parameters	Organ failure, change in APACHE II score, ICU days	Germany
SAP	Fecal microbiota transplant via nasojejunal route	Mortality, infectious complications, inflammatory markers	China (3 separate trials)
SAP	Oral ketorolac	Inflammatory markers, organ failure, local complications	Iran
AP with SIRS	Experimental compound CM-8620	Drug safety, radiographic disease severity	USA
Necrotizing AP	Pancreatic duct stenting 1–2 weeks after the onset of symptoms	Incidence of walled-off necrosis, rates of intervention, procedural complications	USA
Necrotizing AP	Early drainage of necrotic collections before walling off	Mortality, major complications, length of stay	The Netherlands
Predicted SAP without cholangitis	Early ERCP	Mortality, major complications, length of stay	The Netherlands
Idiopathic pancreatitis	Diagnostic endoscopic ultrasound	Incidence of previously undetected gallstone disease	The Netherlands

AP, acute pancreatitis; APACHE, Acute Physiology, Age, Chronic Health Evaluation; CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; ICU, intensive care unit; PiCCO, pulse contour cardiac output; SAP, severe acute pancreatitis; SIRS, systemic inflammatory response syndrome.

pancreatitis resolves over a few days, cholecystectomy with intraoperative cholangiogram is recommended. If choledocholithiasis is found during cholecystectomy, postoperative ERCP with ES is a safe and effective treatment. Although intraoperative common bile duct exploration, lithotripsy, and stone removal are possible, in most institutions, postoperative ERCP is performed. In many cases of moderate to severe pancreatitis, cholecystectomy is deferred. Imaging with magnetic resonance cholangiopancreatography as an outpatient to rule out the need for ERCP once the pancreatitis and its sequelae have resolved can be useful. If the pancreatitis has been severe, however, cholecystectomy too soon after the acute episode is risky and complicated because of ongoing inflammation and scarring. Clinical judgment as to the timing of the cholecystectomy must be judiciously applied. Given the clear advantages of laparoscopic cholecystectomy over open cholecystectomy, the risk of an open procedure if surgery is planned too soon following recovery should be noted.

The Pancreatitis of Biliary Origin, Optimal Timing of Cholecystectomy trial compared same admission versus interval cholecystectomy (after 25–30 days) in mild AP and showed a significant reduction in recurrence in favor of same admission cholecystectomy. For reasons mentioned previously, it is advisable to postpone cholecystectomy in cases of necrotizing pancreatitis until the time at which all collections are either successfully drained or sufficiently walled off and the patient is fully stable and eating. In cases in which gallstones are suspected but not observed, performing an ERCP or magnetic resonance cholangiopancreatography as a method to identify microlithiasis and/or biliary sludge may be useful. If positive, cholecystectomy should be performed to prevent recurrence. Patients with recurrent idiopathic pancreatitis should be referred for genetic counseling and evaluation for autoimmune pancreatitis. Finally, pancreatic insufficiency of either endocrine or exocrine function can occur after a bout of GSP. Timely recognition and treatment of these complications are needed to prevent complications from diabetes and malnutrition in those patients that develop chronic disease.

CURRENT TRIALS

At least 32 trials are actively enrolling patients in interventional or prognostic studies of GSP (Table 3).

Pancreas Divisum and Other Variants of Dominant Dorsal Duct Anatomy

David L. Adams, MD, and Gregory A. Coté, MD, MS

There struggles are used in the surgical management of biliary and pancreatic disorders of the pancreas: improve drainage, resect damaged tissue, or combine the first two with a simultaneous resection and drainage procedure. These principles apply to the management of recurrent acute pancreatitis and chronic pancreatitis associated with dominant dorsal duct anatomy, which is more commonly called pancreas divisum. The prudent surgeon always remembers that pancreas divisum is as common as left handedness: 10% of the population has pancreas divisum. The anatomic variant known as pancreas divisum develops in the boxy 6 week old embryo (Fig. 1). Migration, rotation, and vascularization are happening everywhere in the 6- to 8-week embryonic foregut. During this developmental period, the dorsal and ventral pancreatic buds fuse and realign their ductal systems. In the usual fusion of the ductal system, the ventral duct or duct of Wirsung becomes the main pancreatic duct (Fig. 2A–B). The dorsal duct, the duct of Santorini, is the minor duct (Fig. 2A). When dorsal and ventral ductal fusion is incomplete, the duct of Santorini drains the majority of the pancreas through an orifice that is notably smaller than the orifice of a normal sphincter of Oddi (Fig. 2C–D). The duct of Santorini may have a narrow filamentous pathway to the duct of Wirsung or may drain a portion of the head independently (Fig. 2E). Hence the concept was promulgated in the 1970s that in pancreas divisum there is an anatomic impediment to the normal drainage of pancreatic exocrine secretions, which results in an obstructive pancreatopathy.

In pancreas divisum, which is the main pancreatic duct? Avoiding the descriptor "main" prevents confusion in discussion of pancreas divisum. When divisum anatomy is present, the dorsal duct, formerly known as the duct of Santorini, is called the "*[illegible]* duct". The terms *complete* (fusion) and *incomplete* (fusion) have been used to describe variants of pancreatic ductal anatomy associated with dominant dorsal duct anatomy. Complete divisum typically denotes a dominant dorsal duct with no vestigial communication to the ventral system (duct of Wirsung). Incomplete divisum denotes a dominant dorsal duct with a residual, albeit minuscule, communication between the dorsal duct and the ventral duct. Variations of the dominant dorsal duct are many and infrequent enough that radiologic and endoscopic delineation may be confusing. The classic radiographic image has the dominant pancreatic duct crossing the terminal bile duct and entering the descending duodenum (Fig. 3). Usually a small ductal system drains the ventral head of the pancreas and enters the duodenum through the major papilla with the terminal bile duct. Be aware of the entity called *[illegible] pancreatitis*, which is associated with chronic pancreatitis and malignancy. Either process may result in total occlusion of the ventral duct, causing the duct of Santorini to assume responsibility for pancreatic exocrine outflow via the minor papilla. Whenever there is a question of acquired pancreas divisum (also called *pseudodivisum*) without a demonstrated mass on magnetic resonance imaging (MRI) or computed tomographic scan (CT scan), endoscopic ultrasound (EUS) scan should be undertaken to rule out malignancy.

In the nineteenth century, ductal surgeons were commonly valvulotomists. In the twentieth century, physiology was of increasing importance to the innovative surgeon. The twenty first century has seen the addition of molecular biology to the management of surgical disorders. The history of the understanding and treatment of pancreas divisum has followed a similar pathway. In the past, pancreas divisum was labeled a congenital anomaly that could cause obstructive pain and pancreatitis. With the development of diagnostic endoscopic retrograde cholangiopancreatography (ERCP) in the 1970s, idiopathic recurrent pancreatitis was attributed to pancreas divisum, and became a target for surgical management with dorsal sphincterotomy and minor duct sphincteroplasty. As therapeutic endoscopy developed, endoscopic minor duct sphincterotomy or papillotomy supplanted the open surgical approach. Although sphincteroplasty was successful in the majority of patients in early studies, long term failures became evident, improving patient selection based on physiologic and anatomic parameters with measurement of pancreatic ductal response and exocrine output to hormonal stimulation of the exocrine pancreas was used. However, early optimism of improving patient selection via physiologic assessment did not meaningfully improve long term outcomes.

Chronic pancreatitis and acute recurrent pancreatitis are disorders that lack strong evidence on which surgical practice can be based. Many other similar "gray zone" disorders are multifactorial in origin. Scurvy is a disease with a single and simple cause that can be cured with vitamin C. If chronic pancreatitis were like scurvy and had a single cause, it would be easily curable. Chronic pancreatitis has many known risk factors, many of which are overlapping, such as alcohol and smoking. Anatomic, environmental, and genetic factors are likely to interact with the divisum phenotype in causing or contributing to pancreatitis. Pancreas divisum is clearly associated with a higher prevalence of genetic mutations that predispose to pancreatitis; this has led to the current concept that pancreas divisum is not a cause of pancreatitis by itself but acts as a partner with genetic mutations. In patients with idiopathic pancreatitis, pancreas divisum is not an independent risk factor when compared with controls without pancreas divisum. However, pancreas divisum frequency is higher in patients with genetic mutations and pancreatitis, especially those with CFTR mutations or polymorphisms, suggesting a cumulative effect of these two disorders. SPINK1 and PRSS1 functional genetic anomalies are also associated with pancreas divisum and in the recurrent and chronic pancreatitis.

DIAGNOSIS

The clinical presentation of pancreatitis associated with dominant dorsal duct anatomy has two phenotypes: acute recurrent pancreatitis and chronic pancreatitis. Current concepts suggest that the former leads to the latter. Rarely does chronic pancreatitis associated with pancreas divisum result in severe fibrosing pancreatitis associated with biliary, duodenal, or sphincter vessels obstruction. Pain intractable to medical management is the main reason patients with pancreas divisum seek the help of surgeons and gastroenterologists. Patients with acute pancreatitis associated with pancreas divisum present in the same manner as patients with other etiologies for pancreatitis. Pain that triggers nausea and vomiting is the predominant symptom. The pain is notable for its intensity, character, and location. Patients localize the pain to the epigastrium with radiation into the retroscapular region. Pain is commonly characterized by the sensation of someone twisting a knife in the upper abdomen. The pain is often rated as 11 on a scale of 1 to 10. Serum lipase is elevated, as may be the leukocyte count and other inflammatory serologic markers. When the acute illness is severe, pancreatic and peripancreatic inflammatory changes will be seen on CT scan and MRI studies. If pancreatic necrosis develops in the presence of pancreas divisum, other pancreatitis risk factors should be considered. It is uncommon for acute pancreatitis associated with pancreas divisum to lead to pancreatic and peripancreatic necrosis. The usual course is that of a self limited illness that resolves with expectant, nonoperative

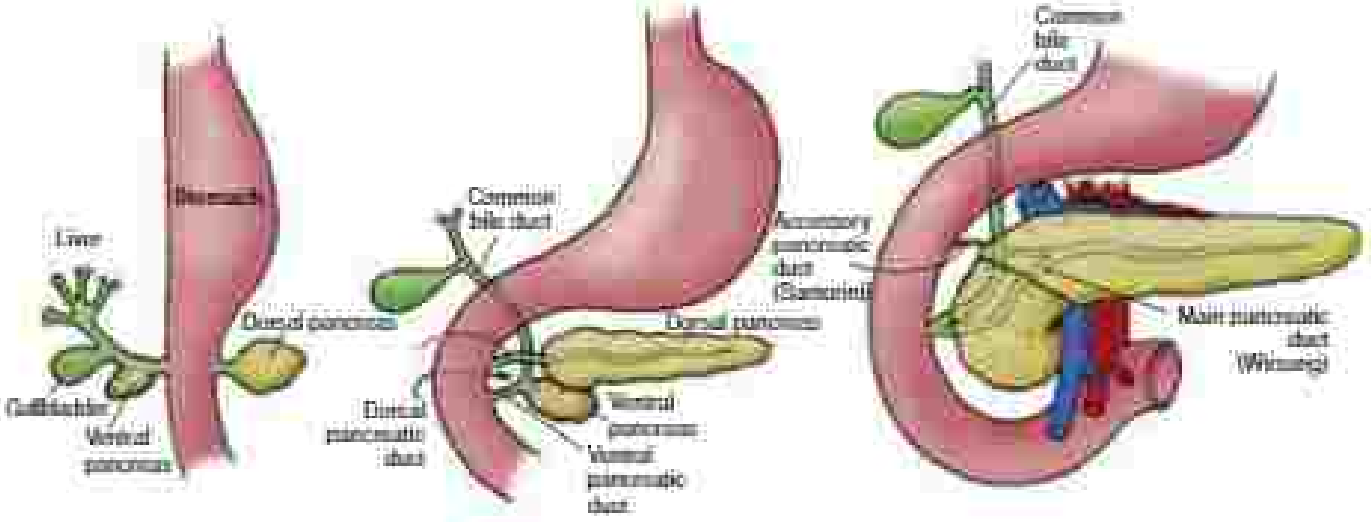

FIG. 1 Embryologic development of the pancreas.

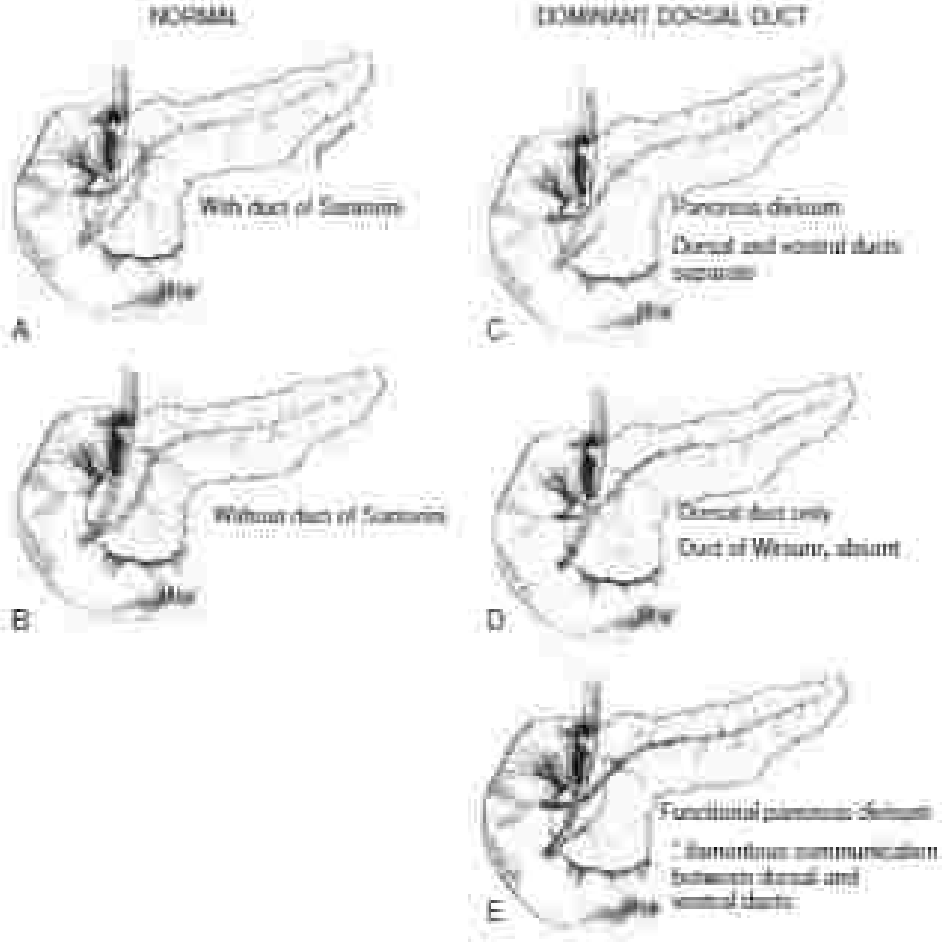

FIG. 2 Most common pancreatic ductal anatomy (A, B) and pancreas divisum and its variants (C–E).

management and hospitalization of less than 1 week. With resolution of the acute illness, patients return to normal function and activities and pancreas morphology presumably returns to normal. If recurrent bouts of acute pancreatitis continue, changes of chronic pancreatitis may become evident on cross-sectional imaging.

A hopeful hypothesis recommends that endoscopic minor duct sphincterotomy be undertaken before the development of chronic inflammatory and fibrotic changes. The goals of endoscopic therapy are to (1) eliminate future episodes of acute pancreatitis, (2) reduce the frequency or severity of recurrent bouts of acute pancreatitis, and (3) prevent the development of overt chronic pancreatitis and its complications, primarily the development of peripancreatic neural inflammatory pathways that lead to centralization of pain. It is generally assumed that if acute pancreatitis bouts can be eliminated, the third objective would follow suit. However, the chief indication for surgical therapy of pancreas divisum is pain; endocrine and exocrine insufficiency is rare, as are biliary, duodenal, and splanchnic venous occlusion.

The more difficult patient is one who has had one bout of acute pancreatitis or no documented evidence of pancreatitis but who has pancreas divisum and chronic pain that is characteristic of pancreatitis. Work patient quality of life is diminished by frequent emergency department visits, work absences, and loss of social contacts, evaluation with MRI and EUS is indicated. If objective evidence of obstructive chronic pancreatitis is noted, then endoscopic or surgical intervention may be indicated. However, the difficulty in waiting for chronic morphologic changes to develop is that once chronic fibrosis has developed in the head of the pancreas, endoscopic and surgical minor duct sphincterotomy have a limited success rate. Division of the sparse smooth muscle fibers of the minor sphincter is unlikely to affect the hardened fibrosis of the surrounding pancreatic parenchyma. The prudent surgeon remembers that when you cut scar tissue, you get more scar tissue. When you operate for pain, you get pain. The splanchnic neural architecture is vast and lacks specificity. Biliary, gastric, esophageal, and intestinal disorders all may appear similar to pain and nausea associated with chronic pancreatitis. Therefore, surgeons and gastroenterologists who undertake the care of patients with chronic pancreatitis and pancreas divisum engage in changing what is possible and offer the hope of helping a patient whose quality of life is diminished by unpredictable hospital visits and isolation from work and family. This care requires the collaboration of pancreatic surgeons, endoscopic specialists in pancreatic disease, behavioral psychologists, and pain management specialists. In general, endoscopic therapy for pancreas divisum is typically recommended for pancreatic type pain in association with obstructive morphology (e.g., a main pancreatic duct stone or stricture) or documented recurrent acute pancreatitis without another clear and reversible cause. Minor sphincterotomy for abdominal pain alone is unproven and a slippery slope; once the orifice is compromised, there is always the possibility of orifice restenosis and bona fide duct obstruction. For patients with idiopathic acute recurrent pancreatitis and pancreas divisum, the impact of minor endoscopic sphincterotomy is currently being investigated in a sham-controlled, multicenter randomized trial (NCT00699946).

FIG. 3 Pancreas divisum magnetic resonance cholangiopancreatography with the dorsal duct (*arrowhead labeled with downward arrow*) crossing the common bile duct, which joins with the ventral duct remnant (*Wirsung labeled with upward arrow*). Dorsal and ventral ducts terminate respectively as major and minor papilla.

ENDOSCOPIC TREATMENT

Identifying the Minor Papilla and Positioning the Endoscope

Although the pathogenicity of pancreas divisum remains controversial, the endoscopic approach to minor papillotomy is more elegant. The first technical challenge in therapy is successfully identifying the minor papilla. Duodenoscopes are designed for optimal orientation at the level of the major papilla, so positioning the endoscope for minor papilla cannulation usually requires a "scout long" position. This is illustrated in Fig. 4, in which the scope is resting along the greater curvature of the stomach. This position is less stable than

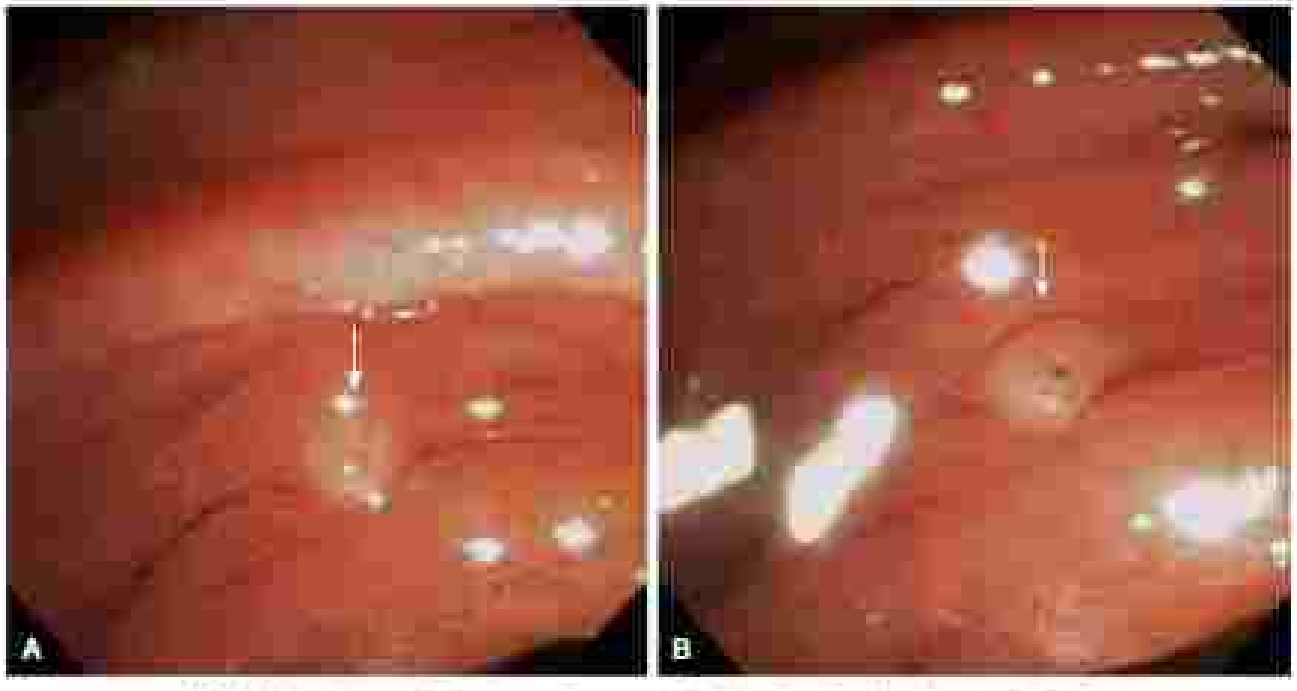

FIG. 4 Endoscopic image of the minor papilla (*arrow*) with a "closed" orifice (A) and an "open" orifice (B).

the traditional "short" position of the duodenoscope used for the majority of major papilla cases. Nevertheless, the semi-long position typically orients the minor papilla directly in front of the working channel; the minor papilla is usually located 2 to 3 cm superior to the major papilla, along the medial wall but slightly lateral to the major papilla. In some cases, the minor papilla may be located underneath an overlying duodenal fold that requires retraction with a catheter or other device before cannulation ensues. Because this procedure requires a long scope position that is uncomfortable for patients who are prone on a fluoroscopy table, it is almost universally performed with anesthesia-administered sedation with or without endotracheal intubation.

Occasionally, the minor papilla is patulous and the actual orifice unidentifiable even after minutes of careful endoscopic observation. Blindly probing with catheters and guidewires rapidly may cause periampullary edema and transform a straightforward procedure into a complicated one. Probing often leads to false tracks adjacent to the true lumen, rarely causing perforation but often making cannulation impossible. Therefore, if a minor papillary orifice is unidentifiable, the minor papilla can be sprayed with a dilute dye such as methylene blue or India ink. After this maneuver, pancreatic juice outflow should lead to clearing of the dye at the minor orifice (Fig. 5). Alternatively, or in conjunction with this approach, secretin may be administered (0.2 μg/kg) intravenously over 1 minute to stimulate pancreatic juice flow. This often unveils the minor papillary orifice within minutes of administration and continued careful endoscopic observation.

An absolute last resort involves the use of a needle-tipped catheter that is gently pressed into the minor papilla, followed by light injection of radio contrast dye to delineate the configuration of the Santorini duct. If the needle is inserted into the submucosal layer of the minor papilla or duodenum, such an injection may result in a submucosal blush and obliterate the papillary anatomy for a short period, often making minor papillary cannulation impossible during that procedure.

Cannulation

Once the minor papillary orifice is clearly delineated, most endoscopists prefer to gain access using a tapered cannula or sphincterotome (5Fr or 6Fr tip) with a hydrophilic, straight guidewire. Most experts prefer a smaller caliber (0.018", 0.025", or 0.035" inch) guidewire because the orifice is considerably smaller than the major papilla. The leading 3 to 4 mm of guidewire protruding from the catheter tip is used to grip the minor orifice; at this point, the endoscopist or assistant may probe gently with the guidewire under fluoroscopic guidance; if the guidewire advances with minimal resistance, then 2 to 3 cm of guidewire may be advanced into the duct before contrast injection. Guidewires should not be advanced deeply in the body or tail of the pancreas without antecedent injection of a small amount of contrast to delineate the course of the duct and avoid side branch puncture. Alternatively, the cannula or sphincterotome may be inserted gently over the minor orifice first, followed by probing with the guidewire. This is suboptimal in many cases because the orifice is usually less than 1 mm (3Fr) and the smallest cannulating devices are 3Fr at the tip.

Once the guidewire is clearly seated in the main pancreatic duct, it should be advanced carefully along the main duct to the distal body or pancreatic tail. This provides adequate rail support over which the cannula or sphincterotome can be advanced deeply into the duct for further opacification and positioning for sphincterotomy.

FIG. 5. Endoscopic image of minor papilloscopy "in progress," which also shows the major papilla downstream for reference (arrow).

Minor Endoscopic Sphincterotomy

There are two approaches to minor endoscopic sphincterotomy, each of which has advantages and disadvantages. There are no data to support one approach over the other. The first approach is a pull-type minor sphincterotomy that mimics the standard technique for biliary and pancreatic sphincterotomy at the major papilla. With a sphincterotome, the device is bowed within the minor orifice, and electrocautery is applied to cut the superior aspect of the "smile." This word is in quotations because many minor papillae have no or minuscule mouth muscle, losing the characterization as a "sphincter muscle" very much in doubt. Electrocautery is typically a blend of (thermally) mixed cut and coagulation currents, to minimize char while permitting an adequate incision to enlarge the orifice. Some experts advocate using a pure cut current for minor sphincterotomy, to minimize the risk of orifice ruin/stenosis; this comes with a slightly higher risk of bleeding and has not been shown to affect long-term outcomes. The advantage of the pull-type technique is that it is most likely to minimize the risk of an incomplete incision; however, if an excessive amount of cut wire is left inside the pancreatic duct during the sphincterotomy, this is likely to induce post-ERCP pancreatitis and delayed high-grade strictures at the orifice.

An alternative and widely accepted approach is to perform a needle-knife sphincterotomy over a pancreatic stent. In this case, a small caliber (3Fr to 5Fr) pancreatic stent is deployed over the guidewire. With a needle-knife sphincterotome, the minor sphincterotomy is performed by cutting in the superior aspect of the stent until the stent is exposed within the duct itself. This technique is believed to have a lower risk of post-sphincterotomy perforation but may be associated with a higher rate of incompletely dividing the minor orifice. In cases of failed minor cannulation, a precut or fistulotomy (without the guidance of a pancreatic stent) needle-knife sphincterotomy may be attempted to expose the minor orifice for deeper access. Given the higher rates of post-ERCP pancreatitis and uncommon technical benefits, this maneuver should be used very sparingly. Unlike the biliary sphincter complex, the duct of Santorini rarely has a long intraductal segment to guide the depth and orientation of the incision.

Pancreatitis Prevention

For the past two decades, the mainstay for preventing post-ERCP pancreatitis has been the use of small caliber pancreatic stents (3Fr to 5Fr). These have been shown to reduce the risk of post-ERCP pancreatitis in multiple randomized clinical trials, presumably by reducing intraductal pressure in the critical hours or days after ERCP and its associated papillary trauma. The efficacy of prophylactic stents after minor papilla endotherapy mirrors that for patients with standard pancreatic duct anatomy. Importantly, patients with pancreas

diseases who undergo ERCP solely for major papilla therapy have a lower baseline risk of post-ERCP pancreatitis, since minor papilla cannulation is attempted, however, the risk approaches that of the highest risk populations. Therefore, most experts are uncomfortable performing an endoscopic minor sphincterotomy without placement of a small caliber pancreatic duct stent immediately before or after the incision. The stents pass out of the minor orifice spontaneously in more than 90% of cases, the minority require a second endoscopy to pull the stent if it is retained after 10 to 14 days on a follow-up radiograph.

Postprocedure, rectal indomethacin (100 mg) is the first widely accepted pharmacologic intervention to minimize the risk of post-ERCP pancreatitis. The medication is administered anytime immediately before, during, or at the completion of the ERCP, and presumably reduces the risk of post-ERCP pancreatitis by interrupting the earliest inflammatory cascades triggered by papillary trauma and intraductal hypertension. Its efficacy as a first-line preventive modality—without pancreatic stents—remains unproven for patients with pancreas divisum undergoing minor endoscopic sphincterotomy. However, the medication is inexpensive and low risk, so has become widely popular as an adjunct for high-risk patients.

Postprocedure Management

The majority of patients undergoing ERCP may be discharged within 2 hours after the procedure. Preprocedure and early postprocedure pain or nausea are important predictors of unplanned admission after ERCP. Intravenous fluids, preferably Lactated Ringer's solution, should be administered during ERCP and in the recovery room in case pancreatitis ensues. If there are no symptoms concerning for post-ERCP pancreatitis and the procedure was otherwise uneventful, patients may be discharged home after a short period of observation.

Approximately 10% to 15% of patients will require overnight observation after ERCP; admission rates after endoscopic minor sphincterotomy are unknown but the post-ERCP pancreatitis rate is also 10% to 15%. The majority of these patients will improve within 72 hours of the procedure, but a small minority (1% to 2% of all patients with post-ERCP pancreatitis) may develop severe acute pancreatitis and local complications such as pseudocysts or necrosis. The potential for post-ERCP pancreatitis—mild or severe—must be considered when weighing the risks and benefits of endoscopic therapy.

SURGICAL TREATMENT

Minor Duct Sphincteroplasty

Operative sphincteroplasty of the sphincter of Oddi was the main stay of therapy before the development of endoscopic sphincterotomy. It is hard to imagine how an operative sphincteroplasty can be better than an endoscopic sphincterotomy, given the sparseness of smooth muscle fibers that surround the pancreatic duct as it courses into the duodenum. Occasional patients with bypassed foregut anatomy may elect open surgical sphincteroplasty and forgo a retrograde endoscopic approach or a hybrid laparoscopic and endoscopic prograde approach. Surgical outcomes with open sphincteroplasty are best when endoscopic sphincterotomy has not been done before. The first cut is the best one. It is tempting to undertake open sphincteroplasty in patients with altered foregut anatomy, such as patients with gastric bypass. These patients may be well served by a hybrid procedure with concomitant laparoscopic gastrostomy of the bypassed stomach and endoscopic prograde sphincterotomy. A gastrostomy tube is left in place to secure access for removal of the anastomotic stent later. Patients who have previously undergone successful endoscopic sphincterotomy with recurrent illness may be candidates for operative sphincteroplasty. The concept is that open minor duct sphincteroplasty with loop magnification and fine absorbable suturing of the duct will have better outcomes than endoscopic sphincterotomy. The difficulty in undertaking this course of action is that patients with chronic illness of the head of the pancreas do poorly with sphincteroplasty, and preoperative identification of pancreatic fibrosis is imperfect.

Technique

The most recent ERCP and magnetic resonance cholangiopancreatography are displayed on the operating theater monitors closest to the surgeon, who has on a headlamp and magnifying loupe. The abdomen is entered through an upper midline incision. The falciform ligament is divided when it limits placement of a wound protector or retraction of the liver. A self-retaining retractor is placed to retract the abdominal wall to divide the lateral duodenal attachments and the ligamentous attachments of the transverse colon to the duodenal pancreatic union. After the wide kocherization of the duodenum and mobilization of the hepatic flexure of the colon inferiorly and laterally, the duodenum is mobilized medially to the midline. Exposure is maintained with the self-retaining retractor placed around the wound circumference, retracting liver, stomach, and transverse colon out of sight. A laparotomy pad is placed behind the duodenum to elevate it toward the midline. A longitudinal duodenotomy is made in the descending duodenum, angled slightly from medial to lateral as the electrocautery knife goes from proximal to distal duodenum. Intraluminal exposure is maintained by grasping the medial and superior duodenal wall with a Babcock clamp or with stay sutures of 3-0 silk. The major papilla is identified with palpation and visualization of bile expressed with manual compression of the gallbladder and common bile duct. Centimeters proximal to the major papilla, the minor papilla can be palpated on the medial wall of the duodenum. Care is taken not to distort duodenal mucosa by direct suction and grasping with forceps, as minor mucosal trauma can obscure visualization of the minor papilla. The minor papilla is palpated and cannulated with a biliary duct probe (Fig. 4). When the papilla cannot be found, secretin stimulation can be used, but this increases the risk of postoperative pancreatitis, particularly if operative drainage has limited success. Sphincterotomy is accomplished by dividing the sphincter muscle with needle knife low-energy cautery over the lateral duct probe. Care is taken to cut only mid muscle fibers. When yellow pancreatic tissue is encountered, the sphincterotomy is complete.

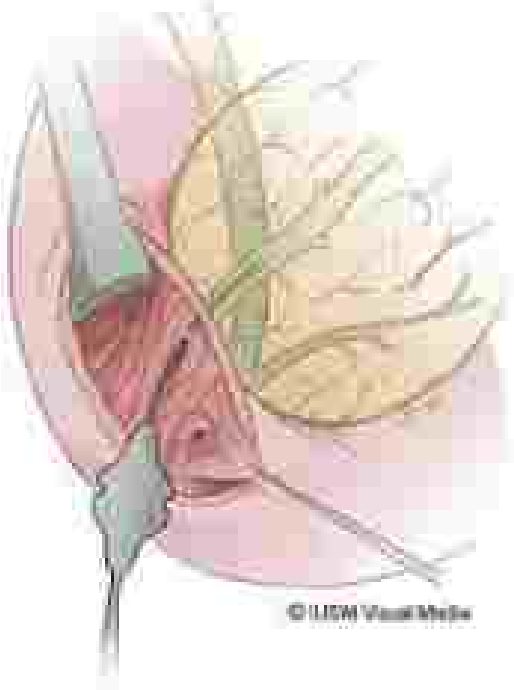

FIG. 4 Through a longitudinal duodenotomy, the minor papilla is identified and cannulated with a biliary duct probe.

Two or three interrupted sutures of 5-0 monofilament absorbable suture are placed to reapproximate duodenal and ductal mucosa (Fig. 7). Minor duct sphincteroplasty is distinctly different from that of a biliary sphincteroplasty in which the common bile duct lies parallel and juxtaposed to the duodenum, which allows for a lengthy sphincterotomy. The minor duct enters the duodenum at right angles from the pancreas. There is not a lot of room to cut this sphincter. A 3Fr or 5Fr double pigtail stent is placed across the anastomosis. It is removed endoscopically a week later. The duodenotomy is closed with a running suture of 3-0 absorbable monofilament suture, reinforced as needed with interrupted sutures of 3-0 silk. The fascia is reapproximated with interrupted non absorbable sutures. The skin is closed with a 4-0 running subcuticular suture. Closed suction drainage of the retroduodenal space is not used routinely. Because stenosis of the major papilla is associated with pancreas divisum, some would advocate performing biliary sphincteroplasty and pancreatic ductal sphincteroplasty whenever minor duct sphincteroplasty is undertaken. This indication is exceptional but not irrational.

Postoperative Management

Patients are managed on a fast track much as one would manage a patient after an open cholecystectomy. Nasogastric and urinary bladder intubation are avoided. Diet is advanced early as tolerated. Complications particular to this operation are pancreatitis and duodenotomy dehiscence (Table 1). Postoperative pancreatitis is uncommon and presents in typical fashion with pain, tachycardia, and serum lipase and leukocyte elevation. Duodenal dehiscence presents in a subtle fashion, similar to a duodenal stump leak after Billroth II gastrectomy. Vague upper abdominal pain and nausea precede by days the appearance of systemic toxicity with fever, tachycardia, tachypnea, and leukocytosis. Alert vigilance for this complication is needed because it is uncommon, subtle in presentation, and devastating if unrecognized early.

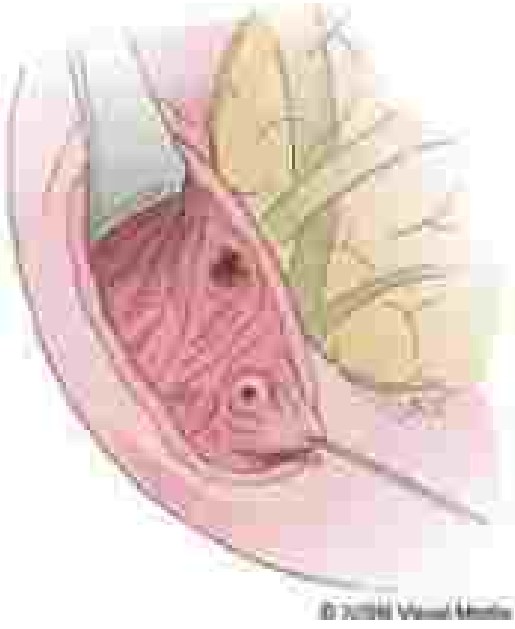

FIG. 7 After division of the muscular fibers of the sphincter of Helm with needle-knife electrocautery, the termination of the dorsal pancreatic duct is anastomosed to the duodenal mucosa with interrupted sutures.

Lateral Pancreaticojejunostomy

Dominant ductal dilation is an indication for lateral pancreaticojejunostomy (LPJ) in chronic pancreatitis associated with pancreas divisum. Outcomes after LPJ are similar to those reported with chronic pancreatitis not associated with pancreas divisum. In particular, the patient with the borderline dilated pancreatic duct not greater than 7 mm in diameter may benefit from LPJ when diffuse fibrosis of the pancreas is present with a fibrotic encapsulation of the pancreas. LPJ has the theoretic advantage of relieving the pancreas from its so-called pancreatic compartment syndrome. Part of the discussion of LPJ in the management of chronic pancreatitis of all causes is that of LPJ fails and the patient progresses to consideration of total pancreatectomy with islet autotransplantation (TPIAT), islet yields are diminished in patients who have had LPJ, related to either the underlying disease state or technical challenges presented by islet isolation in patients who have a longitudinal disruption of the pancreatic duct. The technique of LPJ in pancreas divisum does not differ from that discussed elsewhere in this book. Because the pancreas dissection is extended medially adjacent to the duodenum, the gastroduodenal artery should be ligated before its division.

Whipple Procedure

Pancreaticoduodenectomy may be indicated in patients with pancreas divisum who have failed minor duct sphincteroplasty when changes of chronic pancreatitis develop in the head of the pancreas. The operative technique is not different from that described elsewhere in this book. When a resection of the head is indicated in pancreas divisum, the dorsal neck of the pancreas is usually left with a modified pancreatic duct, not at risk for anastomotic leak. Therefore internal and external anastomotic stenting and postoperative octreotide infusion may diminish the risk of postoperative pancreatic fistulas. If head resection in pancreas divisum fails and patients become candidates for TPIAT, islet yields may be unacceptable. Islet volume is greater in the tail and body than in the head of the pancreas, and islet loss is limited in a head resection for pancreas divisum. When autoimmune obstruction occurs after a Whipple procedure, acinar cells atrophy before destruction of the islets. The resultant islet-rich, acinar poor atrophied pancreas may be favorable isolation for islet autotransplantation. The issue of whether patients with pancreas divisum with chronic pancreatitis should undergo a speculative Whipple procedure or a TPIAT is unanswered.

Hybrid Procedures

Variations of the Whipple procedure and the Puestow procedure have been used in chronic pancreatitis associated with pancreas divisum in a fashion similar to their use in chronic pancreatitis not associated

TABLE 1 Surgical Outcome After Minor Duct Sphincteroplasty in Patients With Pancreas Divisum

Study	N	Morbidity	Mortality	Good Response	Mean Follow-up (mo)
[illegible] et al. (1998)	88	NR	0	71%	53
Bradley (1994)	31	NR	0	58%	40
Madura (1993)	8	25%	0	63%	NR
Morgan et al. (2008)*	1.	10%	0	54%	63

*R, not reported.

with pancreas divisum. Although typically the Roger and Frey procedures are selected for patients with an inflammatory mass in the head of the pancreas, they have been used in pancreas divisum not associated with enlargement of the head of the pancreas. The Frey procedure was developed because of the ascribed failure of the LPT to drain the head and uncinate process of the pancreas. In pancreas divisum, the head should be drained efficiently with a longitudinal duct-to-stomach. The use of multiple resection and drainage techniques is an indication of the difficulty in patient selection and management of chronic pancreatitis associated with pancreas divisum.

Total Pancreatectomy With Islet Autotransplantation

TPIAT is indicated in patients with chronic pancreatitis with intractable pain who have failed medical, endoscopic, and surgical management. Pancreas divisum is a risk factor for chronic pancreatitis in about 10% of the cohort in the reports of TPIAT in the management of chronic pancreatitis. Typical patients with pancreas divisum who are selected for TPIAT have undergone endoscopic sphincterotomy, operative sphincteroplasty, and pancreatic head resection to succumb over many years. The unanswered question is whether TPIAT should be undertaken sooner rather than later if endoscopic treatments fails. That discussion is beyond the scope of this chapter.

CONCLUSIONS

Given the paucity of comparative effectiveness studies evaluating the impact of endoscopic or surgical minor papilloplasty on unobstructive recurrent acute and chronic pancreatitis, the management of pancreas divisum is primarily based on experience. Although the divisum anatomic variant is common, its association with chronic pancreatitis is by no means a *sine qua non*. When pancreas divisum is associated with intractable pain associated with chronic pancreatitis or with recurrent pancreatitis, the approach should mimic that for patients with standard duct anatomy: (1) alcohol and tobacco cessation is necessary; (2) a trial of pancreatic enzyme replacement therapy may be considered, especially if exocrine pancreatic insufficiency is documented; and (3) genetic mutations and polymorphisms should be investigated, knowing that the odds identifying high risk mutations are higher in the setting of divisum. A management strategy based on a regional experience extending with the surgical management of pancreas divisum is suggested in Table 2. The pathway outlined in Table 2 differs from much of the experience in the current literature and underscores the influence of regional population differences and their attendant practices. As the pathogenesis of pancreatitis is better understood, treatment strategies will become less intuitive and experience based and more effective.

To seek and to find evidence on which to base the management of pancreas divisum is to repeat Samuel Johnson's experience described in the preface to his 1755 *A Dictionary of the English Language*, saying: "I saw that one inquiry only gave occasion to another, that book referred to book, that to search was not always to find, and to find was not always to be informed, and that this is pursue perfection, was, like the first inhabitants of Arcadia, to chase the sun, which, when they had reached the hill where he seemed to rest, was still beheld at the same distance from them."

TABLE 2 Management Strategies for Pancreas Divisum in the Setting of Chronic Pancreatitis Intractable to Medical Management or with Recurrent Acute Pancreatitis

Condition	Strategy
Nonfunctional, dilated duct >5 mm	Lateral pancreaticojejunostomy
Familial	Total pancreatectomy with islet autotransplantation
Nondilated duct with recurrent acute pancreatitis	Endoscopic minor papillotomy
Nondilated duct endotherapy failure	Operative sphincteroplasty
Nondilated duct endotherapy failure with moderate to severe chronic pancreatitis in the head	Pancreaticoduodenectomy
Operative sphincteroplasty failure	Pancreaticoduodenectomy
Pancreaticoduodenectomy failure	Total pancreatectomy with islet autotransplantation

MANAGEMENT OF PANCREATIC NECROSIS

David B. Adams, MD, and William P. Lancaster, MD

Consider the pancreas. It sits quietly in the retroperitoneum, excellently churning out proteins to regulate endocrine and exocrine homeostasis. However, when acutely inflamed with activation of pancreatic enzymes in the retroperitoneum, a localized process, pancreatic and fat necrosis may be accompanied by a cytokine-mediated inflammatory response that causes widespread injury to lungs, kidneys, heart, brain, and liver. Fortunately, acute pancreatitis is usually a self-limited disease that responds to supportive care with complete resolution of symptoms and without long-term sequelae. Approximately 20% of patients with acute pancreatitis will develop a more severe form of disease with transient or persistent organ failure and abdominal complications. The most severe complication of severe acute pancreatitis is glandular and retroperitoneal tissue destruction resulting in pancreatic and peripancreatic necrosis. Approximately 5% to 10% of patients with severe acute pancreatitis will develop pancreatic necrosis, and 30% of patients with pancreatic necrosis will develop infected pancreatic necrosis. Conventional wisdom once dictated that infected pancreatic necrosis was an absolute indication for operation. Considering that the attendant mortality of laparotomy in the early course of pancreatic necrosis approaches 100%, this approach has largely been abandoned in favor of thoughtful multidisciplinary management involving surgeons, gastroenterologists, interventional radiologists, and intensivists. Current concepts support the view that operating on patients earlier than 4 weeks after the onset of severe necrotizing pancreatitis is associated with poor outcomes, which can be ameliorated by delaying surgery until after 4 weeks into the disease course. The exceptions to this guideline require a positive answer to this question: What is an operation going to do to improve the patient's physiology and diminish, rather than increase, cytokine release? Operative intervention should be planned in a sequential delayed fashion as much as possible in a stepwise approach from least invasive to more invasive. When this sequence is followed, morbidity and mortality can be minimized.

CLINICAL COURSE

There is a bimodal distribution of mortality in severe acute pancreatitis marked by an early phase (<14 days) and a late phase (>4 weeks). Mortality in the early phase of illness is due to severe systemic inflammatory response syndrome (SIRS) and multisystem organ failure, and mortality in the late phase is most commonly due to infectious complications. The inflammatory insult of pancreatic necrosis leads to organ dysfunction in the first 2 weeks of illness. Patients will often have pulmonary insufficiency requiring mechanical ventilation, acute renal failure, and hemodynamic instability. Aggressive supportive therapies are the mainstay of treatment during the early phase of illness. Usually within 2 weeks, the capillary endothelial leak resolves and the patient stabilizes. During this time frame, the surgeon must be vigilant for the development of complications.

Diagnosis

The 2012 revised Atlanta classification provides expert consensus definition of the severity of acute pancreatitis distinguishing between three forms of disease based on the degree of associated organ failure and the presence of local complications (Table 1). The classification system further defines local complications according to imaging findings and timing relative to the onset of symptoms. Patients with moderately severe or severe acute pancreatitis, by definition, have some degree of associated organ dysfunction, and the surgeon should be suspicious of local complications in patients with persistent or worsening SIRS, fever, worsening abdominal pain, or ileus/paralytic ileus. Contrast-enhanced computed tomography is the imaging study of choice to diagnose local complications of severe acute pancreatitis and can demonstrate the presence of acute peripancreatic fluid collections and necrosis.

Antibiotic Therapy and Nutritional Support

Numerous studies have investigated the role of prophylactic antibiotics in the treatment of severe acute pancreatitis given the high mortality associated with infectious complications. Prophylactic antibiotics are not recommended and may be associated with increased mortality and mortality secondary to the selection of resistant organisms. Antibiotics should be used when infection is highly suspected or when definitive culture data are available from retroperitoneal fluid. Clinical findings that are highly suggestive of infection include worsening physiologic status, increasing leukocytosis, and persistent fever. Radiographic findings that support the presence of infected peripancreatic fluid include air within the retroperitoneum on cross-sectional imaging.

Nutritional support is paramount to severe acute pancreatitis because the metabolic demands are enormous secondary to severe systemic inflammation. Historically, total parenteral nutrition (TPN) was thought to be superior to fight of the abdominal distention and adynamic ileus that is often present in severe acute pancreatitis. It was also believed that parenteral nutrition would minimize pancreatic stimulation and thereby avoid worsening of the disease. Several studies have shown that enteral nutrition is superior to parenteral nutrition. The benefits of enteral feeding are numerous and include maintaining gut mucosal integrity, improved immune function, and decreased cost. Clinical trials comparing enteral and parenteral nutrition have shown enteral nutrition is associated with decreased severity of illness, decreased need for surgical intervention, and decreased length of hospital stay. Feeding can be initiated via nasojejunal tube either into the stomach or distal to the pylorus. Although further study is needed, we feel that postpyloric feeding is the safest approach given the associated gastric and intestinal dysfunction that is frequently present in acute pancreatitis. However, if gastric feeding is tolerated, there is not good evidence not to do so. Similarly, if patients can eat, let them eat. In the rare case that the patient is intolerant of enteral feeding, TPN should be initiated.

Fluid Therapy: Too Much or Too Little?

Aggressive intravenous fluid resuscitation has historically been the mainstay in the management of severe necrotizing pancreatitis. However, as the early complication of renal injury owing to hypovolemia was supplanted by fluid overload and pulmonary failure, fluid management became problematic and how best to prevent organ failure and reduce mortality involved controversies related to rate and type of fluid infusion. Most agree that rapid fluid infusion in the first 12 hours of treatment is indicated, recognizing pulmonary complications if more than 4 L of fluid is given in the first 24 hours. There is an experimental rationale to suggest that lactated Ringer's solution is better than normal saline solution in terms of precipitating an SIRS response. There is little evidence to suggest that fluid resuscitation has a role in altering the rate-limiting step in necrotizing pancreatitis that is the SIRS response. Aggressive resuscitation strategies may protect some organs at the cost of pulmonary failure and abdominal compartment syndrome. Recent consensus guidelines recommended that fluid volume for replacement should be between 2500 and 3000 mL during the first 24 hours, with infusion rates guided

TABLE 1 2012 Revised Atlanta Classification of Acute Pancreatitis

Severity	Definition
Acute pancreatitis	Acute inflammation of the pancreas
Mild acute pancreatitis	Minimal organ dysfunction and disease that responds to fluid administration
Severe acute pancreatitis	One of the following: • Local complications (pancreatic necrosis, pancreatic pseudocyst, pancreatic abscess) • Organ failure • ≥3 Ranson criteria • ≥8 APACHE II points
LOCAL COMPLICATIONS	
Acute fluid collections	Fluid collections in or near the pancreas, occurring early in the clinical course, lacking a well-defined wall
Pancreatic necrosis	Nonviable pancreatic tissue diagnosed by intravenous contrast enhanced computed tomography scan
Acute pseudocyst	Fluid collection containing pancreatic secretions (high amylase level) and a well-defined wall
Pancreatic abscess	Collection of pus, usually near the pancreas, with little or no associated pancreatic necrosis

APACHE II, Acute Physiology and Chronic Health Evaluation II.

by heart rate, mean arterial pressure, urinary output, hematocrit, and thermodilution measured intrathoracic stroke volume.

Local Complications—Bleeding and Fistulas

The inflammatory environment in pancreatic necrosis is driven by leakage of pancreatic enzymes into the retroperitoneum. The enzymes digest surrounding tissues that can include blood vessels and viscera. Arterial bleeding can occur from any visceral artery but is most often from the splenic artery and gastroduodenal artery. The presentation is often heralded by gastrointestinal bleeding or an unexpected decrease in hematocrit. A high index of suspicion must be obtained to ensure timely diagnosis. Diagnosis is made with computed tomography angiography and is manifest radiographically as a pseudoaneurysm (Fig. 1). Treatment is by conventional angiography with either coil embolization or stenting. Attempts at surgical control of bleeding should be reserved for the direst cases as mortality is much lower with angiography. It is not beyond the scope of practice to utilize damage control principles in the operative management of arterial bleeding with the application of abdominal packs and subsequent source control with interventional radiology techniques. Venous bleeding is usually a self-limited process and is treated nonoperatively. In a bleeding patient without evidence of arterial bleeding, correcting coagulopathy and decreasing splanchnic blood flow with an octreotide infusion is usually sufficient.

Enteric fistulae develop as a result of pancreatic enzymes either destroying the blood supply to a segment of bowel causing ischemia or by direct luminal erosion. They occur more commonly postoperatively after debridement but can also occur preoperatively. The most common organs affected are the duodenum and colon. With adequate drainage and nutritional support, approximately 75% will heal without surgical intervention.

FIG. 1 Computed tomographic image showing arterial pseudoaneurysm at the splenic hilum.

Indications and Timing of Debridement

Indications for surgery in pancreatic necrosis include infected necrosis, failure to thrive, and persistent symptoms. In the early phase of illness, surgery should be deferred because of prohibitive perioperative mortality. An additional inflammatory insult to a maximally physiologically stressed patient is the principal reason for high mortality with operative intervention in the early phase. An exception is in abdominal compartment syndrome. In patients with the constellation of findings consistent with abdominal compartment syndrome and concurrent physiologic decline, a laparotomy should be performed. Importantly, pancreatic debridement should not be pursued at the time of laparotomy.

In general, debridement should be pursued only after 4 weeks from the initial onset of symptoms. This allows for systemic inflammation to subside and organ compromise to resolve. Percutaneous drains should be liberally used in patients who develop suspected or confirmed infected necrosis during the first 4 weeks of illness (Fig. 2). The drains serve as a temporizing measure that allow for drainage of infected material and bridge the patient to a time most suitable for definitive debridement. In many cases, percutaneous drainage alone is definitive treatment, especially in cases without a significant solid component within the fluid collection. Percutaneous drains can also be used as part of a "step-up" approach to video-assisted retroperitoneal debridement (VARD).

Percutaneous Drains and Video-Assisted Retroperitoneal Debridement

Percutaneous drains are a useful temporizing measure to treat infectious complications in the early phase of illness. Drains are effective at draining retroperitoneal fluid and pus but are less effective at draining solid debris. In patients with a significant degree of solid necrosis burden, more definitive debridement can be achieved by VARD, termed a step-up approach. This technique utilizes well-placed percutaneous drains as a pathway to the retroperitoneum and the necrotic cavity. An incision is made over the drain and the drain tract is followed into the necrotic cavity. The tract is enlarged and a laparoscope is inserted for direct intracavitary visualization. The necrosis is debrided bluntly with laparoscopic instruments. The advantages of VARD are adequate mechanical debridement through a limited approach, minimizing morbidity. This approach also allows for the placement of large bore drains with lavage capability.

Endoscopic Treatment

Endoscopic techniques offer a minimally invasive approach to pancreatic debridement. The technique is based on the principal of endoscopic cystgastrostomy to allow drainage of peripancreatic fluid and debris into the stomach. Plastic or metal stents are available to maintain patency of the cystgastrostomy. The necrosis cavity can be directly visualized and mechanically debrided with endoscopic instruments. Contained retroperitoneal collections with a relatively low degree of solid necrosis are suitable for endoscopic management. The disadvantage of this technique is that it is labor intensive, often requiring multiple procedures to achieve adequate debridement.

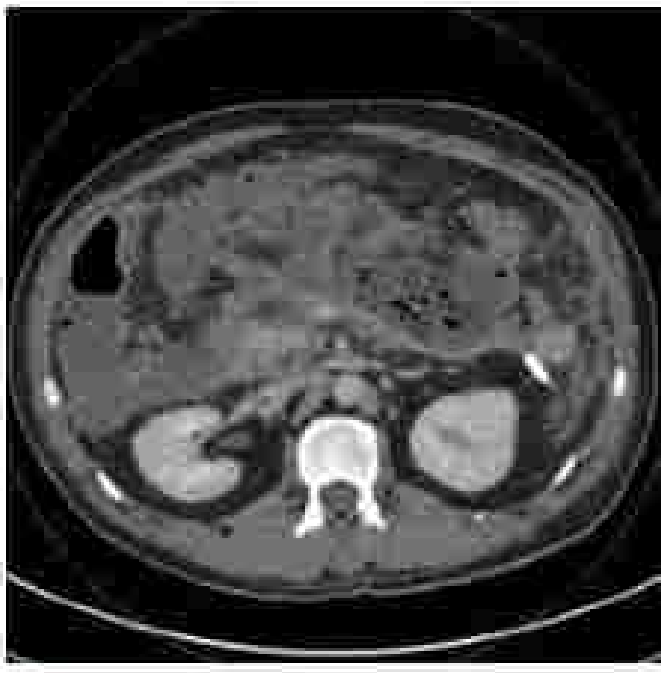

FIG. 2 Computed tomographic image showing percutaneous drain entering the left flank into a retroperitoneal collection.

Principles of Operative Management

The goals of operative management are to reduce septic mortality, decrease septic complications, and minimize the inflammatory insult to the patient. Open debridement via laparotomy is the gold standard, but a number of less invasive techniques can also be used based on the pattern of disease. Fig. 3 outlines a general decision pathway for patients with pancreatic necrosis. The decision as to which approach to utilize depends largely on the distribution of necrosis.

Operative Management—Open and Laparoscopic Transgastric Debridement

Similar to cystgastrostomy, transgastric debridement establishes a communication between the lumen of the stomach and the necrosis cavity. This approach is best when applied for collections that are contained within the retroperitoneal space and to the left of the mesenteric vessels (Fig. 4). There is limited access to the mesenteric root, pancreatic head, and paracolic spaces. The anterior stomach is opened in a longitudinal fashion and the impression of the necrotic cavity is identified. Intraoperative ultrasound can also be used to guide placement of the posterior gastrotomy. The posterior wall of the stomach is incised and the necrosis cavity is entered. All fluid and necrotic debris are removed. A nasogastric tube can be placed within the cavity for lavage and suction. The posterior stomach is sutured to the wall of the necrosis cavity with running absorbable suture for hemostasis. The anterior gastrotomy is closed in a transverse fashion. In many cases, laparoscopic techniques can be used.

Operative Management—Open Debridement

Outcomes for open debridement remain the measure by which less invasive therapies for pancreatic necrosis are measured. Although step-up strategies are usually equal in historical outcomes, open debridement is the definitive treatment when less invasive techniques fail. In the past, management of pancreatic necrosis involved a bilateral subcostal incision, retroperitoneal and pancreatic debridement, wide drainage, cholecystectomy, gastrostomy, and feeding jejunostomy. Following a few basic principles, we now advocate entering the abdomen through a midline laparotomy. The necrosis cavity is accessed through the lesser sac, either through the gastrocolic omentum or through an incision at the base of the transverse mesocolon, usually to

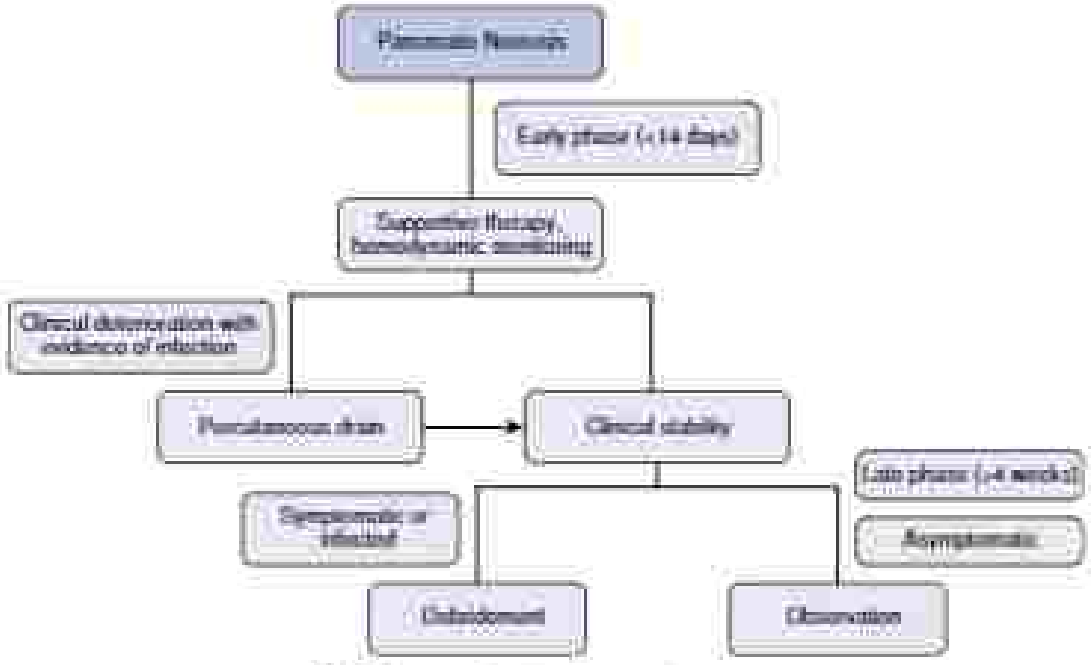

FIG. 3 Treatment algorithm for pancreatic necrosis.

FIG. 4 Computed tomographic image showing a contained heterogeneous necrotic collection.

the left of the middle colic vessels. Necrotic debris is removed bluntly and the cavity irrigated. Ringed forceps and high pressure irrigation help get the job done. Care must be taken to avoid injury to the mesenteric and splenic vessels, as life threatening and difficult to control bleeding can occur. Open debridement is useful in cases in which necrosis extends from the retroperitoneum posterior and tracks bilaterally into the root of the mesentery and the paracolic spaces (Fig. 5).

■ CONCLUSIONS

Pancreatic necrosis remains a surgical disease that requires all the skills that a general surgeon can muster; knowledge of the evidence-based surgical literature, operative experience with the pancreas, empathy with patients who are walking a tight rope between life and death, and surgical intuition that may be the only thing that tells one when to operate, and when to wait. Advances in critical care and thoughtful reassessment of traditional operative strategies and utilization of minimally invasive approaches have decreased the morbidity of pancreatic necrosis, and when carefully applied can diminish mortality. Pancreatic necrosis is a formidable foe, but when confronted head on with perseverance and attention to detail, the result is a patient who returns to a high quality of life at home and at work.

Management of Pancreatic Pseudocyst

Matthew J. Martin, MD, FACS, FASMBS, and Carlos V.R. Brown, MD

Acute pancreatitis is an extremely common disease process and represents the most common gastroenterologic diagnosis requiring hospital admission in the United States. Although most cases are still limited and resolve without complications, there is a well defined subset of patients that will develop local complications including necrosis, infection, or persistent peripancreatic fluid collections that prompt a surgical consultation or referral. Thus, the managing surgeon must have a thorough knowledge and understanding of the disease process and specific complicating factors, and a well developed algorithm to select from the myriad of currently available diagnostic and interventional options. This is particularly important when dealing with pancreatic pseudocysts (PS) because of the history of highly variable and confusing terminology, definitions, and classification systems for pancreatitis and peripancreatic fluid collections that have been used in the literature and that continue to be used in

Management of Pancreatic Pseudocyst

Matthew J. Martin, MD, FACS, FASMBS, and Carlos V.R. Brown, MD

Acute pancreatitis is an extremely common disease process and represents the most common gastroenterologic diagnosis requiring hospital admission in the United States. Although most cases are still limited and resolve without complications, there is a well defined subset of patients that will develop local complications including necrosis, infection, or persistent peripancreatic fluid collections that prompt a surgical consultation or referral. Thus, the managing surgeon must have a thorough knowledge and understanding of the disease process and specific complicating factors, and a well developed algorithm to select from the myriad of currently available diagnostic and interventional options. This is particularly important when dealing with pancreatic pseudocysts (PS) because of the history of highly variable and confusing terminology, definitions, and classification systems for pancreatitis and peripancreatic fluid collections that have been used in the literature and that continue to be used in

clinical practice. This chapter will present a practical, straightforward, and evidence-based approach to the patient with suspected or proven pancreatic pseudocyst.

TERMINOLOGY AND CLASSIFICATION

Arguably the most important foundation for approaching the evaluation and management of a potential PS is the use of accurate and clinically relevant definitions and terminology. We have found that the term *pseudocyst*, has been poorly defined in prior published literature, has been applied to a wide variety of pathologies that are not true pancreatic pseudocysts, and continues to be used by radiologists and other specialties as a catch all term for any well-formed peripancreatic fluid collection. Thus, the first step in the evaluation process should be an accurate determination of whether the pathology truly meets the current diagnostic criteria for a PS or for another entity. This is important not only for nomenclature purposes, but also because the evaluation and management algorithm will often be markedly different. Fortunately, the medical and surgical community has increasingly adopted the more uniform definitions and criteria outlined in the 2012 revised Atlanta classification system for acute pancreatitis. This has ensured vague and confusing terminology such as *pancreatic phlegmon* and *acute pseudocyst* and replaced them with more exact and clinically relevant categorizations.

As outlined in Fig. 1, the revised Atlanta classification divides acute pancreatitis into necrotizing or interstitial edematous (no necrosis present) variants. It then classifies any associated peripancreatic fluid collections based on the time interval from the onset of pancreatitis and using 4 weeks as the cutoff between an early versus "mature" fluid collection. PS is diagnosed as a persistent mature fluid collection (>4 weeks) in association with interstitial edematous pancreatitis (IEP). Before the 4 week time point, the fluid collection is described as an *acute peripancreatic fluid collection*. Most important, the term *pseudocyst* is no longer used in the presence of necrotizing pancreatitis (NP), in favor of the alternative diagnoses of acute necrotic collection at less than 4 weeks or walled off necrosis (WON) after 4 weeks. Thus, a PS is most specifically defined as a mature and sterile simple cystic fluid collection in association with edematous acute pancreatitis. In rare cases in which the PS becomes infected, it may be most accurately described as a pancreatic abscess or infected PS. Although PS is most commonly described and reported as a consequence of acute pancreatitis, it may also be seen in association with chronic pancreatitis (CP) or following pancreatic trauma.

Although the revised Atlanta classification is based on the best available current evidence and uses a clearly defined temporal dividing line at 4 weeks, it is important to realize that this cutoff is largely based on averaged observational data and limited animal models. This should not be strictly interpreted as meaning that a well-formed PS capsule cannot form earlier than 4 weeks, or that all acute peripancreatic fluid collections will have matured to a true PS at the 4 week time point. For any individual patient, this timeline may be markedly different, and in modern practice the most useful modality to make this determination will be the appearance of the fluid collection and the PS capsule on computed tomography (CT) and/or magnetic resonance imaging (MRI) studies. Arguably the most important aspect of maintaining this 4 week cutoff in the definition is to minimize attempts at early unnecessary and often nontherapeutic interventions for peri-pancreatic fluid collections in both IEP and NP.

EPIDEMIOLOGY

Although the reported incidence of PS following acute pancreatitis is 5%, the true incidence and natural history of PS are unknown because many resolve spontaneously and without symptoms. PS has become increasingly recognized and characterized from the more liberal use of CT and/or MRI in the evaluation of acute pancreatitis and postpancreatitis complications. Arguably the most important epidemiologic aspect of PS that must be appreciated is the fact that most peripancreatic fluid collections in association with IEP will be asymptomatic or minimally symptomatic, and 75% to 90% will resolve spontaneously and not require any invasive interventions or surgery. This is in contrast to fluid collections associated with NP, and particularly with infected NP, where the majority will require some type of interventional procedure or surgery. Overall, approximately 5% to 15% of patients with IEP will develop one or more local complications, including PS, and the risk for these complications will generally correlate with the severity of the index episode of pancreatitis. Although less common overall, PS may also be seen in association with CP in up to 40% of cases, and without an identified antecedent episode of acute pancreatitis. The exact underlying etiology and risk factors for PS in the setting of CP remain unclear.

Another potential but much less common cause of PS is pancreatic trauma, which may be secondary to either blunt or penetrating injuries with some element of injury to the pancreatic ductal system (grade 3 or higher injury). These typically present in a delayed fashion, and often in cases where the presence of the pancreatic injury was not visualized on the initial CT scan. The PS is usually identified on a repeat imaging study performed because either symptoms of abdominal pain, fulminant early satiety, or elevated serum amylase/lipase levels. Although any associated traumatic injuries and pathology must also be taken into account, the management of a posttraumatic PS will largely mirror that of the usual pancreatitis-associated PS.

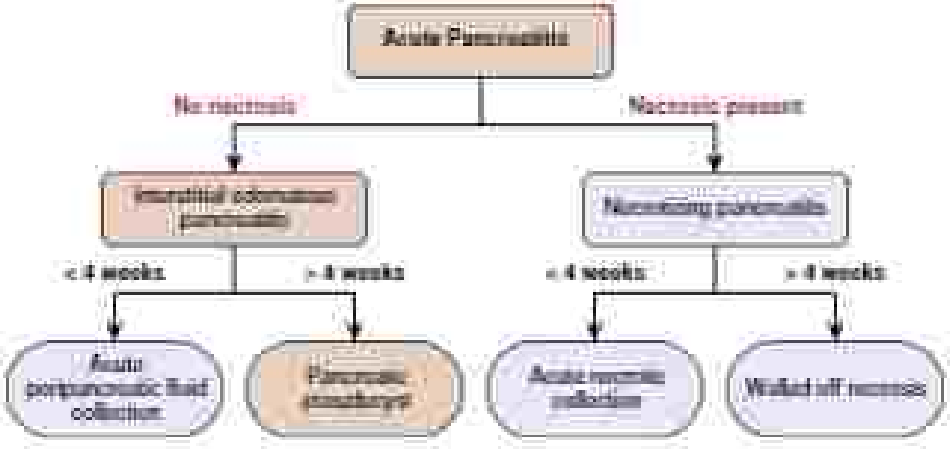

FIG. 1 2012 modified Atlanta classification for acute pancreatitis and associated fluid collections. Pink-shaded boxes indicate the pathway to diagnosis of a pseudocyst.

PATHOPHYSIOLOGY

Pancreatic pseudocyst is a well-formed fluid-filled cystic mass that typically abuts the pancreas, although it less commonly can be partially or wholly intrapancreatic. The primary etiology of the cyst is disruption of the main pancreatic duct or associated ductal branches, with consequent leakage of pancreatic ductal fluid and parenchymal secretions. Therefore, the cyst is typically filled with bicarbonate-rich and high amylase content fluid with inactivated pancreatic enzymes. Although there is certainly a moderate amount of microscopic debris and inflammatory exudates within the typical PS, there should be little to no macroscopic debris or solid component present. The fluid typically collects in the lesser sac and, over time, develops a well-formed capsule that can be distinguished from a true cyst by the lack of an endothelial lining. Interestingly, the incidence of PS is higher with alcoholic pancreatitis versus gallstone related and other causes. Whether this is due to a true pathophysiologic difference between these types of pancreatitis or to confounding factors including higher severity and recurrence rates with alcohol-induced pancreatitis is unknown.

Unlike necrotizing pancreatitis and WON where the risk of infection is extremely high (30%–70%), infection of a PS is rare. In most cases where infection does occur, it is secondary to percutaneous/endoscopic instrumentation of the PS or adjacent pancreas, or in the presence of associated pancreatic necrosis that was initially not recognized or that represents progression of disease from IEP to NEC. Unlike a noninfected PS, infected pseudocysts are rarely asymptomatic and will typically manifest local signs of inflammation, a relatively rapid increase in the size of the PS, and systemic signs of sepsis if not promptly addressed.

Finally, there are relatively rare scenarios where PS may be seen in association with necrotizing pancreatitis, and it is important to be able to clearly differentiate this from walled-off necrosis. This usually happens as a delayed complication following the necrosis of a segment of pancreas or following endoscopic/surgical debridement of a segment of the pancreatic body or tail, and with a persistent pancreatic ductal leak leading to PS formation. In these cases, the diagnosis of PS is made based on the absence of any solid or necrotic components of the fluid collection and is purely related to the ductal leak and not active pancreatic necrosis. Among the most challenging of these cases is the patient with a "disconnected duct" syndrome, caused by necrosis of the mid-body segment of the pancreas resulting in an essentially free-floating distal pancreatic body/tail segment and open ductal system that is no longer in continuity.

INITIAL PRESENTATION AND EVALUATION

Clinical Evaluation

As described in the preceding sections, the underlying etiology and presenting symptoms or complaints of patients with PS are highly variable. There are essentially no symptoms or examination findings that are specific to PS, and the majority of patients will have either minimal or no symptoms. If symptoms are present, they most commonly will feature vague upper abdominal and/or back pain, abdominal fullness or bloating, early satiety, or pain shortly after meals, or less commonly symptoms of gastric outlet obstruction. More acute presentations featuring concerning abdominal exam findings and abnormal hemodynamics are uncommon, and usually only seen in cases of infection of the PS (pancreatic abscess) or in PS-related hemorrhage. In many cases in current practice, the diagnosis of a peripancreatic fluid collection is made based on either screening or surveillance radiographic imaging studies. There are often alone as part of the workup for an identified episode of severe acute pancreatitis or for persistent symptomatology concerning for a possible PS or other local complication associated with acute or CP, or pancreatic trauma. Elevated serum amylase levels are seen in approximately 50% of patients with PS and are often mistakenly attributed to "recurrent pancreatitis" or to failure of resolution of the index episode.

Similar to the physical examination, there are no patient history questions that are high yield or specific for the diagnosis of PS. However, the history can be critical in identifying the likely etiology and in narrowing down the differential of a pancreatic/peripancreatic cystic mass identified on imaging. These questions should focus on the timing of any current or prior episodes of pancreatitis or acute abdominal pain episodes, symptomatology consistent for CP, any prior major abdominal trauma, and then common etiologic factors for pancreatitis including alcohol use, biliary disease, and medications. Patients with a possible PS who have no history of acute/CP episodes or symptoms (or trauma) should prompt consideration of an alternative diagnosis of cystic neoplasm of the pancreas. However, up to 15% of those with PS have no clearly identified antecedent pancreatitis episode or trauma, and a significant percent of pancreatic cystic neoplasms may initially present as an episode of acute pancreatitis. The correct diagnosis can usually be made using a combination of patient history and findings on imaging studies (as outlined in the following section), and less commonly may require percutaneous or endoscopic evaluation with fluid sampling and/or biopsy. Signs and symptoms of pancreatic insufficiency should also be elicited, as this may significantly impact surgical management decisions involving pancreatic resection.

Diagnostic Imaging for PS

Abdominal radiologic imaging with CT and/or MRI has become the standard for evaluating the patient with a known or suspected PS, and for surveilling patients to determine resolution versus persistence of the PS (Fig. 2). In addition to providing critical information about the size, location, and characteristics of the PS, these studies allow for evaluation of the local anatomy to guide any planned intervention, help to differentiate PS from other cystic neoplasms, and can identify any major associated pancreatic abnormalities that may drastically alter the treatment plan. In particular, CT scan is highly accurate for identifying pancreatic necrosis and for differentiating a true PS from necrotizing pancreatitis with walled-off necrosis. CT scan is also the modality of choice for surveillance of an identified early peripancreatic fluid collection to evaluate for resolution versus progression to a PPC, or to assess resolution versus progression to a known PS. It is particularly important for the surgeon to integrate the patient history and carefully review the CT scan characteristics to differentiating true PS from WON or other diagnoses as we continue to see the term pseudocyst erroneously applied as a catch all diagnosis in radiologic reports. Although transabdominal ultrasonography has little role in the initial diagnostic imaging for PS, it can be useful for characterization and serial surveillance imaging in patients with a known PS and to avoid the need for multiple repeat CT or MRI scans.

The role of MRI with cholangiopancreatography (MRCP) as an alternative or complementary study has also increased over time because of the improved ability to evaluate details of the pancreas and biliopancreatic ductal system compared with CT. This can provide critical information that will significantly alter the management, including signs of CP with ductal strictures and dilation, ductal communication with the PS, pancreatic atrophy or calcification, disconnected duct anatomy, and signs suggestive of cystic neoplasm or malignancy rather than PS. In the past, many surgeons advocated for routine endoscopic retrograde cholangiopancreatography (ERCP) in these patients to assess the ductal anatomy and to demonstrate any patient communication between the main pancreatic duct and the PS cavity. We have found that the detail and reliability of MRCP evaluation of the ductal system has supplanted the need for routine ERCP, and that an MRCP will often be requested by most pancreatologists before proceeding to ERCP. In cases in which MRCP is not available or indeterminate, or has identified a ductal abnormality requiring further delineation or intervention, the patient should usually proceed to ERCP for definitive delineation of pancreatic ductal anatomy and any communication with the PS. In addition to being diagnostic, ERCP can provide adjunctive or even definite

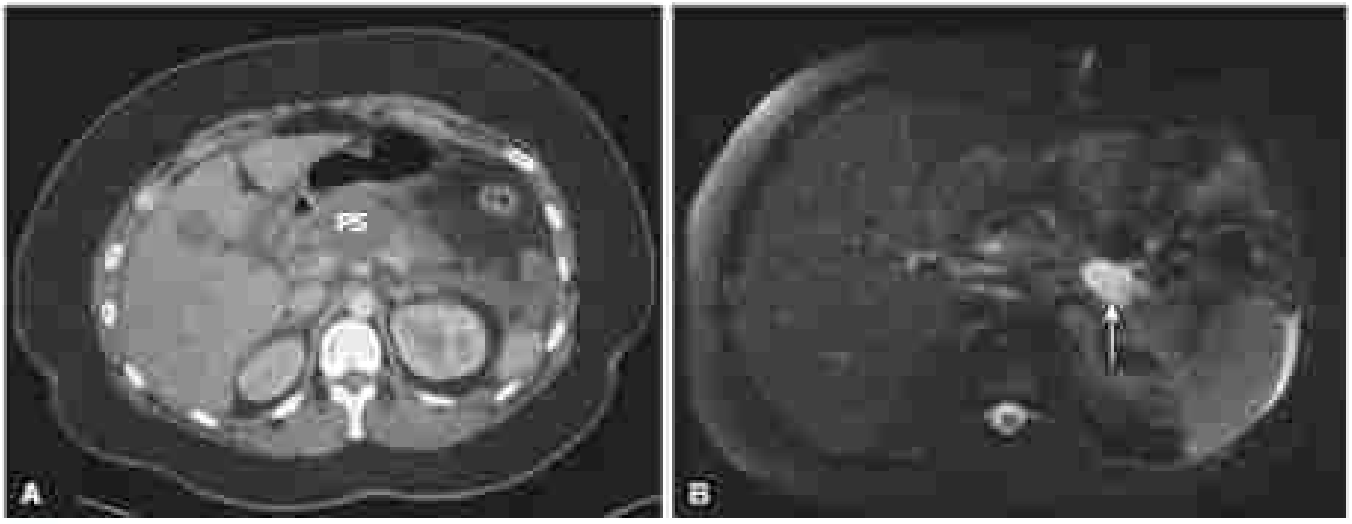

FIG. 2 (A) Computed tomography scan demonstrates a small pseudocyst in relation to the mid-body of the pancreas. (B) Magnetic resonance imaging with T2-weighted imaging shows round and homogeneously enhancing lesion (arrow) in the distal pancreatic body consistent with a pseudocyst. PS, pseudocyst.

TABLE 1 Comparison of Characteristics of PS, WON, and Cystic Neoplasms of the Pancreas

	PS	WON	Cystic Neoplasm
History	Acute HP episode or trauma	Acute NP episode	No prior pancreatitis or acute mild episode
Timing	>4 weeks from HP event	>4 weeks from NP event	Mature cyst present at initial imaging
Symptoms	Minimal to asymptomatic	Systemically ill/sepsis	Minimal to asymptomatic
CT appearance	Round/oval, well formed wall, no debris/septations	Irregular, thick wall, debris, loculations, associated pancreatic necrosis	Irregular, multiple septations, dilated main pancreatic duct, duct wall nodules (IPMN)
Pancreas involvement	Extrapancreatic	Extrapancreatic	Intrapancreatic
Usual location	Body and tail	Body and tail	Pancreatic head (IPMN), body/tail (MC and IC)
Cyst wall	Thick, no epithelialization	Very thick, no epithelialization	Epithelialized cyst wall
Cyst fluid	High amylase, low CEA, no mucin, no epithelial cells	High amylase, low CEA, no mucin, no epithelial cells	Low amylase, high CEA, mucin (IPMN or MC), epithelial cells
Malignant potential	No	No	Yes, highest for IPMN

CEA, carcinoembryonic antigen; HP, interstitial edematous pancreatitis; IPMN, intraductal papillary mucinous neoplasm; MC, mucinous cystic neoplasm; NP, necrotizing pancreatitis; PS, pseudocyst; SC, serous cystic neoplasm; WON, walled-off necrosis.

therapy via balloon dilation of ductal strictures, stenting across pancreatic ductal defects, or providing internal drainage of the PS by transpapillary stent placement. Endoscopic ultrasound (EUS), either alone or in conjunction with ERCP, is an increasingly used modality that can provide additional detailed pancreatic and ductal anatomy information and ultrasound-guided cyst fluid sampling or tissue biopsy. This is most commonly indicated when there is concern that the PS may in fact be a pancreatic cystic neoplasm, and in particular with concern for a possible intraductal papillary mucinous neoplasm (IPMN). In this setting, EUS has a reported sensitivity of up to 90% and specificity approaching 100% and can also reliably distinguish benign from malignant lesions. Findings consistent with an IPMN or other cystic neoplasm on ERCP or EUS include mucin extruding from the ampulla, hypervisible nodules in the duct wall, cyst septations, cyst fluid with mucin or elevated CEA, and epithelial cells on cytology or needle biopsy.

Differential Diagnosis

As should be obvious from the preceding material, one of the most critical components to assessing these lesions and determining the optimal management strategy is to narrow down the differential diagnosis to the correct conclusion. Of utmost importance is not taking a radiologic report stating "pancreatic pseudocyst" at face value and assuming that is the correct diagnosis. Fortunately, the differential is usually limited to only several likely possibilities, and these can readily be discerned by careful review of the history, imaging findings, and select use of additional diagnostic modalities such as ERCP or EUS. The potential diagnoses in these cases usually consists of PS versus walled-off necrosis or a cystic neoplasm of the pancreas, and Table 1 lists some of the key factors and diagnostic criteria that can be helpful in making the correct diagnosis. However, it must be emphasized that very few of these criteria are absolute, and individual factors should not be considered in isolation but rather in relation to one another to

correct diagnosis. One example of this is the common pitfall that a cystic mass in a patient with a current or recent history of acute pancreatitis is likely to be a PS, but epidemiologic studies have demonstrated that 20% to 30% of cystic neoplasms may initially present as an episode of acute pancreatitis. However, unlike PS, which takes weeks to mature, cystic neoplasms are fully formed with a mature cyst wall on the initial imaging studies done at the time of admission or within the first several days. This should prompt additional diagnostic evaluation to evaluate for an IPMN or other cystic neoplasm, and to ensure that a malignant or premalignant lesion is not written off as a PS. Fig. 3 shows side by side examples of characteristic cross-sectional imaging appearance and features of PS versus WON versus a cystic neoplasm (IPMN).

Ductal Evaluation

A key component of the assessment and deciding on the optimal management strategy for PS is an understanding of the interplay between the pancreatic ductal anatomy or associated anomalies and the likely response of the PS to specific interventions. In discussing this in teaching conferences, a standard assertion is that after a PS is identified on cross-sectional imaging an ERCP should be performed to determine "if it communicates with the pancreatic duct" (Fig. 4). However, actual practice is not that straightforward, and has also evolved significantly as noninvasive imaging of the ductal anatomy has improved dramatically. By definition, if the lesion is a true PS, then it either has a communication with the pancreatic ductal system, or it had one that has subsequently sealed. In addition to the issue of an active communication with the duct, other ductal abnormalities associated with pancreatitis that can be seen with PS are critical to delineate. These include the disconnected duct syndrome described previously, ductal stricture with obstruction, and irregular dilation or the string of beads ductal appearance consistent with CP. A useful system for categorizing the duct anatomy and anomalies associated with a PS has been described by Nealon and colleagues (Fig. 5). This ductal characterization is not only important for planning, but is also has major implications to selecting the appropriate intervention and in the risk of failure or complications following intervention. The ductal anatomy can besides be categorized as type I to type IV, and then within each type can be subcategorized (using "a" or "b") by whether a demonstrable connection with the PS is present or absent.

MANAGEMENT AND INTERVENTIONS

Arguably, the most important distinction in selecting the optimal management strategy and intervention for PS is the presence or absence of associated symptomatology. We generally concur with the recommendations from the 2013 evidence-based guideline on acute pancreatitis by the American College of Gastroenterology, stating: "Asymptomatic pseudocysts and pancreatic and/or extrapancreatic necrosis do not warrant intervention regardless of size, location, and/or extension (moderate recommendation, high quality of evidence)." However, there are exceptions to this rule such as the stability rule on a cystic neoplasm, rapidly enlarging PS, and patients in high-risk occupations or locations where immediate medical attention will not be readily available. In addition to the lower likelihood of spontaneous resolution, the risk of subsequent complications such as rupture or infection are higher in larger lesions (>10 cm) and therefore the decision for intervention versus observation should be individualized to each patient. The oft-quoted "rule of nines" that intervention is indicated for PS larger than 6 cm and persisting longer than 6 weeks should largely be abandoned in favor of a more individualized and nuanced approach as outlined here.

For symptomatic PS or those associated with pancreatic or pancreatic ductal pathology that requires intervention, there are now a wide variety of options that range from minimally invasive endoscopic or percutaneous interventions to major open surgery. Key factors in selecting the optimal intervention include not only

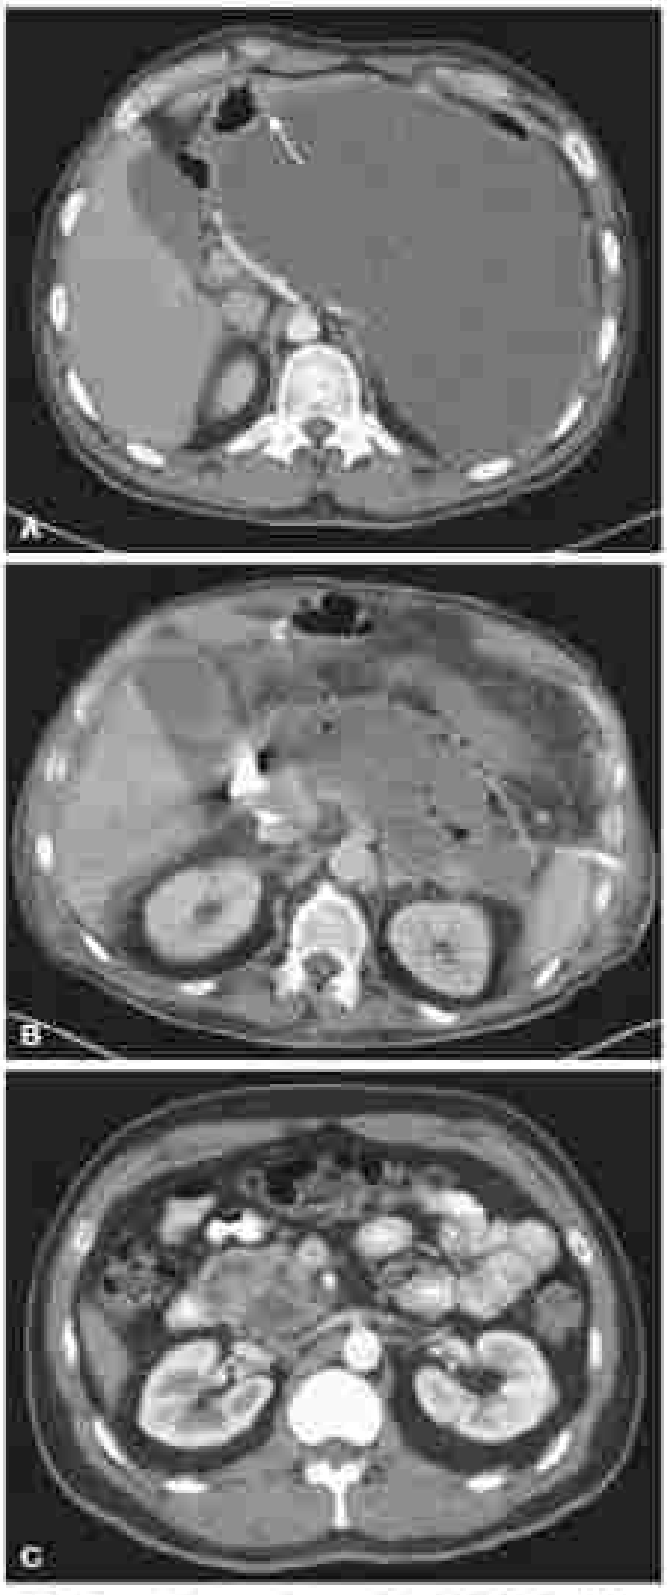

FIG. 3 Characteristic computed tomographic imaging findings for (A) large cystic mass displaying stomach (arrow) with mixed, regular shape and solid components consistent with pseudocyst, (B) irregular cystic fluid collection with debris and air consistent with walled-off necrosis (C) irregular septated cystic mass in head of pancreas consistent with a cystic neoplasm.

the individual procedure's efficacy and complication profile, but also the likelihood of recurrence or need for multiple interventions. In addition, many of these options, particularly some of the advanced endoscopic interventions, are technically difficult and require a significant level of advanced skills and comfort by the gastroenterologist or surgeon. We have found that in many review papers or chapters about PS, these options are all laid out as if they are all routinely and equally available, whereas in reality they may be limited to select settings (urban, high volume, academic), and either patient transfer or proceeding with an alternative intervention must be decided.

Percutaneous Drainage

Image-guided percutaneous drainage (PD) is among the least invasive of the available options for PS, but it should be used in only very specific scenarios as the primary intervention. Although PD can usually achieve complete cyst drainage/decompression, it is associated with a higher rate of treatment failure and PS recurrence, as well as the complication of a persistent pancreatic fistula if used in the setting of a patent communication between the PS and the pancreatic ductal system. In a large national study of more than 14,000 patients comparing PD with open surgery for PS, PD was independently associated with increased complications, PS recurrence, and mortality. However, this (and most) study suffers from significant selection bias, and it did not have an endoscopic intervention group for comparison. Another concern with performing PD, particularly for minimally symptomatic PS, is bacterial seeding and infection which then requires urgent drainage. Although there is a risk of converting a PS to a pancreatic abscess with any instrumentation or surgical intervention, the risk appears to be higher for percutaneous drainage versus most other endoscopic or surgical drainage procedures.

Percutaneous drainage of the PS also does nothing to address any proximal pancreatic duct pathology if present, and therefore we are concerned using PD as a primary therapeutic option only to the setting of a PS with a normal pancreatic duct and no communication (type Ia). When used in the setting of type II to IV pancreatic ductal anatomy, the reported failure rates of PD are high (50%–90%). However, PD may be indicated even in the setting of known ductal pathology as a temporizing and/or initial diagnostic maneuver. These scenarios would mainly include patients with severe physiologic disturbance or comorbid disease that are prohibitive for other more invasive interventions, or in patients with an acutely infected PS (pancreatic abscess). PD has also been proposed by some experts to help with the

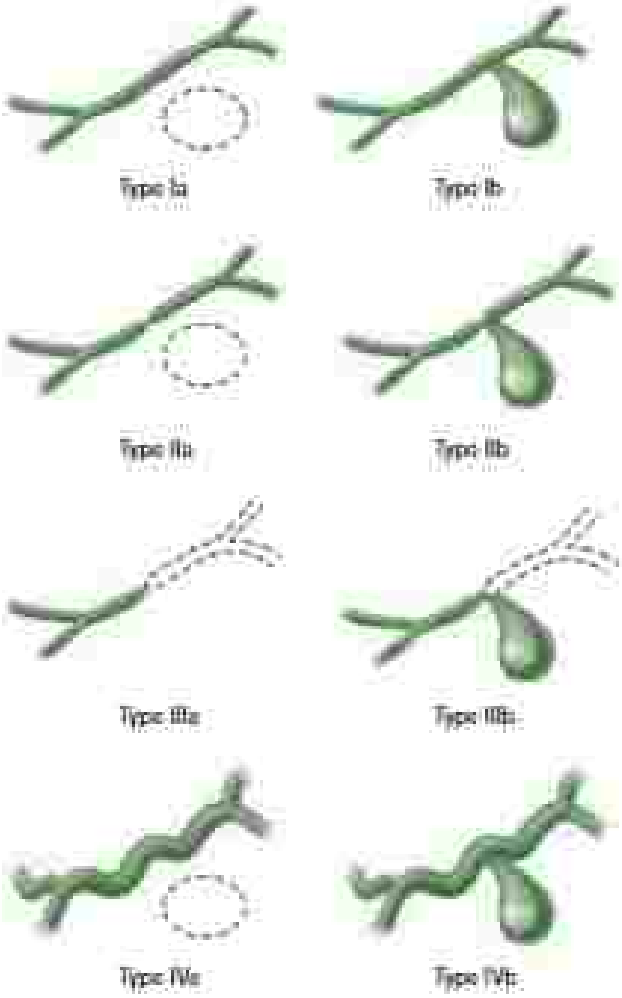

FIG. 5 Classification of associated pancreatic duct anatomy and anomalies: type I, normal ductal; type II, ductal stricture/obstruction; type III, disconnected distal duct; and type IV, irregular main dilation, common with chronic pancreatitis. Subgroups are identified by "a" for no ductal communication with pseudocyst and "b" ductal communication present. (From Adams MA, [illegible])

diagnosis and delineation of the distal pancreatic duct segment when imaging via standard modalities is not possible (i.e., the disconnected duct). In these cases, imaging of the distal pancreatic duct segment can be done with injection of contrast via the percutaneous drain under fluoroscopy, which can aid with characterization of the disconnected ductal segment and planning for the optimal endoscopic or operative intervention.

Endoscopic Interventions

Endoscopic techniques, equipment, and experience with both diagnostic and therapeutic interventions for PS have advanced dramatically over the past decade, and are now arguably the mainstay for management of most uncomplicated PS. In addition to being less invasive than surgical drainage procedures, endoscopic techniques can be used to simultaneously address both drainage of the PS and many of the associated pancreatic ductal lesions or injuries. Endoscopic drainage procedures for PS can be broadly categorized as either internal (via the pancreatic duct) or transmural (via the abutting stomach or

FIG. 8 (A) Endoscopic cystgastrostomy with cystgastric needle aspiration to confirm pseudocyst location, which is usually identified by the bulging of the posterior gastric wall. (B) A covered self-expanding metal stent is deployed to create and maintain the cystgastrostomy tract.

duodenum). In addition, these procedures can either be performed via standard endoscopy or with the addition of EUS guidance. Unlike percutaneous drainage, the presence of a known ductal communication with the PS (Fig. 4) is not a relative contraindication to internal or transmural endoscopic drainage procedures and can often be simultaneously addressed during the endoscopic drainage procedure.

An internal endoscopic PS drainage procedure refers to accessing and transpapillary stenting of the main pancreatic duct to allow internal drainage of the PS fluid back into the duct and duodenum. This obviously is only applicable to PS with a clearly identified and patent communication with the pancreatic ductal system and without proximal obstruction or discontinuity of the duct and is most suitable for the type IIa or IIb duct (Fig. 5). Although this can also be effective for the type IVb duct, there is a higher recurrence rate and likely continued severe symptomatology related to the accompanying CP that should be addressed as outlined below. For the type IIIb duct (disconnected duct), this is usually not a viable alternative because the duct is in discontinuity. There are published descriptions of attempting blind or image-guided stent placement across the defect, or alternatively accessing the distal duct segment through the gastric wall under EUS guidance and placing a transgastric stent. However, these advanced endoscopic procedural skillsets are relatively uncommon and it does not address the long-term problems of the disconnected duct and the isolated distal pancreatic segment.

Endoscopic transmural drainage procedures have become increasingly common, and in many centers have largely replaced surgical drainage for uncomplicated PS or in patients who have prohibitive risk factors for surgical intervention. These are done by creating a wide communication between the PS and the lumen of either the stomach (most common) or duodenum (less common). This is typically done in sequence by: (1) endoscopic inspection of the gastric lumen to identify the site of "bulging" of the posterior wall due to extrinsic compression from the PS, (2) needle aspiration to confirm the location (Fig. 6A), (3) creation of a small gastrotomy into the PS via needle knife, (4) balloon dilation of the tract, and (5) placement of either multiple small double pigtail stents or a single larger self-expanding covered metal stent (Fig. 6B). Tissue from the cyst wall should be collected for pathologic evaluation to definitively rule out a cystic neoplasm or malignancy. In select cases of larger PS or with significant debris present, a nasocystic drain may be left behind for continued cavity irrigation and drainage. Prior or simultaneous ERCP is performed if there is a patent ductal communication or a proximal pancreatic duct stricture requiring transpapillary stenting or other endoscopic intervention to optimize internal drainage and prevent PS recurrence. These stents or pigtail catheters should be left in place for at least 4 weeks because recurrence has been found to be significantly higher with stent/drain removal before 4 weeks. Repeat imaging should be performed to document successful drainage and resolution of the PS prior to stent or drain removal (Fig. 7). A small randomized trial and multiple non-randomized series have demonstrated improved outcomes with endoscopic versus surgical PS drainage, although the incidence of requiring additional interventions is higher. In addition, these studies used open surgery as the comparison group, and it is unclear if different results will be seen with the increased utilization of minimally invasive surgical approaches to PS.

EUS is an important adjunct to these procedures as it can help exactly localize the PS and guide the drainage procedure, assess for complete evacuation and collapse of the PS, and assess for any additional anatomic abnormalities or signs of an alternative diagnosis. There have now been two randomized trials demonstrating the superiority of EUS-guided versus standard endoscopic PS drainage, and we recommend maximal use of this adjunct if available. This is particularly critical if endoscopic cyst-duodenostomy is being performed because there will often not be a visible bulge to locate the optimal puncture site and EUS can readily identify critical structures including the pancreatic duct and common bile duct to avoid iatrogenic injury.

It is important to both the safety and success of endoscopic transmural drainage procedures that enough time has lapsed to allow the PS to mature and have a well-formed capsule that is adherent to the stomach or duodenum. In addition to simply estimating the time interval, it is critical to review the preoperative cross-sectional imaging for signs of an adequately thick and well-formed PS wall, and to assess the location and anatomic relationship of the PS to the adjacent stomach or duodenum. A PS that is not directly adjacent to and abutting the gastric or duodenal wall is generally not a candidate for safe transmural drainage and usually will require a surgical drainage procedure. Optimal endoscopic candidates should also have a PS wall thickness of between 3 and 10 mm, with a common recommendation for surgical drainage in PS with wall thickness greater than 10 mm.

Surgical PS Drainage Procedures

With the marked improvements in endoscopic equipment, techniques, and experience over the past several decades, the need for operative

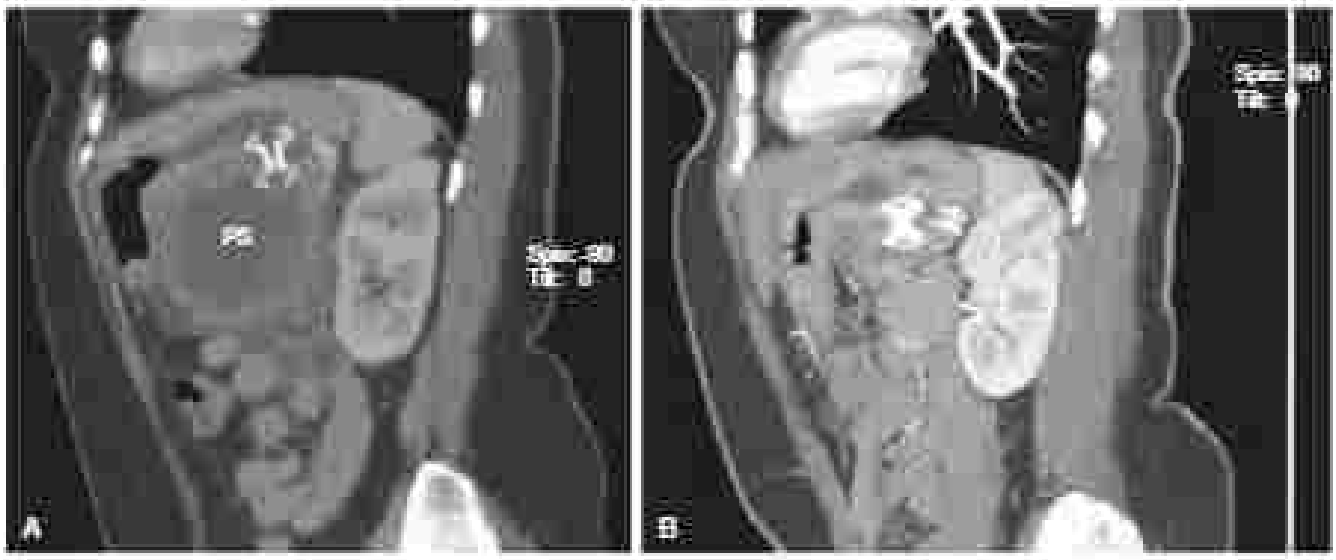

FIG. 7 (A) Computed tomography (CT) scan after endoscopic cystogastrostomy shows stent in good position between the stomach and pseudocyst. (B) CT scan 4 weeks later shows successful cystic drainage with collapse of pseudocyst (PS).

intervention for PS has decreased significantly. However, surgical interventions remain a key and important aspect of PS management and are still frequently required in cases of PS with complex associated ductal or pancreatic pathology. In addition, operative drainage or resectional procedures are still required in cases of failure of percutaneous or endoscopic treatments and may also be used more frequently in settings where there is low access to advanced therapeutic endoscopists. It is not uncommon to see patients who have undergone multiple percutaneous and/or endoscopic attempts at drainage and associated complications prior to any surgical referral. In cases where there has been clear failure or recurrence after an adequate endoscopic drainage procedure, we encourage an initial consultation with an experienced surgeon for input on the pros and cons of additional endoscopic or percutaneous attempts versus prompt surgical intervention.

Surgical treatment for PS typically involves creation of an anastomosis between the cyst wall and the gastrointestinal tract to facilitate drainage and decompression of the fluid, any debris, and obliteration of the cavity. The two most common procedures for accomplishing this are cystogastrostomy and cystojejunostomy, and less commonly cystoduodenostomy, which is typically reserved for smaller PS in the head of the pancreas. Although these operations have traditionally been performed as an open procedure, they can now be readily accomplished using minimally invasive techniques such as laparoscopy and more recently robotic assisted surgery. Although this discussion is often presented as either endoscopic or surgical therapy, the optimal results are obtained with a combined multimodality approach (if needed) to address both the PS and the underlying etiology, particularly for PS with an identified ductal communication. Most commonly this means confirming surgical drainage with endoscopic interventions such as ERCP and pancreatic duct stenting and/or stricture dilation to optimize transpapillary drainage. In highly select cases of large PS that are very well encapsulated and not adherent to surrounding structures, the cyst can be excised en bloc with concomitant ligation or obliteration of any patent fistula with the pancreatic duct.

Selection of the optimal drainage procedure should be based on careful review of the anatomic relationships identified on preoperative cross-sectional imaging, and with consideration of any factors, such as gastric varices or prior gastrointestinal surgery, that would dictate a different surgical plan. Because the majority of PS is limited to the lesser sac and directly abuts the posterior wall of the stomach, cystogastrostomy is the simplest and most commonly performed transmural drainage procedure. Advantages of this approach include minimal manipulation of the gastrointestinal tract, the avoidance of any direct dissection into the lesser sac and pancreas, and shorter operative times. Disadvantages include the usual need for an anterior gastrotomy to access the site and a possibly increased risk of infectious and bleeding complications versus cystojejunostomy, although this continues to be debated in the literature. We have found surgical cystogastrostomy to be a safe and effective intervention, and with a complication profile similar to cystojejunostomy.

Cystogastrostomy is most commonly performed using a transgastric approach through the anterior gastric wall (Fig. 8). For open cystogastrostomy, a longitudinal gastrotomy is made in the anterior wall of the mid stomach and centered as much as possible over the PS. This incision will be more forgiving if extensions proximally and/or distally is needed and can be easily closed in longitudinal or transverse fashion to avoid narrowing the gastric lumen. Stay sutures on each edge of the gastrotomy are helpful to retract the edges and widely expose the posterior wall of the stomach. Inspection typically reveals an obvious bulge at the location of the PS, but if unclear then needle aspiration or intraoperative ultrasound can be performed to confirm the location. Entry into the PS through the posterior stomach wall is then made and the cyst fluid and any debris are suctioned. An adequate anastomosis is then created between the PS wall and the posterior stomach which can either be handsewn or stapled. We prefer a stapled anastomosis for both speed and simplicity. A fragment of the cyst wall should be excised for pathologic analysis, and any remaining fluid or debris is evacuated through the wide anastomosis. The anterior gastrotomy can then be closed with either a running suture or stapled. Less commonly, cystogastrostomy can be performed via an exogastric approach by direct exposure of the PS in the lesser sac and then direct creation of the anastomosis to the posterior wall of the stomach. This is typically reserved for smaller pseudocysts that make transgastric localization more difficult, and that can be readily exposed without risk of cyst rupture or damage to the stomach or pancreas.

Minimally invasive cystogastrostomy typically uses the same basic sequence to approach the pseudocyst and create the anastomosis (Fig. 9A). Although either a handsewn or stapled anastomosis (Fig. 9B) can be performed laparoscopically, the stapled approach is much simpler versus laparoscopic intracorporeal suturing for both the anastomosis and the anterior gastrotomy closure. An alternative technique uses a transgastric laparoscopic approach in which the trocars are inserted into the gastric lumen, which is then insufflated to allow a working space to perform the cystogastrostomy. Either balloon tipped trocars

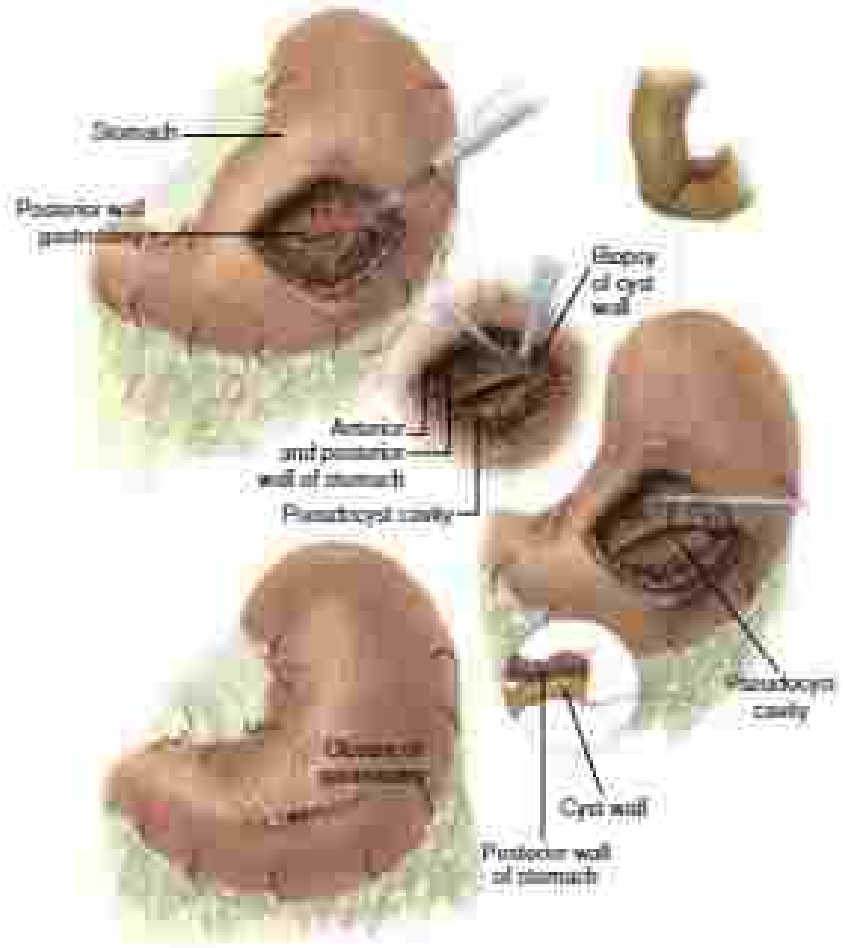

FIG. 8 Surgical cystogastrostomy procedure showing anterior and posterior gastrostomies to expose and then enter the pseudocyst (upper left and inset), creation of full-thickness cystogastrostomy anastomosis (middle), and closure of anterior gastrostomy (bottom).

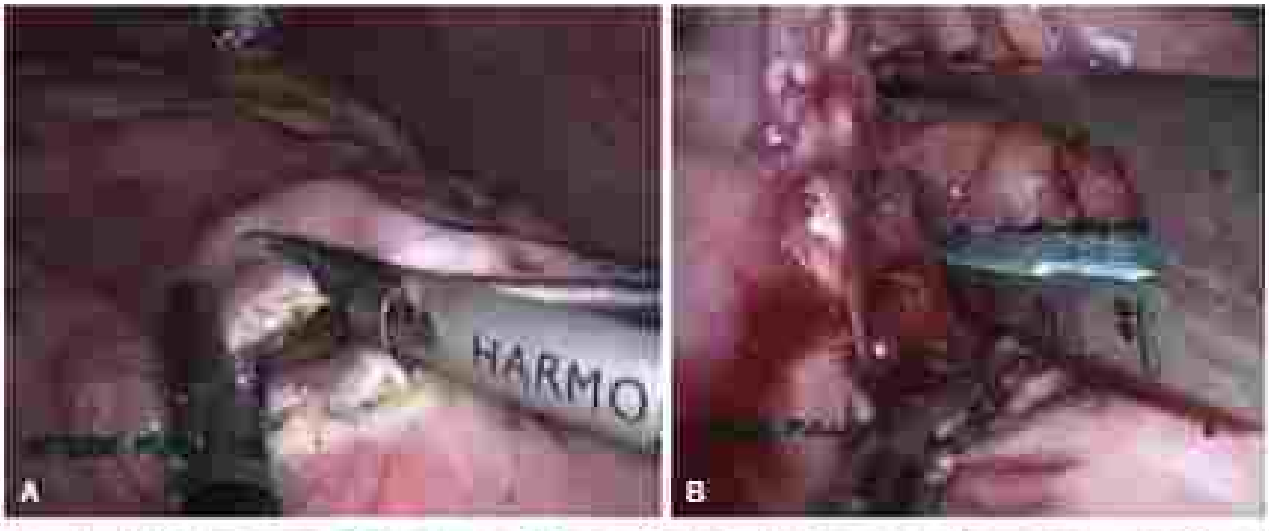

FIG. 9 Laparoscopic or robotic-assisted surgical cystogastrostomy is performed by (A) making an anterior enteral gastrostomy to expose the posterior gastric wall and (B) insertion of linear stapler with one end into pseudocyst cavity and the other end in the stomach to create the cystogastrostomy anastomosis.

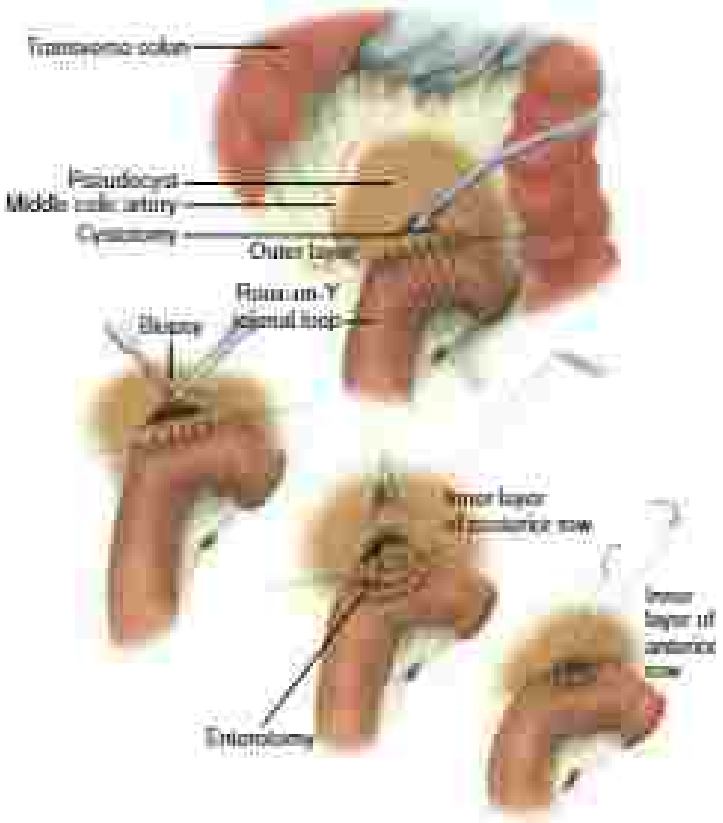

FIG. 18 Surgical cystojejunostomy between a jejunal Roux limb and a large pseudocyst bulging into the transverse colon mesentery (top) with completion of full-thickness posterior layer (middle two panels) and then completion of anterior layer (bottom). or anterior gastric stay sutures at each trocar site are used to prevent the trocars from dislodging and to maintain gastric insufflation. More recently, these procedures have been described using a robotic surgery platform, which are nearly identical to the laparoscopic approach but with much better camera optics and visualization, and with greater ease of intracorporeal robotic assisted suturing.

Cystojejunostomy is the second most commonly performed drainage procedure for PS and offers similar efficacy and success rates as cystogastrostomy. This is typically performed using a proximal segment of jejunum that reaches easily to the area of the PS, and then constructed as a Roux-en- with the cystojejunostomy to the Roux limb and then a jejunojejunostomy to restore continuity (Fig. 18). Cystojejunostomy is clearly indicated for pseudocysts that are not abutting the stomach or duodenum or are located outside of the lesser sac, but can be used for transmural drainage of almost any PS. Advantages over cystogastrostomy include the ability to drain PS in almost any abdominal location and the ability to drain multiple PS, whereas disadvantages include the need for two anastomoses and the more technically demanding nature of the anastomosis. Unlike the cystogastrostomy, it does usually require exposure and visualization of the PS wall for at least enough length to create an anastomosis. Technically, the anastomosis is similar to the cystogastrostomy, and can be stapled (circular or linear) or handsewn. There are some data suggesting that a stapled cystojejunostomy is associated with increased complications (bleeding and infection) compared with a handsewn method, although the series are relatively small and underpowered. The most important factor for technical success with cystojejunostomy is waiting until a thick and well formed wall is present that can readily hold sutures and support an anastomosis. If a linear stapled anastomosis is performed, then particular attention should be paid to closure of the common enterotomy to avoid narrowing of the intestinal lumen which can lead to failure to resolve the PS or to an anastomotic leak.

Surgery for PS With Major Pancreatic or Ductal Pathology

A distinction of successful management and long-term resolution for PS is that the evaluation and management strategy must also focus on identifying critical, related pancreatic or ductal disease that requires concomitant intervention. Several series have shown that failure and recurrence rates are high when a drainage procedure alone is performed in patients with major ductal strictures or obstruction, and that continued symptoms are the rule in patients with PS associated with CP. In these cases, we recommend approaching these scenarios with the mindset that the pancreatic/ductal pathology is the primary issue that requires intervention, and the PS is a secondary effect or manifestation that can only be resolved by treating the underlying cause.

For patients with disconnected duct syndrome (type III in Fig. 5) associated with mild body necrosis and loss of the central segment of the main pancreatic duct, surgical intervention should focus on either resecting drainage to the distal disconnected pancreatic segment or performing operative resection of that segment. Characterization of the distal pancreatic duct is important for preoperative planning, and often, an MRCP can be adequate. If not, then percutaneous drainage of the PS can be performed as an initial measure to decompress the PS and then to perform a fistulogram via injection of contrast through the drain. Surgical options then would include a PS drainage procedure alone (cystogastrostomy or cyst jejunostomy), restoration of pancreatic duct drainage via a pancreaticojejunostomy to the distal segment, or resection via distal pancreatectomy/splenectomy. Intraoperative decompression or excision of the PS is performed, but no formal PS drainage procedure needs to be performed. Deciding among these options is a complex and highly individualized process, and referral or consultation with an experienced pancreatic surgeon is strongly recommended. In addition to the anatomic considerations, a key consideration in the likelihood of postoperative pancreatic insufficiency or

diabetes with resection of the disconnected segment versus preservation and drainage. It is also important to clearly distinguish this patient population from the less common cohort who has a disconnected duct and distal segment resulting from a traumatic injury to the pancreas. These patients usually have an otherwise normal pancreas outside of the zone of injury, may have multiple associated injuries that impact the treatment plan, and will have a different risk/benefit ratio for operative drainage versus resection of the distal pancreatic segment.

These operations can be particularly difficult because the frequent presence of significant scarring, inflammation, and distorted anatomy, and may require opening the PS cavity to access the distal pancreatic segment. If drainage via pancreaticojejunostomy is selected, this should be done with a Roux-en-Y reconstruction and passage of the roux limb through a window in the transverse mesocolon. The type of anastomosis (duct to mucosa, intraluminal, lateral) will be based on the size of the duct, the presence of any strictures, the character of the pancreatic parenchyma (hard vs soft) and individual surgeon preference and experience. An alternative option that has been described is drainage into the stomach via a pancreaticogastrostomy. This option has the advantage of obviating the need for any small bowel manipulation and requires only one anastomosis instead of two. However, many surgeons have less familiarity with this type of anastomosis, and the inflammation of the posterior gastric wall from the pancreatitis and the PS often makes this option less feasible.

Resection of the disconnected pancreatic segment via distal pancreatectomy is the other viable option. Although at first glance this would seem to be the simpler and superior option versus a complicated drainage procedure and high-risk pancreatic anastomosis, resection may have significant longer-term adverse effects that must be considered. Although distal pancreatectomy is routinely performed for other indications (neoplasm, trauma) without significant concern for a functional impact, this should not be extrapolated to these scenarios. Among patients who have had a significant episode of necrotizing pancreatitis with loss of some or all of the tail pancreas (and likely dysfunction of the remaining pancreas), the impact of removing the disconnected distal pancreatic segment must be carefully considered. This can result in significant and lifelong problems, including pancreatic exocrine insufficiency and a high risk of new-onset diabetes or conversion of any insulin dependent diabetes to permanent insulin dependence. An additional concern with resection is the need for concomitant splenectomy, and the long-term risk of postsplenectomy infectious complications. Although spleen preserving distal pancreatectomy is routinely performed in other patient populations, in these scenarios, it is often not practical or possible because of the dense inflammatory and fibrotic changes that make it difficult and risky to attempt to separate the pancreas from the splenic artery and particularly the splenic vein. We advocate for resection in patients who have preservation of a significant portion of the proximal pancreas and no existing pancreatic exocrine or endocrine deficiencies, and where intraoperative inspection confirms that a safe mobilization and resection can be performed. Although this option is less ideal for most patients with pancreatitis-associated ductal loss, we consider distal pancreatectomy with or without splenectomy to be the better option for most patients with disconnected duct anatomy resulting from trauma.

The final cohort that must be clearly distinguished and approached differently are those with PS and symptomatic CP with associated irregular ductal dilation (type IV in Fig. 5). Longitudinal studies have demonstrated that spontaneous resolution of a PS in this patient population is significantly lower (<10%) than in PS associated with acute pancreatitis and the majority will have a patent communication between the PS and the pancreatic duct (type IVb). In addition to delineating whether a communication between the pancreatic ductal system and the PS is present, it is critical to not automatically attribute all existing abdominal symptomatology to the PS rather than the CP. In most cases in our experience, the common symptoms of abdominal pain, anorexia, nausea, and dietary intolerance are much more likely to be secondary to the CP than the PS. This is supported by published series showing that drainage of the PS alone in this setting has a high failure and recurrence rate, and also fails to relieve the major abdominal symptoms in the majority of patients. Thus, a comprehensive management plan that addresses both the PS and the CP, and that focuses on optimizing pancreatic ductal drainage, should be developed. ERCP with dilation and transpapillary stent placement may be effective for select patients, such as those with a focal proximal pancreatic duct stricture and distal dilation. However, for most patients with CP and more diffuse ductal pathology, endoscopic therapy has a high failure rate and limited durability and was found to be inferior to surgery in two randomized trials. The highest success rates for resolution of the PS and relief of the CP associated symptoms have been reported in association with surgical drainage or combined resectional drainage procedures for the CP. Once effective drainage or resection and drainage for the CP has been performed, the PS will typically resolve spontaneously.

SPECIAL SCENARIOS AND CONSIDERATIONS

Preoperative and Postoperative Concerns

There are a number of uncommon but significant associated problems or complications that may be seen in patients with suspected or proven PS that may be directly related to the PS or may be coexisting but not causally related. Infection of the PS, which is then more accurately characterized as pancreatic abscess, typically occurs after some type of instrumentation of the lesion and should prompt immediate source control via percutaneous or endoscopic drainage. Bleeding from the PS is another complication that can occur spontaneously or following a drainage procedure, and is usually from the splenic, gastroduodenal, or pancreaticoduodenal arteries. Emergent angiography and embolization are the preferred interventions, with overall poor outcomes reported with attempts at surgical hemorrhage control. Splenic vein thrombosis due to either the pancreatitis or the PS can result in gastric varices that may alter any treatment or intervention plan. This has traditionally been a relative contraindication to attempting endoscopic drainage, but safe endoscopic cystogastrostomy can be performed with EUS guidance to avoid any variceal vessels. The presence of gastric varices (on imaging or endoscopy) is also an indication for concurrent splenectomy with any operative procedure for the PS. Obstruction of the gastrointestinal tract (typically gastric or duodenal), bile duct, or pancreatic duct can occur from mechanical compression by the PS and represents an additional indication for intervention. However, this is relatively uncommon and should raise the concerns for an associated malignancy or for a benign intrinsic stricture as the true cause. Additional diagnostic workup (EUS/CT/MRI, MRCP) should be performed to better characterize the PS and ductal system rather than performing an immediate intervention that could compromise future options. Finally, the rupture of a PS may result in a picture of diffuse intraperitoneal free fluid (pancreatic ascites) that may be misinterpreted as evidence of diffuse hemorrhage or of ascites related to carcinosis. CT scan analysis of the fluid can usually distinguish blood from ascites, and the history and rapidity of accumulation of the ascites can usually distinguish pancreatic from hepatic sources. Sampling of the fluid for analysis including an amylase level confirms the diagnosis. Because the fluid contains inactivated pancreatic enzymes, there is usually little to no associated abdominal pain, although subjective fullness, bloating, and discomfort can be seen. Urgent intervention for the ascites is not required, and the treatment plan should focus on management of the PS and pancreatic ductal system as outlined here.

Walled-Off Necrosis

Necrotizing pancreatitis with an associated mature, solid-debris–containing infection consistent with walled-off necrosis (WON) must be clearly distinguished from acute nonnecrotizing pancreatitis with subsequent PS formation (Fig. 3). This critical distinction should be made early in

the diagnostic evaluation and treatment planning phases because it will drive key decisions on the type and timing of interventions that will be markedly different versus those for a PS. The optimal approach for WON has evolved from major open surgical debridement to more minimally invasive options including video assisted retroperitoneal debridement (VARD) and endoscopic drainage with necrosectomy. The widely used step-up approach utilizes sequential escalating interventions starting with percutaneous drainage, drain upsizing, and then a VARD procedure if needed. The surgical step-up approach has been validated in the Pancreatitis, Necrosectomy Versus Step-Up Approach randomized trial to be superior to open necrosectomy, and a more recent randomized study found that endoscopic drainage and necrosectomy is equally effective but with less morbidity. We have not infrequently seen both the diagnostic and interventional approach for PS confused with that of WON, which then results in suboptimal outcomes and unnecessary or futile interventions. Among the key differences in approaches are (1) WON carries a much higher infection risk versus PS, (2) percutaneous drainage is usually the first intervention of choice for WON but not for PS, (3) surgical or endoscopic intervention for WON must include debridement of all necrotic pancreatic and debris whereas PS typically requires no debridement, and (4) a VARD procedure *or* the step-up approach is for WON and should not be used for PS.

CONCLUSIONS AND CRITICAL DECISIONS

The evaluation, diagnosis, and management options for pancreatic PS have evolved significantly over the past decade and can be expected to continue to evolve with improvements in imaging, endoscopic, and surgical techniques and technology. The optimal modern management of the patient with a suspected or proven PS involves a stepwise series of critical decisions as shown in Fig. 11 and starts with using the current terminology and definitions as outlined in the 2012 revised Atlanta classification system for acute pancreatitis. Among the most important of these is accurately diagnosing and characterizing any associated pancreatic ductal pathology which will frequently drive decisions on which intervention has the highest likelihood of success and when combined endoscopic and surgical interventions are indicated. Although the trends in the management approach to PS have moved toward expanded use of observation only, percutaneous, and endoscopic interventions, there remains a defined role and need for surgical interventions to select patients with more complicated PS or after failure of less invasive alternatives. Exciting advances in minimally invasive surgical equipment and techniques, including advanced laparoscopic and robotic surgery platforms, are now being applied to the management of this patient population and can be expected to reduce or eliminate much of the morbidity associated with traditional open PS surgery.

Pancreatic Ductal Disruptions Leading to Pancreatic Fistula, Pancreatic Ascites, or Pancreatic Pleural Effusions

Roxanna L. Mansoori, MD, and Z. Jia Hines, MD

DEFINITIONS

Following is a list of terms commonly associated with pancreatic ductal disruption:

- **Acute peripancreatic fluid collection:** A fluid collection near the pancreas that occurs within the first 4 weeks after the onset of pancreatitis. This is to be differentiated from a pseudocyst that occurs later.
- **Pancreatic ductal disruption:** A disruption in the main pancreatic duct resulting in a disturbance of the flow of pancreatic juice from the upstream (body/tail) to the downstream (uncinate) portions of the pancreas. This often occurs as a result of pancreatic necrosis and is commonly found in the watershed neck portion of the pancreas where the splenic and pancreaticoduodenal arcades meet (Fig. 1A). When the ductal disruption is complete and at its most extreme, it will be evident on abdominal imaging, such as a computed tomography (CT) scan.
- **Pancreatic fistula:** A pancreatic fistula that communicates with the peritoneal cavity, usually beginning as a leak into the lesser sac. When a pseudocyst is also present, it is presumed that the leak is from the pseudocyst. This is typically well tolerated unless the pancreatic enzymes are activated, which can happen if the collection is secondarily infected with microorganisms.
- **Pancreatic ductal disruption:** Disturbance in any of the pancreatic ducts along the length of the main pancreatic duct or pancreatic duct branches. Disruptions may be demonstrated by imaging or is assumed to be present in the case of amylase rich fluid sampled from a drain or collection.
- **Pancreatic fistula:** Loss of pancreatic fluid through an area of ductal disruption out of the pancreas. A pancreatic fistula can develop to the intraperitoneal, retroperitoneal, or thoracic cavities and also to other organs or the skin.
- **Pancreatic necrosis:** An area of the pancreas that has lost the blood supply; this is diagnosed by contrast-enhanced CT scan as a lack of enhancement of a portion of the pancreas. When the necrosis is to the tissue outside of the parenchyma, it is termed peripancreatic necrosis. Clinically, the development of necrosis is important because this indicates a more severe condition with both local and systemic complications.
- **Pancreatic pleural effusion:** A leak of pancreatic fluid from a disrupted duct into either one of the pleural spaces. The leak will first communicate with the retroperitoneal cavity and then would connect into the thoracic cavity via the esophageal hiatus or directly through the diaphragm. A ductal leak near the portal vein would likely communicate with the right chest and a leak in the distal duct to the left chest.
- **Pancreatic pseudocyst:** A well-circumscribed intra- or peripancreatic fluid collection that forms from pancreatitis. A fluid collection is characterized as pseudocyst 4 to 6 weeks after an episode of acute pancreatitis.
- **Walled-off pancreatic necrosis:** A parenchymal or peripancreatic collection of fluid and necrotic tissue surrounded by a well-defined inflammatory wall occurring 4 to 8 weeks following pancreatitis.

CLINICAL PRESENTATION AND DIAGNOSIS

When to Suspect Ductal Disruption

Inflammation of the pancreas, whether from pancreatic pathology, pancreatic surgery, or trauma, can lead to a pancreatic ductal disruption. Although a certain amount of hyperamylasemia and/or abdominal pain can be normal and transient with pancreatitis or after surgery, persistent symptoms, or suspicious laboratory results after 1 week are concerning for a ductal leak. Often, the surgeon will be suspicious of this event after reviewing initial imaging. A certain level of ductal disruption can be expected when a patient is noted to have a peripancreatic fluid collection, abscess, pseudocyst, or pancreatic necrosis. After pancreatic trauma, grades III through V can be expected to develop a pancreatic ductal disruption and leak. High suspicion must also be maintained after a major pancreatic surgery and is a main reason for leaving a drain to control the leak.

Diagnosing a Ductal Disruption

Because pancreatic enzymes can be particularly caustic to the retroperitoneum and peritoneal cavity, prompt diagnosis and treatment of a pancreatic duct disruption is critical. The first step for diagnosis is a CT scan with intravenous contrast; this will often show a peripancreatic fluid collection or, in the case of a chronic condition, a pancreatic duct dilation. The location of a fluid collection may help discern the area of duct disruption. For example, ventral leaks often gather in the lesser sac, dorsal tail leaks into the retroperitoneum near the left paracolic space, and dorsal head leaks into the retroperitoneum near the right paracolic space. Given the enclosed space, these fluid collections are unlikely to cause peritonitis and instead often form pseudocysts.

Other initial imaging modalities include endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography. In the perioperative setting, drains are typically left in the vicinity of the surgery and comparing a drain with serum amylase level can aid in diagnosis. If no drain is present, fluid can be drained percutaneously under imaging guidance. When a fistula is present, the drain amylase is often more than or equal to three times the serum amylase.

A disrupted pancreatic duct can also present as a pleural effusion if pancreatic fluid leaks into the thoracic cavity. This can occur in the left chest from a disruption of the pancreatic body or tail and travel through the pleuroperitoneal foramina or hiatus to in the chest. Pancreatic fluid can also enter the right thorax with a disruption in the pancreatic neck or the dorsal pancreatic head and travel behind the hepatoduodenal ligament, also ultimately tracking up through the pleuroperitoneal foramina into the chest. When a leak is near the esophagus, pancreatic fluid can track up into the mediastinum. Studies have shown that patients who undergo early operative intervention tend to have earlier resolution of their pancreaticopleural fistula.

Persistent pancreatic fluid leakage requires drainage. Inadequate drainage can lead to pancreatic pseudocyst formation, erosion into surrounding structures such as blood vessels or organs, pancreatic necrosis, or communication with another body compartment such as the mediastinum, pleural cavity, or abdomen. Patients who are left untreated for prolonged periods may develop further pancreatic damage secondary to surrounding inflammation around the pancreas. This could begin a vicious cycle ultimately leading to sepsis and multisystem organ failure.

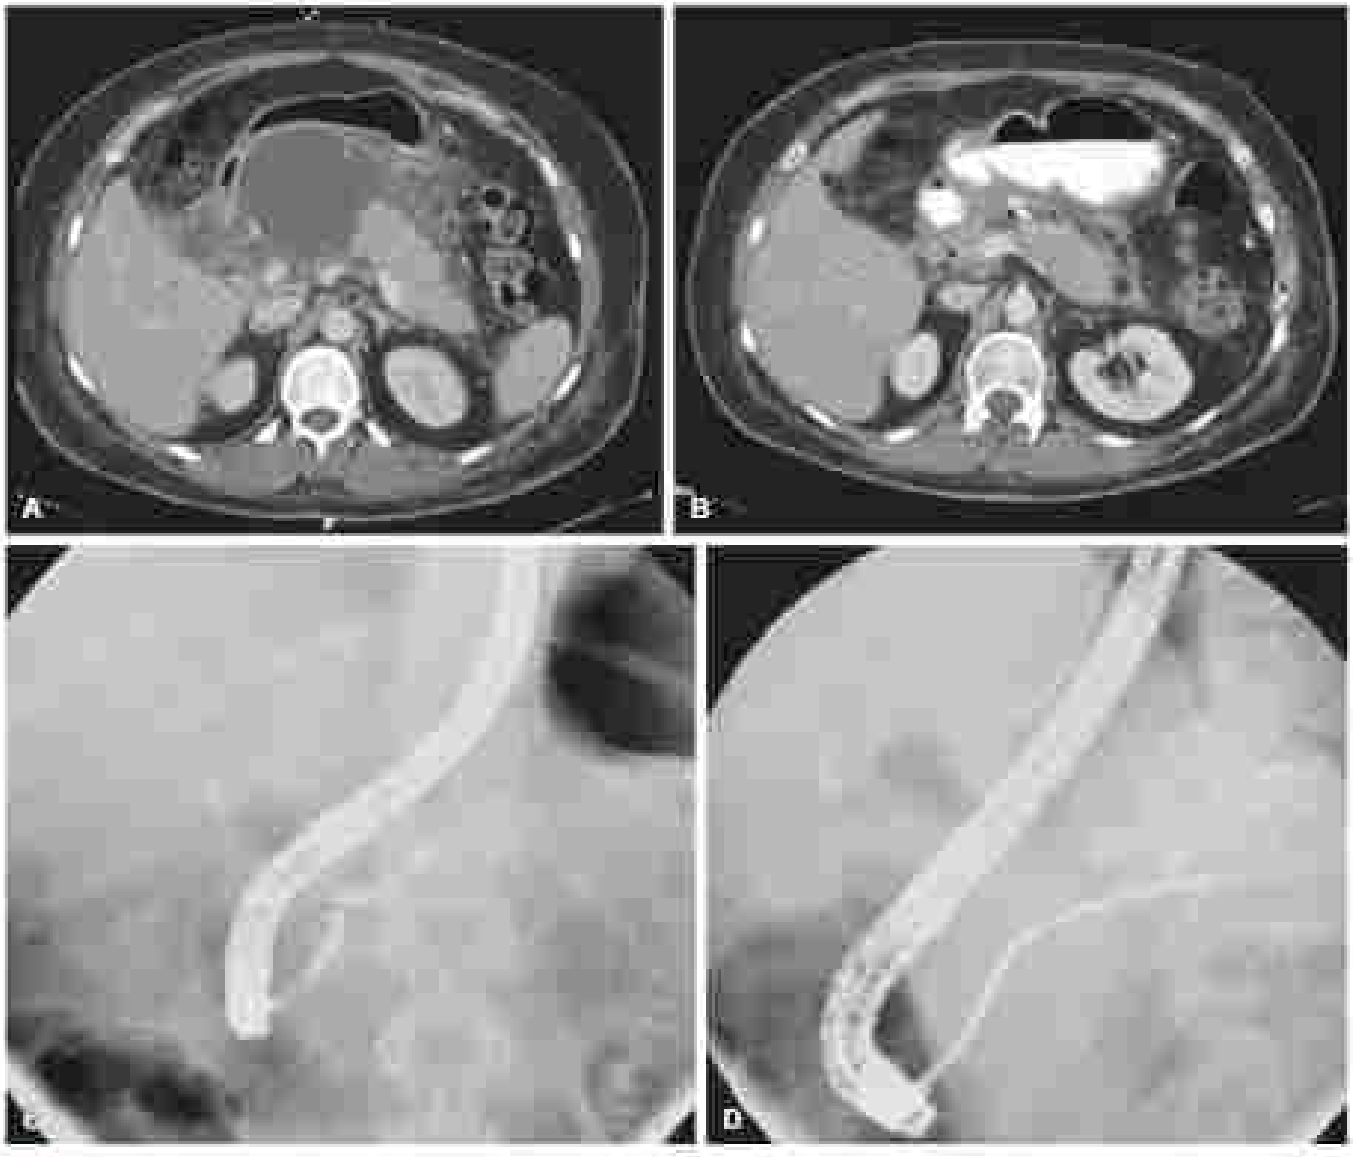

FIG. 1 (A) This patient, with severe acute necrotizing pancreatitis, developed sizeable and an acute peripancreatic fluid collection resulting in a disconnected pancreatic duct (B). Initial management was percutaneous drainage, which resulted in near-complete resolution of the collection but a persistent high-output pancreatic fistula. Endoscopic retrograde cholangiopancreatography revealed a disrupted duct in the neck of the pancreas (C) that was stented, resulting in resolution of the remaining collection and healing of the disruption (D).

TREATMENT

Percutaneous and Transgastric Catheter Drainage: Options

After maintaining a high index of suspicion in at-risk patients and locating a fluid-derived fluid collection on imaging, early drainage is imperative. Because the peripancreatic area is often very inflamed, these patients are a high surgical risk, and treatment should be as minimally invasive as possible to the stable patient. Percutaneous drainage is the gold standard for the treatment of fluid collections from pancreatic ductal disruption.

Percutaneous drainage is typically performed transabdominally via CT guidance through a window clear of major vessels, intestines, or organs. Drains are usually about 12Fr in diameter and can be upsized as needed; sometimes, multiple catheters are required to control the leakage. The drains are attached to a bag with external suction (such as an accordion bag or bulb) and should be flushed with 10 to 20 mL of normal saline multiple times per day to maintain patency. The size of the drained fluid collection will need to at first be frequently monitored to confirm correct placement and functioning. Repeat CT scans are performed on postprocedure days 3 to 5. Once there is confirmation that the drain is functioning appropriately, this interval can be increased to weekly or as needed for an acute change in the patient's clinical status.

The need to upsize the drain if it is not functioning well or add additional drains is common. If possible, drains should be positioned near the site of the ductal disruption and drainage (and not necessarily in the center of the collection) for maximal efficacy. Drain fluid should be sent for amylase level, white blood cell count, bacterial culture, and gram stain. Once the patient is clinically improved, the drainage is minimal, and/or there is confirmation of fluid collection collapse on imaging, the drain can be removed. Once adequate drainage is

achieved, pancreatic necrosis is typically halted. During this process, secondary fluid collections, pancreatic ascites, or pleural effusions may appear. These secondary collections should be drained as well if clinically significant; however, priority should remain adequate drainage at the leak source.

In general, after operating on the pancreas, particularly after a pancreaticoduodenectomy, a drain is left in the operated vicinity in the case of a pancreatic fistula. Recent studies, however, have shown that in patients at a low risk for leak, routine drain placement may be unnecessary. Moreover, most patients who have undergone pancreaticoduodenectomy and develop a pancreatic fistula, can be best managed nonoperatively with percutaneous drainage, as described here.

As mentioned previously, to perform a percutaneous drainage, a clear window for access into the cavity must be available. In some instances, this window is not available and if the collection is in close proximity to the stomach, a transgastric approach is preferred. Further advantages of this approach include an internal system of drainage and avoidance of the formation of future pancreatic cutaneous fistulas.

The drainage process could take between days to months but is preferred to open surgical necrosectomy for most patients. Drainage is minimally invasive and can be completed in the stable patient prophylactically, whereas surgery is typically reserved for patients in which drainage has been inadequate or there is concern for other pathology such as injury or necrosis of other organs. Patients treated with drainage have also shown superior long term outcomes and tend to have lower rates of morbidity and mortality.

Endoscopic Drainage Options

Endoscopically, pancreatic fluid collections can be drained via an ERCP placed stent into the main pancreatic duct (Fig. 1). Placing this stent will allow pancreatic juice to flow down the path of least resistance and through the proper anterograde direction into the intestines, rather than leaking into the retroperitoneum. When distal disruption is mid-main pancreatic duct, the stent can be used to traverse the defect and connect the proximal and distal ends of the ventral duct. One possible drawback to this endoscopic approach is the risk of post ERCP pancreatitis.

In the setting of a pancreatic pseudocyst, endoscopic ultrasound-guided stenting can provide a route for internal drainage when the area of walled off necrosis is adjacent to either the stomach or the duodenum. This can be performed as either a cyst gastrostomy or cyst duodenostomy. Necrosectomies can also be performed endoscopically, rather than surgically.

Although endoscopic drainage has the advantage of avoiding painful external catheters, it is not without its own set of risks. Internal drainage may introduce foreign material into the pancreatic space and transgastric stents can erode into surrounding vessels and organs. There is also the disadvantage of not being able to further characterize the drain fluid by assessing its appearance or sending it for laboratory tests. Procedures combining percutaneous and endoscopic drainage have been described.

Surgical Management

Although the traditional approach to pancreatic necrosis was early surgical necrosectomy, the standard of care is now the minimally invasive step up approach. The step up approach advocates for initial percutaneous drainage, followed by video assisted retroperitoneal dissection, and with the last option being open necrosectomy. When following the step up approach, it was found that approximately 35% of patients were able to avoid open surgery, but mortality was similar between the two treatment methods.

Surgical treatment for a pancreatic leak is dependent on the location of the duct disruption. Distal leaks can be controlled with distal pancreatectomy. Repeated drainage before an attempt at surgery, however, is warranted and the distal pancreas may become atrophic and the leak volume may decrease. Although this may be a long process and involve many drainage procedures, it will spare the patient a surgery and preserve some pancreatic endocrine/exocrine function. Proximal duct leaks refractory to drainage would require operative drainage with a Roux en Y jejunal limb anastomosed to the most proximal aspect of the leak. Often, this involves tracing a drainage catheter, which by definition is in the fistula tract, toward the pancreas. However, failure of both endoscopic and percutaneous drainage in this area is fortunately rare. Retroperitoneal dissection in this setting can be difficult secondary to the dense adhesions in the area and the left sided portal hypertension caused by a thrombosed or scarred splenic vein.

Pancreatic Ascites

Pancreatic ascites occurs when pancreatic fluid drains into the abdominal cavity and traditionally was felt to be a surgical emergency requiring while drainage. This is no longer the case, and it is now largely treated medically with bowel rest, total parenteral nutrition, and anti secretagogues such as octreotide. Other anti secretagogues that been used include atropine, glucagon, acetazolamide, galactose morphate, and aprotinin. The ductal anatomy is interrogated with imaging to identify the duct leak location, and interventions to control this include percutaneous and endoscopic with drainage and ductal stenting. In most cases of acute pancreatitis, pancreatic ascites resolves with these interventions and over time as the pancreatitis resolves. For patients with chronic pancreatitis, this is less likely because of the scarred nature of the duct and ductal stones obstructing pancreatic juice flow, and may require a surgical drainage procedure Roux en Y.

Pancreatic Pleural Effusions

Although pancreatic pleural effusions can result from acute pancreatitis, it is more often a complication of chronic pancreatitis with ductal disruption (Fig. 2). Treatment begins with bowel rest, total parenteral nutrition, repeated thoracentesis, tube thoracostomy, and secretagogues such as octreotide, interventional techniques using ERCP aided stenting or nasopancreatic drainage, or surgery typically consisting of excision of the damaged portion of the pancreatic duct and drainage of fluid collections or remaining pancreatic tissue with a Roux en Y limb of jejunum. Conservative treatment has an historical efficacy of 20% to 60% with a recurrence rate of 15%. Surgical therapy has been typically reserved for patients in whom medical therapy has failed and has a success rate as high as 90%, but with up to 20% rate of recurrence. The operative strategy is highly variable and depends on the ductal anatomy. After reviewing the literature, we found that in patients with complications from pancreatic pleural effusions surgery was successful more often than medical therapy (94% vs 31%).

Multidisciplinary Team Approach

The treatment of pancreatic ductal disruptions can be highly complex and a multidisciplinary team of surgeons, gastroenterologists, interventional radiologists, dietitians, nursing staff, hospitalists, pharmacists, and intensive care staff is critical to the success for the patient. The management is best guided by a weekly conference attended by members of the team where the patient's case is presented, imaging is reviewed, and a plan formulated. Pancreatic ductal disruption is an uncommon and complex condition requiring particular expertise in order to resolve the complications that accompany this diagnosis.

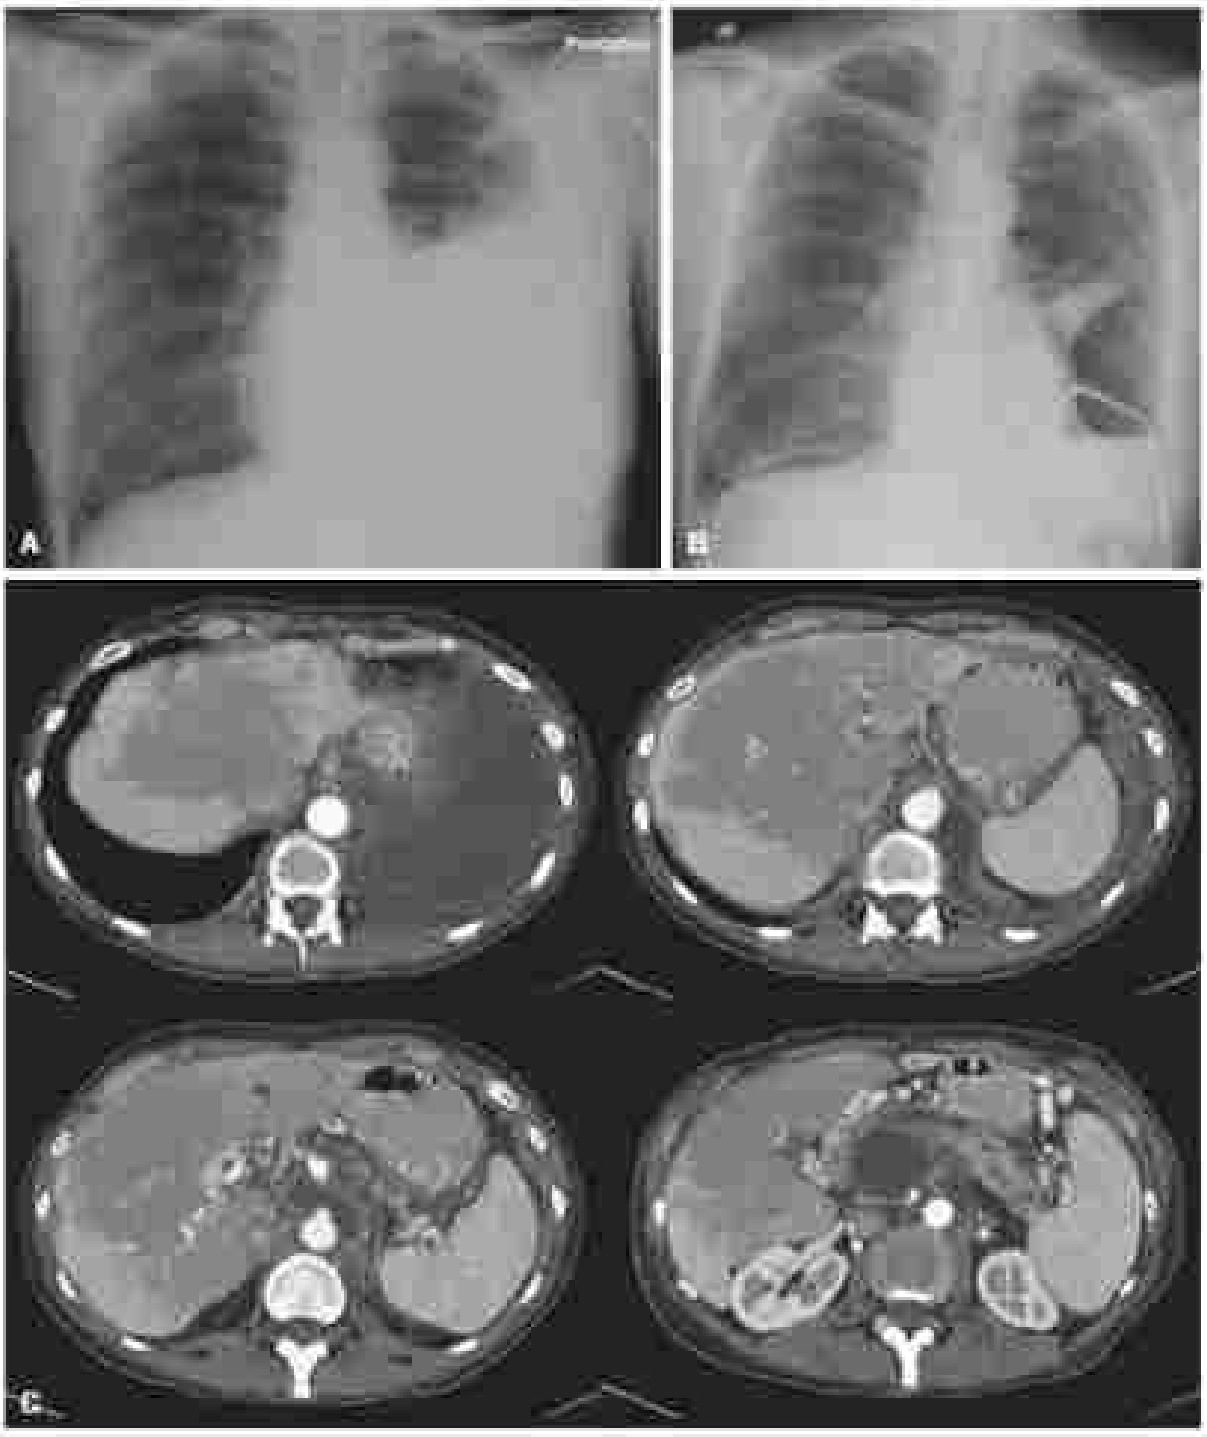

FIGURE 2 Patient with a pancreatic pleural effusion and fistula. (A) Initial chest radiographic demonstrates opacification of the left middle and lower lung zones consistent with moderate sized pleural effusion. (B) After interval drainage of the left pleural effusion, there was a left lower hydropneumothorax with a dense surrounding pleural lining consistent with a trapped left lung. In addition, a curvilinear lucency was seen under the right hemidiaphragm representing intraperitoneal air following a laparotomy to address the fistula. (C) Intravenous contrast tomography scan demonstrates evidence of chronic pancreatitis with parenchymal cystic collections and pseudocysts. One such pseudocyst extends superoposteriorly into the left upper quadrant, where it communicates with the pleural space. A large left pleural effusion is associated with this finding. Other findings include portal vein thrombosis, splenic vein thrombosis, and a 15-mm splenic artery aneurysm.

Management of Chronic Pancreatitis

William P. Lancaster, MD, and David B. Adams, MD

Chronic pancreatitis (CP) is a chronic, progressive, inflammatory disease of the pancreas that is characterized by irreversible destruction of functional pancreatic parenchyma and subsequent fibrosis. In the United States, the estimated incidence is 14 per 100,000 with annual healthcare costs estimated to be greater than $2 billion.

The predominant clinical feature of CP is abdominal pain, most frequently epigastric, often with radiation to the back. The pancreas is the most highly innervated visceral organ and the pain associated with CP is unmatched by other abdominal viscera. Characteristic of the CP pain syndrome is allodynia, hyperalgesia, and centralization of pain. Other common clinical features include signs related to loss of pancreatic parenchyma. Symptoms of exocrine pancreatic insufficiency include bloating, steatorrhea, weight loss or inability to gain weight. Progressive islet cell loss is manifested clinically as diabetes mellitus (type 3c). The exocrine, endocrine, and neurologic (chronic pain) dysfunction associated with CP do not follow a parallel course and each may progress at a different rate.

CP is a multifactorial disease with a strong genetic predisposition. Several risk factors known to contribute to the development of CP are summarized conveniently by the TIGAR-O classification in Box 2. Alcohol remains the most common risk factor for the development of CP in Western countries. However, the North American Pancreatitis Study group has recently reported that excessive alcohol consumption is responsible for only 44.3% of CP cases, with the remaining cases attributable to other causes. It is likely that alcohol plays a lesser causative role in the development of pancreatitis with the actual mechanism being alcohol as an exacerbating factor of preexisting physiologic or genetic circumstances. Mutations in several genes, including cationic trypsin (PRSS1), pancreatic secretory trypsin inhibitor (SPINK1), and cystic fibrosis transmembrane conductance regulator (CFTR) contribute to the development and irreversible progression of CP. Although the genetic underpinnings of CP are continually and currently being elucidated, hereditary pancreatitis is an entity distinct from genetic pancreatitis with a more aggressive natural history. This disease is responsible for 2% to 3% of cases of CP in the United States and is caused by a germline mutation resulting in gain of function of the PRSS1 gene resulting in constitutively active cationic trypsin and subsequent pancreatic autodigestion and inflammation. Patients experience early onset CP developing symptoms in many cases before the age of 20 years.

Autoimmune pancreatitis is a rare cause of CP seen in less than 3% of patients. It is characterized by distinct radiologic and histologic features, most often an inflammatory pancreatic head mass and biopsy showing lymphocytic infiltration without malignant cells. It is treated with corticosteroids with complete resolution in most cases.

Diagnostic Evaluation

The evaluation of patients with suspected CP begins with a careful history and physical examination. The presenting complaint is most often abdominal pain that is often life limiting and without clear etiology. Attention should be paid to the location and character of the pain. Most commonly, patients describe epigastric bursting pain that radiates to the middle of the back. The pain is often constant with few identifiable aggravating or alleviating factors. The patient should be questioned regarding dietary and bowel habits. Especially in the later stages of disease, patients will restrict their diet to carbohydrates alone and consume very little protein and fat because these cause them pain to worsen, and, in many cases, patients are malnourished though they are of normal or even overweight. Greasy, foamy, floating, and frequent stools suggest steatorrhea and associated exocrine pancreas insufficiency.

Imaging studies are helpful in the diagnosis of CP. The most common imaging findings in the setting of CP were described recently in the MAPSS study and include pancreatic duct dilation (68%), atrophy (57%), calcifications (55%), pancreatic duct irregularity (53%), and pancreatic pseudocysts (32%).

Historically, plain abdominal x-ray was the initial imaging study of choice for the diagnosis of CP, with the finding of upper abdominal calcifications considered pathognomonic, but this is only demonstrated in a subset of cases and in the setting of advanced disease. Computed tomography (CT) is now the most common initial imaging study and has a sensitivity of 67% to 80% and specificity of 90%. However, pancreatic calcifications seen on CT must be interpreted with caution as approximately 40% of patients will have other pancreatic pathology. CT is also useful for the identification of the complications associated with CP, such as pancreatic pseudocysts, infection, hemorrhage, pseudoaneurysm formation, pancreatic fistula, and biliary or gastrointestinal obstruction. Magnetic resonance cholangiopancreatography produces detailed images of the hepatobiliary and pancreatic systems in the setting of advanced disease. It has a sensitivity of 75%, but it is of low yield in the early stages of disease, in which the sensitivity is only 25%.

Endoscopic imaging techniques have the highest sensitivity and specificity for the diagnosis of CP. There are criteria for establishing the diagnosis for both endoscopic retrograde cholangiopancreatography (Cambridge classification) and endoscopic ultrasonography (Endoscopic Ultrasound Rosemont criteria). Both diagnostic systems are based on imaging findings that support the diagnosis of CP such as ductal dilation and calcifications. Endoscopic retrograde cholangiopancreatography (ERCP) is arguably the most sensitive and specific test (ranging from 70% to 100%) for the diagnosis of CP. Endoscopic ultrasound can be a valuable aid in the diagnosis of CP in early stage disease before the development of overt anatomic abnormalities. These modalities are of limited utility for the surgeon because surgical intervention is primarily aimed at alleviating the consequences of longstanding disease.

Medical Management

The goals of medical management of CP are to control pain, treat pancreatic exocrine insufficiency, and maintain glucose homeostasis. Alleviation of severe abdominal pain can be treated with nonnarcotic analgesics, although this is often unsuccessful and thus opioids are often required to achieve adequate pain control. Unfortunately, adjuncts to opioid therapy are palpable and gabapentin and frequently can reduce the total dosage of opioids required. In patients with steatorrhea or inability to maintain weight, pancreatic enzyme replacement therapy should be instituted.

Endoscopic Treatment

Endoscopic therapies commonly are used as first line interventions in the setting of obstructive CP. The goal is to relieve pressure in the pancreatic duct and to facilitate drainage of pancreatic secretions into the duodenum. ERCP is the modality of these treatment modalities because it allows dilation of pancreatic duct strictures, division of the sphincter of Oddi, stent placement, and stone removal. ERCP-based therapies are most effective in the setting of main pancreatic duct obstruction caused either by strictures or stones.

Pancreatic duct strictures can be dilated endoscopically and often require stent placement followed by serial stent exchanges usually every 3 months for a period of 2 years. Pancreatic stent removal is associated with a 30% to 40% risk of restenosis. Endoscopic

BOX 1 Indications for Surgery in Chronic Pancreatitis

- Pain
- Relapsing pancreatitis (inflammatory mass in the head, pancreatic ductal stricture)
- Complicated pancreatic pseudocyst

Tumor (intraductal papillary mucinous neoplasm, adenocarcinoma, etc.)

sphincterotomy is performed commonly during ERCP in the setting of CP because it facilitates pancreatic duct decompression, stent placement and stone extraction. Recurrence occurs in 14% of cases after sphincterotomy. Pancreatic duct stones can be removed endoscopically, but stones larger than 7 mm in diameter often require mechanical or extracorporeal shock wave lithotripsy before extraction. Complications associated with ERCP include bleeding, perforation, and post-ERCP pancreatitis.

SURGICAL MANAGEMENT

Surgical management of CP is primarily reserved for patients who have failed medical and endoscopic therapy and/or patients that have developed adjacent organ anatomic complications related to peripancreatic fibrosis such as biliary obstruction, duodenal obstruction, and splenic vein occlusion with gastric variceal hemorrhage. The goals of surgical therapy are palliation of abdominal pain, improvement in quality of life, and relief of secondary complications (Box 1). To that end, the selection of which operation is appropriate for a given patient is based on the pattern of disease evident on cross-sectional imaging. Broadly, the different operations for CP can be categorized as drainage procedures, resection procedures, or combination resection and drainage procedures.

FIG. 1 Computed tomography scan showing calcific proximal pancreatic duct stricture with a dilated distal duct.

Drainage Procedures

Longitudinal Pancreaticojejunostomy

The goal of a drainage procedure is to provide surgical relief of pancreatic ductal obstruction. The mainstay of the management of chronic fibrocalculic pancreatitis is the Puestow procedure, originally described by Puestow and later modified by Partington and Rochelle. The pancreatic duct is opened longitudinally along the anterior aspect of the pancreas and a side-to-side pancreaticojejunostomy is created to Roux-en-Y limb of jejunum. The anastomosis can be created in one layer or two, typically with permanent suture. Lateral pancreaticojejunostomy is reserved for patients with a pancreatic duct size of 6 mm or greater and without significant enlargement of the pancreatic head. It is important to clear the duct of all stones and debris to optimize drainage. Pancreatoscopy and electrohydraulic lithotripsy can be a useful adjunct to this regard (Fig. 1). The calcific pancreas with a dilated duct also lends itself to a laparoscopic approach.

Lateral Pancreaticojejunostomy

Lateral pancreaticojejunostomy results in partial or complete pain relief in up to 90% of patients and is accomplished with acceptable morbidity and mortality. At least 25% of patients will develop transient diabetes during long-term follow-up, and this likely reflects the progressive and irreversible course of the disease. Persistent tobacco smoking and alcohol consumption are significant risk factors for recurrent abdominal pain and surgical failure.

Combined Resection and Drainage Procedures

Frey Procedure

Combined resection and drainage procedures were developed to enhance drainage of the dominant duct in the head of the pancreas and the duct in the uncinate process while preserving pancreatic parenchyma and the duodenum. This operation is best suited for patients with pancreatic duct dilation secondary to obstruction with an enlarged pancreatic head. It combines the lateral pancreaticojejunostomy with local pancreatic head resection. The advantages of the Frey procedure are that it is not necessary to divide the pancreatic neck, which can be particularly treacherous in the setting of severe

chronic inflammation. There are presumed benefits with regard to long term metabolic function with parenchymal and duodenal preservation. The gastroduodenal artery to the right sided boundary of the pancreatic head resection and often must be ligated when encountered. Local pancreatic head resection is limited to the portion of pancreas that is superficial to the intrapancreatic portion of the common bile duct. If the bile duct is entered, it can be effectively drained into the ileum limb. The bile duct edges can be sutured to the surrounding pancreatic head to prevent late stricture. If stricture does occur, a choledochoduodenostomy can be performed. Care must be taken to avoid injuring the underlying portal vein as substantial hemorrhage can occur.

Beger's Procedure

The Beger procedure is an operation that combines pancreatic head resection with drainage of the distal pancreatic duct while preserving the duodenum. Along with the Frey procedure, the Beger procedure is referred to as duodenal preserving pancreatic head resection. It is best applied to circumstances where the pancreatic head is enlarged without significant distal pancreatic duct obstruction. In this operation, the pancreatic neck is divided and a subtotal resection of the pancreatic head is performed. A Roux limb is then used for two pancreatic anastomoses, one in a side to side fashion to the pancreatic head and one in an end to side fashion to the pancreatic body and tail. The Beger operation affords a greater degree of local pancreatic head resection but has the disadvantages of requiring division of the pancreatic neck and the construction of two pancreatic anastomoses. The Berne modification of the Beger procedure preserves pancreatic parenchyma overlying the SMV and portal vein, and, like the Frey procedure, affords a degree of safety when CP presents as a large inflammatory mass in the head of the pancreas. The downside of the Berne, Beger, and Frey procedures is reoperation for biliary stenosis and pancreatic cancer.

Several studies have compared the results of the Frey and Beger operations and the rates of pain relief and endocrine dysfunction are similar. Pain relief can be achieved in up to 94% of patients with either operation and the rate of endocrine dysfunction ranges from 10% to 30%. Rates of exocrine dysfunction are similar. Most of the randomized prospective studies comparing resection and drainage procedures originate from Eastern European experience where genetic and environmental factors appear to be associated with markedly enlarged pancreatic head masses associated with obstructive complications. In the United States, experience with this scenario is less common and the predominant indication for surgery in the United States is pain, less frequently associated with biliary, duodenal, and splenic vein stenosis.

Resection Procedures

Pancreaticoduodenectomy

Pancreaticoduodenectomy (Whipple operation) involves resection of the pancreatic head, duodenum, and distal bile duct. It is most commonly applied to patients with an enlarged pancreatic head but is also useful in cases of head dominant disease with biliary or duodenal obstruction or in situations where malignancy is suspected (Fig. 2). It can be applied for both large and small pancreatic ducts. Classically, the operation involves resection of the duodenum with antrectomy but the pylorus can be preserved in some cases by division of the first portion of the duodenum and creation of a duodenojejunostomy (pylorus preserving pancreaticoduodenectomy). It is our experience that, in cases where it is technically possible, preservation of the pylorus results in a high rate of delayed gastric emptying and intolerance of oral intake and that it is our standard practice to divide the stomach proximal to the pylorus (pylorus sparing pancreaticoduodenectomy). Patients with CP have chronically elevated levels of CCK that leads to impaired gastric emptying, which may be improved with pyloric resection. Opponents of pancreaticoduodenectomy argue that it is an overly aggressive operation performed for benign disease and that efforts should be made to preserve pancreatic parenchyma

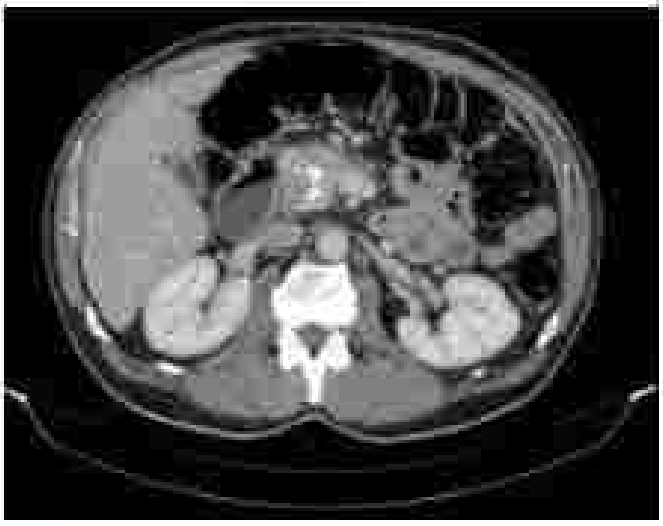

FIG. 2 Computed tomography scan showing an enlarged pancreatic head with calcification.

to allay future risk of endocrine and exocrine dysfunction. In cases where malignancy is suspected or cannot be excluded, pancreaticoduodenectomy should be undertaken.

In appropriately selected patients, pancreaticoduodenectomy provides improvement in abdominal pain and quality of life. It is thus noted that the radical nature of pancreaticoduodenectomy would lead to high rates of endocrine and exocrine dysfunction, with some studies reporting rates of 50%. However, in a recent randomized controlled trial comparing pancreaticoduodenectomy to duodenal preserving pancreatic head resection, rates of endocrine dysfunction were quite low (<5%) for either operation, whereas rates of exocrine dysfunction were also similar (90% for duodenal preserving pancreatic head resection and 89% PD). Importantly, there was no difference in postoperative quality of life.

Distal Pancreatectomy

Distal pancreatectomy usually involves removing some or all of the left side of the gland (i.e., body and tail to the left of the superior mesenteric vein). Indications for distal pancreatectomy include splenic vein thrombosis with minimal (left sided) portal hypertension (Fig. 3), proximal pancreatic duct obstruction that is not amenable to endoscopic management (Fig. 4), disconnected left pancreas, and CP limited to the body or tail of the pancreas. With regard to cases of proximal duct obstruction, the question arises as to remove the obstructed segment of pancreas or to perform internal drainage with Roux-en-Y pancreatojejunostomy. We typically perform distal pancreatectomy unless the duct is 8 mm or greater and there is an appreciable amount of viable parenchyma. When distal pancreatectomy is indicated in CP, the inflammation and fibrosis are advanced to the degree that attempts to save the spleen or to undertake a laparoscopic approach are hazardous and imprudent.

Total Pancreatectomy With Islet Cell Autotransplantation

Total pancreatectomy was viewed historically as a highly morbid and futile operation in the treatment of CP, particularly in alcoholic patients who perished from complications of brittle diabetes. With improvements in islet cell processing and transplantation technique, total pancreatectomy with islet cell autotransplantation (TPIAT) is a safe and useful treatment option in the treatment of CP intractable to medical management. This operation can be applied in patients who have failed other operations and with small duct or so-called minimal change disease. There is increasing evidence that patients with hereditary and genetic pancreatitis can be treated with upfront TPIAT and achieve long term improvements in quality of life.

FIG. 3 Computed tomography scan showing splenic vein occlusion with prominent gastric varices. Also seen is a pseudocyst within the splenic hilum.

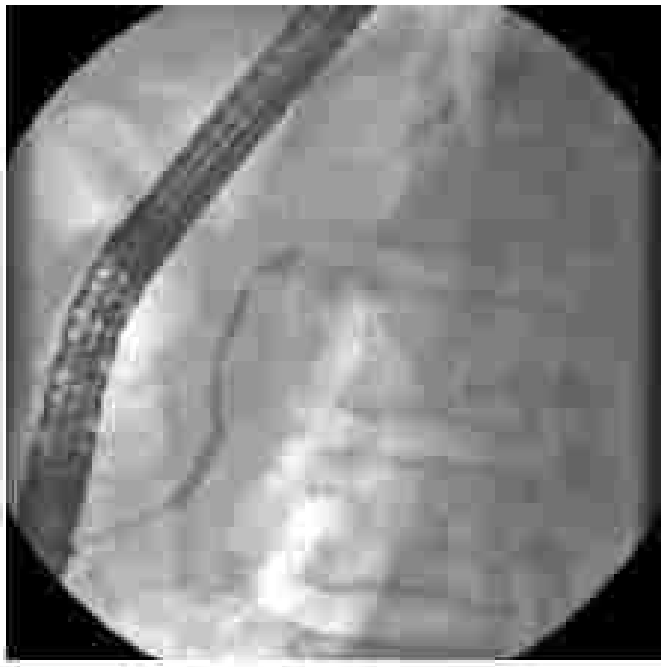

FIG. 4 Pancreatogram demonstrating a severe pancreatic duct stricture in the pancreatic neck.

The principal morbidity of TPIAT is the removal of the gland with complete loss of endocrine and exocrine function. The consequences of endocrine ablation are ameliorated by islet cell autotransplantation with many patients remaining insulin independent or on minimal insulin doses postoperatively. Those patients who require insulin to maintain glucose homeostasis have diabetes that is easier to manage than in patients without islet cell autotransplantation because the counterregulatory islet hormones are also produced by transplanted islets. Quality of life is equivalent in TPIAT patients who are insulin-free and those who are not. Lifelong oral pancreatic enzyme replacement is required and management of pancreatic exocrine insufficiency is frequently more problematic than endocrine insufficiency.

The TPIAT operation involves removal of the entire pancreas, which is then enzymatically digested, and the islets are isolated and infused via the portal vein into the liver. Pancreatectomy can be accomplished en bloc or by pancreaticoduodenectomy and distal pancreatectomy and splenectomy. Reconstruction is with a choledochojejunostomy and downstream antecolic gastrojejunostomy. Islet isolation can be accomplished either in the operating room or in a clean cell facility. Numerous techniques of islet cell autotransplantation have been described. Our practice is to transplant via intraportal injection, either through a catheter placed in the portal vein through a tributary of the middle colic vein or through direct portal venous puncture under radiographic control in the radiology suite. Most centers inject islets directly into the portal vein in the operating room.

Total pancreatectomy with islet cell autotransplantation provides pain relief and improvement in quality of life with acceptable rates of insulin independence (Table 1). Postoperative improvements in quality of life are durable. Remodeling of centrilobular pancreatic pain pathways and resulting patients narcotic free is a long term process that takes months to years with assistance of behavioral medicine pain experts. Patient selection is crucial and patients must undergo thorough preoperative testing and psychological evaluation prior to operation. Patients with genetic pancreatitis, autoimmune, and those who have not had prior pancreatic surgery have the best postoperative outcomes.

TABLE 1 Summary of Outcomes After Total Pancreatectomy With Islet Cell Autotransplantation

Management of Periampullary Cancer

Jonathan G. Shaw, MD, Bradley N. Reames, MD, M , and Jin Ma, MD, PhD, FACS

The term periampullary cancer is broadly used to describe four common malignant neoplasms occurring near the ampulla of Vater. Situated in the second portion of the duodenum, the ampulla of Vater is formed by the junction of the distal common bile duct (CBD) and the main pancreatic duct as it traverses the sphincter of Oddi. As such, neoplastic changes to the epithelium of each of these structures may progress to a primary malignancy. Pancreatic ductal adenocarcinoma (PDAC) accounts for a vast majority of periampullary cancers, followed by distal cholangiocarcinoma, ampullary adenocarcinoma, and duodenal adenocarcinoma. Although not traditionally included in the term periampullary cancer, less common neoplasms occurring near the ampulla of Vater include neuroendocrine tumors, cystic lesions of the pancreas (intraductal papillary mucinous neoplasms, mucinous cystic neoplasms, and serous cystadenomas), acinar and squamous cell carcinomas, solid pseudopapillary neoplasms (Hamoudi tumor), gastrointestinal stromal tumors, sarcomas, lymphomas, and metastases (most commonly renal cell carcinoma, melanoma, and lung cancer). Regardless of the tissue of origin, the definitive surgical management for most periampullary malignancies is pancreaticoduodenectomy (PD).

CLINICAL PRESENTATION

Patients with periampullary cancer most commonly present with obstructive jaundice. Additional symptoms may include pruritus, steatorrhea, dark urine, gastrointestinal distress (nausea, vomiting, diarrhea), and pain (abdominal, epigastric, or back). Other symptoms may include weight loss, anorexia, gastrointestinal bleeding, and episodes of cholangitis, which may cause fevers, chills, diaphoresis, and rigors. The presence of ascites or palpable lymph nodes in the periumbilical (Sister Mary Joseph's) or left supraclavicular (Virchow's) regions may indicate advanced disease.

Following a complete history, physical, and regular laboratory testing, tumor markers including carbohydrate antigen 19-9 should be checked. If concern exists for autoimmune cholangitis or pancreatitis, serum IgG4 levels should be measured.

DIAGNOSIS AND STAGING

Dedicated Imaging

High-quality pancreatic protocol computed tomography (CT) is most useful in delineating tumor vessel relationships and determining resectability, identifying aberrant anatomy, and assessing metastatic spread. Recent studies suggest that more than 25% of hepatic metastases may be missed on nonbiphasic abdominal imaging with suboptimal contrast timing.

Esophagogastroduodenoscopy and endoscopic ultrasound (EUS) can be used to assess tumor location and obtain tissue biopsy. EUS with fine-needle aspiration is necessary for guiding systemic therapy (both neoadjuvant and palliative) and may allow for genetic testing to further personalize therapy. If biliary obstruction is present, endoscopic retrograde cholangiopancreatography can be utilized to decompress the biliary tree with endobiliary stenting for patients with severely symptomatic hyperbilirubinemia, cholangitis, and those requiring biliary decompression prior to the administration of neoadjuvant chemotherapy. Other complementary studies may include a pancreatic protocol magnetic resonance imaging scan and a positron emission tomography-CT scan, which may assist the evaluation of extrapancreatic metastases.

Resectability and Staging

As complete surgical resection is the only curative therapy for periampullary cancer, the primary objective of preoperative imaging is to assess resectability. In PDAC, numerous groups have published standardized criteria for the determination of resectability. At diagnosis, patients with PDAC are classified as resectable, borderline resectable, or locally advanced mainly based on imaging characteristics, and subsequent therapies are tailored to this determination. Resectability criteria focus on the degree of tumor involvement with arterial (aorta, celiac, common hepatic, superior mesenteric, splenic, gastroduodenal) and venous (inferior vena cava, portal hepatis, superior mesenteric, splenic) structures. For patients without distant metastases, the type and sequence of therapy will be determined by the resectability classification and the response to therapy. It is important to note, however, that numerous retrospective studies suggest high-quality imaging may not reliably characterize resectability in borderline resectable and locally advanced patients following neoadjuvant therapy, as 50% to 80% of patients without progression may be successfully resected if explored at high-volume centers. In addition, select centers are investigating resection of both solitary and oligometastatic PDAC on study protocol, as long as the patient's disease has demonstrated favorable biology and response to systemic neoadjuvant therapy.

Following resection, periampullary cancers are staged according to the American Joint Committee on Cancer tumor-node-metastasis (TNM) staging system (Table 1).

MULTIDISCIPLINARY MANAGEMENT

All patients with a diagnosis of periampullary cancer should be discussed in a multidisciplinary setting. Although complete surgical resection remains the cornerstone of curative therapy, advancements in chemotherapy, radiotherapy, and targeted systemic agents have resulted in an increasingly multidisciplinary approach to treatment.

Given its aggressive biology and penchant for systemic spread, there is universal agreement that the vast majority of patients with PDAC should receive chemotherapy at some point during their treatment regimen, regardless of TNM stage. Based on recent clinical trials in Europe, gemcitabine and capecitabine (from the JSWOG 4

trial) or FOLFIRINOX (from the PRODIGE 24 trial) should be considered first line therapy in the adjuvant setting. Recent data from the PRODIGE 13 trial support a total neoadjuvant therapy approach to optimize therapy for true micrometastatic disease, maximize completion of therapy, and test tumor biology. In the metastatic setting, both FOLFIRINOX (from the PRODIGE trial) and gemcitabine with nab-paclitaxel (from the MPACT trial) have been shown to improve survival compared to gemcitabine alone and are considered standard of care.

Unlike PDAC, few trials exist to support the multimodality treatment of distal cholangiocarcinoma. Although retrospective studies of adjuvant radiotherapy are heterogeneous and show mixed results, the regimen of gemcitabine and capecitabine chemotherapy followed by capecitabine chemoradiation has recently gained favor based on phase II data suggesting a median survival of 36 months and 2-year survival of 69% in patients with extrahepatic cholangiocarcinoma and gallbladder carcinoma (from the SWOG S0809 trial). However, current guidelines support observation, gemcitabine- or fluoropyrimidine–based chemotherapy, or fluoropyrimidine chemoradiation may be considered in the adjuvant setting. In patients with advanced (unresectable and metastatic) biliary tract cancer, the largest phase III trial to date (the ABC-02 trial) established gemcitabine and cisplatin combination chemotherapy as the standard of care. Additional chemotherapies considered in this setting include oxaliplatin, capecitabine, and 5-fluorouracil, and radiotherapy (external beam or brachytherapy) may be considered in select cases.

Like distal cholangiocarcinoma, randomized data to support management of ampullary and duodenal adenocarcinoma are sparse, aside from the early trials evaluating mixed periampullary cancers discussed earlier. Currently, patients with ampullary adenocarcinoma are treated in accordance with the ESPAC-4 trial. Although supported by multiple retrospective series, the use of chemoradiation in ampullary adenocarcinoma is controversial, and little data exist to guide the management of advanced disease. Similarly, data evaluating multimodality therapy in duodenal adenocarcinoma are scant. As a result, patients are often treated by extrapolating the literature of colon cancer, as node positive patients and those with advanced disease are offered oxaliplatin and fluoropyrimidine based chemotherapies as first line systemic therapy.

SURGICAL MANAGEMENT

Pancreaticoduodenectomy

PD can be divided broadly into three phases: (1) abdominal exploration to confirm the absence of metastases, (2) resection of the malignancy, and (3) pancreaticobiliary and enteric reconstruction. Multiple variations on the procedure exist including standard PD (which includes en bloc distal gastrectomy) versus pylorus preserving PD (PPPD) (Fig. 1), antecolic versus retrocolic, gastrojejunostomy (GJ), and numerous variants of pancreaticojejunostomy (PJ). However, none of these technical details have been shown to significantly augment perioperative outcomes and largely vary by a surgeon's institution and training history. What follows here is a generalized description based on commonly performed techniques at The Johns Hopkins Hospital.

Abdominal Exploration

The abdomen is explored through either a limited midline laparotomy or via diagnostic staging laparoscopy depending on the surgeon's preference. An initial exploration is emphasized. The peritoneal cavity is closely inspected for evidence of tumor spread, including all visceral and parietal peritoneal surfaces, the omentum, and entire bowel. Intraoperative ultrasound enables better

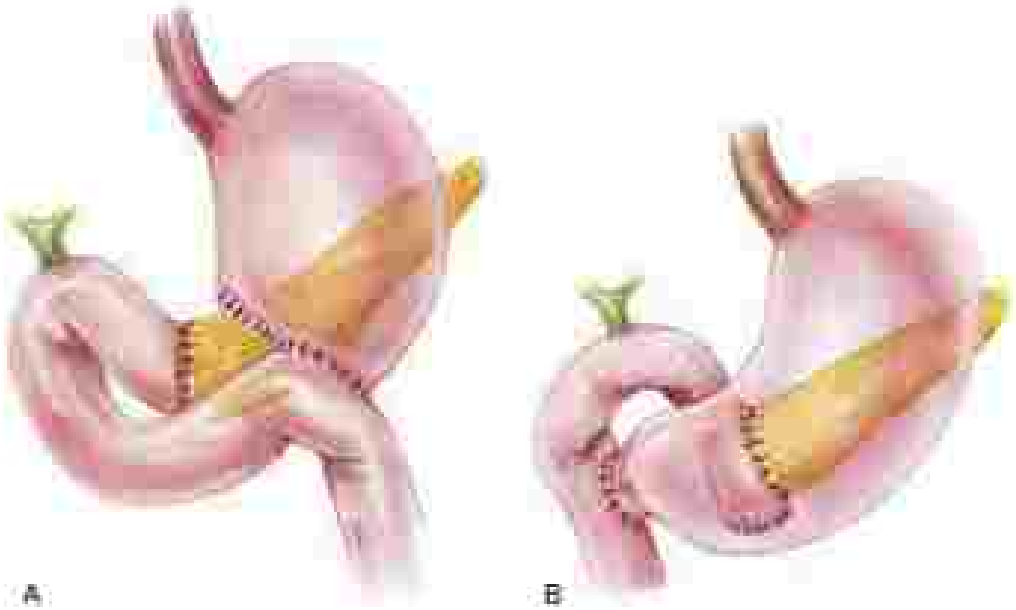

FIG. 1 Standard pancreaticoduodenectomy with hemigastrectomy and gastrojejunostomy (A) versus pylorus-preserving pancreaticoduodenectomy with duodenojejunostomy (B). (From Cameron JL, Sandler C. Atlas of Gastrointestinal Surgery, vol 1. 2nd ed. Shelton CT: People's Medical Publishing House; 2007.)

characterization of indeterminate hepatic lesions found on preoperative imaging, and biopsy with frozen sectioning allows for definitive evaluation of suspicious tissue prior to committing the patient to PD.

Open Resection

After it is deemed appropriate to proceed with PD, the incision may be extended or if a diagnostic staging laparoscopy was utilized, a laparotomy may then be performed. Many surgeons mobilize the hepatic flexure of the colon and the proximal transverse mesocolon with a generous Kocher's maneuver. Extensive Kocher's maneuver to the level of the left renal vein allows better exposure posterior to the portal vein (PV) and superior mesenteric vein (SMV). After removing lymphatic tissue around the left renal vein and retroabdominal aorta (station 16), the root of the superior mesenteric artery (SMA) can be exposed. The lesser sac is entered and the transverse mesocolon is separated from the base area of the duodenum and pancreatic head. The middle colic vein is traced down to its union with the right gastroepiploic vein, which classically forms a common trunk (i.e., gastrocolic trunk or trunk of Henle) draining into the SMV. The gastroepiploic vein is ligated and anterior exposure of the SMV is obtained.

Portal lymphadenectomy is performed after dissecting the gallbladder down from the hepatic cystic plate with the goal to skeletonize the three portal tubular structures. The common hepatic duct (CHD) is divided near the cystic duct junction. The PV is skeletonized and followed down to the pancreatic neck. Care is taken to identify and preserve any variant hepatic arterial anatomy, most commonly a replaced right hepatic artery, which can be found in up to 15% of patients. After identifying the origin of the gastroduodenal artery (GDA) from the common hepatic artery (CHA), the GDA is test clamped to ensure the patient has adequate flow to the proper hepatic artery (PHA). Some patients with celiac stenosis become reliant on retrograde flow from the GDA to supply the liver, therefore ligating the GDA in these patients can be catastrophic. Celiac stenosis identified from preoperative imaging should be addressed prior to proceeding with the PD. After GDA test clamping, the GDA is doubly ligated with silk tie and suture ligated with Prolene and divided. We add a surgical clip to the GDA stump to aid in angiographic identification should a GDA pseudoaneurysm develop postoperatively. In a standard PD, the stomach is divided proximal to the antrum with a GI or linear GIA stapler.

The jejunum is divided with another firing of the stapler 20 cm distal to the ligament of Treitz (Trotz). Dissection of the small bowel mesentery is carried proximally until the Treitz is divided and the distal duodenum and proximal jejunum can be passed underneath the superior mesenteric vessels into the previous plane of dissection on the patient's right side. At this point, a tunnel between the SMV-PV confluence and the pancreatic neck is carefully made from above and below. The pancreatic neck is divided with attention to protect the underlying PV and SMV.

The pancreatic neck and head can now be carefully dissected off of the PV-SMV junction, taking care to identify and control major venous tributaries that include the vein of Belcher (superior pancreaticoduodenal vein) and the first jejunal branch of the SMV. The PV and SMV are retracted to the patient's left to expose the uncinate process and the right side of the SMA. The inferior pancreaticoduodenal artery should be ligated during the separation of uncinate from the SMA. The surgical specimen should now be free and sent to pathology for evaluation. We routinely check intraoperative frozen sections of the pancreatic neck and uncinate margins, and the CBD margin if applicable.

Open Reconstruction

Sequential reconstruction includes PJ, hepaticojejunostomy (HJ), and GJ for standard PD or duodenojejunostomy for PPPD. For construction of a retrocolic PGHJ, the jejunal limb is passed through the transverse mesocolon to the right of the middle colic vessels. The GJ is typically created to an antecolic fashion via a Hofmeister or Reichel-Polya anastomosis.

As various elements of the PD have evolved and improved over the past several decades, the proclivity for the PJ to leak remains the operation's Achilles' heel. A variety of techniques have been developed in an attempt reduce the incidence of PJ leak, some of which have been shown to be superior. These include the broad categories

of anastomotic suture dehiscence. We commonly perform an end-to-side two layer duct-to-mucosa PJ consisting of an interrupted, nonabsorbable outer layer and interrupted absorbable inner layer. We typically use a 3.5 Fr pediatric feeding tube as a stent across the PJ. The JJ is created 5-10 cm distal on the antimesenteric jejunal limb in a position that prevents undue tension or twisting on either anastomosis. This is performed in a single layer interrupted fashion with absorbable suture. Finally, the GJ is created in an antecolic fashion using either a two layer handsewn technique with absorbable suture, or with a stapler near the greater curve of the stomach with the common enterotomy closed with two layers of absorbable suture.

Two soft, closed suction drains are placed anterior and posterior to the JJ and PJ in most cases to monitor for and drain a postoperative pancreatic fistula (POPF). Recent multiinstitutional data suggest that drains can safely be precluded altogether in patients at low risk for POPF as determined by their Fistula Risk Score. If a drain is placed, early removal based on drain amylase levels has been associated with lower clinically significant POPF rates as well as shorter hospital stays.

Major Vascular Resections

Venous Resections

Resection of the portomesenteric confluence is performed when it is not technically feasible to dissect the pancreatic tumor off the underlying veins without leaving gross disease behind or if dissection cannot be performed safely. If venous resection is to be undertaken, vascular control proximal and distal to the PV-SMV confluence must be obtained. The type of venous reconstruction is based on the longitudinal and circumferential degree of vein involvement. When a limited aspect (less than one third circumference) of the vein requires resection, tangential resection with primary closure or patch venoplasty is sufficient. More extensive involvement generally requires segmental resection with either a primary anastomosis or interposition graft repair. Defects of up to 3 cm can be anastomosed primarily with appropriate mobilization (Fig. 2). If the vein ends cannot be reapproximated without undue tension, we prefer using an autologous vein graft (e.g., left renal, saphenous, jugular vein) over synthetic (e.g., polytetrafluoroethylene, Gore-Tex) grafts owing to the potential for infection and reduced long-term patency rates.

Finally, in selected patients with preoperative venous occlusion in whom adequate portomesenteric collateralization has developed, SMV resection without reconstruction can be performed safely. However, this approach should be reserved for high volume centers with experience in this technique.

Arterial Resections

Major arterial resections for PDAC remain controversial. Poor overall survival combined with significant morbidity associated with arterial reconstructions limit the potential benefit of these procedures. Isolated CHA resection can be amenable to primary anastomosis. SMA resection with autologous vein or arterial transposition can be performed in highly selected cases. We do not recommend routine use of SMA resection, as the aggressive biology of PDAC often supersedes the survival benefit of these radical resections.

Minimally Invasive Approaches

PD via minimally invasive surgical (MIS) approaches has gained popularity over the last decade. Included among these are laparoscopic PD, robotic PD (RPD), and combined modalities. Multiple reports have demonstrated oncologic equivalence when comparing MIS and open PD, and associate the MIS approach with decreased pain, shorter length of stay, and fewer wound

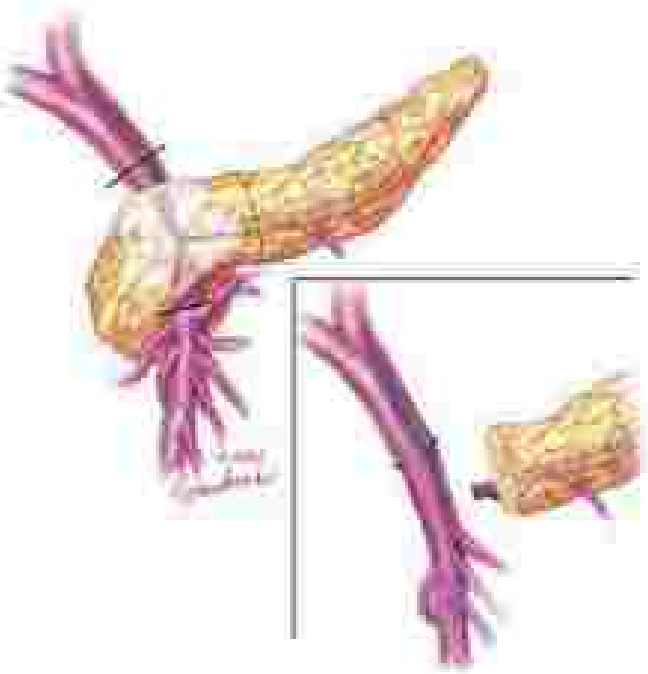

FIG. 2 Resectable tumor involvement at the portal vein–superior mesenteric vein (PV-SMV) confluence. Title is considered resectable because involvement is limited to a single target vessel above and below the accessory region of resection (black line) and does not extend too high on the PV. The vein segment and tissue are resected en bloc, followed by a primary end-to-end reconstruction (vein). Ligation and division of the splenic vein, even absent direct involvement, is often necessary to mobilize the PV and SMV sufficiently for primary anastomosis. (Courtesy Carrie Cunningham, Johns Hopkins Medicine.)

complications. Although no study has clearly demonstrated an oncologic benefit with MIS PD, many proponents believe it has the potential to decrease postoperative complications that may delay or even prevent delivery of adjuvant therapy. A key for successful execution of MIS is careful selection of anatomically and pathologically favorable candidate patients, especially for surgeons new to the approach. Although multiple techniques have been reported, what follows is a description of the approach to RPD at The Johns Hopkins Hospital.

Robotic Pancreaticoduodenectomy Setup and Resection

The supine split leg position is convenient for the bedside assistant. After establishing pneumoperitoneum, we insert a 12-mm trocar in the umbilical position and utilize the robotic camera for a diagnostic staging laparoscopy to evaluate for both metastatic disease and anatomic features (e.g., adhesions) that may prohibit successful RPD. If deemed appropriate to proceed, four robotic trocars (8 mm) are placed transversely across the abdomen at the midpoint of the anterior superior iliac spine and the 12th rib, and the da Vinci Si system (Intuitive) is docked from the patient's left side (Fig. 3).

The ligamentum teres and falciform ligament are divided and secured with an endoloop that is then passed transabdominally to retract the liver anteriorly and cranially. The lesser sac is entered by dividing the gastrocolic ligament and the right gastroepiploic artery is controlled. After controlling the right gastric artery, an Endo GIA stapler is used to divide the stomach approximately 5 cm proximal to the pylorus. The portal triad is skeletonized to expose the CHA, CBD, PHA, and PV. The CBD is transected with scissors and controlled with a clipped vessel loop to limit bile leakage for the remainder of the resection. The PHA is traced proximally to identify the right gastric

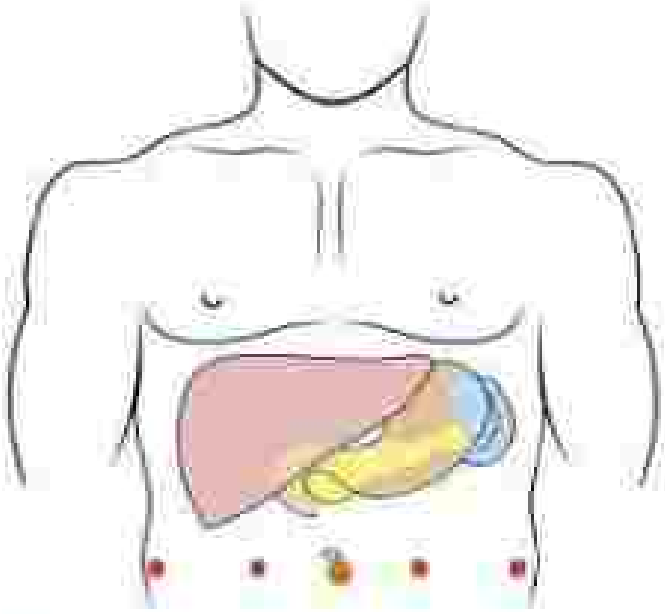

FIG. 3 Trocar placement for robotic pancreaticoduodenectomy. (Modified from Cubertt G, et al. Technical considerations for the fully robotic pancreaticoduodenectomy. JAMA Surg. 2013;148:1.)

FIG. 4 Intraoperative view of the cruse of Henle (arrow). SMV, superior mesenteric vein.

artery, GDA, and CHA. The right gastric artery is controlled with a clip and the GDA is ligated in a similar fashion to the open technique. The GDA is triply ligated with a 2-0 silk tie and clips and divided with the robotic scissors.

The PV is identified at the superior border of the pancreas, taking care not to divide the superior pancreaticoduodenal vein on the lateral side of the PV. The SMV is identified at the inferior border of the pancreas, taking care to identify the gastrocolic trunk of Henle. The trunk of Henle is dissected out sharply and the right gastroepiploic vein is ligated with clips and divided preserving the middle colic vein if technically feasible (Fig. 4). A retropancreatic tunnel on top of the PV is carefully created with blunt dissection. The neck of pancreas is divided with electrocautery or harmonic scalpel.

A Kocher maneuver is performed using a combination of electrocautery and the surgical energy. The inferior vena cava and abdominal aorta are exposed from the patient's right side. However, in contrast to open PD, the fascia can often be divided from the right side of the superior mesenteric vessels and the first portion of the jejunum is pulled through the native duodenal tunnel prior to division with the linear GIA stapler.

Transection of the uncinate along the right side of the SMA is the most challenging aspect of RPD. A vessel sealer can be used to separate the uncinate from the nearby SMA. However, in the setting of tumor abutting SMA, we will often use a combination of hook cautery, harmonic scalpel, and a bipolar Maryland clamp to more finely dissect the tissue off the SMA. Finally, the gallbladder is taken down from the cystic plate. The Whipple specimen and the gallbladder are removed from a Pfannenstiel's incision using a large Endo Catch (Medtronic) bag.

Robotic Pancreaticoduodenectomy Reconstruction

After hemostasis is confirmed, the anastomoses are performed in the same order as open PD: PJ, followed by HJ, and finally the GJ. We favor a retrocolic and to side two layer PJ, with the posterior row comprised of a 3-0 running V Loc suture (Covidien), 5-6 pulse rapid PDS for the inner duct to mucosa layer, and the anterior row comprised of an additional 3-0 running V Loc suture. As in open PD, we typically stent the PJ with a pediatric feeding tube. The HJ is created 5 to 10 cm distal to the PJ using 3-0 PDS suture in an interrupted fashion. The anastomosis typically requires 10–12 interrupted sutures depending on the size of the bile duct. Finally, we create an antecolic side to side isoperistaltic GJ with a blue load Endo GIA stapler, closing the enterotomy with a 3-0 V Loc suture in two layers. We routinely use the existing lateral robotic port sites to place two 19Fr closed suction Blake drains anterior and posterior to the PJ.

POSTOPERATIVE CARE

Over the past decade, enhanced recovery after surgery (ERAS) protocols have introduced evidence based pathways to standardize and improve the postoperative care of patients undergoing PD. Although specific ERAS guidelines vary by institution, the ERAS Society has published PD specific recommendations based on available evidence. These include preoperative smoking cessation, avoidance of hyperglycemia, an attempt at near zero fluid balance, early drain removal, early feeding, and early/scheduled postoperative mobilization (Table 2). ERAS programs have repeatedly demonstrated an ability to decrease the length of hospital stay, however, high quality studies showing their effects on other important endpoints are limited. These serve as general guidelines to help specialize postoperative care systems, and should not take precedence over a clinician's clinical judgment while caring for individual patients.

POSTOPERATIVE COMPLICATIONS

As PD entered the second decade of the twenty first century mortality continues to decrease at high volume centers. However, morbidity associated with the procedure remains high even in experienced hands. The most common postoperative complications are delayed gastric emptying (DGE; 10% to 45%), POPF (7% to 25%), and wound infection (10% to 40%). Postpancreatectomy hemorrhage (PPH) is another important complication that occurs less frequently, however, has potentially devastating and life threatening consequences if not managed appropriately.

Delayed Gastric Emptying:

DGE is a functional postoperative commonly occurring after PD. The International Study Group of Pancreatic Surgery (ISGPS) definition subcategorizes DGE into three classifications based on the severity

TABLE 2 Enhanced Recovery After Surgery Society Guidelines for Perioperative Care for Pancreaticoduodenectomy

Item	Summary and Recommendation	Evidence Level	Recommendation Grade
Preoperative counselling	Patients should receive dedicated preoperative counselling routinely	Low	Strong
Preoperative biliary drainage	Preoperative endoscopic biliary drainage should not be undertaken routinely in patients with a serum bilirubin concentration <250 μmol/L	Moderate	Weak
Preoperative smoking and alcohol cessation	For alcohol abusers, 1 month of abstinence before surgery is beneficial and should be attempted. For daily smokers, 1 month of abstinence before surgery is beneficial. For appropriate groups, both should be attempted.	Alcohol abstention: low Smoking cessation: moderate	Strong
Antithrombotic prophylaxis	Low molecular weight heparin reduces the risk of thromboembolic complications, and administration should be continued for 4 weeks after hospital discharge. Concomitant use of epidural analgesia necessitates close adherence to safety guidelines. Mechanical measures should probably be added for patients at high risk.	High	Strong
Antimicrobial prophylaxis and skin preparation	Antimicrobial prophylaxis prevents surgical site infections and should be used in a single dose manner initiated 30 to 60 minutes before skin incision. Repeated intraoperative doses may be necessary depending on the half life of the drug and duration of procedure.	High	Strong
Nasogastric intubation	Prophylactic use of nasogastric tubes postoperatively does not improve outcomes, and their use is not warranted routinely	Moderate	Strong
Fluid balance	Near zero fluid balance, avoiding overload of salt and water, results in improved outcomes. Perioperative monitoring of stroke volume with transesophageal Doppler to optimize cardiac output with fluid boluses improves outcomes. Balanced crystalloids should be preferred to 0.9% saline solution.	Fluid balance: high esophageal Doppler: moderate Balanced crystalloids vs 0.9% saline solution: moderate	Strong
Perianastomotic drain	Early removal of drains after 72 hours may be advisable in patients at low risk (i.e., amylase content in drain <5000 U/L) for developing a pancreatic fistula. There is insufficient evidence to recommend routine use of drains, but their use is based only on low-level evidence.	Early removal: high	Early removal: strong
Somatostatin analogues	Somatostatin and its analogues have no beneficial effects on outcome after pancreatic oduodenectomy. In general, their use is not warranted. Subgroup analyses for variability in the texture and duct size of the pancreas are not available.	Moderate	Strong
Urinary drainage	Transurethral catheters can be removed safely on postoperative day 1 or 2 unless otherwise indicated.	High	Strong
Delayed gastric emptying	There are no acknowledged strategies to avoid delayed gastric emptying. Artificial nutrition should be considered selectively in patients with delayed gastric emptying of long duration.	Very low	Strong
Stimulation of bowel movement	A multimodal approach with epidural and near zero fluid balance is recommended. Oral laxatives and chewing gum given postoperatively are safe and may accelerate gastrointestinal transit.	Laxatives: very low Chewing gum: low	Weak
Postoperative artificial nutrition	Patients should be allowed a normal diet after surgery without restrictions. They should be continued to begin carefully and to ensure intake according to tolerance over 3 to 4 days. Enteral tube feeding should be given only on specific indications and parenteral nutrition should not be employed routinely.	Early diet as well: moderate	Strong
Early and scheduled mobilization	Patients should be mobilized actively from the morning of the first postoperative day and encouraged to meet daily targets for mobilization.	Very low	Strong

*Condition exists postoperative pancreatic fistula criteria.

of symptoms and the necessity of required interventions (Table 3). The pathophysiology of DGE is not fully understood but is likely multifactorial and modulated by both technical factors and consequent patient morbidity. The management is primarily supportive and involves ruling out other causes of oral intolerance with diagnostic and cross-sectional imaging. A 2016 Cochrane review found no difference in DGE rates when comparing standard PD versus PPPD and antecolic versus retrocolic GJ. When compared to end-to-side GJ, several studies have demonstrated lower rates of DGE when performing side-to-side GJ; however, both are commonly performed at high volume centers.

Pancreatic Fistula

POPF remains one of the most recalcitrant complications after all types of pancreatic surgery. Its severity can range from an asymptomatic laboratory finding to a life threatening systemic condition (Box 1). Multiple technical adaptations to the PJ have been attempted over the years, including invaginations, duct to mucosa anastomoses, and multiple layer closures, none of which have demonstrated a difference in rates of POPF. Stenting across the PJ has also failed to show any effect on POPF rates in multiple studies, but is still commonly performed. Over time, the most reliable predictors of POPF development have been patient- and procedural-related factors including gland texture, duct diameter, intraoperative blood loss, and underlying pancreatic pathology. These factors comprise a commonly used Fistula Risk Score calculator, which some surgeons use to determine the need for postoperative percutaneous external drainage. Conservative management results in spontaneous fistula closure in up to 90% of cases, usually within 4 weeks. Parenteral nutrition and octreotide analogues may also play a role in reducing fistula output. On rare occasions, patients with severe clinical instability or signs of sepsis and organ dysfunction may require surgical reexploration and repair or revision of the PJ anastomosis.

Postpancreatectomy Hemorrhage

PPH is potentially one of the most lethal complications following PD, particularly if not diagnosed and treated expeditiously (Table 4). Early PPH is most commonly the result of inadequate surgical hemostasis and is best treated with a return trip to the operating room. Late PPH often results from inflammatory process (e.g., intestinal ulceration, POPF) leading to arterial pseudoaneurysm formation, rupture, and hemorrhage. CHA pseudoaneurysm rupture is classically seen 5 or more days postoperatively and can be preceded by a "so called *herald bleed*." Interestingly, the presenting location of the hemorrhage can be either an intraluminal or intraabdominal, often obfuscating the diagnosis. In either case, pseudoaneurysmal bleeding is best treated with endovascular coil embolization or covered stenting, depending on the precise location and anatomy.

TABLE 4 International Study Group of Pancreatic Surgery Consensus Definitions of Postpancreatectomy Hemorrhage

A. DEFINITIONS	
Time of Onset	
Early hemorrhage (< 24 hours after the end of the index operation)	
Late hemorrhage (> 24 hours after the end of the index operation)	
Location	
Intraluminal (anastomotic suture line, cut surface of the pancreas, ulceration, pseudoaneurysm)	
Extraluminal (arterial or venous vessels, diffuse bleeding from resection area, anastomotic suture lines, pseudoaneurysm)	
Severity of Hemorrhage	
Mild	
Decrease in hemoglobin concentration <3 g/dL	
No significant clinical impairment	
Transfusion of no more than 2 to 3 units packed cells within 24 hours of surgery or 1 to 3 units beyond 24 hours	
No requirement for reoperation or interventional angiographic embolization	
Severe	
Decrease in hemoglobin concentration >3 g/dL	
Clinically significant impairment (tachycardia, hypotension, oliguria, hypovolemic shock)	
Transfusion requirement >3 units packed cells	
Need for invasive treatment (interventional angiographic embolization or relaparotomy)	

B. GRADING SCALE		
Grade	**Onset, Severity, and Location**	**Clinical Condition**
A	Early, mild, intraluminal or extraluminal bleeding	Good
B	Early, severe, intraluminal or extraluminal bleeding Late, mild, intraluminal or extraluminal bleeding	Good to moderately impaired
C	Late, severe, intraluminal or extraluminal bleeding	Severely impaired, life-threatening

SUMMARY

Periampullary cancer is a heterogeneous group of malignancies presenting unique challenges in its diagnosis and management. Modern therapies require a multidisciplinary treatment team and multimodality therapy. PD is the surgical treatment for these cancers and prognosis is overwhelmingly determined by a patient's disease biology. Advances in MIS techniques and new multimodal therapies offer the prospect for improved outcomes to patients with these difficult diseases.

Vascular Reconstruction During the Whipple Operation

Ammar A. Javed, MD, and Christopher L. Wolfgang, MD, PhD

The development of multidrug regimens such as gemcitabine/nab paclitaxel or the FOLFIRINOX regimen for use in patients undergoing oncologic resection of localized pancreatic cancer (pancreatic ductal adenocarcinoma [PDAC]) has resulted in improved systemic control. Over this same time, improvements in radiation delivery in the form of stereotactic body radiation have improved the ability to achieve an R0 resection in patients with major vessel involvement (stage III). Taken together, the improved systemic control and ability to achieve clear margins had led to more aggressive surgical approaches to PDAC. The cancer specific outcomes with these more complex operations are superior to what was reported historically with less advanced tumors. Moreover, these operations can be performed with low mortality, acceptable morbidity, and a high likelihood of returning to a good quality of life. Resection and reconstruction of the portomesenteric axis with a Whipple operation has become commonplace. The resection and reconstruction of major arteries such as common hepatic artery and superior mesenteric artery (SMA) remains controversial and is performed infrequently currently. The exception to this is the resection of cancers of the body of the pancreas that involve the celiac axis and are resected through a distal pancreatectomy/splenectomy with en bloc resection of the celiac trunk.

This chapter discusses what determines resectability in patients with stage III (major vessel involvement) PDAC of the head of the pancreas, as well as the pertinent surgical anatomy and surgical technique.

PREOPERATIVE EVALUATION AND DETERMINING RESECTABILITY

A high quality pancreas protocol computed tomography (CT) is the single most important test in determining resectability as it is very accurate in assessing the local tumor relationships with the major vessels. A pancreas protocol CT consists of a dual phase CT with arterial and venous phase imaging. Arterial phase images are acquired at 25 to 30 seconds after intravenous (IV) contrast injection, and venous phase images are acquired 60 to 70 seconds postinjection. The contrast is infused through a peripheral IV at 4 to 5 mL/s and water (1000 mL) is used as an oral contrast agent. All images are reviewed in axial, multiplanar (coronal and sagittal planes), and three-dimensional volume rendering and maximum intensity projection. Recent improvement in imaging and the introduction of cinematic rendering (Fig. 1), has significantly improved the ability to appreciate the extent of vascular involvement, and its use is recommended for the evaluation of these patients at all centers where this modality is available. This should not be accomplished by routine exploration of stage III disease. Fig. 1 shows examples of each.

Localized pancreatic cancer that involves the main arteries of the upper abdomen (SMA, common hepatic artery, or celiac trunk) or the portomesenteric axis is classified as stage III. The degree of vascular involvement is determined and can be classified according to the classification system proposed by Ishikawa (Fig. 2). Two joint consensus statements divided stage III pancreatic cancer into either borderline resectable or locally advanced based on the extent of vessel involvement. The details of this staging system are beyond the scope of this chapter; however, controversy exists among high volume surgeons in regard to what defines resectable and on whom should be explored. In general, borderline resectable consists of patients whose have portomesenteric involvement that is technically reconstructible or no more than abutment of a major artery, while locally advanced patients have portomesenteric involvement that cannot be reconstructed or complete encasement of a major artery. Patients with borderline resectable tumors have a high probability of an oncologic resection and should undergo exploration. Certainly a significant percentage of patients classified as locally advanced and "unresectable" can actually undergo an oncologic resection. Determination of which patients in this category should undergo exploration is much more nuanced than borderline resectable and beyond the scope of this chapter.

PDAC is a highly systemic disease marked by early dissemination and most often presenting as metastatic disease. Even in the minority of patients who are diagnosed with localized and potential curable cancers, the predominant pattern of failure following resection is systemic. Thus, to cure localized pancreatic cancer two battles need to be won, a local battle fought with surgical resection and in some cases with the addition of radiation, and a systemic battle fought with chemotherapy and/or biological therapy. All stage III patients should undergo preoperative therapy (neoadjuvant to borderline resectable and induction to locally advanced) before exploration.

SURGICAL ANATOMY OF THE PORTAL VEIN AND SUPERIOR MESENTERIC VEIN

The confluence of the superior mesenteric, splenic, and portal veins is located posterior to the pancreatic neck. The main trunk of the superior mesenteric vein (SMV) is constituted from the jejunal and ileal branches that merge caudal to the pancreas. This main trunk drains the gastrocolic, and middle colic veins. The inferior mesenteric vessel can either drain into the splenic vein before its confluence with the portal vein (PV)/SMV or may directly drain into the SMV (Fig. 3).

The first jejunal branch of the SMV is frequently located posterior to the SMA as it enters the posteromedial ileal branch. This is the junction where these two structures merge to form the main trunk of the SMV. The jejunal branch also receives a branch from the uncinate process as it passes posterior to the SMA.

SURGICAL TECHNIQUE

Tumors of the head of the pancreas are resected through a Whipple operation that removes the distal stomach, the duodenum, and a small portion of the proximal jejunum, the gallbladder, distal bile duct, and the head of the pancreas. The enteric reconstruction consists of three anastomoses: pancreaticojejunostomy (or less commonly pancreaticogastrostomy), hepaticojejunostomy, and a gastrojejunostomy. The details of the standard Whipple operation are described elsewhere in this text. The modifications of the procedure for involvement of the portal vein, splenic vein, and SMV confluence are described within this chapter.

The general principle of approaching tumors of the confluence is to perform the entire dissection leaving the specimen attached only to the PV/SMV and then clamping and resecting the vein to remove the specimen. Specifically, the colon is mobilized off of the head of the pancreas, the duodenum is Kocherized, the common hepatic duct and stomach are divided. The jejunum is divided beyond the ligament of Treitz, the ligament is opened and the third and fourth portions of the duodenum and proximal jejunum are pulled beneath the superior mesenteric vessels into the right upper quadrant. Vascular control is then obtained with vessel loops on the portal vein superiorly and the SMV inferiorly. If the inferior mesenteric vein (IMV) aberrantly enters the SMV and not the splenic vein, a common variant, control of this vessel can also be obtained. In addition,

(A) Axial portal venous phase computed tomography image demonstrating an ill-defined hypoenhancing mass in the pancreatic head (arrow) with abrupt caliber change of dilated main pancreatic duct (arrowhead). (B) Coronal portal venous phase computed tomography image shows tumor involvement and severe narrowing of the portal vein–superior mesenteric vein confluence (arrow). (C) Cinematic rendering of the pancreatic head mass (arrow) with dilated main pancreatic duct (arrowhead). (D) Cinematic rendering better illustrates the degree of portal vein–superior mesenteric vein narrowing (arrow) compared with (B) two-dimensional coronal reconstruction. *From Chu LC, Fishman EK. Cinematic rendering of pancreatic neoplasm: preliminary observations and opportunities. Radiol Imaging Cancer. Radiol. 2019;1:e190021.*

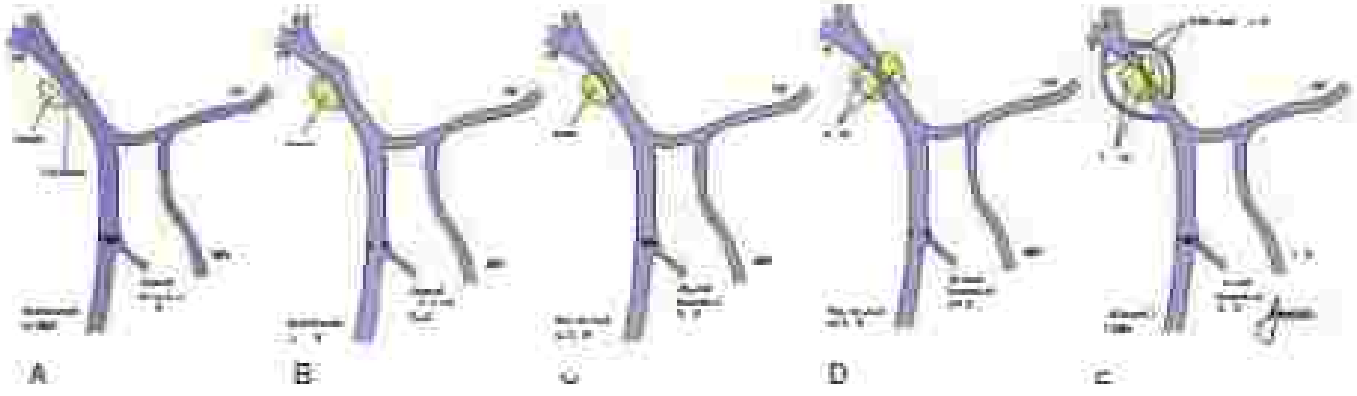

FIG. 2 Vascular classification of portal vein (PV), superior mesenteric vein (SMV) involvement. (A) Lateral venous wall tip plane between tumor and vessel. (B) Smooth shift of vessel with normal caliber. (C) Bilateral narrowing of vessel. (D) Bilateral narrowing of vessel with parietal lesion. (E) Bilateral narrowing of vessel with dilated lumen and formation of collateral veins. IMV, Inferior mesenteric vein; S, splenic vein.

the coronary vein entering the portal vein from the left should be ligated and divided. At this point, the tunnel can be created behind the neck of the pancreas realizing that the only major tributary that is not controlled is the splenic vein. Controlling the splenic vein is difficult prior to the division of the neck. Once the neck is divided, vessel loop control of the splenic vein should be obtained. The final step prior to en bloc resection of the PV/SMV is to divide the uncinate process in a manner that clears the right side of the SMA for 270 degrees in axial plane. The easiest way to accomplish this is to divide the splenic vein thus exposing the anterior wall of the SMA. This will allow retraction of the specimen to the right and the uncinate process can be divided to the left of the vein (Fig. 4). Alternatively, if the tumor involves the SMV only below the insertion of the splenic vein, the splenic vein can be preserved and the uncinate can be divided by retracting the PV/SMV anteriorly. Either way, at this time, the only structure attaching the Whipple specimen to the abdomen in the region of vascular involvement is the PV/SMV. Based on the extent of vascular involvement, appropriate resection and reconstruction is performed as detailed later in this chapter.

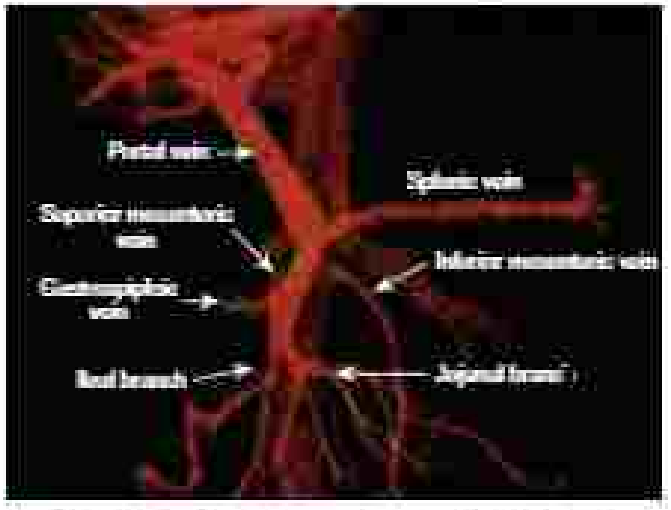

FIG. 3 Peripancreatic vascular anatomic structures. Volume-rendered computed tomography images show normal peripancreatic venous anatomic structures.

■ VENOUS RESECTION AND RECONSTRUCTION

Several techniques have been described to resect and reconstruct venous involvement of the PV/SMV. Four types have been proposed by the IHPBS (Fig. 5). The selection of the appropriate technique depends on the extent of vascular involvement, caliber of the vessel, extent of narrowing of vessel, and the surgeon's preference.

When there is invasion of a small circumference of the vessel, a vascular clamp can be placed to partially occlude the vessel, and a small tangential resection of the involved vessel can be performed (Fig. 6). This can be achieved by longitudinal dissection along the lateral aspect of the clamp. The use of a longitudinal incision is debatable, however, and some surgeons prefer a transverse incision because it minimizes the extent of narrowing of the vessel. Depending the size of the opening in the vessel and its caliber, the resulting defect can be closed primarily using a running 5-0 Prolene suture (lateral venorrhaphy or transverse venorrhaphy) (Fig. 7). If significant narrowing of the vessel is anticipated, the closure can be performed using a venous patch (patch venoplasty), which can be fashioned from the saphenous vein, portosomal patch, or a bovine pericardial patch (Fig. 7).

In the event of a more extensive encasement (circumferential involvement) of the confluence, a segmental resection may be required (Fig. 8). This can be reconstructed using multiple techniques depending on the length of the resected segment as well as the tension on the remaining distal and proximal ends (Fig. 9). For all cases requiring a segmental resection, the inflow and outflow control is established both proximal and distal to the tumor involvement by

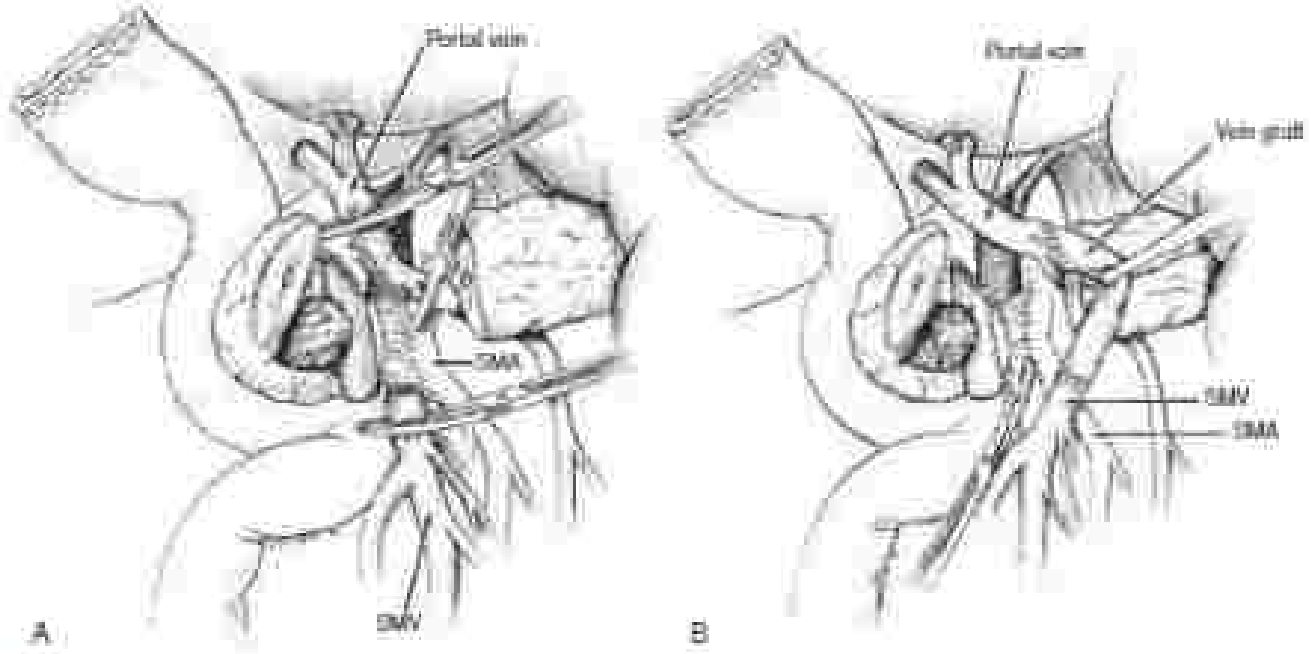

FIG. 4 Technique of venous resection and reconstruction. (A) Segmental resection of the superior mesenteric vein (SMV) is performed while the specimen is still attached to the superior mesenteric artery (SMA) before completion of the retroperitoneal dissection. (B) An internal jugular vein interposition graft enables distal retraction of the reconstructed superior mesenteric-portal vein confluence, allowing access to the retroperitoneum for standard dissection of the tumor from the lateral wall of the SMA. (From Hackert T, Loos M, Chermenegeli C, et al. Survival following pancreaticoduodenectomy with resection of the superior mesenteric-portal vein confluence for adenocarcinoma of the pancreatic head. Br J Surg. 97:805[6]:811-817.)

(3) Segmental venous resection and primary anastomosis. (4a) Interposition of the internal jugular vein (IJV) graft. (4b) Interposition of the SV graft with reanastomosis of the splenic vein (SV) to the IJV graft. *PV*, portal vein.

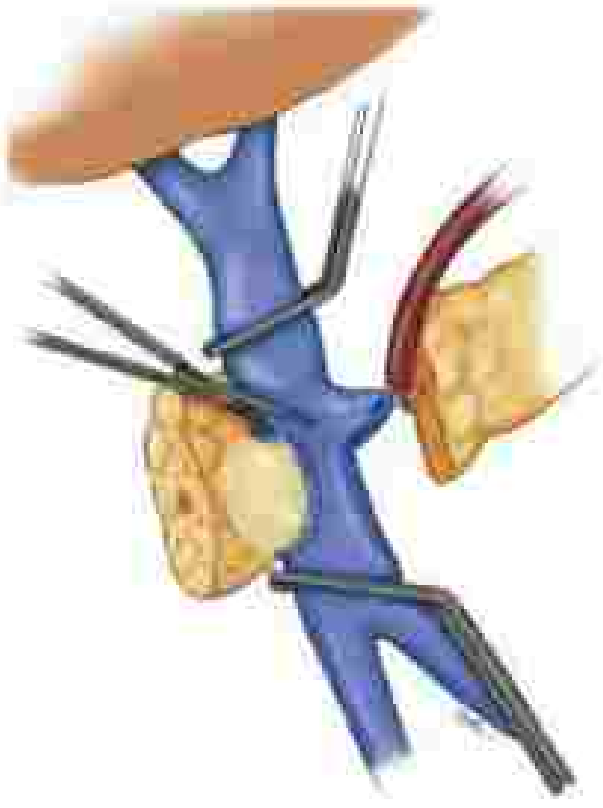

FIG. 4 Pancreatic tumor adherent to a small segment of the portal vein-superior mesenteric vein complex requiring tangential resection. (From Jarufe NP, Bond K, Fagenson A, et al. Pancreatic resections: comparison with venous resection and reconstruction. Current surgical techniques and associated postoperative imaging findings. Abdom Imaging. 2015;40(4):741–754.)

placing vascular clamps. The vessels are then divided both proximal and distal to the location of the tumor. Typically for a resected segment that is 3 to 4 cm in length a primary anastomosis can be performed by approximating the vessels. Once approximated, both ends are sutured together using a 5-0 Prolene suture in usual fashion to perform the anastomosis in a running manner (Fig. 9.4, B).

Rarely, the resected segment of vein is long and a primary anastomosis cannot be performed. In these cases, a venous interposition graft may be needed (Fig. 9.4, C) (3). The most suitable grafts are the internal jugular vein or the left renal vein between the SMV and the gonadal vein as their caliber is similar to that of the portal and superior mesenteric veins. The use of polytetrafluoroethylene as a graft is associated with high incidence of postoperative thrombosis and should not be performed.

It is unclear whether the splenic vein needs to be reimplanted when divided to resect and reconstruct the confluence. The rationale to do so is to avoid left-sided portal hypertension and gastric varices. In our practice, we implant the splenic vein if it receives flow from the IMV. If the IMV enters directly into the SMV, we do not reimplant the vessel.

We do not routinely systemically heparinize to reconstruction of the PV-SMV. However, it is performed by some groups using the intravenous administration of 2500 to 3000 units of heparin 2 to 3 minutes before the occlusion.

Recently, our institution has reported on a few cases of vascular resection without reconstruction in cancers with complete occlusion of the SMV with left-sided collateralization of venous return. In these cases, intraoperatively, the superior mesenteric vessel is ligated at the level of the ileal and jejunal branches, and no reconstruction is performed. Upon follow-up, these patients did not develop any complications of obstructed venous flow. Although this is not common practice, it might be a suitable option for select patients who present with localized disease with isolated involvement of the distal superior mesenteric vein and the presence of collateral vessels.

POSTOPERATIVE CARE

Although perioperative mortality of patients undergoing the Whipple operation has declined significantly, postoperative morbidity remains high. The most frequent complications include delayed gastric emptying, postoperative pancreatic fistula, postpancreatectomy hemorrhage, and surgical site infections. The routine postoperative management of patients undergoing a Whipple operation without vascular reconstruction is detailed in another chapter.

The postoperative management of patients who undergo the Whipple operation with vascular resection is similar to that of patients not requiring a vascular resection. In particular for these patients, although systemic anticoagulation is not required, 300 mg of rectal aspirin is administered daily until the patient is tolerating a regular diet at which time it is switched to 81 mg daily of oral aspirin.

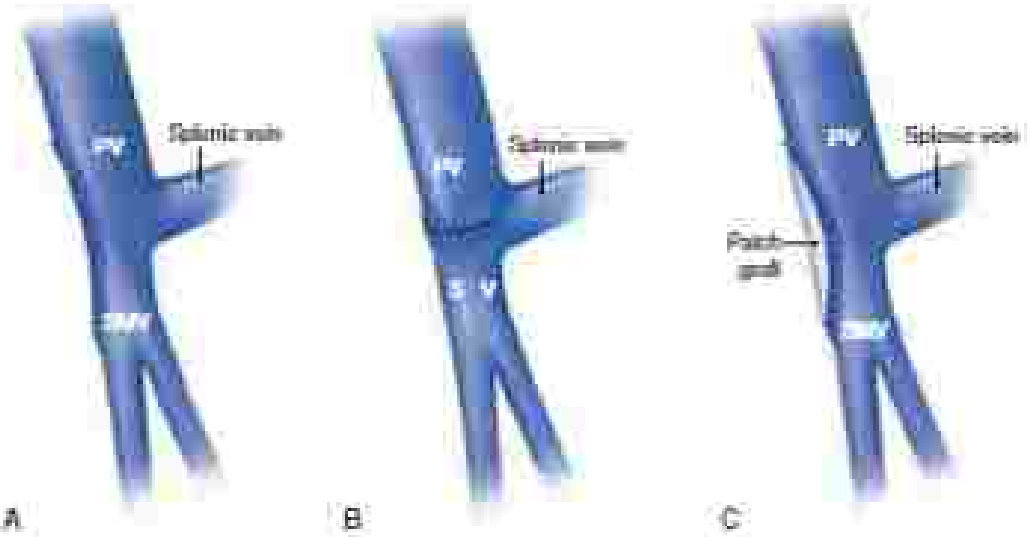

FIG. 7 Segmental resection of tumor and repair using (A) Primary venorrhaphy: longitudinal venorrhaphy. (B) Primary venorrhaphy: transverse venorrhaphy. (C) Patch venoplasty. *PV* portal vein; *SMV* superior mesenteric vein. (From Jagot AA, Black K, Ingraham A, et al. Pancreaticoduodenectomy with venous resection and reconstruction: current surgical techniques and associated postoperative imaging findings. Abdom Radiol (NY). 2019;44(1):119–129.)

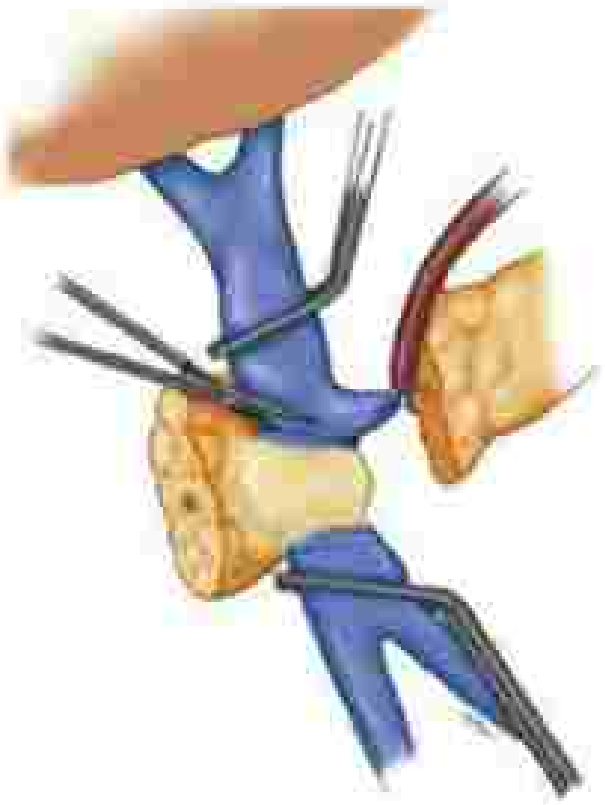

FIG. 8 Pancreatic tumor encasing the portal vein-superior mesenteric vein complex requiring segmental resection. (From Jagot AA, Black K, Ingraham A, et al. Pancreaticoduodenectomy with venous resection and reconstruction: current surgical techniques and associated postoperative imaging findings. Abdom Radiol (NY). 2019;44(1):119–129.)

Furthermore, the patient should be monitored for signs of thrombosis and graft occlusion. The most common signs of this are acute onset of ascites, oliguria, increased fluid requirement, and hypotension. Of note, the liver function tests may frequently be normal even with complete occlusion of the portal vein. If there is a suspicion for graft occlusion or thrombus, a duplex should be performed. In the event that the duplex is inconclusive because of presence of bowel gas or the dressing, a CT angiogram is warranted. For partial thrombosis and with no concern for a technical problem, systemic anticoagulation should be initiated. If complete occlusion exists and/or there is concern for a technical problem, the patient should return to the operating room for surgical thrombectomy and revision of the reconstruction.

POSTOPERATIVE APPEARANCE OF THE RECONSTRUCTED VENOUS VASCULATURE

One of the less frequently discussed aspects of vascular resection and reconstruction during a Whipple operation is the postoperative appearance of the reconstructed vasculature. A vast majority of patients who require these procedures are those that have malignant tumors of the pancreas. These tumors are at a high risk of recurrence; therefore, postoperative imaging is performed at regular intervals to rule out recurrence of disease. Interestingly, in patients undergoing a Whipple procedure with a concurrent vascular resection, aberrant or irregular appearance of the venous structures is common because of the new postoperative anatomy of the vessels.

Postoperative appearance of the venous vasculature was recently studied and defined by our group, and two distinct features of the vasculature were described that included changes to the appearance of the vasculature itself and identification of perivenous changes. Changes to the vasculature can be observed in approximately one half of all patients undergoing venous resections. These can be further classified into concentric smooth narrowing, eccentric irregular narrowing, or the presence of a thrombus (Fig. 10). The most frequent form is concentric smooth narrowing, whereas development of thrombus is a rare event. On the other hand, perivenous changes comprise perivenous fluid-like collections or perivenous soft tissue thickening that has a mass-like effect (Fig. 11). Perivenous changes are also frequently encountered in these patients, with perivenous fluid collections being more common of the two.

These changes observed on postoperative imaging overlap considerably with findings suspicious for the recurrence of disease. Interestingly, however, in the previously mentioned study on long-term follow-up, a majority of patients with these changes did not develop local recurrence, suggesting that these changes in fact are related to the surgically altered anatomy of the vasculature. We believe that a

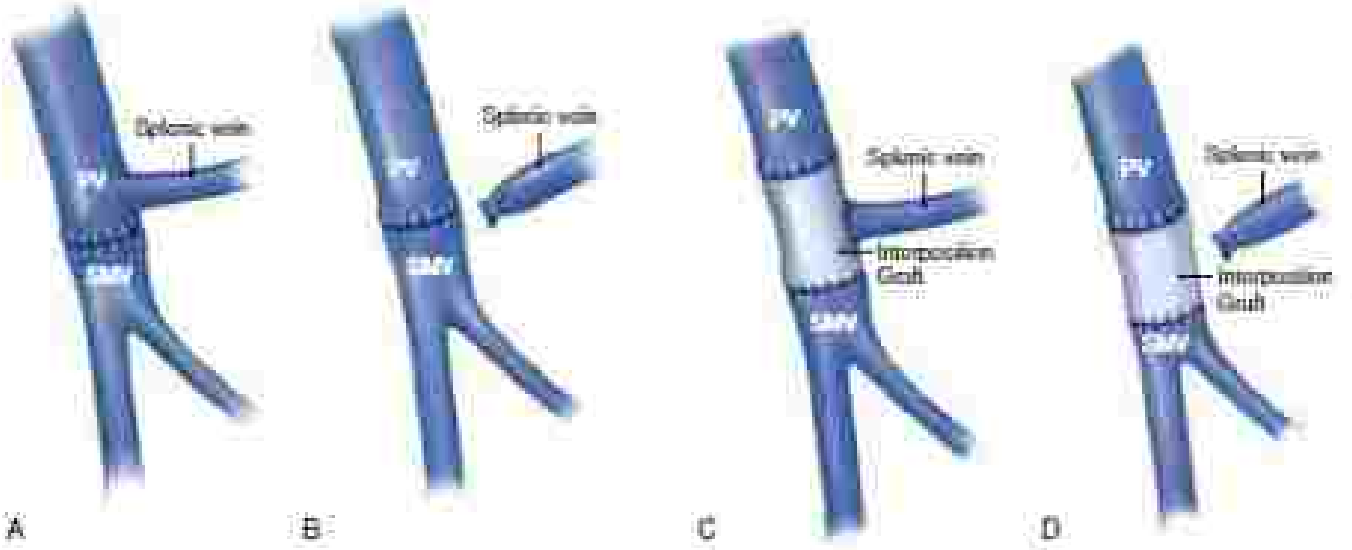

FIG. 9 Segmental resection of tumor and reconstruction with primary end-to-end anastomosis with (A) and without (B) preservation of the splenic vein. In cases of long segment resection, reconstruction can be performed with interposition graft, with (C) and without (D) preservation of the splenic vein. PV, portal vein; SMV, superior mesenteric vein. (From Jamil MA, Reich A, Segami J, et al. Pancreatoduodenectomy with venous resection and reconstruction: current surgical techniques and associated postoperative imaging findings. Abdom Radiol (NY). 2016;41(2):197–209.)

(From Jamil MA, Reich A, Segami J, et al. Pancreatoduodenectomy with venous resection and reconstruction: current surgical techniques and associated postoperative imaging findings. Abdom Radiol (NY). 2016;41(2):197–209.)

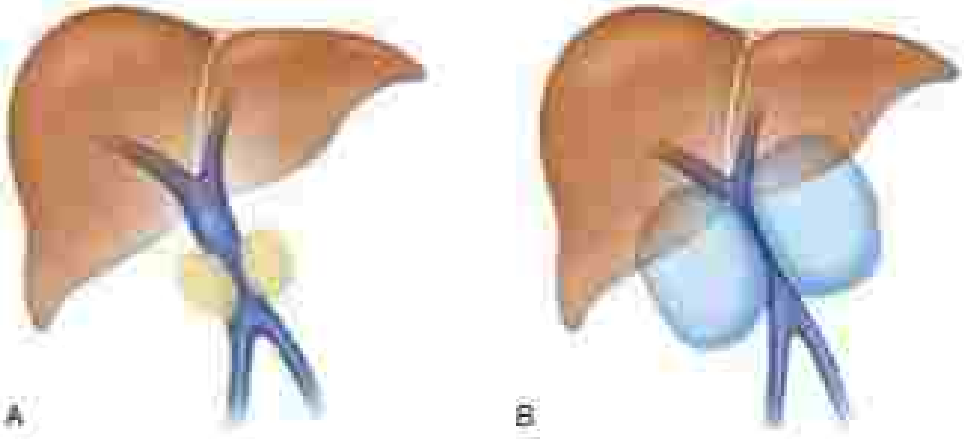

FIG. 11 Categories of peritoneal findings. (A) Peritoneal soft tissue thickening, which can have a mass-like appearance. (B) Peritoneal fluid collection. (From Jamil MA, Reich A, Segami J, et al. Pancreatoduodenectomy with venous resection and reconstruction: current surgical techniques and associated postoperative imaging findings. Abdom Radiol (NY). 2016;41(2):197–209.)

thorough knowledge of the postoperative appearance of the venous vasculature is important for all physicians involved in the care of these patients. If the radiologists, surgeons, or medical oncologists are not well versed in this area, there is a high risk of misdiagnosis of recurrence of disease, which in turn triggers a significant change in the management of these patients.

SUMMARY

With an increased utilization of effective systemic and locoregional therapies in the neoadjuvant setting, a significant proportion of patients with vascular involvement are now undergoing resection. Vascular resection and reconstruction add to the complexity of an already challenging surgical procedure; however, with appropriate preoperative imaging, thorough surgical planning, detailed knowledge of the available techniques, and surgical experience, these procedures can be performed safely. When performed by experienced surgeons at high-volume centers, outcomes similar to that of the standard Whipple operation can be achieved in patients undergoing these complex resections. The oncologic benefits of these procedures have been well established, and as these procedures become more common, patients who would have otherwise succumb to their disease will have a shot at undergoing curative resection. Last, changes in the postoperative appearance of the vasculature associated with altered vascular anatomy should be considered when evaluating these patients postoperatively to reduce the risk of misdiagnosis of recurrent disease.

PALLIATIVE THERAPY FOR PANCREATIC CANCER

Ashley N. Knepline, MD, and Susan Tsai, MD, MHS

Patients with advanced pancreatic cancer often face myriad physical ailments. The overarching goal of palliative care is to improve in quality of life and alleviate pain and suffering for patients. Approaching patients about palliative care can be challenging because patients often have a misperception that palliative care is mutually exclusive from active cancer therapy. In reality, palliative care can be administered simultaneously with active cancer treatment and at times allows patients to return to a condition to be able to tolerate oncologic treatments. In other instances, focus on palliation of symptoms allows patients to achieve a better quality of life with their loved ones toward the end of life. Effective palliation of symptoms often requires consideration of the severity of symptoms while balancing the expected life expectancy and goals of care for the patient. Often, patients may present with multiple interrelated symptoms, which requires a multidisciplinary approach with the input of surgeons, medical oncologists, radiation oncologists, gastroenterologists, and radiologists to effectively address all symptoms. Guidance from palliative care specialists may further augment the development of a multidisciplinary, multimodal plan to comprehensively address symptoms while minimizing hospitalizations and ease the transition to end-of-life planning.

Because of the anatomic location, pancreatic cancers can affect adjacent structures through invasive growth and obstruction. Patients commonly experience gastric outlet obstruction from duodenal obstruction, distal biliary obstruction causing jaundice, and debilitating back or epigastric pain related to the tumor infiltration into the celiac plexus. In addition, debilitating ascites may occur either secondary to carcinomatosis or occlusion of the superior mesenteric vein/portal vein. Finally, patients with advanced pancreatic cancer have the highest rates of depression and suicide among all cancers. Effective counseling and medication can help to alleviate emotional pain and suffering. This chapter will provide an overview of palliative approaches for these problems.

INITIAL EVALUATION

Patients with advanced pancreatic cancer face difficult treatment decisions and open communication about goals of care will help patients to make sound, informed decisions. Fundamental questions which should be addressed with the patient and his/her family are summarized in Box 1. Understanding personal goals and preferences will help shape conversations about treatment recommendations and engage patients in shared decision-making. It is also important to elicit patient preferences for how information is communicated and what level of detail is suitable. Along with a foundational understanding, treatment goals should be revisited as necessary at future encounters. Longitudinal assessment of symptoms at the time of diagnosis and throughout the course of the treatment will help to identify and proactively address problems.

Patients with advanced pancreatic cancer are frequently monitored with imaging, such as a computed tomography (CT) scan of the chest, abdomen, and pelvis, and basic laboratory tests. Although these studies are obtained to assess treatment response, they should also be closely examined for impending complications. These may manifest as signs of current or impending biliary obstruction, bowel obstruction, ascites, tumor infiltration into the abdominal neural plexus (celiac axis), or significant portal venous narrowing/obstruction. In addition, routine assessment of pain, nausea, vomiting, abdominal distension, and cachexia can be helpful. Referral to palliative care services can facilitate addressing multiple symptoms. Notably, patients who are encouraged by palliative care specialists have been found to have decreased rates of intensive care admissions, emergency room visits, and repeated hospitalizations.

BILIARY OBSTRUCTION

More than 70% of patients with pancreatic cancer will present with biliary obstruction leading to jaundice and malabsorption. Jaundice can cause debilitating pruritus, abdominal pain, fatigue, weight loss, nausea, vomiting, and anorexia, which can be resolved with biliary decompression. Durable relief of biliary obstruction is necessary to improve quality of life and normalize liver function tests to allow initiation of chemotherapy. Several series have demonstrated that endoscopic retrograde cholangiopancreatography (ERCP) can

thorough knowledge of the postoperative appearance of the venous vasculature is important for all physicians involved in the care of these patients. If the radiologists, surgeons, or medical oncologists are not well versed in this area, there is a high risk of misdiagnosis of recurrence of disease, which in turn triggers a significant change in the management of these patients.

SUMMARY

With an increased utilization of effective systemic and locoregional therapies in the neoadjuvant setting, a significant proportion of patients with vascular involvement are now undergoing resection. Vascular resection and reconstruction add to the complexity of an already challenging surgical procedure; however, with appropriate preoperative imaging, thorough surgical planning, detailed knowledge of the available techniques, and surgical experience, these procedures can be performed safely. When performed by experienced surgeons at high-volume centers, outcomes similar to that of the standard Whipple operation can be achieved in patients undergoing these complex resections. The oncologic benefits of these procedures have been well established, and as these procedures become more common, patients who would have otherwise succumb to their disease will have a shot at undergoing curative resection. Last, changes in the postoperative appearance of the vasculature associated with altered vascular anatomy should be considered when evaluating these patients postoperatively to reduce the risk of misdiagnosis of recurrent disease.

PALLIATIVE THERAPY FOR PANCREATIC CANCER

Ashley N. Knepline, MD, and Susan Tsai, MD, MHS

Patients with advanced pancreatic cancer often face myriad physical ailments. The overarching goal of palliative care is to improve in quality of life and alleviate pain and suffering for patients. Approaching patients about palliative care can be challenging because patients often have a misperception that palliative care is mutually exclusive from active cancer therapy. In reality, palliative care can be administered simultaneously with active cancer treatment and at times allows patients to return to a condition to be able to tolerate oncologic treatments. In other instances, focus on palliation of symptoms allows patients to achieve a better quality of life with their loved ones toward the end of life. Effective palliation of symptoms often requires consideration of the severity of symptoms while balancing the expected life expectancy and goals of care for the patient. Often, patients may present with multiple interrelated symptoms, which requires a multidisciplinary approach with the input of surgeons, medical oncologists, radiation oncologists, gastroenterologists, and radiologists to effectively address all symptoms. Guidance from palliative care specialists may further augment the development of a multidisciplinary, multimodal plan to comprehensively address symptoms while minimizing hospitalizations and ease the transition to end-of-life planning.

Because of the anatomic location, pancreatic cancers can affect adjacent structures through invasive growth and obstruction. Patients commonly experience gastric outlet obstruction from duodenal obstruction, distal biliary obstruction causing jaundice, and debilitating back or epigastric pain related to the tumor infiltration into the celiac plexus. In addition, debilitating ascites may occur either secondary to carcinomatosis or occlusion of the superior mesenteric vein/portal vein. Finally, patients with advanced pancreatic cancer have the highest rates of depression and suicide among all cancers. Effective counseling and medication can help to alleviate emotional pain and suffering. This chapter will provide an overview of palliative approaches for these problems.

INITIAL EVALUATION

Patients with advanced pancreatic cancer face difficult treatment decisions and open communication about goals of care will help patients to make sound, informed decisions. Fundamental questions which should be addressed with the patient and his/her family are summarized in Box 1. Understanding personal goals and preferences will help shape conversations about treatment recommendations and engage patients in shared decision-making. It is also important to elicit patient preferences for how information is communicated and what level of detail is suitable. Along with a foundational understanding, treatment goals should be revisited as necessary at future encounters. Longitudinal assessment of symptoms at the time of diagnosis and throughout the course of the treatment will help to identify and proactively address problems.

Patients with advanced pancreatic cancer are frequently monitored with imaging, such as a computed tomography (CT) scan of the chest, abdomen, and pelvis, and basic laboratory tests. Although these studies are obtained to assess treatment response, they should also be closely examined for impending complications. These may manifest as signs of current or impending biliary obstruction, bowel obstruction, ascites, tumor infiltration into the abdominal neural plexus (celiac axis), or significant portal venous narrowing/obstruction. In addition, routine assessment of pain, nausea, vomiting, abdominal distension, and cachexia can be helpful. Referral to palliative care services can facilitate addressing multiple symptoms. Notably, patients who are encouraged by palliative care specialists have been found to have decreased rates of intensive care admissions, emergency room visits, and repeated hospitalizations.

BILIARY OBSTRUCTION

More than 70% of patients with pancreatic cancer will present with biliary obstruction leading to jaundice and malabsorption. Jaundice can cause debilitating pruritus, abdominal pain, fatigue, weight loss, nausea, vomiting, and anorexia, which can be resolved with biliary decompression. Durable relief of biliary obstruction is necessary to improve quality of life and normalize liver function tests to allow initiation of chemotherapy. Several series have demonstrated that endoscopic retrograde cholangiopancreatography (ERCP) can

be safely and effectively performed in the vast majority of patients with malignant obstructive jaundice. Early complications after ERCP occur in 5% of patients and most commonly include ERCP-induced pancreatitis, infection, or bleeding. The most common delayed complication following biliary stenting to treat recurrent jaundice secondary to stent occlusion.

Self-expanding metal stents (SEMS) are clearly superior to plastic stents with regard to stent patency and stent-related complications. Because of the smaller lumen, plastic biliary stents are more likely to occlude from biliary sludge or bacterial overgrowth requiring frequent stent exchanges, whereas SEMS are more likely to be occluded with tumor ingrowth of the stent. In general, the patency of a plastic stent is proportional to the size of the stent, for example, an 8Fr stent will be patent for 8 weeks. In contrast, a 10 mm diameter SEMS will provide an equivalent drainage as nine 10Fr plastic stents, and therefore provide much more durable biliary drainage. Covered SEMS have become increasingly used and have demonstrated decreased rates of occlusion and therefore longer stent patency (Table 1). In addition to stent occlusion, another common complication of biliary stents is stent migration, which is more frequently seen with plastic and covered metal stents as opposed to uncovered SEMS.

Operative biliary bypass is an alternative strategy to allow for drainage of an obstructed biliary tree. There are several techniques that may be utilized for a biliary bypass. The most common and durable technique used is a retrocolic choledochojejunostomy with a Roux-en-Y reconstruction. Alternatively, a loop of jejunum may be used rather than a Roux-en-Y. This is a quicker operation and does not require a jejunojejunostomy but is associated with a higher incidence of cholangitis and is not preferred to the Roux-en-Y. If a patient has not had a prior cholecystectomy, a cholecystectomy should be performed in addition to the biliary drainage procedure, even in the absence of cholelithiasis or symptoms.

Resolution of biliary obstruction after endoscopic stent placement or surgical biliary bypass have been shown to be equivalent in several retrospective studies. In a series of 98 patients, 52 underwent surgical biliary bypass and 46 underwent placement of SEMS. Of the 52 patients undergoing surgical bypass, 38% developed perioperative morbidity and 7% with SEMS developed periprocedural complications. Recurrent biliary obstruction as a result of SEMS occlusion occurred in 40% of patients, whereas recurrent biliary obstruction was not identified in patients who underwent surgical bypass. However, the increased durability of a hepaticojejunostomy must be weighed against the potential for perioperative morbidity and an increased length of hospital stay (12 vs 3 days) when compared with SEMS. Biliary bypass has been shown to be more durable than SEMS placement, however, even when including procedure-related readmissions and repeat endoscopy for stent exchange. Biliary stent placement has also been associated with lower costs.

BOX 1 Questions Providers May Use to Engage Patients in Communicating Goals of Care

What is your understanding of your illness?
What are your hopes and fears?
What are your goals and priorities?
What outcomes are unacceptable to you?
What would a good day look like?

GASTRIC OUTLET OBSTRUCTION

Nausea and vomiting in patients with advanced pancreatic cancer can be due to mechanical and/or nonmechanical problems. An initial evaluation should include a thorough history and physical and radiographic studies to identify obstruction related either to the primary tumor (gastric outlet obstruction) or a metastatic deposit (malignant bowel obstruction). In the absence of a mechanical etiology, the symptoms may be related to malignant gastroparesis or to chemotherapy and may be best alleviated with pharmacologic agents. Patients with gastric outlet obstruction suffer from nausea, vomiting, anorexia, weight loss, and malnutrition. Clinical suspicion can be supported by the presence of a dilated stomach on CT scan, and may be confirmed by an upper gastrointestinal fluoroscopy or endoscopy to confirm the diagnosis (Fig. 1A). Traditionally, a gastrojejunostomy is performed to relieve the area of obstruction and palliate symptoms. Palliative gastrojejunostomy for malignant gastric outlet obstruction has been associated with a 30% rate of morbidity, but with advances in surgical treatment, the morbidity has decreased to approximately 10%. Gastrojejunostomy can be performed via an open or laparoscopic approach. Classically, a retrocolic gastrojejunostomy is performed by sewing the posterior wall of the stomach to a loop of jejunum in a stapled or handsewn side to side fashion. This approach is favored over a Roux limb to improve the emptying of the jejunal limb. Studies comparing efficacy of laparoscopic compared with open gastrojejunostomy are limited, however, current studies demonstrate a quicker return to oral intake with a laparoscopic approach and a trend towards decreased length of hospital stay.

More recently with the advent of endoscopic techniques, duodenal stenting has become an alternative strategy to manage malignant gastric outlet obstruction. Duodenal stenting has become a well-established technique to treat malignant gastric outlet obstructions (Table 2). A SEMS is endoscopically placed across a malignant stricture or area of narrowing. Duodenal stenting is typically associated with oral intake within 24 hours after placement, significantly faster than after an open bypass procedure. In a systematic review of 601

patients with malignant gastric outlet obstruction, duodenal stents were successfully placed in 97% of patients. Of the patients who underwent successful placement of a stent, 89% had a clinical success, defined as ability to tolerate soft or regular diet. Reintervention for recurrent symptoms, most commonly resulting from stent occlusion secondary to tumor infiltration, occurred in 18% of patients at a median of 115 days. This can often be managed with the placement of an additional covered SEMS within the existing stent. Other complications included stent migration which occurred in 5% of patients, and a major bleeding or perforation event which occurred in 1% of patients. If there is associated jaundice, biliary stenting should be performed before duodenal stent placement, as placement of a biliary stent after placement of a duodenal stent is technically difficult (Fig. 1B). The decision to perform duodenal stenting or surgical gastrojejunostomy depends on expected survival and goals of care. In patients who undergo duodenal stenting, rapid return of oral intake is possible, but the long-term risk of stent occlusion secondary to tumor ingrowth is high, especially after 4 months. Comparatively, rates of recurrent gastric outlet obstruction after undergoing gastrojejunostomy are quite low, estimated around 2%, but carry an added risk of perioperative morbidity and mortality.

PROPHYLACTIC BILIARY AND GASTRIC BYPASS

Palliation therapy implies that the patient is suffering from active symptoms. But, at times, palliative care decisions are made to prevent future complications in asymptomatic patients. The classic example of this is when patients who were thought to have operable disease are discovered at the time of surgery to have an unresectable pancreatic cancer. Among asymptomatic patients, future complications from local tumor extension results in duodenal obstruction in up to 20% of cases and biliary obstruction in 65% of cases. In a study of 87 patients undergoing exploratory laparotomy for resectable pancreatic cancer resection, patients that were found to be unresectable at time of operation were randomized into prophylactic hepaticojejunostomy or prophylactic hepaticojejunostomy with gastrojejunostomy. Hepaticojejunostomy with gastrojejunostomy was performed in 44 patients, and no patient developed subsequent symptoms of gastric outlet obstruction. In

contrast, 8 (10%) of the 83 patients undergoing hepaticojejunostomy alone developed symptoms of gastric outlet obstruction requiring intervention. Similarly, in a second smaller randomized study of 46 patients who had a nontherapeutic laparotomy, 29 patients underwent hepaticojejunostomy and 36 patients underwent hepaticojejunostomy with gastrojejunostomy. Gastric outlet obstruction occurred in 2 (6%) of the 36 patients who underwent double bypass compared with 12 (41%) of the 29 patients who underwent hepaticojejunostomy alone. Neither study identified increased morbidity, mortality, or difference in overall survival between the two surgical intervention arms; however, it is important to note that the overall perioperative morbidity and mortality from these two trials were 39% to 52% and 0% to 3%, respectively. This early experience supported the routine use of double bypass at the time of a nontherapeutic laparotomy for pancreatic cancer. The largest series of palliative double bypass included 583 patients from a single institution. The series reported a 14% major complication rate and a 1.6% overall mortality rate. In addition, 10% of patients required readmission within 30 days and recurrent biliary obstruction or gastric outlet obstruction occurred in 9% of patients.

Although concomitant prophylactic gastric and biliary drainage at the time of nontherapeutic laparotomy has been the standard practice for many years, more recent minimally invasive approaches of endoscopic stenting has led to a declining use of routine double bypass. Critics of routine surgical bypass at the time of a nontherapeutic laparotomy have reported that 98% of patients who do not receive a surgical bypass can be effectively palliated without an operation. In a study of 155 patients with advanced pancreatic cancer, only 4 patients required a future surgical intervention, and the median overall survival was approximately 6 months. Therefore, the authors argued that a prophylactic palliative operation has a detrimental impact on a patient's quality of life when less invasive treatments are available.

Ultimately, the decision regarding endoscopic versus surgical palliation requires knowledge about the (1) severity of symptoms, (2) expectation of patient's performance status, and (3) understanding of the patient's goals of care to best balance the durability of the intervention with respect to anticipated overall survival (Fig. 2). In the current era of multimodality chemotherapy, the median overall survival of patients with metastatic pancreatic cancer to 11 months with the multidrug regimen 5-FU, leucovorin, irinotecan, and oxaliplatin. Increasingly, patients are undergoing a diagnostic laparoscopy to rule out radiographically occult metastatic disease prior to resection. If patients are found to have radiographically occult metastatic disease and have symptoms of gastric obstruction, which have been inadequately managed with endoscopic therapy, then an open or laparoscopic gastrojejunostomy is indicated. Endoscopic management is usually successful in alleviating biliary obstruction, and therefore hepaticojejunostomy may be reserved for select patients who have been inadequately palliated with endoscopic stenting or for whom gastroduodenal obstruction prevents endoscopic access. In patients who are asymptomatic, emblematical approaches will likely be successful in palliating future symptoms and surgical bypass can be avoided. With expectant nonsurgical management, patients can avoid perioperative complications and receive systemic therapy for their metastatic disease with minimal delay.

Palliative Pancreaticoduodenectomy

A small volume of literature exists describing the benefits of palliative resection for pancreatic cancer. In such series, improved overall survivals were noted among patients who undergo palliative microscopic (R1) or macroscopic (R2) resections compared with patients who undergo palliative surgical bypass. It should be noted that many series which report a survival benefit for palliative pancreaticoduodenectomy include patients who had a R1 resection from an operation performed with curative intent. The survival of these patients, in whom a curative intent surgery was performed, is not surprisingly superior to patients with obvious metastatic disease or residual gross tumor. When curative intent patients are eliminated from the analysis, the survival benefit is lost. In a systematic review of four cohort studies which included 138 patients with pancreaticoduodenectomy performed for palliation has been associated increased risk of morbidity and mortality by 1.75 (95% CI, 1.35–2.26), $P < .0001$) and 2.98 (95% CI, 1.31–6.75, $P = .009$), respectively. Currently, there are no data to support palliative pancreaticoduodenectomy (R2 resection) for pancreatic cancer.

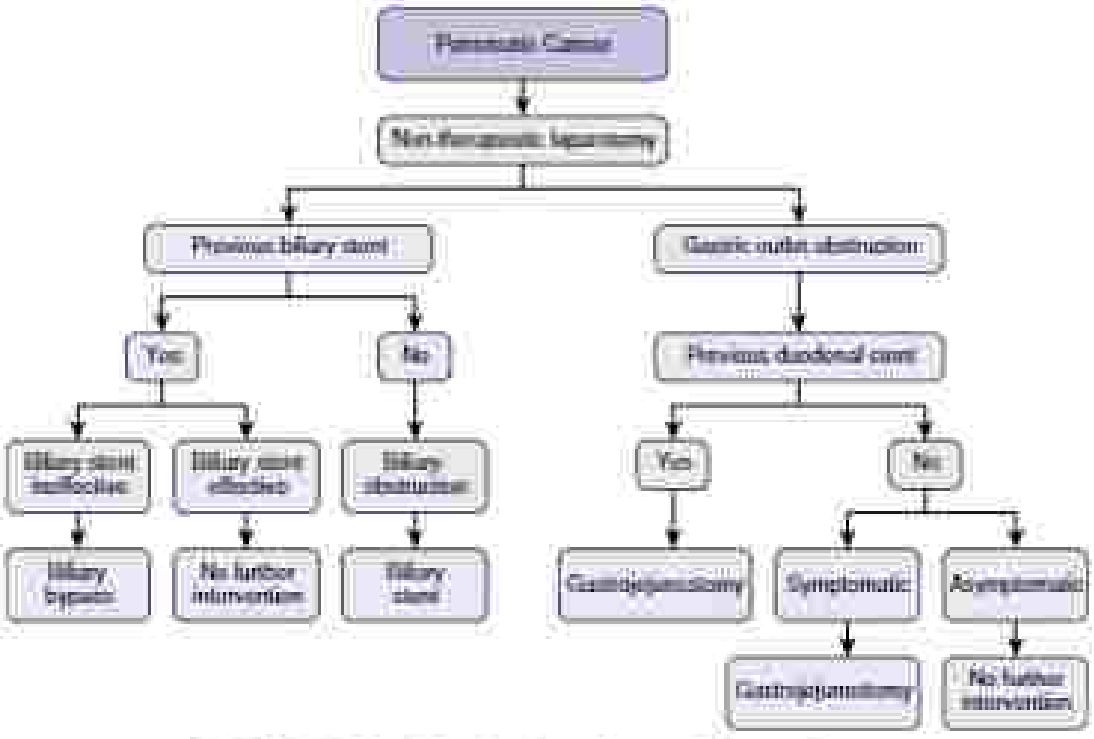

FIG. 1 Algorithm for palliation in patients with unresectable pancreatic cancer.

MALIGNANT BOWEL OBSTRUCTION

Malignant bowel obstruction resulting from peritoneal carcinomatosis is an ominous complication. These patients often suffer from severe, debilitating malnutrition and cancer cachexia which complicates their operative candidacy. In addition, most patients have concurrent malignant ascites, adding to the risk for postoperative complications, including wound dehiscence and seeding of the surgical incision causing local pain. Depending on the location of the obstruction, the success of endoscopic approaches may be limited, especially if the obstruction occurs within the mid to distal small bowel. Patients may find some alleviation of symptoms when abstaining from oral intake. Relief of nausea and vomiting may require gastric decompression with a nasogastric tube in the acute setting. In very select patients who have no ascites and very low volume disease, an operative exploration and surgical bypass may be considered. If patients are not candidates for surgical palliation, after a short interval (5–7 days), they may benefit from transitioning the nasogastric tube to a venting gastrostomy tube for long term palliation. If surgical or endoscopic intervention is not possible, pharmacologic therapy may provide some relief. Adequate pain control with opioids is critical either by intravenous or subcutaneous route in the acute setting and can be transitioned to equivalent transdermal doses when the patient has a stable opioid requirement. Antisecretory agents may reduce splanchnic blood flow, intestinal secretions, and cramping abdominal pain. Octreotide is considered the standard of care for malignant bowel obstruction and has been effective for palliation in prospective trials, with total daily doses ranging from 300 to 1200 mcg. In addition, haloperidol is effective in relieving nausea and vomiting in patients with malignant bowel obstruction. In our opinion, it is imperative to engage a palliative care specialist for these patients to aid in the transition to comfort care.

MALIGNANT ASCITES

Malignant ascites can lead to debilitating abdominal distension and early satiety. Ascites can develop as a result of portal hypertension or carcinomatosis. The etiology of the ascites can often be determined by the serum ascites albumin gradient (SAAG), with SAAG greater than 1.1 consistent with portal hypertension and nonperitoneal causes of ascites, while SAAG less than 1.1 is associated with carcinomatosis. Dietary sodium restriction and diuretics may be helpful in patients with ascites secondary to portal hypertension, but such measures are often ineffective in patients with carcinomatosis, with only 30% of patients seeing a benefit. Therapeutic paracentesis relieves symptoms, but repeated attempts are associated with increased complications, such as infection or bowel perforation. The ideal rate of fluid withdrawal is unknown, but large volume paracentesis of up to 5 L is usually safe. Significant improvement in abdominal pressure is experienced with a removal of 5 L of fluid, but this may be associated with hypotension, renal failure, hypoalbuminemia, and pulmonary embolism. Plasma expanders, such as albumin, have been effective in preventing circulatory collapse and should be considered in select patients based on symptoms. In patients with an anticipated survival of greater than 2 months, the placement of an indwelling pigtail or tunneled catheter to control ascites with drainage at home or in the clinic may be useful. In a meta analysis, tunneled catheters have a lower risk of infectious complications, than nontunneled (pigtail) catheters, which are associated with a 30% incidence of infection.

VASCULAR THROMBOSIS

The incidence of thromboembolic disease in pancreatic cancer is higher than in other malignant cancers and ranges from 10% to 20% in clinical trials and as high as 50% in autopsy series. Thrombosis can occur in the mesenteric veins resulting from tumor compression or in the peripheral veins because of the overall hypercoagulable state. Significant portal venous narrowing or thrombus should be treated with anticoagulation therapy when possible to prevent propagation of the thrombus to complete occlusion. Once mesenteric venous occlusion occurs, refractory ascites may develop, as does venous hypertension, resulting in small bowel edema, ileus, and in rare cases intestinal infarction. Low molecular weight heparin has been preferred over warfarin for anticoagulation for ease of management, but patients often struggle with long term repeated subcutaneous injections. With the advent of direct oral anticoagulants, patients with advanced pancreatic cancer have access to highly effective oral agents which require less monitoring.

TUMOR-ASSOCIATED PAIN MANAGEMENT

Patients with unresectable pancreatic cancer often suffer from tumor-associated abdominal and back pain resulting from direct tumor infiltration into the celiac ganglion. Effective pain management often requires opioid analgesia, which can be supplemented with additional adjunct analgesics for neuropathic pain as needed. Opioids are effective for nociceptive pain, but somewhat less effective for somatic or visceral pain. In addition, opioids have debilitating side effects including dizziness and sedation. More recently, the trend in pain management has been to optimize pain control with the lowest dose of opioids in combination with other adjunct analgesics to provide effective and consistent pain control.

Celiac plexus block has become increasingly used in treatment of pancreatic cancer related pain symptoms. A celiac plexus block involves injecting a 50% alcohol solution or other neuropetic agents into the celiac ganglion or splanchnic nerves under CT, endoscopic ultrasound, or fluoroscopic guidance. In the event a patient undergoes neoadjuvant treatment, celiac plexus block may also be performed at that time. More than 80% of patients experience improvement in pain control after celiac plexus block in blinded or sham studies, as measured by reduction of opioid requirements. Recently, a meta analysis identifying 358 patients undergoing celiac plexus block found improved pain scores at 4 and 8 weeks in patients undergoing celiac plexus block with narcotic therapy compared to patients receiving narcotic therapy alone. A meta analysis of 145 patients demonstrated relief in 90% of patients undergoing celiac plexus block at 3 months and relief persisted in 70% to 90% of patients long term. Short-term effects related to celiac plexus block include diarrhea, hypotension, and pain related to the procedure, which typically resolve with time celiac plexus block should be considered in the initial pain management plan for patients with pancreatic cancer and may be repeated in patients who demonstrated a prior benefit from neurolysis.

DEPRESSION

The rates of depression and suicide among patients with pancreatic cancer are the highest in any cancer population. Elevated levels of circulating cytokines such as interleukin-6 and tumor necrosis factor-α are thought to alter neurohormonal pathways in the brain causing depressive symptoms even before the diagnosis of cancer. Studies report that depression occurs in 25% to 50% of patients and has a significant impact on quality of life. Many symptoms of depression mimic symptoms associated with pancreatic cancer (fatigue, anorexia, weight loss), complicating the diagnosis of depression. However, asking a patient whether he or she has "felt depressed most of the time" is a validated tool with good sensitivity and specificity for identifying depression even among patients who are terminally ill. Antidepressants are effective in patients with advanced cancers and supportive counseling may help patients to strengthen coping strategies and help with anticipatory grief. Depression and anxiety often occur because of unaddressed fears of death or the symptoms that may arise in the process of dying. An early referral to a palliative care specialist can be beneficial to provide address concerns and focus on quality of life for these patients.

CONCLUSION

It is important for surgeons to understand how to improve the quality of life of patients with advanced pancreatic cancer. A multidisciplinary approach to symptom management in coordination with a palliative care specialist will prepare patients for the myriad physical and emotional challenges that occur. Frequent assessment of available imaging and proactive addressing of patient concerns will help providers to identify and manage symptoms more effectively. Clear communications about goals of care within the context of anticipated survival help to engage patients in shared decision making and allow providers to select the appropriate palliative treatment for each individual patient.

Neoadjuvant and Adjuvant Therapy for Pancreatic Cancer

Brett L. Tchue, MD, and Charles M. Vollmer Jr, MD

Pancreatic ductal adenocarcinoma is an aggressive malignancy with low rates of long-term cure even after complete (R0) resection. The frequent and rapid development of systemic disease underscores the importance of multimodality treatment strategies. As such, chemotherapy is used for all stages of disease, including resectable, borderline resectable and locally advanced disease.

DEFINING THE CLINICAL STAGE OF DISEASE

The American Joint Commission on Cancer staging of pancreatic adenocarcinoma follows the Tumor, Node, Metastasis framework. Although this staging paradigm is prognostic of long-term survival, its dependence on postsurgical pathologic evaluation and its lack of definitional precision between resectable versus unresectable disease (i.e., T3 disease may classified as either) together limits its applicability in the preoperative setting. Rather, the National Comprehensive Cancer Network (NCCN) has endorsed the lexicography clinical staging based on the tumor relationship to the key vascular anatomy and the presence of extrapancreatic disease. Following a dedicated contrast-enhanced computed tomography (CT) scan (pancreatic protocol), tumors are classified according to the probability of achieving an R0 resection, and can be: (1) resectable, (2) borderline resectable, (3) locally advanced, or unresectable disease despite the absence of distant metastasis, and (4) demonstrated. The definitions for each are presented in Table 1. The NCCN guidelines forgo potentially vague terms such as "abutment" and "encasement" in favor of degrees of contact with the vessel wall, although abutment can be generally understood to represent involvement less than 180 degrees of vessel circumference without contour irregularity or thrombosis, whereas encasement denotes more than 180 degree involvement. Resectable pancreatic cancer (Fig. 1A) is defined by a primary tumor that does not contact any arterial vessel (celiac, hepatic, or superior mesenteric artery [SMA]) and does not contact the superior mesenteric vein/portal vein (SMV/PV), or contacts the SMV/PV less than 180 degrees without contour irregularity. Borderline resectable disease (Fig. 1B) is defined by limited tumor contact less than 180 degrees with the SMA or celiac artery, any contact (1–360 degrees) with the hepatic artery, or contact with the SMV/PV more than 180 degrees, SMV contour irregularity, or SMV thrombosis. The locally advanced category (Fig. 1C) includes more than 180-degree involvement of the SMA or celiac artery, or extensive involvement of the SMV/PV with no proximal and distal targets for vascular reconstruction. Extensive SMA involvement is considered unresectable because of the poor survival and higher morbidity and mortality expected following SMA resection. Acknowledging the limitations of cross sectional imaging to identifying micrometastases, this clinical framework is crucial to decisions regarding the sequencing of care.

Resectable Pancreatic Cancer

The clinical utility of multimodality therapy is well defined in the setting of resectable disease; yet, the timing of surgery relative to systemic therapy is an area of dispute and active research. Systemic chemotherapy has traditionally been administered after upfront surgery (i.e., in the adjuvant setting), although several institutions have championed the use of neoadjuvant therapy prior to surgical resection. Because complete surgical extirpation is the only opportunity for long-term cure, upfront surgery ensures that surgical resection can occur before the disease progresses to an unresectable state. Neoadjuvant therapy also requires a tissue biopsy, subjecting the patient to potential morbidity from unnecessary pretreatment endoscopic procedures. Jaundiced patients, as is common with pancreatic head lesions, will often require additional procedures for biliary drainage, with a small but attendant risk of complications. Last, neoadjuvant therapy may increase the burden of postoperative complications. Pancreatic fistula is one of the most common and clinically relevant morbidities after pancreatic resection, and accounts for one third of all mortalities after pancreaticoduodenectomy. Although the rate of pancreatic fistula may be less following neoadjuvant therapy, there is some evidence that fistula is associated with increased clinical burden in neoadjuvant cohorts. These data, which need to be confirmed more broadly, at least support that deconditioning from chemotherapy may lead patients to fail to promptly recover once a complication has occurred. In agreement, NCCN guidelines do not recommend the routine use of neoadjuvant therapy for those with clearly resectable disease without high-risk features (e.g., elevated CA 19-9, large tumor burden to the pancreas or surrounding lymph nodes, poor performance status) outside of a clinical trial.

In contrast, the primary benefits of neoadjuvant therapy include: (1) the early treatment of micrometastatic disease, which is common and can lead to early postoperative recurrences, (2)

CONCLUSION

It is important for surgeons to understand how to improve the quality of life of patients with advanced pancreatic cancer. A multidisciplinary approach to symptom management in coordination with a palliative care specialist will prepare patients for the myriad physical and emotional challenges that occur. Frequent assessment of available imaging and proactive addressing of patient concerns will help providers to identify and manage symptoms more effectively. Clear communications about goals of care within the context of anticipated survival help to engage patients in shared decision making and allow providers to select the appropriate palliative treatment for each individual patient.

Neoadjuvant and Adjuvant Therapy for Pancreatic Cancer

Brett L. Eckel, MD, and Charles M. Vollmer Jr, MD

Pancreatic ductal adenocarcinoma is an aggressive malignancy with low rates of long-term cure even after complete (R0) resection. The frequent and rapid development of systemic disease underscores the importance of multimodality treatment strategies. As such, chemotherapy is used for all stages of disease, including resectable, borderline resectable and locally advanced disease.

DEFINING THE CLINICAL STAGE OF DISEASE

The American Joint Commission on Cancer staging of pancreatic adenocarcinoma follows the Tumor, Node, Metastasis framework. Although this staging paradigm is prognostic of long-term survival, its dependence on postsurgical pathologic evaluation and its lack of definitional precision between resectable versus unresectable disease (i.e., T3 disease may classified as either) together limits its applicability in the preoperative setting. Rather, the National Comprehensive Cancer Network (NCCN) has endorsed the lexicography clinical staging based on the tumor relationship to the key vascular anatomy and the presence of extrapancreatic disease. Following a dedicated contrast-enhanced computed tomography (CT) scan (pancreatic protocol), tumors are classified according to the probability of achieving an R0 resection, and can be: (1) resectable, (2) borderline resectable, (3) locally advanced, or unresectable disease despite the absence of distant metastasis, and (4) demonstrated. The definitions for each are presented in Table 1. The NCCN guidelines forgo potentially vague terms such as "abutment" and "encasement" in favor of degrees of contact with the vessel wall, although abutment can be generally understood to represent involvement less than 180 degrees of vessel circumference without contour irregularity or thrombosis, whereas encasement denotes more than 180 degree involvement. Resectable pancreatic cancer (Fig. 1A) is defined by a primary tumor that does not contact any arterial vessel (celiac, hepatic, or superior mesenteric artery [SMA]) and does not contact the superior mesenteric vein/portal vein (SMV/PV), or contacts the SMV/PV less than 180 degrees without contour irregularity. Borderline resectable disease (Fig. 1B) is defined by limited tumor contact less than 180 degrees with the SMA or celiac artery, any contact (1–360 degrees) with the hepatic artery, or contact with the SMV/PV more than 180 degrees, SMV contour irregularity, or SMV thrombosis. The locally advanced category (Fig. 1C) includes more than 180-degree involvement of the SMA or celiac artery or extensive involvement of the SMV/PV with no proximal and distal targets for vascular reconstruction. Extensive SMA involvement is considered unresectable because of the poor survival and higher morbidity and mortality expected following SMA resection. Acknowledging the limitations of cross sectional imaging to identifying micrometastases, this clinical framework is crucial to discussions regarding the sequencing of care.

Resectable Pancreatic Cancer

The clinical utility of multimodality therapy is well defined in the setting of resectable disease; yet, the timing of surgery relative to systemic therapy is an area of dispute and active research. Systemic chemotherapy has traditionally been administered after upfront surgery (i.e., in the adjuvant setting), although several institutions have championed the use of neoadjuvant therapy prior to surgical resection. Because complete surgical extirpation is the only opportunity for long-term cure, upfront surgery ensures that surgical resection can occur before the disease progresses to an unresectable state. Neoadjuvant therapy also requires a tissue biopsy, subjecting the patient to potential morbidity from unnecessary pretreatment endoscopic procedures. Jaundiced patients, as is common with pancreatic head lesions, will often require additional procedures for biliary drainage, with a small but attendant risk of complications. Last, neoadjuvant therapy may increase the burden of postoperative complications. Pancreatic fistula is one of the most common and clinically relevant morbidities after pancreatic resection, and accounts for one third of all mortalities after pancreaticoduodenectomy. Although the rate of pancreatic fistula may be less following neoadjuvant therapy, there is some evidence that fistula is associated with increased clinical burden in neoadjuvant cohorts. These data, which need to be confirmed more broadly, at least support that deconditioning from chemotherapy may lead patients to fail to promptly recover once a complication has occurred. In agreement, NCCN guidelines do not recommend the routine use of neoadjuvant therapy for those with clearly resectable disease without high-risk features (e.g., elevated CA 19-9, large tumor burden to the pancreas or surrounding lymph nodes, poor performance status) outside of a clinical trial.

In contrast, the primary benefits of neoadjuvant therapy include: (1) the early treatment of micrometastatic disease, which is common and can lead to early postoperative recurrences, (2)

TABLE 1 National Comprehensive Cancer Network Definitions of Resectability

	Tumor-Artery Relationship	Tumor-Vein Relationship
Resectable	No radiographic contact between tumor and celiac, hepatic or superior mesenteric artery	No tumor contact with the SMV/PV, or <180 degrees without contour irregularity
Borderline resectable	Tumor contact <180 degrees with celiac or superior mesenteric artery, and/or tumor contact >180 degrees with hepatic artery	Tumor contact >180 degrees with the SMV/PV, or contour irregularity, or short segment thrombosis (amenable to resection)
Locally advanced	Tumor contact >180 degrees with celiac or superior mesenteric artery or aorta	Occlusion of the SMV/PV without suitable targets proximally and distally for vascular reconstruction
Disseminated	Evidence of peritoneal or distant metastasis	

SMV/PV, superior mesenteric vein/portal vein.

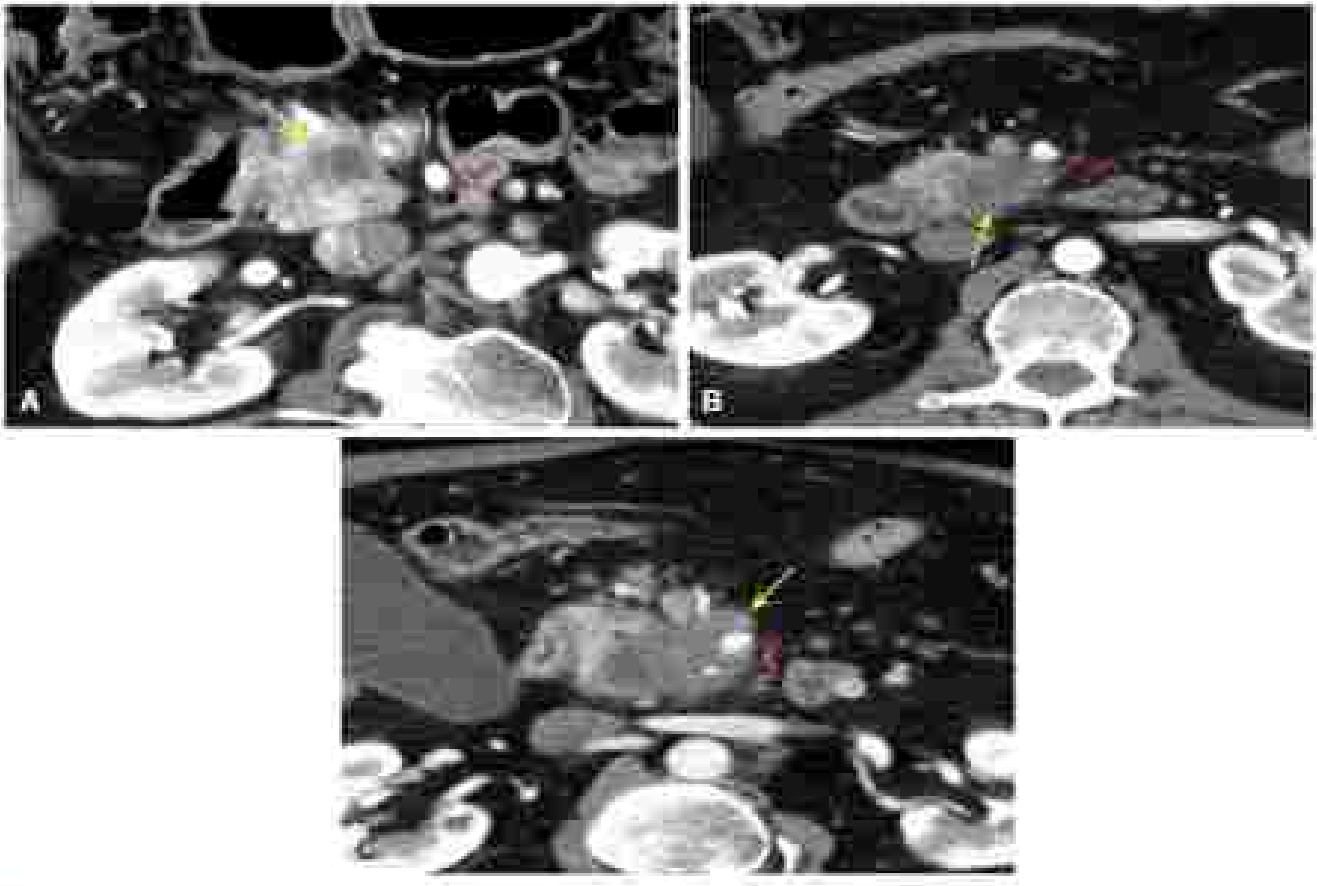

FIG. 1 Clinical staging is based on tumor-vessel contact. Contrast-enhanced axial computed tomographic images show the tumor (yellow arrow), superior mesenteric vein (SMV, blue arrowhead), and superior mesenteric artery (SMA, red arrow). (A) Resectable pancreatic cancer. Hypodense tumor is present in the pancreatic head with preservation of the fat plane between the pancreas and the SMV and without tumor abutment of the SMA. (B) Borderline resectable pancreatic cancer. Note the hypodense tumor that abuts both the SMV and the SMA. (C) Locally advanced pancreatic cancer. The hypodense tumor encases (>180 degrees) the SMA.

enhanced patient selection; (3) improved delivery and completion rates; and (4) enhanced efficacy of chemoradiotherapy (given the well oxygenated environment), with corresponding higher negative margin resection and lymph node negative rates. As many as 25% of patients will have metastatic disease discovered at operative exploration or during the postoperative recovery, thus negating any potential benefit derived from such morbid surgery. Instead, neoadjuvant therapy enriches the surgical population for those most likely to achieve a long-term cure. Additionally, postoperative morbidity influences the use and timing of adjuvant therapies, which are crucial to achieve the goal of long-term survival. More than half of all pancreaticoduodenectomy patients will suffer some postoperative morbidity, and prolonged postoperative recovery prevents the delivery of adjuvant therapy in nearly one quarter of patients. Neoadjuvant therapy ensures the delivery of some systemic therapy. Last, chemoradiotherapy has been associated with improved R0 rates in retrospective series. The benefits of each strategy (neoadjuvant vs. adjuvant) are summarized in Box 1.

At present, there is level I evidence to support the use of adjuvant therapy but no head-to-head randomized prospective data comparing adjuvant and neoadjuvant approaches. Established adjuvant chemotherapy regimens include monthly bolus 5-fluorouracil, which demonstrated superiority to observation alone in the European Study for Pancreatic Cancer (ESPAC)-1 trial; gemcitabine monotherapy following the results of the European Charité Onkologie 001 trial; and combination gemcitabine/capecitabine, which was superior to gemcitabine monotherapy in the ESPAC-4 trial. At present, there is level I evidence to support the use of adjuvant therapy but no head-to-head randomized prospective data comparing adjuvant and neoadjuvant approaches. Established adjuvant chemotherapy regimens include monthly bolus 5-fluorouracil, which demonstrated superiority to observation alone in the European Study for Pancreatic Cancer (ESPAC)-1 trial; gemcitabine monotherapy following the results of the European Charité Onkologie 001 trial; and combination gemcitabine/capecitabine, which was superior to gemcitabine monotherapy in the ESPAC-4 trial. Additionally, more aggressive regimens are the focus of currently enrolling and recently completed trials. The PRODIGE 24-GCCG PA-6 trial evaluating gemcitabine versus FOLFIRINOX in the adjuvant setting found significant improvements in overall survival with the multidrug regimen. Nab-paclitaxel/gemcitabine is superior to gemcitabine alone in the metastatic setting and is currently under evaluation in the adjuvant setting (APACT trial), and a trial has completed enrollment. The benefits of multidrug regimens will have to be balanced against increased treatment-related toxicities in a deconditioned postoperative patient, but we can expect increasing use of FOLFIRINOX when patient fitness allows. The relative efficacy of FOLFIRINOX versus nab-paclitaxel/gemcitabine has yet to be ascertained.

The role of adjuvant radiotherapy (RT) is less clearly defined. Both the Gastrointestinal Tumor Study Group 9173 trial and the European Organization for Research and Treatment of Cancer trial observed benefits for postoperative concurrent 5-fluorouracil plus external beam RT relative to observation. However, these results were not verified in the previously mentioned ESPAC-1 trial, which was a four-arm study that demonstrated a trend toward worse survival for the group receiving chemoradiotherapy. In these historical trials, split-course RT at lower doses (40 Gy) may have limited efficacy. The contemporary phase II European Organisation for Research and Treatment of Cancer 40013 trial evaluated gemcitabine-based chemoradiotherapy and observed that the addition of RT to gemcitabine alone improved local control, although without impacting disease-free or overall survival.

In the neoadjuvant setting, several phase I and II trials have demonstrated the safety and efficacy of many of the previously mentioned therapy regimens. Currently, there is no level I evidence defining the optimal neoadjuvant regimen, or how such therapies compare to their use in the adjuvant setting. PACT-15 (NCT01150630) was a three-arm, randomized, phase II/III trial comparing neoadjuvant gemcitabine, cisplatin, epirubicin, and capecitabine (PEX-C) to adjuvant gemcitabine monotherapy and adjuvant PEXG. As of this year, the study authors have decided not to continue with the phase III aspect of this trial, given ever-evolving adjuvant therapy standards. With 36 in the small cohort of treated patients (n = 36/arm), neoadjuvant therapy demonstrated promising efficacy (66% event-free at 1 year vs 38% event-free in the adjuvant PEXG group vs 23% event-free in the adjuvant gemcitabine group). Likewise, an interim analysis published in abstract form of the phase II/III ESPAC-5F trial comparing neoadjuvant gemcitabine-based chemoradiation with adjuvant gemcitabine-based chemoradiation demonstrated a survival benefit of upfront chemoradiotherapy (median survival, 23 months vs 11 months). Several recruiting trials comparing neoadjuvant with adjuvant therapy are ongoing (e.g., NEOPANC, NCT02047513, neoadjuvant nab-paclitaxel/gemcitabine vs adjuvant nab-paclitaxel/gemcitabine; PANACHE01/PRODIGE30, NCT02562089, neoadjuvant FOLFIRINOX or FOLFOX vs standard adjuvant chemotherapy; NorPACT, NCT02919982, neoadjuvant FOLFIRINOX and adjuvant gemcitabine/capecitabine vs adjuvant gemcitabine/capecitabine). In general, neoadjuvant therapy for resectable disease involves (1) the early initiation of chemotherapy (with or without RT); (2) restaging before surgical exploration, which occurs between 2 and 6 weeks after chemotherapy and 4 and 6 weeks after chemoradiotherapy; and (3) frequent use of additional chemotherapy (with or without RT) following postoperative recovery.

In summary, NCCN guidelines recommended the use of systemic therapies for all patients with resectable disease. Although the timing of such therapy can be justified in either the neoadjuvant or adjuvant setting, at present, neoadjuvant therapy is not yet considered a standard approach for patients with potentially resectable pancreatic cancer outside of the context of a clinical trial.

BOX 1 Potential Advantages and Disadvantages of Neoadjuvant Therapy

Advantages

- Ability to deliver systemic therapy to all patients
- Identification of patients with aggressive tumor biology (manifested as disease progression) at the time of pretreatment and preoperative restaging who thereby avoid the morbidity of surgery
- Increased efficacy of radiation therapy, less radical production in a well-oxygenated environment
- Decreased radiation-induced toxicity to adjacent normal tissue because the radiated field is resected at the time of pancreatectomy
- Decreased rate of positive resection margins, superior mesenteric artery margin in particular
- Decreased rate of pancreatic fistula formation
- Potential for the tumor size to decrease, especially in borderline resectable tumors, which may facilitate surgical resection

Disadvantages

- Potential for complications from pretreatment endoscopic procedures (endoscopic ultrasound scan and fine-needle aspiration, and endoscopic retrograde cholangiopancreatography)
- Biliary stent–related morbidity, stent occlusion during systemic and therapy
- Disease progression obviating resectability, loss of a window of resectability may occur (rarely) in the borderline resectable patient
- Coordination of multiple physicians during the preoperative phase; the care handoff from surgeon to medical oncologist to radiation oncologist (as occurs with adjuvant therapy) is not possible in the neoadjuvant setting

Borderline Resectable Patients

In contrast to resectable disease, less controversy exists regarding the use of neoadjuvant therapy before attempted resection of borderline resectable disease. This category is defined by more advanced locoregional disease at higher risk for incomplete resection, obviating the oncologic benefit of surgical resection because patients who undergo a resection with a microscopically positive margin demonstrate long-term survival comparable to patients who do not undergo any operation. Moreover, although borderline resectable patients are apparently radiographically localized, they have a greater risk for subclinical distant metastases.

The current body of literature is limited by heterogeneity in regimens used and definitions of clinical resectability; nevertheless, many institutions have embraced neoadjuvant combination chemotherapy (with or without RT) for this scenario. The Alliance for Clinical Trials in Oncology Trial A021101 (NCT01821612) recently published the results of a prospective pilot trial using neoadjuvant FOLFIRINOX followed by capecitabine-based chemoradiation in borderline resectable patients, defined in strict accordance with current NCCN guidelines. Among the 33 patients enrolled, 15 (68%) completed neoadjuvant

therapy and proceeded to surgical resection, where 93% of patients underwent an R0 resection. Although not powered for a survival analysis, we notable that median survival for these patients was 21.7 months, which compares favorably to the 24 month survival observed in ESPAC 4 for gemcitabine monotherapy following upfront resection (for less advanced, resectable cancer). This year the Korean multicenter, randomized, controlled phase II/III trial (NCT01464957), which compared gemcitabine based chemoradiation in the neoadjuvant versus adjuvant setting for 50 borderline resectable patients was published. Among patients who underwent surgical resection, R0 resection rates were significantly improved with neoadjuvant therapy (82% vs 33%), which may explain the significant improvements observed in the intent-to-treat survival analysis (median, 21 vs 12 months). These encouraging results led to early termination of the trial.

Beyond enhanced resectability, neoadjuvant therapy can lead to pathologic complete response in a rare number of patients, which is independently predictive of long term survival. In the Korean trial described above, a complete pathologic response was observed in 12% of patients. In a contemporary cohort of borderline resectable and locally advanced patients treated at Johns Hopkins treated with chemoradiotherapy using either FOLFIRINOX or nab-paclitaxel gemcitabine based chemotherapy, a complete pathologic response was more common following FOLFIRINOX (13% vs 7%), suggesting that even greater gains may be expected than those observed with gemcitabine monotherapy in the Korean trial. In general, choice of systemic agents for neoadjuvant treatment has evolved from single-agent gemcitabine to combination therapies, such as FOLFIRINOX or gemcitabine/nab-paclitaxel, given their success in the metastatic and adjuvant setting, and ongoing randomized trials will provide much anticipated data on their efficacy.

Locally Advanced Patients

Locally advanced pancreatic cancer is unresectable, but no distinctly unresectable disease, usually because of interplay of the tumor with the critical local visceral vasculature. Similar to borderline resectable patients, initial management consists of chemotherapy with or without chemoradiotherapy. Although rare (~20%), certain patients with a significant response to therapy may become surgical candidates. These patients will receive a lengthy course of systemic therapy greater than those used in the neoadjuvant setting for resectable disease, and have no evidence of progressive disease by cross-sectional imaging at restaging and a stable/decreasing CA19-9) and good performance status. Given that complete pathologic response is rare with systemic therapy, and that complete surgical extirpation is considered the only means for cure, these patients may be referred from medical oncologists before consideration for maintenance chemotherapy. It is crucial that surgery be applied to such patients based on established criteria for resectability, recognizing that such patients have realized a robust survival benefit without surgery given their positive response to induction therapy.

Reported resection rates for locally advanced patients after neoadjuvant therapy have varied widely (1%–60%), where such population variability likely reflects heterogenous treatment schemes, imprecise definitions of locally advanced disease, and varying surgical capabilities of specific institutions (i.e., types of vascular reconstructions performed). In a recent multinational series from Memorial Sloan Kettering Cancer Center, including 101 patients with locally advanced disease treated with FOLFIRINOX with or without chemoradiation, 31% were converted to surgical candidates, of which one half underwent R0 resection. Hence, 16% underwent curative resection following aggressive multimodality therapy. Notably, the pattern of vascular involvement present at diagnosis varied between those who eventually proceeded to resection and those who did not. Involvement of the hepatic artery and unreconstructable venous involvement were commonly became resectable after neoadjuvant therapy as compared to involvement of the celiac axis, superior mesenteric artery, or multiple vessels.

Celiac artery involvement can be approached, if necessary, with celiac resection in carefully selected patients with tumors of the pancreatic body where the gastroduodenal artery maintains prograde hepatic arterial perfusion. SMA involvement (borderline resectable, <180 degrees; locally advanced, >180 degrees) can often be freely dissected in the plane between the SMA adventitia and the neural sheath. However, there are no data supporting more aggressive resection and reconstruction of the SMA. Similarly, complete 360 degree involvement of the SMA, which would require cutting through the tumor to separate it from the vessel, should be considered unreasonable in unoperable patients, other locoregional therapies include irreversible electroporation, radiofrequency ablation, stereotactic body radiation, and high intensity focused ultrasound.

FUTURE DIRECTIONS

Ongoing trials will clarify the role of multimodality chemotherapy regimens and their role in the neoadjuvant setting. Yet, poor long-term survival, despite aggressive surgery and multimodality therapy, demands the development of novel therapies. At least in the metastatic setting, numerous targeting therapies have been evaluated in clinical trials, but rarely with any benefit. Some failed

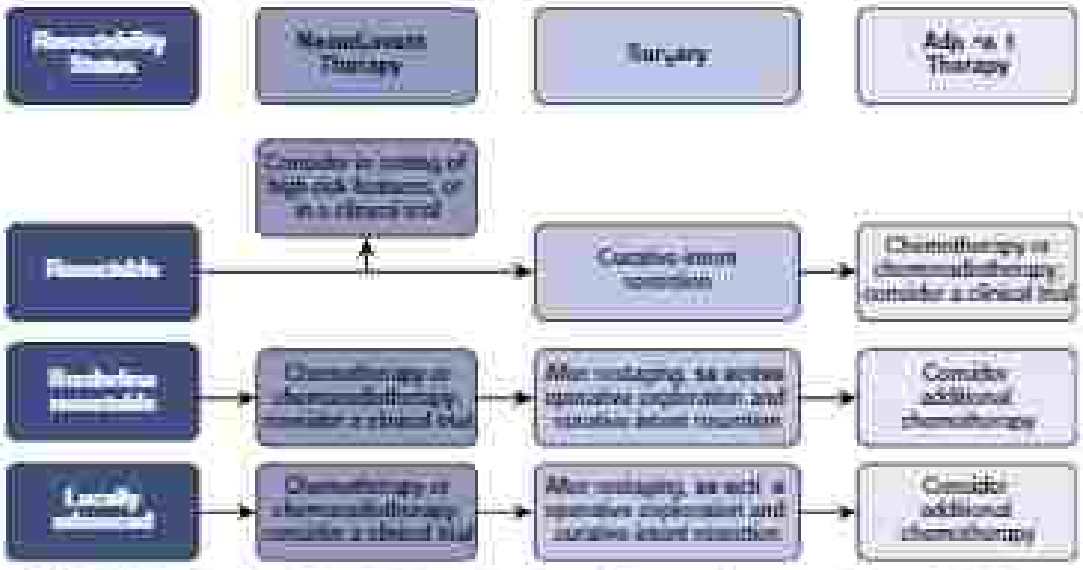

FIG. 1. Multimodality flowchart for the timing and use of systemic therapy and surgery stratified by clinical staging.

targeted therapies include antiangiogenic drugs (bevacizumab and aflibercept), multikinase inhibitors (sunitinib, sorafenib, axitinib, motesanib), anti-insulin-like growth factor 1 receptor antibodies (ganitumab and cixutumumab), and phosphatidylinositide 3-kinase inhibition (rigosertib). Such disappointments might be explained by both high tumor genetic heterogeneity and the influence of the inflammatory peritumoral stroma on signaling pathways and drug accessibility.

Immunotherapy has provided exciting results for several other cancer types, and may have an important role in the management of pancreatic cancer. Long-term survivors of pancreatic cancer have a higher frequency of neoantigens generated from mutations in the gene MUC16 (i.e., CA125) as well as robust T-cell responses (intratumoral and circulating) against mutant MUC16. Moreover, metastatic progression is associated with selective loss of *MUC16* neoantigenic clones. Several trials aimed to leverage the immune response against pancreatic cancer are underway.

Last, for the vast number of patients who do not respond to systemic therapy to the level of either standard or novel therapeutics, sensitive biomarkers are needed to measure therapy response and rapidly guide changes to alternative treatments. Repeat imaging at 2-month intervals, as is often performed, prohibits quick and reactive changes to potentially more effective therapy.

In conclusion, the past 5 decades have been instrumental to standardizing the definitions of clinical staging and establishing the benefit of adjuvant systemic therapy and more recently, the use of neoadjuvant chemoradiation in borderline resectable patients (summarized in Fig. 2). The wide adoption of the NCCN-sponsored clinical staging schema will ensure homogeneous patient populations that will clarify assessment of therapeutic response for novel therapies and/or treatment sequences.

Unusual Pancreatic Tumors

Elliot A. Asare, MD, MS; Douglas B. Evans, MD; and Susan Tsai, MD, MSHS

Symptomatic and incidental abnormalities of the pancreas have become much more common because of the frequent use of cross-sectional imaging (computed tomography [CT] or magnetic resonance imaging [MRI]). Most important for the surgeon, when faced with a new patient who has a pancreatic mass on imaging, is to construct a differential diagnosis, not simply proceed with biopsy or resection. Thoughtful creation of a differential diagnosis should always precede intervention. Patients with solid pancreatic masses, associated with atypical clinical presentations or unusual imaging characteristics may be diagnostically challenging and familiarity with less common pancreatic conditions is necessary for the development of a comprehensive differential diagnosis. This chapter will focus on unusual solid tumors of the pancreas and discuss optimal diagnostic and therapeutic approaches for their management. The combination of a careful patient history, thorough physical examination, analysis of specific laboratory results, and detailed review of all imaging studies will narrow the list of differential diagnoses even before a tissue biopsy is performed.

ACINAR CELL CARCINOMA

Acinar cell carcinomas (ACC) are rare and many surgeons may not see a single patient with this disease. In contrast to pancreatic ductal adenocarcinoma, ACC arises from the acinar elements of the exocrine pancreas, not ductal epithelium. As a result, ACCs often retain the exocrine characteristics of normal pancreatic acini and can produce digestive enzymes such as trypsin, chymotrypsin, and lipase. These tumors are more common among men (male to female ratio of 2:1) and usually occur in the sixth and seventh decades of life. Up to 50% of patients are asymptomatic at initial presentation; many others may complain of abdominal pain or weight loss. Approximately 10% of patients with ACC may present with a paraneoplastic syndrome caused by excessive pancreatic enzyme production, which is characterized by the presence of subcutaneous fat necrosis, bone infarcts, arthritis, and eosinophilia. Although no specific serum or plasma tests exist that are diagnostic for ACC, serum lipase levels are elevated in at least 25% of patients. Serum tumor markers, such as carbohydrate antigen (CA) 19-9, α-fetoprotein, and carcinoembryonic antigen are variably expressed. In our experience, serum lipase and α-fetoprotein are often elevated and, if so, can be quite helpful in assessing response to therapy (as well as disease recurrence for those patients who undergo a potentially curative operation).

ACCs may be noticeably large at presentation, even if within the pancreatic head as bile duct obstruction may be less common than with pancreatic adenocarcinoma. A large tumor in the pancreatic head without bile duct obstruction should raise the level of suspicion for an ACC or a pancreatic neuroendocrine tumor. Classic cross-sectional imaging findings (not present in all patients) include the presence of a large, exophytic, well-circumscribed mass with capsular enhancement but central hypodensity (Fig. 1A). The lesions can be entirely solid when small, but larger tumors often outgrow their blood supply and develop central areas of necrosis. ACC can occur anywhere in the pancreas and the incidence of tumors in the head is not appreciably greater than that of tumors in the body/tail. There may also be interval foci of calcifications although calcifications are not a distinguishing feature. Similar to pancreatic adenocarcinoma, ACCs are often metastatic at presentation with the liver being the most common site of metastasis. The radiographic differential diagnosis of ACC includes pancreatic ductal adenocarcinoma (Fig. 1B demonstrates how ACC can mimic the radiographic appearance of a typical adenocarcinoma), pancreatic neuroendocrine tumor, solid pseudopapillary tumors (SPT), pancreatoblastoma, and mucinous cystic neoplasms.

On histopathologic examination, pure ACCs have two predominant cellular patterns of growth: an acinar pattern consisting of cells growing in well-formed acini and a solid pattern characterized by sheets of cells that lack the prominent stromal component seen in pancreatic ductal adenocarcinoma. Classically the majority of ACCs will have coarse granular apical cytoplasmic staining for trypsin or chymotrypsin. In contrast to the staining pattern of pancreatic ductal adenocarcinoma, ACC generally stains negative for carcinoembryonic antigen and mucicarmine. Although fine-needle aspiration (FNA) biopsy can usually differentiate a pancreatic ductal

targeted therapies include antiangiogenic drugs (bevacizumab and aflibercept), multikinase inhibitors (sunitinib, sorafenib, axitinib, motesanib), anti-insulin-like growth factor 1 receptor antibodies (ganitumab and cixutumumab), and phosphatidylinositide 3-kinase inhibition (rigosertib). Such disappointments might be explained by both high tumor genetic heterogeneity and the influence of the inflammatory peritumoral stroma on signaling pathways and drug accessibility.

Immunotherapy has provided exciting results for several other cancer types, and may have an important role in the management of pancreatic cancer. Long-term survivors of pancreatic cancer have a higher frequency of neoantigens generated from mutations in the gene MUC16 (i.e., CA125) as well as robust T-cell responses (intratumoral and circulating) against mutant MUC16. Moreover, metastatic progression is associated with selective loss of *MUC16* neoantigenic clones. Several trials aimed to leverage the immune response against pancreatic cancer are underway.

Patients with solid pancreatic masses, associated with atypical clinical presentations or unusual imaging characteristics may be diagnostically challenging and familiarity with less common pancreatic conditions is necessary for the development of a comprehensive differential diagnosis. This chapter will focus on unusual solid tumors of the pancreas and discuss optimal diagnostic and therapeutic approaches for their management. The combination of a careful patient history, thorough physical examination, analysis of specific laboratory results, and detailed review of all imaging studies will narrow the list of differential diagnoses even before a tissue biopsy is performed.

ACINAR CELL CARCINOMA

Acinar cell carcinomas (ACC) are rare and many surgeons may not see a single patient with this disease. In contrast to pancreatic ductal adenocarcinoma, ACC arises from the acinar elements of the exocrine pancreas, not ductal epithelium. As a result, ACCs often retain the exocrine characteristics of normal pancreatic acini and can produce digestive enzymes such as trypsin, chymotrypsin, and lipase. These tumors are more common among men (male to female ratio of 2:1) and usually occur in the sixth and seventh decades of life. Up to 50% of patients are asymptomatic at initial presentation; many others may complain of abdominal pain or weight loss. Approximately 10% of patients with ACC may present with a paraneoplastic syndrome caused by excessive pancreatic enzyme production, which is characterized by the presence of subcutaneous fat necrosis, bone infarcts, arthritis, and eosinophilia. Although no specific serum or plasma tests exist that are diagnostic for ACC, serum lipase levels are elevated in at least 25% of patients. Serum tumor markers, such as carbohydrate antigen (CA) 19-9, α-fetoprotein, and carcinoembryonic antigen are variably expressed. In our experience, serum lipase and α-fetoprotein are often elevated and, if so, can be quite helpful in assessing response to therapy (as well as disease recurrence for those patients who undergo a potentially curative operation).

ACCs may be noticeably large at presentation, even if within the pancreatic head as bile duct obstruction may be less common than with pancreatic adenocarcinoma. A large tumor in the pancreatic head without bile duct obstruction should raise the level of suspicion for an ACC or a pancreatic neuroendocrine tumor. Classic cross-sectional imaging findings (not present in all patients) include the presence of a large, exophytic, well-circumscribed mass with capsular enhancement but central hypodensity (Fig. 1A). The lesions can be entirely solid when small, but larger tumors often outgrow their blood supply and develop central areas of necrosis. ACC can occur anywhere in the pancreas and the incidence of tumors in the head is not appreciably greater than that of tumors in the body/tail. There may also be interval foci of calcifications although calcifications are not a distinguishing feature. Similar to pancreatic adenocarcinoma, ACCs are often metastatic at presentation with the liver being the most common site of metastasis. The radiographic differential diagnosis of ACC includes pancreatic ductal adenocarcinoma (Fig. 1B demonstrates how ACC can mimic the radiographic appearance of a typical adenocarcinoma), pancreatic neuroendocrine tumor, solid pseudopapillary tumors (SPT), pancreatoblastoma, and mucinous cystic neoplasms.

On histopathologic examination, pure ACCs have two predominant cellular patterns of growth: an acinar pattern consisting of cells growing in well-formed acini and a solid pattern characterized by sheets of cells that lack the prominent stromal component seen in pancreatic ductal adenocarcinoma. Classically the majority of ACCs will have coarse granular apical cytoplasmic staining for trypsin or chymotrypsin. In contrast to the staining pattern of pancreatic ductal adenocarcinoma, ACC generally stains negative for carcinoembryonic antigen and mucicarmine. Although fine-needle aspiration (FNA) biopsy can usually differentiate a pancreatic ductal

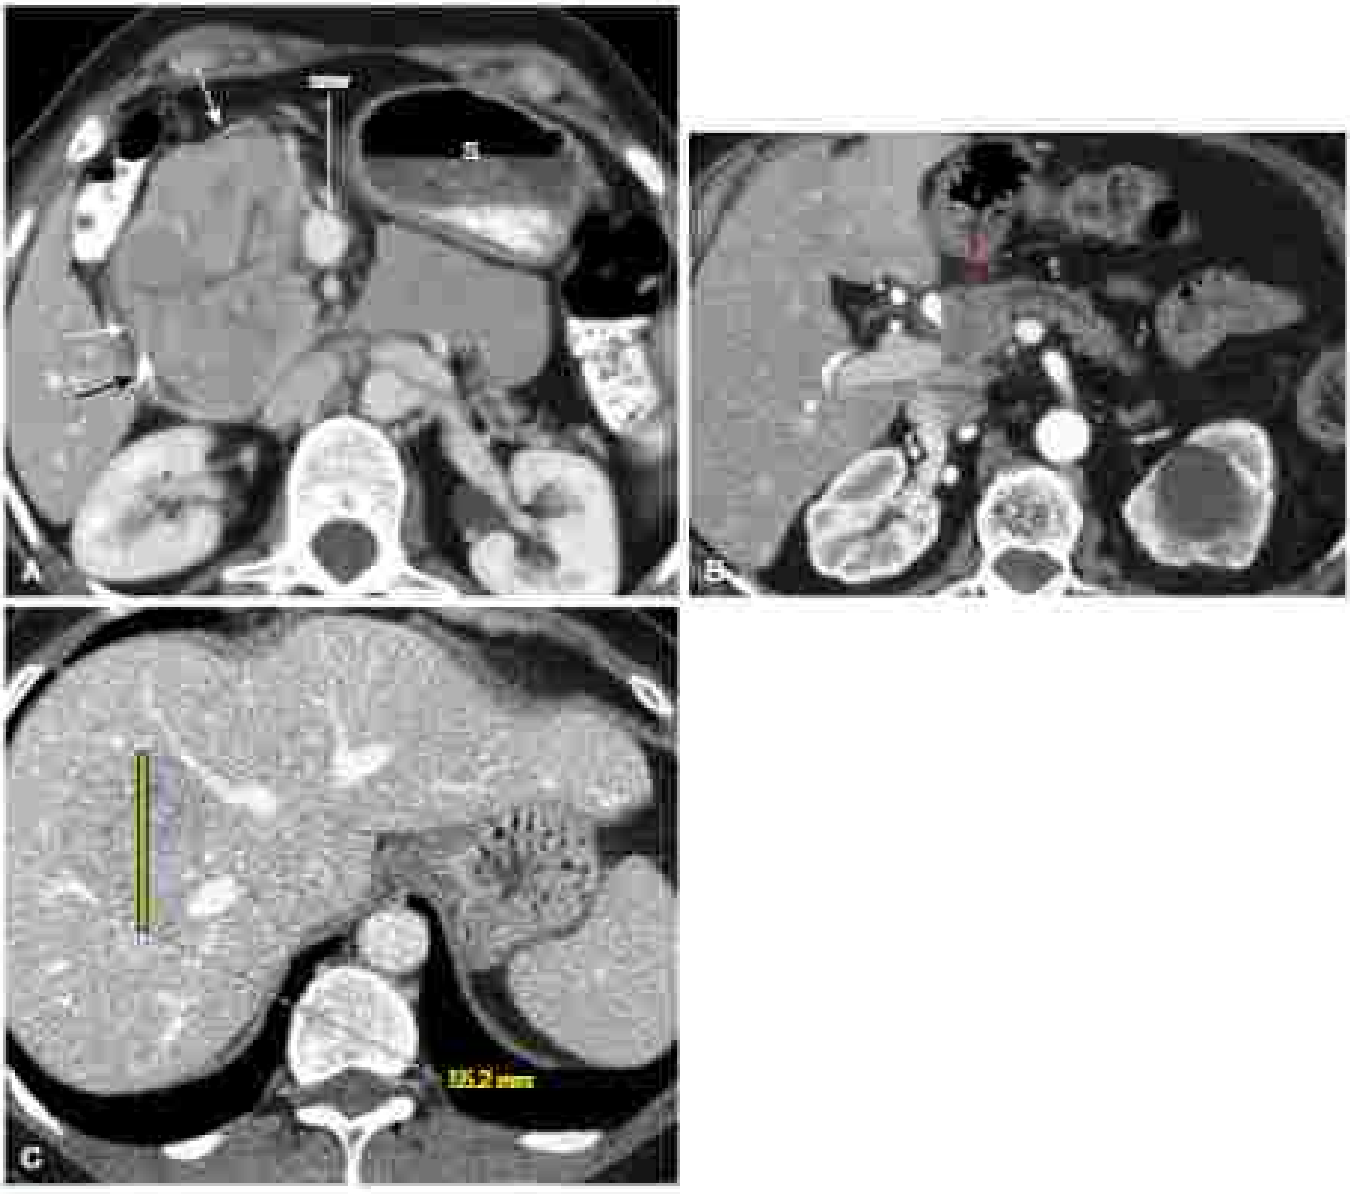

FIG. 1 (A) Axial image of a contrast-enhanced CT scan from a patient with a large acinar cell carcinoma demonstrating local compression of the duodenum (white arrow), causing gastric dilatation (S) and biliary obstruction, which required endoscopic stenting (black arrow identifies the plastic stent). (B) Axial image of a contrast-enhanced CT scan from a 79-year-old man who was believed to have pancreatic adenocarcinoma. The CT image is consistent with a diagnosis of adenocarcinoma of the pancreas. However, the correct diagnosis of ACC was made on review of biopsy specimens. This man developed metachronous lung metastases 4 years later and he died 6 years from the date of diagnosis from progressive metastatic disease confined to the chest. (C) Axial image of a contrast-enhanced CT scan, performed in 2011, demonstrating an ill-defined liver metastasis in a 51-year-old woman who underwent pancreaticoduodenectomy for a large acinar cell carcinoma in 2001. She received 4 months of systemic therapy followed by liver resection. She remains free of disease at her last surveillance evaluation in 2018. The patient featured in parts B and C demonstrates the unusual natural history that can be associated with ACC as compared with pancreatic adenocarcinoma. ACC, acinar cell carcinoma; CT, computed tomography; SMV, superior mesenteric vein.

adenocarcinoma from an ACC, the primary diagnostic dilemma is distinguishing between ACC and a well-differentiated pancreatic neuroendocrine neoplasm and pancreatoblastoma. ACC can have scattered neuroendocrine cells present in up to 40% of cells. Additional immunohistochemistry (performed on cytology specimens or core biopsies), if positive for synaptophysin and chromogranin A, would support a diagnosis of pancreatic neuroendocrine neoplasm. When neuroendocrine cells comprise greater than 30% of the tumor, it qualifies as a mixed acinar neuroendocrine carcinoma. At a molecular level, mutations in *ATM*, *BRCA2*, and *PALB2* have been identified similar to the experience with adenocarcinoma of the pancreas. However, key driver mutations present in pancreatic adenocarcinoma, including *KRAS*, *TP53*, *CDKN2A*, and *SMAD4*, were found to be infrequently mutated in ACC. Interestingly, the genetic mutations associated with the major types of pancreatic cancer are now known to be relatively distinct: pancreatic ductal adenocarcinomas are characterized by mutations in SMAD4, TP53, KRAS, and CTNNA; neuroendocrine tumors by mutations in *MEN1*, *DAXX*, *ATRX*, and the mTOR pathway; mucinous cystic neoplasms by mutations in RNF43; and intraductal papillary mucinous neoplasms by mutations in GNAS and RNF43. Although ACCs are microsatellite stable, they exhibit a high degree of chromosomal imbalances that may help distinguish

them from pancreatic ductal adenocarcinoma and neuroendocrine tumors. The different molecular alterations found in pancreatic tumors makes it possible to use DNA sequencing of a primary tumor or a metastatic biopsy when it proves difficult to classify the tumor solely by histopathologic criteria.

Treatment

Patients who have localized disease should undergo surgical resection if the tumor is operable. For all pancreatic tumors, operability is based on, and defined by, surgeon experience, especially with respect to patients who may require vascular resection and reconstruction at the time of pancreatectomy. In our experience, resection and reconstruction of the superior mesenteric-portal vein confluence, celiac artery, and/or the hepatic artery are procedures performed with reasonable frequency and therefore, very safe in properly selected patients. Such may not be the case at centers with less experience; operability needs to be defined based on surgeon and institution experience. Although ACC tumors are often large in size/dimension, they tend to be well circumscribed and may be amenable to complete surgical resection, in contrast to the uniformly infiltrative nature of adenocarcinoma of the pancreas. In a review of the National Cancer Database, the 5-year survival rate of 865 patients who underwent surgical resection for ACC was 36.2%. Survival durations from single institution series are even more favorable, with median survivals reported as high as 57 months for patients with localized disease who underwent complete surgical resection. Distant recurrence is the most common pattern of failure and, similar to pancreatic adenocarcinoma, liver and lung predominate. For this reason, adjuvant therapy would seem to be a logical alternative to surgery alone. However, there are few data available to guide the selection of adjuvant therapy after complete resection and therefore, many oncologists turn to molecular profiling of the resected specimen for clues to potential sensitivity to available chemotherapeutics. There are now a number of companies that provide this service in addition to the programs available in house at many larger centers. For patients with localized disease in whom the operation to remove the tumor may involve vascular resection/reconstruction, or when there is a concern for a positive margin, neoadjuvant therapy (chemoradiation) is quite reasonable to consider. Anecdotally, we have seen liver and lung recurrence after a long disease free interval (>5 years) in rare patients with ACC. In such situations, resection of a solitary metastasis may be considered in an otherwise healthy patient (Fig. 3C). This also allows for histologic confirmation of the diagnosis and molecular profiling as a guide to further systemic therapy.

SOLID PSEUDOPAPILLARY TUMORS

SPTs of the pancreas are also quite rare but, in contrast to ACC, they have low malignant potential. SPT have been associated with several other names, including Frantz tumors, Hamoudi tumors, and papillary cystic neoplasm. SPTs are well known for their high prevalence among women, most commonly occurring in the third decade of life and even earlier (mean age, 22 years; range, 2–85 years). The most common presenting symptoms and signs (if present) include abdominal pain and/or the presence of an abdominal mass on physical examination. In the asymptomatic patient, tumors may be discovered as a palpable mass on routine physical examination or as an incidental finding on imaging for an unrelated complaint. Serologic tests are often of little value with CA19-9 being rarely elevated.

On CT imaging, SPTs can range from being completely cystic to completely solid; in our experience, a pure cystic SPT is uncommon because the cystic portion is secondary to necrotic degeneration of the primary tumor. They frequently demonstrate peripheral enhancement and central calcification and are characteristically large (often much larger than seen in Fig. 1), heterogeneously enhancing lesions with solid and cystic components. On MRI, SPTs have a low signal intensity on T1-weighted images and a high intensity on T2-weighted images. Although SPTs can occur throughout the pancreas, they are perhaps slightly more common in the pancreatic tail. When they occur in the pancreatic head, they can attain large size in the absence of bile duct obstruction, similar to ACC and pancreatic neuroendocrine tumors. However, SPT can grow into the wall of the superior mesenteric or portal vein; it would be a mistake to operate on a large SPT of the pancreatic head and assume that a narrowed superior mesenteric or portal vein could be successfully separated from the tumor; venous resection/reconstruction may be required. The radiographic differential diagnosis of a SPT should include other cystic neoplasms including mucinous neoplasms or serous cystadenomas, and intraductal papillary mucinous neoplasms, as well as a pancreatic neuroendocrine tumor. However, age is important, in a young woman younger than age 30, SPT and pancreatic neuroendocrine tumor would be most likely. In the absence of an inherited endocrinopathy (such as MEN1 or VHL), an IPT would be most likely. In a young woman younger than age 20, SPT would clearly be the most likely diagnosis as even in MEN1, a large pancreatic neuroendocrine tumor would be uncommon under the age of 20. FNA biopsy may be useful when routine imaging is inconclusive and diagnostic uncertainty exists, however, because of the tumor's largely necrotic composition, FNA biopsy may often be nondiagnostic.

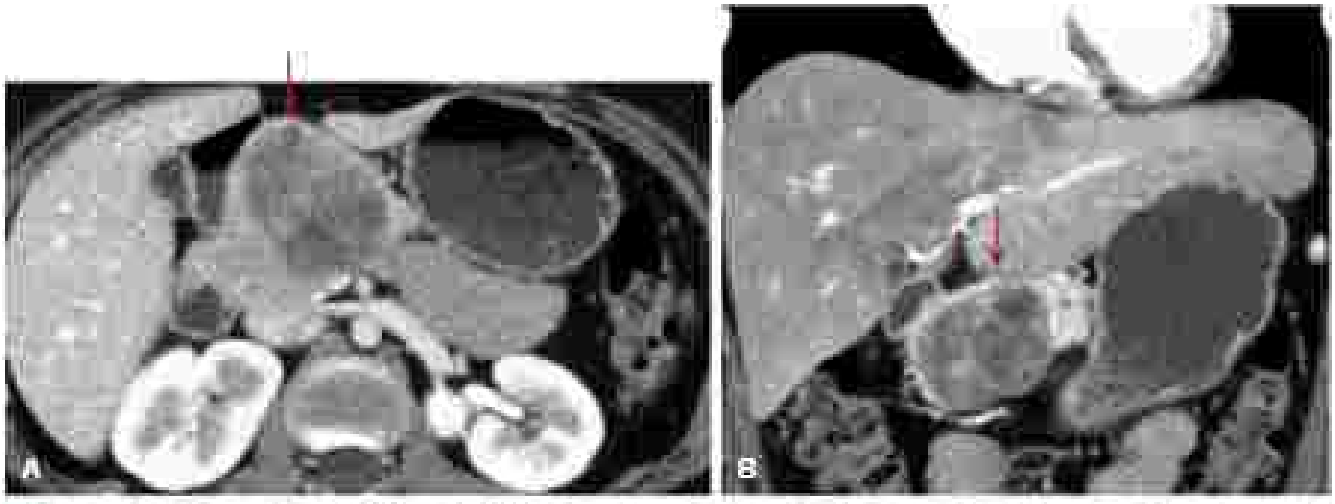

FIG. 3. (A) Axial and (B) coronal images of a contrast-enhanced computed tomography scan from a patient with a solid pseudopapillary tumor (arrows) of the neck of the pancreas with solid and cystic characteristics.

Some defining histologic features of SPTs include the presence of solid cellular hypervascular regions without gland formation, and the presence of branching papillary fronds with fibrotic and degenerative pseudopapillae. Cells stain positively for neuron-specific enolase, CD10, and keratins, chromogranin, synaptophysin, and endocrine pancreatic enzymes are generally not expressed. SPTs often stain positive for progesterone receptors, whereas estrogen receptor positivity is more variable. There are no histologic characteristics that appear prognostic for patients with SPTs. The genetic profile associated with SPT is different from adenocarcinoma, most notably for an absence of *KRAS*, *GNAS*, and *SMAD4* mutations. Almost all SPTs harbor alterations in the APC/β-catenin pathway resulting from a mutation involving *CTNNB1* (exon 3). Nuclear accumulation of β-catenin has been described in 95% of SPTs and 74% of tumor specimens (cyclin D1, a downstream effector of β-catenin). Interestingly, *BCL9*, a β-catenin stabilizing gene, is significantly decreased in SPT, which may help attenuate the protumorigenic effects of overactivation of the Wnt/β-catenin pathway. In addition, genes involved in the Hedgehog and androgen receptor signaling pathways, as well as genes involved in epithelial mesenchymal transition have been shown to be activated in SPT.

Treatment

Surgical resection is recommended for all patients with localized SPT. Although these tumors may be extremely large and can invade critical vasculature, most tumors are usually amenable to complete resection if the operating team is comfortable with resection and reconstruction of the superior mesenteric and/or portal vein. Arterial resection/reconstruction is required much less often. Pancreaticoduodenectomy or distal pancreatectomy can be performed with en bloc resection of involved adjacent organs when indicated. Recurrence is very uncommon; these authors have seen only one patient who had metastatic disease and, in that patient, it was present at the time of diagnosis. We have not seen a patient with SPT who developed a metachronous recurrence following a potentially curative operation. Although recurrence rates are low, long-term surveillance is felt to be important because of the young age of most all patients at the time of diagnosis. Given the excellent survival rates following surgical resection alone, adjuvant systemic therapy is not routinely used. If metastatic disease occurs (very rare), the most common sites include liver, mesentery, and peritoneum. The management of such very patients is anecdotal and for those with single site recurrence, surgery may be a reasonable approach.

AUTOIMMUNE PANCREATITIS

Autoimmune pancreatitis (AIP) is a form of pancreatitis characterized by obstructive jaundice with or without a pancreatic mass, lymphoplasmacytic infiltration, and fibrosis of the pancreas, and a therapeutic response to corticosteroids. The incidence of AIP is unknown, but it has become less frequently found on pathologic examination of surgical specimens following operations for presumed cancer; the diagnosis of AIP is rarely being made more often without surgical resection of the pancreas. Patients with AIP often present with painless jaundice that can mimic pancreatic ductal adenocarcinoma and is due to inflammation and narrowing/stricture of the distal common bile duct. In addition, other common symptoms of AIP include weight loss and abdominal pain but usually in the absence of cachexia and pain requiring narcotic medication. Similar to patients with adenocarcinoma, many of those with AIP are diabetic with impaired glucose tolerance.

AIP is currently classified into two subtypes. Type 1 AIP is associated with an elevation in serum immunoglobulin G4 (IgG4) levels and radiographic evidence of extrapancreatic involvement such as Sjögren syndrome, rheumatoid arthritis, primary sclerosing cholangitis, retinal pseudotumor, and inflammatory bowel disease. Extrapancreatic organ involvement can occur before, synchronous with, or after the diagnosis of AIP and type 1 is more common in older men. Biopsy of extrapancreatic sites can be helpful in making the diagnosis because the affected organs often demonstrate the characteristic lymphoplasmacytic infiltrate rich in IgG4 positive cells. In contrast, type 2 AIP is seen in the absence of elevated IgG4 levels and associated autoimmune disease is limited to inflammatory bowel disease, which is found in approximately 20% of patients. There is also an age predilection to type 2 AIP. Serum IgG4 is the single best serologic marker of AIP with a sensitivity of 80% in patients with type 1 AIP, but only 17% in those with type 2 AIP. IgG4 elevation above twice the upper limit of normal is strongly suggestive of AIP in the setting of obstructive jaundice.

The classic features of AIP on CT or MRI include a diffusely enlarged, sausage shaped pancreas with homogenous attenuation and no visible pancreatic duct. However, when the predominant area of involvement is the pancreatic head and ampulla/papilla, the imaging characteristics can be more challenging (Fig. 3). In contrast to alcohol induced pancreatitis, AIP is not associated with ductal dilation, calculi, and pseudocyst formation. Importantly, although AIP may involve a stricture of the pancreatic duct, the upstream dilation characteristic of pancreatic ductal adenocarcinoma is rarely observed.

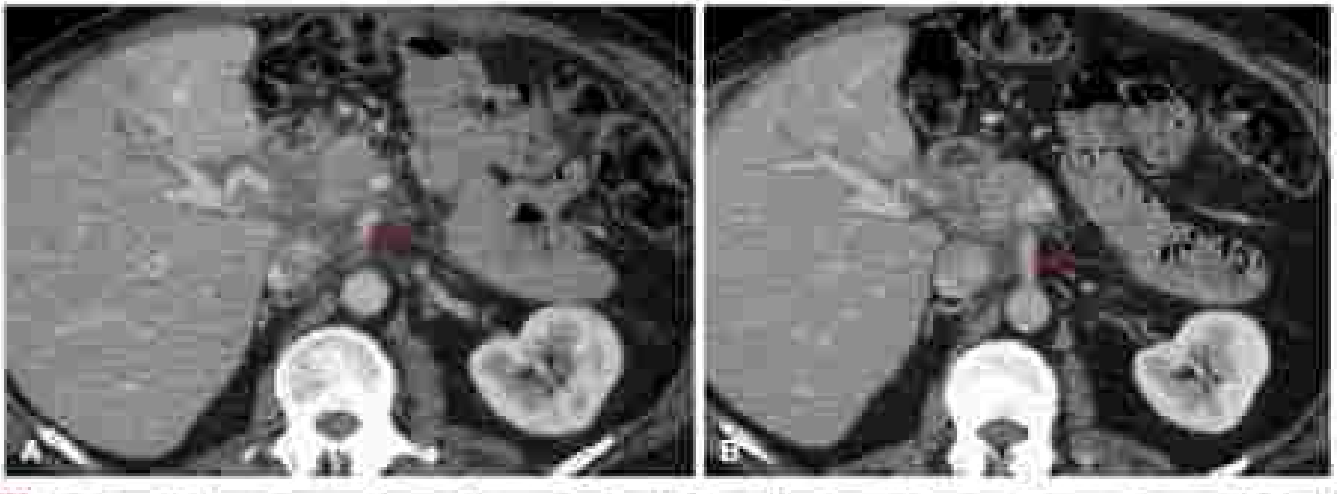

FIG. 3 Axial images of a contrast-enhanced computed tomography scan from a 53-year-old man proven to have type 1 autoimmune pancreatitis before (A) and after (B) steroid treatment. Image taken at the level of the superior mesenteric artery (arrow). Biopsy showed lymphoplasmacytic inflammation and a positive immunohistochemical stain for immunoglobulin G4.

However, occasionally, AIP may present as a focal mass-forming lesion in the pancreas that can be easily confused with pancreatic ductal adenocarcinoma; in such cases, the diagnosis is usually made by the pathologist after the involved pancreas has been surgically excised. Recently, international consensus diagnostic criteria were developed for type 1 and type 2 AIP, which incorporate the findings from radiographic imaging (including ductal imaging with magnetic resonance cholangiography or endoscopic retrograde cholangiopancreatography) as well as serologic and histopathologic data.

Type 1 AIP may not require a histologic diagnosis when the typical clinical, radiographic, and laboratory criteria are present, but since type 2 AIP is often seronegative and lacks other organ involvement, definitive diagnosis requires a pathologic biopsy specimen. Type 1 AIP has three essential features: (1) lymphoplasmacytic infiltrate surrounding small-sized interlobular pancreatic ducts, (2) fibrosis centered around the ducts and veins affecting predominantly the peripancreatic adipose tissue, and (3) obliterative phlebitis affecting the pancreatic veins. Immunostaining often demonstrates abundant (>10 cells/high power field) IgG4 positive cells. Type 2 AIP differs from type 1 by less prominent fibrosis, phlebitis, and the lack of IgG4 positivity. In type 2 AIP, lymphoplasmacytic infiltrates may result in obliteration of the pancreatic duct lumen, in contrast to type 1 AIP, in which the ductal epithelium is generally spared. The diagnosis of AIP (especially type 2) can be difficult, short of removing part of the pancreas as no single diagnostic test is sufficient. A correct diagnosis, made short of removing the pancreas, relies on a combination of cytology/histology of biopsy specimens, cross-sectional and endoscopic imaging, serologic findings, and a detailed clinical history. In general, the diagnosis of AIP requires a multidisciplinary team consisting of a radiologist, pathologist, surgeon, and gastroenterologist with expertise in the disease.

Treatment

AIP is highly responsive to corticosteroid therapy and when this does not occur quickly (in weeks), an alternate diagnosis (especially adenocarcinoma) should be considered. Although AIP can resolve spontaneously, treatment with corticosteroids has been associated with rapid reversal of jaundice, diabetes, and exocrine dysfunction usually within 2 to 4 weeks of starting treatment. The resolution of bile duct obstruction shortly after starting corticosteroids confirms the diagnosis. The International Consensus Diagnostic Criteria for Autoimmune Pancreatitis recommends a trial of 0.6 to 1 mg/kg per day of prednisone for a period of 2 weeks followed by imaging and interval assessment of CA 19-9 levels. If the diagnosis of AIP is correct, the bile duct stricture and gland enlargement should improve with steroid therapy. On clinical and radiologic improvement, the prednisone can be tapered by 5 to 10 mg/day every 1 to 2 weeks until a daily dosage of 20 mg, then decreased by 5 mg every 2 weeks. Because clinical relapse can occur in up to 30% of patients, some have advocated a more prolonged taper or the administration of low dose maintenance prednisone. In Japan, prednisone (2.5–7.5 mg/day) is administered for up to 3 years, which has demonstrated a lower relapse rate in type 1 AIP. Patients with type 1 AIP who experience a rapid decrease in serum IgG4 levels have a low probability of relapse. If corticosteroids are ineffective in disease relapse, other immunologic therapies, including rituximab and azathioprine, have been used. Surgery is reserved for situations where diagnostic uncertainty exists. If the diagnosis of AIP cannot be confirmed and the pancreas has been biopsied more than once, surgical resection of the pancreas (involved segment, Whipple's or distal pancreatectomy) is the most logical approach. If the pancreas (and the patient) are operable/resectable and a trial of steroids is preferred despite diagnostic uncertainty, we would reimage in 3 to 4 weeks and in the absence of improvement, proceed to surgery. If the involved segment or entire pancreas is deemed not resectable because of local anatomy, and AIP is suspected but not confirmed, then a trial of corticosteroids is quite reasonable. If there is no response to corticosteroids, repeat biopsy should be performed. One of the most difficult clinical situations involves a patient with an inoperable pancreas tumor in which the differential diagnosis includes both AIP and adenocarcinoma and the diagnosis cannot be established despite multiple attempts at endoscopic ultrasound (EUS)-guided or percutaneous biopsy and a trial of corticosteroids. In this situation we would not start empiric chemotherapy (patient may not have cancer), but rather, perform a comprehensive reassessment in 4 to 6 weeks and consider rebiopsy at that time. If the correct diagnosis is, in fact, inoperable pancreatic cancer, such a treatment delay will be of little clinical significance and with time, the diagnosis will become apparent.

PRIMARY PANCREATIC LYMPHOMA

Lymphomas involving predominantly the pancreas are extremely rare and can occur exclusively in the pancreas (primary pancreatic lymphoma [PPL]), via direct extension from adjacent peripancreatic lymphadenopathy (secondary pancreatic lymphoma), or originate from lymph nodes distant from the pancreas. PPL is defined by the World Health Organization as "an extranodal lymphoma arising in the pancreas with the bulk of the disease localized to the site, contiguous lymph node involvement and distant spread may be seen but the primary clinical presentation is in the pancreas with treatment directed to this site." PPL is predominantly non-Hodgkin's lymphoma of B-cell phenotype and diffuse large B-cell lymphoma is the most common histological subtype. PPL accounts for less than 2% of extranodal lymphomas. Currently, no specific biochemical markers aid in the diagnosis of PPL. Elevated serum lactate dehydrogenase and β2-microglobulin levels in the setting of a normal CA 19-9 may provide a clue to the diagnosis of PPL. PPLs predominantly occur in men (7:1) and usually present in the fifth to sixth decade of life. Common presenting symptoms include abdominal pain, and symptoms such as fever, night sweats, chills, weight loss, jaundice, and gastric or duodenal outlet obstruction resulting from the bulk of disease.

In patients with PPL, CT or MRI demonstrates the presence of a large mass that focally involves the head of the pancreas (Fig. 4) or occasionally a more diffuse form that is infiltrative and can mimic the appearance of acute pancreatitis. As one would expect, patients with PPL often present with significant lymphadenopathy involving the peripancreatic lymph nodes and most notably, the retroperitoneal lymph nodes below the renal vein in the paraaortic location. The involved lymph nodes lack central necrosis or calcifications and the pancreatic duct is rarely dilated despite what appears to be a large

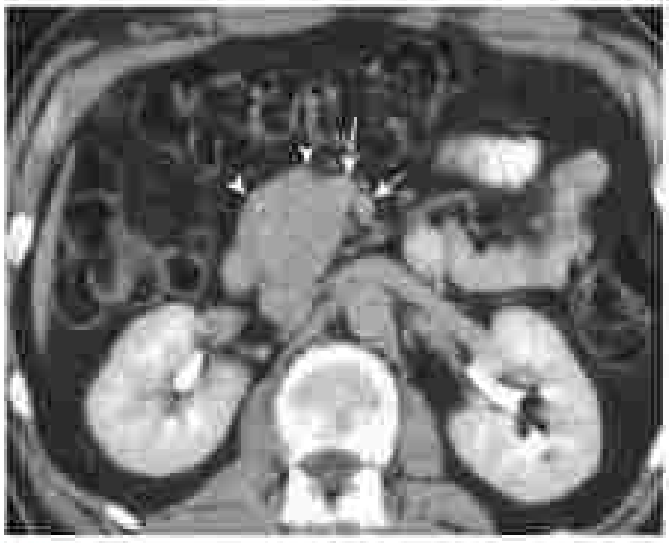

FIG. 4. Axial image of a primary pancreatic lymphoma involving the head of pancreas (white arrowheads) and the hypodense appearance of the mass (arrowheads) and the adjacent abutment of the superior mesenteric vein (long arrow) and proximity to the superior mesenteric artery (short arrow).

pancreatic tumor. Also, narrowing or occlusion of the superior mesenteric or portal veins is rarely present in most patients despite the bulky tumor size. PPLs are said on diffusion-weighted postcontrast magnetic resonance scans with uptake patterns that may be focal nodular, diffuse, or segmental. Such findings prompt biopsy, either with either EUS-FNA (small or core biopsy needle) or percutaneous core biopsy technique. Cytopathologic features include large malignant lymphocytic nuclei, prominent nucleoli, and a background of necrosis. Immunohistochemical stains that are positive in pancreatic endocrine neoplasms, such as synaptophysin, are generally negative in PPL. The use of flow cytometry may be limited by the cellularity of some fine-needle aspirate specimens; therefore, core needle biopsy is usually preferred when the diagnosis of PPL is suspected.

Treatment

The standard of care in the management of PPL is chemotherapy alone, which provides excellent control of symptoms, including jaundice, as well as long-term remission. PPL is most commonly treated with a multidrug regimen such as cyclophosphamide, doxorubicin, vincristine, and prednisone. Complete remission can be expected with multidrug therapy in the majority of patients with large B-cell lymphoma. However, recurrence is common in patients older than age 60. The use of an anti-CD20 antibody, rituximab, and cyclophosphamide, doxorubicin, vincristine, and prednisone has been associated with improved response rates of up to 80% in diffuse large B-cell lymphoma. Other regimens include cyclophosphamide, vincristine, and prednisone and methotrexate, Adriamycin, cyclophosphamide, vincristine, prednisone, and bleomycin. Laparotomy should be reserved for patients in whom the diagnosis is uncertain despite percutaneous or endoscopic biopsy often in the setting of biliary obstruction/endoscopic stenting or for therapeutic purposes (palliative surgery) in the setting of gastrointestinal hemorrhage or gastric outlet obstruction.

METASTATIC RENAL CELL CANCER

Metastatic lesions to the pancreas are also very rare and the vast majority of patients thought to have a metastasis to the pancreas actually have metastases to peripancreatic lymph nodes. The one exception is renal cell cancer (RCC), which metastasizes to the pancreatic parenchyma. Synchronous metastases can occur in up to 25% of patients with RCC and metachronous metastases may occur in up to 40% of all patients with a history of RCC. RCC metastases to the pancreas may present after an extended disease free interval from nephrectomy, and we have seen an accidental patient with a disease free interval of 20 years. This emphasizes the importance of long term follow up for patients with RCC after initial resection. There are no differences in the frequency of pancreatic metastases based on the laterality of the primary tumor and metastases from RCC can occur anywhere within the pancreas; there is not a preferred location (head vs body or tail). Interestingly, many patients have solitary metastases (based on CT/MRI imaging), which are usually asymptomatic (>60%) and identified during follow up surveillance. Occasionally, a metastasis from RCC can erode into the duodenum and cause gastrointestinal hemorrhage (because they are highly vascular tumors) or obstruct the splenic vein resulting in gastroesophageal varices and anemia, melena, or hematemesis. In patients with more widespread disease, abdominal pain, weight loss, or jaundice may be the presenting complaint. Many patients also have intrapancreatic metastases; therefore, a thorough staging evaluation should be performed in patients with suspected or biopsy-proven metastatic RCC to the pancreas (to include an MRI of the brain).

CT is the first test for the evaluation of presumed RCC metastases to the pancreas and is often diagnostic in the absence of a biopsy. The classic hypervascular tumor may demonstrate a central area of low attenuation on the arterial phase (Fig. 5) in a patient with a history of prior surgery for a large RCC is diagnostic. The imaging characteristics can be similar to pancreatic neuroendocrine tumors but this is a clinical dilemma only in patients with VHL who underwent prior nephrectomy for RCC. In contrast to the hypervascularity of RCC metastasis to the pancreas, pancreatic ductal adenocarcinoma is hypodense on the arterial phase of CT imaging. In the majority of patients with a history of RCC, the CT findings are diagnostic, and there is no need for a pancreatic biopsy. However, a tissue biopsy may be helpful if there is a concern over the diagnosis on imaging. Positive immunohistochemical staining for CD10 and PAX8 can be used to distinguish between metastatic RCC and other tumors, such as clear cell carcinoma of the pancreas, clear cell pancreatic endocrine tumor, and the solid variant of serous cystadenoma.

Treatment

In general, surgery is applied only to patients with isolated pancreatic metastases from RCC (uni- or multifocal); those with synchronous extrapancreatic metastases are usually not considered for surgical treatment in the absence of pancreas-associated complications such as bleeding or biliary/gastric outlet obstruction. Patients with isolated RCC metastases to the pancreas who undergo surgical resection may experience a long disease free survival. In a systematic review that identified 321 patients with resected RCC metastases to the pancreas, the 5-year disease free survival and overall survival were 37% and 73%, respectively. However, with improvements in systemic therapies (targeted agents, immunotherapy) to include innovative clinical trials, patients with metastatic RCC may experience prolonged survival without surgery. In addition, antiangiogenic agents such as bevacizumab, sunitinib, and sorafenib, have shown promising results in metastatic RCC, necessitating the need for a multidisciplinary approach to the management of these patients.

CONCLUSIONS

The major diagnostic concern in patients with a pancreatic neoplasm, either suggested or clearly demonstrated on cross-sectional imaging, is pancreatic ductal adenocarcinoma. Remember that most patients with adenocarcinoma of the pancreas will also have an elevation in serum levels of CA19-9 and/or an elevation in hemoglobin A1c (often in the setting of weight loss). For patients with a symptomatic or asymptomatic pancreatic mass, accurate staging with CT or MRI is usually followed by EUS with FNA biopsy. Although EUS-FNA biopsy has become very safe in experienced hands, it should not be used to replace a detailed patient history, physical examination, focused laboratory evaluation and a thorough review of all imaging studies. Rather, pancreatic biopsy should be used in conjunction with all available clinical and laboratory information to arrive at an accurate diagnosis and stage of disease. If the diagnosis is not adenocarcinoma, a thorough understanding of rare and unusual pancreatic neoplasms is important to develop the correct treatment plan. Surgery is the cornerstone of therapy for SPT, ACC, and isolated RCC metastases (especially those with a long disease free interval) if the tumor is operable. For those patients with tumors that are inoperable from the superior mesenteric or portal vein (on preoperative imaging), surgery should only be undertaken if the operative team has experience with venous resection and reconstruction at the time of pancreatectomy. Similarly, if the tumor appears to encase the celiac artery or common hepatic artery, arterial resection and reconstruction may be necessary, such tumor vascular relationships are accurately delineated on preoperative imaging and should not be an unexpected finding at the time of laparotomy. Most important, patients with diagnoses as discussed in this chapter will often live many years even without surgery, mandating that surgery associated mortality be close to zero and morbidity be managed safely. This can be achieved by referral of patients to specialty centers (often referred to as high volume centers) when indicated.

Finally, it is important to remember that medical therapy is the obvious choice for patients with ATP and PPL when the diagnosis can be accurately established. Usually this is possible without an operation (open or laparoscopic).

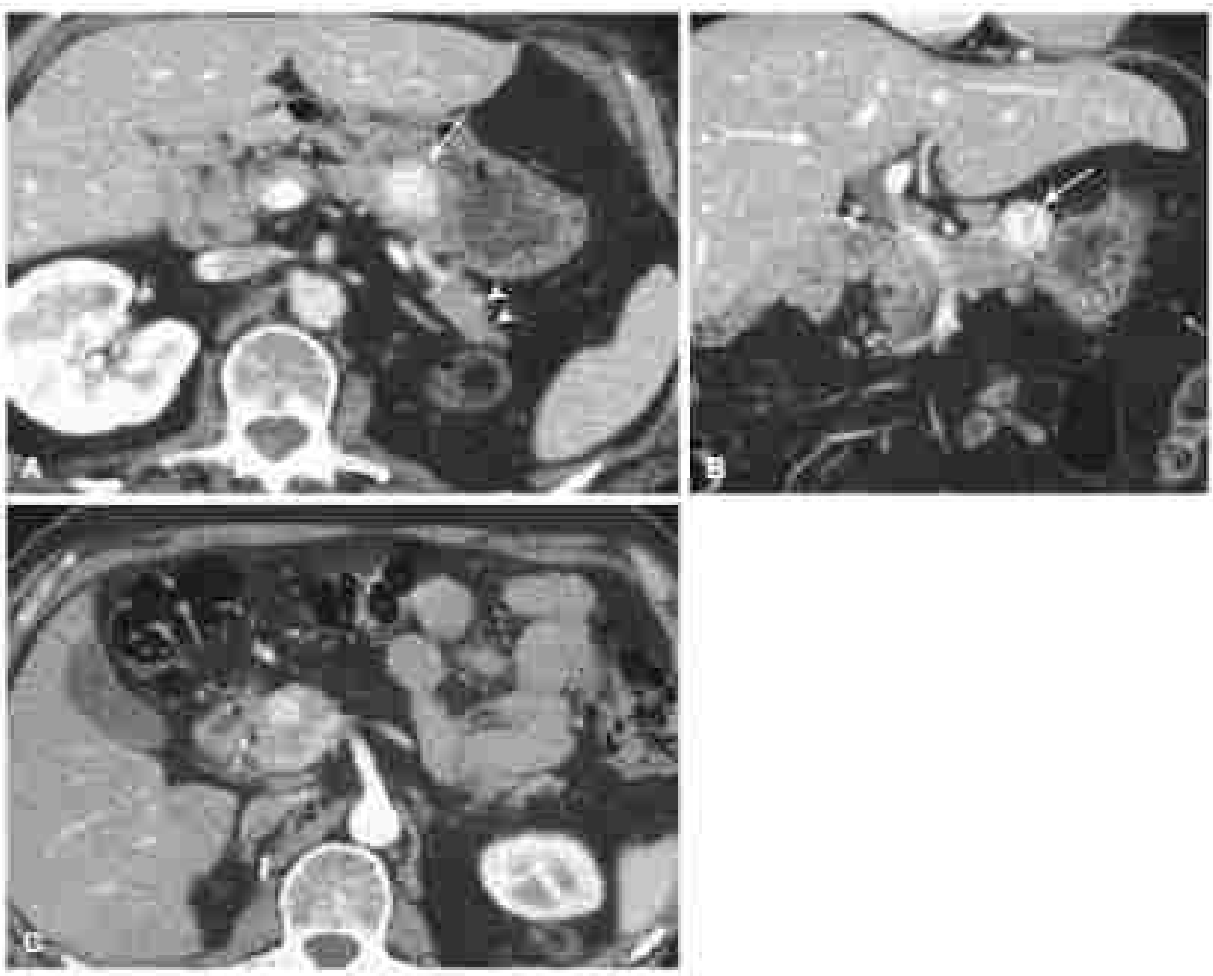

FIG. 1 (A, C) Axial and (B) coronal images of a contrast-enhanced computed tomography scan from a patient who underwent a left nephrectomy for renal cell carcinoma 15 years prior and then developed a metachronous metastasis to the pancreatic body. Note the characteristic bright enhancement of the metastatic lesion (arrow) on arterial phase imaging as well as the posterior displacement of the pancreas (arrowheads) because of the absence of the left kidney.

Intraductal Papillary Mucinous Neoplasms of the Pancreas

Carlos Fernández-del Castillo, MD, and
George Mollica, MD, MPH

Intraductal papillary mucinous neoplasms (IPMNs) of the pancreas were first described in Japan in 1980 and have been increasingly identified over the past 30 years because of the advances of cross-sectional abdominal imaging and its more frequent use in the evaluation of various abdominal complaints. At the Massachusetts General Hospital (MGH) approximately 25% of pancreatic resections are for IPMNs. Based on autopsies, it is suspected that IPMN lesions are found in up to 2% to 3% of the general population. Furthermore, IPMNs are more prevalent in older individuals, with about 10% of individuals older than 70 years being identified with an IPMN. Historically, IPMNs were thought to occur more frequently in men; however, more recent studies and our experience at MGH has been that there is most likely no sex difference in IPMN prevalence. This chapter reviews IPMN characteristics, risk of malignancy, and management recommendations.

CLASSIFICATION OF THE TYPES OF IPMN LESIONS

There are two distinct types of IPMN lesions and these include main duct (MD) IPMN and branch duct (BD) IPMN. Mixed-type IPMN lesions are a third type that include features of MD IPMN and BD IPMN (Fig. 1). IPMNs are categorized as MD IPMN if the main pancreatic duct has segmental or diffuse dilation that is greater than 5 mm without other causes of obstruction. Conversely, BD IPMNs are defined as having a pancreatic cyst that is more than 5 mm in size that communicates with a nondilated main pancreatic duct. Mixed-type IPMN lesions are characterized as having a pancreatic cyst that communicates with a dilated main pancreatic duct. Most IPMNs are identified incidentally when patients are undergoing cross-sectional imaging for abdominal complaints, most often abdominal pain. Although most IPMN lesions are incidentally found using a multidetector computed tomography (MDCT) or a magnetic resonance imaging (MRI), the best imaging modality in the initial workup of a suspected IPMN is a pancreas-protocol MDCT scan of the abdomen and pelvis (Fig. 2). This includes an arterial contrast phase and a portal venous contrast phase that favors imaging of the pancreas.

After a lesion has been identified as being suspicious for an IPMN, the decision must be made to either proceed with observation, diagnostic intervention, or resection. The decision on how to proceed depends on the type of lesion and other characteristics that have been classified as high-risk stigmata and worrisome features. This classification scheme and management recommendations are based on the International Association of Pancreatology (IAP) 2006 Sendai consensus guidelines that were subsequently updated to the IAP 2012 Fukuoka consensus guidelines. These guidelines were most recently revised in 2017, and they are now known as the revised IAP 2012 Fukuoka consensus guidelines.

A distinct feature of IPMN lesions are papillary projections in the pancreatic ductal system. Based on the morphology of these projections, IPMNs are categorized into epithelial subtypes or phenotypes. There are four distinct epithelial phenotypes: intestinal, gastric, pancreatobiliary, and oncocytic. This categorization is important because these phenotypes are associated with tubular, colloid, and oncocytic invasive malignancy with varying degrees of survival.

CLINICAL PRESENTATION

At our institution, the majority of patients (57%) were asymptomatic at the initial time of presentation. Of those patients who were managed with surveillance, 83% were asymptomatic at the initial time of presentation and only 10% of patients progressed to have symptoms at the 6-month mark. Among patients who underwent surgical resection, about 50% had symptoms at presentation that included abdominal pain (43%), weight loss greater than 10 pounds (29%), acute pancreatitis (12%), and jaundice (9%). Additionally, about 34% of patients who underwent resection at MGH had a diagnosis of diabetes mellitus, and these patients had an adjusted twofold elevated risk of having high-grade dysplasia and invasive carcinoma.

FAMILY HISTORY

Although there are currently no clear genetic disorders that are associated with IPMN lesions, at MGH, 11.9% of all patients with an IPMN lesion had a family history of pancreatic cancer. Despite this finding, a family history of pancreatic cancer was not associated with type (MD IPMN, BD IPMN, or mixed-type IPMN), epithelial subtype, or presence of malignancy. Among these same patients, however, there was an associated increase in the incidence of concurrently occurring pancreatic ductal adenocarcinoma (PDAC) (13.1% vs 2.9%, $P = .02$) and extrapancreatic malignancies (35.6% vs 20.1%, $P = .03$). The Johns Hopkins experience has reported that a family history of pancreatic cancer was an independent risk factor for recurrence of IPMN after initial resection, and that it carried a fourfold increased risk of developing a recurrence.

MD-IPMN

MD IPMN lesions usually occur in the sixth decade of life, and they are more often associated with symptoms, with more than 50% presenting with abdominal pain, weight loss, jaundice, or pancreatitis. About 50% of all MD IPMN lesions are intestinal epithelial phenotype. These express MUC2, which produces a thick mucin that may lead to obstruction of the main pancreatic duct and subsequent pancreatitis. Intestinal epithelial phenotype IPMN lesions are associated with high-grade dysplasia and invasive carcinoma and most often progress to colloid carcinoma. Colloid carcinomas have a median survival of 95 months after resection and are more indolent than tubular carcinomas, which have a reported postresection survival of about 26 months. Additionally, colloid carcinomas are associated with GNAS mutations. Oncocytic epithelial phenotype is associated with MD IPMN, but it is only seen in 2% of all IPMN lesions. These lesions are indolent and if they transform into invasive malignancy their median survival has been reported to be approximately 132 months, which is much more favorable than colloid or tubular carcinomas.

According to the revised IAP 2012 Fukuoka consensus guidelines, all MD IPMNs with main duct dilation of more than 10 mm, jaundice, or mural nodules should be considered for surgical resection if the patient is an appropriate surgical candidate. The reasoning behind this recommendation is the increased risk for high-grade dysplasia and invasive carcinoma. The risk of identifying high-grade dysplasia in a resected MD IPMN specimen at MGH is about 52%, and the reported risk of invasive carcinoma ranges from 16% to 70%.

BD-IPMN

The majority of the pancreatic cysts identified in cross-sectional abdominal imaging are suspected to be BD IPMN lesions. The most common epithelial phenotype found among BD IPMN lesions is gastric epithelial subtype (63%), which does not commonly undergo malignant transformation. When malignant transformation does occur, however, BD IPMN lesions transform into tubular carcinomas.

FIG. 1. (A) Sagittal multidetector computed tomography image showing main duct intraductal papillary mucinous neoplasm with focal dilation (arrow) of the main pancreatic duct. (B) Axial multidetector computed tomography image showing a small cystic lesion in the pancreatic tail (arrow) consistent with branch duct intraductal papillary mucinous neoplasm. No dilation is observed in the main pancreatic duct. (C) Mixed-type intraductal papillary mucinous neoplasm on computed tomography scan. There is notable diffuse dilation of the pancreatic duct in the head and body of the gland (arrowheads) and multiple small branch duct lesions throughout the body and tail (arrow).

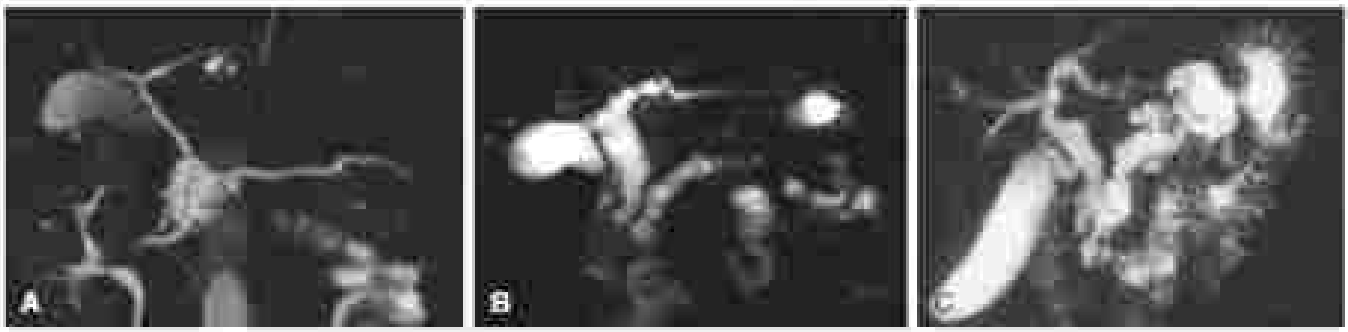

FIG. 2. Radiographic appearance of (A) branch duct, (B) main duct, and (C) mixed-type intraductal papillary mucinous neoplasms. (*From* Tanaka M, Fernández-del Castillo C, Kamisawa T, et al. Revisions of international consensus Fukuoka guidelines for the management of IPMN of the pancreas. Pancreatology 2017;17(5):738–53.)

which are more aggressive tumors. Despite being a more aggressive form of invasive cancer, the 5-year survival of invasive BD-IPMN is still more favorable than pancreatic ductal adenocarcinoma (55% vs 37%).

Pancreatobiliary type epithelial phenotype IPMNs are more often seen in BD-IPMN lesions than in MD-IPMN lesions and are also associated with tubular carcinoma (Fig. 2); however, pancreatobiliary type is difficult to distinguish from gastric type. Overall, the risk of invasive carcinoma associated with BD-IPMN ranges from 9% to 12%, whereas the risk of high-grade dysplasia is about 15% to resected BD-IPMNs.

MIXED-TYPE IPMN

By definition, mixed-type IPMN lesions include dilation of the main pancreatic duct and cystic lesions arising from branches of the main pancreatic duct. At our institution, the risk of high-grade dysplasia and invasive carcinoma for mixed-type IPMN tumors is about 31% and 28%, respectively. This is notably higher than for BD-IPMN, but lower than what has been reported for MD-IPMN. Although recent data have shown that the degree of main duct dilation may play a prognostic role in predicting how mixed-type IPMN lesions behave, the revised IAP 2012 Fukuoka consensus guidelines recommend consideration for surgical resection of mixed-type IPMN with main duct dilation larger than 10 mm, jaundice, or mural nodules and if the patient is an appropriate surgical candidate.

IAP Guidelines for BD-IPMN Lesions

The revised IAP 2012 Fukuoka consensus guidelines provide recommendations on how to proceed when a BD-IPMN lesion is identified. These guidelines are based on the presence or absence of high-risk stigmata and worrisome features. According to the previous IAP 2006 Sendai consensus guidelines, surgical resection should be considered for a BD-IPMN lesion if the patient is evaluated to be an appropriate surgical candidate and if any of the following criteria were met: any symptomatic cyst, asymptomatic cyst that was greater than 3 cm in size, main pancreatic duct dilation that was greater than 6 mm in diameter, or presence of mural nodules within the cyst.

The revised IAP 2012 Fukuoka consensus guidelines were brought forth because many patients were undergoing pancreatic resections for benign IPMN lesions (Table 1 and Fig. 4). The revised IAP 2012 Fukuoka consensus guidelines categorized IPMN characteristics into high-risk stigmata and worrisome features. Surgical resection should be considered for a BD-IPMN lesion if the patient is identified as being an appropriate surgical candidate and if any of the following high-risk stigmata are present: obstructive jaundice in a patient with a cystic lesion of the head of the pancreas, enhancing mural nodule greater than or equal to 5 mm, or main pancreatic duct greater than or equal to 10 mm in diameter. If high-risk stigmata are not present, then management recommendations depend on the presence of worrisome features. Worrisome features include pancreatitis, a BD-IPMN cyst greater than or equal to 3 cm in size, enhancing mural nodule smaller than 5 mm, thickened and/or enhancing cyst wall, main pancreatic duct measuring 5 to 9 mm in diameter, abrupt change in caliber of pancreatic duct with distal pancreatic atrophy, lymphadenopathy, increased serum level of CA19-9, and cyst growth rate greater than or equal to 5 mm over 2 years. If worrisome features are present, then the recommendation is to perform an endoscopic ultrasound (EUS) and fine needle aspiration (FNA) biopsy to further investigate the BD-IPMN. Surgical resection should be considered if

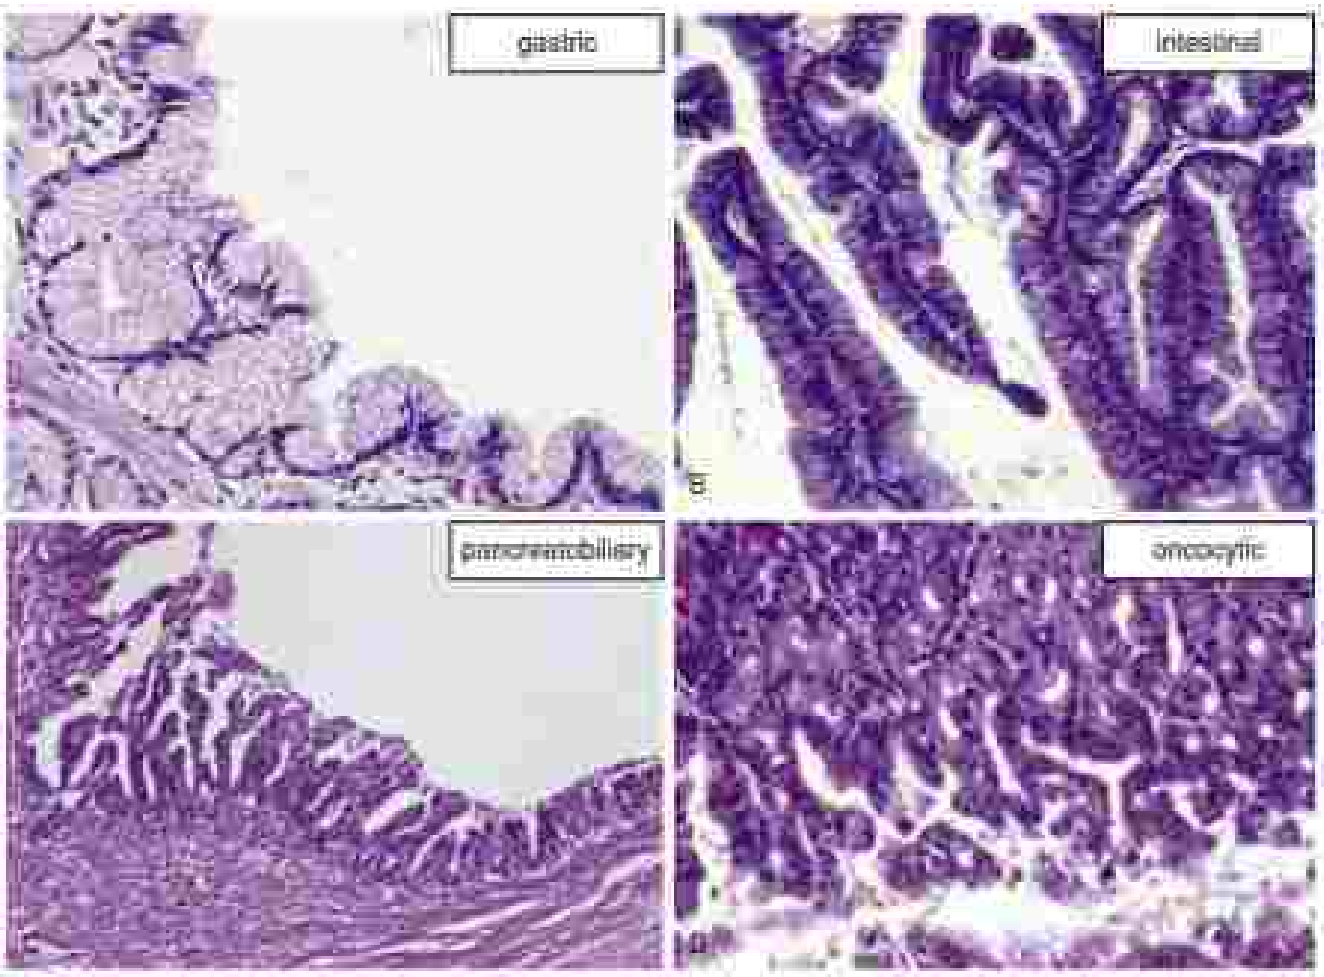

FIG. 1 The four histologic classifications of intraductal papillary mucinous neoplasm are (A) gastric, (B) intestinal, (C) pancreatobiliary and (D) oncocytic. (From Tanaka M, Fernández-del Castillo C, Adsay V, et al. International consensus guidelines 2012 for the management of IPMN and MCN of the pancreas. Pancreatology 2012;12(3):183–97.)

the patient is an appropriate surgical candidate and if any of the following are present during the EUS with FNA: mural nodule, suspicion for involvement of the main pancreatic duct, or cytology from the FNA biopsy that is suspicious or positive for malignancy.

FIELD-DEFECT CONCEPT

The field-defect concept refers to the phenomenon that a patient may have an IPMN in one location in the pancreas and concomitantly have PDAC at a different site of the pancreas. The reported incidence of concomitant PDAC has ranged from 4% to 11%. In addition to concomitant PDAC, patients may have synchronous and multifocal lesions. Independent predictors of concomitantly occurring PDAC are worsening diabetes mellitus and abnormal serum CA19-9. Furthermore, it is important to note that IPMNs can histopathologically range from low grade dysplasia, which can be considered to be similar to adenomas, to high grade dysplasia and invasive carcinoma. Because of the field defect concept, multiple IPMN lesions with varying degrees of dysplasia and presence of invasive carcinoma can be present concurrently. As such, each suspicious lesion should be maximized; multifocality and cyst specific pancreatectomy should be performed rather than total pancreatectomy.

ELEVATED SERUM CA19-9

The revised IAP 2012 Fukuoka consensus guidelines now includes elevated serum CA19-9 as a worrisome feature. This is based on recent findings from a meta-analysis of 15 studies that included 1639 patients and found that elevated serum CA19-9 was significantly predictive of detecting invasive carcinoma in IPMN lesions (pooled sensitivity of 52% and specificity of 88%, respectively). We have found that among resected BD IPMN at MGH, an elevated serum CA19-9 of 100 units/mL or higher had the highest predictive accuracy for detecting invasive carcinoma (93%), when compared with the standard cutoff of 37 units/mL (83%). However, there is no evidence to support a diagnostic cutoff of serum CA19-9 for detecting high grade dysplasia.

IMAGING MODALITIES

Many patients will be diagnosed with an IPMN based on CT imaging performed for the workup of abdominal pain or as part of the workup for another abdominal reason or pathology. If contrast was used, the portal venous phase was most likely not captured, and if it was captured, it was most likely suboptimal. All patients with a known or suspected IPMN should undergo a pancreas protocol MDCT scan or a gadolinium-enhanced with magnetic resonance cholangiopancreatography (MRCP). A pancreas protocol MDCT captures the arterial and portal venous phase and provides the best images of the pancreas. At MGH, MDCT includes negative oral contrast with water and intravenous contrast administration. The amount of IV contrast is weight dependent and is given via bolus at about 3 to 4 mL/s. There is a 50 second delay from when the contrast injection starts to when the arterial phase is captured. The portal venous phase, also referred

to as the mature abdominal phase, is captured after a 75-second delay after the start of contrast injection. Of note, the MDCT should ideally be performed in a dual energy manner. An MRI/MRCP however, might be preferred over a pancreas protocol MDCT because of the lack of radiation exposure, which becomes important when considering that many patients will require long-term IPMN surveillance. Additionally, an MRI/MRCP has been reported to have superior contrast resolution and better delineation of septations, mural nodules, and communication with the main pancreatic duct, when compared with a pancreas protocol MDCT. The accuracy rate of MDCT and gadolinium enhanced MRI to detect high grade dysplasia and invasive carcinoma in IPMN lesions ranges from 75% to 86%.

Although an EUS is an additional imaging modality to survey IPMN lesions, we argue against its use as a surveillance imaging modality. An EUS should be performed to further characterize a BD-IPMN with worrisome features, as previously discussed. Using EUS as a routine long-term follow-up imaging surveillance modality carries risks because of its invasive nature. Although EUS is able to delineate main duct involvement and can detect mural nodules within the pancreatic cyst, it has also been reported to erroneously identify mucin globules as mural nodules. One way to avoid this erroneous identification is to perform a contrast-enhanced EUS, which allows for better discrimination between mucin globules and mural nodules by detecting blood flow signal in mural nodules (sensitivity, 69%; specificity, 92.2%; and accuracy, 75.9%).

EUS AND FNA OF CYST FLUID

EUS with FNA has become an important diagnostic procedure when evaluating IMPN lesions, and in particular BD-IPMNs. EUS with FNA can sample the cyst fluid and biopsy solid or nodular cyst components. Approximately 70% of IPMN lesions have an elevated carcinoembryonic antigen (CEA) in their cyst fluid. Although a cyst fluid CEA level of 192 ng/mL has been found to be associated with IPMNs, cyst fluid CEA cannot distinguish between benign and malignant cysts. In addition to elevated CEA in the cyst fluid, there will also be mucin and, typically, an elevated amylase level.

Other important information that can be obtained from cyst fluid is cytologic and molecular analyses. Although these are more operator-dependent because they are complex to perform and they commonly are limited by indeterminate samples because of insufficient sample volume or cross-contamination with gastric or duodenal wall cells, cyst fluid cytologic and molecular analyses can identify common mutations and high grade atypia or malignant cells. The most common mutations that are associated with IPMN lesions are *GNAS* and *KRAS*; however, identification of these common mutations does not confirm the presence of malignancy. The majority of IPMN lesions (66%) have *GNAS* mutations. *KRAS* mutations in the cyst fluid are found in about 50% of IPMN lesions; however, *KRAS* mutations are also found in mucinous cystic neoplasms. From 45% to 96% of IPMN lesions have either *GNAS* or *KRAS* mutations in their cyst fluid.

Although the presence of *GNAS* and/or *KRAS* mutations does not confirm malignancy, mutations in these two genes are implicated in the progression pathway of IPMN lesions transforming into invasive IPMN malignant lesions. When comparing the presence of *GNAS* versus *KRAS* mutations to colloid versus tubular carcinomas, *GNAS* mutations are more frequently associated with colloid carcinoma (89% vs 52%, $P = .0003$) and *KRAS* mutations are most frequently associated with tubular carcinoma (89% vs 52%, $P = .01$). *KRAS* mutations are also seen in PDAC.

ROLE OF ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

In current practice, endoscopic retrograde cholangiopancreatography (ERCP) is not routinely used in the diagnostic work-up of an

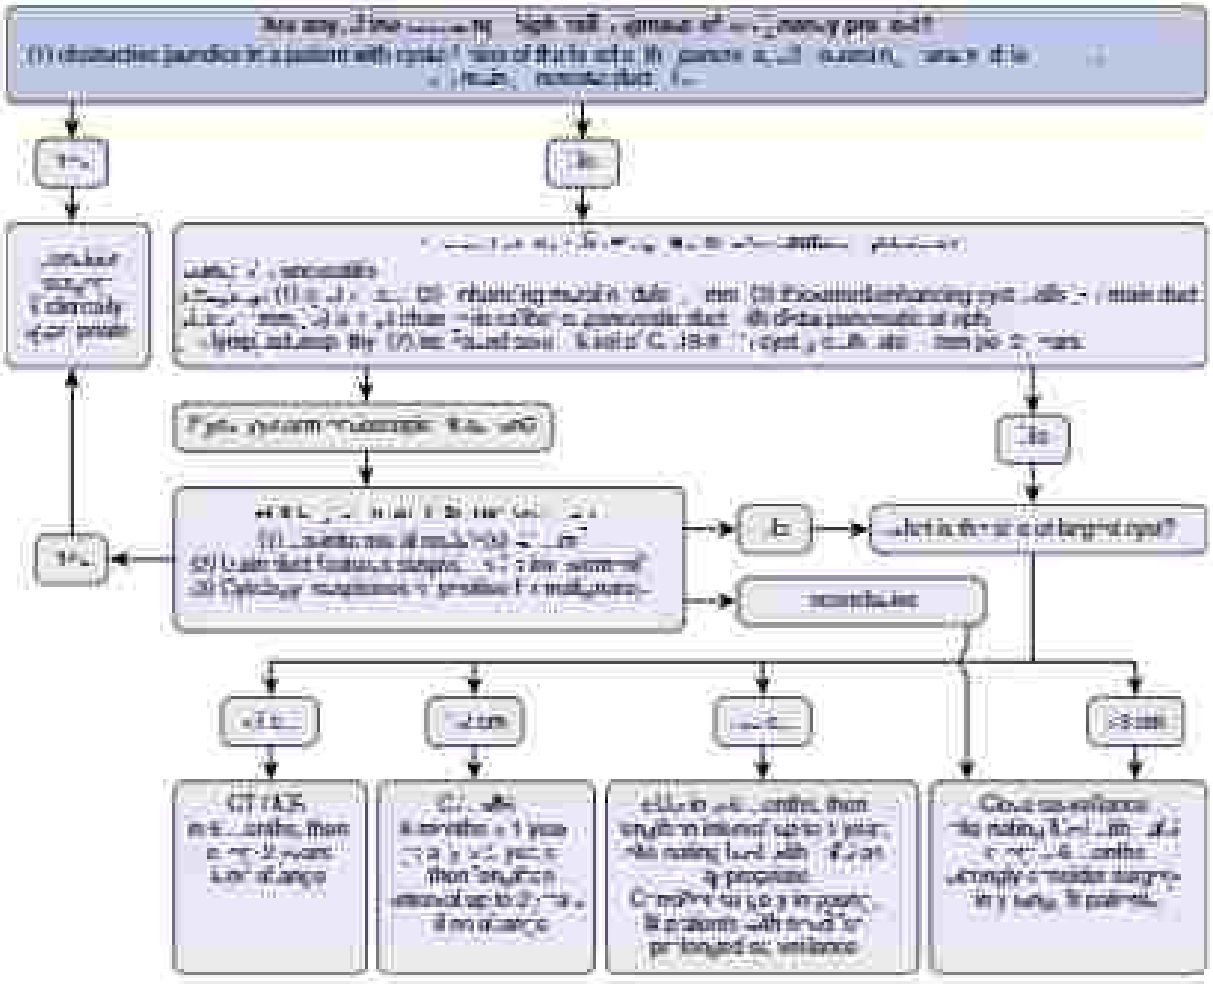

FIG. 4 Algorithm for the management of suspected intraductal papillary mucinous neoplasm (IPMN). Patients may be referred for evaluation of pancreatic cystic lesions or for evaluation of symptoms (eg, abdominal pain, weight loss, new-onset diabetes mellitus, or pancreatitis). Patients with findings suspicious for pancreatic cancer (eg, obstructive jaundice, a pancreatic mass, or dilated pancreatic duct) should undergo pancreatic protocol computed tomography (CT) or magnetic resonance imaging (MRI) with magnetic resonance cholangiopancreatography (MRCP) to evaluate for IPMN. Patients with findings suspicious for IPMN (eg, cystic lesion communicating with the pancreatic duct) should undergo endoscopic ultrasound (EUS) with fine-needle aspiration (FNA) and MRCP to further characterize the lesion and evaluate for worrisome features or high-risk stigmata. Patients with main duct IPMN, mixed-type IPMN, or branch duct IPMN with worrisome features or high-risk stigmata should undergo surgical resection. Patients with branch duct IPMN without worrisome features or high-risk stigmata can undergo surveillance. Surveillance intervals are based on the 2017 International Consensus Fukuoka guidelines for management of IPMN of the pancreas. (From Tanaka M, Fernández-del Castillo C, Kamisawa T, et al. Revisions of international consensus Fukuoka guidelines for the management of IPMN of the pancreas. *Pancreatology*. 2017;17(5):738–753.)

asymptomatic IPMN lesions. EUS with FNA and MRCP are more routinely used since they can identify IPMN lesions and provide information about their malignancy potential without the invasiveness of an ERCP and its postprocedure risk of acute pancreatitis. However, when ERCPs were routinely used in the workup of patients with IPMN lesions, about 25% of patients would have the pathognomonic finding of a bulging ampulla, or a fish-mouth appearance, which extrudes thick mucin. ERCP may be necessary if patients present with obstructive jaundice resulting from an IPMN lesion and therefore need a sphincterotomy and possible stent placement. In this setting, an ERCP would be diagnostic and temporarily therapeutic.

MANAGEMENT

The most important classification when considering management recommendations is whether the lesion is a MD IPMN, BD IPMN, or mixed-type IPMN lesion. Second, the presence of high-risk stigmata and worrisome features is the next layer of classification that plays an important role in management recommendations. Next, we will summarize recommended management strategies based on the type of IPMN lesion and whether high-risk stigmata or worrisome features are present.

LESIONS THAT SHOULD BE RESECTED

All MD IPMN, mixed-type IPMN, and BD IPMN lesions with high-risk stigmata features should be considered for surgical resection. Preoperatively deciding the extent of the pancreatic resection may prove difficult because of the nature of IPMN lesions and how they present on imaging. Oftentimes, there is no discrete tumor that can be identified in a MD IPMN or mixed-type IPMN. Instead, there may only be the presence of a focal dilated area and either a distally or proximally dilated pancreatic duct. The presence of nodular components should raise the suspicion of a site of local malignancy or an adjacent malignancy. After an initial preoperative decision has been made regarding the extent of pancreatic resection (Whipple resection, extended Whipple resection, middle pancreatectomy, distal pancreatectomy, or total pancreatectomy), the surgeon must plan on sending pancreatic margins for frozen section to pathology to ensure that high-grade dysplasia or invasive malignancy is not being left behind. This is important because invasive malignancy spreads microscopically along the duct, and at times without any macroscopic evidence. Conversely, low- or moderate-grade dysplasia may be left in situ because all patients with a history of an IPMN, even following resection, should undergo routine surveillance. Intraoperative ultrasound has not been found to be useful in identifying the extent of malignant

spread of an IPMN lesion. At MGH, in the presence of pancreat[illegible] [illegible] the pa[illegible] [illegible] IPMN [illegible] the setting of [illegible] 404 patients, 58% [illegible] than 3% [illegible] 25% [illegible] [illegible]

[illegible] MD IPMN [illegible] alternatives [illegible]

Lesions That Should Undergo Further Work-Up With EUS and FNA Biopsy

BD IPMN lesions with worrisome features should be further investigated with an EUS and FNA biopsy [illegible] [illegible] appropriate surgical candidate [illegible] during the [illegible] mural nodule, suspected involvement of the main pancreatic duct, or cytology that is suspicious or positive for malignancy.

LESIONS THAT SHOULD UNDERGO FOLLOW-UP

BD IPMN lesions without high-risk stigmata or worrisome features should be followed with surveillance imaging. Small lesions that are between 0 and 2 cm should have a pancreas protocol MDCT or MRCP performed after an initial interval of 6 months. If the IPMN lesion is stable in size and appearance, then the surveillance interval can be lengthened to 1 year. IPMN lesions that are larger than 2 cm on MRCP and EUS should be performed every 3 to 6 months to establish a baseline and to confirm that the lesion is stable in size and in features. Once a baseline is established, then follow-up imaging interval length can be prolonged as appropriate. Another approach is to have a uniform surveillance program for all lesions that fall under the category of necessitating surveillance. This approach could take the form of surveillance with imaging, MRCP or MDCT, every 6 months for 1 year. If the lesion remains stable in size and in features during that 1 year period, then the follow-up interval can be increased to once a year for 3 years. Once again, if the IPMN lesion remains stable in size and in features, then the follow-up interval can be increased to 2 years.

APPROACH TO MULTIFOCAL BD-IPMN

Indications for resection of multifocal BD IPMNs with high-risk stigmata or worrisome features are the same as for unifocal BD IPMN lesions. The operative approach would favor a segmental resection in cases where all cysts are located in the same pancreatic region. However, BD IPMNs located in separate regions of the pancreas should be individually evaluated to assess which, if any, have high-risk stigmata or worrisome features and thus warrant surgical resection. When possible, a segmental resection of the lesion that has the highest oncologic risk is favored.

SURVIVAL AFTER RESECTION OF AN IPMN LESION

The distinction between noninvasive versus invasive disease when treating IPMN lesions is paramount since it has significant effects on survival. Noninvasive would be considered to be low- and high-grade dysplasia, despite the latter being considered to be equivalent to carcinoma in situ. In our experience, the 10-year specific survival after complete resection of a noninvasive IPMN is greater than 95%; however, we have found that survival is significantly decreased after resection for an invasive IPMN with 5-year and 10-year overall survival rates of 47% and 34%, respectively.

GUIDELINES FOR FOLLOW-UP AFTER RESECTION OF IPMN LESIONS

Because of the field defect concept seen in IPMN lesions, patients who undergo resection of an IPMN still need continued surveillance of the remaining pancreas because of the risk of developing new IPMN lesions and/or carcinomas in the remaining pancreas. Approximately 17% of patients who underwent a resection of a noninvasive IPMN lesion developed a new or progressive IPMN lesion on surveillance imaging. A different study found that recurrence in the remnant pancreas differed depending on whether the resection margin of a noninvasive IPMN was positive or negative. If the resection margin was positive the risk of recurrence was [illegible]% versus 2% if the resection margin was negative. The median time to recurrence of a noninvasive IPMN has been found to be about 4 years.

Nevertheless, there is currently a debate about whether the resection margin status of a noninvasive IPMN is associated with subsequent recurrence of an IPMN or development of invasive carcinoma. The Johns Hopkins experience reported that there was no difference in the development of a new IPMN lesion in patients who had a positive resection margin when compared to patients who had a negative resection margin (27% vs 22%, P = nonsignificant). The Memorial Sloan Kettering experience reported that dysplasia of any degree at the resection margin was an independent predictor of recurrent disease in the remnant gland, but not at the resection margin (odds ratio, 2.9; P = .02). However, they reported that dysplasia of any degree at the resection margin was not significantly associated with development of invasive disease. At the MGH, a positive resection margin after resection of a main duct IPMN lesion was significantly associated with survival in a multivariate analysis (hazard ratio, 2.6; P = .044).

SUMMARY

The incidence of IPMNs is increasing because of the rising use of MDCT and MRI in the workup of abdominal complaints. There are two main types of IPMN, MD IPMN and BD IPMN, and a third type that includes MD IPMN and BD IPMN features, which is known as mixed type IPMN. In addition to being categorized into types, IPMN lesions are also categorized into histologic epithelial subtypes. Depending on the type of IPMN and the histologic epithelial phenotype, these lesions have varying degrees of association with malignancy. The revised IAP 2012 Fukuoka consensus guidelines provide management recommendations depending on the type of IPMN. All MD IPMN, BD IPMN, and mixed type IPMN lesions with high-risk stigmata should be considered for surgical resection. Furthermore, BD IPMN with worrisome features should be considered for surgical resection if EUS with FNA biopsy shows a mural nodule, is suspicious for involvement of the main pancreatic duct, or shows cytology that is suspicious or positive for malignancy. Last, routine surveillance with MDCT or MRCP is important for all patients with IPMN, regardless of whether they undergo resection or do not initially meet criteria for resection.

Management of Pancreatic Islet Cell Tumors Excluding Gastrinoma

Dmitriy S. Fedorov, MD, Ph.D., and Jeffrey A. Ramsey, MD

The incidence of pancreatic neuroendocrine tumors (pNETs) is steadily increasing. They comprise 3% of all pancreatic tumors and autopsy studies indicate that between 3% and 10% of people will have pNETs, suggesting that many are small and often asymptomatic. pNETs comprise a heterogeneous group of tumors that secrete signals in each area of the pancreas (head, body, and tail). Some pNETs occur in association with familial disorders, for example, pNETs in the setting of multiple endocrine neoplasia type 1 (MEN-1). The majority (80%–85%) of pNETs, however, occur sporadically. These tumors typically show an indolent course and are difficult to diagnose with a mean time from presentation of symptoms to diagnosis of 6 years. Management of pNETs generally includes a combination of medical and surgical therapy.

CLINICAL PRESENTATION AND ASSOCIATED SYNDROMES

pNETs are found throughout the pancreas and may be single or multiple. They are always multiple when they are present in patients with MEN-1. Patients may present with symptoms from a hormone-secreting or functional pNET that secretes excessive uncontrolled amounts of a hormone that results in a specific syndrome. The two most common pNET functional syndromes are Zollinger-Ellison syndrome (ZES) from excessive secretion of gastrin and hyperglycemia from excessive secretion of insulin. ZES is described in detail in another chapter of this text so it will not be discussed here. Pancreatic NETs can also present with a large mass that causes pain or bleeding if they invade into a blood vessel or obstruct the splenic vein and cause gastric varices. Occasionally the patient will have no symptoms and the tumor is seen as a mass in the pancreas on an abdominal computed tomography (CT) or magnetic resonance imaging (MRI) that was done for another reason. This is particularly true with non-functional pNETs. Nonfunctional pNETs still secrete chromogranin A or pancreatic polypeptide, but they do not secrete a hormone that causes a specific clinical syndrome. Tumor mass and response to therapy of pNETs can be assessed by measuring serum chromogranin A levels and or pancreatic polypeptide. Pancreatic polypeptide and chromogranin A levels correlate with tumor mass and extent of disease, increasing levels suggest more tumor volume. Size greater than 2 cm, intratumoral calcium deposits, and a solid rather than a cystic pNET each portend a more aggressive malignant tumor and should be noted. Malignant pNETs metastasize to lymph nodes and liver. They are shown to decrease survival when metastatic, but they are still indolent, and surgery should still be considered especially if all pNET can be excised.

If functional, patients usually display symptoms related to excessive hormone secretion that allow the smart clinician to make the diagnosis. Examples are Whipple's triad for insulinoma, fasting hypoglycemia, weight gain, and altered mental status with or without seizures with amelioration of symptoms following administration of glucose. In glucagonoma, patients have a rotund red pruritic rash called necrolytic migratory erythema in intertriginous areas plus diabetes, stomatitis, hyperaminoacidemia, and weight loss. In patients with vasoactive intestinal polypeptide (VIP) secreting tumors (VIPoma), severe secretory (watery) diarrhea (>10 stools per day) is present that is associated with hypokalemia, achlorhydria (WDHA syndrome), and hypercalcemia. Secretory diarrhea means that the diarrhea persists even when the patient is made nothing by mouth. The diarrhea cannot be effectively controlled with only intravenous electrolyte replacement therapy. It is best managed with Sandostatin injections that decrease VIP secretion and greatly ameliorate the diarrhea. pNETs can also secrete adrenocorticotropic hormone (ACTH), which causes severe hypercortisolism that is difficult to manage medically with standard medications such as antihyperglycemics, ketoconazole, and metyrapone so subsequently may require laparoscopic bilateral adrenalectomy.

CLINICAL WORKUP

Initially, a complete history and physical examination is performed. For insulinoma, laboratory studies include a diagnostic 72 hour provocative fast measuring insulin and glucose levels at the time of observed neuroglycopenic symptoms. Measuring C-peptide and proinsulin levels is also indicated. The diagnosis is confirmed if the glucose level is below 45 mg/dL, insulin greater 5 mIU/mL, and there are elevated serum levels of C-peptide and proinsulin. The neuroglycopenic symptoms should be ameliorated with either oral or intravenous administration of glucose. For glucagonoma, studies include elevated serum levels of glucagon, elevated fasting glucose levels, and markedly decreased fasting serum amino acid levels. For VIPoma, the diagnosis is made by increased serum VIP levels. For ACTHoma, elevated serum levels of ACTH and cortisol are measured. For somatostatinoma, patients have type 2 diabetes, steatorrhea, and cholelithiasis. Another important component of the clinical work up is to exclude MEN-1. MEN-1 is an autosomal dominant inherited disease with a prevalence of 2 to 3 per 100,000 people, caused by a gene mutation in chromosome 11 (11q13) that encodes for the menin protein. The syndrome is characterized by primary hyperparathyroidism, pNETs (either functional, most commonly gastrinoma, or nonfunctional), and pituitary adenoma. It is best excluded by measuring serum calcium and parathyroid hormone levels as primary hyperparathyroidism is usually the first manifestation of MEN-1.

Preliminary imaging to localize pNET often includes pancreatic protocol CT scan with intravenous contrast or MRI with luminal or gadolinium (Fig. 1), although occasionally with hormone secreting tumors, a mass may not be not localized using standard diagnostic

Management of Pancreatic Islet Cell Tumors Excluding Gastrinoma

Dushka S. Foster, MD, MA, and Jeffrey A. Norton, MD

The incidence of pancreatic neuroendocrine tumors (pNETs) is steadily increasing. They comprise 3% of all pancreatic tumors and autopsy studies indicate that between 3% and 10% of people will have pNETs, suggesting that many are small and often asymptomatic. pNETs comprise a heterogeneous group of tumors that secrete variably in each area of the pancreas (head, body, and tail). Some pNETs occur in association with familial disorders, for example, pNETs in the setting of multiple endocrine neoplasia type 1 (MEN-1). The majority (80%–85%) of pNETs, however, occur sporadically. These tumors typically show an indolent course and are difficult to diagnose with a mean time from presentation of symptoms to diagnosis of 6 years. Management of pNETs generally includes a combination of medical and surgical therapy.

CLINICAL PRESENTATION AND ASSOCIATED SYNDROMES

pNETs are found throughout the pancreas and may be single or multiple. They are always multiple when they are present in patients with MEN-1. Patients may present with symptoms from a hormone-secreting or functional pNET that secretes excessive uncontrolled amounts of a hormone that results in a specific syndrome. The two most common pNET functional syndromes are Zollinger-Ellison syndrome (ZES) from excessive secretion of gastrin and hyperglycemia from excessive secretion of insulin. ZES is described in detail in another chapter of this text so it will not be discussed here. Pancreatic NETs can also present with a large mass that causes pain or bleeding if they invade into a blood vessel or obstruct the splenic vein and cause gastric varices. Occasionally, the patient will have no symptoms and the tumor is seen as a mass in the pancreas on an abdominal computed tomography (CT) or magnetic resonance imaging (MRI) that was done for another reason. This is particularly true with non-functional pNETs. Nonfunctional pNETs still secrete chromogranin A or pancreatic polypeptide, but they do not secrete a hormone that causes a specific clinical syndrome. Tumor mass and response to therapy of pNETs can be assessed by measuring serum chromogranin A levels and/or pancreatic polypeptide. Pancreatic polypeptide and chromogranin A levels correlate with tumor mass and extent of disease, increasing levels suggest more tumor volume. Size greater than 2 cm, intratumoral calcium deposits, and a solid rather than a cystic pNET each portend a more aggressive malignant tumor and should be noted. Malignant pNETs metastasize to lymph nodes and liver. They are shown to decrease survival when metastatic, but they are still indolent, and surgery should still be considered especially if all pNET can be excised.

If functional, patients usually display symptoms related to excessive hormone secretion that allow the smart clinician to make the diagnosis. Examples are Whipple's triad for insulinoma: fasting hypoglycemia, weight gain, and altered mental status with or without seizures with amelioration of symptoms following administration of glucose. In glucagonoma, patients have a rarely red pruritic rash called necrolytic migratory erythema in intertriginous areas plus diabetes, stomatitis, hyperaminoacidemia, and weight loss. In patients with vasoactive intestinal polypeptide (VIP) secreting tumors (VIPoma), severe secretory (watery) diarrhea (>10 stools per day) is present that is associated with hypokalemia, achlorhydria (WDHA syndrome), and hypercalcemia. Secretory diarrhea means that the diarrhea persists even when the patient is made nothing by mouth. The diarrhea cannot be effectively controlled with only intravenous electrolyte replacement therapy. It is best managed with Sandostatin injections that decrease VIP secretion and greatly ameliorate the diarrhea. pNETs can also secrete adrenocorticotropic hormone (ACTH), which causes severe hypercortisolism that is difficult to manage medically with standard medications such as antihyperglycemic, hypocalcemic, and mutagenic so salvagenally may require laparoscopic bilateral adrenalectomy.

CLINICAL WORKUP

Initially, a complete history and physical examination is performed. For insulinoma, laboratory studies include a diagnostic 72 hour provocative fast measuring insulin and glucose levels at the time of observed neuroglycopenic symptoms. Measuring C-peptide and proinsulin levels is also indicated. The diagnosis is confirmed if the glucose level is below 45 mg/dL, insulin greater 5 mIU/mL, and there are elevated serum levels of C-peptide and proinsulin. The neuroglycopenic symptoms should be ameliorated with either oral or intravenous administration of glucose. For glucagonoma, studies include elevated serum levels of glucagon, elevated fasting glucose levels, and markedly decreased fasting serum amino acid levels. For VIPoma, the diagnosis is made by increased serum VIP levels. For ACTHoma, elevated serum levels of ACTH and cortisol are measured. For somatostatinoma, patients have type 2 diabetes, steatorrhea, and cholelithiasis. Another important component of the clinical work up is to exclude MEN-1. MEN-1 is an autosomal dominant inherited disease with a prevalence of 2 to 3 per 100,000 people, caused by a gene mutation in chromosome 11 (11q13) that encodes for the menin protein. The syndrome is characterized by primary hyperparathyroidism, pNETs (either functional, most commonly gastrinoma, or nonfunctional), and pituitary adenoma. It is best excluded by measuring serum calcium and parathyroid hormone levels as primary hyperparathyroidism is usually the first manifestation of MEN-1.

Preliminary imaging to localize pNET often includes pancreas protocol CT scan with intravenous contrast or MRI with luminal or gadolinium (Fig. 1), although occasionally with hormone secreting tumors, a mass may not be not localized using standard diagnostic

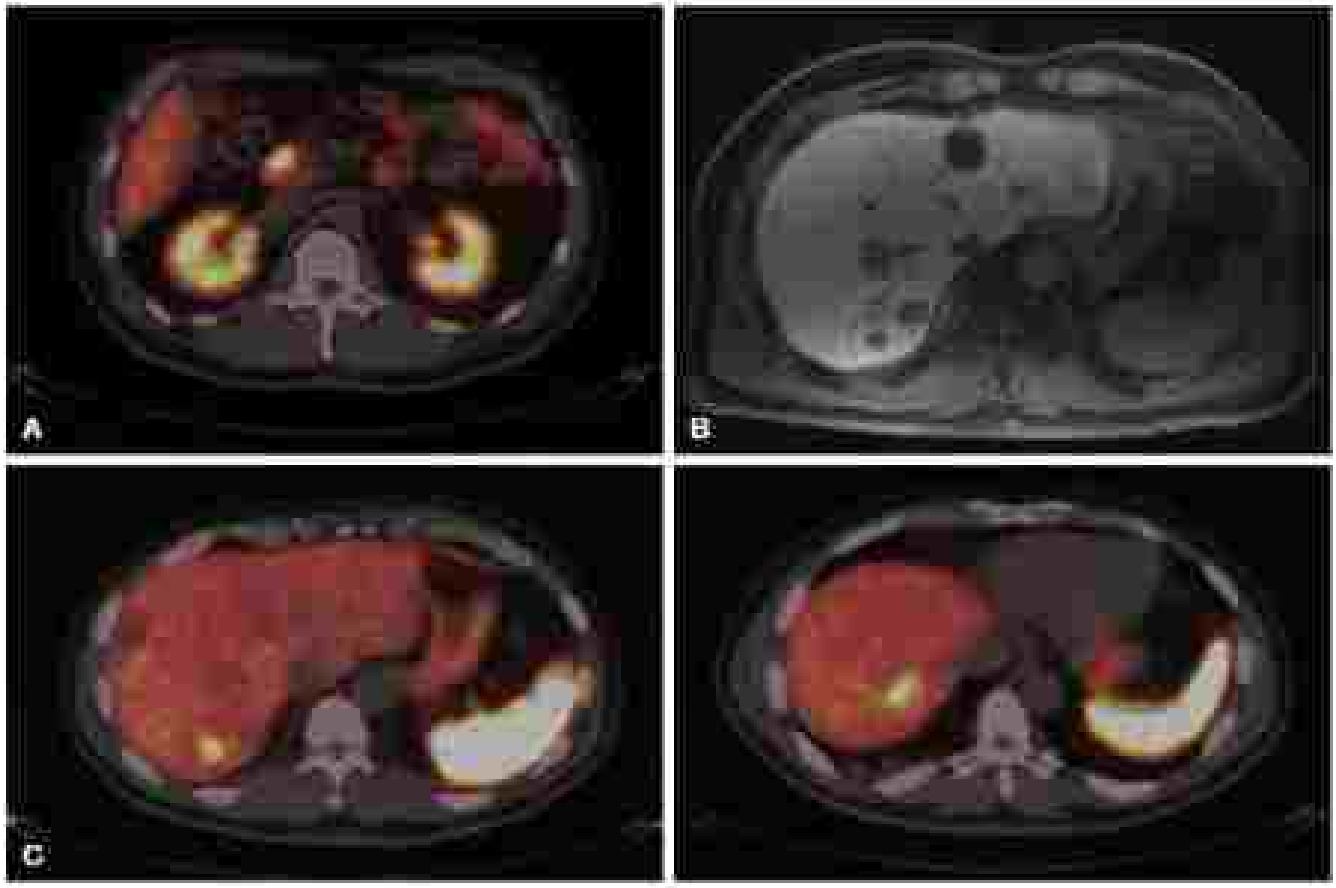

FIG. 1. (A) DOTATOC positron emission tomography scan showing a primary 3-cm pancreatic neuroendocrine tumor in the head of the pancreas. (B) Liver magnetic resonance imaging of the liver in the same patient suggesting multiple tiniest liver metastases such that the patient was thought to be unresectable and he was given everolimus for 3 months without benefit. (C) The same DOTATOC scan as seen in (A) showed only two liver metastases and both were located in the posterior portion of the right lobe. Because of the resectable pancreatic neuroendocrine tumor found on the DOTATOC scan, the patient underwent Whipple's procedure with right posterior segmentectomy and was disease free.

imaging. Somatostatin receptor scintigraphy (Octreoscan) has previously been used to image pNETs. It has been an effective imaging modality for most pNETs except insulinoma. Now, 68Gallium Dotatate (DOTA) positron emission CT imaging has replaced Octreoscan because it is more sensitive and specific for pNETs. This scan is used to localize the primary tumor and to evaluate for distant metastases (Fig. 1). It has dramatically improved imaging for pNETs and is able to detect small, previously unseen tumors. Endoscopic ultrasound can also be used to localize pNETs and lymph node metastases. pNETs appear nonfocal on ultrasound compared with the more echodense pancreas. Primary gastrinomas are most commonly localized to a triangle located around the head of the pancreas including the duodenum, whereas the remainder of the pNETs, including insulinoma, are uniformly distributed throughout the entire pancreas. For small insulinomas (not visualized on CT or MRI), endoscopic ultrasound and calcium angiogram are useful studies to localize a small pNET insulinoma. Calcium angiogram localizes the insulinoma to a region of the pancreas that can be extensively explored with intraoperative ultrasound during surgery. Intraoperative ultrasound facilitates removal of the insulinoma by not only identifying it, but by determining its relationship to the pancreatic duct.

For nonfunctional pNETs, it is important to realize which tumors are potentially malignant and warrant definitive surgery. pNET tumor size has been one of the best determinants of malignant potential. pNETs greater than 2 to 3 cm in diameter have a 60% probability of liver metastases and are considered more malignant. These need to be removed in a more aggressive way, including regional lymph nodes and therefore require definitive resection, including Whipple's pancreaticoduodenectomy for tumors in the head of the pancreas and distal pancreatectomy with splenectomy for tumors in the body or tail. There is controversy about the value of surgery for small nonfunctional pNETs. Small (<1 cm) nonfunctional pNET tumors in the elderly (>65 years) found incidentally on CT or MRI for another indication can safely be watched with serial imaging delaying surgery for an observed increase in size. Other indicators of a more malignant pNET are the presence of calcifications and hypoenhancement on arterial phase CT. Most pNETs are hyperenhancing on arterial CT, but when they are not enhancing their behavior is found to be more aggressive and warrant surgical resection.

CLINICAL MANAGEMENT

When a pNET is diagnosed, it is important to begin symptomatic management immediately, even during the work up. Somatostatin analogs inhibit secretion of most of the relevant hormones and are useful for the management of all functional NETs except insulinoma. For glucagonoma, the necrolytic migratory erythema can be ameliorated with somatostatin analogues. Diarrhea and blood chemical abnormalities in VIPomas are also ameliorated with somatostatin analogues. Lanreotide is currently preferred over Sandostatin LAR because it is administered subcutaneously and binds to more somatostatin receptors than Sandostatin. For insulinoma, medical management generally involves careful maintenance of blood glucose with frequent food intake until surgical resection can be implemented.

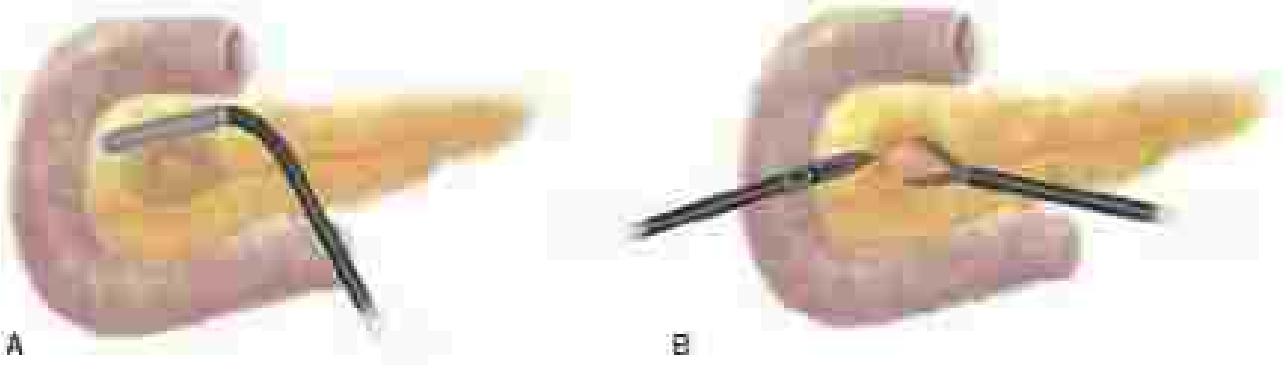

FIG. 2 For patients with well-localized insulinoma (pancreatic neuroendocrine tumor) seen on the preoperative imaging studies, we recommend laparoscopic enucleation of the pancreatic neuroendocrine tumor (pNET). (A) The location of the pancreatic neuroendocrine tumor is identified intraoperatively with a 10-MgHz transducer and its relationship to the pancreatic duct is elucidated. (B) It is enucleated using the harmonic scalpel to dissect the pancreatic parenchyma with the goal of remaining right on the capsule of the tumor.

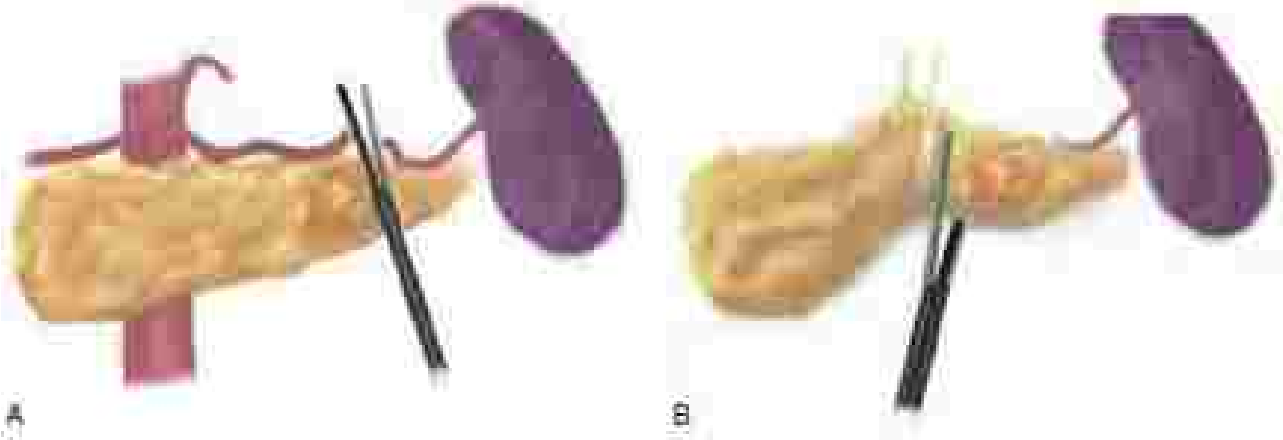

FIG. 3 (A) Division of the splenic artery with a vascular load stapler during laparoscopic distal pancreatectomy. (B) Division of the distal pancreas with umbilical tape in preparation for division of the distal pancreas. Peri-Strips are used to minimize the margin of leakage from the divided pancreatic duct.

Cornstarch mixed with a glucose solution can be administered at bedtime so that the patient can sleep all night and does not develop hypoglycemia while sleeping.

For localized pNETs, surgery is the mainstay of treatment. In the pancreas, NET resection can involve enucleation, distal pancreatectomy or Whipple pancreaticoduodenectomy, depending on the size, type and location of the pNET (body/tail of the pancreas and relationship to the pancreatic duct). Because insulinomas are almost always benign and smaller than 2 cm, enucleation is the procedure of choice. This can be done either laparoscopically (if the tumor is well localized on the preoperative studies, Fig. 2) or open (if not well localized). Intraoperative ultrasound with a 10 MgHz transducer applied to the pancreas is the intraoperative localization study of choice (Fig. 2A). pNETs in the setting of MEN-1 are almost always multiple so tumors in the body and tail are resected with distal pancreatectomy, whereas tumors in the head of the pancreas are enucleated. For laparoscopic enucleation, the patient is positioned with the left side up at 45 degrees. Four to five trocars can be used. We use the harmonic scalpel for dissection of the pancreas around the tumor (Fig. 2B). When you get in the appropriate plane on the capsule of the tumor, the dissection is smooth and bloodless. Care should be taken not to handle the tumor too much because if the capsule is interrupted, little seeds of even a benign insulinoma can implant and cause local recurrence. For distal pancreatectomy, a laparoscopic approach is generally pursued unless the tumor is clearly aggressive and very malignant (involving the splenic vein, stomach, or colon mesentery) (Fig. 3). This is performed using four trocars: periumbilical for the camera, two subcostal ports on the left, and one on the right for instruments. The spleen can either be preserved (Warshaw's procedure, in which blood flow is maintained to the spleen via the short gastric vessels while the splenic artery and vein are taken and divided) or sacrificed at the time of distal pancreatectomy. We divide the splenic vessels using a vascular stapler endoGIA 30 mm 4cl tip stapler with a tan load (Fig. 3A). Then we elevate the pancreas using an umbilical tape and divide the pancreatic tissue proximal to the mass using a 45-mm endoGIA stapler with a black load and Peri-Strips, which help to prevent any leakage from the divided pancreatic duct (Fig. 3B). We divide the pancreas slowly with the stapler to not crush it, such crushing may cause pancreatic leakage postoperatively. Large pNETs (>3 cm) in the head of the pancreas usually require a Whipple's pancreaticoduodenectomy.

Surgery can have a role, even in the setting of metastatic disease. Surgical resection of liver metastases either alone concomitantly as with the pancreatic surgery or as a separate second procedure has been applied to liver metastases with good results and subsequently long term survivals of 40% to 70% at 10 years in various reports. Therefore, accurate staging of the liver is imperative and the presence of liver metastases does not preclude aggressive resection of the primary tumor. A common strategy in liver-sparing surgery that means the use of intraoperative ultrasound to identify all liver

tumors. Wedge resection of tumors that are near the surface of the liver and ablation of tumors within the center of the liver. This has been recently facilitated with microwave ablation that is faster and easier to do than radiofrequency ablation (RFA). Microwave ablation only requires positioning the probe in the center of the lesion, whereas RFA requires multiple overlapping applications. Microwave is still not effective for tumors near a major intrahepatic blood vessel; however, with RFA, if a tumor is near a hepatic vein there is cooling that reduces the effectiveness of the procedure.

The patient in Fig. 1 is a real-time example of the sense of the discussed principles. This patient presented with a 3-cm nonfunctional pancreatic neuroendocrine tumor in the head of the pancreas. Preoperative MRI and CT suggested that he had multiple bilobar liver metastases, so he was treated preoperatively with everolimus; however, this patient had no response to treatment and his primary tumor increased in size. During his chemotherapy he had a DOTA scan that demonstrated much less liver tumor than anticipated on conventional imaging. He only had two liver pNET metastases in the posterior sector of the right lobe (Fig. 1C). Simple cysts were the other liver lesions seen on MRI (Fig. 1B). He underwent a pylorus-preserving Whipple's pancreaticoduodenectomy with right posterior sectionectomy and currently he is disease free and doing well postoperatively. He demonstrates the importance of DOTA scans to carefully stage the extent of pancreatic neuroendocrine tumor and the potential value of aggressive surgery to these patients even with liver metastatic disease.

Further management of liver disease may also involve medical therapy and/or liver-directed therapies. With regard to the latter, radioembolization with radionuclide microspheres, embolization, or chemoembolization can be used. Peptide receptor radiotherapy (PRRT) involves coupling a somatostatin analogue by a linker to a radionuclide emitting beta radiation particle, most commonly ^{177}Lutetium (^{177}Lu DOTA-Tyr^3 octreotate). Lutetium based therapy is available at a number of hospitals worldwide and most recently now in the United States, marketed under the name Lutathera. It is generally reserved for metastatic pNET disease and has been shown to be beneficial in clinical trials. A recently published phase III trial using ^{177}Lu Dotatate for pNETs showed significantly extended progression free survival compared with control (high dose octreotide) and had limited toxic side effects. The somatostatin analogue targets the ^{177}Lu Dotatate to the tumor, where it can be internalized and the radiation can then destroy the tumor. Positive DOTA imaging is a prerequisite criterion for PRRT.

Systemic medical therapies are indicated in the setting of metastatic disease that is clearly progressive on imaging despite use of somatostatin analogs. These include vascular endothelial growth factor inhibitors, and more recently mammalian target of rapamycin (mTOR) inhibitors, such as everolimus, which were introduced with the discovery that many NETs contain mutant genes in the PI3K/Akt/mTOR pathway. Sunitinib, a small molecule receptor tyrosine kinase inhibitor, is also being used in cases of metastatic progressive pNET.

SUMMARY

With the increasing incidence of pNETs and the opportunity for potential cure if early diagnosis and surgery are undertaken, understanding the presentation and key diagnostic and therapeutic goals related to pNETs is important for surgeons. Part of the diagnosis involves consideration of associated inherited disease syndromes such as MEN 1. Several new diagnostic and treatment technologies have recently been introduced, such as DOTA scanning, PRRT, and mTOR inhibitors, which assist in locating these tumors and managing more advanced disease, respectively. Minimally invasive surgical methods can increasingly be used to remove these tumors. Aggressive resection of metastatic and locally advanced tumor is indicated because studies have shown that the prognosis is still excellent.

INTRAOPERATIVE RADIATION FOR PANCREATIC CANCER

Amit K. Mahajan, MD, and Joseph M. Herman, MD, MSc

Although intraoperative radiation therapy (IORT) for pancreatic cancer has a long history of inquiry, improvements in systemic control with multiagent chemotherapy have increased the enthusiasm for aggressive local therapy, including more frequent exploration and attempts at radiation dose escalation. As such, there has been renewed enthusiasm surrounding the potential use of IORT. Indeed, IORT provides an opportunity for the focused delivery of high doses of radiation while shielding radiosensitive structures that often limit the dose of external beam radiation therapy (EBRT). Nevertheless, considerable challenges exist surrounding the development of a successful IORT program. Beyond the need for a dedicated operating room and delivery system, successful administration of IORT requires a coordinated effort between the radiation oncology and surgery teams. As such, it is critical that surgeons interested in administering IORT have an in-depth understanding of both the scientific and technical underpinnings of this treatment modality.

REVIEW OF EXISTING LITERATURE

Early exploration of IORT for pancreatic cancer came from Japanese investigators. In the 1970s, Kyoto University investigators described their experience with IORT for locally advanced disease, in which doses of 20 to 40 Gy resulted in improvements in tumor-related pain. These findings subsequently prompted investigators at the Massachusetts General Hospital (MGH) and the Mayo Clinic to further study IORT for pancreatic cancer in both the unresectable and

tumors. Wedge resection of tumors that are near the surface of the liver and ablation of tumors within the center of the liver. This has been recently facilitated with microwave ablation that is faster and easier to do than radiofrequency ablation (RFA). Microwave ablation only requires positioning the probe in the center of the lesion, whereas RFA requires multiple overlapping applications. Microwave is still even effective for tumors near a major intrahepatic blood vessel; however, with RFA, if a tumor is near a hepatic vein there is cooling that reduces the effectiveness of the procedure.

The patient in Fig. 1 is a real-time example of the sense of the discussed principles. This patient presented with a 5 cm nonfunctional pancreatic neuroendocrine tumor in the head of the pancreas. Preoperative MRI and CT suggested that he had multiple bilobar liver metastases, so he was treated preoperatively with everolimus; however, this patient had no response to treatment and his primary tumor increased in size. During his chemotherapy he had a DOTA scan that demonstrated much less liver tumor than anticipated on conventional imaging. He only had two liver pNET metastases in the posterior sector of the right lobe (Fig. 1C). Simple cysts were the other liver lesions seen on MRI (Fig. 1B). He underwent a pylorus-preserving Whipple pancreaticoduodenectomy with right posterior sectionectomy and currently he is disease free and doing well postoperatively. He demonstrates the importance of DOTA scans to carefully stage the extent of pancreatic neuroendocrine tumor and the potential value of aggressive surgery in these patients even with liver metastatic disease.

Further, management of liver disease may also involve medical therapy and/or liver-directed therapies. With regard to the latter, radioembolization with radionucleotide microspheres, embolization, or chemoembolization can be used. Peptide receptor radiotherapy (PRRT) involves coupling a somatostatin analogue by a linker to a radionuclide emitting beta radiation particle, most commonly ^{177}Lutetium ([^{177}Lu-DOTA^0, Tyr^3] octreotate). Lutetium-based therapy is available at a number of hospitals worldwide and most recently now in the United States, marketed under the name Lutathera. It is generally reserved for metastatic pNET disease and has been shown to be beneficial in clinical trials. A recently published phase III trial using ^{177}Lu-Dotatate for pNETs showed significantly extended progression-free survival compared with control (high-dose octreotide) and had limited toxic side effects. The somatostatin analogue targets the ^{177}Lu-Dotatate to the tumor, where it can be internalized and the radiation can then destroy the tumor. Positive DOTA imaging is a prerequisite criterion for PRRT.

Systemic medical therapies are indicated in the setting of metastatic disease that is clearly progressive on imaging despite use of somatostatin analogs. These include vascular endothelial growth factor inhibitors, and more recently mammalian target of rapamycin (mTOR) inhibitors, such as everolimus, which were introduced with the discovery that many NETs contain mutant genes in the PI3K/Akt/mTOR pathway. Sunitinib, a small-molecule receptor tyrosine kinase inhibitor, is also being used in cases of metastatic progressive pNET.

SUMMARY

With the increasing incidence of pNETs and the opportunity for potential cure if early diagnosis and surgery are undertaken, understanding the presentation and key diagnostic and therapeutic goals related to pNETs is important for surgeons. Part of the diagnosis involves consideration of associated inherited disease syndromes such as MEN 1. Several new diagnostic and treatment technologies have recently been introduced, such as DOTA scanning, PRRT, and mTOR inhibitors, which assist in locating these tumors and managing more advanced disease, respectively. Minimally invasive surgical methods can increasingly be used to remove these tumors. Aggressive resection of metastatic and locally advanced tumor is indicated because studies have shown that the prognosis is still excellent.

Intraoperative Radiation for Pancreatic Cancer

Amol K. Narang, MD, and Joseph M. Herman, MD, MSc

Although intraoperative radiation therapy (IORT) for pancreatic cancer has a long history of inquiry, improvements in systemic control with multiagent chemotherapy have increased the enthusiasm for aggressive local therapy, including more frequent exploration and attempts at radiation dose escalation. As such, there has been renewed enthusiasm surrounding the potential use of IORT. Indeed, IORT provides an opportunity for the focused delivery of high doses of radiation while shielding radiosensitive structures that often limit the dose of external beam radiation therapy (EBRT). Nevertheless, considerable challenges exist surrounding the development of a successful IORT program. Beyond the need for a shielded operating room and delivery system, successful administration of IORT requires a coordinated effort between the radiation oncology and surgery teams. As such, it is critical that surgeons interested in administering IORT have an in-depth understanding of both the scientific and technical underpinnings of this treatment modality.

REVIEW OF EXISTING LITERATURE

Early exploration of IORT for pancreatic cancer came from Japanese investigators. In the 1970s, Kyoto University investigators described their experience with IORT for locally advanced disease, in which doses of 25 to 40 Gy resulted in improvements in tumor-related pain. These findings subsequently prompted investigators at the Massachusetts General Hospital (MGH) and the Mayo Clinic to further study IORT for pancreatic cancer in both the unresectable and

resectable setting. In 1984, MGH reported outcomes among unresectable patients treated with IORT and 50RT, noting high rates of pain improvement and a median survival of 8–9 months. Three years later, Mayo investigators retrospectively reported outcomes among resected patients who received either postoperative EBRT alone or IORT followed by postoperative EBRT, noting higher rates of 1- and 2-year local control in patients who received both modalities. Since then, encouraging data have been reported in both the unresectable and resectable settings, as outlined below.

IORT for Unresectable Disease

Multiple subsequent series, including reports from Mayo and Japan, further explored IORT in the locally advanced setting, suggesting improvements in local control with the use of both IORT plus EBRT compared with EBRT alone. These findings prompted a multiinstitutional US study through the Radiation Therapy Oncology Group, namely report 8505, in which locally advanced pancreatic cancer patients were treated with IORT to 20 Gy followed by 50.4 Gy of EBRT. Unfortunately, median survival in this cohort was only 9 months, which dampened enthusiasm for the role of IORT.

Since then, however, other institutions have published positive long-term results with the use of IORT, with MGH reporting the most robust experience. An analysis of long-term outcomes among 104 locally advanced patients who were treated at MGH with IORT between 1978 and 2010 showed decent outcomes, particularly among well-selected patients with smaller tumors, with a 2-year overall survival of 16% and with a small fraction of patients (3%) experiencing long-term survival more than 5 years. These findings have renewed interest in IORT as a component of therapy for locally advanced pancreatic cancer, particularly with more patients with more advanced disease now undergoing attempted exploration in an era of better systemic control with multiagent chemotherapy.

IORT for Resected Disease

Following the results of the Mayo study of resected patients, the National Cancer Institute conducted a small, randomized trial of 24 patients comparing resection alone to resection with IOHDR. Patients in the IORT arm experienced improvements in local control and survival. Since then, subsequent institutional reports (see the Suggested Readings) have also suggested improvements in local control with the administration of IORT.

The most modern experience with IORT in the postoperative setting comes from MGH, where investigators recently reported outcomes among patients with borderline resectable or locally advanced patients who were managed with a modern regimen of upfront multiagent systemic therapy (primarily FOLFIRINOX or gemcitabine/nab-Abraxane), chemoradiation to a median dose of 50.4 Gy, and surgical exploration with or without IORT. The report analyzed 86 patients who made it through the neoadjuvant regimen without progression, of whom 41 successfully (48%) underwent resection, 18 (22%) had unresectable disease, and 9 (13%) had metastatic disease. Among the 41 patients who underwent resection, 22 were treated with IORT to a dose of 10 Gy. Patients treated with IORT experienced improved survival without additional toxicity or complications. Furthermore, unresectable patients who were treated with IORT to a dose of 15 Gy experienced an encouraging median survival of 24.8 months.

PATIENT SELECTION

As reflected in the literature, well-established guidelines for use of IORT for pancreatic cancer are lacking. Nonetheless, institutional data support consideration of IORT in instances when close or positive margins are expected at the time of resection or when disease may be unresectable, both of which are frequent scenarios with pancreatic cancer. Certainly, the decision to consider IORT should be discussed in a multidisciplinary setting, and its potential use should be defined ideally from the outset of therapy. Importantly, it is unlikely that intraoperative radiation alone is sufficient to achieve immortal doses for either gross or microscopic disease, and as such, IORT should be used in combination with either preoperative or postoperative radiation therapy. Although postoperative radiation can be considered with the use of surgical clips for guidance of radiation fields, preoperative radiation is often preferred for a number of reasons, including the following.

1. Better definition of the intact tumor target in the preoperative setting as compared to the often ill-defined surgical bed in the postoperative setting.
2. Displacement of bowel by the intact tumor in the preoperative setting compared with filling of the surgical bed by bowel in the postoperative setting.
3. Improved oxygenation of target tissue in the preoperative setting, rendering the target potentially more radiosensitive compared with the postoperative setting.
4. Removal of irradiated tissue with the preoperative approach.

EQUIPMENT

IORT can be administered using multiple devices, including Linac-based electron beam radiation therapy (IOERT), low-energy photons, low-dose-rate brachytherapy, or high-dose-rate (HDR) brachytherapy. Each of these modalities are viable strategies with their own relative merits. HDR-based IORT delivers a more concentrated dose at the surface of the target with sharp fall off, which may be optimal for a surgical cavity/margin, whereas IOERT delivers a more homogenous dose of radiation to a greater depth. A significant advantage of an HDR-based technique lies in its method of delivery through use of customized applicators that can allow delivery of radiotherapy to irregular surfaces compared with the rigid cone applicators that are required for IOERT or IOMT with low-dose photons. At our institution, we have primarily used an HDR technique to take advantage of the flexible applicators, and so the technique described in this chapter will primarily focus on the administration of HDR-based IORT. Newer applicators that allow the delivery of low-dose-rate brachytherapy such as the Contura are also under investigation.

As noted, HDR-based IORT requires the use of a sterile flap applicator along with an HDR-based afterloader system. The Freiburg Flap is the applicator used at our institution and consists of silicone balls that are 1 cm in diameter and that are connected to each other to form a flexible planar sheet, through which 4Fr catheters can be inserted. The size and shape of the Freiburg Flap can be customized at 1-cm intervals based on the dimensions of the target site. The afterloader system used at our institution is the Nucletron system by Elekta; however, other applicators and afterloader systems are available.

TECHNIQUE

The first step of HDR-based IORT is for the surgeon to try to retract as much radiosensitive normal tissue such as bowel (see Normal Tissue Toxicity section) out of the field and protect these structures by placing lead shields in front of them. Subsequently, the surgeon and radiation oncologist should jointly identify the high-risk surgical bed and/or gross disease. The target area is measured to inform the size of the applicator. The target area can also be marked out with a marking pen to aid in accurate positioning of the applicator. Once the dimensions of the applicator have been finalized and the prescription dose and depth have been selected, the radiation oncologist's physics team can subsequently begin developing the radiation plan, which primarily consists of determining the amount of time that the radioactive source will spend in each dwell position. While the radiation plan is being developed, the radiation oncologist can preselect an applicator that is closest in size to the desired size. If an exact match is not available, the applicator can be cut to the appropriate size. Before proceeding further, it is a good idea to place

FIG. 1 Freiburg flap in surgical bed connected with catheters to afterloader (not visualized).

FIG. 2 Packing over the Freiburg flap to ensure stability.

the applicator to the surgical field to ensure that the dwell dimensions are optimal and that the applicator fits well into the surgical field. Additionally, the entrance route of the catheters from the afterloader into the surgical cavity and subsequently into the applicator should also be considered to ensure that the catheters will not be kinked due to sharp angling.

Thereafter, 6Fr catheters are thread through the applicator and secured on either side of the applicator. The catheters are subsequently labelled in numeric order. It is helpful to place labels on the catheters both at a point near the applicator (in our institution, we use the labels as one of the mechanisms of securing the catheters to the applicator) as well as at a point a distance away from the applicator. These labels are critical because they allow accurate identification of the catheters even after the applicator can no longer be visualized once packing has been placed.

At this point, the applicator and catheters can be positioned into the surgical field in the location that had been previously defined (Fig. 1). Wet lap sponges can be packed on top of the applicator to help ensure its stability (Fig. 2). If needed, sutures can also be considered to further secure the applicator in place. Additional lead shields can be placed to minimize radiation dose to surrounding structures, with 3 mm of lead roughly reducing the dose by 70%. Of note, it is important to remember to cover lead shields with wet gauze to minimize backscatter dose. Distance from the applicator also helps reduce radiation dose, with the prescribed dose dropping to 70%, 50%, and 35% at 1, 2, and 3 cm, respectively.

Thereafter, the catheters are connected to the after loader, and a dry run is performed without a radiation source to ensure that there are no kinks or other obstacles to successful delivery. The room is evacuated, and appropriate video surveillance of the patient is confirmed. Radiation delivery can subsequently commence. Total treatment time is dictated by the prescription dose, the size of treatment area, and the activity of the source. At our institution, we use an ^{192}Ir source, which has a half life of 73 days.

DOSING

Given that IORT consists of high doses of radiation administered at one time, the biological effective dose of a given IORT prescription dose is significantly higher than an equal EBRT dose administered in a fractionated manner. Conversion factors between IORT and fractionated EBRT doses are primarily derived from in vitro data and animal studies and therefore must be interpreted with some caution. Nevertheless, Table 1 provides helpful estimates for IORT dose conversions. In general, multiplication of an IORT dose by 2.3 to 2.5 yields a rough estimate for an equivalent fractionated EBRT dose to tumor, whereas multiplication of an IORT dose by 3 yields a rough estimate for an equivalent fractionated EBRT dose to normal tissue.

TABLE 1 Conversion Estimates Between IORT and EBRT Doses

IORT Dose	EBRT Tumor Dose	EBRT Normal Tissue Dose (Acute)	EBRT Normal Tissue Dose (Late)
10 Gy	17 Gy	30 Gy	30 Gy
15 Gy	31 Gy	37 Gy	45 Gy

EBRT, external-beam radiation therapy; IORT, intraoperative radiation therapy.

NORMAL TISSUE TOXICITY

Data describing normal tissue toxicity from IORT come primarily from canine models. In general, EBRT for pancreatic cancer will approach the radiation tolerance of bowel, so great effort should be made to limit any further bowel exposure from IORT to minimize the risk of late bowel toxicity such as obstruction, ulceration, perforation, or fistula. Sites used for anastomotic creation should be avoided in particular. As opposed to HDR brachytherapy, IORT may allow for minimization of dose to anastomotic sites.

Dose to the ureter, although usually less relevant to the treatment of pancreatic cancer, should also be minimized because excessive dose to the ureter can result in ureteral stenosis. In canine models, IORT doses above 10 Gy in combination with EBRT doses of 50 Gy led to significant risk of luminal stenosis. Although typical IORT prescription doses tend to be below 10 Gy, effort should still be made to shield the ureter.

Vascular structures have a higher radiation tolerance compared with bowel and ureter. Nevertheless, at high IORT and EBRT doses, clinically significant luminal hyperplasia and medial wall fibrosis have been described, with the potential for subsequent complications including arterial thrombus. Although these risks tend to be less apparent at the IORT and EBRT doses used in the abdomen, caution should nonetheless be taken, particularly if the patient has received prior courses of radiation.

Last, patients should be counseled on the risk of neuropathy, which tends to occur with IORT doses in excess of 15 Gy. For pancreatic IORT, the effect on wound healing should be less relevant compared with IORT in more superficial sites, with modern series from MGH showing no increase in wound complications in patients receiving IORT.

CONCLUSIONS

IORT represents a potential treatment option for decreasing local recurrence in pancreatic patients with resected or unresectable disease, particularly when administered as a boost in combination with other preoperative or postoperative EBRT. Successful delivery of IORT requires a joint effort between the surgical oncologist and radiation oncologist to ensure appropriate targeting and minimization of radiation exposure to surrounding structures. In the era of contemporary multiagent systemic therapy leading to better systemic control, IORT can serve as a tool to provide more durable local control for this disease.

Pancreas Transplantation

Joseph R. Scalea, MD

Pancreas transplantation is the only diabetes treatment that restores normal glucose homeostasis without the complications of severe hyperglycemia or hypoglycemia. Furthermore, pancreas transplantation may stabilize if not improve diabetic complications. Pancreas transplantation has been referred to as a diabetes cure. It is an elegant, technically challenging operation typically performed along with a kidney transplant. The most recent data suggest that combined kidney and pancreas transplantation is the ideal treatment for patients with diabetes and end-stage kidney disease.

HISTORY AND NATIONAL TRENDS

Diabetes mellitus was frequently fatal before the Nobel prize–winning work of Banting and Best. With the knowledge that insulin was critical to survival, success with the first kidney transplant in 1954 began interest in transplantation of the pancreas. Pancreas transplantation was first successfully performed in 1966 at the University of Minnesota by Kelly and Lillehei. A great deal of effort was expended by pioneers of pancreas transplantation to overcome initial poor outcomes. As technical improvements took hold, so too did improvements in pharmacologic immunosuppression, allowing the practice of pancreas transplantation to blossom into the early 1990s. In 2006, the United States saw a peak of volume in pancreas transplant procedures. During that year, nearly 1000 combined kidney pancreas transplants were performed. Despite dramatic improvement in patient and graft survivals, surgical volumes began to decrease. The reasons for decreased volumes are multifactorial but include a lack of appropriate training. As such, this chapter will focus on standard techniques for pancreas transplantation that can be safely performed by competent residents and fellows under appropriate guidance.

INDICATIONS

With rare exception, pancreas transplantation is performed for patients with diabetes mellitus. The vast majority of patients who undergo pancreas transplantation are type 1 diabetic. (Table 1); however, it is now recognized that type 2 diabetics may enjoy excellent outcomes after pancreas transplantation. The most basic tenet of assessing a patient's candidacy for pancreas transplantation is a determination of whether insulin produced by the transplanted pancreas will benefit the recipient. Presuming medical clearance, patients with classic type 1 diabetes are ideal candidates for the operation. Patients who produce large amounts of insulin, as is typically determined by C-peptide level, are likely not ideal candidates for pancreas transplantation.

C-peptide is a molecule produced from the enzymatic cleavage of pro-insulin and is produced in equimolar amounts to insulin. C-peptide level has been adopted by the transplant community as a diagnostic tool for the assessment of type 1 versus type 2 diabetes. Insulin (and thus, C-peptide) levels are downregulated after exogenous insulin administration. Further, insulin and C-peptide levels are increased after eating; thus, timing of C-peptide measurement is potentially important. In Scandinavia, however, where type 1 diabetes is two to three times more common than it is in the United States, population studies have shown that random C-peptide level measurement is an acceptable test for diagnosing type 1 diabetes. According to the United Network for Organ Sharing, a C-peptide level of less than 2.0 classifies patients as having type 1 versus type 2 diabetes.

Diabetes Type 1 and 2

Our understanding of type 1 and type 2 diabetes is changing; however, it is important to recognize that to the most basic physiology, diabetes is a spectrum of disease. The traditional model of diabetes development suggesting that a patient's finite number of islets are destroyed by autoimmune responses initiated by an inflammatory event (e.g., cocksackievirus, cow's milk), is now thought to be incomplete. More recently, in the modern model, we recognize diabetes as a complex process of autoimmunity and sensitivity of beta cells to inflammatory injury, which over a variable period, leads to loss of insulin production and absence of insulin and C-peptide production. It is also thought the development and timing of islet antibodies are associated with time of diabetes onset and perhaps diabetes type. Classic type 2 diabetes generally refers to insulin resistance and is associated with the metabolic syndrome. Nonetheless, patients with type 2 diabetes now enjoy similar graft survivals when compared with patients with type 1 diabetes.

Diabetes "Type 1.5"

Patients may have findings of both type 1 and type 2 diabetes. These patients may be diagnosed as having diabetes 1.5 or latent

CONCLUSIONS

IORT represents a potential treatment option for decreasing local recurrence in pancreatic patients with resected or unresectable disease, particularly when administered as a boost in combination with other preoperative or postoperative EBRT. Successful delivery of IORT requires a joint effort between the surgical oncologist and radiation oncologist to ensure appropriate targeting and minimization of radiation exposure to surrounding structures. In the era of contemporary multiagent systemic therapy leading to better systemic control, IORT can serve as a tool to provide more durable local control for this disease.

autoimmune diabetes of the adult (LADA). As many as 20% of patients diagnosed with type 2 diabetes, may be more accurately diagnosed as having LADA, or type 1.5 diabetes. LADA shares genetic similarities with type 1 and type 2 diabetes and is likely the most common form of autoimmune diabetes in general. Patients with diabetes 1.5 are diagnosed later in life, when compared with type 1, but earlier than for type 2 diabetes. Many of these patients are good candidates for pancreas transplantation. For example, these patients may have detectable C-peptide, but a low body mass index and an insulin requirement of less than 0.5 units/kg per day. For the purposes of this chapter (and for understanding a patient's potential candidacy for pancreas transplantation), it is important to assess physiology, rather than simply relying on a diagnosis of type 1 or type 2. Selected attributes of candidacy for pancreas transplantation are shown in Table 2.

Other Elements of Candidacy

Pancreas transplantation is not performed for pancreatic cancer. Pancreas transplantation was initially considered only for young patients (age <40 years). However, chronologic age alone should no longer determine candidacy. In rare cases, patients with pancreatic exocrine deficiency can be transplanted with a pancreas for nutritional and digestive benefits. These patients make up less than 1% of those transplanted. Pancreatogenic diabetes, or type 3c diabetes (e.g., pancreatic resection, cystic fibrosis, chronic pancreatitis) is also an indication for pancreas transplantation. Seven percent of patients transplanted with a pancreas received the organ not for diabetes but as part of a multivisceral transplant operation (liver + small bowel, etc.).

RECIPIENT WORKUP

Because approximately 80% of pancreas transplant recipients also have kidney failure (or a prior kidney transplant), pancreas transplant candidates uniformly fall into the highest preoperative cardiac risk category according to the revised Lee classification (also known as the revised cardiac risk index). For this reason, pancreas transplant candidates frequently require pretransplantation coronary artery architecture assessment, using computed tomography (CT) imaging or coronary angiography. At my center, pancreas transplant candidates undergo CT imaging and calcium scoring by the Agatston method. If the score is greater than 360, patients are referred for left heart catheterization. Historically, pancreas transplant candidates

TABLE 2 Attributes of Candidacy for Pancreas Transplantation

Factor	Candidacy
BMI	
<18	Likely favorable, nutrition consult
18–30	Favorable
30–35	Likely favorable
>35	Potential candidate, rule out significant insulin resistance
C-PEPTIDE	
<2.0	Favorable
2.0–10.0	Likely favorable
>10.0	Potential candidate, rule out significant insulin resistance
AGE (Y)	
<18	Select cases are reasonable
18–65	Favorable
>65	Potentially unfavorable, address cardiac status aggressively
IDDM	
Yes	Favorable
No	Not a candidate
CORONARY CALCIFICATION	
Mild	Favorable
Moderate	Likely a candidate, aggressive cardiac clearance
Severe	Potential candidate, unfavorable, aggressive cardiac clearance
INSULIN DOSE

0.5–1.0 U/kg/day	Likely favorable
>1.0 U/kg/day	Potential candidate, may indicate significant insulin resistance, address BMI

BMI, body mass index; IDDM, insulin-dependent diabetes mellitus.

have a more than 10% rate of cardiovascular complications after surgery, but this can be minimized with a rigorous workup and with careful patient selection.

Atherosclerosis is a systemic, inflammatory process. Thus, just as patients with diabetes are at risk for coronary disease, pancreas transplant candidates are at high risk for calcifications and luminal narrowing of the iliac arteries. CT imaging of the iliac arteries should be performed in advance of transplantation. It is also important to assess microvascular diabetic complications. Diabetic intestinal dysmotility and gastroparesis can be particularly challenging after surgery because the recipient jejunum is used to drain the exocrine secretions of the transplanted pancreas. Patients with severe pretransplantation gastroparesis may experience prolonged ileus after surgery. This complicates recovery because these patients may have difficulty taking, absorbing, and retaining appropriate levels of important medications such as tacrolimus or mycophenolate mofetil.

TABLE 3 Percentage of Pancreas Transplants Performed With and Without a Kidney

Operation	2017*	2005–2014†

†Gruessner AC, Gruessner RW. Pancreas transplantation of US and non-US cases from 2005 to 2014 as reported to the United Network for Organ Sharing (UNOS) and the International Pancreas Transplant Registry (IPTR). Rev Diabet Stud. 2016;13(1):30–38.

PAK, pancreas after a kidney transplant; PTA, pancreas transplantation alone.

OPERATION TYPES

The most common form of pancreas transplantation is simultaneous pancreas and kidney (SPK) transplantation (Table 3). Solitary pancreas transplantation in the form of a pancreas after a kidney transplant or pancreas transplantation alone (PTA) are also performed. All forms of transplantation require potentially nephrotoxic immunosuppression, and thus PTA has slowly fallen out of favor. If a diabetic patient already requires a kidney transplant, the immunosuppression required for the kidney (and thus the pancreas) is a foregone conclusion. On the other hand, there is a potential risk of kidney failure in patients who undergo PTA. Accordingly, PTA is reserved for type 1 diabetic patients with impeccable kidney function but who have fragile diabetes not manageable with insulin alone. The most common indication for pancreas transplant alone is hypoglycemic unawareness.

TECHNICAL PANCREAS TRANSPLANTATION

Pancreas transplantation consists of three parts. These are: (1) donor organ procurement, (2) donor pancreas preparation, or the "back table" operation, and (3) pancreas transplantation. Again, the vast majority of pancreas transplantations are performed along with a kidney transplantation (described elsewhere in this text). Perhaps unlike other forms of organ transplantation, a great deal of time and effort is required for donor pancreas procurement as well as back table organ preparation. Very little dissection and back table preparation are required for hearts, lungs, kidneys, and variably for livers. However, the dissection alone during pancreas recovery surgery can exceed 60 minutes and the back table procedure frequently takes 120 minutes.

Part 1: Donor Organ Procurement

A midline laparotomy provides access to the abdominal organs. A sternotomy allows access to the chest, but also improves abdominal exposure. Occasionally, recovery teams will also make a transverse cruciate incision at the level of the umbilicus, depending on the visualization required and the instruments available.

First, the surgeon focuses on gaining access to the aorta and the inferior vena cava. To do so, the surgeon mobilizes the right colon and the hepatic flexure. The cecum is elevated, and the peritoneal attachments are divided from lateral to medial. This dissection is limited to the superior mesenteric artery (SMA). Next, a Kocher maneuver is performed to gain access to the vena cava and to the left renal vein, which is present in 95% of patients. Once complete, the right colon should be a mid line structure. A moist towel is then used to bundle the intestines, improving surgical ergonomics. Once bundled, medical students typically enjoy retracting (spiritual) while standing on the donor's left. This gives the primary surgeon, on the patient's right, easy access to the aorta and the inferior vena cava.

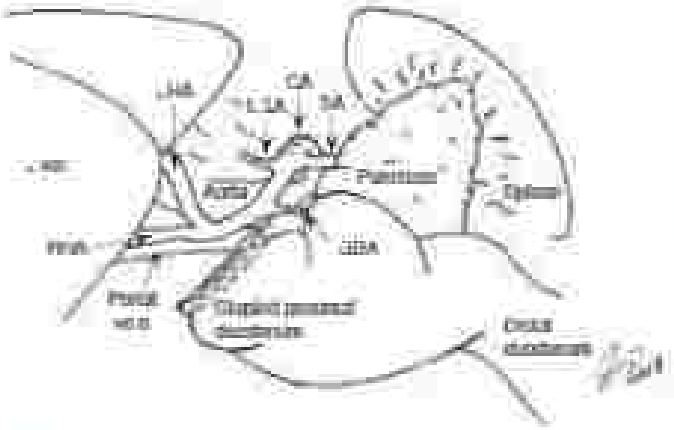

FIG. 1 Surgeon's view of the pancreas and liver during recovery. The surgeon will find the splenic artery at the superior aspect of the body of the pancreas. The splenic artery (SA), the gastroduodenal artery (GDA), the portal vein, and the bile duct (not pictured) need to be divided to separate the liver from the pancreas. *CA*, celiac axis; *LGA*, left gastric artery; *LHA*, left hepatic artery; *RHA*, right hepatic artery.

The aorta is then dissected inferior to superior, beginning at the bifurcation, and the inferior mesenteric artery is divided between heavy silk sutures. The dissection is carried out to the level of the SMA, taking care to identify and mobilize the left renal vein, which is less than 1 cm from the SMA, just anterior to the aorta.

Either before or immediately after the dissection of the aorta and left renal vein, the recovering surgeon will prepare the distal aorta for cannulation. Due to done early in the recovery because if the donor becomes hemodynamically compromised, the organs can be flushed quickly. Thus, the aortic bifurcation is dissected circumferentially. Heavy ligatures, or umbilical tapes, are used instead of heavy silk suture or vessel loops because the entire aorta will need to be ligated later in this case. Once the ligatures or umbilical tapes are placed beneath the bifurcation, the ends are tagged with Mixter tips, and focus is redirected toward completion of the organ recovery dissection.

By convention, the liver is addressed first. The liver dissection is important in the context of pancreas recovery for two reasons: (1) the splenic artery, which arises from the celiac trunk, supplies the tail of the pancreas; and (2) the potential for a replaced right hepatic artery (10%–20% incidence) most commonly arises from the proximal SMA, just beneath the pancreas. The SMA supplies the pancreatic head.

The splenic artery must be divided (after cross clamp) to separate the liver from the pancreas. As the liver surgeon dissects free the common hepatic artery, toward the aorta, the splenic artery will be identified at the superior aspect of the body of the pancreas. It will course inferiorly, and typically orthogonal to the common hepatic artery (Fig. 1). The splenic artery should be dissected free approximately 1 cm from its takeoff of the celiac axis to (after cross clamp) safely divide it without affecting the liver's blood supply. In general, the length of the divided splenic artery that accompanies the pancreas is unimportant, because the inflow to the pancreas will be reconstructed on the back table using donor iliac artery.

The pancreas is addressed after the liver dissection. There are several ways to approach the pancreas. We begin with the spleen. The spleen is recovered en bloc with the pancreas, and the transplanting surgeon removes it on the back table. Notably, a small number of donors are asplenic as a result of trauma, or for medical reasons. This should not preclude donation but should raise a flag of concern that anatomic abnormalities may disallow safe pancreas recovery.

The surgeon, standing on the right, grasps the spleen and gently retracts medially. Cautery is used to incise the posterolateral peritoneum. This should be bloodless because there are no named vessels in

FIG. 2. (A) Normal pancreas. (B) Fatty pancreas.

thin tissue. The dissection is continued both superiorly and inferiorly. The splenocolic ligament is divided as well, and the spleen is then mobile.

With the mesentery flat, the gastrocolic ligament, at the inferior aspect of the stomach, is divided. The division of multiple small branches of the left gastroepiploic artery can be performed with energy devices or between ties. Division of the gastrocolic ligament provides access to the anterior aspect of the pancreas. At this point, the spleen and pancreatic tail are mobile enough to begin posterior dissection.

Next, the surgeon divides the gastrosplenic ligament as well as the short gastric vessels. This may require ties and is frequently difficult in a donor with a high body mass index. Next, the spleen is progressively elevated, and the avascular plane between the pancreas and the retroperitoneum is divided, using cautery. This is critical because the splenic vein can be injured if the surgeon is in the wrong plane. The splenic vein should accompany the pancreas and the adrenal should remain in the donor. If done well, this too is bloodless. Moving lateral to medial, the limit of the dissection is the SMA.

The stomach is then divided proximal to the pylorus. On occasion, as in Fig. 1, the surgeon may feel comfortable dividing the proximal duodenum distal to the pylorus. Before division, the surgeon requests that the organ recovery staff infuse into the donor's nasogastric tube the pancreas recovery cocktail that includes antibiotics and antifungals. Next, two green loads of large TA stapler are used to divide the stomach. The stomach is then retracted cephalad, and the remaining soft tissue between the lesser curvature and the pancreas, in addition to the right gastric artery, are divided. The stomach is then tucked up and out of the way into the left upper quadrant for the remainder of the case.

At this point, the pancreas is free with the exception of the portal vein, the SMA, splenic artery, and the proximal jejunum with its mesentery. The bile duct will have been divided by the liver surgeon. Once the recovery teams are ready, the distal aorta is ligated, and the aortic cannula is inserted and tied with umbilical tapes. A portal infusion cannula is then frequently placed into the inferior mesenteric vein (IMV). Some pancreas transplant surgeons prefer an IMV cannula be placed, but rather portal flush directly through the portal vein. The reason for this is that, theoretically, IMV flushes may cause pancreatic edema. However, in my experience, IMV placement has little or no effect on the pancreas and is safer and easier than a portal flush. With cannulae in place, 30,000 units of heparin are administered. Three minutes later, the aorta is clamped in the chest, and the retrograde aortic infusion of University of Wisconsin (UW) solution commences.

The liver is removed first. To do so, the splenic artery is divided immediately before division, the pancreatic portion of the splenic artery should be tagged with a 5-0 or 6-0 Prolene stitch because it may retract into the soft tissues of the pancreas and become cumbersome to identify on the back table. The portal vein is divided with scissors at the coronary vein. The jejunum is stapled with a GIA blue. Next, the small bowel mesentery is divided with a vascular load. The SMA is divided with scissors. The pancreas is passed off the field and assessed for transplantability. The pancreas should be stored in UW solution at 4°C. There are data to suggest that other preservation solutions, such as histidine-tryptophan-ketoglutarate, are unsafe for pancreas preservation. The gland should be transplanted in less than 12 hours (24 hours maximum) for the optimal results. The pancreas should pass the Oglaten test to ensure transplantability. To pass the test, the pancreas should be supple enough to hang gently over the surgeon's index finger. Whereas a high-quality pancreas will easily bend, the firm, fatty pancreas will remain stiff.

If the donor has a replaced right hepatic artery, the liver surgeon should divide the SMA (with the pancreas surgeon holding retraction) above the level of the replaced right as it exits the SMA. Enough distal artery on the SMA should accompany the liver such that a Hartert's reconstruction (covered elsewhere) can be performed. Replaced right hepatic arteries should not preclude pancreas recovery unless the takeoff of the replaced right hepatic artery is deep within the pancreatic parenchyma.

Part 2: Back Table Preparation

The pancreas is nearly always accompanied by the spleen. The first maneuver on the back table is to remove the spleen. The splenic artery and vein are large and require heavy ties. The smaller vessels can be ligated with small clips, energy devices, or ties. One center prefers silk ties.

Young donor pancreata are typically free of fat (Fig. 2A). Older, heavier pancreas donors may have peripancreatic fat, which needs to be removed from the tail and body of the pancreas (Fig. 2B). Small vessels in this tissue should be addressed. Conservatively, fatty pancreata should be avoided, but with short cold ischemia times they are likely reasonable for the right recipient.

The proximal intestine inclusive of the pylorus is removed by resecting. The staple line is oversewn with interrupted silk 3-0 sutures or running 3-0 Prolene. Similarly, the distal duodenum is also resected, such that the remaining duodenal C loop is approximately 6 to 12 cm in length. Too much redundant donor intestine is not useful and may become problematic postoperatively. The distal staple line is

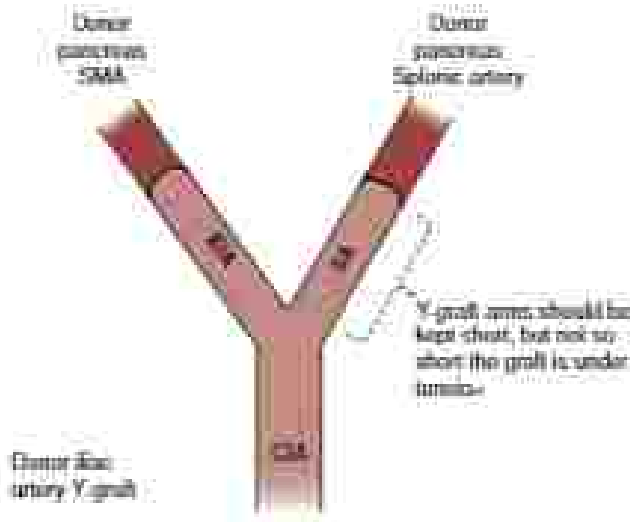

FIG. 3 Donor iliac artery Y-graft. The donor superior mesenteric artery is sewn to the donor external iliac artery and the donor splenic artery is sewn to the donor internal iliac artery. The graft is portioned through the donor Y-graft common iliac artery (CIA). EIA, external iliac artery; IIA, internal iliac artery; SMA, superior mesenteric artery.

reservoir with interrupted silk sutures as well. In the authors' experience the purpose of oversewing is for hemostasis rather than leak prevention. Depending on the recovery team, the transplanting surgeon may also desire to oversew or to reinforce the small bowel mesentery. This is a frequent source of bleeding after reperfusion.

The blood supply to the transplanted pancreas is dual via the SMA and splenic arteries. Thus, the arterial inflow requires reconstruction on the back table. To do so, the iliac arterial system is recovered from the pancreas donor. The iliac artery is referred to as a Y-graft. The external iliac artery typically has a smaller diameter than the external, and is thus sewn to the splenic artery, end to end, using a 6-0 or 7-0 Prolene. Thereafter, the external iliac artery is sewn end to end with the SMA, using a 6-0 or 7-0 Prolene. Each arm of the Y should be short (Fig. 3), to avoid unnecessary decreases in resistance to flow as well as kinking after implantation. These anastomoses are large and represent a good opportunity to teach residents and fellows.

The prudent surgeon will leak test the pancreas, paying special attention to the lymphatic and ganglial tissue between the arms of the Y graft. There are frequently small vessels in this area which can be incredibly difficult to manage after reperfusion.

Part 3: Transplantation of the Pancreas

There are several ways to perform a simultaneous pancreas and kidney transplant. For example, the pancreas can be transplanted before or after the kidney. Both organs can be placed unilaterally (usually on the right), or with the pancreas on the right and the kidney on the left. In rare situations, the pancreas is placed on the left. My standard approach is for the pancreas to be placed on the right (before the kidney) and the kidney on the left. This involves dissection of both iliac systems, which is important because if the patient needs a future transplant, neither side is virgin. The benefit of the unilateral approach is that the left side is untouched and is open for a future organ if required. In solitary pancreas transplantation, the pancreas is usually placed on the right.

A pancreas transplant is typically performed through a midline incision. Gibson incisions can be used in this case because the peritoneum needs to be accessed to complete the bowel anastomosis. It is important to make sure the incision allows access to the bladder for an SPK. Thus, the incision frequently descends right to the level of the pubis. In heavier patients, it is best to use a full laparotomy incision (i.e., to the xiphoid) because it can be quite challenging to retract epithelial fat to the side.

First, the right colon is fully mobilized to include the hepatic flexure. In thinner patients, a bit less mobilization is required. A partial Kocher's maneuver may be required so that the surgeon will have access to the anterior surface of the inferior vena cava. The peritoneal attachments beneath the colon are divided to the SMA, as was done in the donor operation. A Steinmann pin (metal lap pad unfolded and rolled up like a cigar) is then placed at the base of the mesentery, and a moist towel is used to cradle the intestines. The intestines are then retracted to the left upper quadrant, usually with a large malleable or the Bookwalter retractor or with Martin arms.

The right common iliac artery is dissected free, as is the anterior surface of the inferior vena cava. The two vessels are separated. The separation of the right common iliac artery from the vena cava and right common iliac vein can be precarious, so the surgeon should proceed cautiously. During this step of the operation, the recipient's native ureter and gonadal vein should be retracted laterally. Meticulous hemostasis of the retroperitoneum should be achieved prior to transplanting the pancreas, because it can be challenging to see the retroperitoneum after the gland is in place.

The pancreas, in an ice filled bag, is held outside the wound, upside down, and head up. The pancreas is positioned upside down for ease of access to the portal vein. A cantomy is fashioned and the vein flushed with heparinized saline. The portal vein is then sewn to the inferior vena cava using two running 6-0 Prolene stitches. For a pediatric pancreas, a 7-0 Prolene may be used in all cases, because the size of the anastomosis is substantial. In my experience, a shouldered approach to the backwall of the pancreatic portocaval anastomosis is more hemostatic. A bull dog is then placed across the donor portal vein, and the Satinsky clamp is removed to ensure hemostasis of the anastomosis before the artery is sewn.

Proximal and distal control of the common iliac artery are obtained with Debarty (or other) vascular clamps. An arteriotomy is fashioned and the blood vessel flushed with heparinized saline. A single 6-0 Prolene suture is typically used to fashion a running end-to-side anastomosis.

Before reperfusion, the surgeon should communicate with the anesthesia staff. The cold UW fluid in the pancreas can lead to arrhythmias in the recipient after reperfusion. The reperfusion event is generally more substantial than observed with a kidney transplant, but far less so than with a liver transplant. The pancreas is reperfused by first releasing the portal venous bull dog clamp. Large bleeders, if present, are dealt with thereafter, the distal followed by the proximal arterial clamps are released.

Next, a loop of small bowel 40 cm distal to the ligament of Treitz is identified. A side to side, handsewn donor duodenum to recipient jejunum anastomosis is performed. The outer layer is completed with narrowly spaced 3-0 silk sutures. The inner, full thickness layer is generally completed using a double armed 3-0 PDS suture. Hemostasis is achieved by carefully rotating the pancreas back and forth. Small bleeders between the arms of the arterial Y graft can be challenging to see and manage. For these, interrupted 7-0 Prolene repair stitches are ideal.

If an SPK is being performed, and the pancreas is transplanted first, urethral obstruction of inflow and outflow of the pancreas should be avoided while repositioning the ureters for the kidney transplant. The end to side venous anastomosis is performed first, using running 6-0 Prolene suture. Next, an end to side arterial anastomosis is performed using a single running 6-0 or 7-0 Prolene suture. The organ is then reperfused. The arterial anastomosis is performed second to stasis and is completed with 6-0 PDS suture. Most kidney transplant ureteroneocystostomies are performed over a ureteral stent.

Technical Caveats of Pancreas Transplantation

Portal-Venous Drainage

In the procedure described previously, the venous outflow of the pancreas was portocaval. This, however, differs from native anatomy

whereas the venous effluent from the pancreas undergoes first pass metabolism in the liver. During this process, as much as 50% of circulating insulin are removed from the bloodstream. This is potentially important, because systemically drained pancreas recipients may have hyperinsulinemia. Dr. Stephen T. Bartlett helped popularize the technique and showed that portal drainage may yield a lower rate of rejection, perhaps as a result of antigen clearance through the liver.

For portal venous drainage, the portal vein of the donor pancreas can be sewn to the superior mesenteric vein (SMV) of the recipient. This technique is best used in thinner patients, in whom the mesentery is not particularly thick. The SMV is identified in the small bowel mesentery, to the right of midline. Small branches of the SMV may need to be controlled (but not ligated) for sufficient access and visualization. The portal vein is sewn end to side using running Prolene suture. The pancreas will sit high in the mesentery. As a result, the iliac artery Y graft is longer to reach the recipient common iliac artery.

Bladder Drainage of Exocrine Secretions

Bladder drainage was popularized in the mid-1980s by a pioneer of pancreas transplantation, Dave Sollinger. The use of bladder drainage allowed for safe management of pancreatic exocrine secretions in the early postoperative course. Further, bladder drainage allowed for diagnosis of rejection via urinary amylase. However, long-term complications such as bicarbonate loss and cystitis led to the eventual adoption of enteric drainage as the superior technique. Accordingly, many centers stopped routinely performing bladder-drained pancreas transplants in the mid-1990s. The technique, which is not technically dissimilar from enteric drainage requires that the pancreas be placed head-down, as opposed to head-up, as were described previously. Many of the patients who underwent bladder drainage of the pancreas were converted successfully to enteric drainage in the years after their pancreas transplants.

Transmesenteric Pancreas Transplantation

Full mobilization of the right colon can be avoided by performing a transmesenteric approach to the right iliac vessels. Although this minimizes the dissection of the right colon, a transmesenteric approach may require an extension of the donor portal vein using donor iliac vein. Some surgeons are wary of donor portal vein extensions as they may be prone to thrombosis.

Duration After Circulatory Death Versus Brain Dead Donors

Duration after circulatory death (DCD) implies that a person is not brain dead at the time of organ allocation. Thus, life support for these donors is withdrawn, and only once the patient is declared deceased can the organs be removed. In the DCD scenario, the blood pressure and heart rate decrease at variable rates during which time donor organs may experience ischemic damage. The use of pancreata from DCD donors is not worse than for brain dead donors. Surgically, organs are removed rapidly during DCD procurement to minimize surgical tissue injury. Thus, ensuring that the pancreas is recovered quickly (less than 30 minutes of warm ischemia time, and expeditiously after aortic cross clamp) while free from technical injury is important.

Stapled Versus Hand-Sewn Anastomoses

The duodenojejunostomy described previously does not tend to be handsewn. Described by Prudell et al, a stapled duodenoenterostomy can be performed by inserting an EEA stapler through one end of the donor duodenum. Thereafter, the open end can be itself stapled using a GIA stapler. Other stapled techniques have also been described.

Robotic Pancreas Transplantation

The techniques described previously are open. Minimally invasive techniques are challenging in transplantation, because at some point, an incision big enough to allow for organ insertion is required. Nonetheless, robotic minimally invasive SPK has been done and with encouraging results. These techniques are particularly helpful when the recipients are obese. A portion of the benefit for minimally invasive techniques is attributed to a reduction in wound complications after surgery.

Perioperative Management

Pancreas transplant patients are at risk for bleeding, reperfusion injury, thrombosis, and infection. The surgeon should closely monitor recipient blood counts in the hours after surgery. Reperfusion injury severity is reflected in serum amylase and lipase elevation, which may reach 20 to 30 times the upper limit of normal. Lipase should begin to clear rapidly (~12–24 hours), presuming adequate renal function. Pancreas transplantation is associated with a higher rate of thrombosis than with other solid organs. Rapid blood sugar elevation may indicate thrombosis. To avoid thrombosis, care providers at the author's institution are directed to maintain mean arterial pressure above 75 mm Hg in the 72 hours after surgery. In addition, aspirin 81 mg on postoperative day 1 is initiated if bleeding has not occurred. If there is concern for thrombosis, a bedside ultrasound is likely sufficient to make the diagnosis. Infection may occur in the first several weeks after pancreas transplantation. Retroperitoneal abscesses are particularly troublesome because they sit atop the aorta and inferior vena cava, and adjacent to the pancreatic T graft.

RESULTS

In the initial series, fewer than 10% of pancreas transplants survived a year. In the most recent studies, 1 year SPK patient survival rates are 97.4%. In addition, 1 year pancreas graft survival rates are 91.3% and 1 year SPK kidney graft survival rates are 95.5%. The increases in pancreas graft survival were driven, in part, by reduced rates of technical graft loss. High resolution immunologic testing has reduced the rate of rejection, which remains higher after pancreas transplantation than for kidney transplantation alone. There is not 100% concordance with rejection in the kidney versus the pancreas when the recipient undergoes SPK, and biopsy of both organs may be necessary to diagnose rejection.

Pancreas transplantation is superior to exogenous insulin with regard to glucose control. SPK is associated with longer patient survival than for kidney transplantation alone, regardless of whether the kidney alone donor was living or deceased. This finding is likely explained by very high quality organs for SPK donors, when compared with most kidney transplant alone donors (particularly deceased donors). Nonetheless, the elimination of diabetes for patients with kidney failure also contributes to prolonged patient and kidney graft survivals. Pancreas transplantation dramatically improves the quality of life for recipients. As a care provider, there are few experiences more gratifying than telling a patient's family their loved one's diabetes is gone.

Islet Autotransplantation for Chronic Pancreatitis

Charles G. Rickert, MD, PhD; Ji Lei, MD, MSc, MBA; and James F. Markmann, MD, PhD

In the United States, chronic pancreatitis (CP) currently affects approximately 42 in 100,000 individuals, resulting in $635 million in direct inpatient hospital costs. The disease is an irreversible, fibrotic condition of the pancreas resulting from long standing inflammation, which often results in disabling abdominal pain. The initial manifestation of CP in approximately 80% of patients is abdominal pain, often after eating, which radiates to the back and is relieved by sitting forward. It may be accompanied by nausea and vomiting. Throughout the course of the disease, it can progress from intermittent discomfort to continuous pain. Twenty percent of patients will first present with symptoms related to deficiency of endocrine or exocrine function, including severe malnutrition or the development of diabetes mellitus. However, overt diabetes is usually only a factor of late term disease or in patients with a family history of type 1 or type 2 diabetes mellitus. Beyond these symptoms directly related to the inflammation of the pancreas, CP can also result in splenic vein thrombosis, bile duct and duodenal obstruction, pseudocyst formation, ascites, pleural effusion, and pancreatic cancer.

The treatment options for this disease aim at reduction of pain and compensation of pancreatic insufficiency. Initial management focuses on medical therapy and lifestyle changes—cessation of inciting behavior, such as alcohol intake and smoking, eating small meals, and supplementing with medium chain triglycerides. Pain management is initially attempted through suppression of pancreatic exocrine secretion by providing exogenous supplement pancreatic enzymes. Many patients will ultimately rely on some combination of narcotic analgesia, nonsteroidal antiinflammatory drugs (NSAIDs), and low dose tricyclic antidepressant, typically amitriptyline. Some patients will undergo endoscopic decompression via pancreatic duct stent placement.

Operative management is generally considered for patients with medically refractory disease or when pancreatic cancer is suspected. The operative approach selected to treat this disease depends on the location and extent of the pancreatic inflammation. The approaches can be classified as decompression, denervation, and resection—partial or total. Decompression, for example through a Puestow procedure, can be highly effective in patients with refractory pain and a large, dilated pancreatic duct (>8 mm). Initial pain relief of operative decompression appears to be similar to endoscopic approaches, however, 5-year follow up suggests that surgery may be superior for long term management of pain. Denervation is performed by disruption of the celiac ganglion or splanchnic nerves through open or thoracoscopic operative approaches. Overall efficacy of this approach is still an active area of study.

Resection of inflamed pancreatic tissue is often utilized once other alternatives have been exhausted, due to the loss of pancreatic tissue and risk of both exocrine and endocrine pancreatic insufficiency. In a healthy individual, only about 20% of the normal pancreas is required to provide adequate function. However, in CP, much of the pancreas may be nonfunctional, and even a small loss of tissue may result in exocrine insufficiency or diabetes mellitus. Thus great care must be taken in determining which operation will lead to the best outcome for the patient. Operations to remove pancreatic tissue include pylorus preserving and nonpreserving pancreaticoduodenectomy (Whipple), Beger procedure, distal pancreatectomy, and total pancreatectomy (TP). Distal pancreatectomy is most limited in efficacy and reserved for disease that is limited to the body and tail of the pancreas. The Whipple operation provides additional pain relief, even with disease in the tail, secondary to denervation. Total pancreatectomy is the most complete removal of the inflamed tissue and has been shown to improve pain control when other options fail. This operation obligatorily results in exocrine and endocrine insufficiency. Autologous islets, purified from the removed pancreas, provide a potential means of avoiding the endocrine insufficiency of TP. Thus, for the proper patients, TP with islet autotransplantation (TP-IAT) provides the best opportunity for pain relief with minimized sequelae. While TP alone for CP has been performed since the 1940s, Sutherland and colleagues at the University of Minnesota first performed the pancreatectomy with the islet autotransplantation in 1977. Since then, it has expanded with nearly 20 centers now offering the operation. The University of Minnesota recently reported their 500th TP-IAT operation.

PATIENT SELECTION AND PREOPERATIVE EVALUATION

CP is a multifactorial disease that results in both loss of pancreatic function and severe abdominal pain. Proper workup of this disease requires careful assessment of the patient's symptoms, laboratory values, and radiographic findings. For most chronic pancreatitis patients, disease progression occurs over years and, therefore, extensive evaluation and monitoring has occurred prior to referral for surgical assessment. Typically, patients are referred for TP only after failure of less invasive surgical or endoscopic therapies. Delayed

Since then, it has expanded with nearly 20 centers now offering the operation. The University of Minnesota recently reported their 500th TP-IAT operation.

PATIENT SELECTION AND PREOPERATIVE EVALUATION

CP is a multifactorial disease that results in both loss of pancreatic function and severe abdominal pain. Proper workup of this disease requires careful assessment of the patient's symptoms, laboratory values, and radiographic findings. For most chronic pancreatitis patients, disease progression occurs over years and, therefore, extensive evaluation and monitoring has occurred prior to referral for surgical assessment. Typically, patients are referred for TP only after failure of less invasive surgical or endoscopic therapies. Delayed

criteria for TP IAT remain an area of active research and discussion; however, most centers adhere to the consensus guidelines established at PancreasFest 2012 (Box 1). When evaluating patients for TP IAT, it is generally recommended that a multidisciplinary team, consisting of pancreatic surgeon, transplant surgeon, endocrinologist, gastroenterologist, psychologist, social work, and nursing, evaluate the patient for optimal planning of the procedure.

Evaluation of a potential patient must begin with careful assessment of the patient's disease process. When considering any procedure performed to alleviate pain, it is important to first ensure that the patient's symptoms are the result of the disease targeted by the procedure. When considering a TP combination that the pancreas is the source of pain is particularly important because the pancreatectomy will result in loss of any residual pancreatic function. The IAT is utilized to abrogate the loss of endocrine pancreatic tissue, but the graft will be less than 100%, and thus the glucose control may worsen postoperatively.

Taking a careful history is important to understand the underlying etiology of the CP and extent of endocrine dysfunction preoperatively. The etiology can give insight into whether the CP is large or small duct, which can indicate whether a decompressive operation (e.g., Puestow or Frey) or more limited resection may be warranted. Individuals with a history of genetic risk factors for recurrent acute pancreatitis or CP, such as mutations in *CFTR* (cystic fibrosis transmembrane conductance regulator), *SPINK1* (serine protease inhibitor Kazal type 1), or *PRSS1* (cationic trypsinogen), should warrant careful consideration and potentially earlier intervention because of their lifetime risk of pancreatitis and pancreatic cancer. The patient should also be assessed for symptoms of hepatic disease and portal hypertension, as marked portal hypertension is a contraindication for intraportal infusion of islets. Additionally, history of systemic symptoms concerning for pancreatic neoplasm would warrant a more extensive workup. A complete patient history can also be valuable to understand comorbidities and social factors that may significantly impact perioperative care.

Laboratory testing for both exocrine and endocrine functioning should be performed pre-operatively. This includes glucose tolerance test, HbA1C, C-peptide, and fecal elastase measurement. Complete blood count, electrolytes, and liver function tests are also ordered. Most patients with longstanding CP will have some degree of glucose intolerance. The degree of intolerance is indicative of the number of functional islets present in the pancreas. The success of the IAT is highly dependent on the number of islets. Therefore, understanding the degree of islet dysfunction preoperatively will be important when discussing expectations with the patient and planning how to manage postoperative diabetes. There is no generally accepted threshold for pancreatic endocrine function that will dictate whether attempted IAT is appropriate. However, it is generally accepted that an elevated A1c portends poor glycemic control post TP IAT, and the absence of islet function, indicated by the lack of C-peptide production, is a contraindication to TP IAT. Many centers are now advocating for earlier referral, before other surgical interventions that will reduce residual islets, for TP IAT to increase the likelihood of achieving long-term glucose control without need for supplemental insulin.

Radiographic studies for chronic pancreatitis often consist of computed tomography, magnetic resonance imaging, endoscopic retrograde cholangiopancreatography, and/or endoscopic ultrasound. For operative planning, imaging to particularly valuable for assessing the extent of fibrosis (diffuse vs localized), ductal diameter, and evidence of neoplasm. Evidence of head- or tail-dominant disease may indicate that a nonlocal resection is warranted. If the ductal diameter is more than 5 mm, a decompression operation should be considered. Assessment for potential neoplasm is of the utmost importance because neoplastic disease could dramatically impact the extent of pancreatic resection and whether IAT is an option.

If splenectomy is anticipated as part of the pancreatectomy, appropriate preoperative vaccinations should be administered to reduce the risks of overwhelming postsplenectomy sepsis. These vaccinations included pneumococcus, meningococcus, and *H. influenza* type B.

BOX 1 Summary of Guidance Statements from PancreasFest 2012

Inclusion

1. The primary indication for TP IAT is to treat intractable pain in patients with impaired quality of life due to chronic pancreatitis or recurrent acute pancreatitis in whom medical, endoscopic, or prior surgical therapy have failed.

Exclusion

1. TP IAT should not be performed in patients with active alcoholism, active illicit substance use, or untreated/uncontrolled psychiatric illness that could be expected to impair the patient's ability to adhere to complicated medical management. Patients with poor support networks have a relative contraindication due to the cost and complexity of managing diabetes and pancreatic exocrine replacement therapies.
2. TP IAT should not be performed in patients with specific medical conditions, including C-peptide negative diabetes,[a] type 1 diabetes,[a] portal vein thrombosis, portal hypertension, significant liver disease, high-risk cardiopulmonary disease, or known pancreatic cancer.

Evaluation

1. The severity, frequency, and duration of pain symptoms, narcotic requirements, disability/impaired quality of life, residual islet function, rate of disease progression, and age of the patient should be considered in timing of the procedure.
2. Patients who meet inclusion criteria and who are not excluded should be evaluated by a multidisciplinary team, who will review alternative interventions, assess the likelihood of success in reducing pain and preventing or minimizing diabetes, follow the patient through the procedure and provide guidance for long-term care.
3. Evaluation should include confirming that pancreatitis is the primary diagnosis, determining that the pain is of pancreatic origin, monitoring for the presence of diabetes, assessing ß-cell mass (by C-peptide), and assessing the patency of the portal venous system, evaluating for liver disease, and determining the nutritional status.

Follow-up

1. Life-long monitoring for diabetes mellitus shall be performed at least annually and should include self-monitored blood sugar, fasting blood glucose, and hemoglobin A1c. These patients may be followed for ß-cell mass (by C-peptide).
2. Life-long pancreatic enzyme replacement therapy is mandatory. Nutritional monitoring should include assessment of macrocytosis, weight maintenance, and fat-soluble vitamin levels on an at least an annual basis.
3. A physician experienced in pain management should be part of the patient's care team following hospital discharge to assist with the tapering of narcotic medications.

[a]Candidate for total pancreatectomy alone. From Sellin MD, Freeman ML, Gelrud A, et al. Total pancreatectomy and islet autotransplantation in chronic pancreatitis: recommendations from PancreasFest. Pancreatology. 2014;14(1):22–36.

The evaluation process thus is focused on establishing that the patient has severe pain, which would likely improve from total removal of the pancreas, and that none of the contraindications are present (Box 1). Nearly every patient evaluated for a TP should be considered for IAT as well.

PROCEDURE: TOTAL PANCREATECTOMY, ISLET ISOLATION, PURIFICATION, INTRAPORTAL ISLET INFUSION

Definitive operative management of chronic pancreatitis by TP-IAT consists of three connected procedures: (1) TP; (2) islet isolation and purification; (3) infusion of purified islets into the portal circulation (Box 2).

Total Pancreatectomy

The operative approaches for TP for chronic pancreatitis vary between centers and include the traditional TP with splenectomy, as well as splenic preserving and pylorus preserving procedures. As opposed to TP for pancreatic cancer, the removal of the pancreas as part of TP-IAT necessitates minimization of warm ischemic time to ensure the greatest viability of the islets of Langerhans. For this reason, the ligation of the vascular flow to the pancreas is performed only after complete mobilization and preparation for removal, regardless of the specific TP procedure utilized. Early attempts to perform duodenal sparing procedures have been largely abandoned because of the longer warm ischemic time.

The typical approach involves taking down of the hepatocolic and hepatocolic ligaments to mobilize the transverse colon, entry of the lesser sac with direct assessment of the pancreas, medial mobilization of the pancreas and duodenum via Kocher maneuver and small bowel transection, mobilization of the body and tail of the pancreas with spleen, and finally, ligation of the pancreatic and splenic vasculature to undertake. It is also important to avoid injuring the gastric vasculature to decrease the risk of postoperative delayed gastric emptying. Some centers have developed laparoscopic approaches for the TP. The specimen is removed and immediately placed on ice and perfused with cold preservation solution.

Restoration of enteric continuity is achieved through the creation of a hepaticojejunostomy and end to side gastrojejunostomy (or duodenojejunostomy if pylorus preserving resection is performed). The proximal portion of the ligated bowel is mobilized and advanced to a retrocolic fashion and end to side anastomosis of the biliary system to the jejunum is performed. Depending on the site of the small bowel resection, this anastomosis may be between the biliary system and segments three or four of the duodenum. Antecolic gastrojejunostomy is then performed. Alternatively, some centers prefer a Roux-en-Y reconstruction. Additionally, some surgeons may elect to place gastrostomy and jejunostomy tubes during the operation to ensure postoperative nutrition and venting, if necessary for delayed gastric emptying postoperatively. A Blake drain is placed at the hepaticojejunostomy to monitor for possible leak and lymphatic drainage.

The open operative field is covered by a moist, saline soaked drsesing to maintain sterility during islet processing. During this time, patient temperature, electrolyte balances, and blood glucose levels should be closely monitored, and an insulin infusion started immediately after pancreatic resection to maintain serum glucose of 100 to 120 mg/dL. Multiple animal studies have demonstrated that hyperglycemia is detrimental to transplanted islet engraftment, and, therefore, euglycemia may be important for initial graft survival. Some centers prefer to close the abdomen after reconstruction of the gastrointestinal system, with planned percutaneous intraportal islet delivery.

Removal of the pancreas as a single specimen with intact pancreatic capsule allows for single duct infusion of collagenase and protease during the islet processing procedure (see later in the chapter) with more effective distention of the pancreas. Some centers prefer to remove the pancreas in two sections by first removing the distal pancreas and sending that portion to begin processing prior to removal of the head of the pancreas. The specific approach to pancreatic removal is dictated by the degree of pancreatic inflammation and fibrosis and any previous decompression or resection procedures. Studies have shown that between 10% and 20% of TP-IAT patients had previously had distal pancreatic surgery prior to TP-IAT. Regardless, the surgeon should adhere to the principle of decreasing warm ischemia by maintaining the vasculature until complete mobilization of the pancreas and immediate cold perfusion after removal.

BOX 2 Overview of TP-IAT Procedure

Total Pancreatectomy

1. Inspection and mobilization of the pancreas
2. Ligation of vasculature just prior to removal
3. Cold perfusion immediately after removal
4. Drain and gastrostomy/jejunostomy tube placement, if necessary
5. Close monitoring and control of blood sugars during islet isolation

Islet Isolation and Purification

1. Cannulation of pancreatic duct
2. Perfusion
3. Digestion
4. Purification
5. Quality assessment

Intraportal Islet Infusion

1. Catheter placement, splenic, umbilical, mesenteric, directly to portal vein
2. Systemic heparinization
3. Infusion of digested pancreatic islets
4. Portal circulation pressure monitoring; maintain below 20–25 mm Hg

Islet Isolation/Purification

The quality of islet preparation from the removed pancreas often determines whether the IAT will have the desired result of minimizing or eliminating the need for exogenous insulin after the TP. The key factors for success of the IAT are the underlying health of the pancreas, the optimization of islet preparation to minimize ischemic time and unnecessary handling, and the careful monitoring of the pancreas digestion to ensure maximal islet yield without significant enzymatic injury of the islets. With to the best-case scenario, the patient will not require exogenous insulin, often the goal is to provide the maximum number of recoverable islets to protect against life-threatening labile diabetes mellitus.

The processing of the pancreas begins in the operating room with removal of nonpancreatic tissue, including fat and the splenic vasculature that is often closely apposed to the pancreas. Depending on the comfort of the surgeon, the pancreatic duct may also be cannulated with a large bore angiocatheter prior to transport to a specialized islet processing facility (Fig. 1A, B). If any concern for local infection, once the pancreas has been cleared of nonpancreas tissue, it will be decontaminated using a solution containing povidone-iodine, Hank's buffered salt solution and cefazolin. An alternate broad spectrum antibiotic may be utilized depending on the patient's allergy history.

The decontaminated pancreas is then placed onto a perfusion tray in a tissue culture hood. Using an automated or manual perfusion system, the pancreas will be inflated with an enzyme mixture of collagenase and protease (Fig. 1C). Total perfusion takes approximately 10 minutes, with a goal of distending the pancreas while not

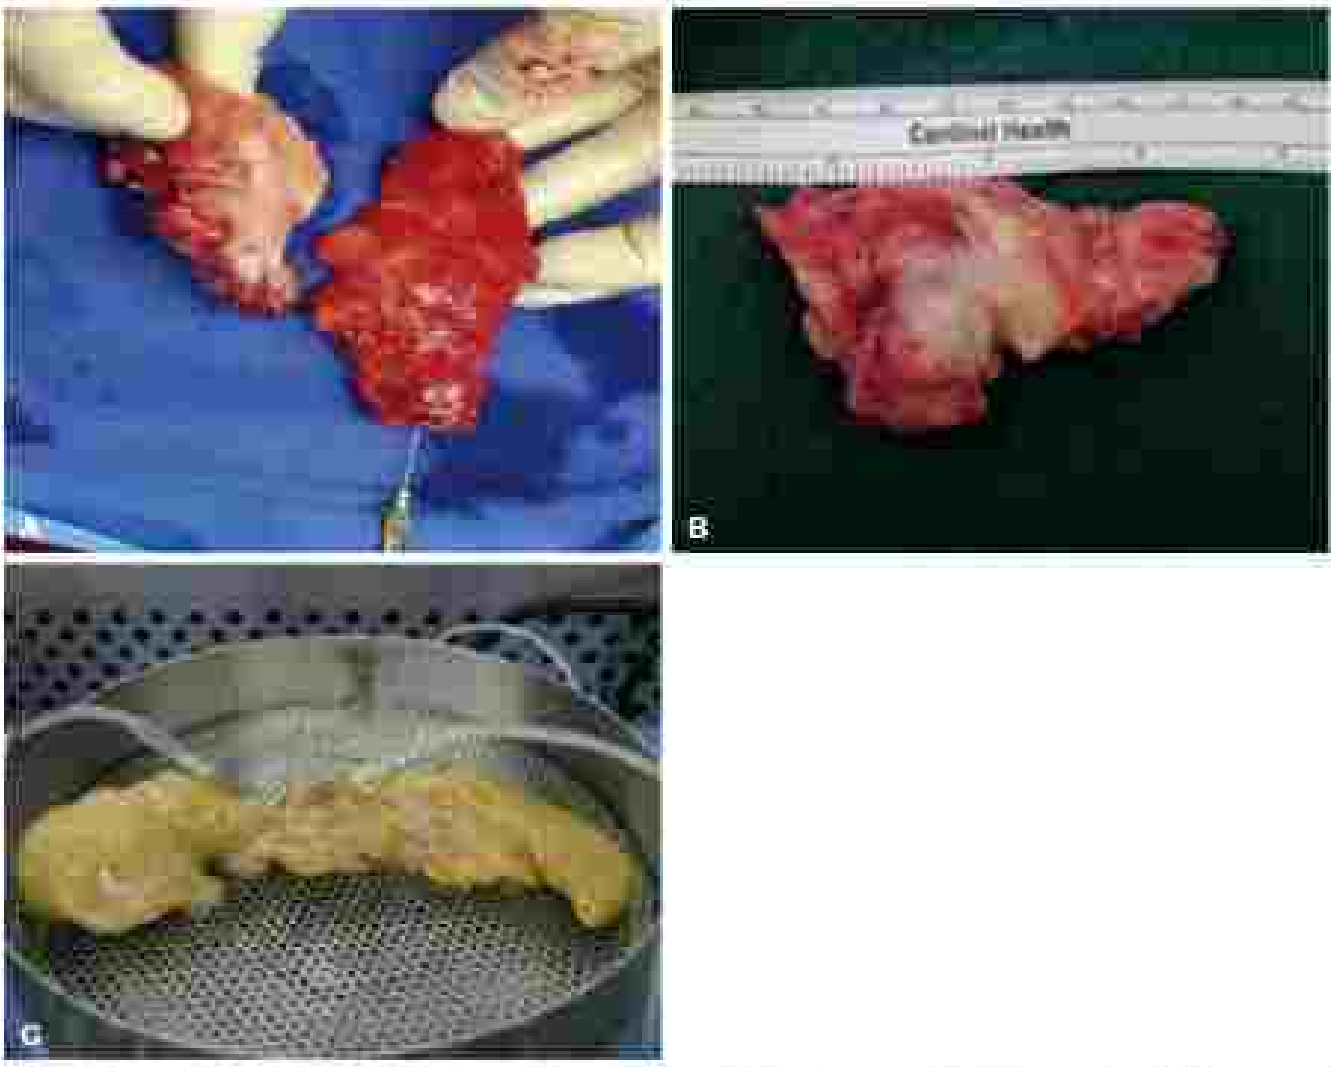

FIG. 1 (A) Whole pancreatectomy—chronic pancreatitis, severe fibrosis. (B) Partial pancreatectomy—post Whipple. (C) Representative gravitic perfusion unit from chronic pancreatitis sample.

causing rupture of the pancreas capsule. In the setting of a severely fibrotic pancreas, where it is not possible to cannulate or infuse the pancreatic duct, multiple injections of enzyme mixture into the interstitium may be the only alternative. Further modification for digestion of a severely fibrotic pancreas include increasing the volume of enzymes, lengthening the digestion, and pulsating enzymes. After perfusion, the pancreas is sectioned into 10 to 12 cubes and placed into a filtered digestion chamber (Fig. 2A–B). Tissue is digested in a 37°C enzyme solution with manual or mechanical agitation. Small samples are assessed every 2 to 5 minutes by microscopy to determine the degree of islet disaggregation, size of exocrine tissue (which can impact ability to deliver sample intraportally), and proportion of islets still imbedded in exocrine tissue. Once the sample is deemed sufficiently digested (Fig. 2C), the enzymatic reaction is stopped through cooling, dilution, and addition of high concentration albumin.

After digestion, the volume of pancreas tissue is measured to determine whether the amount could be safely infused into the portal system. It is generally accepted to target a volume of less than 20 mL for an average adult recipient. For pediatric patients, the University of Minnesota team has recommended 0.20 mL/kg. If the volume of pancreatic tissue greatly exceeds this amount, there are two options. (1) Traditionally, centers have infused as much tissue as feasible based on the capacity of the liver as measured by a rise in portal pressures. If portal pressures rise more than 15 to 20 mm Hg and fail to fall after halting the infusion and observation for 5 to 10 minutes, the infusion is aborted. Any remaining tissue can be injected into the peritoneal cavity or some have injected it into the wall of the stomach. (2) The alternative is to purify the preparation using techniques perfected and standardized in recent clinical trials. Although this adds a few hours to the procedure, we favor this approach. It reduces the risk of portal vein thrombosis by the reduction of tissue volume. Purification is achieved through continuous density gradient centrifugation. For IAT, the goal for purification is to maximize the number of islets while decreasing the exocrine tissue to achieve a safe volume. Because the diseased pancreas often has greatly reduced islet recovery from the digested tissue, it is important to preserve as many as possible. Given that the purification will decrease the yield of islets, the goal of purification is to reduce the volume to an acceptable level while maximizing the maximum number of islets.

Finally, the purified islets are counted, and the yield is expressed as islet equivalents (IEQ). The islet preparation is tested for overall quality using fluorescein diacetate (FDA) and propidium iodide to assess islet cell viability (Fig. 2D). Additionally, endotoxin, Gram stain, and bacterial cultures are performed. The culture data will not be available until post-transplant and can be utilized to guide antibiotic therapy, if necessary. The prepared islets are resuspended in approximately 250 mL of buffered solution, placed in an infusion bag (Fig. 3A) and stored at room temperature to be transplanted within 4 hours.

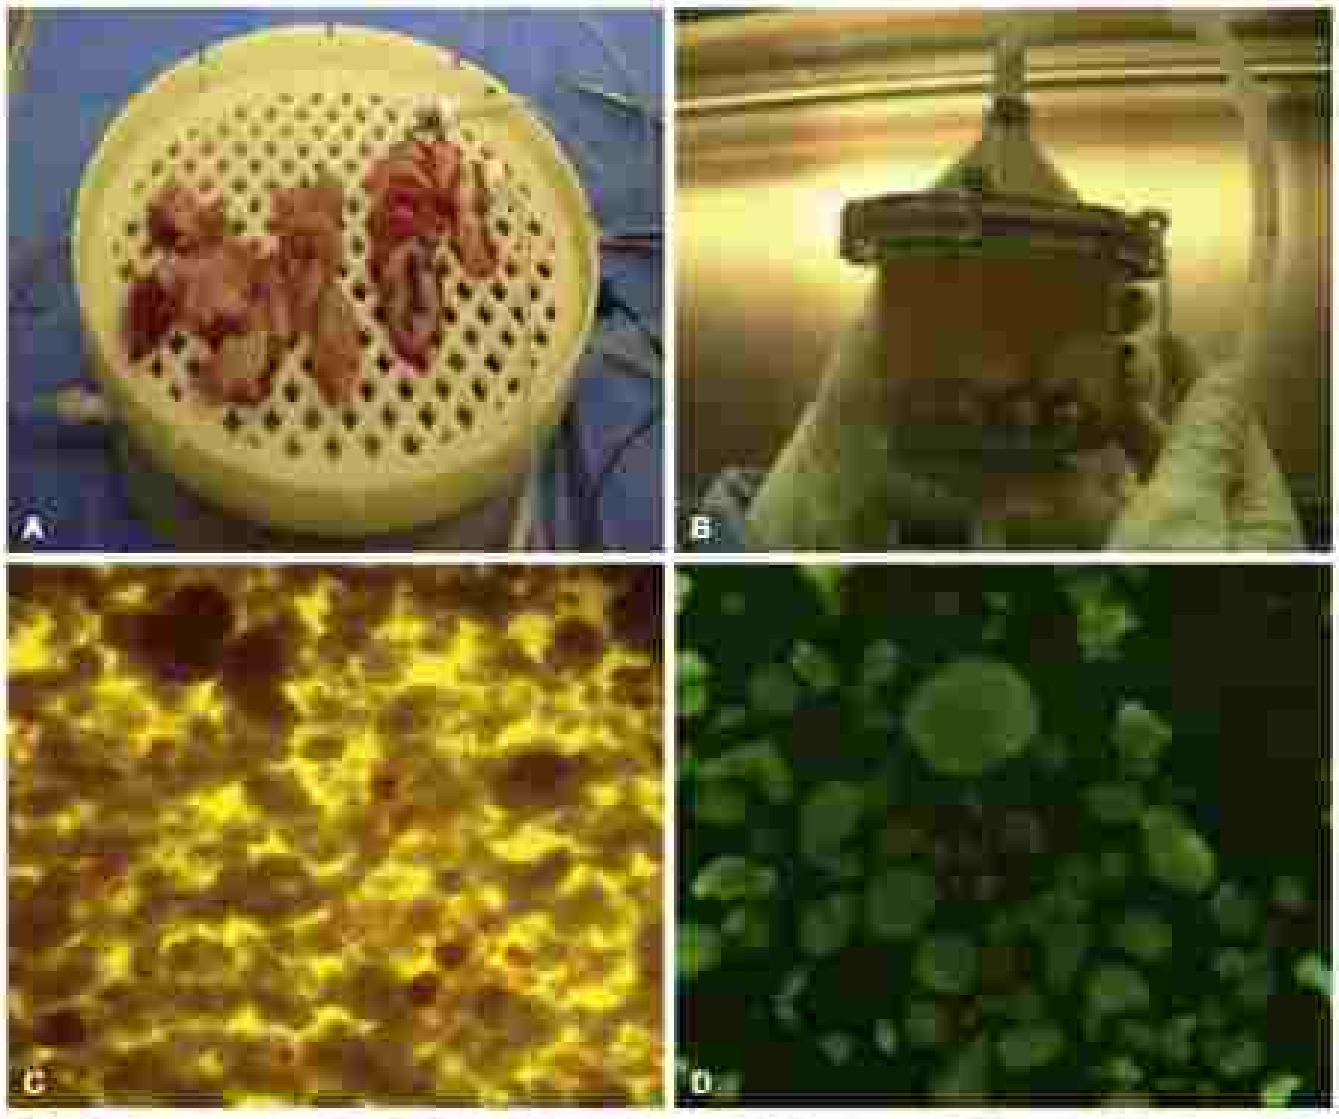

FIG. 2 (A) Traditional pancreas preparation. (B) Closed digestion chamber with partially digested pancreas. (C) Microscopic analysis of pancreatic digestate material. Individual islets exist and with dispersion. Necrotizing tissue is secretive pancreas material. (D) Quality control of isolated islets. Fluorescein diacetate viability assay shows living islets fluorescing green.

Islet Infusion

Islet infusion is carried out through intraportal delivery of the digested and purified islet preparation. It carries the risk of increasing portal hypertension and potential portal vein thrombosis. Studies in animal models have demonstrated alternative sites may be a viable option in the future, but no human clinical studies have demonstrated an alternative site that results in efficient islet survival and restoration of glycemic control.

In the setting of TP, access to the portal circulation for islet delivery is often easily achieved through the splenic vein, umbilical vein, or by directly accessing the portal vein. Alternatively, a catheter may be placed into a mesenteric vessel (Fig. 3B) or access achieved through a fluoroscopically aided percutaneous approach, which is typically utilized by centers that clear the abdomen prior to islet infusion.

The absolute volume of pancreatic tissue that can be delivered via intraportal infusion is highly dependent on the size of the liver and the degree of steatosis. For an average sized healthy liver, up to 20 mL of pancreatic tissue can often be safely tolerated. However, because of the challenges of making an accurate estimate, it is important to transduce intraportal pressure throughout the infusion. A three-way stopcock is attached to the infusion line and connected via transducer tubing to a pressure monitor, which allows for pausing of the islet infusion and assessment of intraportal pressure every 2 to 5 minutes (Fig. 3B). Multiple studies have demonstrated that islets can be safely infused when the intraportal pressure is maintained below 20 to 25 mm Hg. When the intraportal pressure is noted to rise above 20 mm Hg, the infusion is held and the pressure continuously monitored. Often, after a short pause, the infusion can resume once a decrease of portal pressure is noted. Systemic heparinization is started immediately prior to islet infusion and continued postoperatively to decrease the risk of portal vein thrombosis. We often give additional heparin boluses if the portal pressure rises above 20 and is slow to fall.

Once portal pressure has risen above ≥5 mm Hg and does not decrease with resting, additional intraportal infusion must be abandoned. Remaining islet preparation should not be discarded and should be placed in an alternative site. Most centers prefer to place the remaining islet preparation into the gastric submucosa or omentum pouch. No definitive evidence has demonstrated a benefit from placement of islets in an alternative site, but theoretically, even a small amount of islet survival may be beneficial.

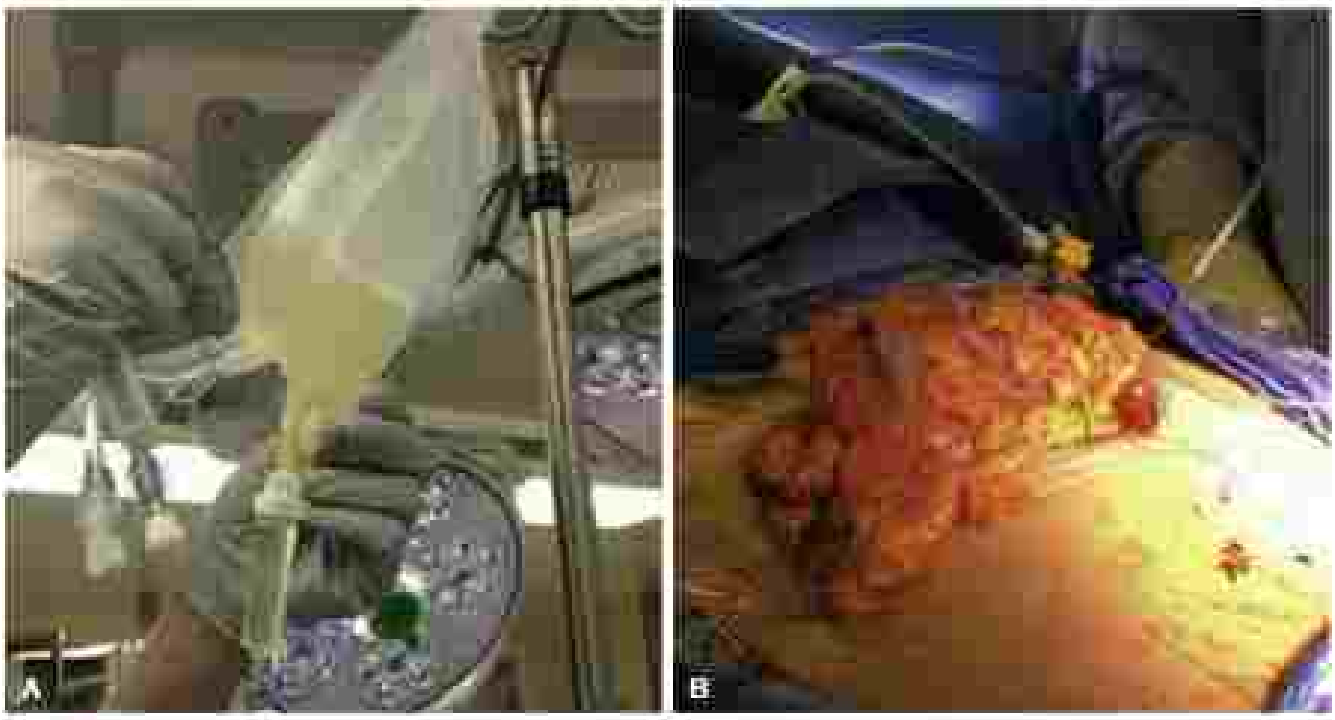

FIG. 3 (A) Ollier axes for infusion. (B) Infusion of line through micrometer site. Three-way stopcock to allow for pressure monitoring.

POSTOPERATIVE MANAGEMENT

In addition to standard postpancreatectomy care, TP IAT patients require very tight glycemic control. The transplanted islets are avascular and rely on diffusion of oxygen and nutrients during the immediate postoperative period. Maintenance of tight glucose control via insulin infusion decreases metabolic activity of the islets and prevents undue stress and apoptosis. Typically, an insulin infusion is utilized to maintain blood sugars at or below 120 mg/dL. Patients are routinely kept on insulin therapy for up to 3 months to decrease the metabolic burden on the transplanted islets and allow for proper engraftment and revascularization. After this period of time, insulin will be weaned to assess for the islets' ability to control blood glucose.

Pain management postoperatively can be challenging given the high likelihood of opiate tolerance secondary to long-standing chronic pain. For this reason, it is recommended to utilize available pain specialists and set up a multimodal pain management plan using ketamine, gabapentin, NSAIDs, lidocaine, benzodiazepines and epidural or paravertebral catheters as necessary.

Early enteral nutrition is important for aiding in wound healing. If enteral tube feeding access is in place, elemental tube feeds should be started at a low rate on postoperative day 1. Tube feeds will be continued until oral nutrition has been well tolerated. Delayed gastric emptying and gastroparesis are common postoperative complications and can be addressed by gastrostomy tube venting. If put in place, gastrostomy and jejunostomy tubes are typically kept in place for 4 weeks. Depending on clinical progress, clear liquid diet is often delayed until approximately postoperative day 10.

Most centers utilize standard perioperative antibiotics, regardless of the results of bacterial culture sent during islet isolation. These culture results, however, are used to guide antibiotic choice if the patient shows evidence of active infection.

Systemic heparinization is continued postoperatively to prevent portal vein thrombosis and liver function tests are monitored daily. Anticoagulation is often continued until postoperative day 30 using enoxaparin on discharge.

Length of stay is approximately 5 to 8 days. Prior to discharge, patient pain management and nutrition must be clearly established and an appropriate insulin regimen in place.

OUTCOMES

The 40 years of experience with TP and islet autotransplantation has established this procedure as a definitive treatment for medically refractory CP, for which other endoscopic or more limited operative management have been ineffective or deemed unsuitable. Studies looking at both pain control as well as endocrine function have established TP IAT as providing highly effective pain management with improved control of blood glucose levels and protection from life-threatening brittle diabetes found in TP alone patients.

TP has long been documented as an effective treatment to control the pain associated with CP, with historical data going back over 50 years showing significant pain relief in greater than 70% of patients. The largest single center outcome study for TP IAT is from the University of Minnesota, with outcomes for over 13 years of postoperative monitoring and includes more than 500 patients in their report. They have demonstrated pain improvement in 85% to 92% of patients, and roughly 40% being narcotic free at 2 years post TP. Importantly, nearly all individuals that had a complete pancreatectomy after a previous Whipple operation reported improvement in pain scores. Furthermore, based on the 36-item Short Form Health Survey, 94% report an improvement in their quality of life, with the highest percentage of improvement among individuals who achieved pain control and insulin independence. Follow-up surveys demonstrated that additional quality of life improvement happened during the second year post-operatively. A large study from the University of Cincinnati has shown 58% of patients with minimal change CP, who underwent TP IAT, achieved narcotic independence. The Cincinnati team has also demonstrated improvements in quality of life at 5 and 10 years of follow up. Other work from centers in Leicester and Alabama has had similar results, with typically 50% to 80% of patients becoming opiate independent. Unfortunately, data show that 10% to 30% of patients will see little to no improvement in pain or quality of life. Overall success of weaning off opiates is likely dependent on several poorly understood factors, but high pre-operative opiate use is associated with persistent postoperative narcotic requirement. Persistent pain has also been associated with pancreas divisum, previous Whipple, more than three previous stents, and body mass index greater than 30.

Patients with TP alone are at high risk for severe, life-threatening type 3c pancreatogenic diabetes with studies showing that up to 77% of TP alone patients experience severe problems with diabetes control. Furthermore, the lack of both insulin producing β cells and glucagon producing α cells greatly disrupts glucose homeostasis and can result in unpredictable responses to exogenous insulin and dangerous hypoglycemic emergencies. The use of IAT has dramatically decreased the rates of diabetes and hypoglycemia unawareness in pancreatectomy patients. Based on large scale studies, approximately 10% to 40% of individuals will achieve insulin independence, with the largest single center study showing approximately 30% of patients independent, 39% with partial islet function, and 27% requiring regular insulin therapy at 3 years post IAT. Importantly, while there is some initial decrease in islet function over the first 3 years, the University of Minnesota reports that among patients for whom they have 10 year follow up, a third remain insulin independent. The longest insulin independence post IAT has been reported to be more than 18 years. Based on C-peptide production, some degree of islet function is found in approximately 90% of TP IAT patients and the vast majority maintain a HbA1C below 7.0%. The success rate correlates very closely with the number of islets transplanted. With more than 5000 IEQ/kg, insulin independence rates are as high as 75% at 3 years, while only 12.5% of patients achieve insulin independence if less than 2500 IEQ/kg are transplanted. The cause of decreased islet isolation is linked to the degree of pancreatic damage from inflammation and fibrosis, and whether there has been any previous resection.

Overall complication rates for TP IAT have been reported in approximately 50%, with mortality rates of 1.4% to 6%. Most common complications reported in major series include pneumonia (18%), delayed gastric emptying (9%), deep venous thrombosis (9%), wound infection (9%), pulmonary embolism (7%), urinary tract infection (7%). The Minnesota series reports a 15.9% rate of reoperation in the immediate postoperative setting, most commonly for bleeding (9.5%). This rate of reoperation for bleeding is significantly higher in patients who had a final portal pressure of more than 25 cm water (18.4 mm Hg), which suggests that the bleeding complication is related to systemic hypertension and/or increased pressure in the portal system. Long term survival for TP IAT has been documented at 90% at 5 years and 62% at 20 years.

The use of TP IAT has been expanded to treat select pediatric patients with chronic pancreatitis, most with genetic risk factors. TP IAT in pediatric patients has achieved narcotic independence in 90%, which was stable for at least 10 years. Insulin independence was achieved in 41.3% of patients. Younger patients (<8 years) had significantly higher rates of insulin independence at 82%, and 100% of these patients became narcotic independent. In these young children, hospitalizations decrease from an average of 5 per year preoperatively to 0.35 per year postoperatively. Mean follow up to this young cohort is only 2.2 years, so longer follow up will be needed to establish the overall success of this procedure in very young children.

Due to the demanding requirements of establishing an islet isolation lab adherent to good manufacturing practice standards, efforts at some institutions have been made to utilize remote islet processing centers for the isolation. Multiple small single-center studies have demonstrated that TP IAT using a remote processing site can be comparable to local processing in achieving insulin independence, with results varying between 33% and 88%.

SUMMARY AND FUTURE DIRECTIONS

Total pancreatic resection with islet autotransplantation has been established as an effective treatment for pain associated with chronic pancreatitis and able to abrogate the severe glucose intolerance that results from TP alone. In patients who have failed to achieve relief from less invasive measures, TP-IAT may provide the only option for long term pain control. Numerous studies have demonstrated that it leads to overall improvement in quality of life for the patients and abrogates the potential risks from labile diabetes. The procedure is now widely accepted as a standard of care for appropriate patients and most insurance companies cover this treatment. However, because of the complexity of the operation and the requirement for a highly specialized processing facility and expert processing team, it is not universally available, and significant work needs to be undertaken to ensure that it is available to more individuals.

A recent workshop led by the National Institute of Diabetes and Digestive and Kidney Diseases identified several research and policy areas to be addressed, including standardization of patient selection, national registry to monitor outcomes, need to better understand the disease process of CP, and optimal timing for operative care. Furthermore, enhancement of intrahepatic islet survival and alternative engraftment sites are key areas of active research.

Total Pancreatectomy With Islet Autotransplantation

Nadeged T. Fachiche, MD, Christi Walsh, BS, MSN, Vikash K. Singh, MD, MSc, and Martin A. Makary, MD, MPH

Chronic pancreatitis (CP) is a challenging clinical syndrome that may present with minimal symptoms or with severe debilitating pain, endocrine and exocrine insufficiency, and radiographic findings at presentation that may not correlate with symptoms. In addition, the diagnosis can be clouded by other conditions that can mimic CP, including functional gastrointestinal disorders, emotional dysmotility, and opioid use disorder. This chapter will briefly review the etiologies and management of CP, with a focus on total pancreatectomy with islet autotransplantation (TPIAT) as a therapeutic modality for select patients. Given that the procedure commits patients to eventual insulin dependence and indefinite pancreatic exocrine supplementation, patient selection for TPIAT versus other hybrid procedures should be exercised very judiciously.

CHRONIC PANCREATITIS

CP encompasses a group of etiologically distinct fibro-inflammatory processes that result in irreversible pathological and structural damage to the pancreas. Progressively diffuse parenchymal and pancreatic fibrosis combined with ductal strictures ultimately lead to decreased endocrine and exocrine function; however, severe debilitating abdominal pain is the most common clinical presentation and indication for therapeutic intervention.

EPIDEMIOLOGY AND RISK FACTORS

The incidence of CP in the United States is about 4 per 100,000 persons per year and has been reported to be as high as 200 per 100,000 in parts of Asia and Europe. Males are twice as likely to be diagnosed. CP is a clinical syndrome with multifactorial etiology. Classification systems such as the toxic-metabolic, idiopathic, genetic, autoimmune, recurrent, and severe acute pancreatitis, obstructive, provide a method of organizing the most common risk factors (Fig. 1). However, this classification scheme has limitations (e.g., acute recurrent pancreatitis is a common pathway to CP in multiple etiologies) and is undergoing revision to focus on the pathophysiology of CP from the early to later stages of disease.

Chronic alcoholic pancreatitis features progressive parenchymal and interlobular fibrosis as well as ductal dilation and intraductal calculi believed to result from recurrent insults caused by direct toxicity from alcohol metabolites and associated increased oxidative stress.

Chronic obstructive CP results from either extrinsic or intrinsic ductal obstruction by calculi, cysts, or strictures. Postobstructive ductal dilation and uneven parenchymal fibrosis are often noted.

Genetic alterations have been identified as an etiology in up to 30% of patients with idiopathic CP. Hereditary CP is caused by a gain of function mutation of the cationic trypsinogen gene (*PRSS1*). Affected patients present with CP within the first 2 decades of life have an accelerated disease progression, and a 22% increased risk of developing pancreatic cancer by the age of 70 years, although developing pancreatic cancer before age 50 is rare with this mutation. Autosomal recessive mutation of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene responsible for cystic fibrosis is the most common cause of CP in children. Impaired cellular transport of chloride in epithelial cells leads to overconcentration of physiologic secretions and subsequent inflammation in organs such the lungs and pancreas. Recent studies have linked minor mutations in the *CFTR* genes with idiopathic chronic pancreatitis. Genetic alteration of the *SPINK1* gene coding for a potent antitrypsin serine protease acts synergistically with other risk factors leading to earlier onset and increased severity of CP.

Acute recurrent pancreatitis (ARP) features recurring episodes of self-limiting acute pancreatitis as defined by the presence of two of the following: epigastric pain radiating to the back, lipase or amylase level three times the normal levels, and radiographic findings suggestive of pancreatitis. ARP can cause a substantial decrease in the quality of life even in the absence of CP. ARP progresses to CP in 8% to 15% of cases and is highest in subjects with a history of alcohol use and idiopathic etiologies. In two-thirds of patients, the etiology of ARP can be identified. Alcohol abuse and genetic alteration of the *PRSS1*, *SPINK1*, and *CFTR* genes have all been implicated in the pathogenesis of ARP.

Idiopathic CP, for which no clear etiology can be ascertained, affects 10% to 30% of patients.

PATHOPHYSIOLOGY

Regardless of etiology, all the subtypes of CP share a common final pathway characterized by diffuse and near complete destruction of

Total Pancreatectomy With Islet Autotransplantation

Nadeged T. Fachiche, MD, Christi Walsh, BS, MSN, Vikash K. Singh, MD, MSc, and Martin A. Makary, MD, MPH

Chronic pancreatitis (CP) is a challenging clinical syndrome that may present with minimal symptoms or with severe debilitating pain, endocrine and exocrine insufficiency, and radiographic findings at presentation that may not correlate with symptoms. In addition, the diagnosis can be clouded by other conditions that can mimic CP, including functional gastrointestinal disorders, emotional dysmotility, and opioid use disorder. This chapter will briefly review the etiologies and management of CP, with a focus on total pancreatectomy with islet autotransplantation (TPIAT) as a therapeutic modality for select patients. Given that the procedure commits patients to eventual insulin dependence and indefinite pancreatic exocrine supplementation, patient selection for TPIAT versus other hybrid procedures should be exercised very judiciously.

CHRONIC PANCREATITIS

CP encompasses a group of etiologically distinct fibro-inflammatory processes that result in irreversible pathological and structural damage to the pancreas. Progressively diffuse parenchymal and pancreatic fibrosis combined with ductal strictures ultimately lead to decreased endocrine and exocrine function; however, severe debilitating abdominal pain is the most common clinical presentation and indication for therapeutic intervention.

EPIDEMIOLOGY AND RISK FACTORS

The incidence of CP in the United States is about 4 per 100,000 persons per year and has been reported to be as high as 200 per 100,000 in parts of Asia and Europe. Males are twice as likely to be diagnosed. CP is a clinical syndrome with multifactorial etiology. Classification systems such as the toxic-metabolic, idiopathic, genetic, autoimmune, recurrent, and severe acute pancreatitis, obstructive, provide a method of organizing the most common risk factors (Fig. 1). However, this classification scheme has limitations (e.g., acute recurrent pancreatitis is a common pathway to CP in multiple etiologies) and is undergoing revision to focus on the pathophysiology of CP from the early to later stages of disease.

Chronic alcoholic pancreatitis features progressive parenchymal and interlobular fibrosis as well as ductal dilation and intraductal calculi believed to result from recurrent insults caused by direct toxicity from alcohol metabolites and associated increased oxidative stress.

Chronic obstructive CP results from either extrinsic or intrinsic ductal obstruction by calculi, cysts, or strictures. Postobstructive ductal dilation and uneven parenchymal fibrosis are often noted.

Genetic alterations have been identified as an etiology in up to 30% of patients with idiopathic CP. Hereditary CP is caused by a gain of function mutation of the cationic trypsinogen gene (*PRSS1*). Affected patients present with CP within the first 2 decades of life have an accelerated disease progression, and a 22% increased risk of developing pancreatic cancer by the age of 70 years, although developing pancreatic cancer before age 50 is rare with this mutation. Autosomal recessive mutation of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene responsible for cystic fibrosis is the most common cause of CP in children. Impaired cellular transport of chloride in epithelial cells leads to overconcentration of physiologic secretions and subsequent inflammation in organs such the lungs and pancreas. Recent studies have linked minor mutations in the *CFTR* genes with idiopathic chronic pancreatitis. Genetic alteration of the *SPINK1* gene coding for a potent antitrypsin serine protease acts synergistically with other risk factors leading to earlier onset and increased severity of CP.

Acute recurrent pancreatitis (ARP) features recurring episodes of self-limiting acute pancreatitis as defined by the presence of two of the following: epigastric pain radiating to the back, lipase or amylase level three times the normal levels, and radiographic findings suggestive of pancreatitis. ARP can cause a substantial decrease in the quality of life even in the absence of CP. ARP progresses to CP in 8% to 15% of cases and is highest in subjects with a history of alcohol use and idiopathic etiologies. In two-thirds of patients, the etiology of ARP can be identified. Alcohol abuse and genetic alteration of the *PRSS1*, *SPINK1*, and *CFTR* genes have all been implicated in the pathogenesis of ARP.

Idiopathic CP, for which no clear etiology can be ascertained, affects 10% to 30% of patients.

PATHOPHYSIOLOGY

Regardless of etiology, all the subtypes of CP share a common final pathway characterized by diffuse and near complete destruction of

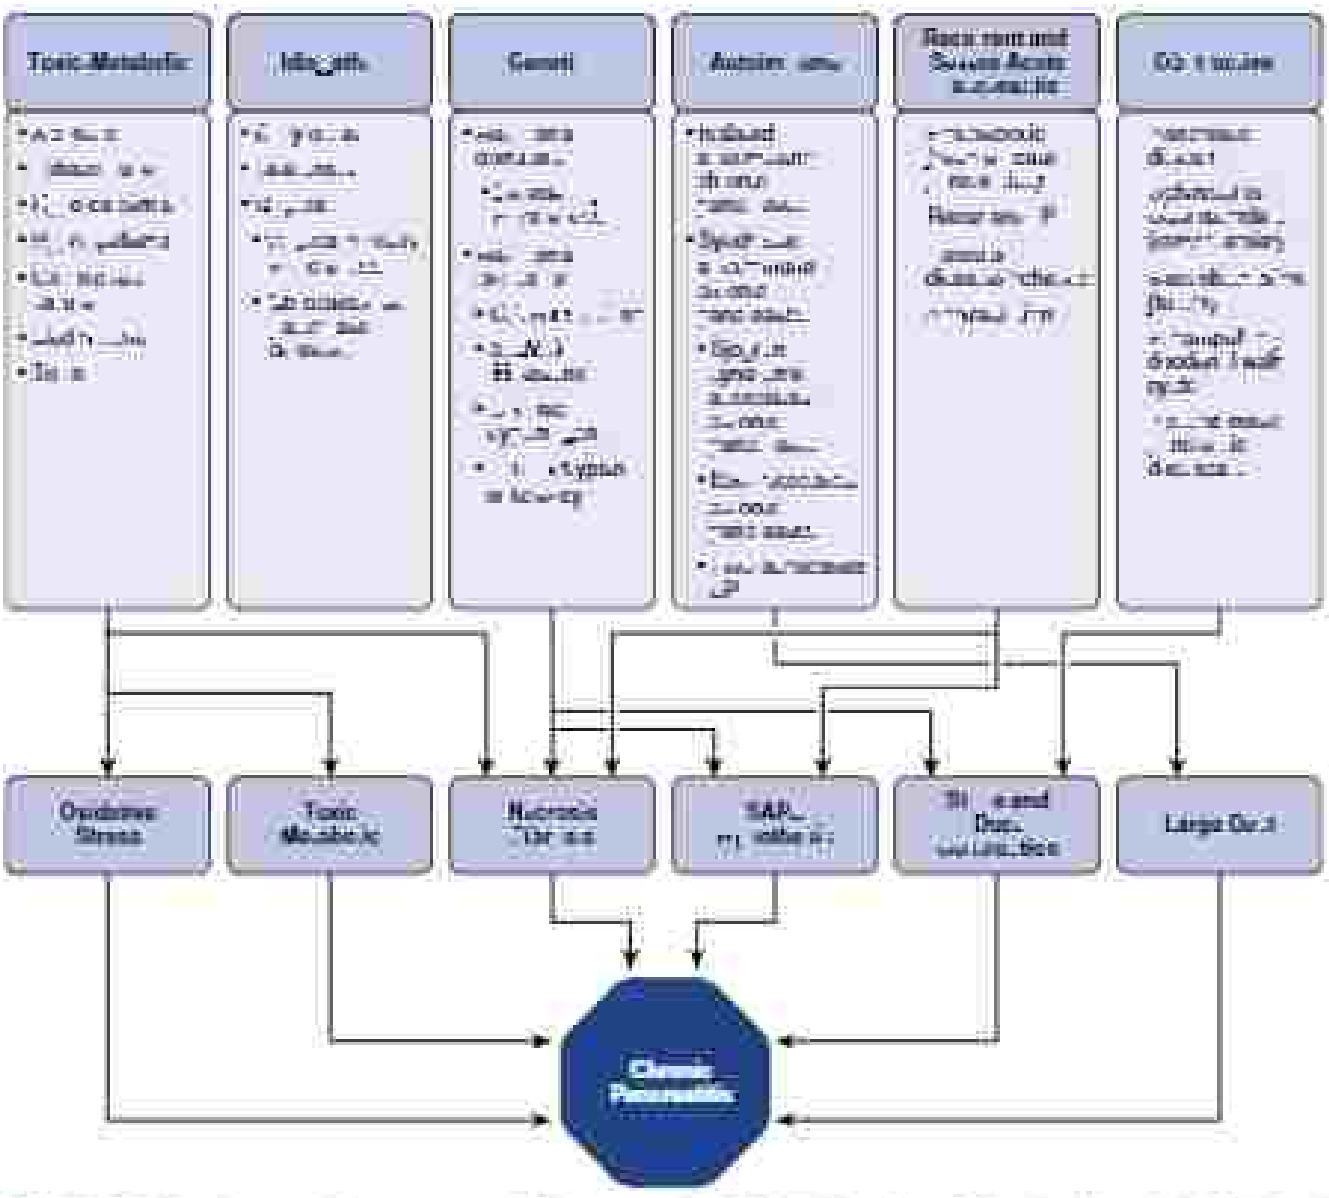

FIG. 1 TIGAR-O classification system. AP, acute pancreatitis; CP, chronic pancreatitis; IBD, irritable bowel disease; PBC, primary biliary cirrhosis; SAP, recurrent acute pancreatitis event.

acinar and islet cells. Acinar destruction leads to exocrine insufficiency because the decreased secretion of fat-digesting enzymes causes steatorrhea and fat soluble vitamin deficiency. Similarly, endocrine dysfunction and resulting diabetes mellitus set in with the destruction of 90% of islet cells. The mechanisms of pain in CP are not fully elucidated. New evidence challenges the long held dogma ascribing pain to increased intraductal pressure and resulting parenchymal ischemia. Recent studies suggest that chronic pain in CP is the result of a complex interplay between peripheral sensitization resulting from activation of pancreatic nociceptors by proinflammatory mediators, pancreatic neuropathy caused by peripheral inflammation of intrapancreatic nerves, and alterations in the central pain mechanisms leading pancreatic hyperalgesia.

CLINICAL PRESENTATION AND DIAGNOSIS

Patients with CP present with severe epigastric pain as the main symptom in 70% to 90% of cases. The pain is often associated with episodes of acute pancreatitis, which may become more and more frequent over several years. Over time, pain may also progress to be chronic and occur between episodes. Although some patients have recurrent acute pancreatitis that progresses to CP, others may have a slowly developing form of the disease that was previously known as late-onset idiopathic CP. These patients may have pathogenic mutations not involving trypsin pathways of disease, for example, the unfolded protein response. A clear lipase elevation associated with each episode of acute pancreatitis is a prerequisite for making the diagnosis, although over time, increasing pancreatic fibrosis results in less amylase and lipase secretion from the pancreas. Lipase is the test of choice for acute chemical pancreatitis but is less reliable for the diagnosis of CP. Amylase testing is redundant and a wasteful addition to a lipase value.

Patients often describe the pain as severe, postprandial epigastric pain radiating to the back, which is relieved by leaning forward or sitting upright. In about 20% of patients, however, CP can be painless. Steatorrhea, insulin deficiency, and malnutrition are additional symptoms, mostly seen in advanced disease.

A thorough history and physical examination combined with imaging studies such as abdominal ultrasonography, computed

tomography scan, and magnetic resonance cholangiopancreatography are typically sufficient to establish both diagnosis and etiology. Imaging features of CP include parenchymal atrophy, ductal dilation, and calcifications. Laboratory evaluation of pancreatic function is adjunctive. Tests measuring the levels of trypsin and fecal elastases may shed light on the patient's baseline pancreatic insufficiency.

The psychosocial issues of patients with chronic pancreatitis are important. As with inflammatory bowel disease, which may affect a patient's mental health, patients with CP are often falsely accused of having a history of alcoholism. We find that CP from alcohol abuse is a small minority of patients that present with chronic pain, and we do not offer these patients a TPIAT based on the experience from the University of Alabama Birmingham, which shows that this subgroup had the poorest outcomes following the procedure. These patients occasionally are candidates for a hybrid Frey procedure.

MANAGEMENT

For most patients with CP, therapeutic interventions are at relieving intractable abdominal pain and palliating exocrine and endocrine insufficiency. Medical and endoscopic interventions for the treatment of chronic pain can sometimes be successful in patients with minimal to moderate disease. Historically the tenets of surgery for chronic pain in CP relied on a simplistic assessment of the etiology of pain and the location of the disease. A Whipple procedure can be ideal for disease localized or dominant in the pancreatic head and a distal pancreatectomy can be ideal for disease localized in the tail. A hybrid procedure such as a duodenal preserving pancreatic head resection (Frey, Beger, and Berne) is our procedure of choice for patients with large duct disease or symptoms resulting from obstructing stones. We limit a lateral pancreaticojejunostomy (Puestow) to patients with ductal obstruction resulting from a pancreatic duct stricture because symptoms can sometimes be due to pressure caused by obstructed pancreatic ducts. We rarely perform a Puestow procedure because the Frey procedure has been shown in large studies to have superior outcomes, most likely because it more completely opens the gland's ductal system. The Puestow and other hybrid procedures can also be performed as a fallback procedure if an operation appears too high risk at the time of surgery.

Of note, a Frey or TPIAT procedure is contraindicated in any patients with a pancreas mass concerning for cancer, and generally we proceed straight to a TPIAT procedure in patients with a PRSS1 gene mutation (hereditary pancreatitis) as well as other pathogenic mutations. Given that benign masses such as chronic pseudocysts are common in patients with chronic pancreatitis, an intraoperative biopsy may be warranted during a Frey procedure. As a minimum, we send the excavated pancreatic head from a Frey procedure for a rapid frozen pathology analysis to rule out cancer given the increased risk of cancer in patients with CP.

A Whipple procedure may not exclude the option of a future TPIAT because pancreatic islets are more concentrated in the tail.

TOTAL PANCREATECTOMY WITH ISLET AUTOTRANSPLANTATION

Total pancreatectomy as a definitive cure for CP is typically decision of last resort, reserved for patients in whom CP has been refractory to all other interventions, and in whom quality of life and the ability to lead a productive life is profoundly compromised because of pain and recurrent acute pancreatitis. Historically, the high morbidity of the procedure, which invariably guaranteed lifelong insulin dependence from surgically induced diabetes mellitus, and pancreatic exocrine replacement therapy for exocrine insufficiency, was a deterrent for both surgeons and patients. Combining total pancreatectomy with islet cells transplantation offered hopes of thwarting the postoperative development of diabetes mellitus. Since the first autologous islet cell transplantation by Sutherland et al. in 1977, TPIAT has gained wider acceptance owing to continued surgical innovation and improved outcomes over the past 4 decades.

Indications

Recently published selection criteria by our institution sought to minimize the effect of the low sensitivity and specificity of diagnostic tools such as endoscopic ultrasound, static magnetic resonance cholangiopancreatography, and endoscopic pancreatic function testing. Our recommendations are summarized in Table 1. TPIAT should be considered for carefully selected patients in whom chronic debilitating pain is unrelated despite maximal medical, endoscopic, and surgical interventions, and who meet the following criteria:

1. CP with chronic abdominal pain and one of the following:
   a. Calcification on imaging
   b. Moderate to severe ductal changes based on the Cambridge criteria
   c. ARP
   d. Pathology confirmed CP at prior surgery
2. Confirmed diagnosis of ARP with impaired quality of life
3. Confirmed hereditary or genetic CP with items 1 or 2

Patient Selection

Careful patient section is essential for successful outcomes after TPIAT. Poorer outcomes have been reported in patients with active alcohol or illicit substance abuse, poorly controlled psychiatric illnesses, chronic abdominal pain exceeding 5 years in duration, and inadequate support systems. Also, many patients with CP may also have undiagnosed or undertreated opioid use disorder, which could cloud the decision-making process. For these reasons, TPIAT is contraindicated in these select patients.

It is imperative that every patient who chooses to have a TPIAT be fully prepared for lifelong severe insulin-dependent diabetes and pancreatic enzyme supplementation. Also, he or she should also be fully aware that these complications are a certainty with a variable time to onset, and that their chronic pain may not improve. Virtually all patients will develop diabetes after surgery with a variable time to onset, and the islet autotransplantation is intended to delay the onset. Islet cells rarely have long-term (10 plus years) adequate insulin-producing function where insulin injections are not required.

Patients without preoperative diabetes or those with minimal preoperative insulin requirement, ARP, and those with concurrent CFTR, PRSS1, or SPINK mutations are more likely to have better outcomes. At our institution, patients are selected based on a consensus decision to recommend TPIAT by attending physicians in a multidisciplinary pancreatitis clinic. Over the decades, our criteria have narrowed for TPIAT given a high complication rate. Using a multidisciplinary approach ensures a careful and exhaustive review of the patient's clinical and surgical history. We also require multiple clinic visits before surgery because having the procedure is a major decision for the patient. Baseline pain assessment using a visual analog pain scale (0–10), baseline exocrine and endocrine function, as well as overall health status, are considered.

Additionally, all patients undergo preoperative evaluations by their primary care and the anesthesiology service. Ultimately, we do not proceed with a TPIAT unless the patient meets our narrow clinical criteria and a patient is willing to trade severe morbid and enzyme dependence for a chance of pain improvement.

Technique

Since Dr. John Cameron first performed the TPIAT operation at Johns Hopkins in the late 1970s, advances in minimally invasive pancreatic tumor as well as in islet isolation and transplantation have lessened the technical challenges of TPIAT. At our institution, laparoscopic total pancreatectomy is now our procedure of choice for select patients and is associated with reduced postoperative pain and wound complications. Open TPIAT is reserved for cases in which a laparoscopic approach would be either unsafe or technically challenging. About 60% of TPIAT operations we perform are done laparoscopically. We have a rule of

conversion is open of about 10%, usually after a rapid inspection of the scar tissue with a laparoscope. Thirty percent are scheduled open, and we also use the robot for some cases depending on surgeon preference.

OPERATING ROOM SETUP

As previously reported, we use a dedicated operating room equipped with an islet isolation laboratory, which allows immediate processing of the resected pancreas within the operative room while gastroduodenectomy and hepatojejunostomy are performed. This step eliminates transfer time from outside facilities while minimizing cold ischemia time.

Laparoscopic Total Pancreatectomy

Crucial to islet yield and successful isolation is to preserve pancreatic perfusion for as long as possible before resection to minimize warm ischemia time. We achieve that objective by sequentially resecting the head and body and reserving the ligation of the vascular supply for last.

1. Following entry into the peritoneum using standard port placement, the lesser sac is accessed through the gastrocolic ligament.
2. The gastroduodenal artery is skeletonized and divided distally (Fig. 1).
3. The portal vein is dissected from above the pancreas, and the superior mesenteric vein is dissected from below.
4. A tunnel behind the pancreatic neck is created, and the stomach is divided just proximal to the pylorus using a laparoscopic stapling device with green or black loads.
5. A cholecystectomy is performed, and the common bile duct divided.
6. The neck of the pancreas is cautiously divided, avoiding injuries to the portal vein and the superior mesenteric vein. This step facilitates the division of the superior mesenteric artery margin, allows a staged removal for the back table team, and enables easy cannulation of the pancreatic duct for collagenase infusion into the duct.
7. Next, we perform a Kocher maneuver to free the ligament of Treitz from the right side, marching distally on the duodenum. After approximately 20 cm of jejunum are delivered to the right side of the ligament of Treitz, the jejunum is divided with a laparoscopic stapling device with a white load (2.5 mm).
8. The small bowel mesentery is then divided in the proximal direction to the uncinate and along the superior mesenteric artery margin until the head of the pancreas is free. It is then extracted through the umbilicus by extending the 12 mm port slightly.
9. The specimen is passed to the laboratory team to isolate the gastroduodenal artery with cellugenase and to clean off the pancreas head.
10. Next, the body and tail of the pancreas are mobilized along with the spleen. The splenic vessels are divided, beginning when possible with the splenic artery followed by the splenic vein. Following extraction, in a similar fashion to the head, the body and tail are perfused, chunked, and dissected into small pieces before processing by the islet laboratory personnel.
11. Next, hepatojejunostomy reconstruction is done using a novel technique pioneered by our team and previously reported, in which the anastomosis is done with a single layer of 4-0 barbed suture anteriorly with interrupted barbed sutures and suture clips.
12. The gastrojejunostomy is then performed in an antecolic retrogastric manner along the posterior wall of the stomach in a stapled side-to-side technique with a laparoscopic stapler.
13. To reduce bile acid reflux, a Braun's jejunojejunostomy is sometimes added to the procedure.

Intraoperative Laboratory Isolation of Pancreatic Islets

For pancreas digestion and autologous islet isolation, we use a modified version of the Ricordi protocol. On the back table in the operating room, the resected specimen is flushed through the gastroduodenal artery and the tail through the splenic arteries with cold University of Wisconsin solution. The pancreatic duct is cannulated and distended with a pressurized mixture of collagenase and thermolysin. The pancreas is then sectioned into 1- to 2 cm^3 pieces, placed in a 600 mL digestion chamber and transferred to a Ricordi islet isolator. Following digestion, the mixture of islets and acinar tissue is collected, washed, and resuspended in 5% human serum albumin supplemented with 70 U/kg of heparin. Final islet counts can be determined using an automated islet counter or a standard manual counting method.

Autologous Islet Infusion

Once the islet solution is ready for autotransplantation into the liver, a metal, hollow-bore, 16-gauge needle with intravenous tubing attached is placed through a 12 mm port site. From within the peritoneal cavity, laparoscopic instruments are used to place the needle into the portal vein (Fig. 3). Once the infusion is completed, the needle is subsequently removed, and direct pressure is applied to the puncture site of the vein to achieve hemostasis. During infusion, the portal vein

FIG. 2 Division of the pancreas along the portal vein and superior mesenteric artery. Gastroduodenal artery is clipped with the white clips at the top of the image.

FIG. 3 Laparoscopic islet autotransplantation infusion into the portal vein.

pressure is continuously monitored using a Transonic vascular flow probe with the aim of keeping it below 15 to 20 mm Hg. Of note, for all advanced laparoscopic pancreas procedures, a 9in. 10 blade scalpel and Mayo scissors are always kept on the Mayo stand in case a rapid conversion to an open procedure is necessary.

Postoperative Care and Follow-up

Postoperatively, patients are admitted to a surgical intensive care unit for monitoring and administered intravenous insulin infusion and dextrose containing intravenous fluids for tight glucose control. After a successful transition to subcutaneous insulin injections, patients are discharged when deemed stable. Unless contraindicated, patients are kept on insulin regimens in an attempt to rest the newly transplanted islets. Insulin requirements following are assessed during each postoperative visit.

TPIAT has one of the highest intrinsic complication rates of any elective operation. Readmission rates can be as high as 50%, and some of the complication management is related to opioid use disorder that may be undiagnosed before surgery.

Complications

Acute endocrine insufficiency is ubiquitous immediately following surgery and is managed with insulin drips and glycemic control measures.

Delayed gastric emptying is very common and affects up to one-half of the patients after TPIAT and could be a rule preoperative dysmotility from chronic opioid use; for most patients, prokinetics and probiotics are an effective therapy.

Portal venous thrombosis/thrombus and resulting portal hypertension are less frequent with the advent of PVP monitoring intraoperatively.

OUTCOMES

Chronic Pain

Four decades of data have demonstrated that TPIAT has been effective in relieving preoperative pain and improving quality of life in the majority of the carefully selected patient. A recent cohort study of 61 patients having undergone TPIAT from 2011 to 2015 conducted at our institution revealed that 89% of patients experienced resolution of their preoperative pain. Interestingly, 83% developed new characteristic abdominal pain and discussed opioid use was noted in only 66% of patients, underscoring the complexity of managing chronic abdominal pain. Furthermore, ARP (odds ratio, 11.66; 95% confidence interval, 1.47 to 92.36; $P = .02$) was independently associated with resolution of preoperative abdominal pain on multiple logistic regression.

Endocrine Insufficiency

The advent of islet autotransplantation has significantly reduced the morbidity of total pancreatectomy. Most series report insulin independence in 25% to 40% of patients with a bigger portion of patients left with manageable insulin requirements. Recently published outcomes by our group reflect these findings. In a prospective cohort of 76 patients having undergone TPIAT, 29% were insulin independent at 1 year. However, all the patients with preoperative findings of impaired glucose metabolism remained dependent within the same period, underscoring the importance of comprehensive patient education preoperatively.

CONCLUSION

In carefully selected patients in whom CP is debilitating and has been refractory to medical interventions, TPIAT can be an effective option. We recommend a Frey hybrid procedure, which does not involve islet autotransplantation, when patients meet clinical criteria, such as large duct disease without a genetic mutation.

BOX 1 Indications and Contraindications for Total Pancreatectomy

Indications

1. Documented CP
2. Chronic abdominal pain with one of the following:
   - Calculi, multiple
   - Main duct >7 mm in diameter changes on CT, MRCP, or ERCP
   - Ductal __ stricture __ and CP on pathology or imaging
   - ...
3. ARP with impaired QOL
   - ... in the setting of acute pancreatitis with ... abnormal imaging and no evidence of a treatable etiology
4. Documented hereditary/genetic pancreatitis with other indications 1 or indication 2

Contraindications

5. Alcoholic/smoking etiology
6. Active substance addiction/abuse
7. Duration of pain <3 years
8. Opioid use >3 years unless patient can successfully wean off and initiate centrally acting drugs (e.g., gabapentinoids) before surgery
9. Poorly controlled psychiatric comorbidity
10. Medical noncompliance

ARP, acute recurrent pancreatitis; CP, chronic pancreatitis; HGP, hereditary genetic pancreatitis; QOL, quality of life.

SPLENECTOMY FOR HEMATOLOGIC DISORDERS

[illegible]

The spleen is a lymphoid organ that [illegible] and immune [illegible] allows [illegible] hematologic disorders [illegible] the main reasons for elective splenectomy. Hypersplenism (symptoms related to splenomegaly and decreased blood counts related to sequestration of blood elements) [illegible] is a common complication and is the most frequent splenic [illegible] splenomegaly [illegible] have normal pain, early satiety, [illegible] and abdominal distention. In addition, splenectomy should be considered for patients with true [illegible] splenomegaly [illegible] for hematologic conditions rarely leads to a cure of the underlying hematologic disorder, [illegible] may be beneficial for the resolution of hematologic abnormalities and improving symptoms [illegible] hematologic diseases that require splenectomy may be treated [illegible] limited to red blood cell [illegible], platelet, lymphoproliferative, and myeloproliferative disorders [illegible].

[illegible] PRIMARY IMMUNE HEMOLYTIC ANEMIA

[illegible] Hemolytic Anemia

Autoimmune hemolytic anemia [illegible] is secondary to antibodies directed against one or several components of the RBC surface. [illegible] should be suspected in patients with anemia, reticulocytosis, elevated lactate dehydrogenase, low haptoglobin, and indirect hyperbilirubinemia. According to the immunochemical characteristics, AIHA can be classified as warm [illegible] or cold [illegible] based on the results of direct agglutination test (DAT). If the DAT is positive for immunoglobulin G (IgG), IgM, or IgA and complement, and then the diagnosis is most precise by WAIH. Conversely, if the DAT is positive for complement and alone, then [illegible] is more likely the diagnosis. In WAIH, polyclonal IgG sometimes IgA autoantibodies, usually directed toward Rh antigens, form a light coat over RBCs that are removed by the spleen. The peak incidence of WAIH occurs between the ages of 20 and [illegible] but it can occur at any age. In children, the disease is often self-limited, occurring after a viral infection and resolving in 1 to 3 months. Initial treatment with corticosteroid therapy (prednisone, 1 mg/kg per day) usually results in improved hemoglobin levels within several days, and remission occurs in 80% of patients. Children generally respond better to steroid therapy than adults. The steroid dose is tapered gradually to the lowest dose needed to control hemolysis. More recently, this [illegible], a monoclonal antibody directed against the CD20 antigen on the surface of mature B lymphocytes, has replaced the other second line medications and it is often associated with a complete response in both the adults and children. Splenectomy should be reserved to older patients who are corticosteroid resistant, for corticosteroid dependent patients who require high doses of corticosteroids, for patients who fail to achieve remission within 3 weeks, or for those who cannot maintain acceptable hemoglobin levels. A response rate of 60% to 80% is usually seen within the first 2 weeks after surgery. Approximately 10% of patients will require postoperative low dose steroids [illegible] to maintain adequate hemoglobin concentrations. In Cold [illegible] monoclonal IgM autoantibodies are active at lower temperatures, usually between 0°C and 20°C, resulting in intravascular complement-mediated hemolysis. In these patients, RBCs are removed by the liver, rather than the spleen. Cold [illegible] makes up [illegible] to 25% of AIHA. This disorder is usually associated with infections, such as mycoplasma pneumonia or with lymphoproliferative disorders. Treatment consists of avoiding cold temperatures, which can prevent an acute hemolytic crisis. Corticosteroid therapy is ineffective and contraindicated because of the risk of infections. Alkylating agents such as chlorambucil and cyclophosphamide have been successfully used for treatment along with plasmapheresis. Splenectomy is also not indicated because of the intravascular location of the hemolysis. Currently, rituximab is the only treatment that has proven long-term response.

Hereditary Spherocytosis

Hereditary spherocytosis (HS) is characterized by the presence of spherocytes on peripheral blood smear, hemolysis, anemia, and increased RBC clearance by the spleen. HS is the most common congenital anemia, prompting splenectomy with a prevalence of 1 in 5000 people in Europe and North America. The disorder is also common in Japanese and African populations. HS, also known as Minkowski-Chauffard disease, is an inherited disease resulting from a genetic mutation encoding red cell membrane components alpha I-spectrin (α-[illegible]), beta-spectrin (β-[illegible]), ankyrin (ANK-1), and band 3 anion transport protein (EPB3). However, some less common variants are inherited through an autosomal recessive pattern (protein 4.2). Membrane protein mutations lead to the destabilization of the lipid bilayer, with subsequent release of lipids from the membrane surface and consequent sphering of the RBCs. Spherocytes have decreased deformability, which impairs their passage through the splenic pulp and increases osmotic fragility; therefore, spherocytes are prematurely destroyed in the spleen. HS may manifest as a mild or severe form. In mild forms, patients may be asymptomatic or suffer only mild jaundice. Patients with more severe forms may present with anemia, jaundice, splenomegaly, and cholelithiasis. Peripheral blood smear demonstrates spherocytes and reticulocytes. Splenectomy is curative for the majority of patients with severe forms and is indicated in the presence of growth retardation, skeletal changes, symptomatic hemolytic disease, anemia induced organ dysfunction, leg ulcers, or development of extramedullary hematopoietic tumors.

Miscellaneous Disorders

Gaucher's disease
Amyloidosis
Sarcoidosis
Felty's syndrome

Preoperative abdominal ultrasonography should be performed for patients undergoing surgery, and cholecystectomy should be taken into account for patients with gallstones. Splenectomy is usually delayed until the age of 5 years to decrease the risk of overwhelming postsplenectomy infection (→ 794). There may be a role for partial splenectomy in younger children as some studies have shown clinical improvements with splenic function preservation.

Hereditary Elliptocytosis

Hereditary elliptocytosis (HE) is a rare disorder that results from mutation of the RBC membrane skeleton proteins spectrin, protein 4.1R, and glycophorin C. HE has a prevalence of 1 to 5 per 10,000 in the United States. Inheritance usually follows an autosomal dominant pattern, and the disorder is more common in people of African and Mediterranean descent. The true incidence is unknown because of the wide variety of clinical presentations. Most patients with the dominant inheritance are asymptomatic with a mild compensated anemia or no anemia at all. Affected cells are morphologically characterized by ovalocytes, elliptocytes, or rod-shaped cells. These cells are much more deformable than spherocytes, and patients have a less severe clinical course. In contrast, the rare autosomal recessive form can lead to severe hemolysis. Patients with mild HE, who are asymptomatic and without evidence of hemolysis, do not require treatment. Patients with chronic hemolysis may require blood transfusions and daily folic acid. Splenectomy is curative and indicated for patients with symptomatic anemia.

Hereditary Pyropoikilocytosis

Hereditary pyropoikilocytosis (HPP) is an autosomal recessive hemolytic anemia with microspherocytosis and thermal instability. HPP represents a subtype of HE, arising from the same molecular defects. Patients with HPP usually have a common HE mutation from one parent and a milder subclinical defect in spectrin from the other parent. The disease usually is seen as anemia and jaundice in newborns and infants. Splenectomy is curative and indicated for patients with severe anemia.

Hereditary stomatocytosis (Hydrocytosis) and Xerocytosis (Pseudohydrocytosis)

Hereditary stomatocytosis and xerocytosis are rare autosomal dominant hemolytic anemias characterized by a variable clinical course. In stomatocytosis, the underlying defect leads to increased erythrocyte permeability and volume. Stomatocytes have a mouth-shaped area with central pallor. In xerocytosis, there is a decrease in intracellular cation content and cell volume, and patients present with target cells and spherocytic cells on peripheral blood smear. For cases of severe hemolysis, splenectomy may improve symptoms but does not fully correct the hemolysis. In these patients, the role for splenectomy should be considered carefully because they can develop severe complications, such as hypercoagulability, leading to catastrophic thrombosis episodes, and chronic pulmonary hypertension. Fortunately, most patients have a mild clinical course and do not require surgical intervention.

Thalassemia

Thalassemia is an autosomal recessive genetic disease characterized by reduced production of alpha-globin protein for alpha-thalassemia and beta-globin protein for beta-thalassemia. The clinical manifestations associated with thalassemia arise from quantitatively imbalanced accumulation of globin subunits and inadequate hemoglobin production. The beta subtype is the most common form of thalassemia in the United States and occurs mainly in patients of Italian and Greek descent. Patients who have the heterozygous form of β-thalassemia (thalassemia minor) are usually asymptomatic with microcytosis and mild anemia. The homozygous form (thalassemia major or Cooley's anemia) is much more severe. Patients are usually asymptomatic until age 6 months because of the presence of fetal hemoglobin, they then develop severe hemolytic anemia, abdominal swelling, growth retardation, tetralogy, jaundice, pallor, splenomegaly, pigmented gallstones, and skeletal abnormalities. Laboratory values show a severe microcytic anemia with nucleated RBCs, acanthocytosis, and poikilocytosis. Patients may also have mild neutropenia and thrombocytopenia. Treatment requires monthly lifelong transfusions of RBCs, in association with iron chelators to avoid iron overload. Splenectomy is reserved for patients with increased blood transfusions in the setting of hypersplenism. Patients requiring more than 100 to 200 mL/kg/yr of RBCs are possible candidates for splenectomy. Usually, a 25% to 50% reduction in transfusion requirements is expected after splenectomy.

Sickle Cell Anemia

Dyspnocytosis (sickle cell anemia) is another autosomal recessive genetic disease resulting from an anomaly of the hemoglobin β chain that leads to the formation of hemoglobin S, which polymerizes under hypoxemic stress, inducing a characteristic sickle deformation in the shape of red cells. Sickle cells cause stasis and vascular occlusion, leading to tissue ischemia, severe pain, and chronic organ tissue damage. Exacerbations of symptoms are referred to as sickle cell crises. Management of this disease relies on general measures, such as hydration and transfusions, to prevent vaso-occlusive events and related complications. Patients who are homozygous for the disorder

have sickle cell disease, and many suffer autosplenectomy by an early age as a result of multiple infarcts. Therefore, splenectomy is rarely indicated but should be considered in the following situations: (1) after a major acute sequestration crisis, which is an absolute life-threatening emergency that requires transfusion; (2) hypersplenism, causing abdominal pain and increased transfusion requirements; and (3) splenic abscess, a rare but classic complication, enhanced by repeated infarctions. Acute splenic sequestration has high mortality, up to 15%, and is characterized by massive splenomegaly, acute exacerbation of anemia, and hypovolemia. This is primarily treated with restoration of blood volume and RBC mass, but recurrence is common. Splenectomy should be considered to prevent further episodes.

Pyruvate Kinase Deficiency

Pyruvate kinase deficiency (PKD) is the most common genetic defect causing congenital nonspherocytic hemolytic anemia. PKD is an autosomal recessive disease that occurs when a defect in the glycolytic pathway results in deficiency of adenosine triphosphate. RBCs are less deformable and often are destroyed in the spleen, leading to splenomegaly. Hemolysis can be exacerbated by acute infections and pregnancy. Patients with PKD have mild to severe anemia and splenomegaly. Clinically, these patients have mild symptoms resulting from the elevated levels of 2,3-DPG in RBCs, which result in a right shift of the hemoglobin–oxygen dissociation curve. This means that affected individuals have an increased capacity to release oxygen into tissues, enhancing oxygen delivery. Treatment is symptomatic, and splenectomy is only rarely indicated for patients with the severe hemolytic variants of PKD.

Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase deficiency is widespread (about 400 million people worldwide are carriers). X-linked genetic disease of the glutathione pathway, which leads to damage of RBCs by toxic oxygen products. It causes acute hemolytic accidents after oxidative stress (acute infections, certain medications, and fava beans), or, rarely, chronic hemolytic anemia. In adult patients, glucose-6-phosphate dehydrogenase deficiency does not usually require transfusion, except during severe hemolytic crises; management focuses on the avoidance of trigger food and medications. Splenectomy is not indicated, except in patients with severe hypersplenism, which requires transfusion dependency.

PLATELET DISORDERS

Immune Thrombocytopenia

Immune thrombocytopenia (ITP; formerly idiopathic/immune thrombocytopenic purpura) is an autoimmune disease caused by one or several antiplatelet antibodies directed against platelet glycoprotein complexes (GPIIb/IIIa, GPIb/IX). ITP leads to platelet destruction by the reticuloendothelial system in the spleen. In addition to humoral immunity, there is a component of cell-mediated immunity involved in this process. This condition is characterized by isolated thrombocytopenia with a platelet count that falls below 100,000/mm^3. Specific therapy is indicated when platelet count is less than 30,000/mm^3, but is also related to bleeding risk, presence of comorbidities, and risks of trauma.

Primary ITP is a diagnosis of exclusion as other illnesses, such as human immunodeficiency virus infection, systemic lupus erythematosus, antiphospholipid antibody syndrome, hepatitis C virus, and lymphoproliferative disorders, can cause secondary ITP. In addition, some medications and drugs may elicit similar immune-mediated platelet destruction (cocaine, antibiotics, antihypertensives, anti-inflammatories, heparin, quinidine, and abciximab). The prevalence of ITP in adults is about 5 per 100,000 people, occurring nearly twice as frequently in women. There is an approximately fourfold increase in prevalence in adults older than 65 years of age. Most patients with ITP are asymptomatic, whereas symptoms occur when platelet counts drop below 20,000/mm^3. Symptoms include bruising, purpura, petechiae, bleeding from the oral mucosa, epistaxis, menorrhagia, and gastrointestinal bleeding. Less than 1% of patients experience intracerebral hemorrhage, the most severe complication. The prevalence of ITP in children is approximately 12 per 100,000 in girls and 9 per 100,000 in boys. Children may present with a sudden onset of petechiae or purpura, usually days to weeks after an infectious disease. In the pediatric population, ITP is usually self-limited, with more than 70% remission within 6 months; the risk of intracerebral hemorrhage is less than 0.2%. Observation is a possible treatment option as long as the platelet count is greater than 20,000/mm^3. Conservative treatment is also reasonable in adults with platelet counts above 30,000/mm^3. However, patients who exhibit persistent thrombocytopenia or platelet counts below 30,000/mm^3 (20,000/mm^3 in children), should start corticosteroid therapy.

First-line treatment consisting of oral corticosteroids (typically prednisone) leads to complete remission in 10% to 30% of patients; high-dose corticosteroids (usually dexamethasone) leads to complete remission in 40% to 80% of patients. The standard initial dose is 1 to 2 mg/kg/d of prednisone for 2 to 4 weeks followed by a steroid taper. Several second-line therapy options are available including azathioprine, cyclosporine, cyclophosphamide, danazol, or dapsone, none of which has been shown to be superior to other therapies. More recently, new medications have been introduced. Rituximab, by its immunosuppressant effect, decreases the production of antiplatelet antibodies leading to a response in approximately 60% of patients and complete remission in about 40% of patients. Synthetic thrombopoietin receptor agonists have been recently developed. The two main medications used today, romiplostim and eltrombopag, lead to high rates of complete response, but relapses are frequent. Intravenous immunoglobulin (1 mg/kg/d for 1 to 2 days) can be considered for patients who would benefit from a rapid increase in platelet count (i.e., in the setting of bleeding or in preparation for an invasive procedure) or for those who are unable to tolerate steroids. Splenectomy has long been considered as the treatment of choice in the wake of corticosteroid failure because patients respond in 65% of cases with a durable 5-year response, without additional treatment in 60% of patients. Splenectomy is indicated for refractory thrombocytopenia, relapses requiring multiple cycles of therapy, or in patients who have experienced side effects of medical treatment. If perioperative platelet transfusion is needed, transfusion should be withheld until the splenic artery has been ligated. Several studies have reported that splenectomy can be safely performed, with minimal bleeding risk, even in patients with platelet count below 10,000/mm^3.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is a severe form of thrombotic microangiopathy characterized by the association of mechanical hemolytic anemia, peripheral platelet consumption, and microthrombosis involving different organs. TTP is a disorder in which a deficiency of the ADAMTS13 protein leads to increased platelet aggregation and subsequent microvascular thrombosis. The interaction between von Willebrand factor (vWF) and platelets is usually controlled by the ADAMTS13 protein, which cleaves von Willebrand factor and prevents platelet aggregation. TTP may occur spontaneously but is often precipitated by different factors such as chemotherapeutic agents (gemcitabine, mitomycin C, or calcineurin inhibitors), quinine, cyclosporine, clopidogrel, ticlopidine, hematopoietic stem cell transplantation, or pregnancy. The annual incidence of TTP is 4 to 10 cases per million. TTP is characterized by microangiopathic hemolytic anemia, severe thrombocytopenia, fever, neurologic complications, and renal failure. Patients have petechiae (most commonly on the lower extremities), fever, myalgia, and fatigue. Neurologic symptoms include headache, mental status changes, seizures, and even coma. Patients can develop congestive heart failure or

cardiac arrhythmias. TTP is suspected with unexplainable hemolytic anemia and thrombocytopenia in the setting of elevated lactate dehydrogenase and bilirubin, a negative Coombs test, and a peripheral blood smear demonstrating schistocytes, nucleated RBCs, and basophilic stippling. Initial therapy consists of daily plasma exchange. Plasmapheresis is carried out with a goal of exchanging 1.5 plasma volumes. Approximately 70% of patients will respond to this therapy. Platelet transfusions are generally not recommended because of the risk of severe clinical deterioration. Rituximab (anti-CD20 antibody) and glucocorticoids are second-line therapies. Until the 1970s, splenectomy was the only treatment modality for TTP. Now, splenectomy is reserved for refractory thrombocytopenia or relapses. When combined with high-dose steroid therapy, splenectomy has been shown to improve disease-free interval; however, the response rate is only 40%.

LYMPHOPROLIFERATIVE AND MYELOPROLIFERATIVE DISORDERS

Hodgkin's Lymphoma

Hodgkin's lymphoma is a malignant neoplasm of lymphoreticular cell origin that usually affects young adults in their second and third decades of life. Primary treatment consists of chemotherapy and/or radiation. Historically, splenectomy was performed as part of a staging laparotomy that included lymph node sampling and liver biopsy. Now, staging laparotomy has been replaced by imaging modalities such as computed tomography (CT) and positron emission tomography. Splenectomy may be beneficial for patients who develop splenomegaly and related thrombocytopenia.

Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphoma represents the most common primary neoplasm with splenic involvement occurring in 65% to 80% of cases. Splenectomy is indicated for symptoms related to massive splenomegaly and cytopenia resulting from splenic sequestration. Splenectomy may be helpful to assist with diagnosis and to determine appropriate therapy. This may occur in situations in which patients have failed therapy or when inadequate tissue is available for proper histologic or cytometric analysis. There are some subtypes of non-Hodgkin's lymphoma that involve the spleen more than others. Splenic marginal zone lymphoma represents a particular entity of indolent B-cell lymphoma in which the spleen is often the only organ macroscopically involved. Marginal zone lymphomas require strict surveillance and the indications for splenectomy should be discussed in symptomatic patients. However, splenectomy in these patients has been shown to lead to partial or complete remission because the spleen is the site of lymphoma origin. The discovery of isolated splenomegaly without any obvious etiology calls for complete work up, which leads to two possible scenarios: (1) splenomegaly remains isolated without a clear diagnosis of hematologic disease and splenectomy should be considered for diagnostic purposes. The alternative to splenectomy is a CT guided biopsy, which is diagnostic in 80% to 90% of cases. (2) When definitive diagnosis has been established, splenectomy might be part of the therapeutic strategy. However, in case of splenic mantle cell lymphoma, follicular lymphoma or diffuse large B-cell lymphoma, the indications for splenectomy are quite limited.

Hairy Cell Leukemia

Hairy cell leukemia is a rare disease, representing 2% of all leukemias. Patients have fatigue, left upper quadrant abdominal pain, fever, infections, and/or coagulopathy. The disease is characterized by B-lymphocytes that possess cytoplasmic projections from the cell membrane ("hairy cells"). This is an indolent disease that commonly occurs in the fifth decade of life with splenomegaly (80% to 90% of patients), pancytopenia, neoplastic peripheral mononuclear cells, and bone marrow infiltration. Pancytopenia is caused by hypersplenism and replacement of bone marrow by leukemic cells. In the past, splenectomy was considered the standard of care with a 40% to 70% improvement in the hematologic cell lines for up to 10 years. Recently, treatment with purine analogs, such as pentostatin and cladribine, has replaced splenectomy as primary therapy. These agents have patient response rates of 92%, with a complete remission rates of 80% and a 40% 10-year survival. Splenectomy is currently reserved for cases of incomplete response to first-line therapy, persistent splenomegaly in the absence of bone marrow involvement, traumatic splenic rupture, and severe bleeding.

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia represents a B-cell leukemia in which there is progressive accumulation of functionally impaired lymphocytes. Chronic lymphocytic leukemia usually arises after the fifth decade of life and is more common in men than in women. Splenic infiltration is common and can lead to severe splenomegaly and cytopenias from hypersplenism. Splenectomy is indicated to relieve symptoms associated with massive splenomegaly, such as abdominal pain, distension, and early satiety. Splenectomy for the treatment of severe thrombocytopenia and anemia, in the setting of secondary ITP or AIHA, has a 50% to 70% hematologic response rate and has been shown to improve survival.

Chronic Myelogenous Leukemia

Chronic myelogenous leukemia (CML) is a disorder resulting from an abnormal proliferation of granulocytes. Ninety-five percent of CML patients have a chromosomic translocation between chromosomes 9 and 22 [t(9;22)] leading to fusion of the breakpoint cluster region and Abelson leukemia virus gene. CML may occur in childhood but it is mainly found in adults with a mean age of 45 years. Diagnosis is commonly made during the chronic phase, which is characterized by splenomegaly in 40% of patients. Despite medical therapy, the disease can progress to an accelerated phase with development of fever, night sweats, weight loss, bone pain, increased white blood cell count, and splenomegaly. An acute blastic crisis with splenomegaly and hypersplenism can occur, resulting in severe anemia, bleeding, and infections. Current first-line therapy is with imatinib, a tyrosine kinase inhibitor. Bone marrow transplantation or interferon-alpha can be used in cases of poor response or relapse. Splenectomy has not shown any survival benefit in the early chronic phase or before bone marrow transplantation, but it may be offered as palliative treatment in patients with severe symptoms due to splenomegaly and hypersplenism.

Primary Myelofibrosis (Myelofibrosis With Myeloid Metaplasia)

Primary myelofibrosis (PMF) is a chronic malignant hematologic disorder that results in hyperplasia of abnormal myeloid precursor cells leading to marrow fibrosis and extramedullary hematopoiesis in the liver and spleen. This can lead to significant splenomegaly, cytopenia, and portal hypertension secondary to sinusoidal thrombosis. PMF is prevalent in patients with history of radiation or toxic industrial agent exposure. It is more common in men than women, with an average age of 65 years. Splenectomy is indicated for patients who develop hemolysis requiring significant transfusions, thrombocytopenia, symptomatic splenomegaly, recurrent splenic infarctions, hypercatabolic symptoms (anorexia, fatigue, fever, night sweats, weight loss), and portal hypertension with refractory ascites and variceal hemorrhage. Splenectomy in progressive myelofibrosis with myeloid metaplasia has a considerable risk of morbidity (15%–30%) and mortality (10%) and should be performed in select patients only. Splenectomy in patients with progressive myelofibrosis with myeloid metaplasia has been associated with hemorrhage, infection, leukocytosis, severe thrombocytosis (18%–60%), progressive hepatomegaly (12%–39%), fatal hepatic failure (7%), and leukemic

transformation (11%–20%). The appropriate use of palliative splenectomy in PMF can result in improved quality of life for patients who are unresponsive to conventional treatment. Perioperative use of platelet-lowering agents such as hydroxyurea, interferon alpha, aspirin, and anagrelide has been shown to reduce thrombotic complications. Ligation of the splenic vein at its confluence with the superior mesenteric vein has been described to improve hepatic flow and decrease portal vein thrombosis. Compensatory massive hepatic enlargement can be treated with low-level radiation and chemotherapy.

MISCELLANEOUS DISORDERS

Amyloidosis

Amyloidosis is a common disorder that results in extracellular deposition of insoluble fibrillar proteins in tissues and organs. Hepatosplenomegaly may occur in 25% of patients, and severe splenomegaly is seen in approximately 10% of individuals. Splenectomy is indicated for symptomatic splenomegaly. In addition, patients with severe hepatic dysfunction may develop coagulopathy associated with factor X deficiency. In these patients, splenectomy may improve factor X levels. Perioperative administration of factor VIIa is important to control bleeding in patients undergoing surgery. However, splenectomy does not modify the ultimate course of the disease.

Gaucher's Disease

Gaucher's disease is a glycolipid storage disease resulting from a deficiency of beta-glucosidase (glucocerebrosidase). This leads to deposition of glucocerebroside in the reticuloendothelial system with severe organomegaly, pulmonary infiltration, and bone marrow infiltration. Patients can have anemia, thrombocytopenia, osteopenia, bone pain, osteonecrosis, and massive hepatosplenomegaly. Splenectomy is indicated for severe and symptomatic splenomegaly and refractory cytopenia. Partial splenectomy has been advocated in children with Gaucher's disease to preserve splenic function. The spleen is a reservoir for storage material; therefore, splenectomy can result in redistribution and deposition in other organs causing severe bone disease (twofold increased risk of osteonecrosis) and worsening of lung and kidney function.

Felty's Syndrome

Felty's syndrome includes rheumatoid arthritis, neutropenia, and splenomegaly in 85% of cases this disease is associated with an HLA DR4 antigen. Patients present with chronic infections as a result of neutropenia, especially when neutrophils are below 0.5×10^9/mm^3. First-line treatment consists of low-dose methotrexate or disease-modifying antirheumatic drugs. Granulocyte colony-stimulating factor may be used for treatment failures, in cases of increased infection risk, or before surgery. Splenectomy is indicated when medical treatment fails and usually results in 80% hematologic response rate. Unfortunately, infectious complications may still occur and do not always correlate with granulocyte counts.

Sarcoidosis

Sarcoidosis is a noncaseating granulomatous disease. Although 90% of patients have primary lung involvement, it can affect every organ in the body. Primary splenic sarcoidosis is very rare, and splenic involvement is often found as part of a multiorgan disease. Up to 40% of patients with sarcoidosis have splenomegaly and 3% have massive splenomegaly. Treatment is usually conservative and includes corticosteroids or methotrexate. Indications for splenectomy include: splenomegaly and hypersplenism, intractable pain, and exclusion of a neoplastic process. Splenectomy does not alter the course of sarcoidosis but has been shown to improve refractory hypercalcemia.

FIG. 1 Accessory spleen.

Idiopathic Splenomegaly

In the setting of splenomegaly without a clear cause, splenectomy has a diagnostic and therapeutic role. Studies have revealed a 40% to 70% occurrence of lymphoma in this patient population. Most of these patients do not exhibit any signs of malignancy or lymphadenopathy. Tissue obtained through splenectomy may be the only way to perform appropriate histopathologic and cytologic diagnosis. When hypersplenism is present, splenectomy can alleviate symptoms of splenomegaly and correct cytopenia.

Preoperative Considerations

Preoperative imaging with ultrasound and/or CT scan is critical for operative planning. CT provides information regarding anatomic relationships, spleen size, vascular anatomy, presence of accessory spleens (Fig. 1), perisplenic lymphadenopathy, and inflammation. The normal spleen measures about 11 cm in length. Moderate splenomegaly, from 14 to 25 cm, should be noted in preoperative planning. Massive splenomegaly, greater than 25 cm length, may change preoperative and intraoperative strategy (Fig. 2). Although not indicated for routine total splenectomy, preoperative splenic artery embolization can be useful in patients with massive splenomegaly to prevent excessive blood loss in the setting of severe thrombocytopenia, or in patients who do not wish to receive blood transfusions. In addition, embolization helps reduce the splenic tissue hypercoagulopathy. Timing is important because patients can develop significant pain from infarcted splenic tissue; we suggest performing angiographic embolization within 24 hours before surgery. A broad-spectrum antibiotic prophylaxis should be administered at the time of induction of anesthesia and continued postoperatively for at least 24 hours. Low-molecular-weight heparin should be administered subcutaneously before induction of anesthesia and should be continued postoperatively for up to 1 month as prophylaxis for splanchnic thrombosis. The use of an orogastric or nasogastric tube can reduce gastric distension and improve visualization and dissection of the short gastric vessels along the greater curvature of the stomach. Blood products must be available intraoperatively, especially platelets for patients with severe thrombocytopenia. Prophylactic platelet transfusions are typically given only when the platelet count is below 50,000 and the platelets are administered only after the splenic artery has been ligated. If patients have been treated with chronic corticosteroids, stress dose steroids should be administered with a rapid taper postoperatively. In elective cases, it is recommended to vaccinate patients against encapsulated organisms (haemophilus influenzae B, polyvalent pneumococcus, and meningococcus vaccines) 2 weeks before splenectomy. If splenectomy is emergent, the patient should be vaccinated postoperatively.

FIG. 1 Massive splenomegaly in a patient who underwent splenectomy for complications of a deep open cut wound.

FIG. 2 Laparoscopic splenectomy, anterior approach.

Surgical Procedure

Laparoscopic splenectomy has become the standard approach for performing splenectomy in patients with hematologic disorders. The laparoscopic approach provides the advantages of shorter length of stay, decreased postoperative pain, and decreased morbidity. Recent studies have shown a trend toward shorter operative times that are comparable to open splenectomy in cases of normal or moderately enlarged spleens. Most data show comparable detection of accessory spleens that can result in disease recurrence in cases of autoimmune hematologic disorders. However, laparoscopic splenectomy is not a forgiving procedure. Methodical control of the hemostasis is the key for success. The splenic parenchyma is fragile, has a rich blood supply, and is particularly vulnerable to capsular tear and hemorrhage. Understanding the variation of splenic anatomy is essential for a safe intraoperative management. Much of the controversy surrounding laparoscopic splenectomy involves the size of the spleen. The normal adult spleen measures up to 11 cm in length and weighs approximately 80 to 300 g. Moderate splenomegaly generally is defined as a spleen that is 11 to 25 cm, and massive splenomegaly represents a spleen that is more than 25 cm. We believe that laparoscopic splenectomy can be performed safely in patients with splenomegaly. Factors to be considered should include medical comorbidities, indication for surgery, blood counts, coexisting coagulopathy, and history of previous splenic embolization. The hand-assisted laparoscopic approach may be useful for inexperienced surgeons to shorten the learning curve and to allow rapid control of hilar vessels and assistance with retraction. Nevertheless, open surgery should never be considered a failure and may be the safest approach in some cases. Laparoscopic splenectomy can be performed with the patient in lateral decubitus position or supine. A bean bag can be used to facilitate positioning for surgeons who prefer the right lateral decubitus approach. A split leg bed can be helpful when the patient is supine; this also allows the surgeon to stand between the patient's legs. For the anterior approach, port placement generally includes a 12-mm periumbilical camera port, and three to four additional ports in a V-shaped placement adjacent to the left upper quadrant, with the initial port for the camera at the base of the V. One line of the V extends from the initial port to the xiphoid process; the other line of the V extends from the initial port to the most lateral left subcostal region. Two dissection ports are placed, one near the midline and one along the lateral V line. A 10- to 12-mm port at this location may be preferable because it is likely the port for introduction of an endoscopic stapler or Endocoby device. An additional port for retraction is placed further lateral at the anterior axillary line (Fig. 2). If a fifth port is necessary for retraction, it is placed in the subxiphoid region. Access to the abdomen can be gained using a Veress needle, an optical trocar, or an open approach depending on the surgeon preference. The patient is then placed in reverse Trendelenburg and tilted slightly to the right. For patients with large liver or splenomegaly, a self-retaining liver retractor, such as the Nathanson device with fan clamp, can facilitate visualization. For the lateral approach, the position is similar to that used for posterolateral thoracotomy and/or laparoscopic left adrenalectomy. Patients are initially positioned supine on a beanbag. Once general anesthesia is established and the airway is secured, the operative team repositions the patient in lateral decubitus with the right side down. The kidney rest is raised, and the operating table is flexed. The goal is to maximize the working space between the left costal margin and the left anterior superior iliac spine. The umbilicus is avoided, and the first port is positioned approximately one-third the distance from the umbilicus to the splenic hilum. After securing access to the peritoneal cavity, typically three additional ports are placed along the costal margin. Depending on the splenic size and body habitus, it may be necessary to place the trocars inferiorly or medially. A 10- to 12-mm port, capable of accommodating an endostapler or large Endocoby device, is typically placed in the left subcostal anterior axillary line. A 5-mm port is placed in the left subcostal region in the midaxillary line. A fourth port, usually 5 mm, is placed in the far left lateral subcostal position. Occasionally, an additional port is required for retraction toward the midline, near the xiphoid process (Fig. 4). The abdomen is explored, paying careful attention to identify any accessory spleens. The liver should also be inspected for signs of cirrhosis. The splenocolic ligament is mobilized and divided with an energy device. This allows for further mobilization and inferior retraction of the splenic flexure of the colon. The gastrosplenic ligament and the short gastric vessels then are divided using an ultrasonic energy device, endoscopic metallic clips, or bipolar energy device. This dissection should be carried up to the level of the left crus, and the stomach can be retracted to the right. The splenorenal ligament then is dissected to identify the splenic artery and splenic vein within the splenic hilum (Fig. 5). These structures then are divided using a vascular load on an endoscopic linear stapling device. The splenophrenic ligament is divided last because it maintains cephalad/lateral retraction of the spleen during dissection of the hilar vessels. The spleen is then placed into an endoscopic bag and morcellated. After extraction, the splenic bed, hilum, and greater curvature of the stomach should be inspected thoroughly to ensure hemostasis. At this point, the abdomen should be examined again for splenunculi or accessory spleens. The most common locations for splenunculi are the gastrosplenic ligament and greater omentum. For open splenectomy, a midline or left subcostal incision may be used. The midline incision may be preferable to patients with massive splenomegaly or with a narrow costal margin.

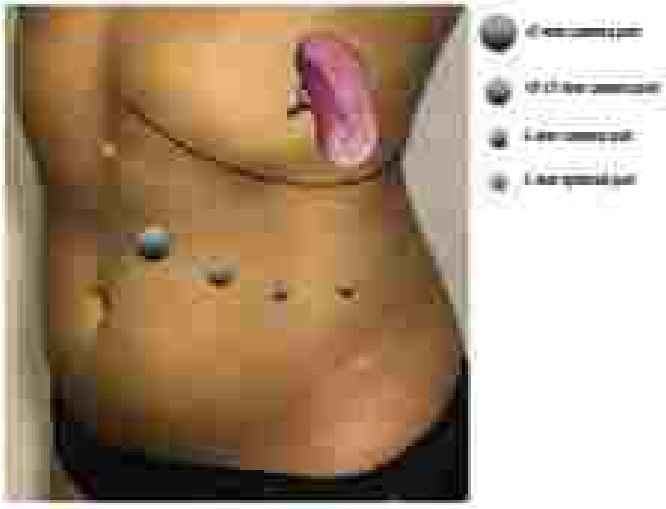

FIG. 4 Laparoscopic splenectomy lateral approach.

FIG. 5 Laparoscopic view of splenic vein ligation.

Postoperative Management and Complications

Postoperative care following a laparoscopic splenectomy is a straightforward process, provided that the procedure is uneventful. Orogastric tubes and urinary catheters are removed immediately after the operation and routine postoperative chest radiograph is not required. However, patients should be monitored for hemorrhage, atelectasis, and infection in the early postoperative period. The most common site of hemorrhage at reexploration is from the undersurface of the diaphragm. Deep vein thrombosis prophylaxis is continued postoperatively with pneumatic sequential compression devices and heparin or enoxaparin, unless contraindicated. A diet is restarted as tolerated. Typical length of stay is 1 day, although many series report average length of stay of 2 to 3 days. Infectious complications include subphrenic abscess and OPSI. All patients undergoing splenectomy should be counseled regarding their increased lifetime risk of infections. If patients were unable to receive preoperative vaccinations, they should be vaccinated 2 weeks after surgery. Vaccinations should be withheld for 3 months after surgery in patients who have been treated with immunosuppressive agents. Patients should receive booster vaccinations every 5 years for pneumococcus and meningococcus. Prophylactic antibiotics have been recommended for at least 2 years in children but generally are not used in adults. Penicillin is the agent of choice (Box 3). In patients with penicillin allergies, trimethoprim-sulfamethoxazole or erythromycin may be used.

BOX 2 Guidelines for OPSI Prophylaxis

Incidence of OPSI

- [illegible] 2 years after splenectomy (4.2% to 9.9%) [illegible] 5.0%)
- Risk factors: Age < 5 years, [illegible] malignancy, [illegible] > suppression

Vaccination and Antibiotic Prophylaxis Recommendations

[illegible] children

- Haemophilus influenzae type B, pneumococcus, meningococcus 2 wk preoperatively (elective cases) or at discharge or 2 wk postoperatively
- If [illegible] received [illegible] immunosuppressive therapy, vaccines 3 mo after treatment
- Booster vaccinations for pneumococcus, meningococcus every 5 yr
- If [illegible] vaccine antibody titers can be followed for need of a booster dose
- [illegible] neither monitoring titers. Fail-save to immunocompromised patients

- Antibiotic prophylaxis
- [illegible] children [illegible] penicillin
- Amoxicillin, lactic acid tablets for [illegible] sensitivity in children [illegible]
- Children [illegible] 5 yr of age [illegible] recommended

[illegible] 2.0 mL/kg [illegible]

The risk for OPSI is higher in children younger than age 5 and within the first 2 years after surgery but does carry a lifelong risk. Risk factors for OPSI include age (14% in children younger than 5 years vs 6.5% in children older than 5 years), splenectomy for a hematologic disorder, and history of immunosuppressant therapy.

PSI has a reported fatality rate of 50%. Streptococcus pneumoniae, Neisseria meningitidis, H. influenzae type B, and group A streptococcus account for most of the severe infections. Escherichia coli, Capnocytophaga species, and intraerythrocytic parasites also pose a risk. Patients typically have an upper respiratory infection that rapidly proceeds to sepsis and multisystem organ failure. An early and aggressive treatment with broad-spectrum antibiotics and supportive measures can be lifesaving. Other postoperative complications include thrombocytosis, leukocytosis, pneumonia, pleural effusion, pancreatitis, pancreatic fistula, venous thrombosis, injury to adjacent organs, and hyperplenism resulting from the presence of a retained accessory spleen. Thrombocytosis can occur postoperatively with a peak at 3 weeks. Antiplatelet therapy is indicated with thrombotic complications or when platelet levels reach 1 million. Patients with an accessory spleen often have an absence of Howell-Jolly bodies, and target cells in the peripheral blood and may require reexploration for accessory spleens or refractory anemia/thrombocytosis. Portal vein or mesenteric vein thrombosis can be a serious complication of splenectomy. Postsplenectomy splanchnic venous thrombosis has been reported in 20% to 50% of patients undergoing splenectomy, with higher rate for laparoscopic splenectomy. For this reason, patients should be maintained on prophylaxis with low molecular weight heparin for 4 weeks. Risk factors for thrombosis include myeloproliferative disorders, hemolytic anemias, long spleens with manipulation, postoperative thrombocytosis, hypercoagulable state, and splenomegaly. Patients present with vague abdominal pain and distention, fever, liver, and nausea and can develop intestinal infarction and portal hypertension. In the setting of splanchnic venous thrombosis, systemic anticoagulation is required, which leads to effective thrombolysis in more than 90% of patients, if promptly treated.

CONCLUSION

Splenectomy remains an important tool for the treatment of a wide range of acquired, congenital, and neoplastic hematologic disorders. Splenectomy can also serve as a diagnostic tool in the setting of idiopathic splenomegaly. To ensure a safe perioperative course, management of patients undergoing splenectomy requires careful preoperative preparation and postoperative management.

Management of Cysts, Tumors, and Abscesses of the Spleen

Anna Lee B. Mann, MD, and Peter Mac A. Villa, MD

Typically found incidentally on imaging, cysts and tumors of the spleen are uncommon entities. When symptomatic, they may be life threatening and warrant surgery. The incidence of splenic abscesses is decreasing with increasing awareness and administration of antibiotics. Splenic abscesses continue to be a source of significant morbidity in affected patients. This chapter describes the presentation and management of the numerous cysts, tumors, and abscesses of the spleen. We focus primarily on laparoscopic splenectomy as the gold standard operative intervention.

SPLENIC CYSTS

There are several known classification systems for splenic cysts. Cysts are categorized as primary (true) or secondary (false) cysts. Secondary splenic cysts are the most common, accounting for 90% of all splenic cysts. They usually are described as developing in the posttraumatic or postinfectious setting, the latter most commonly resulting from mononucleosis or tuberculosis. Another subcategorization is nonparasitic versus parasitic cysts. Parasitic cysts are the most common worldwide and are frequently related to echinococcal infections. This can easily be determined by the presence of calcifications or daughter cysts on imaging with positive serologies. Anaphylaxis, shock, and death have been described after spillage of echinococcal cyst contents, so care must be taken in handling these cysts during surgery. Congenital cysts are usually benign and are subdivided into epidermoid, dermoid, and endodermoid or simple cysts. The epidermoid subtype accounts for 90% of primary nonparasitic cysts.

There is no evidence-based determinant of a threshold for the watch and wait approach management of asymptomatic cysts, although most would advocate intervention when cysts are larger than 5 cm. Further diagnostic testing or biopsies are unnecessary and can often cause increased morbidity. When symptomatic, patients will most frequently report vague upper abdominal pain from capsular distention or mass effect on adjacent organs but may also report nausea, vomiting, early satiety, or diarrhea. Cysts that are either enlarging, symptomatic, or larger than 5 cm should be considered for intervention (Fig. 1). The risk of rupture and infection increase with increasing size, with hemoperitoneum or intraabdominal abscess being the greatest source of morbidity and possible mortality.

Total splenectomy is still considered by many as the gold standard for management of nonparasitic splenic cysts; however, a growing body of evidence is developing that favors organ preservation. Partial splenectomy, when technically feasible, may be superior to total splenectomy because of the benefit of maintaining the immunologic function of the spleen. Thus, the life-threatening complication of overwhelming postsplenectomy sepsis is prevented.

Other spleen preserving management strategies have been described and include percutaneous drainage, cyst fenestration, and marsupialization. Percutaneous drainage has been shown to have a high risk of recurrence. The risk of recurrence decreases with injection of sclerosing agents such as alcohol and tetracycline. Percutaneous drainage has also been described as an adjunct to decrease cyst size preoperatively. This may cause increased adhesions to the left upper quadrant adding complexity to the surgery, however.

Cyst fenestration, in which the anterior cyst wall is unroofed and the contents drained, is effective but also has a high rate of recurrence. Omental flaps may be placed in the region of the cyst and have been shown to decrease recurrence rates slightly. There is no consensus on the amount of cyst wall that needs to be removed for a successful fenestration with low rates of recurrence. A similar procedure, cyst marsupialization, in which the cyst wall is separated from the splenic parenchyma in its entirety, has the lowest rate of recurrence but has the significant complication of bleeding. This hemorrhage is often controlled effectively with electrocautery and hemostatic agents. Marsupialization is recommended for superficial splenic cysts that are easily accessible.

Splenic Peliosis

Splenic peliosis is a rare benign condition that has been reported and is better described in the liver. Sinusoidal dilatation leads to the appearance of multiple blood-filled "cystic" cavities scattered within the splenic parenchyma in the periarteriolar red pulp. Rupture of these cavities may lead to hemorrhagic shock and subsequent death. Risk factors for peliosis include HIV, cytotoxic steroid usage, oral contraceptives, and chronic hematologic disorders, including Hodgkin's lymphoma and multiple myeloma. In most of these cases, both the liver and spleen are involved. Isolated splenic involvement is extremely rare and often presents as hemoperitoneum. Management is total splenectomy even when peliosis is detected incidentally to eliminate the risk of hemorrhage.

CONCLUSION

Splenectomy remains an important tool for the treatment of a wide range of acquired, congenital, and neoplastic hematologic disorders. Splenectomy can also serve as a diagnostic tool in the setting of idiopathic splenomegaly. To ensure a safe perioperative course, management of patients undergoing splenectomy requires careful preoperative preparation and postoperative management.

BOX 1 Splenic Neoplasms

Benign tumors
- Hemangioma
- Lymphangioma
- Hamartoma
- Littoral cell angioma

Malignant tumors
- Lymphoma
- Angiosarcoma

Nonvascular, nonhematopoietic tumors
- Inflammatory pseudotumor
- Mesenchymal tumors

Metastatic tumors

SPLENIC TUMORS

Primary splenic neoplasms are rare entities that can be categorized by their tissue of origin (Box 1). Lymphoid neoplasms arise from the white pulp, whereas vascular neoplasms arise from the red pulp. In addition to this categorization, primary neoplasms can be more readily divided into benign and malignant tumors. Benign tumors include hemangioma, lymphangioma, hamartoma, and littoral cell angioma. Malignant tumors include lymphoma and angiosarcoma. Other tumors such as lipoma and inflammatory pseudotumors have been described but are exceedingly rare with very few reports in the literature. Secondary neoplasms also occur within the spleen with melanoma, breast, lung, ovary, colon, stomach, and pancreatic neoplasms all being reported as metastasizing to the spleen.

Benign Tumors

Hemangioma

The most common benign tumors of the spleen are hemangiomas. Most patients are asymptomatic, and the tumors are found incidentally on imaging. Most are smaller than 2 cm in size and solitary, although multiple and diffuse lesions can be noted rarely with hemangiomatosis and generalized angiomatosis syndromes. Splenic hemangiomas come in two varieties: capillary and cavernous, the latter being the more common. These two patterns have slightly different appearances on imaging. On ultrasound, hemangiomas appear as echogenic lesions with cavernous lesions showing a more complex nature. On computed tomography, punctate peripheral calcifications are characteristic. Hemangiomas larger than 3 cm have an associated risk of bleeding and may be considered for complete or partial splenectomy.

Lymphangioma

Splenic lymphangiomas are benign and slow-growing neoplasms that are more commonly found during childhood. As with hemangiomas, these lesions may be unifocal or part of a systemic lymphangiomatosis syndrome involving multiple organs. Unlike hemangiomas, they can appear multiloculated, lobulated, and cyst like. In children, they still often present as a palpable abdominal mass because they tend to be larger in size. Lymphangiomas detected in adulthood are typically incidental on imaging and patients remain asymptomatic. Three histologic subtypes are capillary, cavernous, and cystic. These entities are hypoechoic on ultrasound and hypodense on computed tomography. They are more common in a subcapsular location and may have enhancing septa and peripheral rim calcification (Fig. 2). The current standard of management for suspected splenic lymphangiomas has traditionally included splenectomy, although splenic preservation with partial splenectomy is increasingly being used.

Hamartoma

Characterized by malformation of the red pulp without organized lymphoid follicles, splenic hamartomas are rare benign lesions. They are usually small in size and discovered incidentally on imaging but can rarely present as a large mass or diffuse splenomegaly. Most patients are asymptomatic, but spontaneous splenic rupture has been reported to associations with this entity particularly in larger masses. Ultrasonography depicts a well-circumscribed homogenous solid mass, whereas computed tomography demonstrates early enhancement with intravenous contrast and uniform delayed enhancement of an isodense mass. With larger hamartomas, more heterogeneous contrast uptake and prolonged retention of contrast may be seen likely because of stagnation within the red pulp sinusoids. Imaging, though suggestive of a diagnosis, is not always definitive and percutaneous biopsy is warranted when feasible. If biopsy is not possible, splenectomy is indicated for definitive diagnosis and management.

Littoral Cell Angioma

The cells lining the red pulp, known as littoral cells, may give rise to a benign vascular neoplasm of the spleen known as littoral cell angioma. This entity was first described in 1991 and has been characterized by diffuse nodular involvement of the spleen. As such, patients may present with splenomegaly and signs of hypersplenism, including anemia, fatigue, and bleeding. Splenic rupture and hemoperitoneum have also been described. Noncontrast computed tomography shows multiple nodular masses of varying size. Following contrast administration, the masses appear hypodense on the early portal phase, returning to an isodense appearance on the delayed phase.

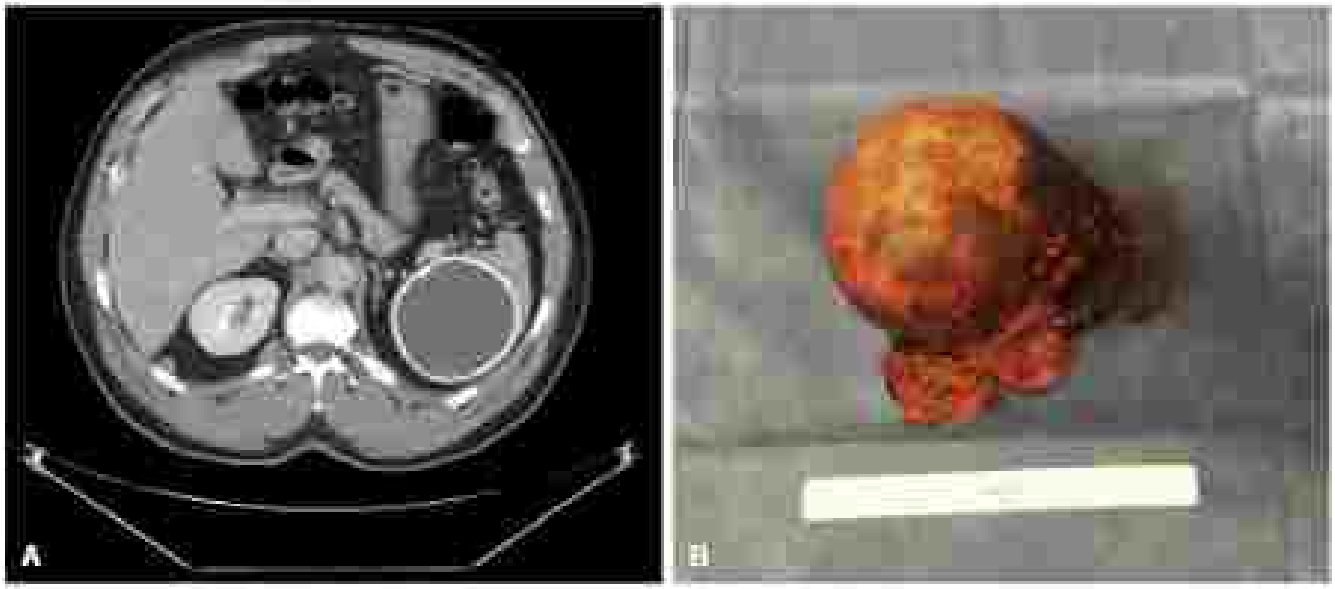

FIG. 2. (A) A large (>6 cm) cavitary splenic lesion was seen on computed tomography. (B) An thin cavitary wall is noted on the surgical specimen after splenectomy.

because of the risk of splenomegaly and hypersplenism, splenectomy is advocated for when littoral cell angiomas are detected. Confirming the diagnosis, pathologic specimens have shown small vascular channels lining cystic spaces with papillary projections on histology.

Malignant Tumors

Lymphoma

The most common primary malignant tumor of the spleen is lymphoma. Primary splenic lymphoma accounts for less than 1% of all lymphomas and usually represents non-Hodgkin's B cell lymphoma. Despite this, secondary involvement of the spleen with lymphoma is far more common than primary disease. Splenomegaly is the most common finding on examination for primary splenic lymphomas and is present in more than two-thirds of cases. Diagnostic criteria have classically included disease limited to the spleen and hilar nodes without recurrence after splenectomy. Thin needle aspiration and core needle biopsy have been avoided in the past resulting from concerns that puncture of the hypervascular, fragile spleen may lead to hemorrhagic complications. This has been disproved in most recent studies and is considered safe practice.

Of special note, splenic marginal zone lymphoma is a slow-growing subtype that almost always presents with splenomegaly. It is associated with hepatitis C virus infection. Treatment has traditionally been splenectomy but more recently rituximab monotherapy has been found to be efficacious as the initial treatment of this subtype of primary splenic lymphoma. The prognosis is good with appropriate treatment with an estimated 5-year overall survival of 80% to 95%.

Angiosarcoma

The most common primary nonhematopoietic malignant neoplasm of the spleen is the rare angiosarcoma. Also known as hemangiosarcoma, these tumors tend to be highly aggressive and carry a poor overall prognosis. Patients often present with advanced disease, already having splenomegaly and evidence of metastasis, most commonly to the liver. Spontaneous splenic rupture is the presenting finding in a quarter of patients diagnosed with this neoplasm. Multiple complex heterogeneous and hypervascular masses are seen on imaging. Calcifications are rarely noted. As with lymphoma, biopsy had been avoided in the past from concerns for bleeding but has now been considered safe when care is taken. Treatment is with splenectomy when feasible.

Other Nonvascular, Nonhematopoietic Splenic Tumors

Inflammatory pseudotumor is an uncommon benign tumor of the spleen. The etiology is unclear but is likely related to an inflammatory reparative response to traumatic or infectious injury. Usually an incidental finding on imaging, patients are frequently asymptomatic but may present with symptoms from mass effect. On computed tomography, these pseudotumors appear as a hypodense mass with delayed contrast enhancement and central scarring. If the patient is symptomatic, or there is question of the diagnosis, splenectomy should be performed. Pathology will confirm the diagnosis by the presence of spindle cell proliferation and plasma cells.

Mesenchymal tumors such as fibroma, fibrosarcoma, lipoma, angiomyolipoma, leiomyosarcoma, and malignant fibrous histiocytoma have been described in the literature and are very rare. Apart from the characteristic presence of fat in lipoma, there are no specific pathognomonic features on imaging with these neoplasms. Patients are frequently asymptomatic and the diagnosis is made after splenectomy.

Metastatic Tumors

Overall splenic involvement in metastatic disease is uncommon. Splenic metastases are found in less than 10% of all untreated malignancies. There are numerous theories for why the spleen is seemingly protected from metastases. These include the lack of afferent lymphatics, the sharp angle of the splenic vessels, and antitumor activity of the splenic lymphoid tissue itself. Hematogenous spread is the most likely route when splenic metastases do occur. The most common primary malignancies to metastasize to the spleen are melanoma, breast, lung, and ovarian cancers.

Rarely, metastases from colon, stomach, and pancreas primaries are also found. Though infrequent, these latter tumors may spread via direct invasion into the spleen. Diffuse infiltration is rare. More commonly, metastatic disease is seen as solitary or multiple masses. Radiologic findings vary with the primary neoplasm. Cystic and necrotic degeneration can occur, particularly with melanoma. Calcifications may be noted with mucinous adenocarcinomas. Carcinomatosis and pseudomyxoma peritonei may manifest as serosal implants on the splenic surface, also visualized as splenic margin scalloping.

SPLENIC ABSCESS

Abscesses of the spleen are uncommon complications of other underlying infectious processes. They most frequently occur via hematogenous spread in the presence of bacteremia or fungemia but can also happen by contiguous spread. Clinically, splenic abscess has been associated with endocarditis, although urinary tract infections and gastrointestinal infections have also been implicated. Patients most commonly present with fever and left upper quadrant pain, often with signs of sepsis. People at high risk for splenic abscess include those who are immunosuppressed (e.g., HIV, diabetes, hemoglobinopathies, amyloidosis, Felty syndrome, abnormalities of the spleen such as cysts, intravenous drug abusers). Those patients with HIV are at the highest risk. Diagnosis is best made using ultrasonography or computed tomography.

Antibiotic therapy should be tailored to cover the most frequently cultured organisms. Gram-positive cocci, including *Staphylococcus* species and *Streptococcus* species, and gram-negative enteric organisms, *Salmonella* species in particular, are most common isolates. In the immunocompromised, coverage for *Mycobacterium* species and *Candida* species should also be considered, especially for those who may present in septic shock.

Definitive management of splenic abscesses with percutaneous drainage has had good success in most recent studies. Patients most likely to achieve complete resolution with percutaneous or image-guided drainage are those with unilocular abscesses. For patients who fail to improve clinically, have multiloculated abscesses, or incomplete resolution after initial drainage, splenectomy is indicated.

SURGERY

Aside from surgery for splenic trauma, surgery is most commonly complicated by bleeding and infection. Given these risks, preoperative planning is of considerable importance and should be performed in every patient. The gold standard of surgical management remains laparoscopic splenectomy. Laparoscopic splenectomy provides the advantages of shorter length of stay, decreased postoperative pain, and decreased morbidity as compared with open splenectomy. The latter still occurs predominantly in the setting of trauma and large malignant tumors not amenable to removal laparoscopically. Other spleen-preserving methods are briefly described earlier in this chapter.

Preoperative Considerations

Preoperative imaging is imperative for operative planning. Computed tomography and ultrasonography are both acceptable options for assessing splenic size. The former may be preferred because it provides better visualization of the anatomic relationships and anatomy, including the presence of accessory spleens and hepatolienopathy. Other factors to be considered in the preoperative assessment include medical comorbidities, splenic size, blood counts, coexisting coagulopathy, history of previous splenic irradiation, or percutaneous manipulation.

Appropriate preoperative antibiotics are given to cover skin flora prior to making skin incision. Despite the risk of bleeding, there is also a risk of splanchnic thrombosis after manipulation of the splenic vessels such that we routinely administer low molecular weight heparin before induction of anesthesia and continue this postoperatively for up to 1 month as prophylaxis. Gastric decompression with an orogastric or nasogastric tube can reduce gastric distention and can improve visualization, particularly when the short gastric vessels are dissected along the greater curvature.

Blood products should be available intraoperatively, particularly in patients with severe thrombocytopenia. After ligation of the splenic artery, platelets are transfused only as needed and not routinely required. In the elective setting, patients are vaccinated against encapsulated organisms (haemophilus influenzae B, polyvalent pneumococcus, and meningococcus vaccines) 2 weeks before splenectomy to minimize the risk of overwhelming postsplenectomy sepsis. If the splenectomy is emergent, the patient should be vaccinated before discharge from the hospital.

Laparoscopic Splenectomy

The spleen is located high in the left upper quadrant of the abdomen and protected by the lower ribs. In a normal, healthy adult it weighs approximately 80 to 300 g and measures 10 to 12 cm in greatest dimension. Laparoscopic splenectomy can be performed safely in patients with splenomegaly, even in cases where the spleen is greater than 20 cm in length. The major limitation in our experience has been the size of the retrieval device. The hand-assisted laparoscopic approach may be a useful adjunct for selected patients with splenomegaly because it allows for rapid control of hilar blood flow.

In the case of massive splenomegaly, preoperative splenic artery embolization with absorbable gelatin powders may also be useful and may allow laparoscopic resection where it previously was not possible. This technique may also be advantageous in the setting of severe thrombocytopenia to minimize excessive blood loss. We do not routinely perform this adjunct because embolization may cause severe pain and ischemia, making patient selection crucial.

For a laparoscopic splenectomy, the patient is placed in either right lateral decubitus or the supine position with a bump under the left side. If the supine position is selected, a split-leg bed can be useful to facilitate dissection when the surgeon stands in between the legs. Access to the abdomen can be gained using either a closed or open technique based on surgeon preference and patient factors. Further port placement generally includes a 5 mm periumbilical camera port, a 5 mm right upper quadrant port, a 5 mm left upper quadrant port, and a 12 mm left sided port placed inferolateral to allow for an endoscopic stapling device. Exposure of the spleen is facilitated by placing the patient in reverse Trendelenburg with the left side up. If required, a Nathanson liver retractor may be placed through a 5 mm incision between the xiphoid process and the left costal margin. The abdomen should be explored at this point to assess for the presence of accessory spleens or splenunculi. The most common locations are the gastrosplenic ligament and greater omentum.

The dissection begins with the inferior attachment of the spleen, the avascular splenocolic ligament. This is mobilized and divided with an energy device and allows for inferior retraction of the colonic splenic flexure of the colon. The gastrosplenic ligament, containing the short gastric vessels, is then divided using an energy device. This dissection should be carried up to the level of the left crus and the stomach can be retracted to the right. Care is then taken while mobilizing the posterior attachment of the spleen, the lienorenal ligament, to identify the splenic artery and splenic vein within the hilum. These structures are then divided with an endoscopic linear stapling device. Care should be taken to avoid injury to the tail of the pancreas in this area. The splenophrenic ligament is the last attachment to be divided as it maintains cephalad and lateral retraction of spleen during division of the hilar vessels.

The spleen is then placed into an endoscopic retrieval bag. The edges of the bag are then brought through the lateral trocar site and the spleen is morcellated using ringed forceps. This piecemeal extraction should be avoided if malignancy is suspected. A hand-assisted laparoscopic approach can still be utilized in this situation by creating a small upper midline laparotomy or a small Pfannenstiel incision. If this is not possible, open splenectomy via a midline or left subcostal incision should be considered. Before closure, the surgical bed is again inspected carefully for hemostasis. Drains are not placed routinely unless there is suspicion for pancreatic injury.

Postoperative Management and Complications

In the early postoperative period, monitoring for hemorrhage is of the utmost importance. The most common site of hemorrhage

al recuperation to the undersurface of the diaphragm. Infectious complications are also common, with subphrenic abscess the most common in the early postoperative state. Overwhelming postsplenectomy infection is a potentially fatal complication with a reported 50% mortality rate. It is usually a late occurrence with most cases occurring greater than 2 years after splenectomy, but they can occur at any time in the patient's postoperative course. Patients typically present with symptoms of an upper respiratory infection that is rapidly progressive to sepsis with multiorgan failure. A high index of suspicion is required and early and aggressive treatment with broad-spectrum antibiotics is necessary. Children younger than 5 years are at highest risk. Vaccinations are critical for prevention with booster vaccines necessary every 5 years for pneumococcus and meningococcus. Despite this, overwhelming postsplenectomy infection is exceedingly rare, and most surgeons cannot recall ever treating a case.

Other postoperative complications include thrombocytosis, leukocytosis, pneumonia, pancreatitis, pancreatic fistula, venous thrombosis, and hypersplenism resulting from the presence of a missed accessory spleen. Reactive thrombocytosis is observed frequently, can occur immediately, and peaks at 3 weeks. Antiplatelet therapy is reserved for patients with thrombotic complications or when platelet counts reach 1 million. Hypersplenism from missed accessory spleens can be treated with selective embolization but may require reexploration if the patient fails and is symptomatic.

Portal or mesenteric vein thrombosis is well described after ligation of the splenic vein. It has been reported in up to 50% of postsplenectomy patients with higher rates with laparoscopic approaches as compared to open. Risk factors include a long splenic vein stump, postoperative thrombocytosis, hypercoagulable state, myeloproliferative disorders, hemolytic anemias, and preoperative splenomegaly. Patients will often present with vague abdominal pain, distention, and fever. Ultimately, if untreated, intestinal ischemia and portal hypertension can occur. Given these potentially devastating outcomes, patients can be maintained on prophylactic doses of low molecular weight heparin for 4 weeks postoperatively.

CONCLUSION

Splenic cysts, tumors, and abscesses, although uncommon, are potentially life-threatening entities of which every surgeon should be aware. Diagnosis is almost always made on imaging, particularly cross-sectional. In the symptomatic patient, surgery is indicated as definitive management to prevent life-threatening rupture with hemoperitoneum. Abscesses may be percutaneously drained with image guidance if amenable. Splenic salvage with partial splenectomy or other techniques may be considered if neoplastic lesions are small and there is no question of malignancy. Laparoscopic splenectomy continues to be the gold standard of treatment for any questionable splenic mass.

SPLENIC SALVAGE PROCEDURES

Yuan-Laur Larry Lee, MD, MS, and David [illegible], MD, FACS

Splenic injury represents the most common solid organ injury after blunt abdominal trauma in adults, and the second most common in children. Though splenectomy remains the definitive management of splenic injury, removal carries a variety of attendant risks, both immediate and remote. Splenic salvage, then, offers an attractive alternative when resources and the clinical situation permit.

RATIONALE FOR SALVAGE

The spleen performs a variety of hematologic and immunologic functions; its absence therefore exposes patients to potential risk, the most well characterized being overwhelming postsplenectomy infection (OPSI). Splenic macrophages are responsible for phagocytosis of opsonized pathogens, whereas resident lymphocytes play a crucial role in humoral immunity through antibody and cytokine synthesis. Splenectomy thereby reduces immunologic responsiveness until these assets can be redeveloped. Unsurprisingly then, OPSI is most common in the years immediately following splenectomy, although risks persist through the patient's lifetime. Despite this process being classically associated with encapsulated organisms, asplenism is associated with increased susceptibility to infections from nonencapsulated pathogens as well, including gram-negative bacteria and even protozoans. Vaccination, therefore, does not confer complete protection. At greatest risk are patients at the extremes of age, warranting a greater interest in salvage in these vulnerable populations.

The current availability of vaccines to encapsulated organisms has potentially aided in the fight against OPSI, although definitive data are lacking. Patients who undergo splenectomy for trauma are at a lower risk of OPSI than those whose spleens are removed for hematologic or oncologic indications. The unpredictable nature of trauma, the relatively suboptimal immunologic state for vaccination experienced in the immediate postsplenectomy period, and the high incidence of poor compliance is further motivation for splenic salvage.

The spleen also serves as a hematologic filter, removing senescent cells from circulation. Splenectomy therefore allows damaged cells and cellular debris to circulate, which may lead to elevated platelet viscosity, platelet activation, endothelial activation, and a general trend toward pro-coagulability. Asplenism therefore has been associated with venous thromboembolism, stroke, myocardial infarction, and pulmonary hypertension, though these sequelae are more commonly identified in patients undergoing splenectomy for hematologic disease. Additionally, loss of splenic elimination leads to leukocytosis and thrombocytosis, which can complicate interpretation of laboratory data in patients with complex presentations. The immunologic functions of the spleen may also have protective functions against malignancy. This risk, although historically described in populations undergoing splenectomy for staging purposes, has more recently been identified following traumatic splenectomies as well. Consequently, the benefits of splenic salvage are lifelong when preservation can be accomplished safely.

at reexploration to the undersurface of the diaphragm. Infectious complications are also common, with subphrenic abscess the most common in the early postoperative state. Overwhelming postsplenectomy infection is a potentially fatal complication with a reported 50% mortality rate. It is usually a late occurrence with most cases occurring greater than 2 years after splenectomy, but they can occur at any time in the patient's postoperative course. Patients typically present with symptoms of an upper respiratory infection that is rapidly progressive to sepsis with multiorgan failure. A high index of suspicion is required and early and aggressive treatment with broad-spectrum antibiotics is necessary. Children younger than 5 years are at highest risk. Vaccinations are critical for prevention with booster vaccines necessary every 5 years for pneumococcus and meningococcus. Despite this, overwhelming postsplenectomy infection is exceedingly rare, and most surgeons cannot recall ever treating a case.

Other postoperative complications include thrombocytosis, leukocytosis, pneumonia, pancreatitis, pancreatic fistula, venous thrombosis, and hypersplenism resulting from the presence of a missed accessory spleen. Reactive thrombocytosis is observed frequently, can occur immediately, and peaks at 3 weeks. Antiplatelet therapy is reserved for patients with thrombotic complications or when platelet counts reach 1 million. Hypersplenism from missed accessory spleens can be treated with selective embolization but may require reexploration if the patient fails and is symptomatic.

Portal or mesenteric vein thrombosis is well described after ligation of the splenic vein. It has been reported in up to 50% of postsplenectomy patients with higher rates with laparoscopic approaches as compared to open. Risk factors include a long splenic vein stump, postoperative thrombocytosis, hypercoagulable state, myeloproliferative disorders, hemolytic anemias, and preoperative splenomegaly. Patients will often present with vague abdominal pain, distention, and fever. Ultimately, if untreated, intestinal ischemia and portal hypertension can occur. Given these potentially devastating outcomes, patients can be maintained on prophylactic doses of low molecular weight heparin for 4 weeks postoperatively.

CONCLUSION

Splenic cysts, tumors, and abscesses, although uncommon, are potentially life-threatening entities of which every surgeon should be aware. Diagnosis is almost always made on imaging, particularly cross-sectional. In the symptomatic patient, surgery is indicated as definitive management to prevent life-threatening rupture with hemoperitoneum. Abscesses may be percutaneously drained with image guidance if amenable. Splenic salvage with partial splenectomy or other techniques may be considered if neoplastic lesions are small and there is no question of malignancy. Laparoscopic splenectomy continues to be the gold standard of treatment for any questionable splenic mass.

Splenic Salvage Procedures

Yuan-Laui Larry Lee, MD, MS, and David T. Efron, MD, FACS

Splenic injury represents the most common solid organ injury after blunt abdominal trauma in adults, and the second most common in children. Though splenectomy remains the definitive management of splenic injury, removal carries a variety of attendant risks, both immediate and remote. Splenic salvage, then, offers an attractive alternative when resources and the clinical situation permit.

RATIONALE FOR SALVAGE

The spleen performs a variety of hematologic and immunologic functions; its absence therefore exposes patients to potential risk, the most well characterized being overwhelming postsplenectomy infection (OPSI). Splenic macrophages are responsible for phagocytosis of opsonized pathogens, whereas resident lymphocytes play a crucial role in humoral immunity through antibody and cytokine synthesis. Splenectomy thereby reduces immunologic responsiveness until these assets can be redeveloped. Unsurprisingly then, OPSI is most common in the years immediately following splenectomy, although risks persist through the patient's lifetime. Despite this process being classically associated with encapsulated organisms, asplenism is associated with increased susceptibility to infections from nonencapsulated pathogens as well, including gram-negative bacteria and even protozoans. Vaccination, therefore, does not confer complete protection. At greatest risk are patients at the extremes of age, warranting a greater interest in salvage in these vulnerable populations.

The current availability of vaccines to encapsulated organisms has potentially aided in the fight against OPSI, although definitive data are lacking. Patients who undergo splenectomy for trauma are at a lower risk of OPSI than those whose spleens are removed for hematologic or oncologic indications. The unpredictable nature of trauma, the relatively suboptimal immunologic state for vaccination experienced in the immediate postsplenectomy period, and the high incidence of poor compliance is further motivation for splenic salvage.

The spleen also serves as a hematologic filter, removing senescent cells from circulation. Splenectomy therefore allows damaged cells and cellular debris to circulate, which may lead to elevated platelet viscosity, platelet activation, endothelial activation, and a general trend toward pro-coagulability. Asplenism therefore has been associated with venous thromboembolism, stroke, myocardial infarction, and pulmonary hypertension, though these sequelae are more commonly identified in patients undergoing splenectomy for hematologic disease. Additionally, loss of splenic elimination leads to leukocytosis and thrombocytosis, which can complicate interpretation of laboratory data in patients with complex presentations. The immunologic functions of the spleen may also have protective functions against malignancy. This risk, although historically described in populations undergoing splenectomy for nonmalignant purposes, has more recently been identified following traumatic splenectomies as well. Consequently, the benefits of splenic salvage are lifelong when preservation can be accomplished safely.

NONOPERATIVE INTERVENTION

The American Association for the Surgery of Trauma (AAST) grading scale remains the most common rubric for categorizing splenic injury severity (Table 1). In the absence of other indication for laparotomy, injuries of grades I and II, absent contrasting risk factors or concomitant injuries, can generally be managed successfully with observation in the vast majority of situations. Serial hemoglobin or hematocrit measurements alongside hemodynamic monitoring in an intensive care unit setting allow for recognition of potential deterioration and conversion to more aggressive interventions as indicated. Higher grade injuries do not necessitate operative intervention, but greater failure rates and the potential for complications with grade III or higher injuries, angioembolization may be beneficial if a nonoperative strategy is pursued in these patients (Fig. 1). Similarly, though not explicitly delineated in the AAST scale, the presence of vascular findings such as active contrast extravasation, or pseudoaneurysms on initial imaging increase the risk of failure and generally benefit from more aggressive intervention.

Hypotension unresponsive to transfusion, peritonitis, or significant transfusion requirement are generally considered failure, requiring salvage angiographic or operative intervention. Transfusion thresholds vary in practice; there are those who set a threshold of any transfusion needed as an indication for operative intervention. Typically, transfusion as a threshold for operative intervention range from more than 2 to 4 units of packed red cells. Failure rate of nonoperative management for injuries of any grade is approximately 10%, and can be as high as 75% in grade V injuries. Selective management practice for splenic injuries varies greatly between adult and pediatric populations, likely secondary to the greater concern for the development of OPSI in children. Pediatric patients are more likely to undergo greater transfusion amounts than adults in the attempt to salvage the injured spleen.

TABLE 1 American Association for the Surgery of Trauma Splenic Injury Grades

Grade	Characteristics
I	<10% subcapsular hematoma <1 cm laceration
II	10%–50% subcapsular hematoma 1–5 cm intraparenchymal hematoma 1–3 cm laceration without trabecular vascular involvement
III	>50% subcapsular hematoma >5 cm intraparenchymal hematoma >3 cm laceration or trabecular vascular involvement
IV	Laceration involving vasculature with >25% devascularization
V	Shattered spleen Hilar laceration with splenic devascularization

Modified from Moore EE, Cogbill TH, Jurkovich GJ, et al. Organ injury scaling: spleen and liver (1994 revision). J Trauma. 1995;38:323–24.

Angioembolization

Splenic angioembolization has become a mainstay of selective management of blunt splenic injury, allowing avoidance of operative morbidity and preservation of splenic tissue while decreasing vascular inflow to control hemorrhage. Hemorrhage control is achieved in 85% to 95% of patients referred for angioembolization; however, typical operative fluoroscopic suites notwithstanding, the presence of labile hemodynamic instability is a contraindication to angioembolization because of limited resuscitative capabilities in most angiographic suites.

Additional considerations include resource availability, operator expertise, and anatomic suitability; vascular injury such as intimal dissection or perforation during angiography is an uncommon but potentially catastrophic complication of endovascular therapy. Nonetheless, this strategy, when appropriate, allows avoidance of the morbidities of laparotomy as well as limiting aspleric or hyposplenic consequences.

FIG. 1 Axial (A) and coronal (B) views of an American Association for the Surgery of Trauma grade 3 splenic laceration.

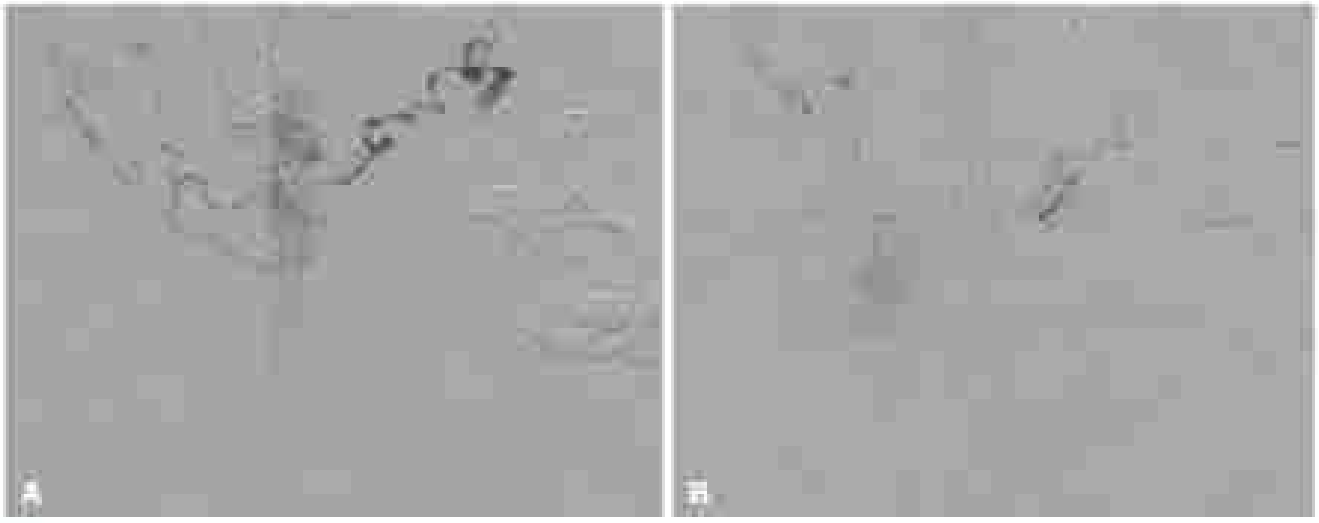

FIG. 2 (A) Angiographic demonstration of splenic artery pseudoaneurysm within splenic parenchyma following abdominal packing at laparotomy. (B) The same patient status after coil embolization.

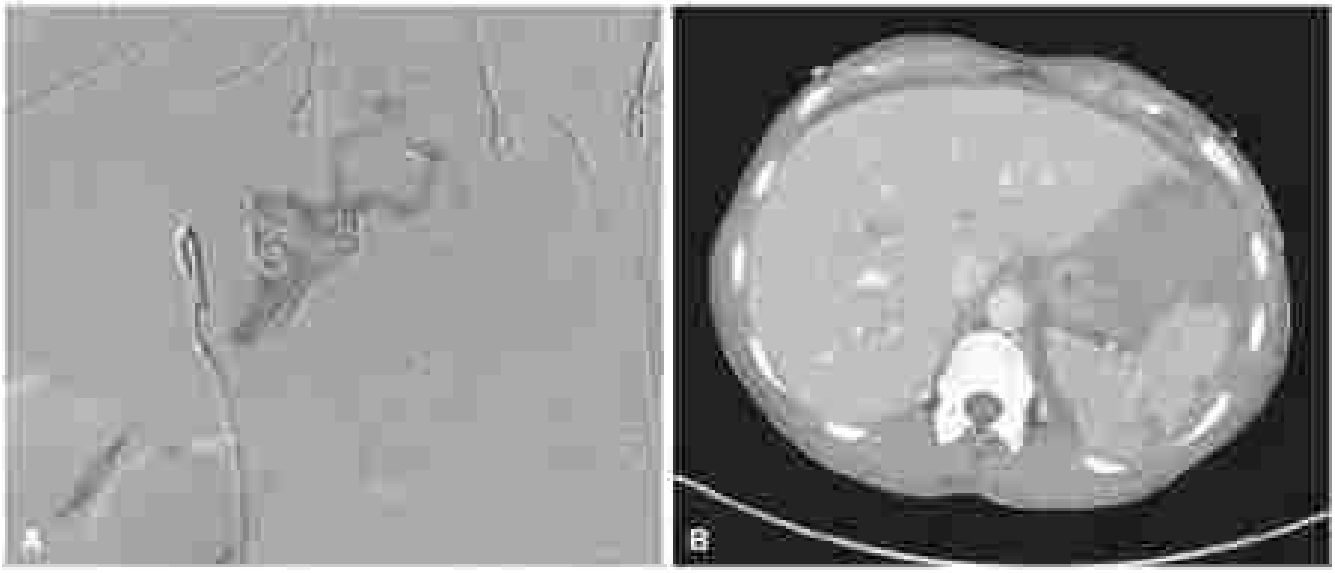

FIG. 3 (A) Combined proximal and distal coil embolization of the splenic arterial supply. (B) Axial computed tomography image of the same patient postembolization demonstrating splenic infarction.

Embolization is typically performed with either metal coils or gelatin sponge (Fig. 2). Conflicting data exist regarding the superiority of embolization material, but tend to favor coils when differences are noted with regard to both success rate and subsequent complications, both hemorrhagic and infectious.

Splenic artery angioembolization can be performed proximally at the main splenic artery or more distally or a combination of both. Proximal embolization reduces global parenchymal perfusion of the spleen (that is, theoretically decreases arterial pressure) to facilitate thrombus formation, whereas distal embolization more definitively abrogates arterial inflow to the affected region. Selection of technique is commonly driven by operator expertise and the location and extent of the injury. Failure, as defined by need for operative intervention appear to be comparable between the two strategies, rates of nonoperative splenectomy are similar as well. Distal embolization unsurprisingly incurs increased risk of infarction, and late complications thereof are uncommon but primarily consist of splenic abscesses and cysts that may necessitate subsequent operative intervention (Fig. 3).

Assessments of splenic function following proximal and distal embolization consistently demonstrate superiority over splenectomy in multiple hematologic and immunologic parameters. Disparities between the two techniques have been subtle, in part because of limited study sizes, but trend toward favoring distal embolization for greater preservation of function when any difference is detected. This finding, in the context of partial splenic infarction after distal embolization, suggests that preserved splenic after distal embolization remains functionally intact, whereas proximal embolization may compromise global function without radiographic evidence of infarction. The data remain far from definitive. Additionally, no strong recommendations can as yet be made to the need for vaccines against encapsulated bacteria following splenic embolization, so practice remains varied.

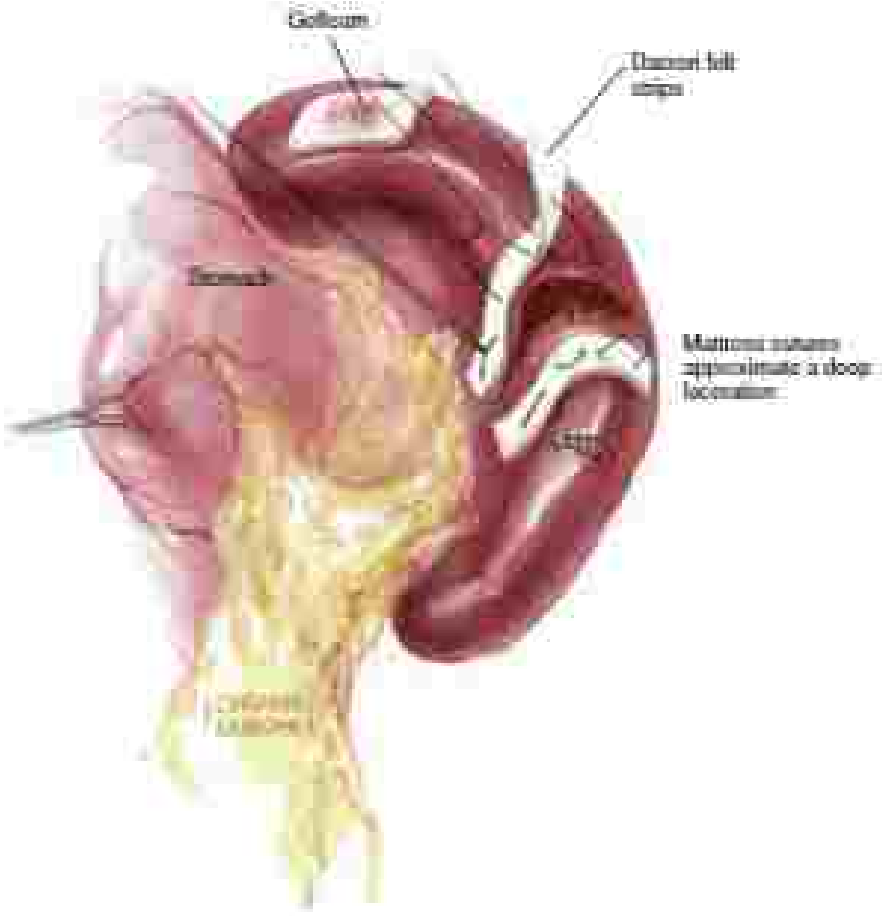

FIG. 4 Demonstration of topical hemostatic agent and technique of pledgeted repair of splenic laceration. [...]

In children, the use of angiography is held for those with evidence of ongoing bleeding but is not recommended prophylactically for patients, even those with pseudoaneurysms or bleb.

Operative Techniques

Although operative management of splenic injury incurs the morbidity of abdominal access and a potential for secondary hemorrhage, operative salvage techniques retain the benefits of preserved splenic function. Use of these techniques, however, should be considered in the context of the scenario mandating operation (e.g., primary operation vs previous failure of nonoperative management, timing, concomitant injuries). Penetrating abdominal trauma, for example, may mandate abdominal exploration that precludes imaging and nonoperative strategies. Because the decision to pursue operative intervention frequently stems from an acuity that makes operative salvage higher risk or time consuming in an often times sensitive situation, and must be weighed against the more definitive hemorrhage control of splenectomy, particularly in patients at risk for coagulopathy and those who will be intolerant of even transient hypoperfusion such as in traumatic brain injury.

After abdominal access, exposure of the spleen is performed in a manner paralleling that for splenectomy. Provided more urgent injuries have been addressed, the omentum is mobilized and the splenic hilum identified. The short gastric, splenocolic, splenophrenic, and splenorenal ligaments are divided if not already dissected by hematoma. The spleen can then be mobilized on its main vascular pedicle adjacent to the tail of the pancreas, either manually or with the assistance of packing along the posterior peritoneum to elevate the spleen into the operative field. Care should be taken to avoid injury to the pancreas during this dissection. Once the spleen is adequately in the field, salvage techniques or splenectomy may then be selected based on the nature and location of injury.

In more minor injuries, direct thermal cautery may suffice with the argon beam (the standard electrocautery device usually does not work by itself). There are a variety of topical hemostatic agents commercially available as adjuncts to direct pressure and packing. Available as powders, foams, gels, and sheets of various dimensions, these products may contain either active or passive hemostatic agents, most commonly cellulose or kaolin. Impregnated gauzes in particular offer the ability to maintain adherence to injured tissue and simultaneously allow application of direct pressure to promote hemostasis, though not all products are appropriate to leave in the abdomen outside of damage control situations.

Pledgeted suture splenorrhaphy offers more stability when anatomically practical, most commonly deeper linear lacerations (Fig. 4). As with similar repairs for hepatic injuries, pledgets are commonly fashioned from polyethylene terephthalate, fibrocellulose strips, or other hemostatic materials and secured with large mattress sutures, 0-0 or 2-0, with care taken to avoid further lacerating parenchyma while securing the suture.

If the injury extent is not amenable to topical or suture repair but is limited to one anatomic aspect of the spleen, partial splenectomy allows for splenic salvage of remaining viable tissue (Fig. 5). After embolization of the splenic, the distal branches of the splenic artery are isolated. The vessel supplying the infarcted pole can be clamped or encircled with a vessel loop to assess for adequate hemostasis on vessel occlusion; if not, an alternate technique or splenectomy should be used. The vessel is then suture ligated and sharply divided, and a demarcation of ischemic tissue identified. Depending on tissue dimensions, a linear stapler with a vascular load or cautery may be

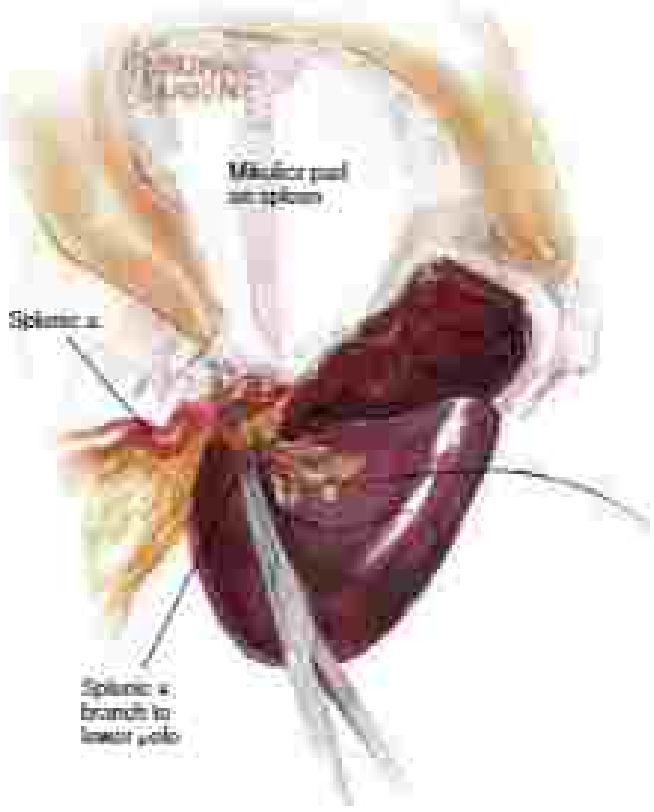

FIG. 1 Technique of partial splenectomy. (From Cameron JL, Maddern GJ, Atlas of Gastrointestinal Surgery, 2nd ed. Vol 1. Hamilton, ON: BC Decker Inc; 2007, p. 1.)

mesh for the parenchymal resection. The raw visceral surface is then oversewn with running suture or can be reinforced with reabsorbable pledgets or omentum.

When the injury pattern is not amenable to pledgeted repair or partial splenectomy, mesh splenorrhaphy remains an alternative for tamponade, but has somewhat fallen out of favor because the technique can be relatively time consuming, implants a foreign body with concomitant infectious concerns, and requires an organ sufficiently injured to preclude alternative strategies while remaining viable. A mesh of polyglactin or similar material is sized and trimmed, then a purse string suture is initiated hemitransdiaphragmatically. After fully mobilizing the spleen and achieving vascular control of the hilum, the mesh is wrapped around the lateral surface and then bunched around the hilar vessels with the sutured perimeter posterior. The purse string can then be completed along the anatomical circumference to the appropriate tension to achieve hemostasis in the parenchyma. Care should be taken to avoid strangulation of hilar vasculature when tightening the purse string so exciting excessive pressure on splenic tissue causing ischemia.

Although damage-control laparotomies have become commonplace for managing polytrauma, caution should be exercised if considering salvage in the form of abdominal packing for all but the most trivial splenic injuries. Even though prompt recuperation limits the mortality of temporary closure, splenectomy at initial operation can be performed rapidly for definitive hemorrhagic control and may facilitate correction of physiologic derangements during the resuscitative phase.

Intensive Care Unit Considerations

Patients with splenic injuries managed by salvage techniques should be serially monitored for potential rebleeding. Hemoglobin measurements are typically obtained at intervals ranging from every 2 to 4 hours during the first 12 to 24 hours, then spaced out as the patient demonstrates hematologic and hemodynamic stability. After 24 to 48 hours, and depending on injury severity and selected management strategy, level of care can then be deescalated, but clinicians should be cognizant of the possibility for delayed splenic rupture. Delayed splenic rupture typically occurs in fewer than 5% of patients and carries a higher mortality in the 10% range, likely from delayed recognition. Although case reports for delayed rupture have described events sometimes months removed from initial injury, the first week is the typical window for this complication.

Leukocytosis and thrombocytosis are commonplace following both splenectomy and splenic salvage as cells normally removed from circulation by the spleen are allowed to persist, and the relative proportions of different hematologic lineages may vary over time. Splenectomy typically produces more pronounced leukocytosis than embolization and similar degrees of thrombocytosis. However, unlike splenectomy, these alterations often normalize by between 4 and 6 weeks postintervention for angioembolization. Distinguishing expected leukocytosis from infection can be challenging, but existing literature for splenectomy suggests a white blood cell count greater than 15,000/μL and a platelet/white cell ratio less than 20 on or after postoperative day 5 are indicative of ongoing infection. Similar thresholds for angioembolization and other salvage techniques have not been established, but trends in the appropriate direction should raise the index of suspicion in these patients.

Anticoagulation, most commonly as prophylaxis against venous thromboembolism, must be weighed against hemorrhagic risk following splenic salvage. Though not studied rigorously, the available evidence suggests prophylactic low molecular weight heparin can be initiated within 24 to 48 hours with comparable outcomes and transfusion requirements. Meanwhile, delay of prophylaxis in a trauma population significantly increases risk of venous thromboembolism, with reports of a significant increase after 72 hours. Optimal timing of therapeutic anticoagulation when indicated remains unclear.

Follow-up

Late complications such as arteriovenous fistula or pseudoaneurysm formation, though rare, may occur, particularly when observation without operative or angiographic intervention is used. As the initial posttrauma thrombus resolves, pseudoaneurysms previously not appreciated may be identified. Though there are no formal recommendations regarding repeat imaging in these scenarios, a venous contrast abdominal computed tomography (CT) scan is commonly selected when any imaging modality is used. Timing of repeat examinations is also controversial, and have ranged from 48 hours to 1 week in the literature depending on the center. If any abnormalities are identified at this point, angioembolization is recommended.

The utility in the outpatient setting is even more unclear, often falling under the purview of primary care physicians, with Doppler ultrasound or CT being described. Injury grade is proportional with rate of healing. Most will studied in children and adolescents, specific time to radiographic healing has varied between reports, ranging from 1 to 6 months for grade I injuries and 5 to 11 months for grade IV. Consequently, return to physical activity is similarly contentious, but light activity at 1 month postinjury and full activity after 3 months has been suggested in the general population. Imaging as a tool to guide activity restrictions is not supported in existing data.

Though vaccination against encapsulated organisms has been used in the past with splenic salvage, immunologic data and peripheral smear findings affirm the preservation of splenic immunologic function and suggests this is likely unnecessary in most patients after splenic salvage. Volumetric assessments of residual splenic tissue have not been well correlated with immunocompetency. The decision to vaccinate therefore should reflect the clinician's assessment of anticipated splenic function given the nature of the injury and selected salvage technique.

SUMMARY

Splenic salvage offers multiple benefits over splenectomy and should be attempted in patients with sufficient stable tissue and appropriate clinical risk. With injury patterns that do not mandate primary abdominal exploration, low grade (I–II) injuries can often be observed, whereas higher grade (III–V) injuries should be offered angioembolization. The decision to pursue open intervention does not preclude salvage but is generally higher risk given the underlying process mandating exploration.

MANAGEMENT OF INGUINAL HERNIA

Gina L. [illegible] M.D., F.A.C.S. [illegible] and Mark [illegible]

[illegible]

INDICATIONS AND TIMING OF REPAIR

[illegible]

CONSIDERATIONS IN SELECTING THE OPTIMAL APPROACH

A variety of surgical repairs has been developed. Selection of the appropriate technique is largely surgeon dependent based on experience, with the best outcomes associated with the repair most frequently performed. Patient and hernia characteristics should guide decision making in procedural selection. Although there are no absolute contraindications to laparoscopic repair, those patients who are not candidates for general anesthesia are better approached with an open technique that can be performed with spinal or local anesthesia with sedation. Although laparoscopic inguinal hernia repair can be performed under epidural anesthesia, inadequate muscular relaxation limits the working space with this approach so that the large majority of these repairs are conducted with general endotracheal anesthesia. The choice of total extraperitoneal repair (TAPP) versus transabdominal preperitoneal repair (TAPP) may also be dictated by the patient characteristics as well as surgeon experience. Patients who have previously undergone surgery may have adhesions that make laparoscopy more difficult, in particular, patients who have had a prostatectomy have usually obliterated the preperitoneal space required for minimally invasive techniques.

There is compelling evidence to support laparoscopic inguinal hernia repair for patients with bilateral inguinal hernias as well as recurrent inguinal hernias after prior open inguinal hernia repair. For the majority of inguinal hernia patients, open and minimally invasive mesh repairs are equivalent.

OPEN INGUINAL HERNIA REPAIR

Tissue Repair

Although direct comparisons are limited and available randomized controlled trials are of low quality and subject to bias, the Shouldice repair is the best-researched inguinal hernia repair technique with supporting level IA evidence. Compared with other tissue repairs, Shouldice reports lower recurrence, hematoma, and chronic pain rates. Surgeon experience and meticulous technique have significant impact on outcomes. From a 2012 Cochrane systematic review, the recurrence rate for Shouldice was tighter than mesh Lichtenstein repair. There was no significant difference in chronic pain, surgical site infection, or seroma. Because there was inclusion of heterogeneous studies with questionable external validity, the comparison was not robust. Given the risk of mesh repair in contaminated cases and strangulated hernias as well as increasing patient concerns about mesh, it is important to have a primary tissue repair in one's surgical armamentarium.

Lichtenstein Repair

The most common open mesh repair is the Lichtenstein, which was the original tension-free repair that reinforces the inguinal floor with a prosthetic mesh. Initially described in 1987, the repair involves fixation of mesh using a permanent suture to the anterior rectus sheath, internal oblique aponeurosis, the pubic tubercle, and the shelving edge of the inguinal ligament. The approach is via an incision inferior and medial to the anterior superior iliac spine which is extended medially for approximately 6 to 8 cm. The dissection is carried down to the aponeurosis of the external oblique muscle which is opened in the direction of the muscle fibers. Using Metzenbaum scissors, this incision in the aponeurosis is extended through the external inguinal

ting. Upon opening the aponeurosis, the ilioinguinal nerve will be visualized and should be preserved. The internal oblique fibers are dissected bluntly from the overlying external oblique muscle flaps that reveal the shelving edge of the inguinal ligament. In addition, the iliohypogastric and ilioinguinal nerves are identified and preserved. The spermatic cord, along with an indirect hernia sac if present, should be identified and encircled with a Penrose drain. The hernia sac will usually be seen on the anteromedial surface of the cord structures. At this point, the genital nerve is visualized along the inferolateral surface of the cord adjacent to the external spermatic vein. The floor of the inguinal canal should be carefully assessed for weakness indicating a direct hernia. The medial aspect of the mesh is secured to the aponeurotic tissue overlying the pubic tubercle with an overlap of approximately 2 cm. The mesh should be secured using a running nonabsorbable monofilament suture, which is continued laterally along the inferior edge of the mesh to the shelving edge of the inguinal ligament to just lateral to the inguinal ring. The mesh is split to encircle the spermatic cord, with two thirds of the mesh above and one third below. The two tails are secured with a single nonabsorbable suture to the shelving edge to recreate a new internal ring. Interrupted absorbable monofilament sutures firmly secure the superior edge of the mesh to the internal oblique aponeurosis and muscle with avoidance of entrapment of the iliohypogastric nerve. The layers of the abdominal wall are then closed, starting with the aponeurosis of the external oblique, Scarpa's fascia, and skin. A modification of the Lichtenstein repair uses the addition of a mesh plug that is placed through the internal ring to the case of an indirect inguinal hernia. For a direct hernia, the plug is sutured to Cooper's ligament, the inguinal ligament, and the internal oblique aponeurosis. However, the use of mesh plugs is discouraged due to the risk of migration, mesh contraction, and chronic pain.

Local Anesthetic Block

Local anesthetic block is a safe and cost-effective method of delivery of anesthesia for open inguinal repair and postoperative analgesia. Regardless of whether general anesthesia is used, preoperative local anesthetic injection before the surgical incision may decrease postoperative pain by reducing the stimulation of nociceptors. A 50:50 mixture of 1% lidocaine and 0.5% bupivacaine is used with addition of epinephrine. Subdermal infiltration under the planned incision is performed transversely with approximately 5 mL followed by intradermal injection to raise a wheal at the incision. Deeper subcutaneous vertical injection is performed. Proximal ilioinguinal nerve anesthesia is applied with injection medial to the anterior superior iliac spine though there is risk of direct nerve injury with this blind technique, injecting 10 mL of the local anesthetic directly under the exposed external oblique aponeurosis bathes the peripheral inguinal nerves with additional solution reserved for injection at the spermatic cord and pubic tubercle and final subaponeurotic and subcutaneous injection before closure.

MINIMALLY INVASIVE INGUINAL HERNIA REPAIR

Transabdominal Preperitoneal Repair

The transabdominal preperitoneal inguinal hernia repair is performed with the patient in the Trendelenburg position with tilt toward the contralateral side to allow the viscera to fall away from the operative field. The abdomen is accessed via a curvilinear incision at the inferior umbilical rim and placement of a 10-mm port. There is a less a concomitant umbilical hernia, this should be assessed by examination preoperatively and at the time of incision. The TAPP approach is well suited to the patient with an umbilical hernia because it allows use of this abdominal wall defect for midline port placement after clearance of the hernia contents, avoids the risk of leak of insufflation into the peritoneal cavity that could be seen with the total extraperitoneal approach, and provides for repair of the umbilical and inguinal hernias. Visual inspection of both inguinal regions allows

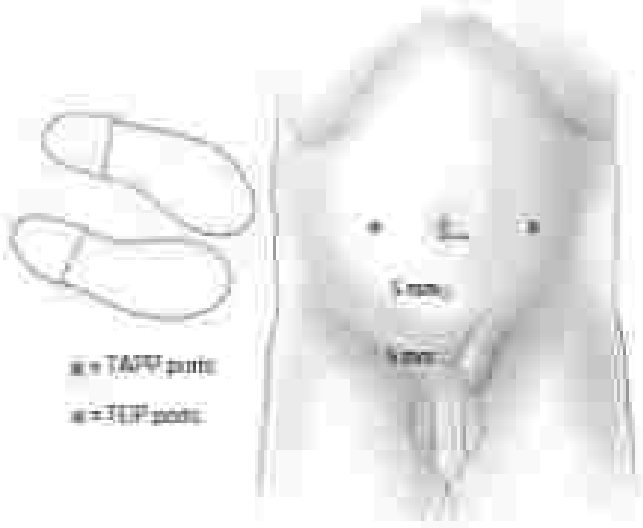

FIG. 1 Proper ports placement for one operator working for one component TAPP and one component TEP. The umbilical port is placed at the level of the umbilicus and at least 1 cm (ideally 2 cm) from the superior extent of the operative field. The 5-mm ports are placed at least 10 cm apart to allow for triangulation of instruments. TAPP, transabdominal preperitoneal; TEP, total extraperitoneal.

for port placement adjustment to triangulate the instruments to the target space. A 5-mm 30 degree laparoscope is preferred. Bilateral hernias are approached via two 5-mm working ports placed about 8 cm lateral to and slightly below the umbilical port. For the unilateral repair, the ipsilateral 5-mm trocar is placed at the level of the umbilicus, whereas the contralateral 5-mm trocar is placed several centimeters lower than the umbilicus for ergonomic optimization (Fig. 1). Robotic TAPP can also be performed, in which case the three robotic ports are placed at or above the level of the umbilicus at least 15 cm (10 cm from the superior extent of the operative field), with one midline port and two working ports 8 to 10 cm on each side of the midline.

Wide exposure of the preperitoneal surface is critical to the operation. The peritoneum is opened from just lateral to the inferior superior iliac spine to the medial umbilical ligament and dissected down to well over the pubis and iliac vessels leaving the bladder down (Fig. 2). Although the size of the opening in the peritoneum may be reduced after gaining experience with the technique to limit the time for peritoneal closure, the preperitoneal dissection should be ample to allow for identification of all hernia defects at the preperitoneal surface and for wide mesh coverage. A wider opening allows the peritoneal flap to lay down more fully and this visual advantage can be helpful early in the surgeon's experience. Lateral and the most medial dissections are performed first to allow the peritoneum to fall away and improve operative exposure prior to dissection of the indirect hernia sac. The inner edge of the peritoneum should be at minimum 1 to 2 cm away from the inferior edge of the mesh to avoid folding of the mesh when the peritoneum is closed.

The lipoma of the direct hernia defect should be fully reduced and removed. The white edge of the attenuated transversalis fascia can be seen at the intersection with the lipoma and denotes the plane of dissection (Fig. 3). Caution is exercised to identify and avoid injury to the corona mortis, the sometimes present aberrant vessels from the epigastric vessels to the obturator vessels located below the direct defect at Cooper's ligament. The external iliac vein should be visible. If there is overlying fat, this suggests a femoral hernia with lipoma that should be reduced.

The hernia sac at the indirect space is dissected from the cord structures during cephalad retraction of the hernia sac. The TAPP approach provides an advantage during complex hernia cases, such as the scrotal inguinal hernia, by allowing visualization from both the preperitoneal and peritoneal spaces of herniated viscera. The fat and tissue should be cleared between the vas deferens and Cooper's ligament, and the hernia sac and peritoneum should be separated fully

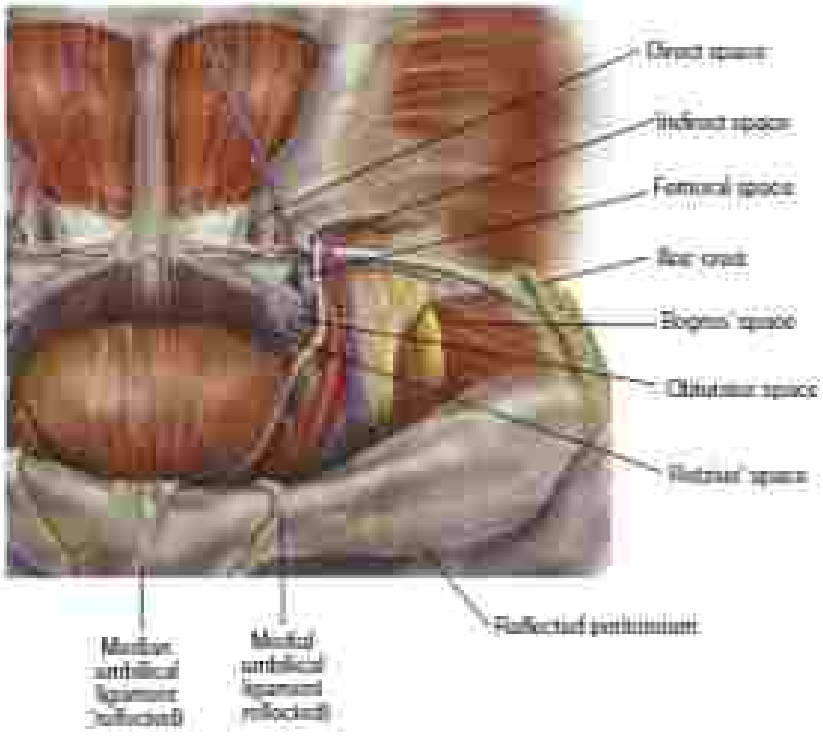

FIG. 2 Preperitoneal sagittal anatomy.

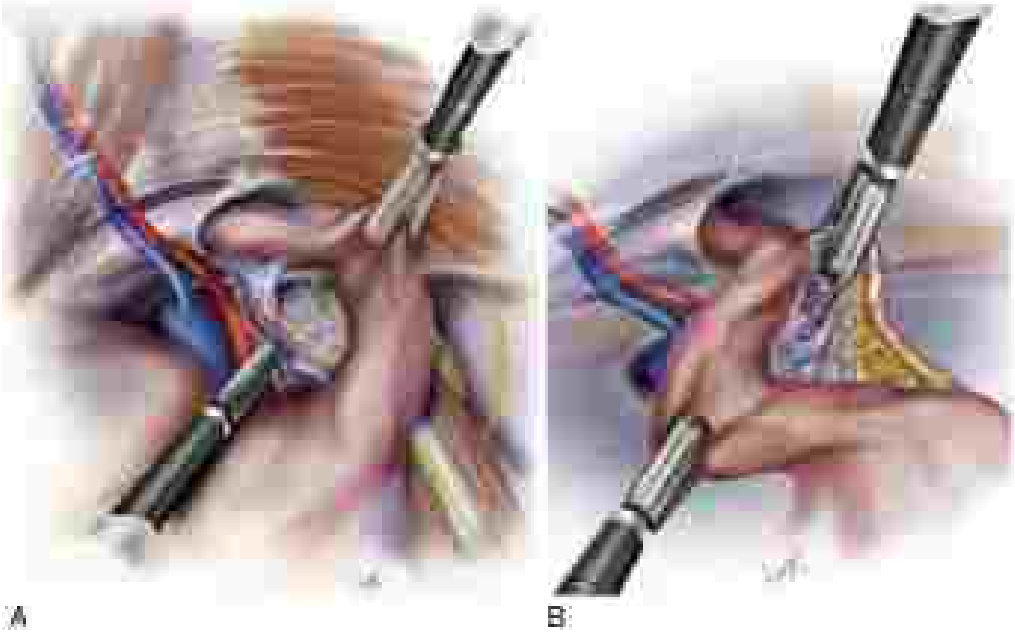

FIG. 3 (A–B) Dissection of the hernia sac. Apply gentle traction on the hernia sac and carefully dissect away from the spermatic structures.

from the cord structures well over the iliac vessels and psoas. The indirect lipoma is identified just lateral to the vas and gonadal vessels and this is retracted cephalad and fully reduced. This may appear small but can be larger beyond the inguinal ring. Leaving a retained lipoma may result in continued groin pain.

Meticulous attention should be paid to fascial closure and other aspects that can reduce the risk of hernia recurrence. The weakened transversalis fascia of the direct hernia sac should be inverted and sutured to reduce the hernia recurrence risk for larger direct hernias and likely decrease the seroma rate. A wide mesh should be used for ample coverage of the myopectineal orifice (Fig. 4). The mesh should lay smoothly against the abdominal wall extending below the pubis and Cooper's ligament and anterior to the bladder so that the mesh will not shift when the bladder fills. Fixation of the mesh may not be needed routinely; however, if there is a large hernia defect, fixation is recommended whether by sutures, a minimal number of tacks, or self-gripping mesh to avoid shifting of the mesh because of seroma or contraction of the mesh.

The mesh should be completely repetitionealized. The peritoneum closure should be complete without gaps. Sutured closure with absorbable 2-0 or 3-0 suture is preferred. A self-locking knot is placed on the suture before lowering the suture reduces operative time. Caution is urged regarding barbed suture to ensure it is well covered and exposure minimized to avoid bowel adherence to the barbs.

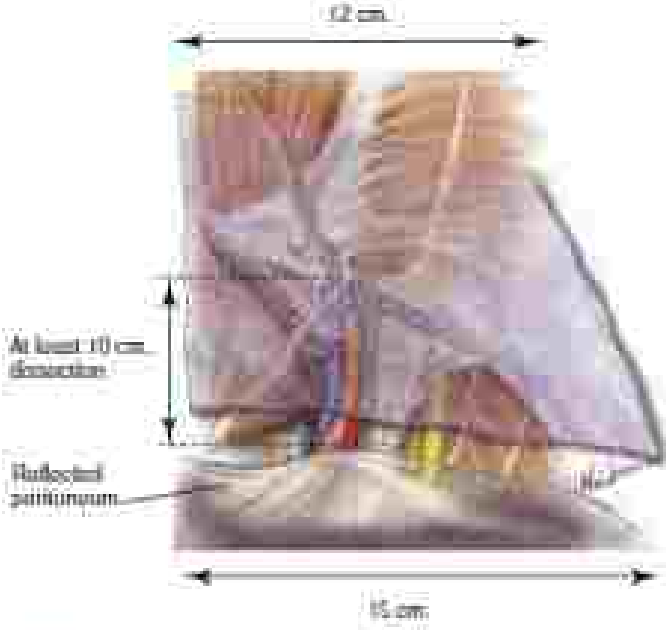

FIG. 4 Preperitoneal mesh placement with white arrows at the myopectineal orifice.

Total Extraperitoneal Repair

Patient preparation is similar for both TEP repair and TAPP: the patient is supine with arms out or tucked and the abdomen and inguinoscrotal areas are clipped if necessary. Patients are required to void before surgery; however, a urinary catheter is used by many surgeons to ensure bladder emptying. Entry is via an infraumbilical 12 mm port through which the anterior rectus sheath is incised just off the midline. After opening the sheath, the rectus muscle is split to access the posterior sheath, and a balloon trocar can facilitate the dissection of the preperitoneal space. By inflating the balloon under direct vision, the epigastric vessels can be visualized along the anterior abdominal wall, and the hernia is usually identified as well. Inadvertent entry into the peritoneal cavity will be readily apparent and may occasionally require conversion to a TAPP or open repair. Once the balloon has expanded the preperitoneal space, it is removed and the space is insufflated to a pressure of 12 to 15 mm Hg. A 10 mm camera is used, preferably a 45- or at least 30-degree angled scope. Two 5-mm ports are placed in the midline, allowing for several fingerbreadths between the lowest port and the pubic symphysis as well as between the ports themselves. The lateral abdominal wall is identified first, by bluntly dissecting the fatty areolar tissue anterior to the hernia sac but inferior to the epigastric vessels, which should be identified and protected. Medially, Cooper's ligament is identified and cleared of any overlying fat while taking care to avoid the venous circle of Taradeau as well as the femoral canal tributary. The spermatic cord and hernia sac can be grasped and retracted cephalad while taking care to reduce an adherent cord lipoma as well. If the peritoneum is inadvertently torn during dissection, which most commonly occurs in patients who have had prior surgery, the defect should be closed, if possible, with an endoscopic clip or with an EndoAcus. In addition, the resulting pneumoperitoneum may decrease the working space significantly and the pneumoperitoneum can be decompressed via a Veress needle or 5 mm port in the left upper quadrant of the abdomen.

TAPP VERSUS TEP?

The International Guidelines for Groin Hernia Management published by the HerniaSurge Group and endorsed by multiple major international hernia societies offer statements and recommendations regarding comparison of laparoscopic TAPP and TEP techniques. These are largely equivalent operations with similar operative time and cost, complication risk, pain incidence, and recurrence rates. Robotic assisted TAPP adds additional cost. TEP confers a higher conversion rate than TAPP but the incidence is low. The Guidelines note that although very rare, there is a trend for more visceral injuries in TAPP and more vascular injuries in TEP. Meticulous fascial closure at the umbilical port site in TAPP is avoided. Though the risk of port site hernia is very low with TAPP, there is a known increased incidence of port site hernia for umbilical sites. Because the surgical outcomes are similar, the choice should be based on the surgeon's skills, training, and experience.

There are certain situations that are better suited for one minimally invasive approach over another. The recurrent hernia after laparoscopic repair is better addressed by TAPP or open repair rather than TEP. TEP holds an advantage for the bilateral inguinal hernia without a large scrotal component as the midline does not require peritoneal closure. Patients with prior lower abdominal surgery, particularly by midline laparotomy incision, scrotal hernia particularly with incarceration, prior prostatectomy, prior inguinal hernia plug and patch repair, and those with uncertain diagnosis in which diagnostic laparoscopy would be beneficial, should undergo laparoscopic or robotic assisted TAPP rather than T/P. The enhanced TEP techniques with access to the preperitoneal space higher or more lateral in the abdominal wall addresses some of these shortcomings with traditional TEP, allowing an extraperitoneal approach in cases in which lower abdominal surgery would otherwise be prohibitive.

Risk Factors for Inguinal Hernia Development and Recurrence

Patients with family or personal history of inguinal hernia, older age (direct hernias), male sex, collagen disorder with decreased mature type I collagen, and history of prostatectomy are risk factors for inguinal hernia development. Interestingly, in contrast to risk factors for ventral incisional hernia, obesity is protective to inguinal hernia development, with lower body mass index associated with higher inguinal hernia incidence.

An outlined, surgical technical factors contribute to the risk of hernia recurrence, including decreased mesh overlap. Lower case volume is associated with a higher recurrence risk. Surgical outcomes are poorer for female patients. Direct and sliding hernias are associated with a higher rate of recurrence.

CHRONIC PAIN AFTER INGUINAL HERNIA REPAIR

The incidence of chronic pain after groin repair is higher than the risk of recurrence. There is a higher risk of pain associated with open repair. The ilioinguinal, iliohypogastric, and genitofemoral nerves should be identified during open repair. Retraction of the nerves and disruption of the perineurium should be avoided. The genitofemoral nerve is often the hardest to identify by the spermatic vessels. Neurectomy proximal to the site of nerve injury should be performed at the time of repair if an injury is suspected. The nerve should be allowed to retract into the muscular bed.

Chronic groin pain is a small but known risk after laparoscopic inguinal hernia repair. The lateral femoral cutaneous nerve may be seen in the fatty layer below the iliopubic tract and this should be left undisturbed with avoidance of disruption of the perineurium. The femoral branch of the genitofemoral nerve is seen more medially. The genitofemoral nerve will be found medially near the spermatic cord vessels. In the female patient, the genitofemoral nerve will join the round ligament closer to the inguinal canal. When performed, division of the round ligament should be performed close to the peritoneum to avoid nerve injury. If mesh fixation tacks are used, care is taken not to press too deeply into the abdominal wall to avoid a nerve injury superficially. The number of tacks used should be minimized because the risk of chronic pain increases resulting from potential nerve injury. Fixation should be performed medially to the epigastric vessels and anteriorly with avoidance of the lateral space, particularly below the iliopubic tract (Fig. 5).

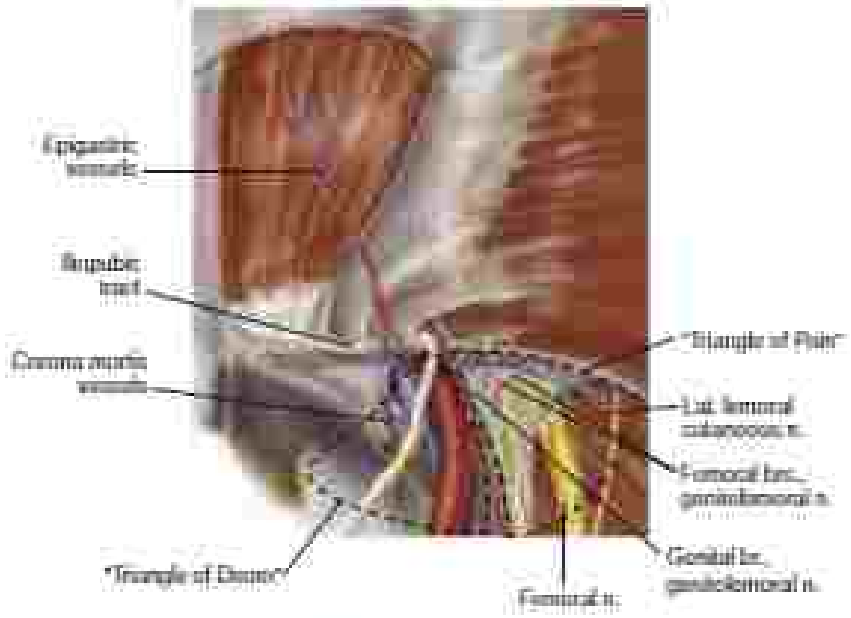

FIG. 3 Triangle of pain.

CONCLUSION

Elective repair of symptomatic inguinal hernias is recommended; however, observation is appropriate for those without symptoms or who do not wish to undergo surgery. The choice of minimally invasive or open repair is primarily surgeon preference, and the use of prosthetic mesh will significantly reduce the risk of recurrence. The major risks of operative repair are usually minimal, but some patients may develop chronic pain from nerve injury and potential mesh complications. These morbidities must be considered during the preoperative discussion regarding repair, particularly in those patients with minimal symptoms.

MANAGEMENT OF RECURRENT INGUINAL HERNIA

Brian Jacob, MD, and Kathryn Ely Pla ce Chaspari, MD

Inguinal hernias are common, with a lifetime risk of 2 % in men and 3% in women. More than 500,000 inguinal hernia repairs are performed each year in the United States. With many diverse ways of performing an inguinal hernia repair and no consensus proving that one method is more optimal than another, the published data often conflict regarding a recommended technique. As such, hernia surgeons and general surgeons continue to perform the technique that they are best trained to perform. Recurrences will happen regardless of whether the repair was performed via open anatomic (tissue)-based, open mesh–based, or minimally invasive technique (with or without mesh). Inguinal hernia recurrence remains frequent, with many large studies reporting a recurrence rate as high as 10%. Even the most experienced surgeon will encounter recurrences. When it comes to the topic of outcomes after inguinal hernia repair, recurrences are just one outcome metric that is important. Other important postoperative issues, such as chronic groin pain, will be discussed in other chapters.

DEFINING RECURRENT INGUINAL HERNIAS

Recurrent inguinal hernias that happen in the first 3 to 6 months after the surgery are called early recurrences and are generally considered a result of a technical error during the initial repair, although this is not always the case. Technical factors that may contribute to hernia recurrence are discussed in the following sections. Patients with a chronic cough who have a coughing attack during the first few weeks after a repair, or violent intubation immediately after a repair, are also at risk for developing a recurrence despite having a solid repair the first time.

MANAGEMENT OF RECURRENT INGUINAL HERNIA

Brian Jacob, MD, and Kathryn Ely Pierce Chaspis, MD

Inguinal hernias are common, with a lifetime risk of 27% in men and 3% in women. More than 500,000 inguinal hernia repairs are performed each year in the United States. With many diverse ways of performing an inguinal hernia repair and no consensus proving that one method is more optimal than another, the published data often conflict regarding a recommended technique. As such, hernia surgeons and general surgeons continue to perform the technique that they are best trained to perform. Recurrences will happen regardless of whether the repair was performed via open anatomic (tissue)-based, open mesh–based, or minimally invasive technique (with or without mesh). Inguinal hernia recurrence remains frequent, with many large studies reporting a recurrence rate as high as 10%. Even the most experienced surgeon will encounter recurrences. When it comes to the topic of outcomes after inguinal hernia repair, recurrences are just one outcome metric that is important. Other important postoperative issues, such as chronic groin pain, will be discussed in other chapters.

DEFINING RECURRENT INGUINAL HERNIAS

Recurrent inguinal hernias that happen in the first 3 to 6 months after the surgery are called *early recurrences* and are generally considered a result of a technical error during the initial repair, although this is not always the case. Technical factors that may contribute to hernia recurrence are discussed in the following sections. Patients with a chronic cough who have a coughing attack during the first few weeks after a repair, or violent extubation immediately after a repair, are also at risk for developing a recurrence despite having a solid repair the first time.

Late recurrences occurring after 6 to 12 months are generally from patient factors (discussed later); however, late recurrence can also be due to the same technical factors seen after early recurrence, as well as from mesh shrinkage or migration.

When considering repair of a recurrent inguinal hernia, it is important to know how and when the initial hernia was repaired. Because the previous repair always dictates the optimal approach to repair of a recurrent inguinal hernia, all efforts should be made to obtain the previous operative report before a repair is planned. Patients who had a previous inguinal hernia repair as a child likely had an open nonmesh repair. Patients can also be divided into having a previous open (anterior) repair with or without mesh or into having a previous laparoscopic (or robotic) repair with or without mesh. If a previous anterior repair was performed with mesh, it is important to know what type of mesh was used (e.g., Lichtenstein, plug and patch, PHS system).

RISK FACTORS FOR RECURRENT INGUINAL HERNIAS

Technical Factors

The most important technical factor contributing to hernia recurrence is failure to achieve a tension-free repair. Mesh-free repairs such as the Bassini, Halsted, and McVay techniques have been shown to have a 30% to 75% higher recurrence rate than mesh repairs from tension on the approximated tissue. The use of mesh to achieve tension-free repair is now considered the gold standard. There has been some debate over the use of heavyweight versus lightweight mesh, but meta-analyses have shown no difference in recurrence rate based on the weight of mesh used. Additionally, no difference in recurrence rates has been found when comparing self-gripping mesh to suture- or tack-secured meshes.

Other technical factors that contribute to hernia recurrence include incomplete dissection of the preperitoneal orifice from anterior superior iliac spine to symphysis, insufficient reduction of the hernia sac, insufficient reduction of hernias, inadequate mesh implant size or material, mesh migration, or mesh folding (claw-shelling). Failure to resect a cord lipoma may also result in primary recurrence, so care should be taken to reduce or excise these lipomas. Complete and masterful dissection following the steps as outlined by Daes and Felix and originally described to the International Hernia Collaboration closed Facebook group will minimize early recurrence rates. That said, a recurrence does not mean that the procedure was performed incorrectly or that a technical error was experienced during the surgery. Hernia recurrence is a known risk and should always be mentioned in the informed consent.

One source of debate is whether a laparoscopic inguinal hernia repair is associated with higher recurrence rates than open hernia repair. Studies vary significantly, with many studies pointing toward an increased recurrence rate with laparoscopic repair; however, several large meta-analyses did not find a significant long-term difference between recurrence rates in laparoscopic and open approaches. Other studies have demonstrated that surgeon experience with laparoscopic repair has a significant impact on recurrence rates, those performing a higher volume of laparoscopic repairs experience a lower recurrence rate, eventually equaling that of open repair.

Patient Factors

Any risk factor for poor wound healing contributes to the risk of hernia recurrence, including immunosuppression, smoking, diabetes, and obesity. Smoking not only contributes to tissue hypoxia, but also alters collagen synthesis and remodeling, leading to weaker tissue. Obesity puts undue strain on the initial repair and increases the risk of wound infection. Additionally, a large meta-analysis found that being female, initial operation for direct inguinal hernia, and operation for recurrent hernia were all risk factors for recurrence. Female sex risk is hypothesized to be due to the higher incidence of femoral hernias that may be missed at initial open operation. The reason for a higher recurrence after initial operation for direct inguinal hernia is unclear, but may be due to inherent tissue weakness. Although this study did not find family history of recurrent hernias to be a significant risk factor, it is well documented elsewhere that collagen synthesis disorders such as Marfan's syndrome and Ehlers-Danlos syndrome carry a higher risk of hernia and poor wound healing. The recovery from the original surgery may also play a role in recurrence rates. It is important to note any postoperative infections, hematomas or seromas, especially if the mesh implant shifts or migrates secondary to that process.

Mesh Factors

We, as authors, do not intrinsically blame the mesh for a recurrence. We believe that the products on the market have been adequately studied such that causation of recurrences cannot be attributed to the mesh alone; thus, when referring to mesh factors, we are describing what happens to the mesh after it is implanted. Shrinking of the mesh can lead to recurrence, as well as pain from the product pulling on surrounding structures. Some three-dimensional shaped mesh (plugs, PHS systems, and others) placed during open repairs can also shrink, migrate, or are designed to mesh, leading to a space for a recurrence, and often chronic pain. Mesh can also migrate or fold, which usually happens very early after it is placed. Additionally, it can conform to the space it was bridging. Imaging is indicated when a mesh issue is suspected. We usually prefer investigation with a computed tomography (CT) scan; however, a normal CT scan does not necessarily rule out a mesh factor. Mesh issues related to recurrences after a laparoscopic repair, in our opinion, can only be truly confirmed with diagnostic laparoscopy.

DIAGNOSING RECURRENT INGUINAL HERNIAS

Diagnosing a recurrent inguinal hernia involves taking a careful history, performing a focused physical examination, and contributing imaging. Most patients are asymptomatic and do not realize they are experiencing a recurrence; therefore, not all inguinal hernia recurrences will need immediate repair. When patients are symptomatic, they will sometimes state that they had a previous inguinal hernia repair with an interval without symptoms, followed by the onset of vague, temporary, discomfort located in just one spot near the inguinal canal. As the size of the hernia grows, patients will often complain of an intermittent bulge with or without localized nonradiating pain. Nevertheless, there is no single way a recurrent inguinal hernia presents. The symptoms are usually present or exacerbated when standing, exercising, or lifting. Once symptomatic, a repair is typically indicated.

When a patient with a history of inguinal hernia repair presents with groin pain, it is vital that the surgeon not assume that the pain is from a recurrent inguinal hernia until all other possible etiologies have been ruled out and documented. Other causes of groin pain are numerous (Table 1). Often, the history alone will help the most in determining the cause of the pain. In general, pain from a recurrent hernia is intermittent and elicited directly over the bulge or defect. Pain from a recurrent hernia should not generally be made worse with movement of the hip joint or leg or with palpation of the symphysis or pubic tubercle. Acute onset of pain after an event (sport or traumatic) is musculoskeletal injury until proven otherwise. Cyclic pain can be from an endometrioma or endometriosis. Constant pain can be due to old sutures, mesh, fractures, infections, or other causes, but is usually not from a recurrent inguinal hernia. If history suggests a hernia recurrence, then the workup may also include sonography, CT, or magnetic resonance imaging (MRI) with an athletic pubalgia protocol. Once other etiologies have been ruled out, an inguinal hernia repair can be safely planned.

Sometimes, recurrent inguinal hernias are not palpable and are not seen on imaging, which can be especially true for tiny femoral hernias or tiny indirect inguinal hernias (as well as for small lipomas).

TABLE 1 Causes of Groin Pain by System

System	Cause
Musculoskeletal	Avascular necrosis Avulsion fracture Osteoarthritis Sacroiliitis Muscle strain or tear Tendinitis Piriformis syndrome Athletic pubalgia Referred or radiating back pain
Genitourinary/gynecologic	Epididymitis Orchitis Retrograde ejaculation Hydrocele Varicocele Testicular cancer/tumor Endometriosis/endometriosis Kidney stone
Gastrointestinal	Inguinal hernia Colitis/diverticulitis
Neurologic	Sciatica Nerve entrapment
Infectious	Lymphadenopathy Urinary tract infection Sexually transmitted infection

These are termed hidden hernias or occult hernias. All types can be symptomatic and are best identified during a diagnostic laparoscopy.

Role of Physical Examination and Imaging With a Recurrent Inguinal Hernia

The diagnosis of a recurrent inguinal hernia is essentially the same as for a primary inguinal hernia and, again, is largely a clinical diagnosis, based on history and physical examination. Imaging is useful when the diagnosis is unclear. Nevertheless, it is important to again state that inguinal hernias may be missed on imaging; therefore, normal imaging does not exclude the presence of a recurrent inguinal hernia.

Ultrasound is an inexpensive tool with a sensitivity of greater than 90% and a specificity of approximately 85%. This method allows for the groin to be examined both at rest and under a Valsalva maneuver. CT of the abdomen and pelvis has a role in the diagnosis of recurrent inguinal hernia because it can detect mesh mass, metallic tack location, and recurrences that may not be readily palpable on examination. CT has a sensitivity less than 80%, with a specificity of only 25% to 85%. When pain is part of the complaint, we strongly recommend that a radiopaque marker be placed at the site of the pain while obtaining the CT scan because this can more precisely define the location of the structure involved. An MRI, on the other hand, though more expensive and time consuming, has a very high sensitivity, greater than 95%, and can also be performed at rest and with Valsalva. Although not essential for the workup of most inguinal hernias, MRI is recommended by Miller et al. in the workup of an occult hernia because it demonstrates the highest sensitivity, specificity, and negative predictive value compared with ultrasound and CT. The authors of that study state that MRI scans resulted in correct identification of an inguinal hernia in 91% of the cases of a false negative CT scan. Representative images of an ultrasound, CT scan, and MRI of inguinal hernia are shown in Fig. 1.

Repair of the Recurrent Inguinal Hernia

Repair of a recurrent inguinal hernia is often more difficult than the initial operation because of distorted tissue planes. Repair operations carries a higher rate of complications, including chronic pain, damage to cord structures, ischemic orchitis, and a higher risk of recurrence. Before repair of an inguinal hernia, patient controlled risk factors should be optimized, particularly smoking cessation and weight loss, and counselling regarding the previously mentioned risks.

Watchful waiting for asymptomatic inguinal hernia is a well established option to primary inguinal hernias, but has not been specifically studied for recurrent hernia. This is, however, included as an option for recurrent inguinal hernia in many of the guidelines. Surgical repair is specifically recommended for the symptomatic recurrent hernia. The only true contraindication to repair of a recurrent inguinal hernia is active infection because mesh should be used in all repairs and use of prosthetic mesh is contraindicated in infection.

To minimize risks, as discussed in The International Guidelines for Groin Hernia Management, the main tenet of recurrent inguinal hernia repair is to approach the hernia through unfamiliar tissue planes. Thus, the approach will be dictated by the prior surgery as discussed in the following section. A summary of our approach to a recurrent inguinal hernia is found in Fig. 2.

Recurrent Inguinal Hernia After a Previous Open (Anterior) Repair

Following an open inguinal hernia repair, recurrence is more likely to occur in the direct space, most often from inadequate mesh coverage at the pubic tubercle. These cases should almost always be approached by minimally invasive surgery (MIS) posterior method (laparoscopy or robotic) to avoid dissected and scarred anterior tissue planes. Dissecting through previously dissected tissue planes increases the risk of nerve entrapment, chronic pain, and testicular atrophy. In addition, the MIS approach has been associated with earlier return to work and lower incidence of chronic groin pain. Either transabdominal preperitoneal repair (TAPP) or total extraperitoneal repair (TEP) is reasonable. The choice of approach depends on surgeon preference and whether the surgery will be done laparoscopically or robotically. Although a minimally invasive approach is recommended, if expertise in MIS technique is not available, an open posterior approach is acceptable as well.

Recurrence After a Previous Laparoscopic or Robotic (Posterior) Repair

Following a minimally invasive hernia repair, recurrence is more likely to occur in the indirect space or inferiorly near the femoral canal, possibly resulting from incomplete reduction of the hernia sac or herniation of the sac around the mesh. Also, retained spermatic cord lipomas are not uncommon. Guidelines still recommend an anterior open repair of a recurrent inguinal hernia initially repaired using an MIS technique to avoid the dissected posterior tissue planes and mesh. With growing experience and comfort, however, laparoscopists are increasingly able to identify and repair a recurrence via MIS approach, even after a previous TEP or TAPP technique. The major advantage to MIS repair is that the surgeon possesses a view of all potential sites of recurrences, which is especially helpful when the location of the recurrence (direct, indirect, or femoral) is unclear. Because the dissection of the preperitoneal tissue plane is more difficult after a prior posterior repair, an attempt at TEP often results in tearing of the peritoneum, thus forcing conversion to TAPP. Any surgeon who is attempting a MIS revision of a recurrent hernia after a prior MIS repair must be comfortable with both TEP and TAPP techniques.

Recurrence After a Previous Anterior and Posterior Repair

For complex cases in which a patient is presenting with more than one recurrence, in which case both the anterior and posterior planes have

FIG. 1 (A) Coronal reconstructed image of an inguinal hernia. (B) Computed tomography image of an inguinal hernia. (C) Ultrasound of a left inguinal hernia at rest and with valsalva maneuver.

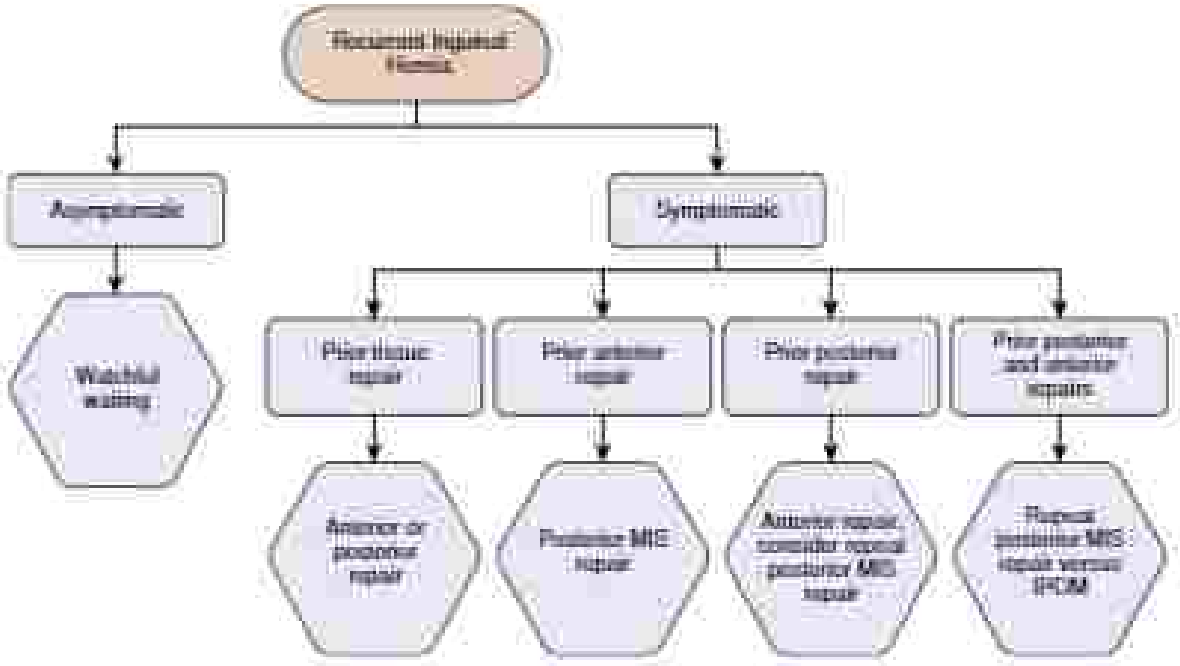

FIG. 2 Algorithm for management of recurrent inguinal hernia. IPOM, intraperitoneal onlay mesh; MIS, minimally invasive surgery.

been violated and mesh exists in the anterior and/or posterior space, the procedure of choice will depend on the surgeon experience. In our group, we prefer laparoscopy (or a robotic approach) in most of these cases initially as a diagnostic tool, to identify precisely the location and etiology of the recurrence. Often the prior MIS placed mesh can be taken down to identify the femoral space, the direct space, and the indirect space sufficiently to make a diagnosis and perform an MIS repair. In cases in which the peritoneum is damaged during the dissection, an intraperitoneal onlay mesh repair can be safely performed. The mesh can be sutured to the anterior abdominal wall or to the old mesh, as well sutured to the retroperitoneum. No tacks should be deployed in the region of the nerves below the inguinal ligament.

CONCLUSIONS

Recurrent inguinal hernias should not be taken lightly. Careful review of the history, a focused physical examination, selective imaging, and using a standard technique will help optimize the outcomes. Having a detailed history, including the previous operative reports, not only dictates the approach for the recurrent hernia, but gives the surgeon an idea of what to expect at reoperation.

Some operations for recurrent inguinal hernias will be straightforward, but some of them will be quite difficult. As with the index operation, the approach will ultimately depend on surgeon skill, comfort, and preference. It is unreasonable to expect a surgeon who is uncomfortable with laparoscopy to use an MIS approach to address a recurrent hernia solely because it was repaired using an open technique previously. Conversely, it is acceptable for a surgeon who is comfortable and proficient with MIS hernia repair to approach a recurrence using MIS techniques even if the initial hernia was repaired laparoscopically or robotically.

For any inguinal hernia, including the recurrent hernia, the surgeon should be sure to look for and expect any cord lipoma because a cord lipoma alone can present as an inguinal bulge that creates the same symptoms as a true hernia. Even if a hernia itself is repaired or recurrent, if a cord lipoma is left behind, the patient may still be symptomatic.

Finally, the steps for MIS inguinal hernia repair, as outlined by Bates and Felix in their paper "Critical View of the Myopectineal Orifice" (2017), applies to recurrent hernias and should be thought of as the "nine commandments" of inguinal hernia repair. These rules describe wide and safe dissection of the myopectineal orifice, adequate visualization of all potential hernia defects (direct, indirect, femoral), sufficient reduction of hernias and cord lipomas, and secure placement of the mesh. If these rules are followed by the surgeon during MIS inguinal hernia repair, fewer recurrences can be expected.

Inguinal hernia is a prevalent surgical problem, and with recurrence rates of approximately 15%, every general surgeon will encounter recurrences in their career. Defining and diagnosing the recurrent inguinal hernia, as well as ruling out other causes of inguinal pain, are of paramount importance before reoperation. Surgical approach to repair is dictated by the method of the index surgery as well as the surgeon's comfort with minimally invasive surgical techniques. In all, general surgeons should have a thorough understanding of inguinal anatomy from both anterior and posterior approaches and be comfortable with both minimally invasive and open repair of the inguinal hernia.

Incisional, Epigastric, and Umbilical Hernias

Jason A. H. Ilham, MD, MS, and Mike K. Liang, MD*

Ventral hernias are a common clinical problem with nearly 350,000 ventral hernia repairs performed each year in the United States. Despite this, ventral hernia repair is associated with a high rate of surgical complications, such as infection and hernia recurrence. To obtain optimal outcomes, there are a number of important clinical decisions that should be considered when approaching a patient with a ventral hernia. This chapter discusses patient selection and optimization, surgical techniques, and complex settings (including emergent repairs and cases with contamination). Primary (e.g., umbilical or epigastric hernias) and incisional ventral hernias have considerable differences in anatomy, pathophysiology, and outcome; therefore, they are discussed separately.

PATIENT SELECTION

For elective cases, careful patient selection is critical. Nonoperative management of ventral hernias is safe and feasible and should be the strategy of choice in certain patients. Significant comorbidities, including metastatic cancer, advanced arthritis, severe cardiopulmonary disease, and other conditions causing a life expectancy less than 2 years are relative contraindications to elective surgery.

Patients with certain modifiable risk factors should also be initially managed nonoperatively. These patients can benefit from medical optimization before elective surgery. If and when they are able to meet the goals set out for them, then can be offered elective repair. For example, patients who smoke should not be offered elective surgery because of an increased risk of wound complications and hernia recurrence. Rather, they should be educated on smoking cessation and offered resources to aid with successful smoking cessation. In addition, obese patients should be counselled on weight loss before elective surgery. Elective surgery is considered for patients with a body mass index (BMI) less than 30. For patients with a BMI greater than 40, we opt for nonoperative management until the patient is able to lose weight. For patients with a BMI between 30 and 40, we recommend preoperative weight loss with individualized patient goals. Referrals to a physical therapist and a dietician can be offered to help patients with weight loss. Patients with poorly controlled diabetes should be referred to their primary care physician to better control diabetes before scheduling elective surgery. At our institution, a hemoglobin A1c less than 8.0% is recommended. Finally, asymptomatic or oligosymptomatic patients should be considered for nonoperative management because these patients are unlikely to see any improvement in quality of life following repair.

All patients managed nonoperatively should be counseled on signs and symptoms that should prompt a visit to the emergency department. Symptoms may include increased pain at the hernia site, obstructive symptoms such as nausea, vomiting, distension, or obstipation. Signs may include changes in hernia characteristics such as increased firmness, new inability to reduce the hernia, and changes to surrounding skin color.

been violated and mesh exists in the anterior and/or posterior space, the procedure of choice will depend on the surgeon experience. In our group, we prefer laparoscopy (or a robotic approach) in most of these cases initially as a diagnostic tool, to identify precisely the location and etiology of the recurrence. Often the prior MIS placed mesh can be taken down to identify the femoral space, the direct space, and the indirect space sufficiently to make a diagnosis and perform an MIS repair. In cases in which the peritoneum is disrupted during the dissection, an intraperitoneal onlay mesh repair can be safely performed. The mesh can be sutured to the anterior abdominal wall or to the old mesh, as well sutured to the retroperitoneum. No tacks should be deployed in the region of the nerves below the inguinal ligament.

CONCLUSIONS

Recurrent inguinal hernias should not be taken lightly. Careful review of the history, a focused physical examination, selective imaging, and using a standard technique will help optimize the outcomes. Having a detailed history, including the previous operative reports, not only dictates the approach for the recurrent hernia, but gives the surgeon an idea of what to expect at reoperation.

Some operations for recurrent inguinal hernias will be straightforward, but some of them will be quite difficult. As with the index operation, the approach will ultimately depend on surgeon skill, comfort, and preference. It is unreasonable to expect a surgeon who is uncomfortable with laparoscopy to use an MIS approach to address a recurrent hernia solely because it was repaired using an open technique previously. Conversely, it is acceptable for a surgeon who is comfortable and proficient with MIS hernia repair to approach a recurrence using MIS techniques even if the initial hernia was repaired laparoscopically or robotically.

For any inguinal hernia, including the recurrent hernia, the surgeon should be sure to look for and expect any cord lipoma because a cord lipoma alone can present as an inguinal bulge that creates the same symptoms as a true hernia. Even if a hernia itself is repaired or recurrent, if a cord lipoma is left behind, the patient may still be symptomatic.

Finally, the steps for MIS inguinal hernia repair, as outlined by Bates and Felix in their paper "Critical View of the Myopectineal Orifice" (2017), applies to recurrent hernias and should be thought of as the "nine commandments" of inguinal hernia repair. These rules describe wide and safe dissection of the myopectineal orifice, adequate visualization of all potential hernia defects (direct, indirect, femoral), sufficient reduction of hernias and cord lipomas, and secure placement of the mesh. If these rules are followed by the surgeon during MIS inguinal hernia repair, fewer recurrences can be expected.

Inguinal hernia is a prevalent surgical problem, and with recurrence rates of approximately 15%, every general surgeon will encounter recurrences in their career. Defining and diagnosing the recurrent inguinal hernia, as well as ruling out other causes of inguinal pain, are of paramount importance before reoperation. Surgical approach to repair is dictated by the method of the index surgery as well as the surgeon's comfort with minimally invasive surgical techniques. In all, general surgeons should have a thorough understanding of inguinal anatomy from both anterior and posterior approaches and be comfortable with both minimally invasive and open repair of the inguinal hernia.

Incisional, Epigastric, and Umbilical Hernias

Julie L. Heiffan, MD, MS, and Mike K. Liang, MD

Ventral hernias are a common clinical problem with nearly 400,000 ventral hernia repairs performed each year in the United States. Despite this, ventral hernia repair is associated with a high rate of surgical complications, such as infection and hernia recurrence. To obtain optimal outcomes, there are a number of important clinical decisions that should be considered when approaching a patient with a ventral hernia. This chapter discusses patient selection and optimization, surgical techniques, and complex settings (including emergent repairs and cases with contamination). Primary (e.g., umbilical or epigastric hernias) and incisional ventral hernias have considerable differences in anatomy, pathophysiology, and outcomes; therefore, they are discussed separately.

PATIENT SELECTION

For elective cases, careful patient selection is critical. Nonoperative management of ventral hernias is safe and feasible and should be the strategy of choice in certain patients. Significant comorbidities, including metastatic cancer, advanced arthritis, severe cardiopulmonary disease, and other conditions causing a life expectancy less than 2 years are relative contraindications to elective surgery.

Patients with certain modifiable risk factors should also be initially managed nonoperatively. These patients can benefit from medical optimization before elective surgery. If and when they are able to meet the goals set out for them, then can be offered elective repair. For example, patients who smoke should not be offered elective surgery because of an increased risk of wound complications and hernia recurrence. Rather, they should be educated on smoking cessation and offered resources to aid with successful smoking cessation. In addition, obese patients should be counselled on weight loss before elective surgery. Elective surgery is considered for patients with a body mass index (BMI) less than 30. For patients with a BMI greater than 40, we opt for nonoperative management until the patient is able to lose weight. For patients with a BMI between 30 and 40, we recommend preoperative weight loss with individualized patient goals. Referrals to a physical therapist and a dietician can be offered to help patients with weight loss. Patients with poorly controlled diabetes should be referred to their primary care physician to better control diabetes before scheduling elective surgery. At our institution, a hemoglobin A1c less than 8.0% is recommended. Finally, asymptomatic or oligosymptomatic patients should be considered for nonoperative management because these patients are unlikely to see any improvement in quality of life following repair.

All patients managed nonoperatively should be counseled on signs and symptoms that should prompt a visit to the emergency department. Symptoms may include increased pain at the hernia site, obstructive symptoms such as nausea, vomiting, distension, or obstipation. Signs may include changes in hernia characteristics such as increased firmness, new inability to reduce the hernia, and changes to surrounding skin color.

TREATMENT OF PRIMARY VENTRAL HERNIAS

Umbilical and Epigastric Hernias

Umbilical hernias are a defect through the umbilical ring not associated with a prior incision, whereas epigastric hernias are primary ventral hernias located along the linea alba and superior to the umbilical ring. Primary ventral hernias are an extremely common problem, present in nearly one half of the population on radiologic imaging or physical examination. In low risk patients with a BMI less than 30 and small defects (<2 cm), we use an open approach. For an umbilical hernia, a supraumbilical incision is made for a bulge superior to the umbilicus, and an infraumbilical incision is made for a bulge inferior to the umbilicus. The tissue is dissected down to fascia, and the umbilical stalk is freed circumferentially. The hernia sac is then dissected off the umbilical stalk down to the fascia. The layers of the abdominal wall are freed around the umbilicus, so the fascia is incised circumferentially 2 mm from the umbilical ring to enter the preperitoneal space without entering the retromuscular space. The preperitoneal space is bluntly dissected in a radial fashion developing a space 3 to 5 cm in radius circumferentially. A large piece, mid-density polypropylene mesh is placed in this preperitoneal space. The fascial defect is closed with transverse interrupted 2-0 polydioxanone sutures. Small epigastric hernias (<2 cm) are repaired similarly. An incision is made directly over the hernia defect. The hernia sac is freed circumferentially and dissected down to fascia. It is reduced. With epigastric hernias, the fascia does not need to be incised because the planes are not fused. Simple blunt dissection to free the preperitoneal space is adequate. Mesh is placed in the preperitoneal plane, and the defect is closed transversely with interrupted 2-0 polydioxanone sutures.

A laparoscopic approach is preferred for larger umbilical or epigastric hernias (>2 cm). This is because, for a larger hernia, an open approach would require a much larger incision to achieve adequate mesh overlap. We also use laparoscopy for patients at increased risk for wound complications, such as patients with a BMI greater than 30. The use of laparoscopy has been shown to decrease surgical site infections compared with open repair. For laparoscopic repair, the abdomen is entered with a 5-mm optical port in the left upper quadrant. A second 5-mm port is placed along the left flank (Fig. 1). The peritoneum and preperitoneal fat are incised circumferentially around the hernia defect. It is best to perform this dissection at least 2–3 cm from the hernia edge. The hernia sac and preperitoneal fat are gently reduced en bloc. We place a 10- to 12-mm port through the defect to minimize port site hernias and use this larger port to introduce an antiadhesion barrier coated mid-density polyester or polypropylene mesh into the abdomen. We aim for at least 5 cm of mesh overlap on each side of the hernia but typically use a 12- or 15-cm rounded mesh. For smaller defects (<3 cm), the mesh is small enough to be held in place by a central stay suture while it is secured circumferentially using permanent tacks placed in a double crown. For a larger defect, transfascial stay sutures (0 polydioxanone sutures) are placed in each side of the mesh, and the mesh is then secured circumferentially with a double crown of permanent tacks (Fig. 2). After the abdomen is desufflated, the fascia is closed through the 10- to 12-mm trans-hernia port site with 0 polyglactin suture. For umbilical hernias, the umbilicus can also be tacked or secured to the fascia with a 2-0 polyglactin suture.

The role of robotics in primary ventral hernia repair remains to be established. There are multiple approaches that can be used for robotic primary ventral hernia repair, including standard laparoscopic intraperitoneal onlay mesh, retromuscular, or preperitoneal techniques. Preperitoneal placement of the mesh is attractive because it allows for mesh placement outside of the peritoneal cavity without violating the retromuscular space and for the use of uncoated mesh. When possible, we prefer a preperitoneal technique. The abdomen is typically entered with a 5-mm optical port in the left upper quadrant. Two 8-mm ports are placed along the left flank and just medial and superior to the ipsilateral anterior superior iliac spine (Fig. 3). The

original 5-mm port is exchanged for a third 8-mm port. The bed can be flexed to increase space between the costal margin and anterior superior iliac spine in smaller patients. A bump placed under the patient on the side with the ports can also facilitate more lateral port placement. Ports placed too close to the costal margin or anterior superior iliac spine may interfere with movement of the robotic arms.

Before docking the robot, we insert a 2-0 barbed suture, an appropriately sized uncoated mid-density polypropylene mesh (typically 10 × 15 cm), and a 0 barbed suture (inserted in this order). The robotic platform is docked. To optimize the proportional dimension, we typically use saline into the preperitoneal space to dissect the space 3–6 cm lateral to the hernia on the right and left sides. The preperitoneal space is inflated and dissected to allow for at least 3 cm of mesh overlap but preferably 5 cm of overlap. The proportional fan is reduced and defect is closed with 0 barbed suture. The uncoated polypropylene mesh is inserted into the preperitoneal space, and the flap is closed with a 2-0 barbed suture.

Treatment of Incisional Ventral Hernias

An incisional ventral hernia is a ventral hernia associated with any prior incision. Incisional hernias are associated with a substantially higher risk of complications than primary ventral hernias (with mesh, 24% vs 5% recurrence at 2–3 years postoperatively). We prefer a laparoscopic approach for incisional hernias whenever feasible because laparoscopy has been shown to have fewer surgical site infections and a shorter hospital length of stay with no difference in hernia recurrences compared with open repair. Open repair is reserved for large incisional hernias in which defect closure is not feasible laparoscopically. Large incisional hernias are typically greater than 10 cm in width. Hernias with loss of domain, where the majority of visceral contents lies outside of the abdomen, also fall into this category (Fig. 4).

For laparoscopic incisional hernia repair, the abdomen is typically entered with a 5-mm optical port in the left upper quadrant. A right-sided approach can be used for patients more likely to have left-sided adhesions (e.g., prior left colon resection, splenectomy, gastric surgery). A second 5-mm port is placed along the left flank (Fig. 1). The hernia is reduced using gentle traction and dissection. Unlike in primary hernia repair, the hernia sac is not excised for incisional hernias because it is often too scarred to excise and can be used to assist with defect closure. For hernias larger than 3 cm, we close the hernia defect using transfascial sutures. For hernias smaller than 3 cm, we do not typically close the defect. Before defect closure (when applicable), the hernia is measured to determine appropriate mesh size. The edges of the hernia are marked on the skin. The abdomen is desufflated, a mesh is chosen that will allow for coverage of the hernia with at least a 5 cm overlap on each side. The mesh is prepared by placing 0 polydioxanone stay sutures on the four sides of the mesh. A 10- to 12-mm port is placed through the hernia defect, the mesh is introduced into the abdomen through this port. When closing the hernia defect, 0 polydioxanone sutures are placed 1 to 2 cm apart for the length of the defect. Occasionally, we will lower the abdominal pressures from 15 down to 8 to 12 mm Hg to assist with suture passage. A stab incision is made in the skin in the midline of the hernia defect. A suture passer is used to tunnel through the subcutaneous tissue, along the hernia sac, to the edge of hernia defect, and 1 cm lateral to the fascial edge. The suture passer is then placed through the same stab incision and tunneled to the opposite side of the defect to grasp the suture. The most cranial and most caudal sutures are placed first, and the abdomen is desufflated as these are tied down. We include the hernia sac in the closure to reduce the risk of seromas. The abdomen is reinsufflated and the remainder of the fascial closure sutures are then placed (Fig. 5). All fascial closure sutures are tied with the abdomen completely desufflated. The four transfascial sutures on the mesh are then positioned and tied down. The mesh is secured circumferentially using a double crown of permanent tacks (Fig. 2).

Open incisional hernia repair is reserved for large hernias. Often, these large hernias can still be closed primarily; however, we will discuss options for closure when primary closure is not possible. A laparotomy incision is made along the midline. Adhesiolysis is performed to clear the abdominal wall. The hernia sac is excised. Our preferred mesh location is in the sublay or retromuscular position because this is associated with the fewest surgical site occurrences and hernia recurrences. If the fascia is able to be primarily closed, the retromuscular space is entered taking care not to damage the underlying peritoneum. Before closing the peritoneal cavity, we placed antiadhesion barrier sheets throughout the abdomen. The posterior rectus fascia is closed with running 0 polydioxanone suture. The retrorectus space is developed to accommodate the mesh with additional lateral, superior, and inferior dissection. A mid-density polypropylene mesh is used in most cases; however, in contaminated settings, a biologic mesh such as porcine acellular dermal matrix can be considered. We fixate the mesh with a limited number of 0 polydioxanone sutures. After placing the mesh, the anterior rectus fascia is closed

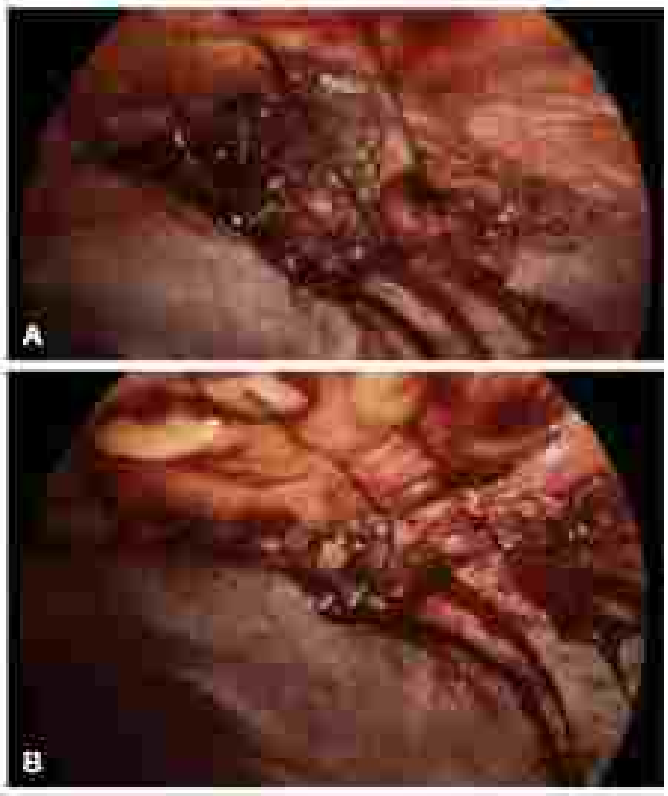

FIG. 1 (A) Transfacial sutures spanning hernia defect used to close the defect laparoscopically. (B) Closed hernia defect.

using running 0 polydioxanone sutures. In some cases, there can be significant excess skin that is excised to minimize seroma formation.

When the fascia is unable to be closed, there are a number of options, the simplest of which is a bridged repair. This is where the fascia is left open, and a mesh is used to span the hernia defect. This type of repair has a high rate of surgical site occurrence and hernia recurrence and should be avoided when other options are available. However, a bridged repair may be considered in the setting of an emergent repair, a contaminated case, or in an unstable patient where the goal is to temporize the patient rather than create a durable repair.

In stable patients with defects too large to close primarily, a myofascial advancement flap, or component separation, may be necessary. An anterior component separation can provide the most release, up to 7 to 10 cm per side. Anterior component separations can have significant wound complications because of undermining and creation of large skin flaps. A perforator sparing anterior component separation preserves the blood supply to the abdominal wall near the umbilicus, which can alleviate some of these complications but can be technically challenging for surgeons who do not routinely perform these procedures. For an anterior component separation, skin flaps and subcutaneous fat are dissected free from the anterior rectus sheath leaving a few millimeters of fat on top of the fascia. The external oblique aponeurosis is identified and incised 2 cm lateral to the semilunar line, separating the internal from the external oblique muscles. We prefer to err farther lateral to the semilunar line compared with what others report. Care must be taken to avoid accidentally incising the semilunar line or damaging the internal oblique. After completing the external oblique incision, the external oblique and internal oblique muscles must be gently separated through a combination of blunt and electrocautery dissection carried to the spinal muscles. This dissection is needed to "separate the components" and allow medial retraction. The anterior rectus fascia is then approximated. If large flaps are created, we consider placement of drains in the lateral space to minimize formation of fluid collections.
